The severity of reduced RBF resulting from ureteral obstruction has prompted a thorough investigation of potential mediators of renal vasoconstriction. Much attention has focused on eicosanoids as mediators of vascular tone, and the initial increase in RBF resulting from ipsilateral UUO has been shown to be associated with increased renal production of vasodilator prostaglandins (194). The later increase in vasoconstriction, on the other hand, has been ascribed in the past to increased production of the vasoconstrictor prostanoid, thromboxane A2 (195–197). Glomeruli from rats with bilateral ureteral obstruction (BUO) produce increased amounts of PGE2, 6-keto-PGF1a and TxB2, all of which can be suppressed by angiotensin converting enzyme inhibition (198). This suggests that phospholipase A2 or cyclooxygenase is stimulated by enhanced angiotensin II formation by glomeruli from kidneys with BUO. In rats with congenital unilateral hydronephrosis, the reduction in single nephron GFR is due to a reduction in the ultrafiltration coefficient mediated by both angiotensin II and thromboxane A2 (199). Urinary excretion of PGE2 and thromboxane B2 is increased in human neonates and infants with congenital obstructive uropathy (200). A balance between vasoconstrictors and vasodilators may play an important role in determining the vascular tone of kidneys with ureteral obstruction. Increased glomerular phospholipase A2 and cyclooxygenase activity are reduced to normal when animals with BUO are treated with either angiotensin or thromboxane inhibitors (201).

An important finding that is discussed in more detail below is an increased production of vasodilator prostanoids by glomeruli from the intact kidney (as well as the obstructed kidney) of rats with UUO (202). This increased prostaglandin synthesis could be suppressed by angiotensin converting enzyme inhibition, and restored by angiotensin II, suggesting that the prostaglandin

production is angiotensin-dependent (202). The reverse may also be the case: the increased renin release by glomeruli from kidneys with UUO can be abolished by prostaglandin inhibition (194). In this regard, the administration of a cyclooygenase-2 inhibitor reduces TGF-β1 and interstitial fibrosis in the obstructed kidney (203).

Angiotensin

The role of the renin-angiotensin system in mediation of vasoconstriction resulting from ureteral obstruction is of particular interest in the maturing animal, because the activity of this system is markedly enhanced in early development. The involvement of angiotensin in renal vasoconstriction is suggested by a doubling of the renin content of the obstructed kidney during partial UUO and its normalization after relief of obstruction (54). Chronic administration of enalapril (an angiotensin converting enzyme inhibitor) to neonatal guinea pigs with partial UUO prevents the decrease in RBF and glomerular contraction normally resulting from obstruction (204, 205). This confirms the dependence of vasoconstriction on angiotensin.

Although RBF does not return to normal following relief of 5 or 10 days of partial UUO in the neonatal guinea pig, enalapril has no additional salutary effect (54). While enalapril has no effect on RBF of the intact kidney of neonatal guinea pigs with persistent contralateral UUO, following relief of obstruction, enalapril reduces renal vascular resistance of the intact kidney by 40% (54). Moreover, the vasoconstrictor response of the intact kidney to exogenous angiotensin II infusion is increased, suggesting an increased sensitivity of angiotensin II receptors in the intact kidney in response to relief of obstruction in the contralateral kidney. Thus, other factors are presumably responsible for the persistently depressed RBF of the postobstructed neonatal kidney. However, administration of captopril to rats during 1–3 weeks of UUO resulted in better preservation of kidney weight and GFR of the postobstructed kidney 3 months after relief of obstruction (206). As discussed above, angiotensin inhibitors to protect the developing kidney from obstructive injury can aggravate, rather than ameliorate renal lesions if administered during nephrogenesis or subsequent renal maturation.

Arginine Vasopressin

Plasma levels of vasopressin are elevated in rats with 24 h of BUO, but not in those with UUO (207). The increase in vasopressin in rats with BUO is most likely due to hypernatremia and hyperosmolality. Treatment of animals with a specific antagonist of vasopressin V1 receptors increases GFR of the postobstructed kidney by 60% and effective renal plasma flow more than doubles (207). These results suggest that vasopressin contributes to the vasoconstriction and renal functional impairment resulting from BUO.

Kininogen-Kinin System

Earlier studies of the adult rat following relief of 24 h of UUO showed that administration of either carboxypeptidase B (which destroys kinins) or an inhibitor of kinin synthesis does not diminish the salutary effect of captopril on RBF of the postobstructed kidney (195). This suggests that angiotensin converting enzyme inhibition does not act through potentiating of vasodilator kinins in this model. In fact, inhibition of kallikrein by aprotinin further decreases renal vasoconstriction following relief of 24 h of UUO (208). This action appears to be due to stimulation of thromboxane and angiotensin by kinins in the postobstructed kidney (208). However, kallikrein mRNA and protein are significantly reduced by chronic ipsilateral UUO in the rat (209). The role of the kininogen-kinin system in ureteral obstruction therefore remains to be clarified.

Nitric Oxide

After unilateral release of BUO in adult rats, infusion of L-arginine, the substrate for nitric oxide synthase, increases effective renal plasma flow and GFR (210). Treatment of rats subjected to UUO with enalapril prevents many of the sequelae of obstruction in part by an increase in nitric oxide generation (211). Additional effects of UUO include an increase in glomerular soluble guanylyl cyclase activity (through angiotensin II stimulation) while blocking phosphodiesterase activity (212). By increasing the production of cyclic GMP, a vasodilator, these actions would serve to counter angiotensin-dependent vasoconstriction. Endogenous nitric oxide production also counters tubular apoptosis triggered by tubular stretch secondary to UUO (213), and attenuates interstitial fibrosis resulting from UUO (214). Mice lacking functional endothelial nitric oxide synthase (eNOS) develop spontaneous tubular apoptosis and glomerulotubular disconnection similar to lesions resulting from chronic partial UUO (50, 215).

Endothelial cells also produce endothelin, a potent vasoconstrictor. Following relief of temporary UUO in the rat, abnormal responses of the postobstructed kidney to angiotensin II are mediated by endogenous endothelin (216).

Summary

Urinary tract obstruction induces marked changes in the activity of local vasoconstrictors and vasodilators, with a shift in the balance toward vasoconstriction. The role of angiotensin and eicosanoids appears to be clearly established, while that of other compounds, such as kinins and endothelial factors, remains to be elucidated. Interpretation of studies is made more difficult by the complex interactions among the vasoactive compounds, including stimulation of vasoconstrictors by vasodilators and vice-versa. In addition, the protean effects of many vasoactive compounds include the regulation of cell proliferation, apoptosis, and fibrogenesis, all of which are profoundly affected by urinary tract obstruction.

Tubular Responses to Urinary Tract Obstruction

Postobstructive Diuresis

Following the relief of BUO, natriuresis and diuresis are increased; a phenomenon described as postobstructive diuresis. Much of the effect is presumably due to an osmotic diuresis resulting from excretion of accumulated solutes. However, in addition to changes in tubular transport characteristics, altered circulating factors, such as increased circulating atrial natriuretic peptide and enhanced synthesis of prostaglandins may play a role (217, 218). In addition, altered sensitivity of the tubuloglomerular feedback mechanism also contributes to the diuresis (219). It is of interest that in addition to BUO, relief of UUO in neonates can be associated with postobstructive diuresis (220). This may be due to a relative glomerulotubular imbalance.

Sodium

Ureteral obstruction results in decreased reabsorption of sodium and water in juxtamedullary proximal tubules (188). Following relief of obstruction, sodium reabsorption is decreased in the thick ascending limb of Henle, which contributes to a reduction in medullary tonicity. Sodium transport is reduced also in the medullary-collecting duct (221). It appears that the impaired sodium transport can be explained at least in part by alteration in the lipid environment of the basolateral membrane, leading to reduced Na/K ATPase activity (222, 223). Another factor implicated in postobstructive diuresis is a "functional denervation" of the kidney following relief of BUO (224). Acutely, postobstructive natriuresis may be beneficial in providing mobilization of extracellular fluid, and reducing hypertension. However, prolonged salt wasting in some patients can lead to severe volume contraction and circulatory impairment. Chronic sodium depletion can also aggravate renal interstitial fibrosis resulting from UUO (100). Whereas sodium depletion normally stimulates endogenous renal antioxidant enzyme activity, UUO impairs this response, thereby contributing to the fibrogenic stimulus of renal oxidant injury that results from UUO (100, 140). Since infants and children with severe obstructive uropathy frequently have significant salt wasting, adequate sodium supplementation may be beneficial in slowing progression of renal interstitial fibrosis.

Urinary Concentration

As indicated above, reduced removal of solute from the thick ascending limb of Henle leads to decreased solute content of the papillary interstitium, and reduces the urinary concentrating capacity. A relative increase in blood flow to the papilla increases washout of solute, contributing further to the loss of concentrating capacity. A third factor leading to the impairment of the concentrating capacity is a reduced response of the cortical collecting duct to vasopressin. This occurs at a site distal to the generation of cyclic AMP (225). Frokiaer et al. have demonstrated that BUO and release of obstruction in the rat is associated with downregulation of the vasopressin-regulated water channel aquaporin (226, 227). Renal sodium transporters and aquaporins are downregulated in response to partial UUO in the neonatal rat, associated with increased sodium excretion and decreased solute-free water reabsorption (228). The maximal urinary concentration following administration of DDAVP to young rabbits with UUO and contralateral nephrectomy is inversely proportional to the degree of hydronephrosis (229). This may be due at least in part to the distortion of the medullary architecture: loops of Henle are splayed and atortuous 3–4 days follow after UUO in the rabbit (230). Temporary ureteral occlusion in the adult rat results in ischemic tubular necrosis in the inner and outer

medulla, which also presumably contributes to the "concentrating" defect (231). In addition, there is a disproportionate loss of juxtamedullary nephrons. The severity of the renal concentrating defect in children with obstructive uropathy is highly variable, but in some patients it can approach that of nephrogenic diabetes insipidus, leading to episodes of hypernatremia in affected infants (232). Chronic polyuria secondary to obstructive uropathy may accelerate renal injury: in weanling rats with partial UUO, chronic high urine flow rates induced by osmotic diuresis resulted in a significant decrease in GFR (233).

Potassium and Hydrogen Ion Handling

Obstructive uropathy leads frequently to defective distal tubular potassium and hydrogen ion secretion ("type 4" renal tubular acidosis) (234, 235). This can be due to impaired turnover of the sodium/potassium pump, diminished sensitivity of the distal tubule to aldosterone, or the loss of H + -ATPase in the apical surface of intercalated cells. Clinically, these changes lead to hyperkalemia and metabolic acidosis, even with unilateral obstruction, and may not resolve following surgical correction of obstruction (235–237).

Calcium and Phosphorus Handling

Experimental UUO results in reduced urinary calcium and phosphorus excretion due in part to a decreased renal response to PTH. In patients with distal renal tubular acidosis due to obstructive uropathy ("type 1"), urinary calcium excretion can be increased. Release of UUO in thyroparathyroidectomized dogs results in hypophosphaturia, due to reduced filtered load of phosphate and increased tubular phosphate reabsorption (238).

Renal Counterbalance

While the UUO model represents an extreme case of asymmetrical kidney function, the severity of urinary tract obstruction in clinical practice is often unequally distributed between the two sides. Partial UUO in the immature guinea pig results in a compensatory increase in GFR of the intact opposite kidney; the younger the animal at the time of ureteral obstruction, the greater the response (239). The concept of "counterbalance" by the intact kidney in response to the loss of function by the obstructed kidney was developed by Hinman in 1923 (240). The exaggerated adaptive response by the intact kidney of animals undergoing UUO in early development is demonstrated also by the remaining kidney following loss of renal mass in the neonate (241, 242). The dynamic nature of the response is illustrated by the attenuation of compensatory hypertrophy of the intact kidney following relief of UUO in the guinea pig at 10 days of age (15), or in the mouse at 7 days of age (50). Temporary UUO in the neonatal rat inhibits growth of the obstructed kidney, and accelerates growth of the opposite kidney in direct proportion to the duration of obstruction (*Fig. 56-7a*) (243). Similarly, renal growth is impaired (50), and contralateral renal growth increases (244) in relation to the severity of obstruction. Compensatory growth takes place at the single nephron level, as glomerular area in the contralateral kidney is proportional to renal mass (*Fig. 56-7b*). This demonstrates clearly the very fine tuning of the counterbalance mechanism in early development. Also demonstrating the plasticity of the counterbalance phenomenon is the maintenance of normal RBF and glomerular volume in kidneys of neonatal guinea pigs with ipsilateral UUO, if the contralateral kidney is removed at the time of birth (245).

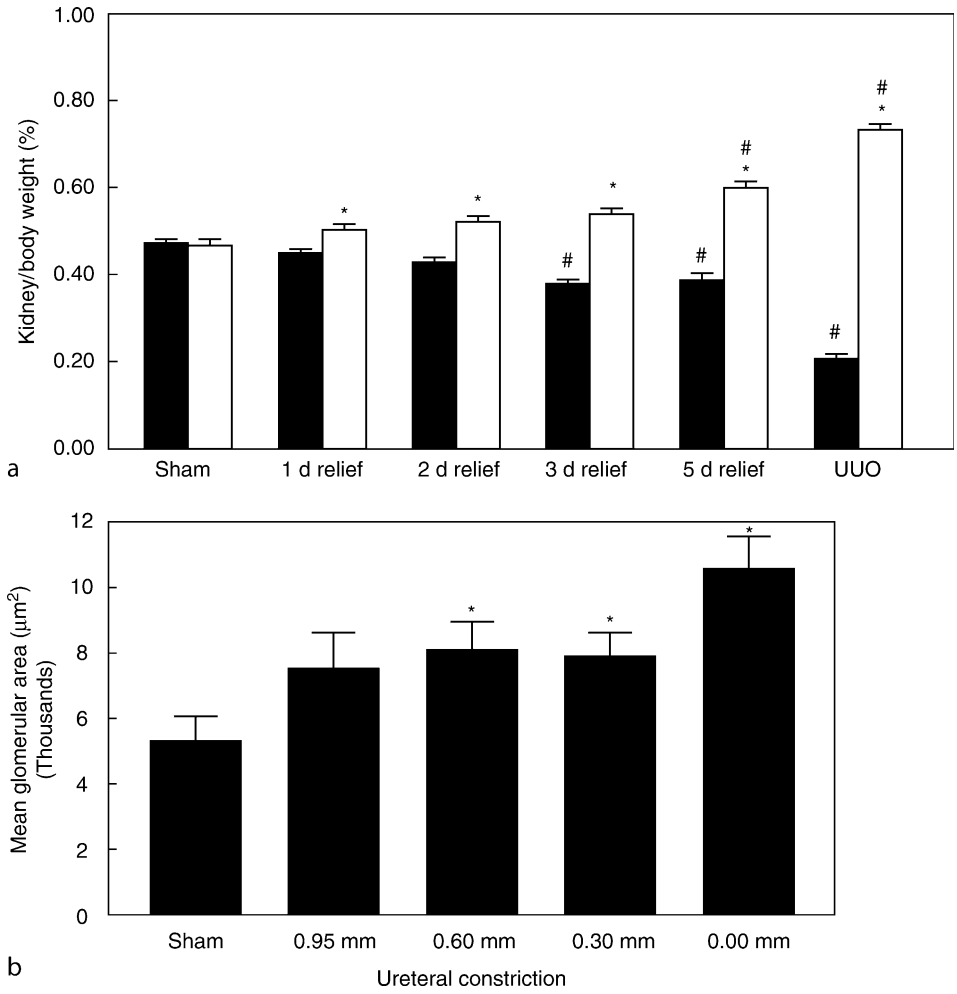
Clinical Implications of Experimental Studies of Urinary Tract Obstruction

Fetal Diagnosis and Intervention

The results of experimental fetal studies have important implications for the management of infants found to have severe obstructive uropathy in utero: prenatal intervention may allow preservation of renal mass prior to completion of nephrogenesis as well as improved pulmonary development. The major problem is the lack of accurate prognostic criteria for the identification of infants who would benefit from intervention. The primary limiting factor at present is the difficulty in visualizing the developing kidneys by ultrasonography prior to 18 weeks gestation (246). In a report of a ten-year experience with prenatal intervention for hydronephrosis due to lower urinary tract obstruction, successful vesicoamniotic shunt placement was found to aid pulmonary development, but often did not prevent renal insufficiency (247). The experience at Children's Hospital of Philadelphia was similar, with one third requiring dialysis and transplantation, although the majority reported a satisfactory quality of life (248). Significant technical advances will be required to allow the required anatomic definition, as well as the development of reliable functional parameters.

Figure 56-7

A. Kidney weight (factored for body weight) of obstructed (black) and contralateral (white) kidneys of neonatal rats 28 days following sham-operation, following relief of 1–5 days ureteral obstruction, or with persistent ureteral obstruction (UUO). *p < 0.05 vs. opposite kidney; #p < 0.05 vs. sham. There is a fine balance between the growth of the obstructed and opposite kidneys, such that combined renal mass remains constant. From reference (243), with permission. B. Mean (± SE) glomerular area vs. ureteral constriction of intact kidneys from 45 day-old rats subjected to neonatal contralateral partial UUO. *p < 0.05 vs. sham. From reference (244) with permission.



Use of Biomarkers in the Evaluation and Management of Obstructive Uropathy

The lack of reliable markers of significant urinary tract obstruction is a critical issue. A biomarker has been defined as, "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention" (249). Currently utilized markers of congenital obstructive uropathy include sonographic renal pelvic diameter, quantitative diuretic renography, and markers of glomerular and tubular function (250). Numerous experimental studies have demonstrated renal activation of TGF-β1 in the hydronephrotic kidney, and TGF-β1 may provide an index of obstruction. Urinary TGF-β is increased in children with severe urinary tract obstruction, and the correlation provides 80–100% sensitivity (251–253). The urinary concentration of TGF-β1 in

the pelvis of the obstructed kidney is 4-fold than that of bladder urine, which in turn is 3-fold higher than in controls (252). Upregulation of renal MCP-1 and suppression of EGF are also a consequence of experimental UUO, and urinary MCP-1 is increased, while EGF concentration is markedly reduced in children with severe UPJ obstruction (114). While attempts to correlate renal histological changes with differential renal function have been disappointing (34, 254), in situ hybridization and immunohistochemical analysis may improve specificity. Renal TGF-β1 expression is increased and EGF decreased in patients with UPJ obstruction (255).

Isolation of urinary polypeptides by capillary electrophoresis and mass spectrometry (CE-MS) was shown to predict the outcome of infants with UPJO (256). Comparison of urinary polypeptide patterns with currently available renal imaging studies allowed assignment of infants to a group likely to resolve and a group likely to require surgical intervention (*Fig. 56-8*). A combination of proteomics (to discover new biomarkers) and testing of candidate molecules (identified from mechanistic studies of animal models) should be complementary (257). Ultimately, a broad approach will be necessary to develop the most effective matrix of biomarkers to predict which patients will require surgical or medical intervention, and to track the evolution of the renal lesions over time. In addition to identification of molecules of interest in urine, similar identification in blood or amniotic fluid may be useful in evaluation of the fetus (258). Moreover, imaging or analysis of biopsy tissue (including immunohistochemistry or laser-capture microscopy) may provide significant advantages. Marked changes in renal structure and function follow normal development from fetus to neonate to adulthood, and biomarkers must be established for each developmental stage. In the case of unilateral obstruction, urine from the contralateral kidney may complicate detection of markers originating from the obstructed kidney, such that it may be necessary to obtain renal pelvic urine samples.

Recovery and Long-Term Outcomes

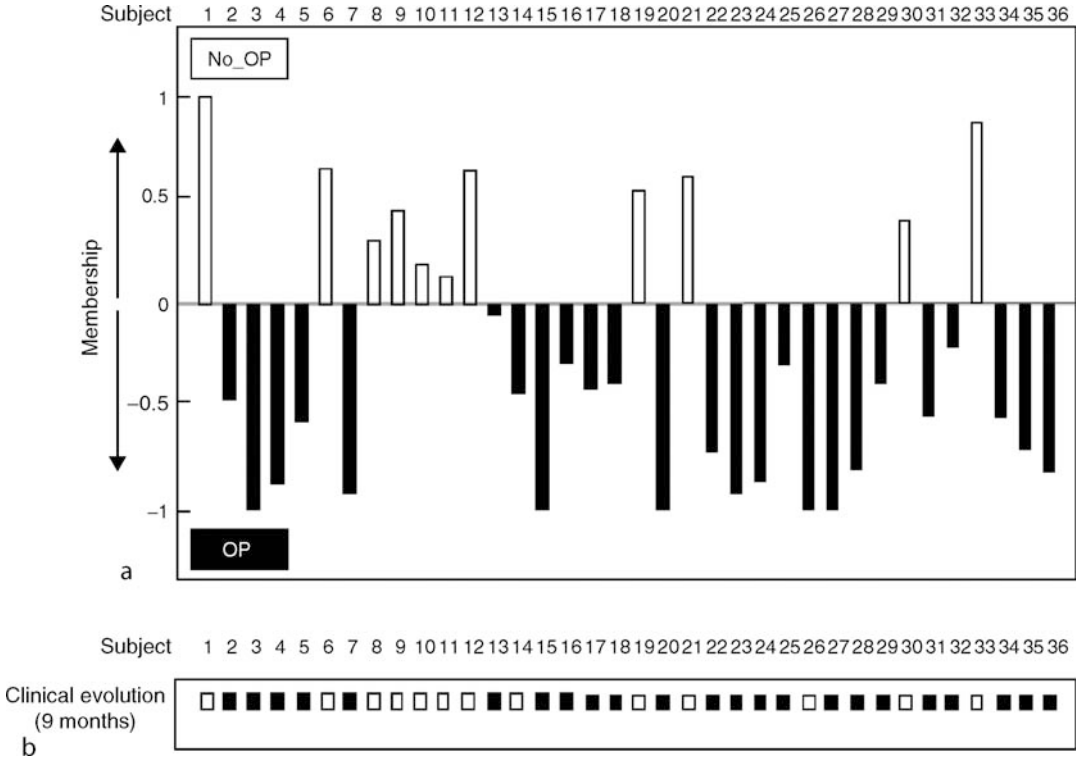
One of the primary concerns in the management of infants with obstructive uropathy is the expected recoverability of renal mass and renal function following relief of the obstruction. Temporary UUO in the neonatal rat impairs renal growth proportional to the duration and severity of obstruction prior to relief (*Fig. 56-7*) (243, 244). Although relief of complete UUO attenuates the renal cellular injury, and GFR of the postobstructed kidney is normal one month following relief (53), one year later, GFR is decreased by 80%, and proteinuria has developed (49). Importantly, glomerular sclerosis, tubular atrophy, macrophage infiltration, and interstitial fibrosis are increased not only in the postobstructed kidney, but also in the opposite kidney (49). These findings suggest that despite normal early postoperative GFR in infancy, children undergoing pyeloplasty for UPJO should be followed into adulthood. Following relief of 5 days complete UUO immediately after the completion of nephrogenesis, renal damage and loss of renal function are even more severe than those following relief of UUO during nephrogenesis (47). This suggests that if significant urinary tract obstruction is diagnosed either in the prenatal or neonatal period, its relief should not be delayed.

Timing the relief of obstruction in the postnatal period is complicated by differences in available experimental models. As described above, severe partial UUO in the neonatal guinea pig leads to arrested growth of the ipsilateral kidney, which is not improved by relief of obstruction after 10 days (15). This suggests that any delay in relief of severe neonatal obstruction can result in irreversible damage. Measurement of renal function by nuclear scintigraphy in rats studied up to one year after neonatal UUO reveals a 40% reduction in function, and a similar reduction in kidney weight (259). Early relief of neonatal partial UUO in the rat prevents the development of hydronephrosis, and reduction in renal function (260). If weaning rats are subjected to partial UUO, the morphologic effects are less severe than those resulting from UUO within the first two days of life (261). If partial UUO is delayed even longer (performed at 6 weeks of age), the impairment in GFR is minimal and does not progress over 15 weeks despite the presence of hydronephrosis (262). Thus in the rat, as in the guinea pig, susceptibility of the kidney to injury from ipsilateral ureteral obstruction decreases with age, while recoverability depends on the duration and severity of obstruction.

In the neonatal mouse subjected to moderate partial UUO, proximal tubular apoptosis leads to glomerulotubular disconnection, a process that can be arrested by relief of obstruction (50) (*Fig. 56-4*). Relief of severe partial UUO does not result in recovery. Atubular glomeruli are also found in the kidneys of children with obstructive uropathy, as well as in a variety of renal disorders, including pyelonephritis and cystinosis (263). Since glomerulotubular disconnection is presumably irreversible, a better understanding of the mechanisms of nephron loss is of critical importance in the development of improved interventions and therapies.

Figure 56-8

Membership of urinary proteomic patterns of 36 newborns with intermediate ureteropelvic junction obstruction (UPJO) and the clinical outcome of these individuals 9 months after group membership prediction. (a) Urinary protein profiles of individuals from the OP_Poss group (n = 36, grade 3/4 hydronephrosis and/or Pd > 15 mm and mild functional obstruction (isotopic MAG3 renogram)) were classified using a hierarchic disease model based on the polypeptides used to discriminate between healthy newborns, No_OP and OP groups. Each OP_Poss individual was scored with this model using support vector machines. This scoring results in membership values between -1 and 1. A negative value suggests evolution toward the OP profile and a positive value suggests evolution toward the No_OP profile. White bars indicate membership to the No_OP profile and black bars indicate membership to the OP profile. (b) Clinical outcome of the OP_Poss individuals 9 months after sample analysis. White squares indicate that the individual had evolved toward the No_OP group (spontaneous resolution of the obstruction) and black squares indicate that these individuals underwent surgery (OP). This resulted in 34 out of 36 correct predictions (94%). From reference (256) with permission.



The solution to this dilemma will depend on improved methods for imaging the developing kidney, as well as more reliable means of monitoring renal function. In view of the exaggeration of renal "counterbalance" in early development, the greater adaptation of intact nephrons may mask the deterioration of obstructed ones, necessitating the accurate measurement of differential renal function. Such advances, along with improved understanding of the mechanisms underlying the renal response to urinary tract obstruction during maturation, should allow intervention prior to the development of irreversible changes in remaining nephrons.

Congenital Obstructive Uropathy: Clinical Evaluation and Management

The clinical management of COU continues to be a challenge to the pediatric nephrologist and urologist due to the wide spectrum of severity, the variable clinical progression, the inability to predict long-term functional consequences, and the inability to alter established renal damage incurred during development. Nonetheless, COU is a common clinical entity and represents the largest cause of end-stage renal failure in young boys. The advent of prenatal ultrasonographic imaging has revealed a large

number of children with asymptomatic hydronephrosis, some of whom will have no long-term ill effects, yet others are at risk of severe renal damage. This section will review the common clinical entities causing COU, the basics of clinical evaluation and fundamental management principles.

Clinical Definition of Obstruction

At the heart of much of the controversy surrounding COU is a lack of agreement as to the definition of urinary obstruction in children. Obstruction present during the development of the kidney and urinary collecting system is fundamentally distinct from that acquired later in life. The effect on kidney development is something that cannot occur once the kidney has fully formed. In this way, COU must be seen and defined separately from later acquired obstruction. A common definition of obstruction is "a condition of impaired urine flow that if untreated will result in loss of renal function" (264, 265). Yet, if a child is born with an obstructive condition in which one or both kidneys are not functioning normally, it would make no sense to wait for deterioration of function to consider intervention. Impaired development, just as with pediatric growth retardation, represents a pathological condition, and if due to obstruction, intervention should be considered. Intervention may not always normalize or even improve function, but it may prevent further deterioration. This question becomes very important and controversial when approaching children with asymptomatic hydronephrosis where the uncertainty regarding the necessity of intervention is significant. Choosing between an observational or interventional approach has become the focus of current debate.

Operationally, it is the authors' view that congenital obstruction is a condition of impaired urine flow or transport that has impaired or can impair normal renal functional development (266). It would seem as this were a cautious and protective view with regard to the child's developing renal functional potential.

Ureteropelvic Junction Obstruction (UPJO)

The most common cause of COU is ureteropelvic junction obstruction (UPJO) (267). More severe versions are less common. The process is more common on the left (2:1 – left to right) and more common in boys (2:1 – male to female) (268). Bilateral obstruction is uncommon, but present in 10–40% (269), depending upon the diagnostic threshold. UPJO represents an obstructive process at the proximal portion of the ureter where the pelvis narrows into the ureter. It may be either intrinsic or extrinsic, or both. Intrinsic obstruction is considered to be an abnormality of the development of the ureteral wall and histologically is seen as disordered bundles of smooth muscle with a preponderance of extracellular matrix material (270). It may appear visibly as a simple narrowing of the proximal ureter with a dilated pelvis above, or as a tortuous segment of the ureter, often fixed to the inferior aspect of the pelvis with fibrous bands (*Fig. 56-9*). Nearly always the lumen is patent, albeit narrow and irregular. Studies have examined the possible underlying causes, including abnormal innervation, expression of various cytokines, and disordered regulatory proteins of the smooth muscle and matrix (34, 271, 272). All of these studies are interesting, yet fundamentally limited due to there being no way to determine cause and effect; they are simply associational. Similar studies have examined the distal aspect of the ureter in the context of ureterovesical junction obstruction, with similar limitations. How these

Figure 56-9

Operative view of the ureteropelvic junction (UPJ) in a child with significant obstruction. The obstruction appears to be related to several fibrous bands (arrow) and not a typical crossing vessel. The pelvis (P) is dilated but ureter (U) itself does not appear markedly abnormal. The UPJ is usually resected and re-anastomosed. (See color plate 34)

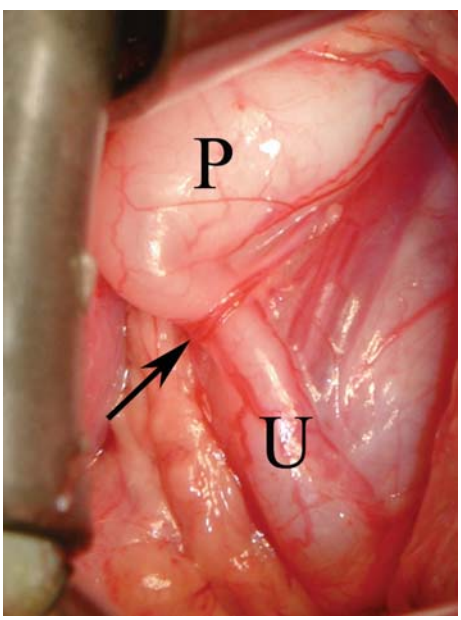


Figure 56-10

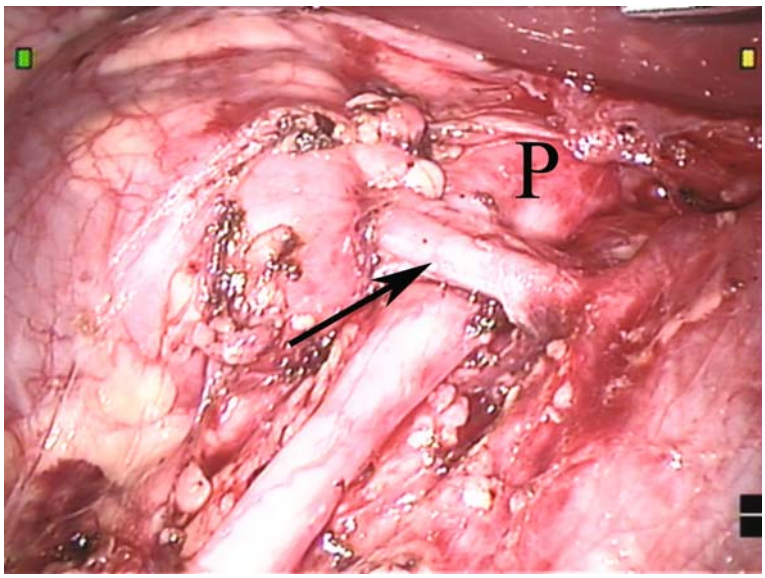
Operative (laparoscopic) picture of a lower pole crossing vessel (black arrow) associated with UPJ obstruction. At this point the pelvis (P) is not markedly dilated, but the patient experienced episodic severe pain with associated hydronephrosis. Pain resolved after surgical pyeloplasty with transposition of the ureter anterior to the vessel. (See color plate 35)



observations relate to the genetic models of UPJO remains to be determined (273).

In some instances, a clear intrinsic cause is seen in the form of a ureteral polyp, usually based just at the UPJ (274). These are fibroepithelial polyps that are entirely benign, although on occasion, pathological interpretation may indicate low-grade papilloma. In children the risk of malignant transformation is exceptionally low.

Extrinsic obstruction is somewhat more apparent, and usually represents a mechanical effect of a lower pole renal vessel, either artery, vein or both (*Fig. 56-10*) (275, 276). This fixes the ureter in position and with pelvic dilation, abrupt kinking may occur. Not all so-called "crossing vessels" are obstructive and it may be difficult to discern at times. It is also unclear as to how often the ureter is abnormal in addition to there being a "crossing vessel". This is emerging clinically in the form of surgical attempts to correct obstruction by simply moving the vessel up onto the pelvis and leaving the ureter alone (see below).

Clinical Presentation

Most UJPO is detected prenatally today, but some may still emerge with symptoms of abrupt flank pain, nausea, vomiting and dehydration. In the extreme form, this pattern, termed Dietl's crisis when bilateral (277), is characteristic, yet continues to be clinically unrecognized. Many of these children are thought to have gastrointestinal symptoms and a few have been through extensive negative workups. The pattern of abrupt onset with severe abdominal or flank pain associated with nausea and vomiting, often in the late evening is typical. Some of the children note that leaning over a chair or curling up may help. They will dehydrate and the pain subsides completely, usually within 2–4 h. The frequency and intensity of this pattern can evolve, yet may be unpredictable. If suspected, imaging with ultrasound during an episode will usually reveal the cause. When not symptomatic, the affected kidney may be normal, but usually has some degree of hydronephrosis.

Infection is an uncommon presentation for UPJO, and should prompt an evaluation for vesicoureteral reflux or bladder abnormalities. Infection in the setting of UPJO can be quite severe due to urinary stasis, and may require urgent intervention and drainage.

Prenatal detection of hydronephrosis has revealed a large population of children with an even wider spectrum of effect and usually without any symptoms (278). While mild dilation with no ureteral dilation is technically a

form of UPJO, some chose to consider this as "physiological hydronephrosis", "non-specific hydronephrosis", or a normal variant. These may be appropriate, but finding the line of demarcation is challenging. It also requires some sense of natural history of the condition, which is not always apparent. Guidelines for evaluating and managing these children remain in evolution. At present, there is a movement away from intervention, which may produce delays in treatment (279–282).

Natural History

One of the remarkable aspects of UPJO, as with ureterovesical junction obstruction (UVJO), is the potential for spontaneous improvement of the apparent obstructive effect (283–286). This is manifest by the resolution of the hydronephrotic changes and is most often seen in children with prenatally detected dilation. The mechanism of resolution, as with the mechanism of obstruction, remains undefined. The fact of resolution should not be interpreted to mean there was no obstruction, only that it was a transient effect. It may produce some negative renal consequence, although that is very difficult to determine. The possible causes include maturation of the pelvi-ureteric function as peristaltic pumps, or changes in down-stream urinary dynamics, particularly the bladder. It is known that apparent UPJO is more common in boys, who are also known to void at high pressure early in life, presumably due to sphincteric immaturity. With maturation of this system, up-stream dilation may slowly resolve. This has been indirectly shown in the fetal sheep (286), yet the correlation with humans is speculative. It is unquestioned, however, that significant hydronephrosis can resolve with an apparently normal kidney remaining. All management of asymptomatic UPJO must consider this aspect.

Consequences

The spectrum of UPJO ranges from minimal renal effects to a non-functioning kidney. The mechanisms of effect have been discussed, but it is clear that UPJO can produce severe renal impairment, both pre and postnatally. The ability to detect this effect clinically is sometimes limited and our current methods are not ideal. Biopsy studies have shown a wide range of changes and a lack of agreement between conventional clinical imaging and pathological changes (34, 35, 254, 287). Global renal functional impairment in the setting of unilateral UPJO with a normal contralateral kidney is rare, yet bilateral obstruction poses the risk of global functional impairment. Even so, some have advocated observational management, as the severity of one side may often be minimal (288). Later development of symptoms is a potential long-term consequence, and while this can be prevented with intervention, a wait and see approach is often chosen. Late onset hypertension is documented to occur, although uncommonly (289, 290). Certainly any child with hydronephrosis or surgically treated obstruction should be monitored for hypertension. On occasion, early onset hypertension will respond to surgical cure.

Ureterovesical Junction Obstruction (UVJO)

Ureterovesical junction obstruction (UVJO) represents a similar clinical process to UPJO at the distal end of the ureter. The term obstructive megaureter, or primary obstructive megaureter (POM), is often applied to this entity, and should be distinguished from a refluxing megaureter. The term non-refluxing, non-obstructive megaureter is often used, but again begs the question as to the definition of obstruction. The same controversy applies to UVJO as to UPJO. Histological studies have demonstrated changes of disordered smooth muscle and excessive, disordered extracellular matrix in resected UVJO, but again, the underlying cause remains indeterminate (*Fig. 56-11*). UVJO is less common than UPJO, representing 23% of cases of prenatally detected hydronephrosis compared with the 41% being UPJ obstruction (267). As with UPJO, UVJO is seen more often in boys and left sided involvement is more common. Bilateral involvement occurs and may pose major challenges to reconstruction and maintenance of normal renal function.

Clinical Presentation

UVJO rarely presents with pain and while it is now mostly detected through prenatal ultrasound, infection is clearly a more frequent clinical presentation. In all cases, evaluation for VUR is important as obstruction and reflux may occur concomitantly. This combination is particularly a matter of concern for severe infection. In the setting of presentation with infection, it should be borne in mind that during acute infection the magnitude of the ureteral dilation may appear far greater than when uninfected (291). This is presumably due to the effect of bacterial toxins on the ureteral smooth muscle tone. Further evaluation after the acute episode is important to clarify the pathophysiology.

Figure 56-11

Operative view of primary obstructive megaureter with narrow distal segment and abrupt transition to the dilated proximal ureter. The narrow segment will be resected and dilated ureter tapered for reimplantation. (See color plate 36)

Natural History

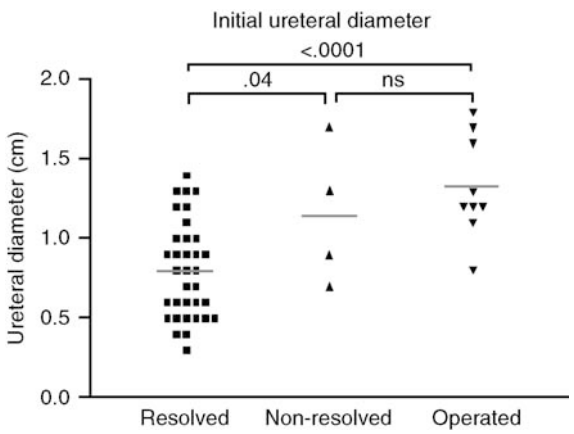
As with UPJO, UVJO can resolve spontaneously, perhaps even more readily (292–294). Similarly, however, it is difficult to predict with any precision just when and in whom it may resolve. The more severe the dilation, the longer it will likely be before resolution (*Fig. 56-12*). The pattern of resolution is clearly one of cranial to caudal, and often the distal ureteral dilation is the last to disappear. Indeed, isolated distal ureteral dilation with a normal kidney may be seen in older children and adults. It is unlikely to pose any risk. Reports of spontaneous resolution demonstrate the high degree of variability and the potential for late deterioration. The author (CAP) has seen functional decline in the affected kidney as late as 8 years postnatal, and similar reports are in the literature (295).

Implications

There are no data as to the renal pathological effects specifically of UVJO, since it is difficult to biopsy these kidneys, even at the time of surgery. It may be presumed that they would follow a similar pattern as seen with UPJO, and the limited correlation of histopathological changes with conventional clinical imaging must be considered.

Figure 56-12

Outcome of children with non-refluxing primary megaureters in relation to initial ureteral diameter. Although it cannot be stated strictly that ureters larger than 1 cm all need surgical intervention, follow-up should be more cautious. From reference (294), with permission.



Posterior Urethral Valves (PUV)

Posterior Urethral Valves (PUV) represents a very different element of COU, largely due to the usually greater severity and because it affects the entire urinary system.

The long-term implications are profound in boys and it remains a leading cause of end-stage renal failure. The ability to intervene in utero is technically present, yet the selection of appropriate cases and the long-term outcomes remain highly problematic. Unlike UPJO and UVJO, there is little controversy as to the need for intervention, and in the context of PUV, the challenge rests in maximizing renal functional development and maintaining the best level of bladder function possible. It is the impact of PUV on bladder functional development that can pose the most significant impediment to maintaining maximal renal function and can impact on functioning of a renal transplant in the setting of renal replacement. The details of these management strategies are beyond the scope of this chapter, but it is essential that any child with PUV be recognized as having potentially serious bladder dysfunction (296–298).

Description

PUV has been recognized as a pathological entity since the mid-1800s, although the clinical implications were best described by HH Young in 1919 (299). PUV occurs exclusively in boys, and any bladder outlet obstruction in a girl would be a distinct entity and very rare. The name is probably not appropriate as the obstructive process is not a valve and the term COPUM (congenital obstructive posterior urethral membrane) has been proposed (300, 301). It is unlikely to catch on and PUV continues to be the best understood term. PUV are seen as a web of abnormal tissue emanating from the veru-montantum in the posterior urethra with an opening inferiorly and fusing anteriorly to look somewhat like a spinnaker sail (*Figs. 56-13* and *56-14*). It is presumed to be an abnormal remnant of the site of ureteral budding, although this is speculative. The typical PUV or Type I of Young's classification, is located at the distal aspect of the veru, but a second type (Type III) can be seen distal to the sphincter and often is a concentric web with a tiny opening, or even a "wind-sock" appearing structure. Young described a Type II valve from the bladder neck to the veru, yet these are likely just folds of non-obstructing prostatic tissue made apparent by the dilation of the prostate from Type I valves or from a sphincteric abnormality.

The upstream effects of developmental obstruction are associated with PUV and these may be profound. In the most severe cases, renal development is very abnormal (302), there is massive hydronephrosis and ureteral dilation, and the bladder is markedly thickened from smooth muscle hypertrophy and matrix deposition (303). The bladder neck may appear markedly thickened and some have considered it to be obstructive in the past, even to the point of resecting it. In fact, it is simply made more evident by the dilation of the bladder above the posterior urethra below, and is not likely to be functionally obstructive. The clinical evidence of ongoing bladder dysfunction has come to be recognized as a manifestation of secondary bladder dysfunction from the PUV and not from bladder neck obstruction (298, 304).

There is a mortality associated with PUV, although it has decreased markedly in recent decades. In the 1950s, 50% of children with the diagnosis of PUV would die in childhood. Today that number is likely to be close to 1%, and those probably represent children with pulmonary insufficiency due to the most severe degree of obstruction associated with oligohydramnios and pulmonary hypoplasia (305).

This aspect of PUV has challenged the perinatal caregiver and prompted ongoing attempts at fetal decompression to permit enhanced lung and kidney development (247, 248, 306–308). These efforts are still evolving,

Figure 56-13

Posterior urethral valves as evidenced on a voiding cystourethrogram with massive left vesicoureteral reflux. The bladder is not markedly trabeculated but the posterior urethra is dilated. The valve leaflets are indicated by the white arrow. The very thin caliber of the urethra is indicative of the severity of obstruction and limited flow, but is of normal caliber.

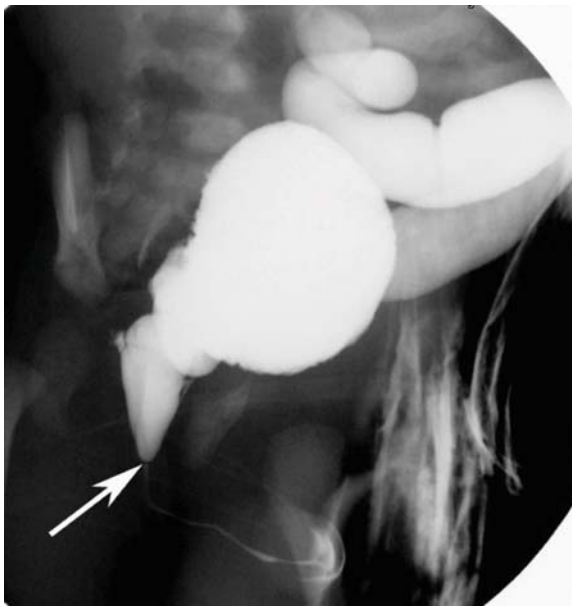


Figure 56-14

Endoscopic image of posterior urethral valves with the veru montanum in the center and the posterior valve leaflets emanating from it laterally and distally. The anterior aspect of the valve is not visible in this image. (See color plate 37)

particularly in the area of patient selection for salvageable renal function. The pathophysiological mechanisms of oligohydramnios-associated pulmonary hypoplasia remain incompletely defined (309–311), yet the association is clear, and these children with PUV are most at risk. Even without pulmonary hypoplasia, renal functional impairment is a significant risk, and it may be slow to emerge.

Clinical Presentation

PUV is often detected prenatally, yet even today many cases are not identified until later in childhood. The severity of the obstruction is a major determinant of the likelihood of prenatal detection and the subsequent delay in clinical diagnosis. The wide spectrum of severity makes this challenge even more difficult. Prenatally, the identification of a male fetus with bilateral hydronephrosis, particularly if the ureters are dilated, and with bladder dilation or thickening, should trigger consideration for PUV (312–315). The status of the amniotic fluid is important as it is related to lung development. The character of the renal parenchyma can predict renal functional outcomes to some degree. Sonographically "bright" kidneys in the setting of PUV may be associated with early renal insufficiency, although the precision of these estimates is poor (313). The pattern of change during gestation may offer some insight as to the outcomes, particularly with rapidly enlarging renal units. The definitive diagnosis of PUV cannot be made with certainty prenatally, but it should be considered probable until proven otherwise. Unless there is consideration for fetal intervention, there is little change in obstetric management that would be undertaken except the site of delivery. Early delivery has not been shown to offer benefits and exposes the child to the risks of prematurity. Evaluation at birth will usually reveal the underlying cause.

In older children, the clinical presentation may be widely variable, ranging from urosepsis and renal insufficiency, to incontinence or UTI. Milder degrees of PUV may not present until adolescence and while it had been common wisdom that late presentation was less severe, it has been clear that these boys can be severely affected (316). Suspicion for PUV should be raised in a boy with a weak stream, failure to thrive, urosepsis or UTI, or even new onset renal failure with no predisposing factors. In most cases, there will be evidence of an abnormality on renal ultrasound and confirmation of PUV by cystography can then be made.

Natural History

The natural history of PUV reflects its wide spectrum. While there are no formal studies of the outcomes of untreated valves, the clinical presentation of older boys, often with severe renal and bladder dysfunction, provides that information. The long-term implications of even acutely treated PUV highlight their natural history.

Long-Term Implications

PUV is a life-long condition (317). While a few boys will have no long-term sequelae, this should not be assumed until they have been followed for several years. For the majority, renal impairment and bladder dysfunction will be a part of their early years and have consequences into adulthood. Recognition of the sometime slow progression of both renal and bladder dysfunction in these boys is critical to any treatment program and it is essential to permit optimizing renal function and bladder control. The dynamic and interdependent nature of the renal and bladder functional impairment continues for years and must be recognized and anticipated. For example, impaired renal concentrating ability exposes the bladder

to higher urine volumes per unit time, which will further aggravate a small capacity, stiff, poorly compliant bladder, thereby raising intravesical and subsequently intra-renal pressures (318). This will only serve to further exacerbate the concentrating defect, creating a vicious cycle of dysfunction. Recognition and interruption of the cycle is essential. Infection is always a threat to both renal and bladder function, and may require a variety of interventions to protect the urinary tract and the child.

As with any condition affecting childhood renal function, PUV can have profound systemic effects on growth, development, and with the attendant medical interventions, socialization. Caring for these children is a lifelong involvement.

Basics of Clinical Diagnosis of COU

The clinical management of COU is defined by imaging. The aim of any evaluation approach is to define the anatomy and functional state of the entire urinary tract. Failure to recognize the potential for other areas of abnormality or dysfunction is a common cause for misdirected therapy. No one imaging technique is ideal in representing the state of the urinary tract or kidney in obstructive conditions, and we are constrained by their limitations. Developing a means by which to integrate these studies into our clinical management is essential to deal with the wide spectrum of severity of COU and provide reasonable treatment recommendations to patients and their families.

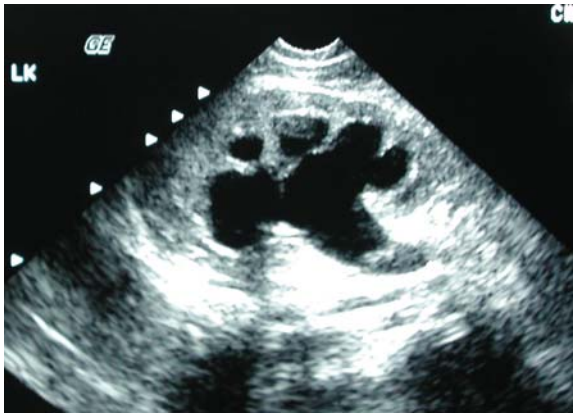
Modalities

Ultrasonography

The most common and perhaps the most versatile imaging tool today is the ultrasound. It offers a non-invasive means to obtain detailed structural information about the urinary tract with ready inference of functional data. While ultrasound is a static image and is often referred to as non-functional, appropriate inference can afford functional information. The state of hydronephrosis relative to bladder filing is important. If the kidney is dilated with a full bladder and yet drains with bladder emptying, all visible on ultrasound, the degree of hydronephrosis must be interpreted differently than if it is unchanging. The degree of hydronephrosis is an excellent basic marker of the severity of obstruction. In the absence of calyceal dilation, it is fairly clear that the degree of obstruction is limited. Indeed in these patients we would not recommend functional imaging such as a renal scan. In contrast, dilation of all of the renal calyces, even with less renal pelvic dilation (*Fig. 56-15*), suggests a greater degree of obstructive change than when these are non-dilated. Pelvic dilation is often measured as an indicator of severity, yet may be exaggerated with an extra-renal pelvis that makes this number high and worrisome, yet may be relatively insignificant.

Figure 56-15

Ultrasound image of hydronephrosis consistent with a ureteropelvic junction obstruction (UPJO) based on the absence of any ureteral dilation. All calyces are dilated. The renal parenchyma is distended but not markedly stretched.



The degree of hydronephrosis and the state of the associated renal parenchyma are key factors in describing any hydronephrotic state, along with laterality, the state of the bladder, and whether there is ureteral dilation as well. While there is no universal ultrasound grading system for the kidney, the Society of Fetal Urology (SFU) system is as close as available (319). This provides a level of grading that is useful and facilitates communication. Simply stating the presence of hydronephrosis is completely inadequate in a radiological or clinical communication and an indication of the relative severity, distribution and associated findings is essential.

The severity of hydronephrosis is a fairly good representation of the severity of obstruction in most cases (320). This correlation will fail in previously operated cases, in the co-existence of reflux, and in some anatomic conditions such as megacalycosis (321). In the transplant population, hydronephrosis is not always present in the setting of an obstructive effect. In general, however, all obstruction produces hydronephrosis, but not all hydronephrosis represents obstruction. From a practical

standpoint, simple pelvic dilation is rarely associated with a functionally significant obstruction. As relative severity increases, progressive dilation of the calyces and distention of the cortical tissues will be evident. The change in the shape of the kidney does not always indicate loss of function or tissue. The use of terms such as cortical atrophy or cortical thinning suggests loss of function, yet this may simply be stretching of the tissue with dilation.

In the child with asymptomatic hydronephrosis, usually with prenatal detection, the degree of dilation has correlated with the risk of functional loss on longitudinal studies (322). There is no clear cutoff at which it is safe to ignore the finding, and it is unclear what effect longer times of observation might reveal with lesser degrees of dilation. Despite modern imaging, this is one of the few clear findings that predicts functional outcome statistically. However, it is difficult to translate that into clinical practice in many cases. Further imaging is usually used to better define the status of the kidney and the risk of deterioration.

Nuclear Renal Imaging

The most commonly used means to assess the severity and functional effects of obstruction is the MAG-3 diuretic renogram. MAG-3 (MercaptoAcetyl tri-Glycine tagged with ^{99m}Technetium) is principally secreted by the tubules with 10–20% filtration. The measure of relative uptake is comparable to the relative function by GFR, and is measured by the relative amount of tracer uptake by each kidney 2 min after injection. It is always important to recognize that this does not assess global function unless the total fraction extracted by the kidneys is estimated and these estimates can be difficult and imperfect. When a kidney is markedly dilated, the assessment of relative function may be less precise due to a greater impact of background uptake, particularly on the right with the overlying liver. On occasion the affected kidney will demonstrate greater than the expected 50% uptake and it remains controversial as to whether this is a real effect of obstruction or a technical artifact (323–325).

The washout phase is used to assess the severity of obstruction and is conventionally performed by administering a dose of furosemide when the affected renal pelvis is full and monitoring the time required to clear one-half of this amount (t1/2) in minutes. The conventional interpretation is that if the half-time is less than 10 min then drainage is normal, while 10–20 min is indeterminate, and over 20 min is indicative of obstruction (*Fig. 56-16*). It is necessary to interpret these numbers in the context of the individual and to examine the patterns of washout to permit a clinical interpretation. Simply going by the number is unlikely to be satisfactory. Some washout curves are biphasic with a rapid decline to partial drainage than a flat curve. Depending upon the means used to calculate the half-time, these curves may give falsely high or low numbers (326). Other factors that may cause differing interpretations of a diuretic renogram include posture, the fullness of the bladder and whether a catheter is used, and the timing of the diuretic administration. More recently interest has developed with diuretic administration concurrent with or 15 min prior to the tracer, the so-called F-0 and F-15 renal scan (327–330). It is critical to recognize that none of these studies or their thresholds for obstruction has been validated in any useful way in the infant population. In a study of the histopathology of pediatric UPJO, diuretic renal scan findings correlated poorly with histological changes (35).

The timing of the MAG-3 is subjective and some advocate not using this study in the very young child, but it is clear that reasonable results may be obtained in children at one month. The other issue is the need for repeat studies. This is a complicated and invasive study by most parents' perceptions, and accordingly, we try to limit its use. In the typical patient with significant hydronephrosis and generalized caliectasis, the MAG-3 would be performed at 2–3 months of age, then again at 1 year. If the relative function is decreased initially, a study at 6–9 months may be obtained, but this is rarely different from the initial study. Patterns of change over time are probably the most useful parameters to indicate the status of the affected kidney.

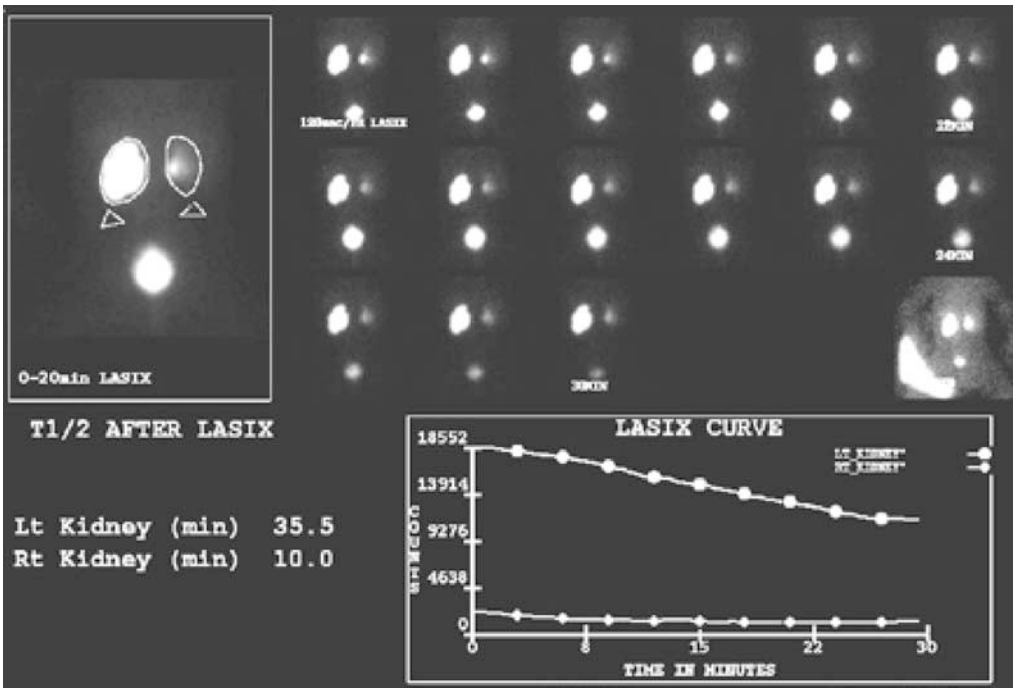
Nuclear studies remain the "gold-standard" for the functional assessment of the hydronephrotic kidney, but better modalities are clearly needed.

Magnetic Resonance Imaging (MRI)

The most promising new modality for functional imaging of the urinary tract is magnetic resonance imaging (MRI) with the ability to provide exquisite detail of the anatomy as well as providing functional assessment (*Fig. 56-17*) (332). The anatomic value is best seen in complex cases where the ultrasound images are difficult to interpret. This is most often in cases of duplication and where the ureter is obstructed near the bladder and may be ectopic. With fine resolution, the presence of a crossing blood vessel causing ureteral obstruction may be detected. These cases are the minority of pediatric hydronephrosis where the anatomy is well defined by ultrasound, but the functional implications are uncertain. In this regard there is much potential with MRI, but it has not yet moved to that level of widespread use. Several centers have focused on using this study, but the functional assessment of obstruction

Figure 56-16

MAG3 diuretic renogram in prenatally detected ureteropelvic junction obstruction (UPJO), demonstrating delayed washout of the tracer on the left side (posterior view). The $t_{1/2}$ of 35 min would be strongly suspicious for obstruction. The slightly elevated $t_{1/2}$ for the right side only reflects the fact that by the time the diuretic was given and counting began, the pelvis has washed out nearly completely.



remains at a level similar to that of the MAG-3. The correlation with functional outcomes has yet to be established. Until that time, it will be difficult to justify the extra expense of these studies in the routine UPJO in whom the functional impact of the obstruction is uncertain.

Excretory Urography

The IVP (intravenous pyelogram) remains a tried and true standard to provide anatomic and functional information regarding the urinary tract. While uncommonly performed today, it remains a useful tool in select situations. As with the MRI, these are cases in which the anatomy is not fully defined by ultrasound. The functional interpretation of the IVP rests on the fact that the contrast agent is handled similarly as with most other tracers and the rate and symmetry of passage through the kidney is a clear indicator of the level of obstruction. However, because it cannot be quantitated, and there are no numbers attached to this assessment, it has been considered subjective. This is true and for longitudinal comparisons, the diuretic renogram is preferable, but it must be recognized that the actual significance of any of the numbers on a renal scan is to some degree subjective. The radiation exposure of a well performed IVP, and the reduced cost are attractive, yet it is being used increasingly less in most centers.

Retrograde and Antegrade Pyelography and Pressure Perfusion Studies

It is rare that direct contrast instillation into the affected kidney provides information that is necessary to define clinical management. However, when this is needed, either retrograde pyelography or antegrade pyelography can be a useful tool. Often they can be performed in conjunction with an operative procedure or after a temporary nephrostomy has been placed for drainage. Both are invasive and require general anesthesia in most cases in children. Retrograde pyelography requires cystoscopy to place the ureteral catheter and it is important to recognize that this may trigger a significant infection if no other drainage procedure is performed. It is very risky to use a

Figure 56-17

simple diagnostic retrograde pyelogram to assess a UPJO if a stent or operation is not performed.

Antegrade pressure perfusion studies have had some interest in the past, but their utility remains limited. Several versions of the classic Whitaker test (333, 334) have been introduced using different patterns of flow into the renal pelvis to stress the drainage system and to determine pressure differentials between the kidney and ureter or bladder (335). Most are non-physiologic, and none have been correlated with functional outcomes in the population most of interest. They have some utility in the previously operated kidney with persisting dilation that may simply represent ectasia of a dilated system or ongoing obstruction. Static renal pelvic pressure measurements have been explored as possible indicators of the severity of obstruction, but are not clinically used to date (336). Interpretation of these studies remains more of an art than science and they are rarely used.

Cystography

The voiding cystourethrogram (VCUG) is an essential part of most basic evaluations of the child with hydronephrosis, even when the presentation was asymptomatic. Since reflux can both cause and co-exist with hydronephrosis, and contribute to separate obstruction due to ureteral dilation, its assessment is important. In addition, the VCUG provides a thorough evaluation of bladder function in terms of the structure of the bladder, the patency of the urethra, bladder emptying and if there is reflux, an anatomic definition of the upper tracts. In the setting of reflux and hydronephrosis, grading of reflux is difficult if some element of obstruction is present. This is most evident when there is a mismatch between the ureter and renal pelvic dilation; it is also evident if there is dilution of the refluxed contrast due to renal stasis. In such a setting, it is imperative that the radiologist perform delayed images to look at washout of the contrast agent. Prompt washout of a dilated system eliminates the need to obtain a diuretic study and confirms non-obstructive dilation. There are some situations, however, when discriminating between ureteral dilation from reflux and a possible co-existing UPJO is very difficult. At times a somewhat arbitrary choice to correct one is needed followed by close observation to determine the response of the other (337).

Clinical Interpretation

Creating a synthesis of the imaging information with the clinical scenario remains a challenge and must reflect the

apparent severity of obstruction, the health of the child, the preferences of the parents, the ability to maintain follow-up, and the availability of surgical resources. There is no single formula for managing the child with asymptomatic hydronephrosis. In contrast, the child who presents with symptoms or who develops them on observation can be moved to surgical correction promptly. While it may at times be uncertain whether the symptoms are due to the obstruction, most often this is evident. There is very little reason to delay therapy.

General Management Principles

As a practical approach for the infant with asymptomatic hydronephrosis, usually after prenatal detection, segregation by severity can be based on the initial ultrasound. Those children with moderately severe to severe hydronephrosis, with caliectasis, will require ongoing monitoring and functional assessment. This will be with a MAG-3 diuretic renogram and the differential function and washout times will be the most closely followed. If the initial function is lower than 45%, follow-up MAG-3 may be appropriate in 6–9 months rather than waiting for 1 year. Ultrasound imaging should be obtained in the short term, 4 months, to ensure that this is not increasing, a rare but obviously important observation. We have found that assessment at one year to be most useful if no significant improvement has occurred, and function is stable, then it is less likely that spontaneous improvement will occur within the first 5 years of life. It appears as if the first year is the most dynamic, either for better or worse. These are not hard-and-fast rules and require adaptation to the clinical context.

For patients with less severe hydronephrosis, functional imaging is not usually useful and regular ultrasound imaging can provide useful data and can detect worsening hydronephrosis that would warrant a functional assessment. Imaging intervals are usually increased over time. It is our practice to monitor until normal, and while there are no data to indicate that this is essential, it seems cautious.

The child with posterior urethral valves or an anatomic abnormality that will not resolve spontaneously, such as an ectopic ureter or ureterocele, is best managed with definitive intervention and decompression. While there are some reports of expectant management of ureteroceles (338), this seems to be inappropriately risky with little real advantage. We have seen several cases of initial presentation of ureteroceles, and even ectopic ureters that are more complex than if they had been treated early in life. There seems little rationale for planned delayed management of obvious structural anomalies in children.

Specific Management

The management of each specific form of urinary obstruction is well defined and there is relatively little controversy in this regard. New modalities that are intended to be less morbid are in the process of replacing open surgical methods, although they are still not in the realm of being the gold standard. Their introduction has raised the question of changing the threshold for intervention if that intervention results in less morbidity.

UPJO Management

UPJO is best treated with a dismembered pyeloplasty, either open or laparoscopic. This is a well-established and predictable operation that can be performed with minimal invasiveness and children can be sent home on the same or the first post-operative day. Laparoscopic pyeloplasty is not yet widespread and even with open surgery; children do very well with this operation. Alternatives such as endopyelotomy or cutting of the stenosis and stenting to permit healing in an open state, is attractive, but has not had adequate outcomes (339–342). Even for reoperative procedures, this modality has not lived up to its initial enthusiasm.

Laparoscopic pyeloplasty in children has been used for over a decade (343), but still remains of limited availability. This is largely due to the difficulty of learning to perform accurate and efficient suturing for this procedure. Success rates are good and morbidity seems to be decreased. With the advent of robotic surgical technology, the learning curve for this type of laparoscopic surgery is markedly shortened (344–347). The DaVinci® (Intuitive Surgical Corp., Sunnyvale, CA) surgical system permits precise, well visualized and delicate surgery for this type of reconstruction in children as young as 3 months with good outcomes. While not yet widely available or used in children, this technology offers significant potential for reducing morbidity for complex reconstructive surgeries. The procedure is performed through three laparoscopic ports, guided through a master-slave "robotic" system with the surgeon controlling the movements at a console. Visualization is in three dimensions and the precision is excellent. While the system was not designed for children, it has been used successfully. Older children will demonstrate a more apparent improvement in

operative morbidity over open surgery, but it can be seen subjectively in younger children as well.

Open surgery is still the gold standard for correction of UPJO through the dismembered pyeloplasty. This can be performed in the flank position or through a dorsal lumbar incision. Both are cosmetically reasonable and do not require muscle cutting. The procedure consists of resection of the stenotic segment, some reduction in the size of the dilated renal pelvis, and re-anastomosis of the ureter to pelvis. This is often performed with an internal ureteral stent to facilitate early healing and drainage; some surgeons use a wound drain or a nephrostomy. Success rates should be in the 95–97% range based on reduction in hydronephrosis and on functional parameters on renal scan (348).

Recovery is quick in infants but slower in older children, with 1–4 day hospital stays. The exposure is excellent. There has been a movement toward smaller and smaller incisions, largely in response to laparoscopy, and this has raised concerns regarding exposure and the ability to manipulate delicate tissues precisely. Exposure is a critical principle of surgery and the current laparoscopic images offer exceptional views of the kidney. This should facilatate surgical reconstruction. Where minimally invasive technology will evolve for pediatric renal surgery remains uncertain, but there has clearly been significant progress in reducing perioperative morbidity due to a variety of means, and this is likely to continue.

Management of Ureterovesical Junction Obstruction (UVJO)

Obstruction of the distal ureter is more difficult to repair than to just resect the obstructed segment as with a UPJO. The stenotic segment is at the end of the ureter, which must then be detached and re-anastomosed into the bladder, and in such a way as to prevent urinary reflux. The standard procedure today is a tapered ureteral reimplantation. This author (CAP) favors an excisional tapering to provide adequate reduction in ureteral caliber to permit effective reimplantation. The key elements of this procedure are to preserve ureteral vasculature and provide an effective anti-reflux reimplantation. Ureteral stenting is necessary but can be done with internal stents and extraction strings, limiting the hospital stay to 2 or 3 days. Ureteral plication has been used widely as well, but is not satisfactory for larger ureters. Success rates in general are good, approaching 90% with no residual obstruction or reflux (349).

Less invasive methods have been described but have few data to support their widespread use to date (350). These include prolonged stenting of the obstructed megaureter to permit dilation (351). This method has been used in infants, but is reported to require an open incision. Laparoscopic methods have been used to a limited degree, with success, but this is a challenging operation with a subjective loss in manipulative ability due to the working area. In time, this is likely to develop as methods are evolved to facilitate surgical manipulation.

In general, megaureter repair is a less frequently performed operation and as a result, many surgeons are less comfortable with it and will often avoid it. When it is deemed appropriate, an experienced surgeon should be involved, as the consequences of failure are significant.

Management of Posterior Urethral Valves (PUV)

Surgical management of PUV begins with endoscopic valve resection in most children, but frequently requires multiple further surgeries to address the secondary consequences of bladder obstruction, including ureteral reimplantation, often with tapering of the ureters, bladder reconstruction with augmentation or continent catheterizable stomas. The details of these procedures are beyond this chapter and are readily available in basic surgical texts. Managing the child with valves requires experience and a willingness to employ these procedures.

Endoscopic resection of valves is a brief procedure using a cystoscope, usually passed through the urethra. It requires significant skill and experience (352). Even after years of experience, this author (CAP) finds this procedure a significant challenge and it should never be viewed as simply snipping some tissue. The potential for injury to the urethra and creation of strictures is significant. Parents are usually counseled that a lesser resection is safer, even if it requires a second operation to achieve complete valve resection. None-the-less, endoscopic valve resection is a well-established and successful procedure with limited morbidity. It can be done as an outpatient in the healthy child and may or may not require a catheter. Follow-up cystography is needed to confirm patency of the urethra and to reassess any reflux.

Subsequent clinical follow-up is dependent upon the initial status of the urinary tract to address the response to decompression, both functional and anatomic. Long-term monitoring of the renal and bladder function is essential in most cases.

In the rare case of very severe valves, temporary proximal diversion may be appropriate to permit growth and development of the infant with maximal renal drainage. This can be in the form of a vesicostomy or ureterostomies. The latter are rarely performed today, but may

be useful in cases where the bladder is profoundly abnormal and there is ineffective drainage from the ureters into the bladder. In general, these diversions are only used when the child is too small to undergo endoscopic resection or if catheter drainage of the bladder does not produce satisfactory improvement in renal functional parameters or hydronephrosis (353, 354). Controversy persists as to the optimal approach in these patients, and in the impact on bladder and renal function (304, 355). Diversion is always performed with a plan for re-functionalization after a period of decompression, often 6–12 months, depending on the renal function and particularly the bladder function.

Ectopic Ureter and Ureterocele

Management of the obstructed elements associated with an ectopic ureter or ureterocele are dependent upon the anatomy, functional status of the affected renal segment, and associated conditions such as reflux. The basic approaches include removal by way of a partial nephrectomy if there is a poor function or a drainage procedure. Drainage can be accomplished by joining the affected ureter to the unaffected segment or by ureteral reimplantation of the affected ureter, usually in combination with the unaffected ureter (a so-called double-barrel or common-sheath reimplantation). Similar strategies are applicable with ureteroceles, except that it is possible to decompress a ureterocele through a simple endoscopic incision, with the risk of developing new reflux that may need later surgical management (356, 357). This less invasive approach is particularly useful in the infant.

As noted above, some have advocated for an observational approach to ectopic ureters and ureteroceles, and indeed a rare few might never cause a problem, but this is a condition that will not resolve on its own and due to stasis of urine, is at risk for infection. Late presentations of previously asymptomatic ureteroceles and ectopic ureters would argue to definitively correct the obstruction at presentation.

Summary

Congenital obstructive uropathy remains a challenging and important clinical condition affecting large numbers of children to widely varying degrees. In parallel with most pediatric conditions, the overall goal in managing COU is that of maximizing the functional potential of the urinary tract. The unique aspect of COU being ongoing during the development of the kidney and urinary tract is a key aspect of this condition that distinguishes it completely from acquired obstruction and demands a distinct perspective. The most appropriate management must be determined individually, although broad guidelines are clear. It remains an essential element of management to perform a thorough functional and anatomic assessment of the entire urinary tract and to avoid focusing exclusively on the affected segment. Clearly some of these conditions will resolve spontaneously without apparent harm, but others will inevitably progress and produce irreversible renal injury or developmental retardation. Distinguishing those patients is the crux of the current clinical challenge and requires a clinical synthesis that recognizes the inherent uncertainties. It is clear that current clinical indices are not fully reflective of the developmental renal pathology present. An approach that may allow some over-treatment is seen as preferable to one that may permit under-treatment.

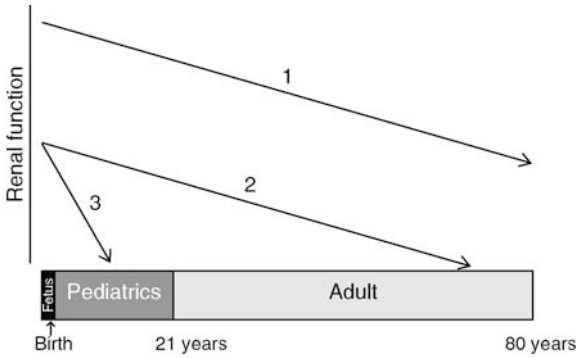
Long-Term Follow Up

The long-term prognosis for infants and children with congenital obstructive uropathy is poorly defined. Unfortunately, many children undergoing pyeloplasty for UPJO, and found to have a satisfactory immediate postoperative course, are lost to follow up after several years. In light of the experimental evidence, as well as the limited clinical data available, it is likely that some of these patients will eventually develop proteinuria, hypertension, or chronic renal insufficiency. Although a large proportion of infants with equivocal hydronephrosis identified prenatally appear to have normal renal functional development without intervention (358), others may demonstrate progressive impairment (359, 360). Failure of the patient's family to comply with follow up imaging may contribute to renal functional deterioration if surgical correction is deferred (361). Obstruction has thus been defined as "a condition of impaired urinary drainage which, if uncorrected, will limit the ultimate functional potential of a developing kidney" (266).

The prognosis for children with PUV is more grim: a majority of patients diagnosed in fetal or neonatal life develop renal insufficiency by 10 years (307, 362). The rate of deterioration of renal insufficiency for an individual patient with congenital obstructive uropathy depends on both the severity of fetal renal maldevelopment and ongoing injury due to obstruction or infection. Mild fetal obstruction is likely to have a minimal impact on renal growth or function, although changes may become apparent in late adulthood. Moderate obstruction may lead to significant renal deterioration in early adulthood, while severe obstruction results in renal insufficiency in

Figure 56-18

Scheme showing long-term impact of congenital obstructive uropathy. The urinary tract abnormality develops in embryonic and fetal life, but if mild (1), the consequences of the condition may become apparent only later in adulthood, if at all. If moderate (2), progression of renal insufficiency may develop earlier in adulthood. If severe (3), renal failure develops in infancy or childhood. Fetal intervention should take into account not only the health and welfare of fetus and mother, but the long-term implications of perinatal management. From reference (258) with permission.



infancy or childhood (*Fig. 56-18*). At a minimum, all children with obstructive uropathy should have regular measurement of blood pressure, plasma creatinine, urinalysis, and periodic renal ultrasound. Every attempt must be made to maintain normotension, and to minimize proteinuria. Nonsteroidal anti-inflammatory drugs should be avoided. In the transition of care from pediatrician to internist, this follow up should be maintained throughout adulthood.

57 Bladder Dysfunction in Children

Michael E. Mitchell, MD · Anthony H. Balcom, MD

Normal Bladder Development

In Utero Development of the Bladder

Although the molecular biology of bladder development is still the subject of research, some basic developmental phases of bladder embryology are known. The bladder starts to develop in the fourth week of gestation and probably represents the fusion of two different structures. The first is the urogenital sinus, the anterior portion of the cloaca, which is contiguous with the allantois derived from endoderm. The second is the caudal end of the mesonephric duct, the common excretory duct derived from intermediate mesoderm, which joins with the urogenital sinus on the 24th day of gestation and proceeds to differentiate into the trigone, posterior bladder neck and posterior proximal urethra.

The result is that the urogenital sinus becomes the body of the bladder, or the detrusor, and the mesonephric duct differentiates into the bladder base and proximal urethra. Because of this fusion of different embryonic tissues it is not surprising that innervation and vascular supply may also be unique relating to tissues of origin. Furthermore, the need for coordination in function in the "developed" organ may be complex.

By the 10th week of gestation the bladder is tubular in shape, lined by a single layer of cuboidal epithelial cells and connected with the allantois via the urachus. By 12th week the urachus is closed and the bladder is now lined with two layers of cuboidal epithelium. At 12 weeks the bladder wall has thickened with the development of connective and muscle tissues. This process starts at the bladder dome and progresses to the bladder base. By the 21st week the epithelium is similar to mature urothelium (4–5 cell layers thick).

Bladder compliance is low initially but increases throughout in utero development. This process seems to correlate with production of urine and bladder filling and empting, which is intuitively logical, and a very important concept that can be expanded and applied to repair of an abnormal bladder. The mechanism of the bladder wall change seems to be that of decrease and change in the collagen structure of the developing bladder wall and the increase in smooth muscle fibers (1). Beuboeuf, et al. (2) used a mouse model to demonstrate that mechanical forces influence bladder wall structure and organization.

On the other hand continence mechanisms in utero have not been the focus of study so far. However, it is known that by 15 weeks gestation there is condensation of smooth muscle fibers at the caudal extent of the developing bladder that ultimately forms the bladder neck and proximal urethra. The distal portion of this smooth muscle is wrapped anteriorly with striated muscle. The result is the formation of the voluntary urethral sphincter (3). In boys this is connected laterally to the prostate, but in girls it is attached to the lateral aspect of the distal vagina as both of these structures are developing at this point.

The development of the bladder and sphincteric mechanisms has been tightly linked with the production of urine in utero determined by ultrasound (4) (*Fig. 57-1*). However these fetal bladder volume measurements may actually correlate more accurately with the development of functional bladder storage. Clearly, bladder storage and urine production are closely related. Support of this concept comes from the well-known observation that in the fetus with renal agenesis the lower urinary tract does not progress in its development; the bladder and ureters are present but hypoplastic. Thus, not only is there apparent bladder storage in utero, but also bladder empting. This would imply that the developmental process is also associated with development of a complex neurologic control of the lower urinary tract. Furthermore, because of the convergence of two different embryonic tissues one might predict that the neurogenic coordination of the mature organ may be complex. This may help to explain the complexity of the spectrum of dysfunction of the bladder.

The First Year of Life

The bladder of the newborn child is not like that of an older child in terms of structure and function. During growth and development, before and after birth, the bladder is in a state of continuous change. (1, 5) The impetus

© Springer-Verlag Berlin Heidelberg 2009

Figure 57-1

In Utero ultrasound image of the Fetus. This image demonstrates a pathologically enlarged urinary bladder at about 26 weeks of gestation, consistent with either Prune-Belly Syndrome (which was the diagnosis established after delivery of this fetus), or Posterior Urethral Valves.

for this change seems to relate to the physical forces exerted, both filling and emptying, on the developing bladder wall (6). In utero the bladder is small with low compliance. After birth there is continuous bladder change with increasing capacity and compliance which reflects bladder wall elasticity. Truly coordinate voiding, however, does not occur until after the first few months of life, which may partially explain the increased potential for infections in this period. As far as urine control is concerned, however, it is evident that voiding remains automatic; coordinate but not socially appropriate, until the end of the first year of life. Thereafter, potential for volitional voiding function develops with the ability to inhibit automatic voiding. However socially appropriate voiding; potty training, does not usually occur until ages 2–5 depending on numerous factors related in part to the maturation of the spinal tracts and social norms and pressure. What we are coming to realize is that, just as there is change with normal growth and development, pathologic conditions in the bladder originating prior to birth do have potential to reverse in the first years of life given the appropriate physical stimuli, specifically filling and empting (7).

Physiology of the "Normal Bladder" Defined by Anatomy and Function

The physiology of normal bladder function is a complex 'moving target' in young children. Bladder function is usually defined by the measurable characteristics of storage and empting.

Bladder storage function is defined and dependent on four parameters. These are:

1. *Bladder Volume or capacity* (V in ml.) which is usually measured at the point of maximal filling, the point of desire to void, or overflow leaking.
2. *Bladder Compliance*, or elasticity, measured by the ratio of detrusor pressure at a given volume, V/P, ml/cm H_2O, or the slope of filling phase curve. This is the Pressure in the bladder plotted against the Volume instilled into the bladder.
3. *Bladder Sensation* measured as both the first sensation of fullness, and point of desire to void.
4. *Sphincteric function* measured by the ability of the bladder neck and proximal urethra to remain closed during bladder filling. This observation is usually made with fluoroscopy, or by simply observing leakage from the urethral meatus.

Each of these parameters changes with normal development and depends on multiple parameters such as patient age, size and development.

Bladder empting function is both defined and dependent on two parameters. These are: 1. The ability of the bladder detrusor to contract and generate pressure to facilitate flow; and 2. the ability of the sphincteric mechanism to relax in a consistently coordinate manner, usually measured by Electromyographic (EMG) activity of the

pelvic floor musculature. However, functionally, bladder empting is measured by urine flow rate during voiding and ability to empty the bladder completely.

Urodynamics is the mechanism by which the parameters of filling and empting are evaluated. In this study the bladder is filled with either H_2O, or CO_2 while the pressure is monitored in the bladder via bladder catheter and in the abdomen via rectal balloon while monitoring the EMG activity of the pelvic floor, measured by needle or surface electrodes in the perineum. The study is often performed with fluoroscopy, "Video Urodynamics", so that the appearance of the bladder wall, presence or absence of vesico ureteral reflux, efficiency of empting, and most importantly, the appearance of the bladder neck and urethra, and their respective pressures can be simultaneously evaluated and recorded. With a carefully performed study and with proper patient cooperation, which is the real limiting factor in using this evaluation in children, the anatomy and physiology of the lower urinary tract can be defined.

The idealized data of a normal urodynamic study is shown in *Fig. 57-2*. The tracing shows the relationship between the true detrusor pressure (corrected by subtracting abdominal pressure from measured bladder pressure: P_{ves}- P_{abd} = P_{det}) and the volume in the bladder. Bladder pressure and vesical pressure are both terms for the same parameter, while detrusor pressure is a subtracted pressure. The rate of filling in ml/min is usually 0.1x anticipated bladder capacity, e.g., a 200 ml bladder would be filled at 20 cc/min.

Bladder capacity is defined as the volume at which the patient either voids spontaneously, or leaks, or requests the filling stop because of discomfort or the strong urge to void. Compliance is defined by the slope of the filling phase (tonus limb) curve prior to the initiation of voiding. Sphincteric, striated or external sphincter EMG activity will increase with bladder filling ("recruitment") but stop abruptly with initiation of void. Bladder neck competence and opening with voiding is best seen with fluoroscopy. Efficiency of voiding is measured by measuring urinary flow rate and completeness of bladder empting. Abnormal bladder function represents deviation from anticipated normal values.

In reality, however, a good history of normal bladder function can be elicited from parents and older pediatric patients, which obviates the need for, or can accurately predict the findings of a urodynamic study. Prior to potty training wetting should be periodic without dribble between or undue straining with voiding. Most parents will have observed a child's voiding "stream" and will be able to characterize it as full, thick or thin, continuous or interrupted, so called "staccato voiding". Toilet training in years 2–4 is normal, persistent daytime wetting accidents after age five may indicate a problem. Nighttime accidents are not uncommon through age seven years. Most parents can usually accurately describe the various forms of incontinence (stress, urgency, dribble, and insensate) in their child but will usually not volunteer the information unless specifically questioned.

The Abnormal Bladder

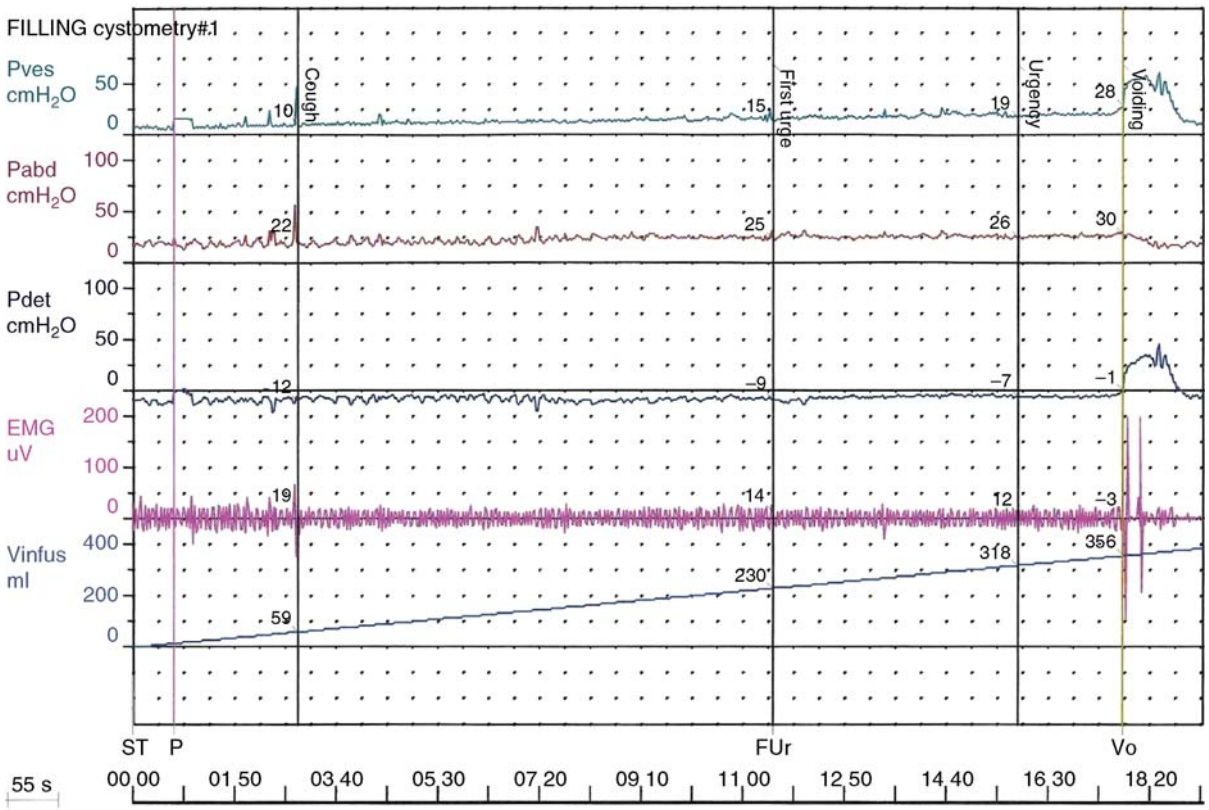
Pathophysiology of Bladder Dysfunction

The pathophysiology of the "abnormal" or "dysfunctional" bladder represents a breakdown of any one, or a combination of some or all of the physiologies of the normal bladder, and can represent a broad spectrum of potential pathologies and abnormal physiologies resulting in the symptoms of incontinence or infection. For example, urinary incontinence related to abnormal storage is characterized on urodynamic studies by uninhibited bladder contractions, e.g., overactive bladder, especially in the first third of filling or, the middle part of filling, rather than at near capacity. Urinary incontinence may also relate to small bladder capacity, e.g., congenitally small bladder, or normal potential capacity with poor bladder compliance, e.g., bladder scarring from infection or surgery, posterior valves, myelodysplasia, or sacral agenesis. Abnormal storage of urine can also be characterized by poor compliance; that is, bladder pressure rises too quickly with bladder filling, this can be observed in patients with bladder out flow obstruction cause by urethral valves, myelodysplasia or after bladder neck and urethral surgery. *Figure 57-3* shows a urodynamic study of a child with these findings.

Bladder neck dysfunction is also discernable with a video urodynamic study as prematurely opening during filling, associated with stress incontinence, or remaining closed during attempted voiding; resulting in overflow incontinence, urge incontinence and large post void residuals. Normally, the bladder neck is closed until voiding begins, at which point it opens completely. However, some children demonstrate a fixed, open bladder neck: myelomeningocele, neurogenic, and bladder exstrophy patients after surgical repair. An alteration of the normal sacral spinal cord nucleus (Onuf's nucleus) including the afferent and efferent nerves can cause a spectrum of bladder neck dysfunction. For example, lower motor neuron injuries will typically contribute to an open, patulous

Figure 57-2

Normal Urodynamic study. This figure depicts normal bladder storage and emptying characteristics during urodynamic evaluation. The patient is a 9-year-old female found to have a thickened filum terminale by Magnetic Resonance Imaging (MRI), but normal voiding. The bladder pressure curve, Pves, the top line, demonstrates a normal filling phase with the first sense of urgency at volume of 230ml. Bladder pressure stays low, which is normal, up to volume of about 356ml, at which point patient begins voiding with true detrusor contraction. The second line from the top is Pabd, a reflection of "abdominal pressure" by rectal catheter. The third line is Pdet, "detrusor pressure", which is a subtracted pressure: Pves minus Pabd. The fourth line from the top is EMG activity, demonstrating normal baseline activity of the striated pelvic floor musculature, and then quieting with voiding. The bottom line, Vinfus, is "volume infused in milliliters", representing bladder capacity at each point. On this urodynamic study one can see a frequent clinical situation we encounter, which is "the computer" subtracting abdominal pressure from measured intravesical pressure, which results in a "negative" pressure in the bladder, which is artifactual.

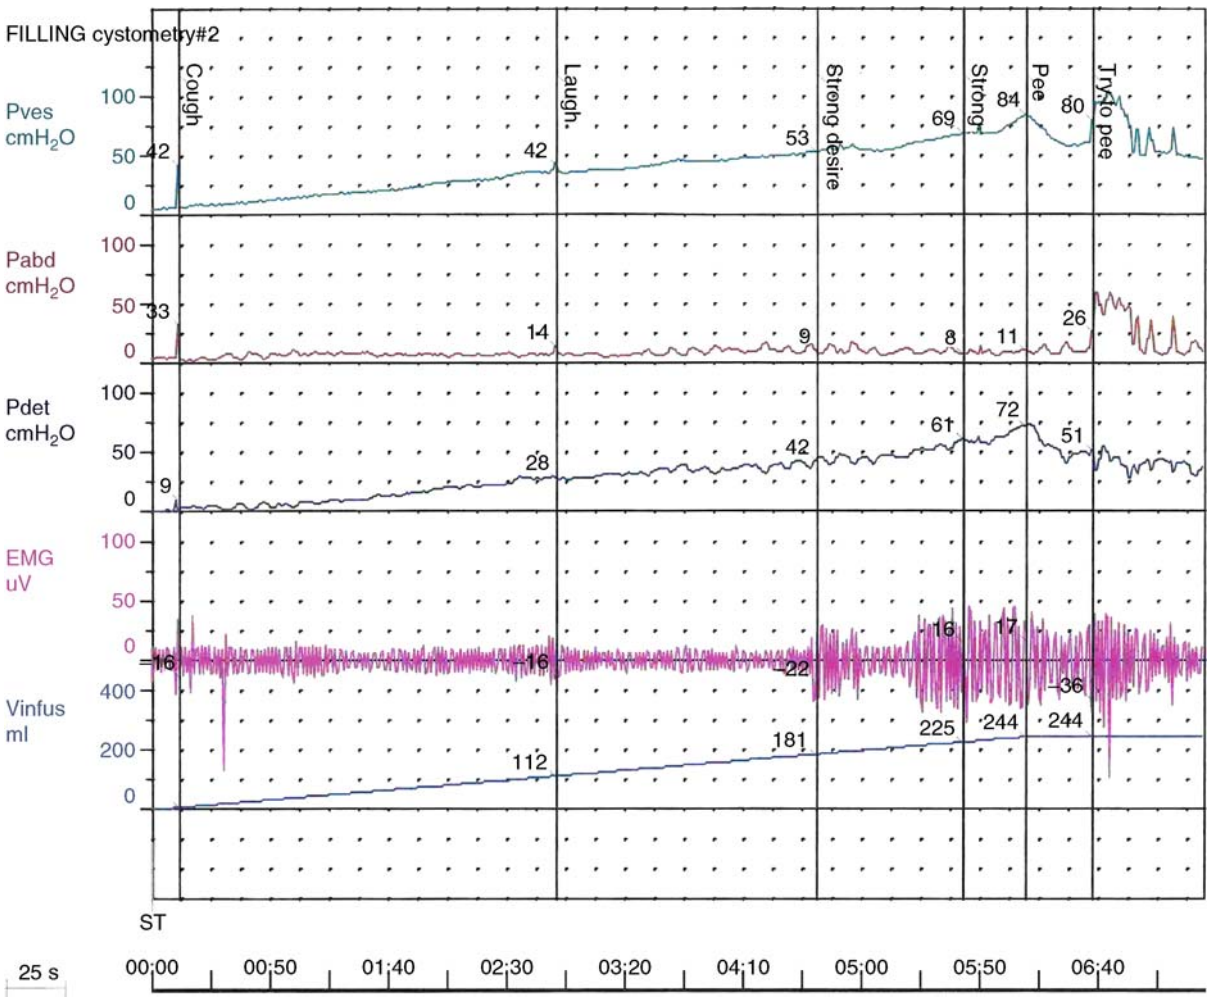


bladder neck. However, in some patients a "tightening" of the bladder neck with filling can be observed (this may also be observed in patient with posterior urethral valves).

Urethral sphincteric dysfunction can also represent a broad spectrum of pathologies including spinal cord injury patients, bladder exstrophy, or myelodysplasia, and is associated with dysfunctional voiding, which is the lack of consistently coordinate sphincteric relaxation with detrusor contraction. However this problem can also be seen in otherwise neurologically intact children who demonstrate by voiding cystourethrogram (VCUG) a "spinning top" urethra configuration, or by videourodynamics showing bladder neck hypertrophy with failure to completely relax the pelvic floor, with increased EMG activity, with voiding. These patients will also demonstrate significant post void residuals and abnormal flow rate (either reduced flow rates or interrupted flow during voiding attempts) and recurrent infection. All three would be demonstrated by non-invasive urodynamic studies: uroflow (urine flow rate) and post void residual urine volume by ultrasound measurement easily performed in the clinic setting, as shown in *Figs. 57-4* and *57-5*.

Figure 57-3

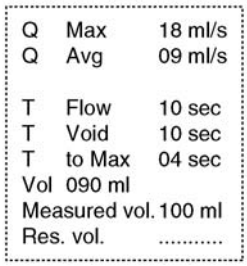
Example of urodynamic study demonstrating 1) very poor bladder compliance, and 2) uninhibited contractions near capacity. The patient is a 14-year-old male with spina bifida and subsequent neurogenic bladder dysfunction who, without treatment (intermittent catheterization and anticholinergics) is at risk to develop hydronephrosis. This study also demonstrates 3) detrusor-sphincter dyssynergia, EMG activity increases inappropriately with detrusor contractions.



Bladder detrusor abnormality and urethral dysfunction are often intertwined and interdependent. Abnormal urethral function often results in abnormal bladder detrusor function and vice-versa. Not surprisingly, the result may be wetting or infection because of inappropriate bladder emptying and/or poor bladder storage. Detrusor inactivity/hypoactivity, a large poorly contractile bladder, can be determined by a combination of video urodynamics and uroflow studies. Poor detrusor contraction is seen in the bladder pressure tracing curve; flat or sloped tonus limb without evidence of contractions, and an inconsistent interrupted pattern of voiding demonstrated on uroflow study. However, detrusor inactivity can still result in elevated bladder pressures and even progressive hydronephrosis if there is a problem with bladder empting, e.g., voiding dysfunction in poorly managed myelodysplasia or mechanical obstruction from valves or stricture. This condition typically arises because of dyscoordinate-type voiding and collagen deposition in the bladder wall muscle fibers. The bladder neck vs. the external sphincter

Figure 57-4

Uroflow study. This non-invasive urodynamic evaluation determines the voided volume and the flow pattern. Depicted here is the apparatus for measuring uroflow, and a normal uroflow pattern for an 8 year old boy. The voided volume, 100 ml, is low for age; a normal 8 year old boy would be expected to have a maximum bladder capacity of 300 ml; 8 + 2 = 10, 10 × 30 = 300 ml.



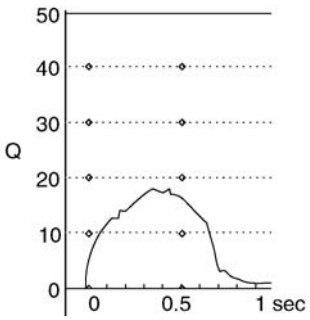


Figure 57-5

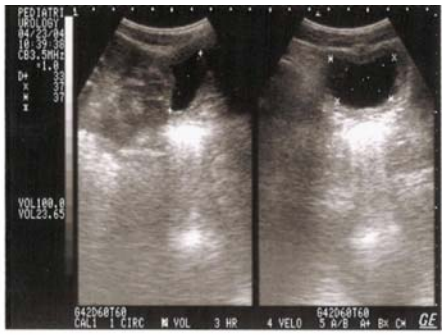
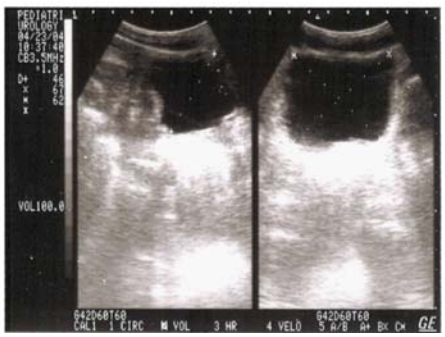
Post void residual urine (PVR) volume determination by ultrasound of the bladder in the clinic. This non-invasive technique measures the volume of urine in the bladder after a uroflow study. Combining the uroflow and the PVR non-invasively provides (1) functional bladder volume, (2) uroflow pattern, and (3) voiding efficiency.





can also be dyssynergic. A commonly misunderstood physiology is that hydronephrosis related to lower urinary tract dysfunction results primarily from high urethral resistance not from the bladder *per se*. Even in a small bladder poor compliance alone cannot cause hydronephrosis without associated elevated outflow resistance (usually > 40 cm H_2O). The proximal urethra may also show dyssynergy best seen on video urodynamic studies.

Definition and Spectrum of Bladder Dysfunction

The definition and spectrum of bladder dysfunction has been characterized according to the International Children's Continence Society (8). Recent advances in enuresis and incontinence research require clarification and modification of terminology for bladder dysfunction. There are now well-standardized definitions of urinary incontinence in children as shown in *Table 57-1*. Functionally however, the basis of lower urinary dysfunction can be grouped into three major categories, relating to (1) abnormal anatomy, (2) abnormal innervation, and (3) not associated with any known abnormality.

1. Anatomic causes that would include such diagnoses as: bladder exstrophy/epispadias, urogenital sinus malformations cloaca, ectopic ureter, ureterocele etc. Patients with anatomic abnormalities may also have a neurogenic basis for bladder dysfunction, as in the exstrophy patients and cloacal malformation patients.
2. Abnormal innervation or neurogenic causes would include such diagnoses as: spinal cord injury, myelodysplasia, sacral dysgenesis/agenesis, tethering of the spinal cord, tumors of the spinal cord, transverse myelitis etc.
3. Dysfunctional causes are probably the most common and yet most poorly defined category of voiding dysfunction as it occurs in otherwise normal patients, therefore treatment of these patients can represent a major challenge.

Signs and Symptoms of Bladder Dysfunction in Children

Often a urinary tract infection is the first sign of bladder dysfunction in children. The tight linkage between bladder dysfunction by any mechanism and infection cannot be overemphasized. Therefore, clinically, the initial symptoms are those of a urinary tract infection, dysuria, frequency, suprapubic pain, gross hematuria, chronic urinary incontinence, and even new onset of urinary incontinence. The cause of the infection may not be uncovered until after treatment of the infection. Most commonly, after treatment of a urinary tract infection in a child, either new or recurrent, consideration of potential for poor emptying due to bladder dysfunction is very important even in the apparently "normal" child. Unfortunately this consideration is often forgotten. Perhaps infection of the urinary tract should be considered more the inability to clear the

Table 57-1

Terminology Related to Lower Urinary Tract Dysfunction

Older, Previous Terminology:	International Children's Continence Society Preferred Terminology
Wetting	*Incontinence;* *A. Continuous Incontinence* (Implies Day-time) 1. Primary 2. Secondary, i.e., after a dry interval of 6 months B. Intermittent Incontinence 1. Day-Time incontinence a. Primary b. Secondary, i.e., after a dry interval of 6 months C. Nocturnal Incontinence = Enuresis (Implies Night time only)
Bladder Instability	*Overactive Bladder;* Usually *Idiopathic Detrusor Overactivity,* a urodynamic diagnosis, implies lack of identifiable neurologic lesion.
Detrusor Hyperreflexia	*Neurogenic Detrusor Overactivity;* implies known/identifiable neurologic lesion.
Discoordinated voiding	*Detrusor Sphincter Dyssynergia;* requires urodynamic diagnosis, implies neurologic lesion.
Voiding Dysfunction	*Dysfunctional Voiding;* Inability to relax sphincter with voiding. Diagnosis is by Uroflow measurement. Implies lack of identifiable neurologic lesion
Stress Urinary Incontinence	*Urodynamic Stress Urinary Incontinence;* requires urodynamic diagnosis.
Lazy Bladder	*Underactive Bladder;* requires urodynamic diagnosis.

inevitable ascension of bacteria from the perineum. The primary cause of this failure is inability to consistently empty the bladder, commonly caused by increased pelvic floor activity, with high bladder pressure. Other host defense mechanisms may be altered, i.e., GAG layer disruption, bladder wall ischemia from high intravesical pressure, poor lymphatic flow from high intravesical pressure, and the child has difficulty clearing bacteria.

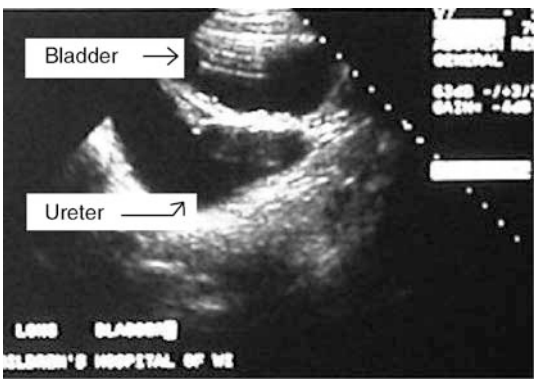
Symptoms of voiding dysfunction can also mimic those of infection. For example, new urinary incontinence can be the symptom of overflow incontinence that has developed from increasing post void residuals and bladder decompensation. Or, more commonly, urinary incontinence in children may relate to detrusor overactivity, the "overactive bladder" causing leakage of relatively small amounts of urine. Complete uninhibited detrusor contractions can also occur for a few years after potty training, causing a flood-type of urinary incontinence. Therefore, patients symptomatic but with negative urine culture may be manifesting a true voiding dysfunction and should be evaluated by a careful history, physical exam and ultrasound study of kidneys and bladder.

Hydronephrosis, particularly bilateral hydronephrosis, can on rare occasions be the presenting sign of significant bladder dysfunction in children. This typically is associated with a major degree of bladder outflow obstruction; however, other anatomic causes must be ruled out these would include bilateral ureteral pelvic junction obstruction or bilateral distal ureteral obstruction, known as obstructive megaureters (*Fig. 57-6*).

The failure to achieve potty training is often the presenting symptom of bladder dysfunction in children, particularly in those children with anatomic cause of the incontinence. Because of the wide variation in timing of potty training a true problem is often delayed in diagnosis until the onset of formal education when diapers no longer are acceptable.

Figure 57-6

Megaureter: Ultrasound study of the pelvis showing a dilated distal ureteral adynamic segment, also known as megaureter, behind a normal bladder.



Anatomic Causes of Bladder Dysfunction in Children

Classic anatomic conditions that can contribute to bladder dysfunction and urinary incontinence routinely misdiagnosed would include female epispadias, ectopic ureter, urogenital sinus, occult neurogenic bladder, tethering of the cord and sacral deformities. Even though labeled anatomic, each condition may be associated with a degree of bladder dysfunction.

Undiscovered female epispadias is a classic but uncommon reason for "failure to potty train" in little girls. A thorough history will usually reveal a stress component to the leakage. A careful inspection of the perineum will demonstrate a bifid clitoris and short urethra (*Fig. 57-7*).

Although the anatomic malformation in bladder exstrophy results in abnormal development of the bladder neck and proximal urethra (sphincteric incompetence), bladder dysfunction, specifically a small bladder with poor compliance, may result from poor urethral resistance. The bladder develops abnormally because of low urethral resistance. Most of these changes can be corrected by a single operation performed shortly after birth to reconstruct the bladder neck and proximal urethra. These maneuvers facilitate normal bladder cycling and normalization of bladder function just like in classic bladder exstrophy in males. The problem is that most of these females are not diagnosed soon enough to take advantage of the window of opportunity that seems to close sometime during the first few months of life.

Epispadias is also often associated with incontinence in the boy and is easier to diagnose. As in the girl it should be treated as early as possible to salvage bladder function. Unfortunately, this is has not been the general practice and many boys with epispadias have delay in bladder neck repair and resultant poor bladder function.

Fundamentally, the lower urinary tract anatomy and physiology reflect the embryology of the urinary tract. The ureteric bud, arising from the mesonephric duct, classically was felt to have one-way induction, that is, be responsible for the induction of the metanephric blastema to become the functioning kidney. However, it is becoming more and more clear that there is also induction of the mesonephric duct by the developing ureter, i.e., there is induction of adjacent mesenchyme in both directions. In fact recent evidence shows that the ureter may develop

Figure 57-7

Female Epispadias: This condition was not recognized at birth, and the child was referred at 3 years of age for continuous urinary incontinence. Note the short urethra, the bifid clitoris, and the widely separated pubis. Ideally correction at birth allows proper bladder cycling, and therefore definite bladder growth.

from the center outward to initiate the formation of the kidney, and also in the other direction to initiate development of the trigone, bladder neck, and proximal urethra; to the urethral meatus in the female and just distal to the prostatic utricle in the male. This important role would include the stimulus for neurologic development of these structures. Therefore, abnormalities detected in the ureter must lead one to anticipate potential abnormalities not only in the kidney but also in the bladder base, bladder neck and proximal urethra (*Fig. 57-8*).

Vesico-Ureteral Reflux and Bladder Function

High grade vesicoureteral reflux may indicate significant abnormality in development of the trigone and the bladder base. This is not dissimilar to the effect of abnormal positioning or timing of appearance of the ureteric bud during early embryology on the metanephric blastema resulting in renal dysplasia (9). Children with high grade vesicoureteral reflux, particularly those with bilateral reflux, should signal significant abnormality in development of very delicate and highly tuned structures which affect bladder and bladder neck coordination and function. It is not surprising, and rather is to be anticipated, that children with high-grade bilateral reflux have higher potential for renal dysmorphism and low potential for spontaneous resolution, in large part because of high potential for dysfunction of both the bladder neck and sphincter. Treatment with antibiotics and reimplantation surgery without recognizing the high potential for voiding dysfunction can lead to very unacceptable results.

Ureterocele

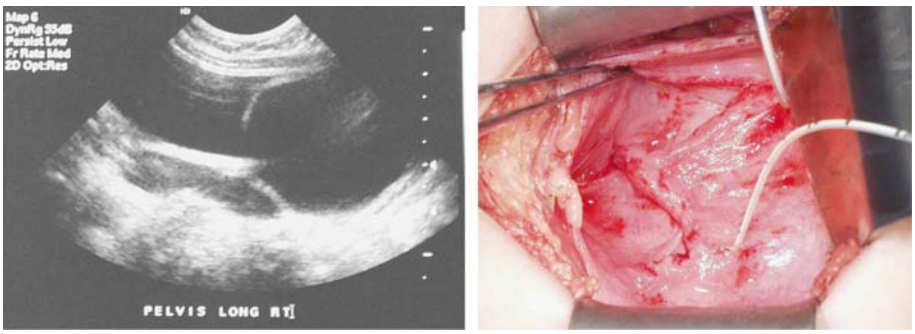
Ureterocele is an abnormality of the distal end of the ureter, an obstructive cystic dilatation of the caudal end of the ureter. A ureterocele is frequently associated with the upper pole in a duplex kidney, and this associated renal segment frequently shows cystic dysplasia. It should be viewed as a cystic induction of the trigone, but may also involve the bladder base, neck and proximal urethra. Bilateral large ureteroceles that extend down the urethra (ceco-ureterocele) must be considered to be associated with high potential for bladder dysfunction. Fortunately, because most ureteroceles are associated with less severe dysplasia of the trigone and bladder neck, surgical excision results in quite good potential for coordinate voiding and continence. The classic treatment is resection of the involved renal moiety and ureter, however, transurethral puncture of smaller ureteroceles may be considered as potentially curative. Puncture of a larger ureterocele which involves the bladder neck or proximal urethra may result in high grade reflux or "valve like" mechanical obstruction of the proximal urethra from a flap from the wall of the intraurethral ureterocele. Urinary tract infection or incontinence can be a consequence in cases of severe, bilateral ureteroceles (*Fig. 57-8*).

Ectopic Ureter in Girls

An ectopic ureter, with ureteral insertion distal to the sphincteric mechanism in a young girl will cause persistent wetness day and night in the face of normal

Figure 57-8

An example of abnormal, dysplastic development of the trigone and bladder neck from the presence of bilateral ureteroceles. The ultrasound image shows abnormal laxity of the posterior bladder wall/trigone form the ureterocele. The photograph of the opened bladder demonstrates severe thinning of the trigone after the ureteroceles have been resected.



voiding and bowel control post potty training. A unilateral ectopic ureter ("single ectopic ureter") is not usually associated with bladder dysfunction per se, therefore the usual presentation of uteral ectopia in a girl is that of normal voiding and potty training with voiding in the face of chronic low grade wetness, unresponsive to all efforts at therapy, in many cases including psychotherapy.

An ectopic ureter in a girl is frequently the upper pole ureter of a duplex renal collecting system. These ectopic ureters frequently "bypass" the sphincteric mechanism and kidney and may be either unilateral or bilateral. Continuous urinary incontinence develops. The child will typically void normally every 2–4 hours, but mothers notice that their child is wet within 15 min of voiding and report that the girl is "always" wet. Ectopic ureters can go to the bladder neck, mid-urethra, fourchette, vagina, cervix uterus, uterus, or Fallopian tube. The upper tracts in patients whose ureter enters the bladder neck typically are poorly functioning, dysplastic. Diagnosis can be difficult, but usually a Renal Ultrasound and VCUG suggest the anomaly. Other than the constant wetting, bladder function in these patients will be normal.

Ectopic ureters are never a continence problem in boys because a ureter can only link up with mesonephric duct derivatives, and the external sphincter in the male is distal to the mesonephric duct derived tissues.

Diagnosis can be difficult, but usually renal ultrasound suggests a duplication anomaly. VCUF typically show VHCR Computed Tomography can be helpful in elucidating the exact anatomy, and Magnetic Resonance Imaging with contrast is emerging as a useful technology in this regard.

Treatment of ectopic ureter in the female is guided by the amount of associated function in the renal parenchyma, with upper pole partial nephrectomy being a good option when poor renal parenchymal function exists, compared to uretero-neocystostomy or ipsilateral uretero-ureterostomy when good renal function is present in the associated renal moiety.

Bilateral Single Ectopic Ureter in Boys and Girls

Bilateral single ectopic ureters, with uppertract single systems bilaterally are often associated with bladder hypoplasia and dysfunction; again, because of the absence of bladder filling and empting in utero. The very rare situation of bilateral single system ureters ectopic to the bladder neck presents with urinary incontinence or urinary tract infection in females and UTF in males. Girls tend to have very poor outcomes when subjected to uretero-neocystostomy without recognition of the abnormal bladder neck. They frequently require institution of clean intermittent catheterization (CIC), and if they fail anticholinergic medication, progress to bladder augmentation. Boys with single system ureteral ectopia to the bladder neck are exceedingly rare, and may succumb in utero to renal failure. If they survive, they invariably have renal compromise, and despite efforts like CIC, anticholinergic medication, and bladder augmentation, usually progress to renal transplantation.

Cloaca and Urogenital Sinus

In girls, a cloaca represents the persistence of a common cavity composed of the (1) lower urinary tract, (2) genital

tract and (3) hind gut. A urogenital sinus anomaly represents the confluence of the urinary tract and genital tract. Each is part of a broad spectrum of pathologies that may involve the bladder, bladder neck and urethra, as well as spinal cord development. The cloaca, which is by definition a junction of the urinary tract and the GI tract, represents severe embryologic perturbation of early development, week 3–4 of gestation. The "urorectal partitioning" by the urorectal septum is usually quite altered. There may also be an abnormality of the tail bud during embryogenesis contributing to this anomaly.

Urogenital (UG) sinus malformations can result in poor formation of the posterior bladder wall and urethra. The spectrum of this malformation is broad, and is associated with the entire range of poor bladder formation and sphincteric incompetence. There are three basic categories: (1) the low confluence of the urethra and the vagina, (2) the mid-level confluence, and (3) the high confluence.

The imperforate anus in a cloacal anomaly is frequently located in the vaginal portion of the urogenital sinus. Urogenital sinus secondary to excessive androgen stimulation, the adreno-genital patients with congenital adrenal hyperplasia, is not generally associated with bladder and urethral dysfunction, except in the most severe cases in which the proximal urethra is severely foreshortened.

The spectrum of malformation in the cloaca patients is even broader than that of the UG sinus group. The rectum frequently connects with the vaginal portion of the urogenital sinus. There is often also a pelvic floor dysmorphism that is associated with failure of development of appropriate nerve supply to the pelvic diaphragm. The pelvic floor tends to be fibrotic and somewhat "non-relaxing" in these patients. The bladder may be poorly developed, and the complete spectrum of ureteral abnormalities, i.e., reflux, ectopia of the ureters, poor trigonal development and bladder neck malformations is present.

Early treatment of the cloaca in the neonatal period entails fecal stream diversion with double barreled colostomy. This limits fecal soiling of the common chamber and maximizes the potential to maintain sterile urine. Surgical reconstruction is usually done at a later date through a posterior sagittal approach. A perineogram, whereby contrast is injected into the single perineal opening, is extremely helpful in terms of guiding surgical intervention. The perineogram is usually done with a "Christmas tree" adapter on a syringe of contrast in the operating room by the pediatric urologist at time of reconstruction, and is frequently followed immediately by endoscopy to gain further insight into the anatomy. Then, typically a posterior sagittal approach for surgical correction is undertaken. Anterior repair of the urogenital sinus can be performed at the same time. On rare occasions, this may often involve complete mobilization of the urogenital sinus. Depending on the anatomy in terms of urethral length, the urethra and bladder base frequently require reconstruction. The native vagina may also need to be repositioned.

The spinal cord develops at the same time as the lower urinary tract; therefore, the patients with cloaca malformations have significant potential for abnormalities of the spinal cord. These would include tethering of the spinal cord, a tight filum terminale, intradural lipomas, diastematomyelia, and syrinx of the spinal canal.

In the case of patients with cloaca or high imperforate anus, but in almost all girls with cloacal malformations, bladder dysfunction must be considered to be the rule rather than the exception. Approximately 33% of children with cloacal or urogenital sinus anomalies will have demonstrable abnormality of the central nervous system, especially the spinal cord. Bladder dysfunction is to be found in 80% of these patients (10, 11). Most of these children have difficulty with coordinate voiding and often are dependent on intermittent catheterization. Because of the associated anatomic abnormalities of the urethra many require construction of alternative channels to the bladder such as an appendico-vesicostomy. Some of these children also have neurogenic bladder dysfunction resulting in small or poorly compliant bladders and require anticholinergics or bladder augmentation. Some benefit from temporary urinary diversion.

Technically boys do not have cloaca or urogenital sinus malformations. However, boys with imperforate anus, particularly high imperforate anus, are subject to the same potential bladder dysfunction as girls with cloaca. Any child with high imperforate anus should be assumed to have high potential for bladder and urethral dysfunction and minimally should be evaluated initially with ultrasound to evaluate the kidneys and a VCUG to evaluate for vesicoureteral reflux and bladder configuration.

Exstrophy/Epispadias Cloacal Exstrophy Complex

Exstrophy represents a spectrum of pathology that impacts bladder, bladder neck and urethral anatomy and function. It is unique in that it seems to be the result of premature senescence of the infraumbilical abdominal wall creating a defect (a hole) through which developing

structures herniate. The timing of this herniation dictates the degree of severity of the condition. If the event occurs at 3–4 weeks gestation, the period of the cloaca, cloacal exstrophy develops which involves bladder, kidneys, hindgut, genitalia, urethra and spine. Often, the lower extremities and upper abdominal wall are involved as well (*Fig. 57-9*).

Classic Bladder Exstrophy represents an event that occurs at approximately weeks 4–7, and involves only the bladder, urethra and genitalia. Epispadias represents a problem after 7–8 weeks gestation and can involve the urethra, bladder neck and genitalia. All forms of the spectrum of exstrophy are associated with abnormalities of urine storage and emptying, except for boys with minimal form of epispadias, because of the structures involved: bladder, bladder neck, and proximal urethra (*Fig. 57-10*).

The cause of the defect is not known but may represent a problem with epigenetics. The important consideration with exstrophy is that the classic and epispadias forms are rarely associated with other significant problems. If the bladder, bladder neck and urethra are repaired early, i.e., first month of life, there is reasonable potential to achieve normal function in terms of voiding with continence. However, delaying repair or not achieving bladder cycling early after birth results in reduced potential for normal function. The condition is rare, 1/30,000 births, but provides a window into the potential for surgical repair and physiology of the lower urinary tract. For example, the bladder histology of the patient with classic exstrophy at birth is similar to that of a pre-20-week fetus, before significant urine production and bladder cycling have occurred. With careful repair at birth however, normal function of the bladder can be achieved. Restoring the anatomy therefore can potentially achieve normal function in many patients with classic exstrophy and epispadias. With early repair of classic and epispadias patients it should be possible to achieve voiding with continence in more than 80% (12). In contrast, the significant potential for spinal involvement in the cloacal exstrophy group severely limits the potential for normal bladder and urethral function and the same may be true for the earlier forms of classic exstrophy. The spectrum does point to the tight linkage between ectodermal (central nervous system) and mesodermal organ systems. An example of a urodynamic study in a girl with classic bladder exstrophy is shown in *Fig. 57-11*.

Figure 57-9

Cloacal Exstrophy. This newborn male has the anatomical conditions of cloacal exstrophy, including two separate bladder halves separated by the posterior wall of the cecum, prolapsed ileum, and a small omphalocele.

Posterior Urethral Valves

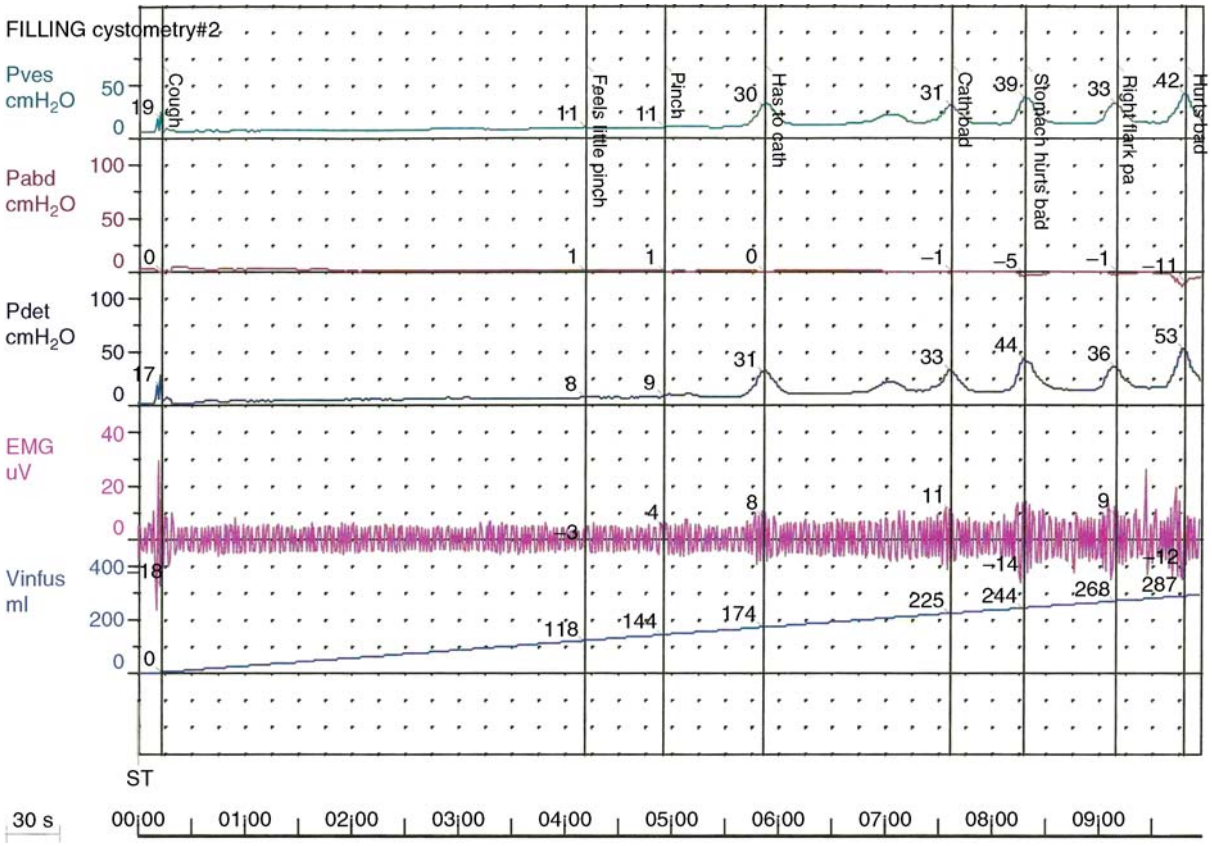
Boys with posterior urethral valves (PUV) can represent the complete spectrum of bladder dysfunction. In fact, it might be said that if one completely understood the potential pathologies of a patient with valves one would

Figure 57-10

Classic Bladder Exstrophy in a newborn boy. Note the exposed bladder plate, the epispadiac penis, and the widened pubic symphisis.

Figure 57-11

Example of urodynamic study demonstrating detrusor overactivity in a 12-year-old female with classic bladder exstrophy. Vesical pressure, Pves, demonstrates beginning of abnormal, uninhibited bladder contractions at a volume of about 174ml. These contractions become more frequent until capacity of about 287ml.



have the complete grasp of bladder dysfunction in children. The protean nature of this pathology relates to physics of pathologic stress during development in utero. Obstruction at the distal end of the prostatic urethra, perhaps a pathologic junction of the proximal and distal urethra, occurring at weeks 10–12, just prior to the production of urine by the developing kidneys (13) seems to be the cause of PUV. Development in the face of high-grade bladder outlet obstruction in utero impacts all aspects of the urinary tract.

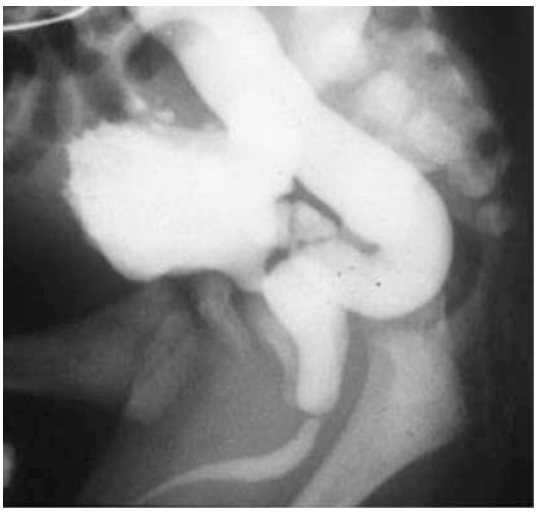
The kidneys become hydronephrotic, and in severe cases dysplastic, but most importantly often lose distal tubular function and cannot produce concentrated urine, hence the patient has obligatory high urine volumes. The ureters develop in an environment of obstruction and pressure work and are dysmorphic and are ineffective in peristalsis. The bladder develops in an environment of high pressure work and becomes dysmorphic with cellules, diverticuli, hypertrophy of muscle and encasement of muscle with collagen (14). The dynamics of the bladder are altered and demonstrate loss of compliance and capacity (*Fig. 57-12*).

At potty training the child tries to hold against abnormal pressures and develops a learned dyssynergia. The symptoms of daytime and nighttime wetting, polyuria, urgency/frequency, and constipation because of chronic state of dehydration predominate. Clinically the patient becomes more hydronephrotic and may go into renal failure. Urodynamics demonstrate increasing bladder pressures with filling, poor compliance; decreased sensation to extremely high bladder pressures, relatively poor capacity; and, to make matters worse, inability to completely empty the bladder, dysfunctional bladder wall kinetics, and sphincteric dysfunction (*Fig. 57-13*).

This constellation of pathologies is called the "Valve Bladder Syndrome" (VBS) (15, 16). Interestingly, if pati-

Figure 57-12

Voiding Cystourethrogram of a newborn boy with Posterior Urethral Valves. Note the dilated posterior urethra, the valve leaflets in the membranous urethra, the bladder trabeculation at the dome, and the massive vesico-ureteral reflux.



ents are treated by early valve ablation in the first weeks of life, and with subsequent normal filling and empting of the bladder many of the pathologic functions of the lower urinary tract can be reversed (17). Unfortunately, the abnormal renal function is not affected by early ablation.

Treatment of the patient with VBS includes: improvement of bladder volume and compliance with anticholinergics or bladder augmentation, or rarely diversion; improvement of bladder empting with biofeedback and/or intermittent catheterization, often through a Mitrofanoff channel and possible drainage at night; and, careful management of the renal failure.

Neurogenic Causes of Bladder Dysfunction in Children

Spinal Dysraphism

Myelomeningocele: Children with myelomeningocele had abnormal neural tube development between 2 and 5 weeks of gestational age. The neurologic dysfunction is multifactorial and has definite contributions from dysplasia of the neural elements from failure of the neural tube to completely form, and amniotic fluid "irritation" of the lower spinal and nerve roots (18).

Urodynamics should be done after spinal "shock" from newborn closure of the myelomeningocele resolves, typically at 6 weeks. Urodynamics will typically show that 2/3 of these children will have bladder contractions; about 1/3 will have detrusor areflexia. They frequently will have bladder sphincter dyssynergy characterized by pelvic floor/striated sphincter increased EMG activity concomitant with detrusor contraction (19). This combination potentially places the upper tracts at risk of hydronephrosis because of the increased bladder pressures. Therefore, clean intermittent catheterization would be initiated if the detrusor pressure at leak point is greater than 40 cm of water; and/or if the detrusor sphincter dyssynergia is clearly demonstrated with bladder filling (20). Oral anticholinergics (Ditropan, Detrol or Vesicare) are frequently initiated. Recently, placement of nighttime catheter gravity drainage has been advocated to keep the bladder completely decompressed for at least 8–10 h/day (21). Such early and aggressive treatment of these patients has resulted in a reduction in the need for bladder augmentation in many of these patients by protecting the development of the bladder in the first year of life (*Fig. 57-14*). In some cases urinary diversion with vesicostomy has been used as an alternative to early CIC (22).

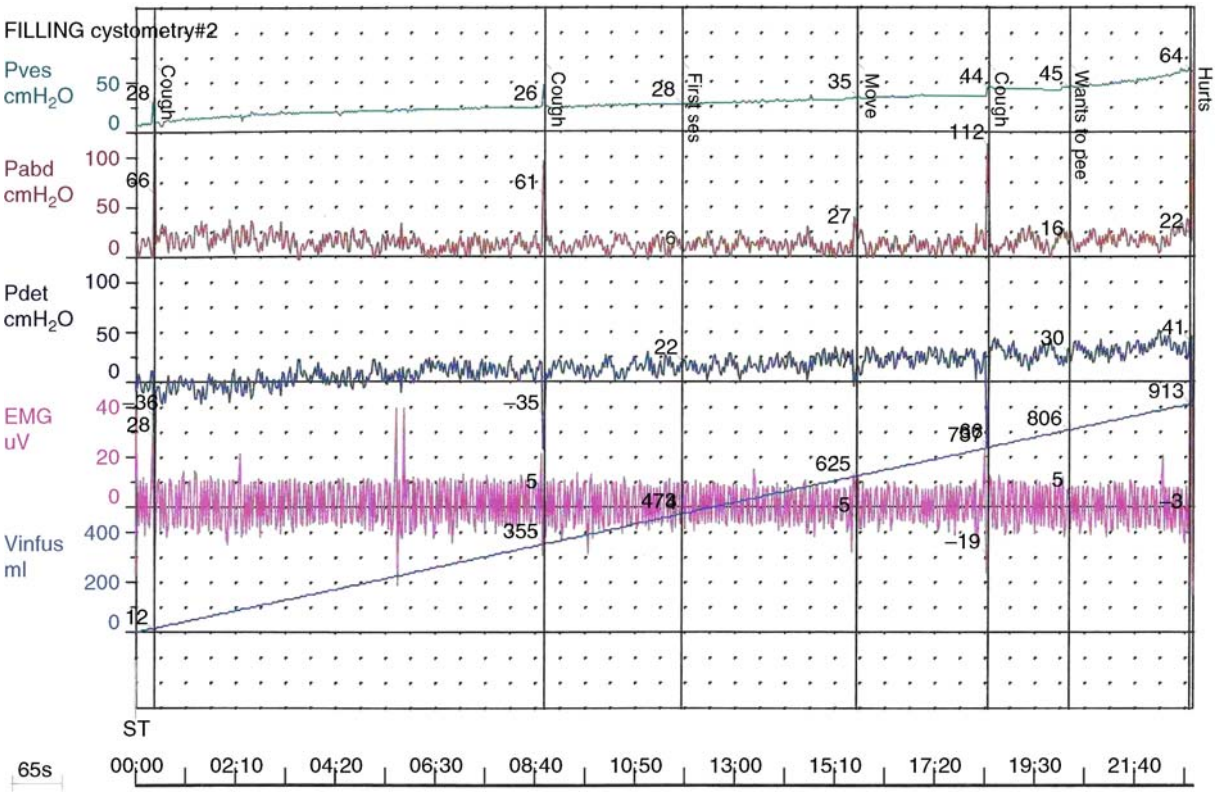
Lipomeningocele represents a challenging disorder to treat. Children with this disorder are somewhat similar to those with sacral agenesis in that they frequently do not have motor abnormalities of their lower extremities, therefore, socially, they are in diapers, but they ambulate normally. This increases the propensity for teasing and such by peers. Their bladder dysfunction is typically characterized by incontinence from uninhibited detrusor contractions, poor bladder wall compliance, and, particularly, an open bladder neck. They usually need to undertake intermittent self-catheterization in conjunction with anti-cholinergic medication to achieve social continence (23).

Sacral Malformations

Lower spinal canal lesions such as sacral agenesis, both partial and complete, are technically anatomic abnormalities which can affect bladder function. Most commonly these conditions result in detrusor-sphincter dyscoordination, but because they represent lower spinal cord lesions, they can be associated with the complete spectrum of obstruction and to low outflow resistance problems. Children have bladder dysfunction that is in some ways similar to myelomeningocele, but in some ways different.

Figure 57-13

Example of urodynamic evaluation on 15-year-old male with history of posterior urethral valves (PUV). This study demonstrates poor compliance of the bladder as seen on the top (Pves, or intravesical pressure) curve. Bladder pressure steadily rises to about 35cm/water at 625cc. This is abnormal. From this point on the filling curve pressure rises even further to a pressure of 64cm/water at a volume of about 913ml. This is definitely an abnormal cystometrogram demonstrating "valve bladder;" poorly compliant, but with typically preserved capacity.

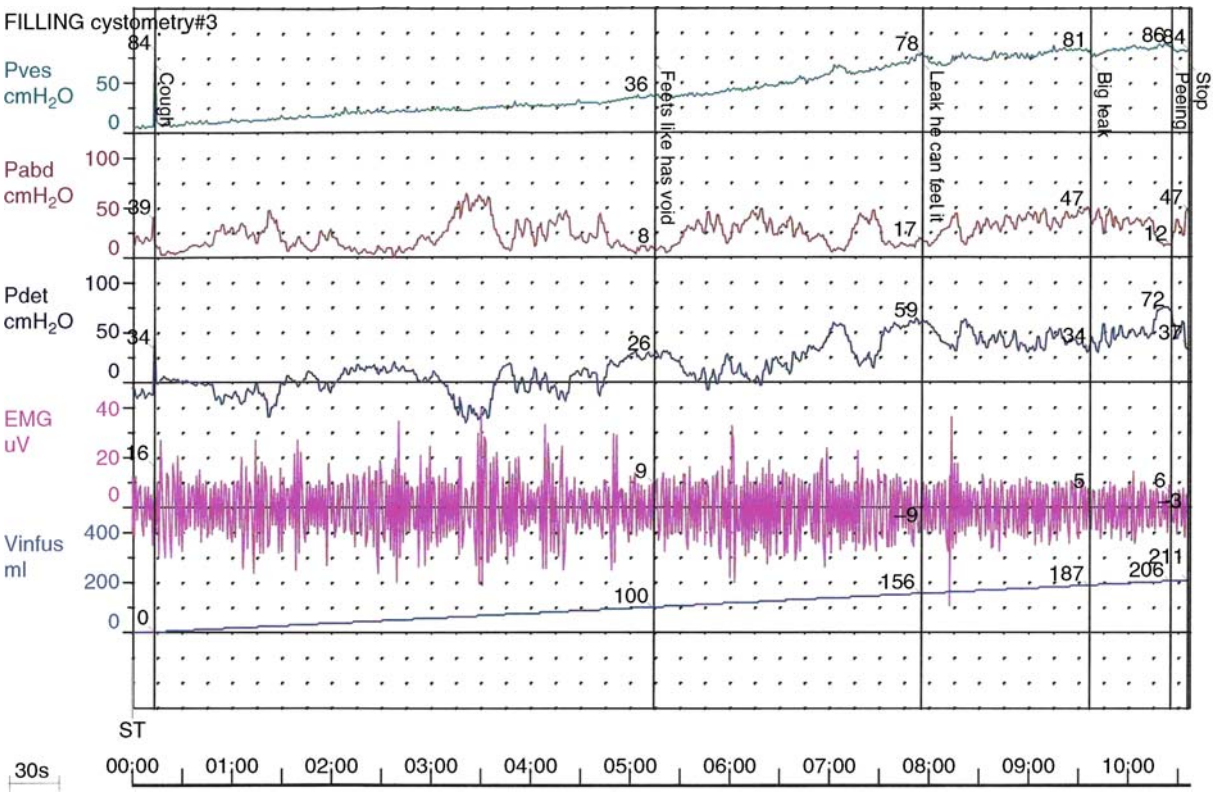


The difficulty with sacral malformations relates to the broad spectrum of potential anatomical defects from hemi sacrum with essentially no neurologic deficit to sacral regression with severe corporal deformity and neurologic bladder deficit resulting in total incontinence, with these patients usually requiring construction of a continent urinary reservoir. However, even in the less severe sacral deformity patient with normal lower extremity function severe urinary incontinence, from low urethral resistance and small bladder capacity, is very possible. Approximately 25% of children with sacral agenesis have no sign of denervation of the bladder, while 35% have upper motor neuron lesions and demonstrate overactive detrusor activity and detrusor-sphincter dyssynergia. The 40% of children with lower motor neuron lesions from sacral agenesis have detrusor areflexia and an open bladder neck, and usually present with urinary incontinence (24, 25).

Children with sacral malformations frequently have high-pressure bladders that do not empty well and can have acquired renal damage unless diagnosed and treated early. Many of these patients require major bladder surgery including bladder augmentation and a bladder neck procedure, and intermittent catheterization to achieve continence, even though by all other clinical measures they seem to be normal. They frequently have fecal incontinence that can be controlled with oral regimens and enemas, but they often will need both intermittent catheterization of their bladder to maintain continence and protect their upper tracts, and construction of antegrade continent enema stoma to achieve bowel continence.

Figure 57-14

Example of urodynamic study demonstrating poorly compliant, atonic neurogenic urinary bladder from myelomeningocele. Patient is 13-year-old male with spina bifida. Note how Pves curve shows steady rise in pressure without detrusor activity. Patient was not on anticholinergics at time of study.



Sacro Coccygeal Teratoma and Spinal Cord Tumors

Neurologic abnormalities of bladder dysfunction can occur from tumors, both sacro coccygeal teratomas and spinal tumors such as vascular or central nervous system tumors. A rare child will have a spinal cord injury in childhood. The evaluation and treatment are very similar to that of the bladder dysfunction from myelomeningocele.

Tethering of the Spinal Cord

Children with tethering of the spinal cord can present primarily with bladder dysfunction, as opposed to the children who have tethered spinal cord associated with spina bifida aperta (cystica), and the children with tethered spinal cord that present with musculoskeletal conditions. The urological problems frequently are initially diagnosed as "behavioral", and frequently the diagnosis of the tethered spinal cord is prolonged and difficult. The presence of secondary onset of urinary incontinence, or prolonged primary incontinence is the tip-off to looking for a tethered spinal cord as the source of the bladder dysfunction. Only half of the patients presenting with urinary complaints who were found to have a tethered spinal cord had other clinical signs thereof, such as back or leg pain, scoliosis, or club foot. The idea of early diagnosis of tethered spinal cord to obviate permanent damage to the urinary tract has been difficult to substantiate. Evaluation is essentially the same as for any child with dysfunctional voiding, with the emphasis on MRI evaluation of the spinal cord if suspicion of spinal cord tethering by history and/or physical exam exists. Treatment is similar if not identical to that discussed in the neurogenic causes of bladder dysfunction section (26).

Evaluation and Treatment of the Child with Anatomic and/or Neurogenic Bladder Dysfunction

Evaluation of the Dysfunctional Bladder

The fundamental approach to evaluating children with neurogenic and/or anatomic bladder dysfunction includes kidney and bladder ultrasonography, VCUG and urodynamic evaluation. VCUG in particular evaluates for vesicoureteral reflux and bladder neck function. Lasix renal scan is employed if there is hydronephrosis to evaluate for uretero-pelvic or uretero-vesical obstruction.

Medical Management of the Dysfunctional Bladder

The management of the patient with dysfunctional bladder is as varied as the spectrum of causes and dysfunctions. Basically, the common denominators are functional bladder size and urethral resistance, impacting effective bladder storage, and securing dependable bladder empting; the mainstay of this is Clean Intermittent Catheterization, (CIC). The basis of all management of abnormal bladder function is clearly CIC. If satisfactory bladder capacity cannot be achieved with anticholinergics or Botox injection, then bladder augmentation will be used. Because of the long-term consequences of bladder augmentation with bowel; infections, mucus, acidosis, stones, potential rupture, and cancer risk, alternatives are contemplated. These would include use of other tissue such as ureter, engineered bladder using autologous tissue culture techniques, or even growing a new bladder with stem cells. However, the problem of bladder expansion has not yet been solved. Malone antegrade continent cecostomy is frequently beneficial to the child with concomitant neurogenic bowel incontinence. There are a few techniques presently employed to make bladders larger and more compliant. These techniques will hopefully evolve in the future. *Table 57-2* lists medical and surgical options in regard to management of bladder problems in childhood.

Bladder Augmentation

Bladder augmentation, also known as Enterocystoplasty, is accomplished by reconfiguring the patient's bladder, using their own tissues. These techniques include the use of segments of large and small bowel and stomach, flaps made from dilated ureters, and tissue produced in the laboratory. Regeneration of new bladder tissue has been attempted; autoaugmentation and implantation of material that forms a framework for new bladder growth, all with some success but at significant cost as well.

Classic bladder augmentation with intestine was described in the 1950s by Gilchrist, using the intact cecum, separated from the GI tract on its vascular pedicle, reconstituting the GI tract, and anastamosing the inverted cecum to the dome of the bladder. Gilchrist also described complete replacement of the bladder: a continent urinary reservoir. Clinical experience, however, taught us that one needs to detubularize the colon segment to obviate peristaltic contractions, so the more "modern" era of bladder augmentation began in the 1980s, where large series of intestinal augmentation of the urinary bladder in children were reported (27). There are different intestinal segments available for use; ileum has been used most frequently, followed by the sigmoid colon. The use of a segment of

Table 57-2

Medical and Surgical Treatment of Anatomic and Neurogenic Bladder Problems in Childhood

Problem	Small Bladder Capacity	Poor Bladder Compliance	Bladder Neck and/or Sphincter Incompetence

stomach to augment the bladder has a very special niche; that is, in the patient with renal failure. Gastrocystoplasty, however, is now being largely abandoned because of the concern of malignancy at a rate of about 10% in the gastric portion, which is unfortunate because gastrocystoplasties tended to work well. When ileum is used for bladder augmentation, typically a 20–25 centimeter segment is detubularized along the antimesenteric border and retubularized into an upside-down "cup," which is then anastomosed to the spatulated bladder. The ileum, however, does absorb urine and "recirculates" it, which can lead to metabolic problems; specifically hyperchloremic metabolic acidosis. Some people favor the use of the sigmoid colon for augmentation of the bladder. This is frequently a sigmoid loop that is mobilized on its vascular pedicle, detubularized along its antimesenteric border, retubularized into an upside-down "cup," and then anastomosed to the dome of the bladder. The sigmoid colon does not seem to be quite as compliant as the ileum, so typically 25 cm of sigmoid is used. The sigmoid colon is also frequently used for re-do augmentation when the patient has had an ileal augmentation but has insufficient capacity or compliance.

When undertaking ileal augmentation enterocystoplasty one needs to avoid the distal 20 cm of ileum as this is where vitamin B_{12} absorption occurs. Also, from a technical standpoint the front wall of the ileal augmentation frequently is extended anteriorly; almost to the bladder neck. This helps prevent the "hourglass" configuration that can develop after a bladder augmentation. The "hourglass" configuration causes the patient to catheterize only the "lower chamber," which is the native bladder, resulting in incomplete emptying, leading to complications such as stones, infections and potentially perforation (28). Patients augmented with ileum need lifelong monitoring of their serum bicarbonate levels, and sometimes venous pH. If hyperchloremic metabolic acidosis is diagnosed, which is rather frequent in this patient population, they are typically placed on either sodium bicarbonate or potassium citrate supplements orally to try to prevent osteopenia from the systemic acidosis. The incidence of bladder calculi in children with intestinal augmentation using ileum and sigmoid approaches 15% (29). This is felt to be from epitaxic calcification on mucus, so these patients are instructed to irrigate their bladders with large volumes (200–300 cc) of sterile water at least once a day to minimize stone formation.

Augmented bladders can become chronically overdistended, and then perforate, causing peritonitis, which can be life-threatening. For this reason, a great deal of effort goes into evaluating the patient preoperatively in terms of their compliance with an intermittent catheterization schedule. These children are basically almost never able to safely empty on their own, even with the Valsalva voiding. To achieve dryness they frequently need some type of bladder outlet procedure, via injection of a bulking agent, periurethral sling procedure, bladder neck plasty, artificial urinary sphincter or bladder neck closure in combination with appendicovesicostomy, Mitrofanoff's principle. However, the tendency to close the bladder neck frequently, which existed in the 1980s and 1990s, has diminished, and most clinicians are accepting a bit of urinary incontinence near capacity rather than subject the patient to the risks of perforation of the intestinal augmentation.

The potential for development of a malignant tumor in an intestinally augmented bladder seems to approximate 3% at 20 years (30). For this reason some advocate annual screening via cystourethroscopy of the patient who has an augmented bladder. However, malignancies can develop in between annual cystoscopies and become quite clinically significant (31). Efforts are underway to evaluate laboratory methods, such as NNP53 and FISH types of urine evaluations, to enhance the success of screening programs.

If bladder calculi develop in augmented bladders the smaller stones can be dealt with endoscopically via the existing urethra or continent catheterizable channel, with larger stones amenable to treatment by percutaneous access of the augmented bladder. The rare very large stone requires open excision.

In summary, intestinal segments in the urinary tract can be associated with metabolic acidosis and poor bone growth, mucus production with increased potential for infections and stone formation, and potential for cancer to develop with time. Stomach segments are associated with potential for metabolic alkalosis, hematuria/dysuria syndrome and potential for cancer to develop with time. Data for bladder regeneration alternatives is new, and at this point preliminary, as is the potential for engineering artificial bladders for implantation.

Voiding Dysfunction in the Apparently Normal Child

Voiding dysfunction, that is non-anatomic, non neurogenic bladder dysfunction, is by far the most common cause of urinary tract infection and urinary incontinence in children. The typical presenting symptoms of bladder dysfunction in a child are daytime incontinence and urinary tract infection. The history is extremely important in assessing the "normal" child with voiding dysfunction. The age at which they potty trained

is of significance. Typically this would be from 18 months to 3½ years of age. The ease of which they potty train can have some significance; difficult potty training generally leads to many more years of daytime incontinence. The dry interval by history, which is typically 90–240 min in the normal child, needs to be assessed. This interval may be shorter in a child with a neurological abnormality, so this is a useful screening question.

The evaluation typically includes a careful history, a careful physical exam looking for palpable kidneys and/or bladder, examination of the introitus to evaluate for bifid clitoris with epispadias, for example, or labial fusion, which can contribute to a dribbling type of incontinence and recurrent cystitis (*Table 57-3*). The most important part of the physical exam is assessing the lumbosacral spine. Sacral dimples, hairy tufts, hemangiomas and lipomas are all associated with tethered spinal cord, so children with these types of findings need to be evaluated with MRI.

One needs to be cognizant of normal, coccygeal dimples; these are only associated with neurological abnormalities on an extremely rare basis.

Table 57-3
Physical Clues to Neurogenic Bladder

• Sacral dimple, especially with a fixed base (not coccygeal dimples)
• Sacral/lumbar hemangioma
• Sacral/Lumbar hairy tufts
• Sacral/lumbar cutaneous sinus tracts
• Sacral/lumbar lipoma
• Flattening of the intragluteal cleft
• Abnormally-shaped buttock area consistent with sacral agenesis
• Non-palpable sacrum consistent with sacral agenesis
• Imperforate anus
• History of sacral-coccygeal teratoma resection

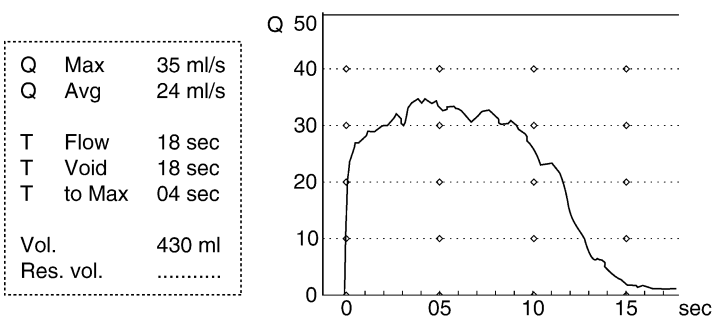
Radiographic Evaluation

The cornerstone of evaluation of the child with dysfunctional voiding is ultrasound of the kidneys and bladder. This study is usually reassuringly normal, but if hydronephrosis or bladder wall thickening are present, further investigation is warranted. If febrile urinary tract infections are occurring, or if upper tract involvement is seen by ultrasound, one needs to consider evaluating the child for vesicoureteral reflux with a voiding cystourethrogram.

Non-Invasive Urodynamic Evaluation

Uroflow is accomplished easily and painlessly in the clinic setting, providing a wealth of information about the lower urinary tract dynamics, without the need for catheterization of the urethra. Use of ultrasound to measure the post-void residual urine volume in the bladder after uroflow completes the investigation of the child's functional bladder capacity and voiding efficiency (*Figs. 57-4* and *57-5*). There are many types of uroflow patterns in children with dysfunctional voiding. A "Normal" uroflow pattern has a relatively rapid rise to a gentle peak, then a gradual decline to no flow (*Fig. 57-15*).

Figure 57-15
Example of normal uroflow study in 14-year-old male. Note rapid rise to peak flow and sustained peak flow phase of curve, followed by a relatively rapid decline to no flow. This is the so-called "Ayres Rock" configuration for normal uroflow in pediatric patient.



A "start and stop" pattern usually signifies some degree of straining with voiding, and is rare in children suggesting detrusor hypotonia. A "staccato" pattern, whereby the flow rate rapidly increases and decreases, but does not stop in between, is very suggestive of incomplete relaxation of the pelvic floor with voiding, the classic "dysfunctional voiding" situation (Fig. 57-16).

A "low flow" pattern is suggestive of urethral stricture in boys, and is almost never seen in girls (Fig. 57-17).

Uroflow with simultaneous evaluation of pelvic floor EMG activity is frequently of value in evaluating the child with refractory voiding dysfunction. Normally, the pelvic floor EMG activity abates with voiding (Fig. 57-18).

Figure 57-16

Staccato uroflow pattern, consistent with inability to relax the pelvic floor with voiding. This is the classic uroflow finding in a girl with dysfunctional voiding.

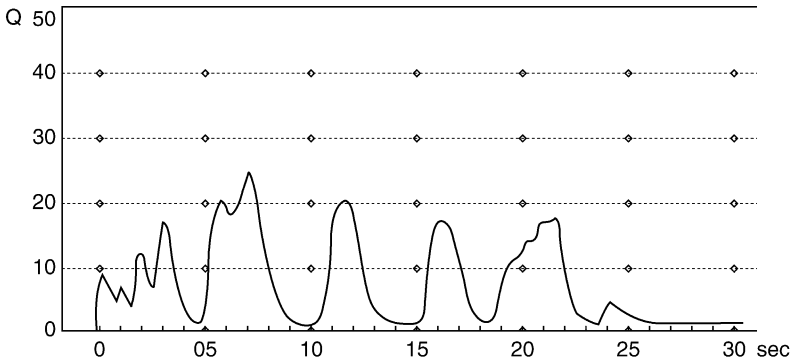


Figure 57-17

Abnormal low uroflow rate from known urethral stricture disease, with elevated post-void residual urine volume by ultrasound of the bladder in the clinic setting. This 15 year old boy with urinary incontinence and trisomy 21 should have a uroflow rate exceeding 30 ml/ sec, and the tracing above shows a maximum flow rate of only 4 ml/ sec. His PVR is clearly elevated at 493 cc.

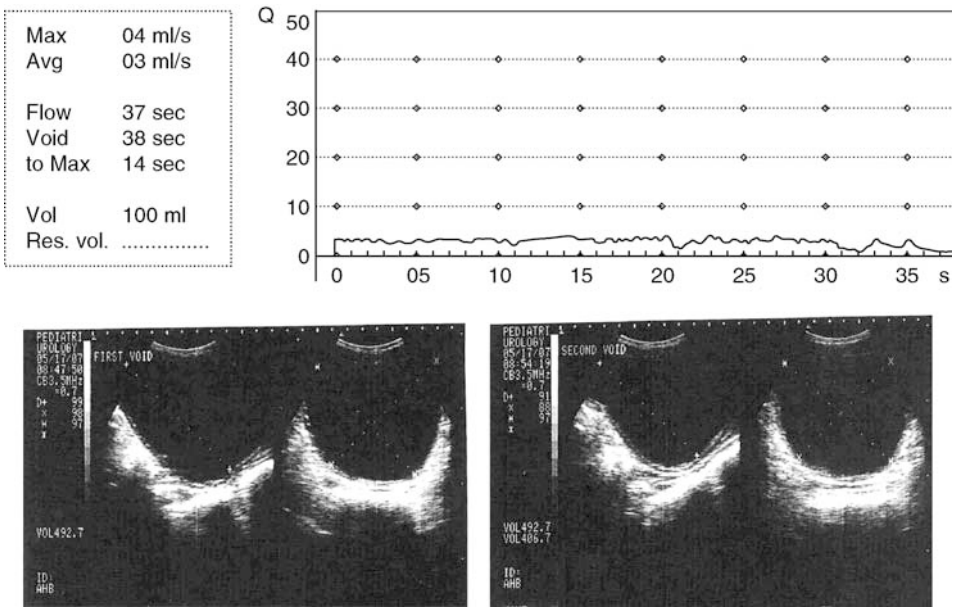

Figure 57-18

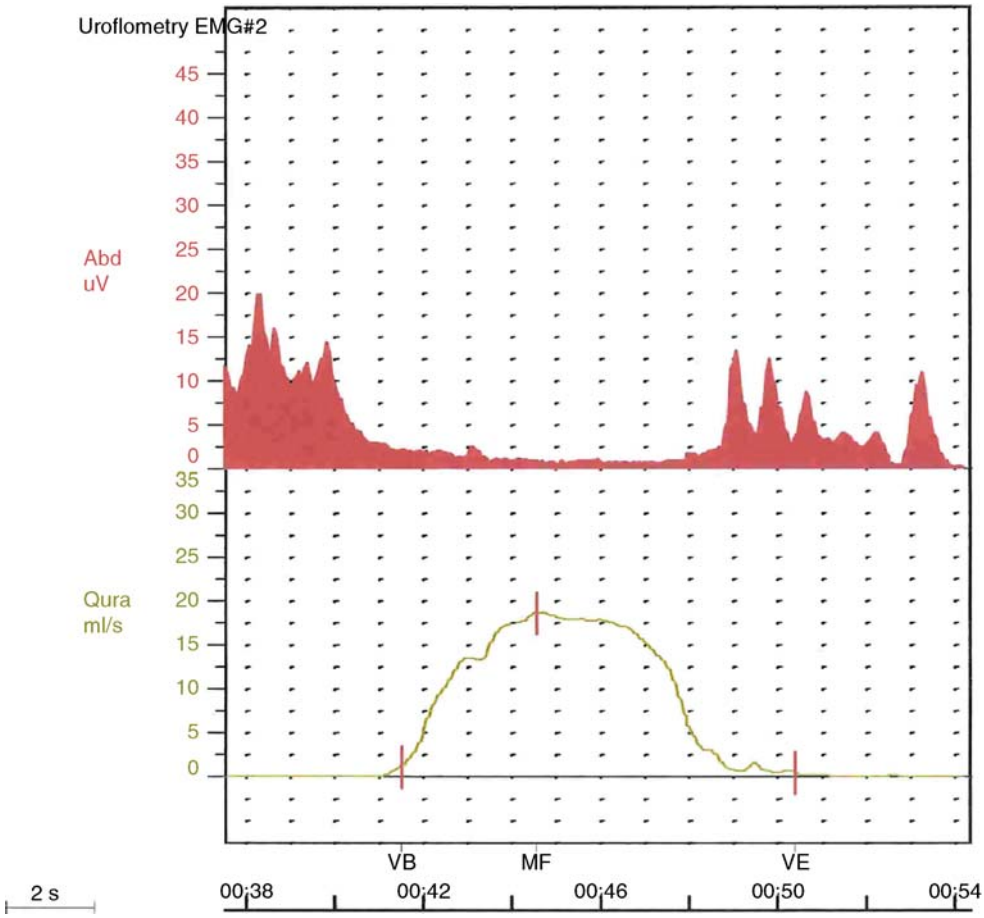
Example of normal uroflow/ EMG tracing, note how the upper curve, representing EMG activity of the pelvic floor, disappears completely with voiding, represented by urine flow rate in the lower tracing.



Some dysfunctional voiders are unable to relax their pelvic floor with voiding, frequently as a mal-adaptive learned behavior from intentionally delaying voiding, or from chronic constipation (*Figs. 57-19* and *57-20*).

Full Urodynamic Evaluation

Full urodynamic evaluation is only rarely necessary in the "Dysfunctional Voiding" patients, and should be used only for the most difficult patients who do not respond to therapy, or who present with other signs and symptoms which would implicate a possible anatomic or neurologic cause of the bladder dysfunction.

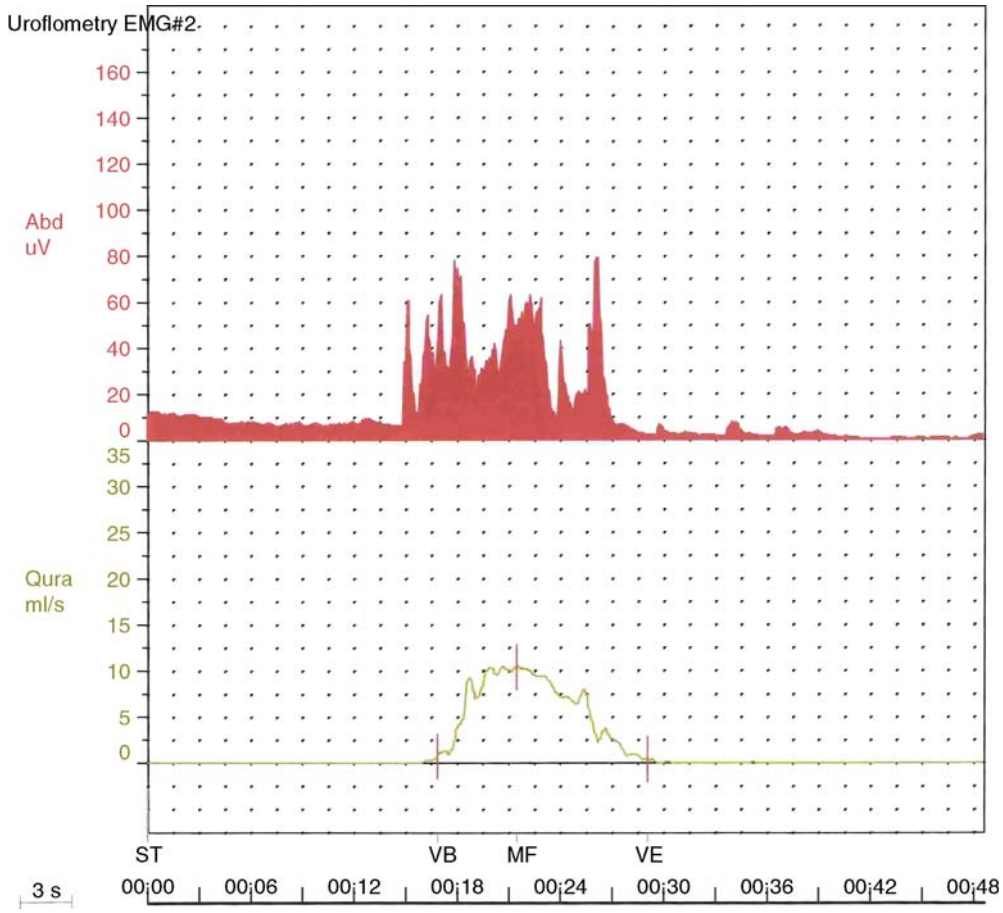
Management of the Child with Voiding Dysfunction

The management of the "normal" child with non-anatomic, non-neurogenic voiding dysfunction begins with behavioral modification. The cornerstone of this is timed voiding, and "star charts" providing visual reward for the child are helpful. Sometimes oral anticholinergic therapy has a role while the child continues to become more aware of how to void properly. Treating constipation if present, which it frequently is, early on with oral regimens is extremely critical to success of achieving continence.

The "normal" child with non-anatomic, non-neurogenic bladder dysfunction frequently has significant constipation that is unrecognized by the child or the parents.

Figure 57-19

Abnormal uroflow/ EMG. This 12 year old girl presented with urinary incontinence and recurrent afebrile urinary tract infections, cystitis. Her study shows a very abnormal amount of activity of the pelvic floor by EMG, as depicted in the upper tracing. The lower tracing shows abnormal low flow rate, from functional bladder outlet obstruction. This patient underwent pelvic floor biofeedback therapy and the results can be seen in *Fig. 57-20*.

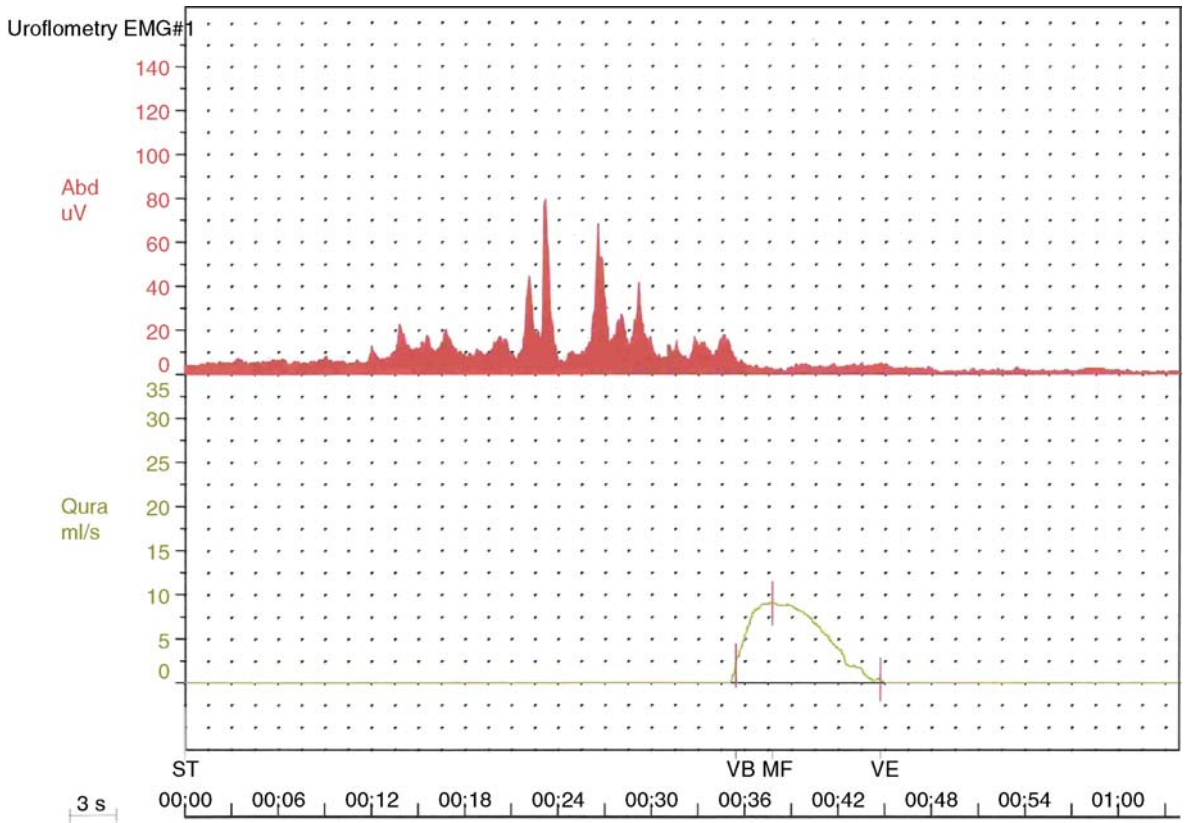


Chronic constipation is usually dietary in origin, and also there is a strong component of behavioral factors such as constantly "being in a hurry." As the "external sphincter" becomes the only way the child can control their bowel movements, they develop the inability to relax the external sphincter/pelvic floor apparatus with voiding, then carry higher residual urine volumes leading to urinary tract infection and incontinence. In order to help these children properly evacuate their rectum a number of recommendations need to be observed by the child and the family. Oral dietary fiber can succeed, but it is important to rotate different fiber sources because any child will typically tire of mandarin oranges, for example, within about 3 days. It is also very important to "make time to go to the potty," and not be in a hurry in the bathroom. Advising the child to get up early enough before school so they can eat breakfast and then have another ½ hour or so at home to take advantage of the "gastrocolic reflex" is important. Many children have resolution of their urinary incontinence with just this maneuver alone, primarily because many children are hesitant to go to the bathroom at school, citing concerns of: it is "dirty" or "not private enough."

For the "normal" child with non-anatomic, non-neurogenic bladder dysfunction who fails conservative measures such as behavioral modification and/or treatment of constipation, the next step is typically empiric anticholinergics. A number of different medications are available, such as oral anticholinergics, alpha blockers, antipsychotics, and occasionally medications like Ritalin will have

Figure 57-20

This shows normal uroflow/EMG curves after pelvic floor biofeedback in this 12 year old girl (see *Fig. 57-19*). Initially, patient has increased pelvic floor EMG activity with initiation of voiding, but then "quiets" her pelvic floor and voids satisfactorily.



value. There is some emerging evidence that a significant proportion of children that are "normal" with non-anatomic, non-neurogenic bladder dysfunction have psychological disturbances (32, 33).

Children who fail anticholinergic treatment are often referred for pelvic floor biofeedback. Non-invasive electrodes are applied to the skin overlying the rectus abdominus muscles and the perineum. Each of these channels is reflected visually on a computer screen for the child. They are initially taught to "contract" the pelvic floor muscles, and then they are taught how to properly identify the pelvic floor muscle group. Only then are they capable of learning how to relax their pelvic floor with voiding. This typically requires sessions twice a week for 2–6 weeks to properly identify and isolate the pelvic floor muscle group from the rectus abdominus muscle group. The motivated child is then expected to undertake these exercises at home, without which pelvic floor biofeedback is doomed to fail.

Non-Neurogenic Neurogenic Bladder, or "Hinman's Syndrome"

The worst end of the spectrum of the "normal" child with voiding dysfunction, even including urinary retention, is the so-called "Hinman's syndrome." This goes by the rather confusing name of "Non-Neurogenic Neurogenic Bladder" dysfunction. Fundamentally, this means that no identifiable neurological lesion is present by MRI. This likely represents an extreme end of the spectrum of voiding dysfunction whereby the child has learned to avoid urinary and fecal incontinence by overusing the striated sphincter/pelvic floor complex. They frequently have vesicoureteral reflux, urinary tract infections and hydronephrosis, and can proceed to renal failure. One needs to screen for a history of for psychological trauma and/or child abuse.

Management of these children is very difficult because these behaviors are very difficult to reverse. Timed voiding, bowel programs, pelvic floor biofeedback,

anticholinergics and alpha blockers are the initial treatment, but many of these children go on to intermittent catheterization. Some of them actually benefit from urinary diversion, at least temporarily, until they are motivated and compliant with intermittent catheterization. Botox injection into the dome of the bladder is beneficial in rare occasions. Also, Botox can be injected into the pelvic floor/striated sphincter apparatus in some children with hypertrophy of the striated pelvic floor musculature, but this is not being done commonly in children at present.

Conclusions

Bladder dysfunction in children represents a very broad spectrum of diagnoses that stretches from a "normal" child with retentive behavior who requires pelvic floor biofeedback and encouragement, to children with severe neurologic and anatomic problems. In most difficult cases our ability to treat lags far behind our ability to diagnose. In a few cases we are able to treat early and coax an abnormal bladder into normal physiology, i.e., newborns with posterior urethral valves and children with exstrophy/epispadias. But for most children with severe abnormalities that result in poorly functioning bladders, we have not yet developed the therapies that result in normalcy.

The critical phase of bladder growth is almost certainly in the first six months of life. When bladder outlet obstruction, such as posterior urethral valves, exists in utero, the bladder does not develop properly and the classic thinking was it is the luck of the draw whether or not the child would have good bladder function. However, there is accumulating evidence that normal bladder cycling, that is complete emptying of the bladder on a regular basis, is a major determinant in terms of beneficial healthy bladder growth. This complete emptying of the bladder also helps determine whether or not the patient can clear infection. Urinary infections are linked with bladder function. Vesicoureteral reflux is much more tightly linked, but not necessarily by cause and effect, to dysfunctional voiding than has been appreciated, almost certainly from an embryological basis of abnormal induction of the trigone from an abnormal ureteric bud.

58 Urolithiasis

Dawn S. Milliner

Introduction

Urolithiasis is increasingly recognized in pediatric patients and is encountered in a variety of clinical settings: the 8-year-old boy who presents with hematuria, the 14-year old with cystinuria experiencing her fourth episode of renal colic in the past 6 years, the 10-year old with inflammatory bowel disease whose two renal stones were recognized incidentally during imaging for evaluation of abdominal pain, the premature infant with asymptomatic nephrocalcinosis and a stone, the 4-year old in the emergency room with gross hematuria and abdominal pain after recently starting indinavir medication. All have in common particulate material of mineral origin within the urinary tract. An understanding of how and why stones form, along with knowledge of the pathophysiologic states that promote urinary tract calculi, provide the basis for effective clinical management.

Epidemiology of Urolithiasis in Children and Adolescents

Urinary tract calculi account for between 1 in 1000 and 1 in 7600 hospital admissions in children and adolescents in the United States (1–3), a rate that is approximately 1/50th–1/75th that reported in adults (4). However, hospitalization is becoming more frequent. From 1999 through 2001, Pearle noted an increase of 34% in the number of pediatric and adolescent patients hospitalized in the U.S. with a primary diagnosis of urolithiasis (5) Since most patients with urolithiasis do not require hospitalization and there is a continuing shift to outpatient care for stone episodes, such data underestimate the frequency of this clinical problem.

With recent appreciation that presenting symptoms of urolithiasis may be different in children than in adults and improved radiographic techniques used more liberally than in the past, the diagnosis is now being made more often in pediatric patients. The frequency of occurrence has also been influenced in recent years by factors predisposing premature infants to nephrocalcinosis and urinary tract stones and advances in medical care that have resulted in survival through childhood and adolescence of increasing numbers of patients with medical conditions, such as cystic fibrosis, that are associated with urolithiasis. Finally, there is an increasing incidence of urolithiasis overall in recent decades in population based studies in industrialized countries (6).

An explanation for the lower incidence and prevalence of urolithiasis observed in children than in adults is incomplete, but may be related to higher concentrations of urinary inhibitors of crystal formation and crystal cell attachment such as citrate, magnesium, and certain macromolecules in children when compared with adults (7–9). Miyake et al. (8) noted that nucleation of calcium oxalate crystals was more strongly inhibited in urine from children compared with adults. Another study demonstrated greater inhibition of calcium oxalate crystal growth by the urine of stone formers and control subjects less than 20 years of age when compared with older individuals (10). Urinary macromolecules from pediatric patients more strongly inhibit the adhesion of calcium oxalate crystals to renal tubular epithelial cells In vitro than do those from adults (7). Robertson defined a risk index for calcium oxalate lithiasis and also found this index to be lower in children (11).

Among children and adolescents, males show a mild preponderance for stone disease overall (12–15). Male to female ratios of 1.4–2.1:1 were reported in four pediatric series from the United States, United Kingdom, Brazil, and Armenia (16–19). This contrasts with symptomatic adult stone formers, among whom males predominate by a ratio of 2–3:1, reaching a maximum of 4.8:1 from ages 40–60 years (6). There are exceptions among certain groups of stone formers, such as young children with developmental anomalies of the urinary tract and associated infection, who tend to be male and younger in age (12, 17).

Ethnic differences in stone prevalence have been observed. Caucasians appear to have the highest incidence followed by Hispanics, with individuals of African American descent less likely to form stones (20–22). Regional differences in diet, fluid intake, and climate may also influence stone prevalence, for example, a “stone belt” is recognized in southeast U.S.

© Springer-Verlag Berlin Heidelberg 2009

Clinical Features

Symptoms of renal colic and gross hematuria, pathognomonic of urolithiasis in adults, are seen less reliably in children (12, 23). Flank or abdominal pain or hematuria accounted for initial presenting features in 94% of adolescents, 72% in school age children, and accounted for presenting features in just 56% of those from birth to 5 years of age in one series (*Fig. 58-1*). In younger children, most report or are observed to have nonspecific abdominal pain, rather than typical renal colic. Indeed, among children up to 5 years of age the diagnosis of urolithiasis was made following a urinary tract infection or as an incidental radiographic finding during evaluation of other problems in nearly half of the patients (12).

In North American series, 60–78% of urinary tract calculi are present in the kidney at the time of diagnosis (12, 16, 24). The majority of those found in the ureters, bladder, or urethra have also originated in the kidneys. The bladder appears to be the site of stone formation in less than 10% of North American children, though in other areas of the world bladder calculi may be more often seen and are often referred to as endemic bladder stones (19, 25). Primary bladder stones tend to occur in younger children (11, 19). Such stones appear related to dietary factors (26, 27). A diet with a high content of whole-grain cereals and/or oxalate-rich vegetables together with a low content of calcium, animal protein, and phosphate is believed to be responsible (11, 25). The resulting urinary biochemical profile favors precipitation of ammonium acid urate and calcium oxalate, the most frequently occurring constituents of endemic bladder stones (25). Endemic bladder stones of childhood are common in several areas of the world including Thailand, India, Turkey, Syria, Iran, Iraq, Tunisia, Pakistan, Indonesia and the Sudan (11). There has been a striking decline in such stones in Europe and other developed countries over the last century (11, 27). Calculi that form in the bladder in North American children are nearly always associated with bladder malformations or prior surgery, such as augmentation cystoplasty, and are characterized by infection.

Stones from the upper urinary tract are comprised of calcium oxalate in 40–60%, calcium phosphate in 15–25%, mixed (usually calcium oxalate and calcium phosphate) in 10–25%, magnesium ammonium phosphate (struvite) in 17–30%, cystine in 6–10%, and uric acid in 2–10% as reported in several pediatric series (1, 12–14, 16, 19, 28).

Diagnostic Evaluation

Recommended initial evaluation of children or adolescents with urolithiasis (*Table 58-1*) includes complete medical and diet histories; family history of stones, hematuria, osteoporosis, or renal failure; and urinalysis with determination of pH, osmolality, and presence or absence of

Figure 58-1

Clinical features at time of initial presentation of 221 children and adolescents with urolithiasis. (Reproduced with permission.)

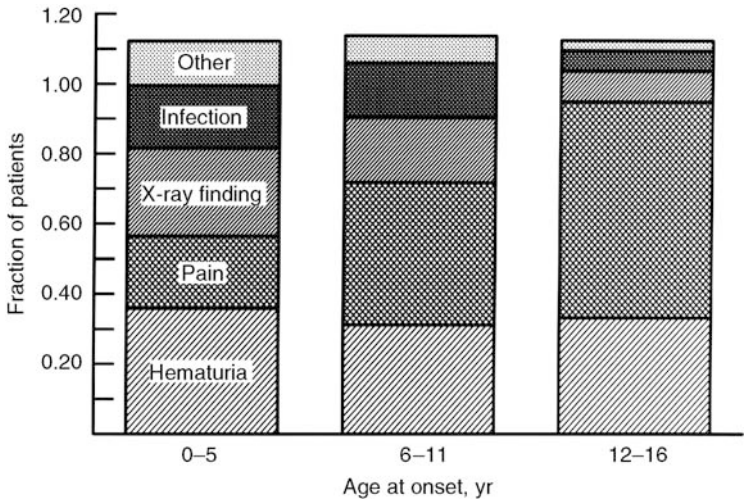

Table 58-1

Initial evaluation of the pediatric or adolescent patient with urolithiasis

Medical history
Diet, fluid intake
Medications, including vitamins, minerals, herbs
Family history
Physical examination
Radiologic appearance of stones and urinary tract
Urine analysis, including pH and microscopy
Urine culture
Urine calcium, oxalate, citrate, sodium, uric acid, phosphorus, cystine[a], creatinine, and volume and/or osmolality
Serum calcium, phosphorus, sodium, potassium, bicarbonate, uric acid, magnesium, creatinine, alkaline phosphatase
Stone analysis[b]

[a]Where indicated
[b]If stone available

crystals. Serum chemistries including calcium, phosphorus, uric acid, bicarbonate, sodium, potassium, magnesium, creatinine and alkaline phosphatase should be obtained. An estimate of daily fluid intake is an important aspect of the dietary history, as is an estimate of the daily intake of calcium, sodium, oxalate, protein, and fluid. The medical and diet histories should also include inquiry regarding use of over the counter food supplements, vitamins, minerals, or herbal preparations. Analysis of stone composition is very helpful in directing metabolic evaluation (*Table 58-2*) and should always be performed when stone material is available.

Urine concentrations, and where possible excretion rates, of solutes should be measured. In infants or young children, older children with developmental delay, or when a reliable timed urine collection cannot be obtained, random urine specimens with solute to creatinine ratio can be very useful. However, care is advised in interpretation since normal values often vary by age, diurnal status, and prandial state. Whenever a child is able to cooperate with a timed 24-h urine collection, this will provide more complete information including daily urine volume. Completeness of each collection should be verified with measurement of urine creatinine. Urine should be analyzed for calcium, phosphorus, oxalate, citrate, uric acid, sodium, creatinine, and total volume. Cystine measurements should be performed if there is any suggestion of cystinuria (stones unknown or of intermediate density, cystine crystals in urine, family history of cystinuria). Metabolic evaluation should be performed while the patient is on his or her usual diet, usual fluid intake, and normal activity. The studies should not be performed shortly after ESWL or a stone removal procedure and should not be obtained when the child is receiving intravenous fluids. If abnormalities are found, further metabolic evaluation such as a full supersaturation profile may be indicated.

Normal values for urine analytes are shown in *Table 58-3*. Excretion rates are higher in infancy. After 2 years of age, urine uric acid/creatinine and oxalate/creatinine ratios vary, decreasing by age, but excretion rates are consistent throughout childhood when determined in a timed collection and expressed as mg/1.73 m^2/24 h (29–32). Uric acid can also be expressed as mg/dL GFR, measured in either a random or timed urine collection (33). Reported normal values for some analytes vary from study to study and for oxalate vary by the measurement method. Ethnic and regional differences can also influence normal values (34). As urine solute measurements are used to guide treatment strategy, it is helpful to keep in mind that the excretion rate of each of these analytes is a continuous variable and should be regarded as a modifiable risk factor rather than focusing on a strictly defined threshold for normal.

Evaluation should include imaging studies of the urinary tract. Renal imaging can provide important clues to the nature of the urolithiasis (*Fig. 58-2* and *58-3*). Stones comprised of calcium oxalate or calcium phosphate are radiodense and readily seen by both ultrasound and CT. Struvite and cystine stones are of intermediate radiodensity. Uric acid, xanthine, 2,8 dihydroxyadenine, and orotic acid stones are radiolucent by conventional radiography but visible by ultrasonography or unenhanced computerized tomography (CT). Indinavir stones and rare matrix stones are radiolucent on conventional radiographs, of low density on CT, and may be difficult to distinguish from surrounding soft tissue by both ultrasound and unenhanced CT. Ultrasonography will be sufficient in most circumstances (35), while CT or intravenous pyelography will be required at times, as will voiding cystourethrography. Small stones and ureteral stones, in particular can be difficult to see by ultrasound. Nimkin compared imaging modalities for detection of stones in the pediatric population, and reported a sensitivity of 57% for plain films, and 77% for ultrasonography when compared with stone detection by CT (3). Others have reported better overall sensitivity for ultrasonography (36), but it may miss 30% of small papillary or calyceal stones (37) and may miss ureteral calculi (36).

Table 58-2
Stone type and associated conditions

Stone type	Associated conditions
Calcium oxalate	Idiopathic stone disease
	Hypercalciuria, idiopathic or of any cause
	Hyperoxaluria, idiopathic or secondary
	Enteric hyperoxaluria
	Primary hyperoxaluria
	ADPKD
	Cystic fibrosis
Calcium phosphate	Idiopathic stone disease
	Hypercalciuria, idiopathic or of any cause
	RTA
	Dent's disease
	Lowe syndrome
Magnesium ammonium phosphate (struvite)	Infection related stones
Carbonate apatite	
Uric acid	Hyperuricosuria
	Metabolic syndrome
	Ketogenic diet
	HPRT deficiency, partial or complete
	Tumor lysis syndrome
	Glycogen storage disease, type 1
	ADPKD
Cystine	Cystinuria

For acute renal colic, noncontrast helical CT scanning is more sensitive and specific for ureteral calculi than all other imaging modalities (38). Computerized tomography also has the advantage of providing detailed anatomic information (usually without the need for intravenous contrast administration), and improved sensitivity for very small stones or those that are poorly radiopaque (35). However, recent information suggesting an increase in malignancies following computerized tomography in childhood has raised concern regarding the degree of radiation exposure with this imaging modality (39). With careful attention to radiographic technique, the radiation exposure with CT can be significantly reduced while maintaining good imaging quality (38, 40) and may be less than that with other renal imaging techniques such as an IVP (41). Nonetheless, ultrasonography is the mainstay for imaging of urinary tract stones in children and adolescents with other modalities used only when specifically needed. For visualization of ureteral stones large enough to be seen by conventional radiography, KUB can be used to supplement an ultrasound.

Urine culture should be obtained in every patient with stones. Colony counts of bacteria in the urine in patients with infected stones may not reach the threshold of 10^5 cfu/mL, such that even lower colony counts should be further evaluated. In selected circumstances, such as suspected Ureaplasma, Corynebacterium urealyticum, or anaerobic infection, special culture techniques may be needed.

Management of the Acute Episode

Stones causing obstruction, acute renal colic, stones with a high potential for acute obstruction (e.g., a large stone in the renal pelvis), and infected stones should be evaluated jointly with a urologist. The majority of stones less than 5 mm in diameter will pass spontaneously, even in young children (15). The use of alpha adrenergic antagonists or calcium channel blockers to facilitate passage of ureteral stones has recently been introduced.

Table 58-3

Urine chemistry: Normal values

	Age	Random, mg/mg creat	Timed	Comments
Calcium[c](34, 143, 262) (52, 230, Butani 2004)	0–6 months 7–12 months ≥ 2 years	<0.8 mg/mg <0.6 mg/mg <0.21 mg/mg	<4 mg/kg/24 h	Prandial variation Sodium dependent

[c]Regional and ethnic variations have been described (Butani Ped Neph 2004)

The proposed mechanism is relaxation of ureteral smooth muscle, with subsequent inhibition of ureteral spasms and dilatation of the ureter. Tamsulosin has been the most frequently used agent. Meta-analysis of available studies in adult patients suggests benefit when either of these agents are added to standard therapy, with a mean time to stone expulsion of less than 14 days in those receiving alpha-adrenergic antagonists (42, 43). This approach has been most successful with distal ureteral stones. To date, little information is available in pediatric stone patients. Use of corticosteroids or non-steroidal anti-inflammatory agents to reduce ureteral edema, either alone or in combination with alpha adrenergic antagonists, has shown mixed results (42).

Dissolution of cystine, uric acid, or struvite stones can sometimes be accomplished but is challenging, and best reserved for selected situations (44). Calcium stones are not amenable to dissolution.

Larger symptomatic stones are likely to require surgical intervention. The range of effective surgical interventions continues to increase, and now even very young patients can often undergo extracorporeal shock wave therapy (ESWL), ureteroscopic lithotripsy or removal, or percutaneous stone removal procedures (PCNL). Open lithotomy is rarely required. In recent years, improvements and miniaturization of endoscopic instruments have led to an increase in the proportion of stone procedures in children that are accomplished by ureteroscopic approach (45, 46). Outcomes have been good (45, 47, 48). Nonetheless, ureteroscopic procedures may be associated with ureteral or urethral injury, particularly in boys, or vesicoureteral reflux, and require a greater degree of technical proficiency in children than in adults (47).

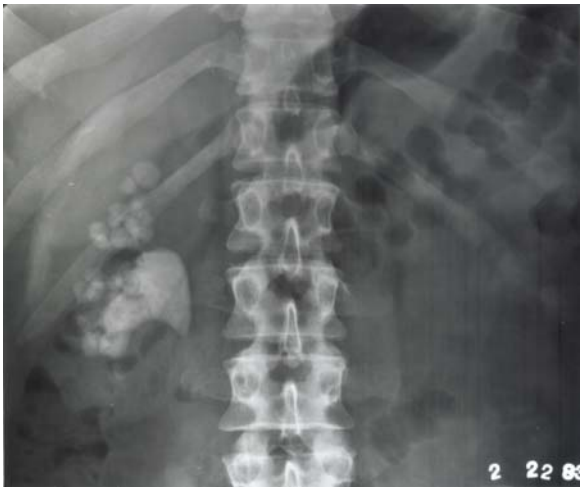
Due to the potential for high energy shock waves to permanently damage renal tissue, there has been concern regarding possible long-term adverse effects of ESWL on the developing kidney. Similar concerns have been raised regarding percutaneous nephrolithotomy (PCNL) which requires insertion of a nephrostomy tube or other catheter through the renal tissue. A careful study of 16 children

Figure 58-2

Multiple calcium oxalate stones in both kidneys of a 5-year-old boy with primary hyperoxaluria, type I.

Figure 58-3

Staghorn calculus in right kidney of a patient with cystinuria



treated for a single stone found no morphologic changes in the kidneys by ultrasound following ESWL, and no significant changes in serum creatinine, but did document significant posttreatment increases in urinary beta 2 microglobulin and enzymuria (49). These changes were considered evidence of proximal renal tubule dysfunction, and resolved by 14 days post procedure. One study suggested impaired growth of kidneys in children following ESWL (50), though a more recent study found no difference in observed versus expected growth of treated kidneys during a mean of 6.2 years following ESWL, ureteroscopic stone removal procedures, nor PCNL (46). The number of PCNL patients was small, however. Most information with second or later generation lithotriptors does not suggest clinically significant renal parenchymal scarring, impaired renal growth, permanent renal function abnormalities, nor hypertension in children following ESWL or PCNL (46, 51–53). Information to date is still limited, particularly in children under the age of 6 years at the time of treatment.

The best treatment for infection related stones involves eradication of the infectious agent. Since stone material is often not well penetrated by antibiotics, removal of infected stone material is often required. Urease inhibitors such as acetohydroxamic acid (AHA) can be helpful but have a high incidence of adverse effects (54). Patients with infected stones requiring ESWL, percutaneous ultrasonic lithotripsy, or an open procedure require attentive antibiotic management as bacteria may be released rapidly from stone material on fragmentation during lithotripsy or instrumentation. Struvite stones may be soft and friable, with particular vulnerability to stone fragment retention following ESWL. Any stone fragments remaining may harbor bacteria in the interstices of the fragments, making eradication of the infection very difficult. In addition, stone fragments provide a nidus for new struvite stone formation, which can occur rapidly. It is for this reason that percutaneous nephrolithotomy is still sometimes required to assure complete removal of stone material.

Stones that are not infected and not causing symptoms or associated with impending or established obstruction may be managed medically. Growth in size of existing stones and formation of new stones are common. Treatment is directed to minimize the likelihood of this occurring. For all forms of urolithiasis, increased oral fluid intake to maintain a urine volume of greater than 750 mL/day in infants, 1000 mL/day in children under the age of 5 years, 1500 mL/day to the age of 10 years, and greater than 2 L/day in older children and adolescents is recommended. Avoidance of dietary excess of calcium, oxalate, and sodium are important. However, reduction to less than the RDA may be problematic with respect to nutritional adequacy, normal growth, and development. Reduction to the appropriate RDA for age for calcium, and not lower, is recommended even in children with known hypercalciuria. Indeed, recent epidemiologic studies in adults suggest that dietary calcium reduction is

associated with an *increased* likelihood of urolithiasis (55), perhaps due to greater absorption of dietary oxalate when less calcium is present in the intestinal tract. Dietary sodium restriction is of particular importance in patients with hypercalciuria and those with cystinuria, as it can reduce the urinary excretion of calcium (56, 57) and cystine (58–61), respectively.

Patients with idiopathic urolithiasis who have normal urine chemistries or mild hypercalciuria and a single stone may be managed initially with increased fluid intake and dietary modification alone. If metabolic stone forming activity is not adequately controlled by this approach, addition of potassium citrate therapy, or for those with hypercalciuria a thiazide, is the next step. For patients with predisposing metabolic or other factors, treatment should be directed specifically to the abnormality(ies) found. Suggested initial therapy, and second line therapy if problems persist despite initial intervention, are shown in *Table 58-4*. For optimal management of patients with significant predisposing factors and those with complex and recurring stone disease, an understanding of the mechanisms of stone formation as well as causative factors and pertinent disease states is necessary.

Mechanisms of Stone Formation and Nephrocalcinosis

Several steps are required for stone formation, beginning with crystal formation. Growth of crystals, their aggregation, and adherence of crystals to epithelial cells of the urinary tract follow. Although the concentration of urinary solutes is the principle determinant of supersaturation, and thus of crystal formation, other factors play a role as well, including ionic strength, pH, and naturally occurring promotors and inhibitors present in the urine. Urine in normal individuals is often supersaturated with calcium oxalate, calcium phosphate, or sodium urate, yet most individuals do not develop stones. That is because concentrations of mineral solutes, ionic strength, pH, promotors, and inhibitors in the urine vary throughout the day as influenced by fluid intake, dietary constituents, and normal metabolism. A dynamic process of crystal formation, growth, aggregation, disaggregation, and dissolution of crystals accompanies the diurnal variations in the physicochemical state of the urine.

Promoters of crystallization are not well characterized but may include urinary macromolecules and lipids (62). Lipids are integral to the organic matrices of mineralized tissues as well as to pathologic calcifications (62). Urinary tract stones are no exception. Another type of promotion that has received attention is the role of crystals of one salt in inducing crystallization of another. For example, sodium urate (63, 64) or calcium phosphate (65) acts as a nidus for calcium oxalate crystal formation. These principles help to explain the observation that some patients with calcium stones are hyperuricosuric yet do not demonstrate hypercalciuria (66).

Inhibitors of crystallization act at the crystal surface, most often interfering at active crystal growth sites (67) and by forming soluble complexes with potential crystal ions. Naturally occurring inhibitors of calcium oxalate and

calcium phosphate crystal formation in the urine include citrate, pyrophosphate, magnesium, and urinary macromolecules such as glycosaminoglycans, and nephrocalcin. These properties can be used to therapeutic advantage in patients with calcium oxalate and calcium phosphate stones (68, 69).

From the time filtrate is formed at the glomerulus until the urine reaches the bladder there is an environment of constant flow, such that crystals formed are generally washed out of the urinary tract. In order for stones to form, the crystals must either aggregate to a size sufficient to obstruct a renal tubule and impair flow (free particle theory) or the crystal must adhere to the renal epithelial cell, the papillary tip, the wall of a calyx, or other location in the urinary tract (fixed particle theory). Adherence is favored by injury to the renal tubular epithelium or the urothelium. Injury may be induced by toxins, by infection, or by crystals themselves. Once crystals are relatively stationary in the urinary tract, permitting growth and aggregation, a stone may develop. Stasis of the urinary tract, with or without frank obstruction, is an important contributor. Among children who do form stones, predisposing metabolic factors, infection, and/or urinary stasis are identified in the majority (4). Predisposing factors should be systematically sought in every pediatric or adolescent patient with stones, since such factors form the basis of effective treatment interventions.

Nephrocalcinosis is caused by microscopic mineral deposits in renal parenchyma, usually in the medullary regions (70). It is often seen concomitant with urolithiasis and appears to share many of the same metabolic risk factors and pathophysiologic mechanisms. When it occurs independent of urolithiasis, metabolic changes such as marked hypercalciuria or hyperoxaluria, or renal immaturity are typically present (*Table 58-5*). Nephrocalcinosis occurs more often in infants and young children and is more often associated with loss of renal function than is urolithiasis. In one study of 152 children and adolescents with nephrocalcinosis, various hereditary renal tubular disorders were identified in 32% (71). A family history of nephrocalcinosis or urolithiasis was noted in 7.2% and 19.1%, respectively (71).

Causative Factors in Urolithiasis

Seventy-five percent of children and adolescents with urolithiasis have identifiable predisposing causes for stone formation (12–14, 28). From compilation of studies that included 492 North American pediatric patients with urolithiasis Polinsky noted that metabolic causes accounted for approximately 33 %, structural urinary tract abnormalities for 32 %, and infection related stones for 4 %, although differences in classification complicated combining individual studies. In most published series, complete metabolic evaluations were not performed in all patients, likely underestimating the contribution of metabolic risk factors. This impression is supported by a study in which all patients were screened for metabolic abnormalities in which a metabolic cause for stone formation was identified in 25/47 patients (53%) (72). In some pediatric reports, especially from Europe, a higher proportion of patients have infection cited as the primary cause of urolithiasis (4, 17, 19, 73), though this pattern may be changing (74). In most series, infants and young children more frequently have infection related stones than do older children or adolescents (12, 17), while adolescents account for the majority of those with idiopathic stone disease. No contributing cause for stone formation was identified (idiopathic stone disease) in 28 % of North American patients and 14% of the European patients compiled by Polinsky (4).

It is common to find more than one predisposing factor in a given patient (12). In one study of 221 pediatric patients with urolithiasis, 36% of those with structurally abnormal urinary tracts were also found to have metabolic abnormalities predisposing to stone formation and 39% had chronic infection (12). Among the patients with infection related stones, 29% also had metabolic abnormalities. Thus infected, obstructed, or structurally anomalous urinary tracts do not obviate the need for careful metabolic assessment. Because of the high likelihood of

identifying causes of stone formation in children and adolescents and their many future years at risk for further stone disease, complete assessment for stone forming factors is indicated in all children.

Metabolic Factors Predisposing to Stone Formation

High urinary concentration of calcium, oxalate, uric acid, or cystine resulting from either increased renal excretion or low urine volume results in supersaturation of the urine, thus favoring crystal and stone formation. Among naturally occurring inhibitors of stone formation in the urine, citrate, magnesium, and pyrophosphate are the best defined. A number of urinary macromolecules including glycosaminoglycans, osteopontin, and urinary prothrombin fragment 1 appear to play a role but as yet are not well studied in children and adolescents (75). Identification of the specific predisposing metabolic factors (*Table 58-6*) in each patient is of importance in developing the most effective therapeutic regimen.

Solute Excess

Hypercalciuria

Hypercalciuria as currently defined (>4 mg/kg/day or > 0.21 urinary calcium/creatinine ratio) is common, occurring in from 5–10 % of healthy children (34, 76). Regional and ethnic variations in urine calcium excretion have been observed (34). Hypercalciuria has been associated with hematuria, dysuria, urinary urgency, and perhaps recurrent urinary tract infections (77–80) as well as to urolithiasis. It is the most common metabolic factor in children and adolescents with urolithiasis, accounting for approximately half of such abnormalities identified. Urine calcium is influenced by a number of dietary constituents. Physiologic hypercalciuria related to dietary excess of sodium, calcium, or protein or to deficiencies of potassium or phosphorus should be identified and is readily addressed. Most hypercalciuria is idiopathic. Inherited forms have been well described, and some appear to follow an autosomal dominant or codominant pattern (81–85). However, when one considers the respective roles of the gastrointestinal tract, bone, and the kidney in calcium economy, it is not surprising that hypercalciuria more often appears to be a polygenic trait. A number of rare, specific monogenic causes of hypercalciuria have also been identified involving the proximal renal tubule (Dent's disease, hereditary hypophosphatemic rickets with hypercalciuria due PHEX gene mutations, Lowe syndrome), thick ascending loop of Henle (Bartter syndrome, activating mutations of the calcium sensing receptor gene, familial hypomagnesemia with hypercalciuria and nephrocalcinosis due to mutations of the claudin 16 gene /paracellin 1) and the distal tubule (pseudohypoaldosteronism type II, primary renal distal RTA), Detailed discussion of each is beyond the scope of this chapter, but the reader is referred to recent reviews (76, 85). Not all are associated with urolithiasis. A family history of stones, isolated hematuria, or early osteoporosis can be informative. Among the monogenic causes of hypercalciuria, a few deserve further mention. They include the x-linked disorders related to mutations of the CLCN5 chloride channel, the gene for which is located on chromosome Xp11.22. This chloride channel is expressed in the cortical proximal tubule, medullary thick ascending limb of the loop of Henle, and α-intercalated cells of the human nephron (91). Mutations of this channel have now been demonstrated in four conditions, previously described as separate clinical entities: X-linked nephrolithiasis with renal failure, Dent's disease, x-linked recessive hypophosphatemic rickets, and low molecular weight proteinuria with hypercalciuria and nephrocalcinosis. These conditions have in common hypercalciuria, nephrolithiasis, nephrocalcinosis, renal tubule dysfunction characterized by low molecular weight proteinuria and impaired absorption of phosphorus, progressive renal insufficiency, and in some cases rickets (92). It has recently been suggested that all be referred to collectively as Dent's disease (93).

Hypercalciuria in patients with Dont's disease is typically of moderate degree, although may be as high as 10 mg/kg/day in some children. The reason for the hypercalciuria is not well understood, but it appears to be responsive to treatment with thiazide diuretics (94). Amiloride was not found to be helpful (92, 94). Proteinuria of up to 1 gram per day in children is a diagnostic feature of males affected with Dent's disease (92) and is frequently present in lesser amounts in carrier females (95, 96). Urinary retinol binding protein is distinctly elevated and of value in diagnosis (95).

Other mechanisms have been implicated in idiopathic hypercalciuria and include renal tubular phosphate leak, increased 1,25 dihydroxyvitamin D synthesis, increased renal prostaglandin E2 production, and enhanced bone resorption, among others (76, 85). A complex interplay of environmental and genetic factors involving the intestinal tract, bone, and kidney appears responsible for hypercalciuria in most patients (86).

Table 58-6

Metabolic abnormalities associated with urolithiasis

Metabolic abnormality	Idiopathic	Physiologic or secondary	Renal tubule transport disorder or inborn error of metabolism
Hypercalciuria	Polygenic trait	Dietary salt excess	Dent's disease (CLCN5 mutations)
		Dietary calcium excess	Lowe Syndrome (OCRL1 mutations)
		Vitamin D excess	Hereditary hypophosphatemia with rickets and hypercalciuria (PHEX mutations/NPT2a)
		Ketogenic diet	
		Loop diuretics	
		Immobilization	RTA (ATP6B1, AE1 mutations, carbonic anhydrase deficiency)
		Metabolic acidosis	
		Phosphate depletion	
		Prematurity	Familial hypomagnesemia – Hypercalciuria (Claudin 16 mutations)
		Prostaglandin E_2	
		Hypercalcemia	Calcium sensing receptor
		Hyperparathyroidism	Mutations
		Hyper- or hypothyroidism	
Hyperoxaluria	Mild, associated with idiopathic stone disease	Dietary oxalate excess	Primary hyperoxaluria I and II
		Enteric hyperoxaluria	
		Gastric bypass surgery	
		Parenteral nutrition in premature infants	
		Orlistat	
		Ethylene glycol	
Cystinuria	–	Renal tubule immaturity in infants	Cystinuria
Hyperuricosuria	Mild, associated with idiopathic stone disease	High protein diet	HPRT deficiency, complete (Lesch Nyhan) or partial
	Familial forms	Ketogenic diet	
		High dose pancreatic enzyme therapy	
		Diabetes	
		Tumor lysis	Glycogen storage disease 1
		Myeloproliferative, lymphoproliferative disorders	
		Sulfinpyrazone	
		Phenylbutazone	
Hypocitric aciduria	Mild, associated with idiopathic urolithiasis	Metabolic acidosis	Distal RTA
		Ketogenic diet	
		Hypokalemia	
		Bacteriuria	
Xanthinuria		Allopurinol therapy	Hereditary xanthinuria

Among children with idiopathic hypercalciuria who did not have urolithiasis at initial diagnosis, the likelihood of developing calculi was 4–17% during 3–11 years of follow-up in three studies involving a total of 121 patients (56, 78–80). The risk of urolithiasis appears to increase with age (79). In addition to the development of urolithiasis and urinary tract symptoms, idiopathic hypercalciuria is associated with reduced bone mass in as many as half of affected patients (87, 88). Fractures have been observed. Treatment with thiazide diuretics is effective in normalizing urine calcium in most patients with idiopathic hypercalciuria, though thiazide failure has been observed in some (89).

Secondary forms of hypercalciuria are common and may occur in response to administration of medications such as loop diuretics or carbonic anhydrase inhibitors. Prolonged immobilization in children or adolescents, excess intake of calcium or vitamin D, and high concentrations of circulating parathyroid hormone all predispose to hypercalciuria. Phosphate depletion causes a hypercalciuria mediated by an increase in 1,25 dihydroxyvitamin D synthesis (90). Chronic metabolic acidosis from any cause has the potential to result in hypercalciuria due to bone resorption. In distal renal tubular acidosis, the deficiency in acid secretion results in significant hypercalciuria. Once the metabolic acidosis is corrected with exogenous administration of base, the hypercalciuria resolves. Hypercalcemia of any cause is likely to result in secondary hypercalciuria.

Hyperoxaluria

Hyperoxaluria accounts for 2–20 % of metabolic factors identified in children and adolescents with urolithiasis (12, 97, 98). Mild idiopathic hyperoxaluria (ranging from 0.45 to 0.6 mmol/1.73 m^2/24 h) is not infrequently observed in conjunction with hypercalciuria in patients with idiopathic stone disease (98, 99). The etiology of the hyperoxaluria is unknown, but has variably been ascribed to metabolic variations resulting in increased oxalate production or to enhanced gastrointestinal absorption (99–101). Approximately 10–20% of the oxalate in the urine has traditionally been regarded as derived from dietary sources (102), although some have argued that the contribution of dietary oxalate is higher (103). Dietary oxalate excess (particularly if there is concomitant low dietary calcium) (99, 103) can lead to hyperoxaluria. Ingestion of starfruit (carambola) or large amounts of sorrel have been associated with acute oxalate nephropathy (104). Ethylene glycol, found in antifreeze, is metabolized to oxalate. Acute ingestion may result in acute renal failure due to oxalate nephropathy.

Under normal conditions, only a small fraction (less than 10%) of oxalate ingested from the diet is absorbed in the gastrointestinal tract (101, 105, 106). Other dietary constituents influence absorption of oxalate, particularly calcium containing foods which reduce absorption by binding to available oxalate. In recent years there has been interest in degradation of fecal oxalate by certain anaerobic bacteria that populate the colon in a significant proportion of healthy individuals. It has been suggested that loss of colonization with such organisms may result in increased GI absorption of oxalate leading to hyperoxaluria and stone formation (98, 107, 108). Of interest, in one carefully done epidemiologic study in adults, the presence of Oxalobacter in the stool correlated inversely with stones across all strata of age, gender, race/ethnicity, and region. Yet median urine oxalate excretion was the same with or without O. formigenes colonization (109), raising the possibility of other mechanisms. Oral administration of oxalate degrading bacteria or the responsible enzyme is currently under investigation as a potential treatment strategy (110).

Increased absorption of oxalate resulting from gastrointestinal disease is termed enteric hyperoxaluria. Any abnormality of the intestinal tract that is associated with malabsorption of fat can result in enteric hyperabsorption of oxalate. Mechanisms include binding of calcium by fatty acids. This leaves less calcium in the lumen to combine with oxalate, and oxalate is thus absorbed more avidly. In addition, bile salts cause injury to the colonic epithelium promoting enhanced oxalate absorption. The degree of hyperoxaluria caused by enteric disease is highly diet dependent and quite variable, from mild to severe. Consequences can include not only recurrent urolithiasis but also oxalate nephropathy leading to renal failure. Treatment includes reduction in dietary oxalate, addition of calcium supplements to bind oxalate in the intestinal tract, increased oral fluid intake, a low fat diet, and in some patients administration of sequestrants of bile acids. If hypocitric aciduria or hypomagnesuria are present, oral supplementation may be helpful to enhance urinary inhibition of calcium oxalate crystal formation.

The primary hyperoxalurias are autosomal recessive inborn errors of metabolism due to deficiency of hepatic alanine:glyoxylate aminotransferase (type I) or glyoxylate reductase/hydroxypyruvate reductase (type II) and are associated with marked elevation of urine oxalate excretion (111, 112). These enzymes are important in the metabolic disposition of glyoxylate, a precursor of oxalate found in hepatic cells. In type I disease, a large number of

mutations of the AGXT gene have been described, all of which lead to a reduction in AGT enzyme activity and/or to mistargeting of the enzyme from the peroxisome to the mitochondria where it is ineffective in disposition of glyoxylate. A marked increase in the hepatic production of oxalate and variable increases in glycolate result. Since excess oxalate must be excreted by the kidney, resulting high urinary concentrations lead to supersaturation of the urine for calcium oxalate. In type II disease deficiency of GRHPR enzyme activity leads to hyperoxaluria and hyperglyceric aciduria. Studies from France suggest a prevalence of type I disease of 1.05 per million population (113). Type II is rare, with fewer than 50 cases to date reported in the literature. Molecular diagnosis can now confirm the diagnosis of type I or II PH in most patients (115, 116). Liver biopsy with measurement of enzyme activity is required in a minority of patients. A small number of children have been reported with marked hyperoxaluria and clinical features similar to those with type I and II, but who have normal hepatic AGT and GRHPR activity. Whether these children have an as yet undefined error of hepatic metabolism or whether another mechanism is responsible remains to be established (98, 106, 114).

Due to the degree of hyperoxaluria and its presence from birth, primary hyperoxaluria is characterized by particularly aggressive stone formation and renal failure. The majority of patients demonstrate urolithiasis and/or nephrocalcinosis during infancy or childhood (*Fig. 58-2*). Over time, due to repeated stone episodes which may involve obstruction or infection and due to nephrocalcinosis and other effects of oxalate on the renal tubules and interstitium, renal failure often results. Type I disease is more severe than that of type II (117), with a higher proportion of type I patients progressing to end stage renal disease at an earlier age. However, there is wide variability of clinical expression in both types, with some patients progressing to renal failure in infancy and others retaining satisfactory renal function through the fourth or fifth decade of life (118, 119). Once the glomerular filtration rate falls below 30 mL/min/1.73 m^2, the plasma oxalate concentration rises rapidly, with resulting deposition of calcium oxalate in multiple organ systems (oxalosis). If oxalosis cannot be prevented or reversed by intensive dialysis and early transplantation, severe morbidity and death are the consequence.

Approximately a third of the patients with type I PH respond to pharmacologic doses of pyridoxine with a marked reduction in, and in some cases normalization of, urine oxalate excretion (118, 120). PH I patients should receive a trial of pyridoxine to assess their response. In all patients with PH intensive efforts to minimize calcium oxalate crystallization and stone formation in the kidneys appear to be helpful in preservation of renal function (118). Neutral phosphate therapy has been shown to reduce both urinary supersaturation for calcium oxalate and to increase urinary inhibitory activity for calcium oxalate crystal formation (121). Citrate therapy has also been advocated (122). There has been recent interest in oral administration of oxalate degrading bacteria, such as Oxalobacter formigenes and in oral administration of oxalate degrading enzymes for treatment of PH (123). These agents appear to not only degrade oxalate within the lumen of the gastrointestinal tract, but to also stimulate enteric oxalate secretion (124, 125).

Cystinuria

Cystinuria accounts for 2–8 % of children with metabolic stones (4, 12). An inherited defect in renal tubular reabsorptive transport of cystine and the dibasic amino acids (ornithine, arginine, and lysine) accounts for the high concentrations of cystine in the urine of patients with this disorder. Cystine stones form due to cystine excretion rates that exceed solubility at usual urine volumes. At physiologic pH of less than 7, solubility is limited to 1000 µmol (240 mgm)/L (126). Characteristic hexagonal crystals can sometimes be seen in the urine of patients with cystinuria (*Fig. 58-4*). Cystine solubility is enhanced at an alkaline urine pH, such that alkalinization of the urine is an important component of treatment regimens. However, even at an optimal urine pH of 7, cystine solubility in the urine is limited to approximately 1250 µmol (300 mg)/L of urine (126). The prevalence of cystinuria in the general population in the United States and Europe is estimated at 1 in 7000, but varies widely in various parts of the world ranging from 1/2500 in Jews of Libyan origin to 1/100,000 in Sweden (127, 128). The mutant gene appears to be common, with a frequency approaching 0.01 (127–129).

Historically, three clinical subtypes have been described, based on the level of urinary cystine and dibasic amino acids in obligate heterozygotes (130). Type I accounts for approximately 70% of patients with clinically evident cystinuria and is completely recessive. Patients with type I/I show cystine excretion rates that are generally greater than 1000 µmol/gm creatinine by 1 year of age, with a mean excretion rate of 4500 µmol/gm creat (130). Half or more of such patients develop stones within the first decade of life (130). Mutations of the SLC3A1 gene on chromosome 2p encoding the rBAT protein important

Figure 58-4

in dibasic amino acid transport have been shown to be responsible for type I cystinuria (131, 132). Types II and III are incompletely recessive, identified by elevated cystine excretion in obligate heterozygotes (133). Heterozygotes with type II/N have cystine excretion from 400–2400 µmol/gm creatinine and may form stones. Those with III/N have lower cystine excretion and typically do not develop urolithiasis. Patients with types II/II and III/III have cystine excretion rates similar to I/I. Compound heterozygotes are common. Mutations of the SLC7A9 gene on chromosome 19 are responsible for types II and III (132, 134).

With increasing molecular genetic information, some have challenged the traditional classification system, specifying type A disease as due to two mutations of SLC3A1, and type B disease as due to two mutations of SLC7A9 (135). Type AB patients have been recognized. However, there is not a strict genotype- phenotype correlation with types A and B. It is also recognized that defects in these two genes do not explain all cases of cystinuria (135, 136). Due to immaturity of renal tubule function during infancy, and the complexity of compound heterozygosity, it is difficult to definitively establish the diagnosis of cystinuria prior to 1 year of age (137).

Patients with homozygous forms of cystinuria frequently experience their first stone episode during childhood or adolescence and have recurring, life-long stone formation (*Fig. 58-3*). Medical therapy can be highly beneficial. First line therapy consists of increased oral fluid intake and a low salt diet to reduce urine cystine concentration to less than 300 mg/L, combined with urinary alkalinization to a pH of 7.0. If formation of cystine stones is not well controlled with these measures, addition of alpha-mercaptopropionyl glycine or D-penicillamine is recommended. Though both of these agents have been associated with significant side effects, they can be effective in stone dissolution as well as prevention of new stone formation (135, 138, 139). Titration of dose to maintain free urine cystine below 100umol/mmol creatinine appears helpful (139). Alpha- mercaptoprotionylglycine appears better tolerated than D-pencillamine (140). Captopril has been advocated but results have been inconclusive (141). However, even with optimal medical management urologic procedures are periodically required. With advancing age, elevated serum creatinine concentrations can be encountered in 17–50% of patients, with a small proportion (approximately 3%) eventually requiring dialysis (135, 141, 142).

Hyperuricosuria

Hyperuricosuria is found in 2–10% of children and adolescents with metabolic stones. Mild idiopathic hyperuricosuria may be a cause of hematuria (143) and is often found in conjunction with hypercalciuria (12, 144). A defect in renal tubular transport of uric acid, either due to reduced proximal tubular reabsorption or to increased secretion may be found (143, 145, 146). Idiopathic renal hyperuricosuria is often familial and asymptomatic.

Secondary hyperuricosuria may result from diets high in protein, or to ketogenic diets (147), and from medications including dicumarol, ascorbic acid, probenicid, phenylbutazone, salicylates, and citrate as well as pancreatic extract therapy in patients with cystic fibrosis (143). It can be seen in association with diabetes (148) and the syndrome of inappropriate secretion of antidiuretic hormone (149).

Although uric acid crystals in the urine may contribute to urolithiasis by forming a nidus for calcium oxalate crystallization, uric acid stones are uncommon in childhood. When they occur in children, uric acid stones are generally due to marked overproduction of uric acid such as occurs in tumor lysis syndrome, lymphoproliferative or myeloproliferative disorders, or rare inborn errors of metabolism such as complete (Lesch Nyhan syndrome) or partial deficiencies of hypoxanthine phosphoribosyl transferase (HPRT) enzyme activity. Urolithiasis occurs in a high proportion of patients with Lesch Nyhan syndrome, and not infrequently develops during the first year of life. Of those with partial HPRT deficiency, up to 75% develop uric acid urolithiasis (4). High fluid intake and restriction of dietary purines are recommended. Treatment with alkalinization to a pH of 7.0 will increase solubility and a trial of allopurinol may be beneficial.

Other Solute Excess

Xanthine calculi may occasionally be seen in patients treated with allopurinol for hyperuricemia related to Lesch Nyhan syndrome or as part of tumor lysis syndrome during chemotherapy (150). Markedly increased urine concentrations of xanthine and hypoxanthine are also seen in patients with a rare autosomal recessive deficiency of xanthine oxidase activity. Xanthine calculi develop in approximately a third of patients with hereditary xanthinuria (103, 151). Urinary tract stone disease in childhood may result from urinary solute excess due to other rare inborn errors of metabolism including orotic aciduria, alkaptonuria (152), and adenine phosphoribosyltransferase (APRT) deficiency leading to 2,8 dihydroxyadeninuria (153, 154). Treatment with allopurinol is effective in ARPT deficiency as it blocks production of 2,8 dihydroxyadenine.

Inhibitor Deficiencies

Citrate is a naturally occurring inhibitor of calcium oxalate and calcium phosphate crystallization. Hypocitric aciduria is a frequent finding in a subset of adult patients with idiopathic urolithiasis (155). In a study by Tekin and colleagues, urinary citrate excretion was significantly lower in their population of pediatric calcium stone formers than in a control group of healthy children and was felt to be the most important risk factor identified (156). Baggio found lower urinary concentration and excretion rates of citrate in stone forming children than in controls, but the differences did not reach statistical significance (157). Whether or not citrate is a primary factor in stone formation in a particular patient, increasing a lower citrate concentration to a higher one can be beneficial in minimizing calcium stone forming activity.

Deficiency of urinary citrate occurs predictably as a result of hypokalemia, and systemic or intracellular acidosis. However, in most such situations, the hypocitric aciduria is transient. In distal renal tubular acidosis, hypocitric aciduria appears to be a major contributor to stone formation and persists until the metabolic acidosis is corrected. Citrate measured in the urine may be artifactually low in the presence of a urinary tract infection, and should be repeated after antibiotic treatment. Interpretation of urinary citrate concentrations is complicated by relatively few studies of urinary citrate in healthy children, and the fact that citrate is influenced by prandial state, dietary composition, and age. Pyrophosphate and magnesium in the urine are also known to act as inhibitors of calcium oxalate and calcium phosphate crystal formation. Although both are used for therapeutic benefit, deficiencies of pyrophosphate or magnesium have not been described as a primary cause of urolithiasis.

A variety of urinary macromolecules appear to inhibit calcium oxalate crystal formation. Those studied include glycosaminoglycans, osteopontin, nephrocalcin, and urinary prothrombin fragment 1, among others. Some investigators have observed relatively lower concentrations of some of these inhibitors in the urine of children who form stones when compared with healthy children (158). However, considerable controversy exists regarding the role of urinary macromolecules in clinical disorders of stone formation (159).

Clinical Conditions Associated with Urolithiasis

A number of clinical conditions are associated with metabolic factors that predispose to stone formation. Impaired acidification of the urine favors calcium stones, due to reduced solubility of calcium salts in an alkaline environment, as well as metabolic acidosis (160). Distal renal

tubular acidosis results in hypocitric aciduria, hypercalciuria, low titratable acidity, and high urine pH. Multiple small calcifications in the papillary tips of the kidneys, comprised of calcium phosphate and/or calcium oxalate, are typical and are seen with both incomplete and complete forms of distal RTA (*Fig. 58-5*). In long term follow-up of distal RTA in childhood, Caldas, et al. (161) found nephrolithiasis and/or nephrocalcinosis in 14/28 patients. Nephrocalcinosis tends to occur with increasing age (161). Experience suggests that early initiation of alkali therapy may obviate the development of nephrocalcinosis by correcting the hypocitric aciduria and hypercalciuria (162, 163). A few patients have been reported among kindreds with RTA that appeared to develop nephrolithiasis and/or nephrocalcinosis due to hypercalciuria without systemic acidosis (164). This and other observations in hereditary RTA suggest that the relationships among hypercalciuria, the renal tubule acidification defect, and nephrocalcinosis/urolithiasis are complex (164).

Several autosomal recessive mutations resulting in carbonic anhydrase II deficiency have been described with variable degrees of distal and/or proximal RTA and associated urolithiasis and nephrocalcinosis (165–167). Mutations in the red cell anion exchanger (Band 3, AE1) gene have been confirmed in several families (168), are associated with distal RTA, and usually show autosomal dominant transmission (169). Urolithiasis is a frequent manifestation (168). Secondary distal RTA such as occurs in Wilson's disease and Sjogren's syndrome has also been associated with urolithiasis (170, 171). In type 1 glycogen storage disease hypercalciuria and hypocitric aciduria, which increase with age, and distal RTA have been implicated in the development of nephrolithiasis (172–175). Incomplete distal RTA and urolithiasis have also been reported in cerebrotendinous xanthomatosis, an autosomal recessive lipid metabolic disorder (176).

Urolithiasis is not usually associated with proximal RTA (177, 178) nor with type IV RTA (179). Despite hypercalciuria in proximal RTA, the high associated urinary citrate concentrations may protect against stone formation. In type IV RTA, reduced excretion of calcium appears sufficient to compensate for the reduced urine citrate, such that urinary saturation of calcium oxalate remains within normal limits (179). Lower phosphorus and uric acid excretion in patients with type IV RTA may also mitigate against stone formation (179).

Obesity and the associated metabolic syndrome is a risk factor for stone formation. Insulin resistance results in impaired renal ammonia production (180). Uric acid stone formation follows, related primarily to the low urine pH. Well-studied in adult patients, this complication of obesity has now been recognized in early adolescence (181). In addition to metabolic effects of obesity, bariatric surgical procedures, which are increasingly performed in adolescents and even younger children, are associated with hyperoxaluria, low urine volumes, and nephrolithiasis (182). Enteric hyperabsorption of oxalate related to malabsorption is the postulated cause (183). The hyperoxaluria can be marked and in some adult patients has led to renal failure due to oxalate nephropathy (184). The emerging epidemic of obesity in children and adolescents will likely lead to an increased prevalence of renal stone disease.

Medullary sponge kidney is frequently associated with recurrent calcium urolithiasis. Hypercalciuria, hypocitric aciduria, incomplete RTA, and increased urine pH have been variably observed in such patients (185). Nephrolithiasis is seen in 20–36% of patients with autosomal dominant polycystic kidney disease, with approximately half of the stones comprised of calcium oxalate and the other half uric acid (186). The most consistent metabolic abnormality is hypocitric aciduria, with a minority of the patients having hyperuricosuria or hypercalciuria (186, 187). Thin basement membrane nephropathy has been associated with hypercalciuria, hyperuricosuria, and resulting nephrolithiasis (188). An increased frequency of urolithiasis and nephrocalcinosis has also been reported in cystinosis (189–192). Children and adults with Wilson's disease may develop urolithiasis. Distal renal tubular acidosis is the most commonly observed factor (170). However, some of the patients demonstrate hypercalciuria and urolithiasis without evidence of renal

Figure 58-5

tubular acidosis (193). Since urolithiasis may be diagnosed before Wilson's disease is clinically evident, any patient with renal stones and unexplained neurologic, bony, or hepatic abnormalities should be screened for Wilson's disease (170).

Inflammatory bowel disease and other diseases of the gastrointestinal tract associated with malabsorption can cause hypocitric aciduria and hypomagnesuria due to loss of bicarbonate and magnesium in the stool, hyperoxaluria from enhanced enteric oxalate absorption, hyperuricosuria due to increased cell turnover, and low urine volume because of diarrhea, which together result in reduced inhibitor activity, low pH, and high solute concentrations in the urine (194, 195).

Calcium oxalate urolithiasis has been reported in 5.2–10.4% of young patients with cystic fibrosis (105, 196, 197) and nephrocalcinosis has been observed in another 6.3% (105). Katz found microscopic nephrocalcinosis at autopsy in 35/38 (92%) of patients with cystic fibrosis, including in six patients who were less than a year of age at the time of death (198). Hyperoxaluria appears to be the primary factor (105, 196, 197, 199) although hypocitric aciduria (105, 197) and hyperuricosuria (105) have also been observed. Urine calcium has been variably reported as reduced (199), normal (105), or increased (105, 197). Crystalluria is commonly seen (196, 197). Pancreatic insufficiency with fat malabsorption and resulting enteric hyperoxaluria are suggested by the clinical setting although no correlation could be established between the degree of fat malabsorption and the urine oxalate excretion in two studies (197, 199). Deficiency of enteric Oxalobacter formigenes due to repeated courses of antibiotics has also been suggested as a risk factor for hyperoxaluria in this patient population (107). Pancreatic enzyme replacement and high protein diets may contribute to hyperuricosuria. Damage to renal tubules by antibiotic treatment has been implicated by some authors as a contributing cause with hypercalciuria following a renal phosphate leak (197).

Premature infants have an increased incidence of nephrocalcinosis and nephrolithiasis when compared with healthy term infants (*Fig. 58-6*). In three prospective studies of infants born at less than 1500 gm or less than 32 weeks gestation, renal calcifications occurred in 64, 16, and 28% of infants (200–202). The risk of renal calcifications appears greatest in smaller infants, those receiving furosemide, postnatal corticosteroids, a longer duration of mechanical ventilation and parenteral nutrition, white race, and in those with a family history of urolithiasis (202). Metabolic disturbances including hypercalciuria (200), hypophosphatemia and hypercalcemia (both of which can induce hypercalciuria) (203), and hyperoxaluria related to parenteral nutrition (204) have been implicated. Abnormalities of urine composition related to renal tubule immaturity may play a role. Nephrocalcinosis resolves within a few years time in approximately half of the patients and new stone formation appears to abate in the majority of patients. However, longer term studies performed at 4–12 years of age in very low birth weight children who had a history of renal calcifications demonstrated hypercalciuria, hypocitric aciduria, and reduced ammonium excretion in

Figure 58-6

Nephrocalcinosis and a shadowing stone in the pelvis of the kidney of a 3-month-old infant born prematurely.

response to furosemide when compared with a control group of children born at term (205). At the time of study 18% of the children still had renal cortical hyperechogenicity and 9% had urolithiasis. Whether the renal tubule abnormalities are the long-term result of renal tubular immaturity at birth, secondary to renal damage from nephrocalcinosis, or due to other factors remains to be established.

Pharmacologic Agents Implicated in Urolithiasis

Urolithiasis can result from use of a variety of medications. Renal excretion of the medication or a metabolite may exceed its solubility in the urine, or stones may form due to metabolic effects induced by the medication. The protease inhibitor indinavir, used widely in the treatment of human immunodeficiency virus (HIV), can cause ureteral obstruction and colic, observed in 2–28% of patients treated with this agent (206–208). Indinavir is filtered by the kidney, poorly soluble in the urine at a pH of greater than 5, and can precipitate as radiolucent stones. Distinctive birefringent crystals with plate and starburst structures are observed in 20–25% of patients receiving this antiretroviral agent (*Fig. 58-4*) (207, 209). The indinavir crystals or small stones may also act as a nidus for calcium oxalate or calcium phosphate, and thus can also be associated with partially radiopaque stones of mixed composition. There are a number of such reports in children (206, 210, 211). Due to the radiolucent nature of pure indinavir stones, they are not visible on noncontrast renal tomography and may be difficult to distinguish from soft tissue on CT scanning (210). Ultrasonography, IVP, or contrast-enhanced computerized tomography may be needed to demonstrate indinavir stones and associated ureteral obstruction. Dissolution of stone material may be observed with discontinuation of indinavir, increased fluid intake, and urine acidification (211). Other medications that can precipitate to form urinary tract stones are ceftriaxone (212, 213) sulfonamides, ampicillin, amoxacillin, triamterene, guafenesin (214), phenazopyridine, and oxypurinol (215). Urinary tract stones are rarely observed with these agents, however.

Carbonic anhydrase inhibitors, used for management of epilepsy and glaucoma among other uses, result in alkaline urine, reduced urine citrate, and hypercalciuria (215, 216). Agents of this class, including zonisamide, topiramate, and dorzolamide have been reported to be associated with calcium phosphate and calcium oxalate urolithiasis in children and adolescents (217–219). Commonly used agents such as calcium supplements, vitamin D, and its analogues can be associated with hypercalciuria and can predispose to stone formation. Cyclosporine A has been associated with hypercalciuria. Aminophylline results in hypercalciuria, alkaline urine, and phosphaturia countered, in part, by its diuretic effects (220). Lithium can induce hypercalcemia and hypercalciuria. Orlistat, a lipase inhibitor, can lead to enteric hyperoxaluria and has been associated with oxalate nephropathy (221).

Dietary Considerations

Diets low in animal protein, but high in cereals contribute to formation of endemic bladder stones in children (27, 222). High intake of animal protein predisposes to higher urine uric acid, calcium, and oxalate excretion and reduced urinary citrate and pH, all of which favor calcium oxalate stone formation (6). Frassetto noted that contemporary net acid-producing diets (rich in animal protein and deficient in plant protein and potassium alkali salts) produce a low-grade systemic acidosis in otherwise healthy adults (223). He and others have postulated that the ensuing metabolic changes may, in part, explain the increasing prevalence of urolithiasis in industrialized countries in recent decades (6, 223). Large dietary intake of sodium or calcium may induce hypercalciuria. High dietary oxalate, particularly if diet calcium is low, can result in hyperoxaluria. Fructose intake has been identified as a risk factor for stone disease, based on large epidemiological studies (224). The cause is unclear though fructose intake can lead to hyperuricosuria, insulin resistance, low urine pH, and can be associated with hyperoxaluria (225). Non-fructose carbohydrates do not appear to be a risk factor for stone disease (224). Contemporary weight loss diets low in carbohydrates but high in animal protein, such as the Atkins diet, lead to higher calcium, reduced citrate, and low pH in the urine, increasing the likelihood of urolithiasis (226).

Ketogenic diets used for the management of seizures are associated with nephrolithiasis (147, 227, 228). Stone formation has been noted as early as 1 month after initiation of the diet, but with a median occurrence of 2 years in a 6 year study (147, 227–229). The risk of stones in children may be as high as 25% after 6 years on a ketogenic diet (229). Stone composition includes uric acid, calcium phosphate, mixed calcium and uric acid, and ammonium urate (147, 227) Urolithiasis appears to be related to ensuing hypercalciuria, hypocitric aciduria, low urine pH, and reduced oral fluid intake (147, 227, 230).

Urine uric acid excretion is normal in most, but not all patients (147, 227), such that uric acid stone formation appears related primarily to the low volume and acidic pH of the urine. Based on early clinical experience, treatment with potassium citrate may reduce the formation of stones (229).

Infection as a Lithogenic Factor

Infection of the urinary tract with bacteria producing the enzyme urease leads to hydrolysis of urea with resulting production of ammonium and bicarbonate ions in the urine. In the presence of the increased pH, dissociation of phosphate occurs, with supersaturation of the urine for magnesium ammonium phosphate (struvite) and calcium phosphate apatites, including carbonate apatite (231). Precipitation of stone material follows. A variety of bacterial species produce urease, including Proteus, Staphylococcus, Klebsiella, Providentia, Pseudomonas, Enterobacter, Ureaplasma urealyticum, Corynebacterium urealyticum, and some anaerobes. Struvite tends to form staghorn calculi that can grow rapidly and are challenging to treat. It is difficult to eradicate infection while stone material remains, as antibiotics do not penetrate well within the interstices of the stone where bacteria reside. Just under half of the patients with infected staghorn calculi can be rendered stone free by ESWL (232), such that combined procedures including percutaneous nephrolithotomy are often needed (233). Retained stone fragments can serve as a nidus for early recurrence.

Xanthogranulomatous pyelonephritis is a rare but serious infectious process leading to nonfunction of the infected kidney. Obstruction caused by renal calculi has been found in 68% of affected children (234), with approximately half of such calculi being of the staghorn variety (234). Another author reported nephrolithiasis and/or nephrocalcinosis in 71% of such children (235). Proteus, Escherichia coli, Klebsiella, Pseudomonas, and Enterobacter bacteria (several species of which produce urease) are most often responsible (236). In xanthogranulomatous pyelonephritis, renal stones, obstruction and infection exacerbate each other. Nephrectomy is required in most circumstances (234–236).

Encrusted pyelitis is another unusual manifestation of infection and mineralization (237). Infection of the kidney with Corynebacterium urealyticum, a urea splitting organism, leads to encrustation of the wall of the renal pelvis with struvite and associated apatite crystals and proteins (238). Infection with this slow growing aerobic organism is usually acquired after urologic manipulations of the urinary tract and is most often observed in immune suppressed patients. Most reports in the literature are in renal allograft recipients (237, 239, 240). Obstructive uropathy and loss of renal function are common (239, 240). The encrustations are tightly adherent to the mucosa and are difficult to dislodge. In addition to prolonged antibiotic therapy, placement of percutaneous nephrostomy tubes for irrigation with acidic Thomas solution (237) or use of acetohydroxamic acid (237, 240, 241) have been advocated.

Although infection with urease producing organisms can itself produce urolithiasis, often the infection exacerbates underlying metabolic factors. With careful evaluation, 20–61% of patients with infection stones can be also be demonstrated to have metabolic factors predisposing to stone formation (12, 242). Stasis due to urinary tract abnormalities also predisposes to infection, further demonstrating the interaction among infection, metabolic factors, and structural abnormalities of the urinary tract in the genesis of calculi.

Structural Abnormalities of the Urinary Tract

Stasis of urine often accompanies structural abnormalities of the urinary tract, whether congenital or acquired. By compromising the normal continuous flow of urine from the upper urinary tract or interfering with regular and complete emptying of urine from the bladder, stasis promotes crystal retention and stone formation as well as infection. A wide range of structural abnormalities has been associated with urolithiasis including medullary sponge kidney (185), autosomal dominant polycystic kidney disease, calyceal diverticuli (243), ureteropelvic junction obstruction (156, 244), horseshoe kidney (245), ureteroceles, primary megaureter (24), posterior urethral valves (24), and the bladder extrophy-epispadius complex (246). Medullary sponge kidney is frequently associated with recurrent calcium urolithiasis. In medullary sponge kidney and autosomal dominant polycystic kidney disease, tubular ectasia and cyst formation, respectively, are felt to contribute to stasis of the urine that exacerbates metabolic abnormalities. Patients with myelodysplasia or spinal cord injury often have impaired bladder emptying, recurrent urinary tract infections, and hypercalciuria from relative immobilization. Partial obstruction from any cause can result in defects in renal acidification with accompanying hypocitric aciduria. Enterocystoplasty and urinary diversion employing intestinal mucosa are particularly prone to local formation of stones, with 16–50% of

patients with enterocystoplasty reported to form bladder stones (247–249). The difficulty in eradicating bacteria from the enteral mucosa, stasis, an alkaline urine pH due to infection or to exchange of chloride for bicarbonate across the mucosa, and the presence of mucous in the bladder all favor stone formation in this setting (248). The length and location of intestine resected may also influence the metabolic stone environment if either chronic diarrhea or malabsorption ensues. Foreign bodies such as sutures or staples, or indwelling stents also can act as a nidus for stone formation.

However, with the exception of enterocystoplasty, the overall incidence of stones in children with structurally anomalous, obstructed, or infected urinary tracts is low, on the order of 1–5% (250). This suggests that while these factors are permissive, children who form stones may also have underlying metabolic abnormalities. Hypercalciuria, hyperoxaluria, or hypocitric aciduria have been identified in 66–80% of patients with structural abnormalities of the kidneys or ureters who also had urolithiasis and underwent metabolic evaluation (244, 251). Tekin and colleagues demonstrated a similar degree of hypocitric aciduria and hyperoxaluria in patients with ureteropelvic junction obstruction and urolithiasis as in those with calcium stone formation but without urinary tract abnormalities. Both were significantly different from the control group of normal children (156). The importance of metabolic abnormalities in patients with stones and urinary tract abnormalities is further suggested by long term follow-up of a group of pediatric patients with ureteropelvic junction obstruction and renal calculi. Recurrent urolithiasis developed in 68% of the patients despite successful UPJ repair. Further, 10/19 (53%) of recurrent stones formed in the contralateral, uninvolved kidney (244). Accordingly, complete metabolic evaluation is just as important in children with structural abnormalities of the urinary tract or infected stones as it is in those without.

Long-term Management of the Stone Patient

Urolithiasis in children and adolescents, like that in adults, frequently recurs. In one study of 221 children followed for a mean of 59 months (median 36 months), 67 % developed two or more stones during initial evaluation and follow-up (12). Other authors have reported recurrence rates of 20–40 % with variable follow-up periods (15). Recurrence rates are higher in children with demonstrable metabolic abnormalities (15). Accordingly, long-term follow-up with periodic reassessments is indicated. Evaluation of metabolic stone forming activity, as determined by growth in size of existing stones or formation of new stones over time, is important in monitoring the effectiveness of treatment. The frequency of renal imaging required will depend upon the type and number of stones and the severity of the metabolic abnormalities detected. In most circumstances and in the absence of symptoms or infection, once yearly or every other year imaging is sufficient. Patients with significant metabolic problems such as primary hyperoxaluria, cystinuria, marked hypercalciuria, and those with infected stones (which can develop and grow quickly) may require more frequent evaluations. Acute symptoms at any time should prompt reevaluation.

Ultrasonography has the advantage of visualization of radiolucent as well as radiopaque stones, detection of hydronephrosis, and the absence of radiation exposure and is preferred for most routine follow-up assessments. However, lack of sensitivity for small stones, difficulty in comparing size of individual stones over time, lower sensitivity for visualization of ureteral stones, and the possibility of obstruction in the absence of hydronephrosis will, at times, dictate other imaging modalities.

If existing stones increase in size, or new stone formation occurs despite treatment, a more intensive regimen should be implemented. In patients with active stone formation, additional studies can be helpful in assessing the degree of metabolic stone formation and providing guidance as to the most effective therapies. These may include determination of crystalluria by phase contrast microscopy, supersaturation of the urine (252), measurement of urinary inhibitor activity, or measurement of enteral absorption of oxalate, among others. Though tests intended to differentiate between absorptive and renal leak hypercalciuria have limited utility in pediatric stone patients, they can be helpful in selected circumstances.

In children of all ages, if compliance with recommendations can be secured, response to treatment is typically excellent, with reduced frequency or elimination of active stone formation. However, many metabolic abnormalities, such as idiopathic hypercalciuria, are life long. Subtle degrees of damage to the renal tubule are suggested by studies showing increased urinary excretion of renal N-acetyl-beta-glucosaminidase in children with hypercalciuria (253) and in children with urolithiasis (254), a deficiency of distal acidification in children with hypercalciuria and urolithiasis that is not seen in children with hypercalciuria alone (255), and families in which hypercalciuria appears to be the primary event, with distal RTA developing over the years as an apparent complication of hypercalciuria (164, 256). Others have argued that the

renal tubule acidification defect is primary and that the hypercalciuria and urolithiasis occurs secondarily (257). Jaeger and colleagues studied renal tubular function in patients with urolithiasis related to primary hyperparathyroidism, medullary sponge kidneys, hyperuricemia, cystinuria, struvite stone disease, idiopathic hypercalciuria, and normocalciuric idiopathic urolithiasis (58). They found that a significant number of stone formers have dysfunction of the proximal renal tubule, that the abnormalities were found in patients of all of the diagnostic groups, and that the occurrence was related to the presence of stones in the collecting system at the time of study (58). The authors concluded that tubulopathy in nephrolithiasis is the consequence, rather than the cause, of stone disease.

The risk of renal insufficiency has been estimated at 1.7% in idiopathic calcium oxalate urolithiasis (258). In a group of 40 patients with a mean duration of cystinuric stone disease of 26 years, renal insufficiency was found in 30% of patients, though none had reached end stage renal disease (259, 260). In cystinuria patients, stone-preventive treatment appeared effective in preserving renal function (259, 261). Infection staghorn stones eventually are associated with end stage renal disease in 20–30% of adult patients with unilateral involvement and a higher percentage of those with bilateral stones (258). Several forms of more severe urolithiasis, such as primary hyperoxaluria, Dent's disease, and 2,8 dihydroxy adeninuria are frequently associated with renal insufficiency or end stage renal disease.

For these reasons, and despite the excellent response to treatment noted in most children with urolithiasis, long-term nephrologic care is indicated particularly for those with more complex forms of renal stone disease.

59 Pediatric Renal Tumors

Elizabeth A. Mullen · Christopher Weldon · Jordan A. Kreidberg

Overview

Renal cancers in pediatric patients are relatively common, with an incidence of almost 8 per 1,000,000 representing approximately 7% of all childhood cancers (1). The vast majority (95%) of these are Wilms Tumors (WT) but several other histologic types of renal tumors also occur in children (*Table 59-1*). The incidence of each type of renal tumor is tightly correlated to the age of the patient. WT, most common in children under age five, is very rarely seen in adolescents and young adults. An adolescent with a renal tumor is more likely to have renal cell carcinoma. Rhabdoid tumor of the kidney (RTK) and congenital mesoblastic nephroma (CMN) are seen almost exclusively in infants less than a year, and clear cell sarcoma almost always occurs in children less than four years old.

This chapter will touch on several pediatric renal tumors, but, given the overwhelming prevalence, will focus largely on WTs. The principles of the diagnostic evaluation, surgical management, and the use of appropriate chemotherapy and radiotherapy used in WT can be generalized to some of the other less common renal tumors.

In 1899, Max Wilms made a critical contribution to the field of pediatric renal tumors, describing seven children suffering from renal "mixed tumors" – later identified as nephroblastoma, or Wilms Tumor (*Fig. 59-1*) (2). He provided a meticulous description of the triphasic morphology of this tumor, comprised of three defining components: epithelium, blastema, and stroma (*Fig. 59-1*). It is now recognized that WTs can have great histologic diversity. Cell types seen in normal developing kidney can be present, as well as diverse elements such as adipose tissue, cartilage, skeletal muscle, and neuroglial tissue. These elements appear to arise from stromal differentiation. Epithelial differentiation can be seen with the presence of renal tubules, glomeruli, or comma and S-bodies. Tumors can be triphasic, with all three components; monophasic, with epithelial differentiation only; or biphasic, containing exclusively blastemal and stromal cells. Max Wilms also offered the important insight that all of these tumor components developed from a common undifferentiated germ cell. Along with the observation that the morphology of WT correlates with phases of normal renal development, this has helped build an understanding into the link between organogenesis and tumorogenesis in the kidney (3). Study of this relationship has fostered understanding of the correlation between WT and a variety of renal abnormalities. It has also helped elucidate the connection between the persistence of embryonic renal tissue (termed nephrogenic rests) and risk for the development of WT. The expanding knowledge of the genetics of WT has added both answers and new questions into this link.

Genetics of Wilms Tumor and Associated Syndromes

Approximately 90% of WTs are unilateral and considered to be sporadic. The most often present in children 5 years old or younger, without a male or female preference (4, 5). A smaller portion, ranging in studies from 5 to 5% of cases, is caused by sporadic mutations in the Wilms tumor-1 tumor suppressor gene (*WT1*). The low percentage of WTs in which mutations of the *WT1* gene are found suggests that other tumor suppressor genes may be involved in the pathogenesis of WTs. Recently, one such additional tumor suppressor gene for WT, *WTX*, located on the X chromosome, has been identified (6). Much less commonly, in around 1–2 percent of cases, WTs are caused by inherited mutations in genes that in some cases have yet to be identified (7). Finally, there is recent evidence that mutations in *CTNNB1* (encoding β-catenin), a gene important in several major signal transduction pathways and in cell-cell adhesion, may have an important role in WTs (8–11). A summary of molecular pathways leading to various types of WTs is shown in *Fig. 59-2*.

The "Two Hit" Hypothesis

WTs can either be unilateral or bilateral. The median age of onset of bilateral tumors is earlier, at age of 32 months compared with 44 months for unilateral disease (4). The earlier onset of bilateral WTs is similar to what is observed for retinoblastoma, another childhood tumor that can present either unilaterally or bilaterally. These observations led Knudsen and Strong to propose a "two-hit"

Table 59-1

Pediatric renal tumors

Nephroblastomic tumors	Nephroblastoma (Wilms Tumor)
	• Favorable histology
	• Anaplasia (diffuse, focal)
	Nephrogenic rests and Nephroblastomatosis
	Cystic nephroma and Cystic partially differentiated Nephroblastoma
	Metanephic tumors
	Metanephic adenoma
	• Metanephic adenofibroma
	• Metanephic stromal tumor
	• Favorable histology
Mesoblastic nephroma	Cellular, classic, mixed
Clear cell sarcoma	
Rhabdoid tumor	
Renal epithelioid Tumors of childhood	Papillary renal cell carcinoma
	Renal medullary carcinoma
	Renal tumors associated with Xp11.2 translocations
	Oncocytic renal neoplasms following neuroblastoma
Angiolipoma	
Ossifying renal tumor of infancy	

A variety of histologic types of renal tumors occur in children, the overwhelming majority however (95%) are Wilms Tumors

hypothesis for these tumors (12, 13). This model suggests that genetic predisposition to a tumor is conferred by an inherited or de novo germline mutation in one allele of a tumor suppressor gene, such that only one additional "second hit" during somatic development is sufficient to cause somatic homozygosity by inactivating the second allele. In contrast, individuals without this genetic predisposition would require two distinct genetic events, resulting in the deletion or inactivation of both copies of a tumor suppressor gene, and would therefore present at a later age (14).

Loss of Heterozygosity in Wilms Tumors

Loss of heterozygosity (LOH) is the hallmark of a tumor suppressor gene, and is the molecular correlate of the "second hit" discussed in the preceding section. For a tumor to result from loss of a tumor suppressor gene (assuming it is encoded on an autosomal chromosome), both copies of the gene must be lost in a cell that initiates the tumor. Thus, a first event, or "first hit" must be the loss of one allele of a tumor suppressor gene. This loss may be inherited in the germ line or may occur in somatic tissue. At a molecular level, LOH is an event in which an individual loses function of the remaining second allele. This is referred to as LOH because the cells involved are no longer heterozygous for the tumor suppressor gene, but rather, harbor mutations in both copies of the gene. LOH may occur through point mutation or deletion of the second allele, either through a local event, or loss

Figure 59-1

(a) and (b) (Gross and microscopic views) favorable histology. Gross pathologic specimen of favorable histology Wilms Tumor. Typically, these tumors are described as friable, pink or variegated in color, often with cystic changes, areas of hemorrhage and necrosis. Classic triphasic histology of Wilms Tumor, containing blastemal, stromal and epithelial elements.

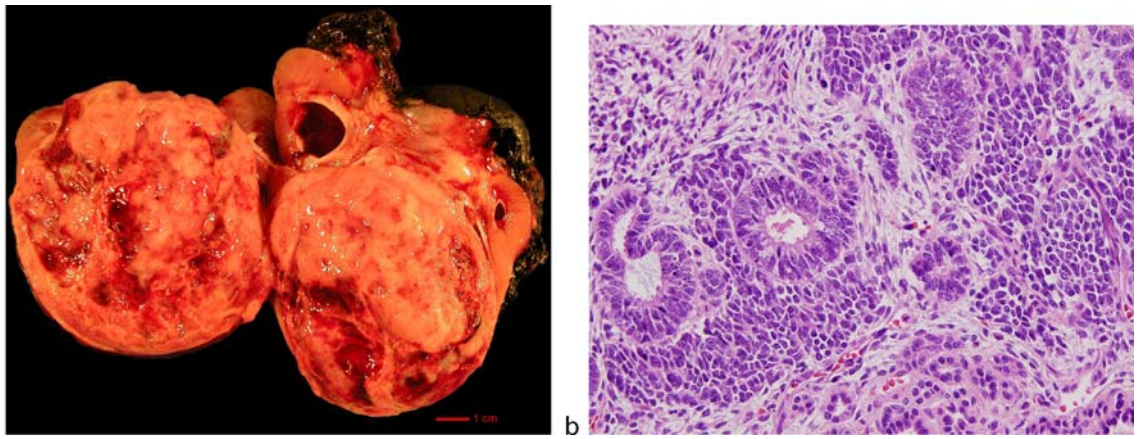

Figure 59-2

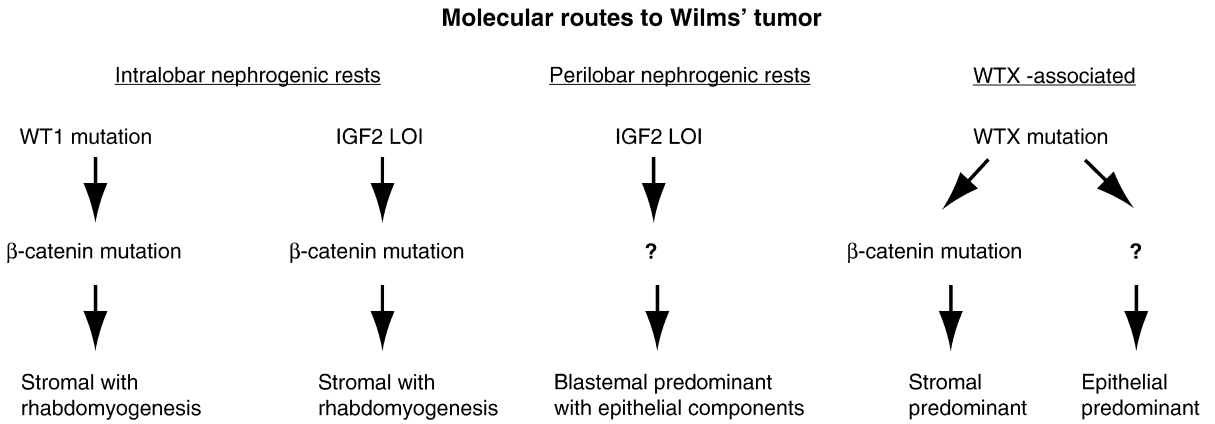
A summary of the presently identified molecular pathways leading to various types of Wilms' Tumors. The references are cited in the text. It is not known yet whether WTX mutations will be found to be mainly associated with perilobar or intralobar nephrogenic rests. Since the presently identified mutations and epigenetic changes are not found in all tumors, this figure must be considered incomplete. Additionally, it is likely that additional mutations and chromosomal aberrations are involved in tumorigenesis, that remain to be identified. Additionally, exceptions to these generalizations are described in the literature. Abbreviation: LOI, loss of imprinting.



of the entire chromosome or a gene conversion event that copies a mutation from the originally mutated allele to the second copy.

LOH at chromosome 11 occurs in 30–40% of WTs, encompassing allelic loss of both the *WT1* locus at chromosome 11p13 and the locus telomeric to it at 11p15 (15–18). Other chromosomes at which LOH is evident in WTs are chromosome 16, for which LOH is observed in 20% of sporadic WTs (19), and at chromosome 1p with a frequency of 11% (20, 21). Notably, patients with tumor-specific LOH at these locations have significantly worse outcomes (22), indicating that additional tumor suppressor genes may exist on these chromosomes. A further 5% of cases exhibit LOH at 4p, 7p, 8p, and 17, 17q and 18q (22, 23).

Loss of Imprinting in WTs

WTs are often associated with loss of genomic imprinting (LOI). Imprinting refers to situation in which only one inherited allele, either the maternal or the paternal, is transcribed. LOI is common to several embryonal cancers and many other tumor types (24). The 11p15 locus, containing the *IGF2* and *H19* genes is a well-known site of genomic imprinting. LOI at 11p15 is observed in 30% of sporadic WTs (25–27), and involves activation of the normally silent maternal allele of *Insulin-like growth factor 2* (*IGF2*) resulting in biallelic *IGF2* expression (26), silencing of the normally active maternal allele of *H19* (28, 29), and hypermethylation of the differentially methylated region upstream of the maternal copy of *H19* (30). It is likely that increased expression of *IGF2* associated with LOI at 11p15 may have a role in the pathogenesis of some WTs (31–34). 11p15 may also harbor as yet unproven WT suppressor genes (35, 36).

Known Tumor Suppressor Genes and Oncogenes Involved in WTs

To date, *WT1* (16, 37, 38) and *WTX* (6) are the two identified WT suppressor genes. Loss-of-function mutations in *WT1* account for 10–15% cases of sporadic WT (39). *WT1* mutations include both nonsense and missense changes, as well as the generation of aberrant splice forms, and are distributed throughout the coding sequence (40–42). These same tumors may also exhibit constitutive activation of β-catenin, the central effector of the *Wnt* signaling axis (3, 11, 43), implicating another signaling pathway critical for normal kidney development in WTigenesis (16), and suggesting potential genetic cross-talk between the *WT1* and *Wnt* signaling axes. However, most sporadic tumors express wild-type *WT1,* often at high levels (44), suggesting that downstream *WT1* signaling is affected in these tumors, or that genetic disruption of other cellular pathways is responsible for tumorigenesis.

WTX is a recently identified tumor suppressor gene involved in Wilms Tumors (6). *WTX* is encoded on the X chromosome, such that males only have a single copy, but females have two, though only one allele should be expressed due to X-inactivation. X-inactivation complicates the understanding of the significance of mutations in *WTX*, since some mutations have been found in the unexpressed allele and are therefore of questionable significance for the tumor (45). *WTX* was originally suggested to be mutated in as many as a third of WTs but more recent studies suggest a frequency closer to 15% (6, 45, 46).

Syndromes Associated with WTs

Ten to fifteen percent of WTs occur in children with recognized malformations, including hemihypertrophy, cryptorchidism, hypospadias, or in association with a recognizable genetic syndrome (7).

WAGR Syndrome (WT, Aniridia, Genitourinary Malformation, Mental Retardation Syndrome (47–49))

WAGR syndrome is caused by a microdeletion at 11p13 that deletes both *WT1* and *Pax6* (47, 49). WAGR is associated with aniridia in all cases resulting from hemizygosity for *Pax6* (50–52), but is variably associated with WT (50% risk of WT) (53) and genitourinary malformations due to hemizygosity for *WT1*. WAGR is also variably associated with mental retardation and congenital heart disease; however the gene(s) on 11p13 responsible for these defects have not been identified (54).

Denys-Drash Syndrome (DDS)

DDS includes the triad of WT (90% risk of WT development) (55, 56), genitourinary malformations and nephropathy (mesangial sclerosis), but various combinations of theses features have been reported (57–59). DDS is caused by intragenic *WT1* point mutations that either eliminate or alter the structure of the zinc finger region. The most common mutation is an arginine-to-tryptophan transition in exon 9 (Arg 394), or other missense alterations in the zinc-finger domains encoded by exons 8 and 9 (3, 16). The increased severity of kidney disease associated with DDS, as compared with WAGR, raises the possibility of a dominant-negative effect that is mediated by dimerization of mutant and wild-type proteins through their N terminal domains (60, 61).

Frasier syndrome bears similarity to DDS, and is characterized by gonadal dysgenesis, often resulting in XY sex reversal in males (3), progressive glomerular nephropathy (focal segmental glomerulosclerosis) (62), gonadoblastoma. Interestingly Frasier Syndrome (FS) (63, 64) much less commonly (less than 5%) includes WTs among its features. FS is caused by mutations in intron 9 of *WT1* that affect splicing and prevent expression of the +KTS isoforms of WT1 (discussed below) (63, 64).

*B*eckwith-*W*iedemann *S*yndrome (BWS) is the most common WT-associated condition, affecting 1 in 13, 000 children, and is probably related to a large degree to LOI at 11p15 (65–67), resulting in hyper-expression of *IGF2*. BWS is characterized by prenatal overgrowth and increased incidence of embryonal tumors of liver (hepatoblastoma), muscle (rhabdomyosarcoma), and kidney. This syndrome carries a 10% risk of WT (68). While the genetics of WT formation in BWS is not completely understood, at least 20% of BWS patients exhibit paternal uniparental disomy for 11p15 that contains the *IGF2* and *H19* imprinting locus strongly associated with sporadic WT (65), and these children have a high risk (64%) of developing embryonal tumors (67). In addition, familial BWS is linked to chromosome 11p15 (69). A third, unidentified tumor suppressor gene on 11p15 has been linked to rhabodomyosarcoma (70), suggesting that at least three genes on 11p15 may predispose to growth abnormalities and WT as well as other embryonal tumors.

Other genetic syndromes associated with increased incidence of WT (71, 72), include Simpson-Golabi-Behmel Syndrome (linked to Xp26) (73–76), Perlman Syndrome (77–80), Sotos Syndrome (linked to 5q35) (81, 82), and Bloom's Syndrome (linked to 15q26) (83, 84).

Familial Wilms Tumor

True familial WT is extremely rare, accounting for only 1–2% of all cases (13), suggesting that de novo germline mutations, rather than familial transmission of a mutant allele underlie the genetic predisposition (3). In addition, reduced fertility may be associated with germline mutations in genes that regulate urogenital development (68). The low number of familial cases may reflect the historic lethality of this cancer in before individuals with tumors reached reproductive age. With the advent of effective therapy in the past few decades, such that most individuals with WTs survive to adulthood, it will be important to observe in the future whether familial cases become

more common in the population. Two familial WT genes have been mapped – *FWT1* (*Familial WT 1 locus;* also known as *WT4*) at 17q12–21 (85) and *FWT2* at 19q13.4 (86), but neither gene has been identified. In addition, familial cases unlinked to any previously identified loci have been reported, indicating that other familial WT genes may exist (87).

The *WT1* Gene, mRNAs and Proteins

Gene Identification

A major step towards the discovery of the *WT1* locus was the identification of cytogenetically visible, germline interstitial deletions in 11p13 as the locus for WAGR Syndrome (48). Together with the discovery that some individuals with sporadic, non-syndromic WT also showed LOH in 11p13 (88, 89), a minimal 30 kb region on 11p13 was identified as an critical locus in the development of WT, and was given the designation of the "*WT1*" locus (90, 91). Two groups independently identified the *WT1* gene by mapping the smallest region of overlap among chromosomal deletions in germline and sporadic tumor specimens (92, 93), and *WT1* was shown to be mutated in several patients with sporadic WT (94).

Structure of WT1

The *WT1* gene is comprised of 10 exons, and encodes a 55-kDa zinc-finger transcription factor with both DNA- and RNA-binding activity (*Fig. 59-1*) (95). Consistent with a probable role as a transcription factor, the carboxyl (C) terminus of WT1 contains four Krüppel-type (Cys_2His_2) zinc-finger domains and two nuclear localization domains that mediate DNA binding. The zinc-finger region and its alternative KTS splice site are critical for WT1 function, as mutations in the zinc-finger domain are associated with WTigenesis as well as the severe urogenital abnormalities observed in DDS (42). The amino (N) terminus of *WT1* contains a glutamine/proline-rich transactivation domain, a dimerization domain (96, 97) and putative RNA-binding domain (92, 98).

Multiple Isoforms of the WT1 mRNA

The *WT1* transcript is alternatively spliced at two major sites, that result in the expression of four major *WT1* transcripts (99), which are expressed at relatively constant ratios in all tissues throughout development and across species (40, 100). The first alternative splice inserts exon 5, this exon is unique to the *WT1* gene of placental mammals. Exon 5 encodes 17 amino acids (99). However, the biological function of the WT1 isoform containing exon 5 remains obscure as mice lacking this exon develop normally and are fertile (101). Nevertheless, *WT1(+exon5)* is often over-expressed in WT and other malignancies (102), and in vitro studies have suggested a role in the regulation of cell division and cell survival (103).

An alternative splice donor site at the end of exon 9 inserts the amino acids lysine, threonine and serine (KTS) at the end of the third zinc fingers, serving to alter the DNA-binding affinity of WT1 (98, 100). The +KTS/−KTS ratio of WT1 protein is tightly regulated and highly conserved from zebrafish to humans (99), and the relative expression levels of the +KTS versus –KTS isoforms is critical for normal urogenital (104) development. Additionally, alternative translation initiation sites both upstream and downstream of the major translational start site (105, 106), along with alternative pre-mRNA splicing (100) and RNA editing (107) can theoretically result in the generation of 24 *WT1* isoforms.

WT1(–KTS) As a Transcriptional Regulator

An emerging body of evidence suggests that the +KTS and –KTS serve distinct functions in the nucleus, with (–KTS) isoforms playing a role in transcriptional regulation, and (+KTS) proteins implicated in posttranscriptional modification of target genes via RNA editing (104, 108). WT1(–KTS) exhibits characteristic properties of a DNA-binding transcription factor (109) and the best predictor of endogenous gene transactivation is a high-affinity 10-bp EGR1-like (WTE) motif (5′GCGTGGGAGT3′) identified from genomic DNA (3, 110).

Early studies demonstrating over-expression of *IGF2* and *Platelet-Derived Growth Factor (PDGF)* in WTs, led to the hypothesis that WT1 functions as a transcriptional repressor of growth-promoting genes (111–113). Subsequently, WT1 was shown to bind and repress promoters of numerous other growth-promoting genes expressed in the kidney including *Pax2* (114), *c-myc* (115), *N-myc* (116) (111), *B-Cell CLL/lymphoma 2 (Bcl-2)* (117, 118), *EGR* (119) *epidermal growth factor receptor (EGFR)* (96) and *colony stimulating factor-1 (CSF-1)* (120, 121), as well as *WT1* itself (122).

Several genes implicated in the control of kidney development appear to be upregulated either directly or indirectly by WT1 in vivo, including *Sprouty1 (Spry1)*

(119, 123) *Amphiregulin (AREG)* (124, 125) and the podocyte-specific genes *Nephrin (NRHS1)* (126–131) and *Podocalyxin (PODXL)* (132–134). Consistent with its role as a tumor suppressor, WT1 activates *p21* (135), leading to G1 cell cycle arrest. WT1 has also been shown to activate the anti-apoptotic gene *Bcl2* (117, 118, 136), previously shown to be repressed by WT1(115). Many other genes have also been suggested to be regulatory targets of WT1, but their possible roles in urogenital development or tumorigenesis is less clear (126, 137, 138).

WT1 as a Regulator of RNA Processing

The KTS insertion disrupts the linker region between zinc fingers 3 and 4, thereby decreasing the DNA binding affinity of WT1 to known target sequences (109). Several results are consistent with the possibility that WT1 (+KTS) functions to regulate RNA processing. Whereas WT1(–KTS) isoforms exhibit diffuse nuclear expression typical of transcription factors, punctate or "speckled" sub-nuclear WT1(+KTS) protein is detected within RNA spliceosome domains (139) and colocalizes with that of RNA splicing factors such as U2AF65 (140) and WTAP (141) as well as small nuclear ribonucleoproteins (snRNPs) (142, 143). An interaction of WT1(+KTS) with *Igf2* mRNA has been demonstrated in vitro (139), and WT1(+KTS) interacts with RNA-export machinery to stimulate translation of unspliced RNA (108).

Developmental Expression Pattern of WT1

WT1 mRNA and protein expression is first detected in the intermediate mesoderm lateral to the coelomic cavity, and is crucial for development of both the kidneys and gonads (144). As WTs derive from the condensing nephrogenic mesenchyme, it was expected that a WT suppressor gene would be expressed in the condensed mesenchyme and not in the reciprocally-induced ureteric bud (68). Indeed, *WT1* expression in the developing kidney is limited to the metanephric mesenchyme and its derivatives. *WT1* is expressed at low levels in uninduced metanephric mesenchyme and expression increases dramatically in the condensed nephrogenic mesenchyme as induction proceeds. During epithelial reorganization, *WT1* expression becomes restricted to the posterior portion of induced nephrogenic structures (145), the region that will form the epithelial podocyte population of the glomerulus by the S-shape stage of nephron development (114). Once kidney development is completed, *WT1* expression declines, except in podocytes, which express *WT1* throughout adulthood (146).

WT1 in Wilms Tumors

Since most WTs do not seem to arise through inactivation of the *WT1* gene, it is equally important to consider the role of *WT1* in these tumors, as well as the molecular consequences of the loss of *WT1*. This consideration is complicated by the many genes identified as putative regulatory targets of the WT1 gene (discussed above), such that there is no single potential target gene, the over or under-expression of which, could likely account for tumorigenesis Indeed, the role of WT1 in WT is likely to be complex and relate to the abnormal transcriptional and post-transcriptional regulation of many genes. Emerging evidence, that finds *CTNNB1* and *WT1* mutations to often occur in the same tumor, and WT1 mutation to be common in stromal or mesenchymal-type tumors, may provide hints to the role of *WT1* in these tumors (9, 11, 147). *WT1* mutations are also associated with a myogenic phenotype in WTs (148–150). In examining mutations within intralobar nephrogenic rests, that are considered to be "precursor lesions" for WTs, it was found that *WT1* mutations were present, but mutations in *CTNNB1* were not, suggesting that mutation of *WT1* is the earlier, *CTNNB1* the later event (10). In a related study by the same authors, LOI for *IGF2* was examined, with regard to its relationship with *WT1* and *CTNNB1* (151). Whereas *WT1* mutations are more often associated with intralobar nephrogenic rests (152–155), tumors associated with loss of imprinting of *IGF2* often arise from perilobar nephrogenic rests (156, 157). Two distinct morphologies were observed among *IGF2* LOI tumors, a blastemal morphology associated with perilobar rests and a myogenic phenotype associated with intralobar rests (151). Several of the intralobar tumors also had *CTNNB1* mutations, despite not having *WT1* mutations, demonstrating that *CTNNB1* mutations may be a hallmark of intralobar rests regardless of their *WT1* genotype (151).

WTX, CTNNB1, and Wnt signaling in Wilms Tumors

β-catenin is a multifunctional protein, acting both as a component of the cadherin cell-cell adhesion apparatus, and as a major protein involved in the "canonical" Wnt signaling pathway. Wnt proteins are secreted signaling molecules that serve as some of the most important signals

regulating developmental processes. Among the several signal transduction pathways regulated by Wnt proteins, the best characterized is the so-called "canonical" pathway, the major purpose of which seems to be to prevent the degradation of β-catenin, which allows it to translocate to the nucleus, form a complex with Tcf/Lef family transcription factors, and regulate genes involved in cell proliferation and differentiation (158). A role for β-catenin in BMP and TGF-β signal pathways, through the interaction with Smad proteins has also been demonstrated (159–161), such that β-catenin appears to be one of the most central proteins in cell growth and differentiation. Mutations in the *CTNNB1* gene have been found in about 15% of WTs, often in the same tumors that carry mutations in *WT1* (9, 11, 43), suggesting that mutation of *CTNNB1*, rendering it constitutively active, may constitute an additional "hit" beyond loss of WT1, in the pathogenesis of WT.

The identification of the *WTX* gene as a second tumor suppressor gene has strengthened the case for a role for Wnt signaling and β-catenin in WT. WTX has been shown to be a negative regulator of the Wnt pathway through its ability to form a complex with β-catenin that promotes it degradation (162). This suggests a mechanism whereby loss of WTX may serve to abnormally up-regulate signaling through β-catenin and contribute to tumorigenesis (162). Indeed, WT1 itself has also been suggested to negatively regulate signaling through β-catenin (163) and some WTs have been found to contain mutations in *WT1, WTX* and *CTNNB1* (9), suggesting that hyperactive canonical Wnt signaling may be a centerpiece of WTs (8, 164, 165). In a particularly intriguing recent report, it was shown that mesenchymal-type WTs appeared to be Wnt-dependent, characterized by mutation and nuclear accumulation of β-catenin and expression of known Wnt target genes, whereas more epithelial-like tumors appeared to be Wnt-independent by these criteria, i.e., no nuclear accumulation of β-catenin or activation of target genes (166). Interestingly, however, *WTX* mutations were found among both groups of tumors, both those that seemed to be Wnt-dependent and independent, indicating that much is still to be learned about the molecular mechanisms involved in the pathogenesis of WTs.

Treatment

The treatment of WT is a paradigm of multimodality management, as well as an example of the importance of collaborative studies in pediatric cancer. Acquisition of knowledge of the appropriate usage of active chemotherapy agents, as well as appreciation of the radiosensitivity of WT, along with advances in surgical techniques and post-operative care, have led to remarkable improvement in the outcomes of children with WT. A universally lethal disease at the turn of the nineteenth century, survival increased to about 25% with surgery only in the early 1900s; the use of routine post-operative radiation therapy resulted in an almost 50% survival rate in the 1950s; the discovery of the effectiveness of chemotherapy drugs (initially vincristine and actinomycin) increased survival to the 70–80% range in the 1970s (167). Further improvements in both the overall outcome of patients with renal tumors, and a decrease in overall toxicity through limiting exposure to unnecessary therapy for low risk patients have come about through the work of large collaborative groups. Although many groups have made important contributions, the two largest are the International Society of Pediatric Oncology (SIOP) and the National Wilms Tumor Study Group (NWTS.) NWTS no longer exists, but the work of this group on the study of renal tumors in North America has now been taken on through the Children's Oncology Group (COG). Although these two groups (SIOP and NWTS/COG) have fundamentally different approaches to the treatment of WT, both have strategies which have resulted in overall survival (OS) rates approaching 90%. SIOP therapies have been based on pre-nephrectomy chemotherapy, and NWTS/COG approach has advocated up-front nephrectomy in almost all cases. Although outcome from each approach has been excellent, it is difficult to extrapolate improvements in therapy from one group to the other, given the confounding variable of the surgical timing.

Risk Stratification

Staging

The treatment of WT is stratified according to the risk of relapse of the tumor. Known prognostic factors, such as age of the patient, size of the tumor, stage, histology, and most recently, genetic factors, are used to risk stratify the patients. NWTS/COG staging is based on anatomical staging at presentation; SIOP staging is based on post-chemotherapy findings. A comparison of the two systems is presented in *Table 59-2*.

Histology

The most powerful prognostic factor for outcome in WT is the histology of the tumor. NWTS and COG define WT as Favorable Histology (FH) if anaplasia is not identified

Table 59-2

Staging systems for pediatric renal tumors

Stage	COG (before chemotherapy)	SIOP (after chemotherapy)
I	(a) Tumor is limited to the kidney and completely excited (b) The tumor was not ruptured before or during removal (c) The vessels of the renal sinus are not involved beyond 2 mm (d) There is no residual tumor apparent beyond the margins of excision	(a) The tumor is limited to kidney, or surrounded with fibrous pseudocapsule if outside of the normal contours of the kidney. The renal capsule or pseudocapsule may be infiltrated with the tumor but it does not reach the outer surface, and it is completely resected (resection margins "clear") (b) The tumor may be protruding into the pelvic system and "dipping" into the ureter (but it is not infiltrating their walls) (c) The vessels of the renal sinus are not involved (d) Intrarenal vessel involvement may be present
II	(a) Tumor extends beyond the kidney but is completely excised (b) No residual tumor is apparent at or beyond the margins of excision (c) Tumor thrombus in vessels outside the kidney is stage II if the thrombus is removed en bloc with the tumor *Although tumor biopsy or local spillage confined to the flank were considered stage II by NWTSG in the past, such events will be considered stage III in COG studies*	(a) The tumor extends beyond kidney or penetrates through the renal capsule and/or fibrous pseudocapsule into perirenal fat but is completely resected (resection margins "clear") (b) The tumor infiltrates the renal sinus and/or invades blood and lymphatic vessels outside the renal parenchyma but it is completely resected (c) The tumor infiltrates adjacent organs or vena cava but is completely resected
III	Residual tumor confined to the abdomen (a) Lymph nodes in the renal hilum, the periaortic chains, or beyond are found to contain tumor (b) Diffuse peritoneal contamination by the tumor (c) Implants are found on the peritoneal surfaces (d) Tumor extends beyond the surgical margins either microscopically or grossly (e) Tumor is not completely respectable because of local infiltration into vital structures	(a) Incomplete excision of the tumor which extends beyond resection margins (gross or microscopic tumor remains post-operatively) (b) Any abdominal lymph nodes are involved (c) Tumor rupture before or intraoperatively (irrespective of other criteria for staging) (d) The tumor has penetrated though the peritoneal surface (e) Tumor implants are found on the peritoneal surface (f) Tumor thrombi present at resection margins of vessels or ureter, transected or removed piecemeal by surgeon (g) The tumor has been surgically biopsied (wedge biopsy) prior to preoperative chemotherapy or surgery
IV	Presence of hematogenous metastases or metastases to distant lymph nodes	Hematogenous metastases (lung, liver, bone, brain, etc.) or lymph node metastases outside the abdominal-pelvic region
V	Bilateral renal involvement at the time of initial diagnosis	Bilateral renal tumors at diagnosis. Each side should be substaged according to the above criteria

NWTS/COG and SIOP staging systems differ mostly in timing of staging, prior to chemotherapy versus after chemotherapy

(*Fig. 59-1*). Anaplasia may be focal or diffuse, and is defined by the presence of large mitotic figures, large and bizarre nuclei, and hyperchromasia (*Fig. 59-3*). Anaplasia is associated with worse outcome (168, 169), and merits intensification of therapy. Patients with low stage focal anaplasia do better than those with diffuse anaplasia (170, 171).

Rhabdoid tumor of the kidney (*Fig. 59-4*) and clear cell sarcoma were initially believed to be subsets of unfavorable histology of WT, but are now understood to be completely distinct tumor types (170, 172).

SIOP bases its histologic classification of WT largely on response to therapy. A revised working classification of all renal tumors was developed by SIOP in 2001 (173)

Figure 59-3

(a) and (b) (Microscopic view) Anaplasia in Wilms Tumor. There is diffuse nuclear enlargement, at least 3 times normal size (compare with tumor cells in top center), with marked pleomorphism. Abnormal, enlarged mitotic figures reflect an increased DNA content.

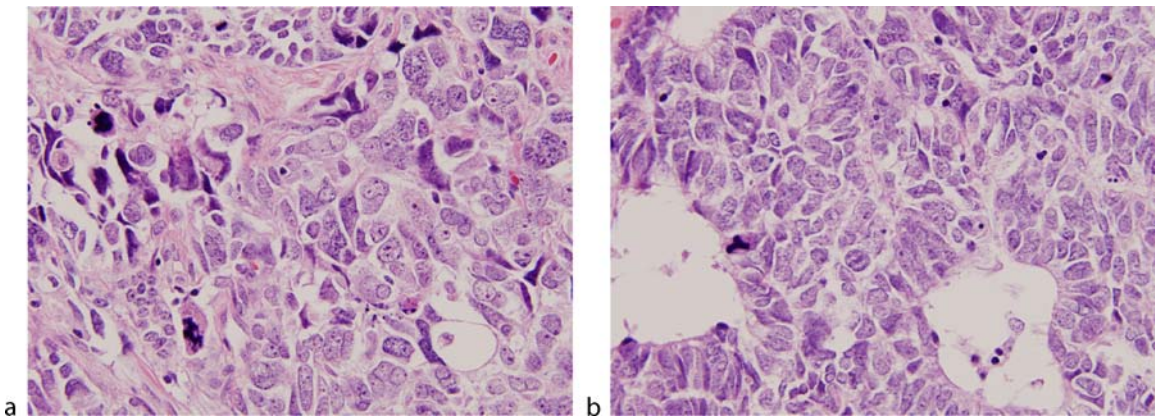


Figure 59-4

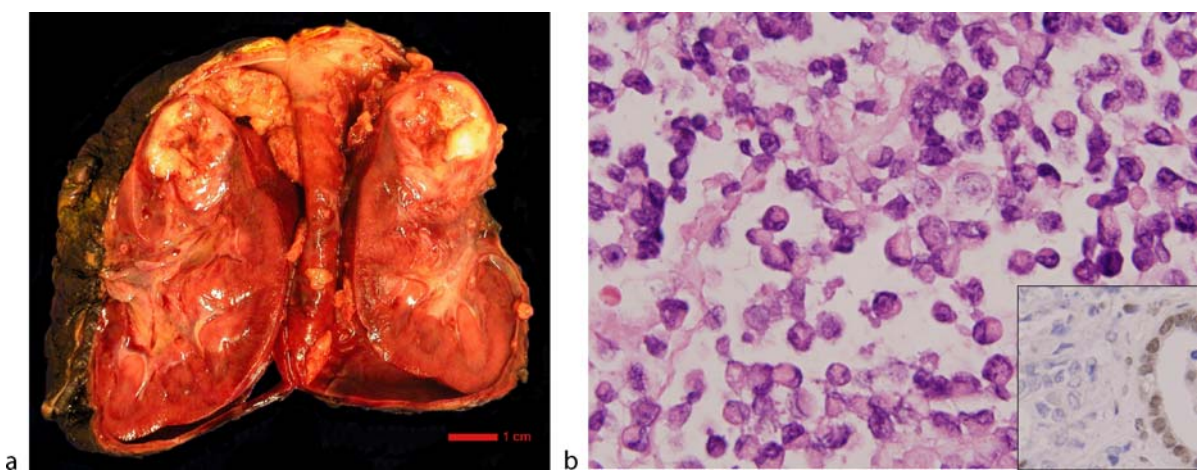
Rhabdoid Gross and Microscopic Images. (a) Rhabdoid tumor of the superior pole with extrarenal extension extending to Gerota's fascia. The tumor ruptured the renal capsule and formed a desmoplastic neo-capsule seen at the superior portion of the specimen. There was extensive microscopic extension into the renal sinus vein. (b) Microscopic appearance of a rhabdoid tumor. The tumor cells are frequently discohesive with vesicular nuclei and prominent nucleoli. The nuclei are often indented by an eosinophilic cytoplasmic inclusion composed of whorled aggregates of intermediate filaments. Rhabdoid tumors are characterized by a loss of chromosome 22q11.2 in an area involving the *INI1* gene. The inset is an immunohistochemical stain for *INI1* demonstrating retention in normal renal tubular cells (right) and loss in the tumor cells (left).



(*Table 59-3*). WTs are classified into three risk groups: high risk (blastemal or diffuse anaplasia), intermediate risk (regressive, stromal, mixed, epithelial, or focal anaplasia), and low risk (completely necrotic, or cystic partially differentiated).

Age

Increasing age has been shown to be correlated with decreased prognosis by both cooperative groups (174, 175). Age is used by COG as a prognostic factor,

Table 59-3
Revised S.I.O.P. working classification of pediatric renal tumors

A. For pretreated cases
I. Low risk tumors
Mesoblastic nephroma
Cystic partially differentiated neproblastoma
Completely necrotic nephroblastoma
II. Intermediate risk tumors
Nephroblastoma – epithelial type
Nephroblastoma – stromal type
Nephroblastoma – mixed type
Nephroblastoma – regressive type
Nephroblastoma – focal anaplasia
III. High risk tumors
Nephroblastoma – blastemal type
Nephroblastoma – diffuse anaplasia
Clear Cell sarcoma of the kidney
Rhabdoid tumor of the kidney
B. For Primary nephrectomy cases
I. Low risk tumors
Mesoblastic nephroma
Cystic partially differentiated nephroblastoma
II. Intermediate risk tumors
Non-anaplastic nephroblastoma and its variants
Nephroblastoma – focal anaplasia
III. High risk tumors
Nephroblastoma – diffuse anaplasia
Clear cell sarcoma of the kidney
Rhabdoid tumor of the kidney

along with tumor size. A subset of patients less than 2 years of age, with tumors less than 550 g have been shown to do well with nephrectomy only (176, 177). Adult event-free survival rates of WT have been shown to be lower than WT in pediatric patients, but may be confounded by greater toxicity of treatment seen in adults (178–180).

Biologic Factors

As with other tumors, there is much interest in identifying biologic factors that correlate with prognosis. LOH of both 1p and 16q was found to be a significant adverse prognostic factor in the fifth NWTS trial (181), and is being used prospectively to risk stratify patients on the first COG renal protocols.

Surgical Considerations in Renal Tumors

Surgery was the first modality used in the treatment of renal tumors, and it continues to be of critical importance today. Regardless of tumor type or multimodality treatment protocol, surgery serves as the mainstay to achieve local control, histopathologically assess, and anatomically stage children with renal tumors.

History and Physical Exam

Children with renal masses frequently present asymptomatically, and are often diagnosed either by the caregiver during a routine activity (bathing) or by the healthcare professional on a well-child visit. Seldom do these patients appear sick, and the diagnosis is often surprising to the parents and healthcare professionals who first encounter the child. Patients can also present with symptoms of hematuria or with gastrointestinal complaints, most often constipation. Findings of an abnormal hemogram or urinalysis testing or unexplained hypertension are not uncommon in both symptomatic and asymptomatic patients. Any of these findings should prompt a through abdominal exam and consideration of abdominal imaging.

Surgical consultation is warranted from the time of diagnosis. Once the presence of a mass is confirmed, additional history of associated medical problems that might compromise therapy or predispose the child to risks of peritreatment morbidity should be established. History should include any evidence of developmental delay or unusual growth patterns that may be consistent with predisposing genetic syndromes, as well as any possible history of bleeding disorders in the patient or the family. The accurate assessment of vital signs cannot be overstated. The degree of hypertension in these children can be significant, and this may change the perioperative anesthetic management. The degree of thoracic and abdominal compromise from the mass should also be investigated thoroughly to determine the anesthetic and operative risk for the patient as well. Despite very large masses, most children do not have significant respiratory embarrassment at presentation unless there is considerable metastatic pulmonary disease. Documenting the resting respiratory rate, decreased or absent breath sounds, and presence of effusions or consolidative processes are important. The abdominal exam should focus on the site of the mass and any evidence for involvement of the contralateral side. The presence of ascites should also be considered. A genitourinary exam is also important to investigate the presence of

"new" hernias, hydroceles, or varicolceles that may give indications about the size, location and vascular structures affected by the mass. Tenderness on exam should also alert the physician to the presence of tumor hemorrhage or rupture with subsequent peritoneal irritation.

Laboratory Evaluation

Baseline laboratory studies include urinalysis, complete blood count with differential, chemistry profile, liver function tests, coagulation profile, and blood typing for possible transfusion during surgical intervention. An association of WT and Von Willebrands disease is well established, and should be investigated preoperatively (182, 183).

Radiographic Evaluation

Radiographic studies consist of plain radiography and axial imaging. An abdominal and chest radiograph series are procured to evaluate the presence of disease and associated findings of ascites, effusions, consolidative processes, or the suggestion of metastatic disease. These studies are followed by either computed tomography (CT) (*Fig. 59-5*) or magnetic resonance (MR) (*Fig. 59-6*) imaging techniques with axial, coronal and sagittal formatting to enable three dimensional reconstruction; and hence, the adequate documentation of tumor size, location, organ invasion, intravascular involvement, lymphadenopathy, the presence of contralateral disease, the presence of a solitary kidney, horseshoe kidney, or other anatomic variant, the presence of metastatic disease, and the suggestion of tumor spillage or rupture at diagnosis. Furthermore, one must make sure that the tumor in question truly arises from the kidney and not from simply the retroperitoneum or an adjacent organ (germ cell tumor, sarcoma or neuroblastoma). Differentiating this fact can be difficult, especially with neuroblastoma, but with primary renal tumors the parenchyma is splayed out around the mass ("claw sign" (*Fig. 59-7*)) as opposed to simply being compressed or indented. Delayed sequences can also be ordered to evaluate for the presence of tumor within the collecting system (CT-ureterogram). Ureteral involvement can also be documented on an intravenous pyelogram. One has to consider the risk of radiation-induced malignancy when contemplating which exam to

Figure 59-5

CT images (axial (a) and coronal (b)) showing left renal mass with renal vein and IVC extension with evidence of pulmonary metastasis (c).

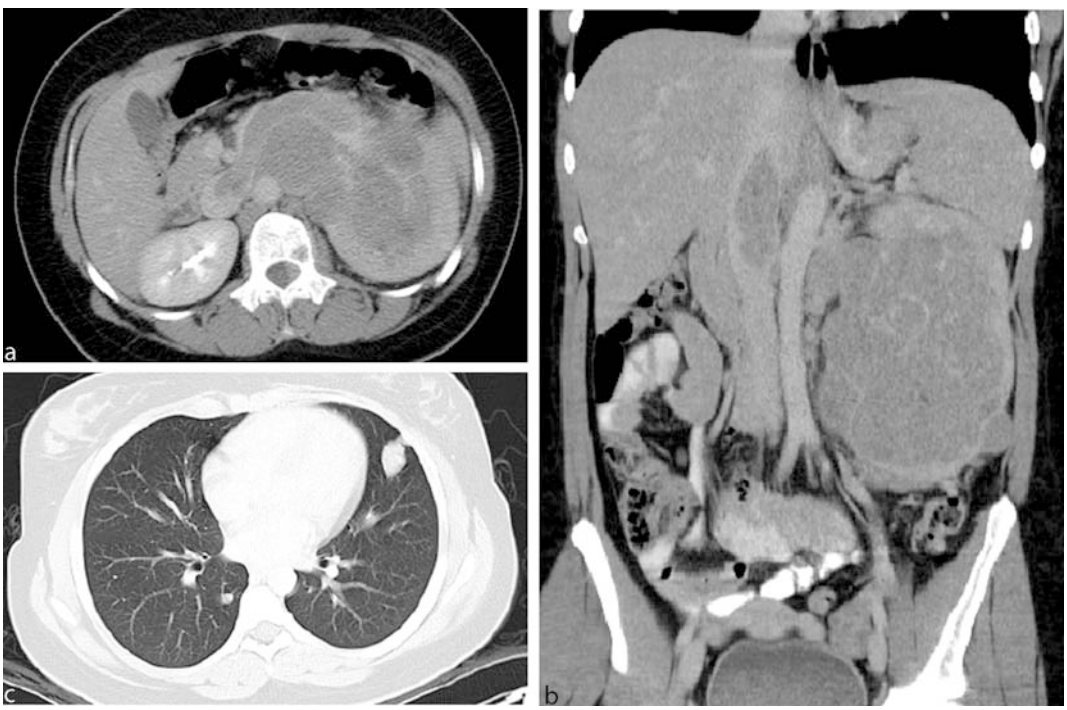


Figure 59-6

MRI Bilateral Nephroblastoma. (a) [T1] and (b) [T2] at diagnosis showing bilateral masses. After 2 months of chemo Rx masses have decreased in size (c) [Coronal T2], (d) [Axial T2], and (e) [Axial T1].

order (CT vs. MR) (184), but accurate preoperative planning must take precedence over the concern for secondary malignancies if there is any question. Adjuvants to these studies include vascular ultrasonography (US) that is probably more sensitive for diagnosing inferior vena cave and renal vein involvement. If renal vein and/or IVC involvement is discovered, then further studies may be warranted to document the degree of tumor thrombus progression including the presence of atrial (echocardiogram) or suprahepatic vein IVC involvement (CT venogram). Furthermore, US is also an excellent modality to investigate the kidney parenchyma to better define the architecture and assist in defining the characteristics of the mass and the contralateral kidney. Nuclear imaging studies do not have a role in these patients except to possibly document the baseline glomerular filtration rate and renal function contributed by each kidney in anticipation of a nephrectomy. However, these tests are seldom performed preoperatively and often do not change preoperative management of the patient. A bone scan (*Fig. 59-8*)

Figure 59-7

CT images (a) [axial], (b) [axial], and (c) [coronal] of right renal mass with evidence of a "claw sign" (white arrow) and with extension into the renal pelvis/proximal ureter causing obstruction.

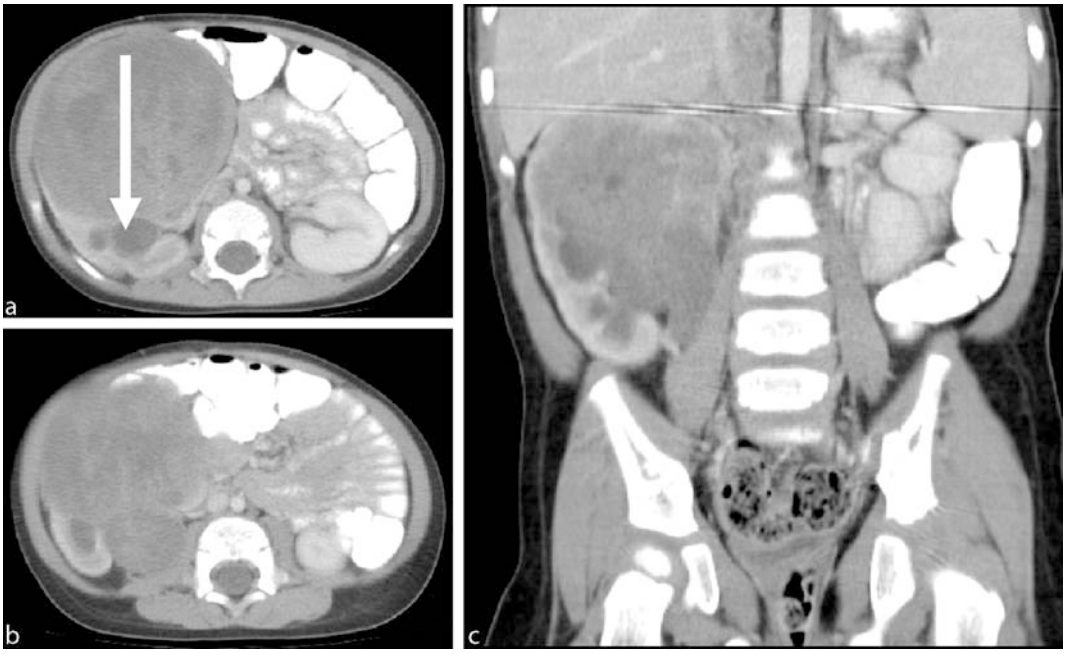

Figure 59-8

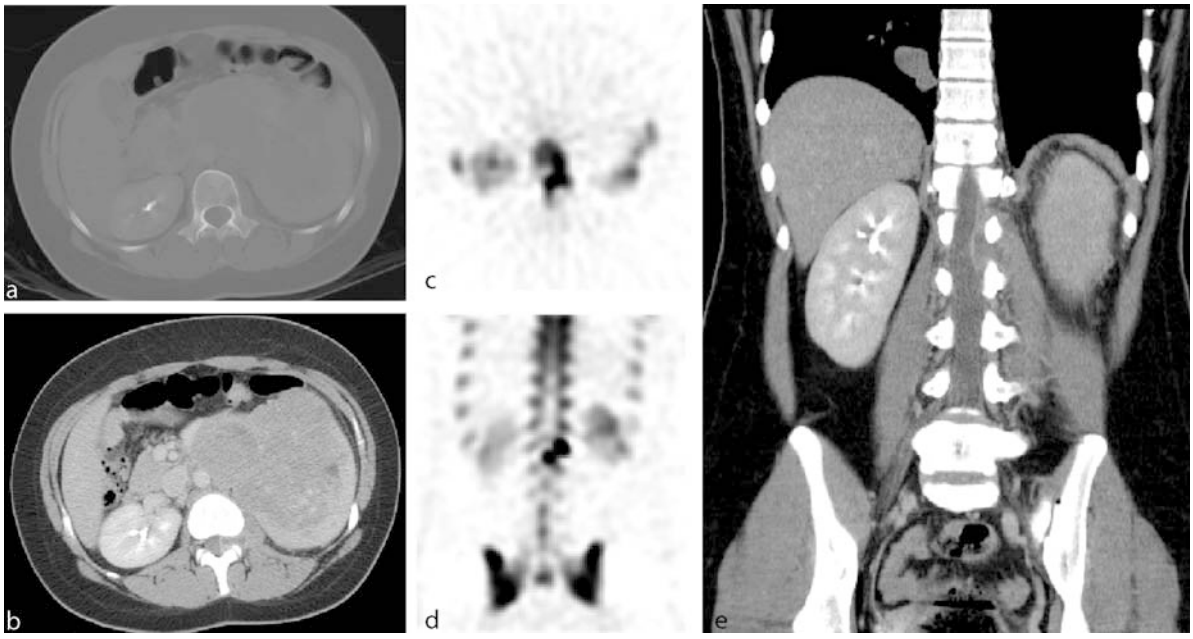
CT images (a) [bone window] and (b) [abdominal window] showing intraspinal extension of tumor and bone metastasis, (c) (axial) and (d) (coronal) display corresponding bone scan images, and (e) CT coronal image shows extent of intraspinal spread.



may be ordered to document the presence of bony metastasis if the mass is thought to be a clear cell sarcoma of the kidney. Bone scan is not routinely done in WT. A CT of the brain is often used to document metastasis in renal rhabdoid tumors, but not in other variants as the other tumors are not prone to neural involvement.

Anesthetic Evaluation and Perioperative Considerations

Once the child has been properly assessed and evaluated, primary resection as opposed to biopsy and neoadjuvant chemotherapy is espoused by most North American centers. This pathway differs from the regimens proposed by SIOP, and this issue will be discussed in greater detail below. Prior to surgery, anesthetic preparation concerning the child's pulmonary function, renal function, degree of anemia and hypertension, and the extent of the planned resection is performed. Discussions between the surgical team and the anesthesia team are critical to assess the risk of hemorrhage and the probable conduct of the operation. An intraarterial line is of vast important for hemodynamic monitoring and arterial blood gas sampling during the operation to ensure optimal respiratory function. A nasogastric tube and transurethral bladder drainage catheter ("foley" catheter) are inserted as well to drain the gut and to monitor urine output. Furthermore, gross hematuria can also be assessed during the operation with the use of a transurethral bladder catheter. Several intravenous lines are also placed in the upper extremities for rapid fluid administration and resuscitation during the operation, and the largest bore intravenous catheters that can be placed are recommended. Furthermore, the lower extremities are avoided as IV sites if possible, so as to ensure resuscitation can proceed in the event that the IVC is clamped during the operation. Previously-typed blood products should be available in the operating room prior to beginning the operation. Finally, an epidural catheter is recommended for intraoperative hemodynamic stability and postoperative pain management. This catheter blunts the body's physiological response to the operative insult by controlling the sensation of pain from the beginning of the case. The patient's hemodynamics are generally more stable with fewer swings in the patient's blood pressure and heart rate. Furthermore, with the incisional pain blunted postoperatively by the epidural catheter, the patient can be extubated at the end of the operation assuming that there were no intraoperative complications and hemorrhage was kept to a minimum. The epidural catheter can then be used in the postoperative period for all analgesia needs, and it can remain in until there is return of bowel function and an oral pain regimen can be started (usually within 5–7 days).

Operative Considerations

The operation then begins with the child positioned either supine or slightly raised on an ipsilateral flank roll to 15–20 degrees of elevation from the operating room table. These positions afford the greatest exposure to the abdomen – retroperitoneal and intraperitoneal spaces. A report from the NWTSG documented the importance of the type and size of the incision with which to remove the involved kidney without subsequent rupture or intraoperative complications (185). A generous transverse or bilateral subcostal incision is generally recommended as opposed to flank or paramedian incisions secondary to the higher reported rates of rupture of the tumors (185). Furthermore, an ipsilateral thoracoabdominal incision centered over the greatest diameter of the mass to ensure adequate exposure to the entire retroperitoneum and adjacent chest cavity can also be employed. This latter approach allows for a wide field of view via the abdominal portion of the incision, and the thoracic extension of the incision provides the unique exposure to the retroperitoneum superiorly and posteriorly where the tumor is most likely to be adherent to the diaphragm and surrounding soft tissues. Furthermore, the entire IVC can be exposed (right-sided tumors) for adequate proximal and distal control if a caval or renal vein thrombectomy is needed, or for left-sided tumors the incision can be carried over to the right anterior superior iliac spine to allow for adequate exposure of the IVC from the left side. At the conclusion of the operation, a thoracostomy tube may be required, but not always as the pneunothorax can usually be evacuated without issue. Regardless of the type of incision, upon entering the abdomen, a peritoneal survey is conducted to look for evidence of occult metastatic disease. The entire peritoneal surface is palpated, as is the liver and contralateral kidney. Any free fluid is removed and sent for cytology, especially if there is evidence of rupture. Once these maneuvers are performed, the ipsilateral colon is mobilized and brought to the center via the medial visceral rotation technique. Care should be taken to define the tissue planes appropriately so as not to injure the colonic mesentery or to dissect too closely to the renal capsule so as to increase the risk of inadvertent perforation. Early recommendations had advocated dissecting the hilum first to gain vascular control, but this led to increased intraoperative hemorrhage

and other morbidities. It is now recommended to defer the renal hilar dissection until the kidney has been fully mobilized and the renal pedicle is easier and safer to manipulate, isolate and divided. The kidney and tumor should be circumferentially dissected off the retroperitoneal structures. The ipsilateral adrenal gland is often removed as well. The utmost care must be taken so as not to injure the tumor capsule and allow for iatrogenic rupture and tumor spillage. A generous margin of soft tissue should be included with the kidney and mass if needed and possible to decrease the risk of perforation. This may even necessitate removing a portion of the diaphragm. Prior to dividing the renal vein, directly palpate the renal vein and IVC to ensure there is no tumor thrombus. If present, then complete resection of all tumor including a caval thrombectomy is in order so as to not cut across the tumor and create iatrogenic intraperitoneal spillage. If the mass on exploration is too extensive as to require adjacent organ resection (colon, spleen, liver, etc.), or intravascular involvement precludes safe tumor thrombectomy, then only a biopsy of the mass should be performed and adjuvant therapy begun prior to formal resection and local control. If the kidney and tumor can be removed, then the ipsilateral lymph nodes should be sampled so as to adequately stage the tumor, regardless of histopathological type. The lymph node areas involved should be hilar, paraaortic, and paracaval. A formal retroperitoneal lymph node dissection is neither warranted nor indicated as earlier studies have confirmed (186). All renal tumor types necessitate lymph node sampling, though data are only available for nephroblastoma. Studies conducted through NWTSG have shown that gross inspection of the lymph nodes by the operative surgeon is not adequate to define lymph node involvement in nephroblastoma (187). Inadequate lymph node sampling has led to understaging patients, and hence undertreatment with an increased incidence of local recurrence as demonstrated in NWTSG 4 (185). Finally, the ureter should be transected as close to the bladder as possible without forming a diverticulum or outpouching that can then serve as a source of infection. Generally, the ureter is carefully traced to the pelvic rim and dissected anteriorly to the junction with the bladder, and then transected where convenient. Palpation of the ureter should also take place prior to transaction to ensure there is no intraureteral tumor involvement. If the ureter is transected across tumor, then it is considered spillage with subsequent possible upstaging of the tumor and resultant increased therapy. Cystoscopy and ureteroscopy (or retrograde ureterograms) are only advocated for those with preoperative gross hematuria to define the possibility or bladder or ureter involvement (188).

At the conclusion of the operation, and under the same anesthetic, consideration should be given to the placement of an intravenous vascular access device for adjuvant therapy. An intraoperative frozen section can be performed on the tumor prior to abdominal closure to determine the histopathological subtype. Once known, a discussion between pathologist, oncologist and surgeon should be held to determine the need for adjuvant chemotherapy. If the tumor type is amenable to chemotherapy, then permanent vascular access should be placed at the same operative setting. If there is any doubt about the diagnosis or if the tumor is not amenable to adjuvant therapy (renal cell carcinoma), then the placement of a vascular access device is deferred.

Postoperative Course

Postoperatively, the patient is generally extubated in the operating room if there are no intraoperative complications, significant resuscitation with crystalloid or colloid fluids, and a functioning epidural catheter. The patient is transferred to the intensive care unit for monitoring for 24 h, and then he is transferred to the floor the next day. The nasogastric tube is left in place until there is adequate bowel function and enteral intake is begun. The epidural catheter is generally left in until an oral pain management regimen is started, or the catheter is not functioning. Once the epidural catheter is removed, the bladder catheter is removed. Attention should be directed to ensure adequate hemodynamic parameters, urine output and euvolemia, and normal renal function by laboratory monitoring during the postoperative period. Once the patient is adequately ambulating, eating, drinking, has normal renal function, and is on an oral pain control regimen, he is discharged or transferred to the oncology service for the administration of chemotherapy. This usually occurs within 7 days after surgery. NWTSG reviews in the past 30 years have shown that small bowel obstruction (SBO) is the most frequent postoperative complication (185, 189). However, a special note should be made concerning early postoperative SBO in these patients as an intussusception can occur in these patients for an as yet unknown reason. It will present early in the postoperative period with signs and symptoms consistent with a SBO. However, worsening abdominal pain and increasing nasogastric tube output should alert the surgeon to order abdominal radiographs and an US to document the presence of this condition. If needed, reoperation is indicated to relieve the obstruction, or depending on the age of the patient, an air contrast enema can be used to reduce the intussusception.

Surgical Questions and Controversies

Neoadjuvant Therapy Versus Upfront Resection

Primary nephrectomy with subsequent adjuvant therapy has been and continues to be the NWTSG/COG recommendation for all renal masses. This view is not shared by SIOP, however, and they have recommended neoadjuvant chemotherapy – with or without a tissue biopsy – for over 3 decades. Both approaches have merit, and both have resulted in comparably good overall outcomes. From a surgical perspective, the SIOP recommendation is based on many factors, but not the least of which is a greater risk of tumor spillage and rupture in patients undergoing upfront nephrectomy (190). SIOP has reported greater rates of these complications than NWTS studies (191).

Another argument for surgical resection prior to chemotherapy is that this approach allows for procurement of untreated tissue for full histologic and biologic assessment, as well as complete surgical staging, including biopsy of suspicious sites and lymph node sampling. NWTSG review of surgery related factors predicting local recurrence revealed that failure to sample lymph nodes was an adverse prognostic factor, even when compared to patients with documented nodes positive for tumor (185). The hypothesis to explain this is that a subset of patients that did not have lymph node sampling were understaged, and therefore undertreated. Results of SIOP 6, where adjuvant radiotherapy was withheld in a cohort with negative lymph nodes after resection but with preoperative chemotherapy, demonstrated the importance of accurate lymph mode sampling. The study was stopped midway after there was an increase in local recurrence in this cohort when compared to the radiotherapy cohort, and these results seem to support this concern (192, 193). The SIOP perspective on this "loss of staging information" however views that patients who respond well to therapy and are found to be lower stage at the time of resection may appropriately be treated with less intensive therapy, particularly with avoidance of anthracycline and radiotherapy (194).

Another controversy in WT management involving the surgeon is the use of neoadjuvant chemotherapy with or without a tissue biopsy. The SIOP approach allows neoadjuvant chemotherapy based on diagnosis made from imaging studies and does not mandate a pretherapy biopsy. A series of reports from the NWTSG and SIOP addressed concerns with this approach (191, 195). Namely, without a tissue biopsy, the mass could be benign or a different malignancy, and it was in almost 7–10% of cases reported in these studies (191, 195). Furthermore, a study from the United Kingdom further highlighted this result where almost 12% of there patients would have had different pathological findings in one report (196). An additional concern that is often raised is that histopathology may change after pretreatment, and patients may not be appropriately treated.

Even for those who advocate upfront nephrectomy in the majority of cases, it is clear that not all patients with WT should undergo primary resection. In order to preserve as much renal tissue as possible, patients with WT occurring in a single kidney, horseshoe kidney, or bilaterally should not undergo upfront nephrectomy. Patients presenting with significant respiratory compromise from extensive metastatic disease are not appropriate for initial surgery. Two studies by the NWTSG have further addressed which renal masses should receive a primary biopsy and neoadjuvant therapy. These reports documented the intraoperative and perioperative morbidity from surgery for nephroblastoma, especially intraoperative hemorrhage, adjacent vascular or organ injury, and mortality. Tumors that were very large (>10 cm), had extensive IVC involvement (above the hepatic veins and into the right atrium), and required resection of adjacent organs should all undergo biopsy and neoadjuvant chemotherapy prior to resection for local control. These studies also pointed out that resections performed through suboptimal incisions (flank or paramedian laparotomy) and by non-pediatric specialists were also at greater risk of intraoperative perforation and spillage and increased morbidity (185, 197). Tumors that appear to have perforated with free intraperitoneal spillage at diagnosis may also warrant biopsy to confirm the pathological diagnosis and then neoadjuvant chemotherapy.

The technique of biopsy, percutaneous versus open, as also been an area of debate and study (198). Biopsies performed via a percutaneous core needle technique increase the risk of discordant pathology and seeding of the needle tract. Open biopsy with lymph node sampling at the time of diagnosis is another method that has traditionally been used. Based on results of NWTS studies demonstrating that patients undergoing any type of prechemotherapy biopsy had higher rates of relapse, all patients undergoing initial biopsy will be considered stage III in the COG staging system (199).

Gross Hematuria at Presentation

Ureteral extension of nephroblastoma is a rare phenomenon present in only 2% of cases in a recent NWTSG review (188). This correlates with the few reports in the literature to date. In reviewing the NWTSG reports, the

authors found that of the cohort of children with ureteral involvement, 49% had evidence of gross hematuria. This symptom serves as a significant clue to the presence of tumor extension into and through the collecting system, and hence, due diligence should be undertaken by the treating medical personnel. Preoperative imaging studies may find evidence of ureteral tumor thrombus in almost 63% of patients, and CT was the most helpful modality. Prior to resection, however, cystoscopy, retrograde ureterograms, and direct palpation of the ureter to determine the presence of tumor thrombus are all warranted so as to define the extent of disease and have a complete resection. If the tumor thrombus is inadvertently missed and transected at surgery, then this would be considered intraoperative tumor spillage with subsequent tumor upstaging.

Pulmonary Metastases

Patients with WT and pulmonary metastasis have been shown to do better with intensified chemotherapy with or without radiation therapy (200–202). Although centers have recommended primary pulmonary metastasectomy to spare the morbidity of expanded therapy (201, 203), the NWTSG has demonstrated the superior efficacy of chemotherapy and radiotherapy over chemotherapy and surgery, regardless of pathological subtype (204, 205). Specifically, Green and colleagues demonstrated that metastasectomy did not have an effect on outcome in NWTS 1–3, nor was there a role for pulmonary metastasectomy in patients with stage IV disease. Furthermore, Ehrlich and colleagues recently demonstrated the importance of pretreatment biopsy of pulmonary lesions not radiographically consistent with metastatic disease as critical to avoiding overtreatment of children who may have other reasons for small pulmonary lesions (206).

Intravascular Extension

A minority of children present with evidence of intravascular involvement with nephroblastoma (4%) (207). Diagnosis includes a combination of axial imaging (CT and/or MR) in addition to ultrasonography, including echocardiography to establish atrial involvement if warranted. Surgical extirpation of all disease – including the entire thrombus – is recommended. Furthermore, if all intravascular disease can be resected, there is no change in prognosis (208). However, recommended timing of the resection has changed. An upfront resection followed by adjuvant therapy was initially recommended, but it has too great a morbidity in comparison to neoadjuvant chemotherapy and subsequent nephrectomy (185, 209). A recent report from NWTSG documented the success of this approach and the clear ability of neoadjuvant chemotherapy to safely facilitate the subsequent nephrectomy and thrombectomy (207). Specifically, the surgical morbidity was reduced by 50% (26–13%) with neoadjuvant chemotherapy, and the most severe complications occurred in the upfront surgery cohort.

Bilateral Disease

Bilateral renal masses in children has been defined as stage V disease. Diagnosis and staging of these patients is similar to those children who present with unilateral disease save for the overriding mandate to save renal parenchyma. Whereas North American and European centers have differed on the management of unilateral disease (neoadjuvant chemotherapy vs. upfront resection), a common pathway has emerged in the treatment of children with bilateral disease. The goal of treatment in this cohort of children has been renal preservation to avoid the need for permanent renal replacement therapy. The forthcoming Children's Oncology Group protocol will mirror SIOP's approach and dispense with the need for pretreatment biopsies (open or percutaneous). However, if tumors do not respond to neoadjuvant chemotherapy, then biopsy is recommended to ensure concordant histopathological results and adequate chemotherapeutic regimens. Discordant tumors (unfavorable on one side and favorable on the other side) exist and if missed, this scenario can allow for the undertreatment of the patient. Ideally, after neoadjuvant chemotherapy (three drug regimen assuming favorable histology), successful partial nephrectomies can be performed. The NWTSG evaluated this cohort of patients in NWTSG-4 (210), and total gross resection of disease was accomplished in 88% of cases. However, there was a higher percentage of both local recurrence (8%) and positive margins (16%) in this cohort. These results were deemed acceptable secondary to a substantial, successful partial nephrectomy rate (72%) and overall survival (81% at 4 years). The success of this pathway was also echoed by other authors (211).

The Role of Partial Nephrectomy

Nephron sparing surgery for unilateral nephroblastoma has not been adequately studied using prospective, randomized trials. Data amassed from the cohort of patients

with bilateral tumors has shown this surgical extirpative modality to be an effective procedure when married to pretreatment biopsy and neoadjuvant chemotherapy (see prior section on Bilateral Tumors). The dominant philosophy when dealing with the children with bilateral tumors is to preserve renal parenchyma and avoid permanent renal replacement therapy. Pursuant to this goal, several groups (212–214) have attempted to apply parenchymal sparing surgery to unilateral disease recognizing the long-term morbidity of radical nephrectomy for unilateral tumors, including other renal injury (trauma, infection, obstruction), decreased glomerular filtration rate and the onset of renal failure, and metachronous nephroblastoma in the contralateral kidney. Haecker and colleagues evaluated their cohort of patients undergoing partial nephrectomy in nephroblastoma and recommended that it only be used for patients with small, favorable histology tumors after neoadjuvant chemotherapy (213). There was a higher local recurrence rate in the partial nephrectomy cohort, as well as a lower survival in unfavorable histology tumors. Hence, the authors concluded that partial nephrectomy is feasible in small lesions, histologically favorable tumors that responded to neoadjuvant chemotherapy. Linni and colleagues published their result in analyzing the role of partial nephrectomy in unilateral nephroblastoma and recommended that this approach is not ready for universal application (214). However, they did stress that in specific cases it is reasonable to consider partial nephrectomy if the tumor decreases by 50% or greater in volume after neoadjuvant chemotherapy, if the tumor is easy to resect (unipolar lesion), if preservation of greater than 50% of the kidney remains after resection, and if there are pathologically negative para-aortic lymph nodes. Finally, the results of the UKW-3 trial has been reported by Arul and colleagues and the feasibility of unilateral, partial nephrectomy in favorable histology nephroblastoma was evaluated (212). The study attempted to determine the ability of the surgeon to adequately define the resection plane ("marking") on the nephrectomy specimen ex vivo in light of the following criteria: (1) clear resection margins, (2) no vascular invasion, (3) no pelvic invasion, and (4) >50% of the kidney preserved. The study was unsuccessful as there were no specimens officially "marked," but of the specimens identified by the surgeon as being a candidate for partial nephrectomy, 70% were deemed pathologically not to meet the above criteria to be eligible for a partial nephrectomy. However, whereas intraoperative ultrasound was not available during this study 18 years ago, it may facilitate partial nephrectomy by defining the proper plane of dissection today.

The Role of Laparoscopy

The role of laparoscopic partial and radical nephrectomy is well established in adult renal cancers (215). However, there is minimal data to support these approaches in pediatric patients, and especially in the case of nephroblastoma. The role of minimally invasive surgery to resect other pediatric malignancies has been reported (216), but North American centers that stressed the importance of primary resections with adjuvant chemotherapy following surgery for nephroblastoma have not encouraged primary laparoscopic radical nephrectomies. Generally the tumors are large, bulky, and the concern for extirpation without rupture is of paramount importance so as not to intensify the postoperative therapy a child should receive. A minimally invasive approach for tumor biopsy (unilateral or bilateral) in patients deemed poor candidates for primary resection is both feasible and realistic. European centers that espoused neoadjuvant chemotherapy with tumor reduction have a cohort of patients whose tumors are more amenable to this minimally invasive approach. Duarte and colleagues documented the success of laparoscopic nephrectomy after neoadjuvant chemotherapy following SIOP protocols in two separate reports (217, 218). They report on a total of 10 patients with no evidence of recurrence (mean follow-up 5–23 months), no complications, and no port-site implants. The authors document that the renal tumors are smaller and encased in a fibrous capsule after neoadjuvant chemotherapy which facilitates the ability to safely and completely resect these tumors and involved lymph nodes. However, the operative times for this approach are longer in comparison to open procedures.

Chemotherapy

Multiple chemotherapy agents have been shown to be appropriate in WT. These drugs act through a wide spectrum of mechanisms, and have both overlapping and unique toxicity profiles (*Table 59-4*). NWTS and SIOP studies have helped refine the schedules and dosages appropriate to the patient's stage and histology, balancing the risk of relapse with avoidance of the risk of toxicity from the chemotherapy. It is well established that low stage FH WT can be effectively treated with vincristine and actinomycin, with minimal acute and long-term toxicity (192, 219). Doxorubicin is added for higher stage patients. Although doxorubicin is a very active agent in all WT, it confers both a greater risk of toxicity on therapy, largely due to myelosuppression, and a small, but real risk of long-term cardiac toxicity (220). Cyclophosphamide,

Table 59-4

Chemotherapy agents commonly used in renal tumors

Drug	Category	Mechanism of action	Common toxicity[a]
Vincristine	Vinca alkaloid	Mitotic inhibitor; inhibition of microtubule assembly and cellular metaphase arrest.	Vesicant, NT, A, SIADH, hypotension, A
Dactinomycin	Antitumor antibiotics	Intercalation; DNA strand breaks (Topo II)	M, N and V, A, mucostitis, vesicant, hepatic (VOD)
Doxorubicin	Antitumor antibiotics	Intercalation; DNA strand breaks (Topo II); free radical formation	M, mucostitis, N and V, A, diarrhea, vesicant, cardiac (acute, chronic)
Cyclophosphamide	Alkylating agents	(Prodrug) alkylation; crosslinking	M, N and V, A, cystitis, water retention; cardiac (HD)
Etoposide	Plant products	DNA strand breaks (Topo II)	M, A, N and V, mucostitis, mild NT, hypotension, HSR, secondary leukemia, diarrhea (p.o.)
Carboplatin	Alkylating agents	Platination; crosslinking	M (Plt), N and V, A, hepatic (mild), HSR
Ifosfadime	Alkylating agents	(Prodrug) alkylation; crosslinking	M, N and V, A, cystitis, NT, renal; cardiac (HD)
Topotecan	Plant products	DNA strand breaks (Topo II)	M, diarrhea, mucostitis, N and V, A, rash, hepatic
Irinotecan	Plant products	(Prodrug) DNA strand breaks (Topo II)	M, diarrhea, N and V, A, hepatic, dehydration, ileus

[a]*M* myelosuppresion, *SIADH* secretion of inappropriate diuretic hormone, *a* alopecia, *N* and *V* nausea and vomiting, *nt* neurotoxicity

etoposide, and carboplatin are active chemotherapy agents with significant risk of toxicity that are reserved for high risk patients, including some patients with diffuse anaplasia, Stage IV disease, poor initial response to therapy, and as well, some patients with RTK and CCS. Toxicities of these drugs include significant myelosuppression, and subsequent increased risk of serious infections, decreased renal function, hearing loss, hemorrhagic cystitis, and secondary leukemias (*Table 59-4*). Irinotecan, topotecan, and ifosfamide are also agents used in very high risk patients, largely in the relapse setting (221, 222). Very high dose chemotherapy with stem cell transplant has been successful in some relapsed patients, but has proven to be very difficult to study given the very small number of patients (223).

Special Circumstance

Children with WT, particularly bilateral WT, are at risk for development of renal failure during treatment. Patients may become anephric if surgery is necessitated in critical areas of both kidneys. Patients with remaining renal tissue after surgery may develop renal failure due to chemotherapy agents, or radiotherapy. The three main drugs use in newly diagnosed WT, vincristine, actinomycin, and doxorubicin, can be given safely and effectively to patients with renal failure (224). In a review of 28 of 5,910 children registered on NWTS studies 1–IV, treated with chemotherapy with concomitant renal failure, it was concluded that reduction of dosing of these agents is not necessary, and that reasonable cure rates were observed. These patients do require close individual monitoring, and accurate pharmacologic and pharmacokinetic studies are vital.

Radiation Therapy

WT are very radiosensitive, and it was this modality that offered the first true cures in WT. However, radiation therapy carries the risk of significant long term toxicities, including secondary malignancies, scoliosis, radiation pneumonitis, cardiac toxicity, pregnancy related complications, and renal compromise or failure. Early NWTS and SIOP studies have both demonstrated that low stage patients could be cured without radiotherapy, therefore radiation therapy is reserved for patients with higher risk disease (192, 225, 226). The appropriate use of radiation therapy in patients with FH WT is still being investigated. Patients with stage IV pulmonary disease have been

shown to have better outcome with radiation therapy on NWTS compared to similar patients treated on a United Kingdom Children's Cancer Study Group trial (202, 225). However, SIOP studies show good outcomes while withholding radiation therapy in a subset of patients with initial pulmonary disease that resolves quickly with chemotherapy (202). The first COG FH WT High Risk protocol is designed to assess whether patients treated with a backbone of NWTS therapy that show resolution of pulmonary metastasis within 6 weeks can safely avoid radiation therapy.

Screening

For patients with genetic syndromes associated with increased risk of developing WT, routine radiologic surveillance is recommended. Although not unanimously agreed upon, a schedule of US every 3–4 months through age 7 has been shown to aid in detection of WT, and proposed to be cost-effective in identifying tumors at an earlier stage (227–229).

Acknowledgments

The authors thank Sunny Hartwig Ph.D. for helping to research and write the genetics portion of this chapter, and Valerie Schumacher for helpful discussions. We would also like to thank Drs. Stephan Voss and Kyle Korek for their assistance in compiling the radiology and pathology figures, respectively.

Hypertension

60 Epidemiology of Hypertension

Midori Awazu

Introduction

Hypertension (HTN) is a significant global health issue. It is the major risk factor for atherosclerosis, leading to the development of cardiovascular disease (CVD). There is increasing evidence that HTN has its antecedents during childhood and that atherosclerosis is already present in adolescents. Thus early detection and intervention are crucial. HTN is also a risk factor for the progression to end-stage renal disease, a topic extremely relevant to pediatric nephrologists. While children are more likely to have secondary HTN, the prevalence of primary HTN appears to be increasing due to an epidemic of obesity. To identify children with HTN, clinicians should know normative values of blood pressure (BP) as well as the definition of HTN. Prevalence of HTN, factors influencing BP, and sequelae of childhood HTN are also reviewed in this chapter.

Normative Blood Pressure Values in Children

Casual Blood Pressure

The National High Blood Pressure Education Program (NHBPEP) Working Group established guidelines for the definition of normal BP in children in its Report of the Second Task Force on Blood Pressure in Children-1987 (1). Normative casual BP values were updated in 2004 by The Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents (2). Since the 1996 Update on the 1987 Task Force Report (3), the working group has reexamined the childhood BP database and has added new data from the 1999 to 2000 National Health and Nutrition Examination Survey (NHANES). BP values are based on gender, age, and height, and 50th, 90th, 95th, and 99th percentiles are provided (*Tables 60-1* and *60-2*). There is minimal change from the 1996 report in the numbers that designate the 90th and 95th percentile for systolic or diastolic BP. The 90th and 95th percentile are BP levels that define prehypertension and HTN, respectively. The 99th percentile and the 50th percentile are given to facilitate clinical decision-making in the plan for evaluation and to provide the clinician the BP level at the midpoint of the normal range, respectively. To determine the height percentile, clinicians are instructed to use the CDC growth charts (4). Since these procedures are time consuming and may lead to the underdiagnosis of HTN (5), easier ways to determine childhood BP categories have been made available by calculators or modified BP tables (6, 7). The BP tables are based on auscultatory measurements and the definition of diastolic BP is the 5th Korotkoff sounds. One should note that values measured by oscillometric devices frequently used in clinical practice are not interchangeable with auscultatory values. Park et al. reported that the oscillometric systolic BP (SBP) averaged 10 mm Hg higher and the oscillometric diastolic BP (DBP) averaged 5 mm Hg higher than the auscultatory BP readings (8). The fourth report recommends rechecking oscillometric BP measurements greater than the 90th percentile with the auscultatory method. One should also note that the Task Force Report norms are based on a single BP measurement, not in accordance with the currently recommended multiple measurements (see Chapter "Evaluation of Hypertension in Childhood Diseases). In addition, it should be pointed out that BP measurements obtained with standard practice vital sign station screening may be different from those obtained by trained personnel in accordance with fourth report recommendations (9). Seventy-four percent of the readings were reported to be higher at the vital sign station, and only 12% differed by <5 mm Hg for both SBP and DBP.

Although the Task Force standards have been adopted worldwide, many local reference values are also used, especially in Europe. De Man et al. have shown that the normative values for European children are different from those for American children (10, 11). Pooling data from six European studies (Germany, France, Denmark, and the Netherlands) showed that the 95th percentile for mean BP was higher in European children by 6 mm Hg for SBP and 3 mm Hg for DBP. Menghetti et al. found that normal BP values for Italian children differed from both the American data and from de Man's (12). In Italian children, the 90th and 95th percentiles were 3–8 mm Hg

© Springer-Verlag Berlin Heidelberg 2009

Table 60-1

BP levels for boys by age and height percentile

Age, y	BP Percentile	SBP, mm Hg							DBP, mm Hg						
		Percentile of height							Percentile of height						
		5th	10th	25th	50th	75th	90th	95th	5th	10th	25th	50th	75th	90th	95th

The 90th percentile is 1.28 SD, the 95th percentile is 1.645 SD, and the 99th percentile is 2.326 SD over the mean

higher for SBP and DBP between 5 and 12 years of age, and 2–3 mm Hg higher in older males than American standards. With respect to Northern Europe, levels in Italy were similar or slightly higher in the lower ages and lower in late adolescence.

In Great Britain, reference BP values in children and young adults aged 4–23 years were established using an oscillometric device (Danamap 8100) (13). BP percentiles were based on demographic data obtained from seven national surveys that recorded three BP measurements at different occasions. The BP values are higher than those provided by the fourth report, due probably to the use of an oscillometric device. Several other countries have reported reference BP values for their own populations (10, 11, 14–16).

The second report of 1987 provided standards for infants less than 1 year old (1, 3) (*Fig. 60-1*). These values were obtained by the auscultatory method and the fourth Korotkoff sounds were used for DBP. Zubrow et al. and Kent et al. provided normative BP values obtained using the oscillometric method for newborns and infants during the first year of life respectively (17, 18).

Ambulatory Blood Pressure

Ambulatory BP monitoring (ABPM) is more reliable and reproducible than casual BP as it provides multiple readings over time. It also enables computation of the mean, daytime, and night-time ambulatory BP (ABP) by measuring BP during regular activities, detects white coat effect (higher casual BP than 24-h or daytime ABP) or reversed white coat effect (lower casual BP than 24-h or daytime ABP), and provides information regarding diurnal BP pattern. The utility and tolerability of ABPM in children have been documented (19). Increasing age and higher mean arterial pressure are factors that improve the success rate of ABP measurement (20, 21). ABPM has also proved to have higher reproducibility than clinic BP in children and is now widely used (22–26).

Studies from the United States, Spain, Germany, and Taiwan reported normal values for ABPM in children by age and gender (27–30). As office BP, ABP values rise with age and tend to be higher in boys than for girls. Normal ABP values by height are also available (31–33). Wuhl et al. analyzed the data of Soergel et al. using the

least mean square (LMS) method (34) to correct for the skewed distribution of the original cohort, and provided normalized data to gender, and age or height (35) (*Table 60-3*). Although the original data by Soergel et al. have been used most widely, the data by Wuhl et al. provides the most complete and appropriate reference data for ABP in children.

It is important to use different norms for ABPM and casual BP measurement as awake ABP values are higher than BP values found in the fourth report, which are based on a single daytime auscultatory reading (36, 37).

Home Blood Pressure

While ABPM is useful, it is expensive and not available for every pediatrician. In adults, self-measurement of BP at home and work is regarded as an alternative, and recent guidelines recommend self-measurement of BP (38, 39). Readings of <130/80 mm Hg and >135/85 mm Hg are generally considered normal and hypertensive, respectively, in adults (38). Self-measurement of BP has the following advantages: (1) distinguishing sustained HTN from white coat HTN (see below), (2) detection of masked HTN (see below), (3) assessing response to medication, (4) improving patient adherence to treatment, and (5) reducing costs by avoiding ABPM or drug therapy.

In children, home BP monitoring has been utilized (40–42). Investigators in Greece confirmed the reproducibility of home BP in children (43). They first validated the Omron 705 IT oscillometric device for use in children and adolescents (44), and provided reference values for pediatric populations (45). This is currently the only reference values available in children (*Table 60-4*). The same group of investigators reported on the relationship between home BP and office measurements (46). In younger children (6–12 years), both diastolic and systolic home BP levels were higher than office BP. This difference is reduced with advancing age and eliminated after the age of 12 years. This is in contrast to adults in whom home BP tends to be lower than office BP (47).

More than 70% of the pediatric nephrologists in Germany use home BP measurement for children, and 64% consider home BP more important than office measurement, although it is less accurate than ambulatory BP (48). There were, however, wide discrepancies for standards of home BP in children and adolescents. Wuhl et al. reported that home BP is superior to clinic BP measurement but neither clinic BP nor home BP detected HTN with enough sensitivity or specificity to replace ABPM (49). The greater specificity of home BP compared to clinic BP may suggest that home BP is more suitable for diagnosis rather than screening of HTN in children.

Proper validation and regular calibration of the device by the clinician are necessary for home BP measurement. Future goals include standardization of BP devices and measurement, as well as prospective studies to demonstrate that home BP measurement better predicts cardiovascular outcomes compared to office BP recordings in children.

Definition of Hypertension in Children

Casual Blood Pressure

The definition of childhood HTN is statistically defined based on the normative distribution of BP in healthy children. This is in contrast to adult HTN defined clinically as the level of BP that makes an increase in morbidity and/or mortality (2, 3, 38). This definition could not be applied to children because data associating childhood HTN with morbid events have been scarce. Ongoing longitudinal investigations should provide new insights into the long-term significance of high BP in childhood (50–52). In the fourth report, HTN is defined as average SBP and/or DBP that is ≥95th percentile for gender, age, and height on three or more separate occasions. BP levels that are ≥90th percentile or ≥120/80 mm Hg but <95th percentile is termed prehypertension. The fourth report has added a method for staging the severity of HTN by providing the range of BP elevation for stage 1 and stage 2 HTN. Stage 1 HTN is defined as being from the 95th to the 99th percentile plus 5 mm Hg. Stage 2 HTN is 5 mm Hg or more above the 95th percentile and represents a level of BP that requires prompt evaluation.

In Great Britain, high BP is defined as either SBP or DBP above 98th percentile for gender and age, and high normal BP as BP between the 91st and 98th percentile (13). This percentile system, different from both American and European counterparts, predicts prevalence of high BP (>2 SDS) and high-normal BP (>1.33 SDS) to be 2.3 and 6.9%, respectively. These values are similar to those in other countries.

In children younger than 1 year of age, SBP has been used to define HTN. Standards for SBP and DBP for infants <1 year old have not been changed since 1987 (1).

There are several problems in using population percentiles to define normal BP (53). One relates to the evolution in the epidemiology of the reference population. BP percentile values may change as the demographics and characteristics of population change. The second problem is the need to account for secular

trends. The SBP and DBP among children and adolescents in the United States increased by an average of 1.4 mm Hg and 3.3 mm Hg, respectively, between 1988 to 1994 and 1999 to 2000 due, at least in part, to the increase in the prevalence of overweight and obesity (54). An increase in average BP levels among American children was confirmed by several investigators (54–56). If new BP data are collected, the 95th percentile values will increase and allow higher BP to be considered normal. In a similar manner, if separate criteria for each ethnic group are used due to ethnic differences, it may cover the cardiovascular risk associated with ethnic predispositions to HTN.

Ambulatory Blood Pressure

For ABPM values, HTN is generally defined as daytime or 24-h ABP either systolic or diastolic greater than 95th

percentile by gender, and age or height. Simple dichotomous cutoff values for normal BP versus HTN, however, may not be sufficient. Zachariah et al. developed the concept of "BP load," defined as the percentage of ABPM readings ≥140 mm Hg for SBP and ≥90 mm Hg for DBP in adults (57). In children, the BP load is defined as the percentage of total BP measurements exceeding the upper limit of normal for age, body size, and time of day. BP load has been related to target organ damage and may be more appropriate for the definition of HTN (58, 59). The acceptable limit of BP load, however, is not determined even in adults. BP loads of 25% or more are generally accepted as HTN (60).

Epidemiology of Hypertension in Children

Prevalence of Hypertension

By definition, 5% of children would fall into the category of HTN. The normative data provided by the Task Force, however, are from the first measure obtained for each child. With repeated measurement, only approximately 1% of children and adolescents proved to be hypertensive (1, 60). Adrogue et al., using the 1996 criteria, reported that systolic HTN was found in 2.7% and diastolic HTN in 2% of children after the screening (61). After the rescreening, systolic HTN had fallen to 0.8% and diastolic HTN to 0.4%. Over the last decade, however, HTN has increased, affecting up to 5% of adolescents in the United States (60–63). The childhood obesity epidemic appears to be associated with the increasing prevalence of HTN (54, 64–66). Chiolero et al., however, after reviewing literature published over the past 20 years, reported that a definite conclusion will depend on future studies (66). More recently, Din-Dzietham et al. assessed high BP secular trends in children and adolescents enrolled in US national surveys, and concluded that the increase was largely attributable to the increase in obesity (56).

The prevalence of HTN in other countries has been reported to be between 1 and 22% (62, 67–78). Many of these studies also documented the association of HTN with obesity. In Great Britain, which utilizes a different criteria, the prevalence of HTN is reported to be 2.3% (13). The prevalence of HTN seems to be increasing in association with BMI in Canada as well (69). In Northern Ireland, however, large decreases in BP have occurred among adolescents aged 12 and 15 years over the decade from 1990. The magnitude of the trends could not be accounted for by confounding factors including BMI (79).

The majority of hypertensive children have mild HTN, most often primary. A small group of children have higher BP that is usually due to a secondary cause. Younger children generally have secondary HTN, whereas essential HTN is most common in adolescents. The prevalence of secondary HTN is estimated to be 28% in children with HTN as opposed to 5% in adults with HTN (80), and 0.1% in the general population (81).

The prevalence of prehypertension ranges from 5.4 to 15.7% (13, 63, 69, 78). A recent study showed that prehypertension also increased 2.3% between 1988 and 1999 (56). Obesity increase partially explained the rise in prehypertension similar to the rise in HTN.

White Coat Hypertension

White coat hypertension (WCH) is a condition where casual BP is high but the BP during ABPM is normal (82), whereas white coat (WC) effect refers to a pressor response in the medical setting. While WC effect has been described in children and adolescents (83, 84), the diagnosis of WCH has become possible only after ABP normative values in children became available (85). Subsequent studies showed that the prevalence of WCH in children ranged between 12.9 and 88% depending on the criteria used (86–89). In the fourth report, WCH is defined as BP measured in a physician's office >95th percentile, whereas average BP is <90th percentile outside of a clinical setting (2).

In adults, the risk of CVD is thought to be lower in patients with WCH than in those with persistent HTN and higher than in those with normotension (39). In children, however, WCH may represent a prehypertensive state. Increased LVMI were reported in children with WCH (90) in contrast to a previous study which showed no significant difference in LVMI and intima-media thickness of the carotid arteries (88). Further follow up of these patients is needed.

Masked Hypertension

Masked HTN (MH), a high ABP in the presence of normal office BP, is being recognized as a risk factor for cardiovascular complications in adults (91). It has previously been called "reverse WCH" or "WC normotension". MH has been associated with more extensive target organ damage than is seen in true normotensive subjects (92, 93). MH has been found to be prevalent in the

pediatric population ranging from 7.6 to 26% (88, 89, 94–96) consistent with the values found in adults ranging from 5 to 23% (91). Studies showed high prevalence of MH in renal transplant recipients (97, 98).

Children with MH are more likely to have higher body mass indexes, a parent with HTN, greater left ventricular mass, or higher prevalence of left ventricular hypertrophy compared with normotensive controls (88, 89, 95, 96).

Factors Influencing Blood Pressure

Age

The Task Force Report and other studies demonstrate that age is the major determinant of BP (2, 3, 13). SBP increases sharply between birth and age 2 months (1). There is no significant difference between SBP at ages 2 months and 1 year. BP then increases progressively with age and more rapidly during puberty (1, 13). The prevalence of HTN also increases progressively with age (69).

Gender

BP levels, especially after 12–14 years, are higher in boys than in girls, consistent with findings in adults. The mechanisms responsible for the gender differences in BP levels are not clear, although interactions between sex hormones and the kidneys are speculated to play a role (99).

The incidence of HTN is greater among boys than girls (56, 100, 101) with the relative risk of HTN 1.50 (confidence interval: 1.15, 1.95) (62).

Height

Height is a major determinant of BP and predicts BP independent of age (102, 103), which led to the inclusion of height in normative BP tables (2). The more important role of height than weight has previously been reported (102, 104).

Obesity

Currently, the most important factor influencing BP is obesity. Weight was a strong determinant of BP even after adjustment for height (105). In contrast to the previous reports, a recent study suggests a greater effect of weight on BP than height (13). There is a strong association between HTN and weight/obesity (13, 106). The prevalence of HTN in obese children is higher and ranges from 11 to 30% (62, 69–71, 107, 108). As described earlier, the childhood obesity epidemic appears to be associated with an increase in prevalence of HTN in childhood (54, 65).

Brion et al. reported that lean mass and total body fat mass independently and positively correlated with increased BP in 9-year-old children (109). The correlation was stronger for SBP than DBP. Sugiyama et al. confirmed a positive association between BMI and SBP (110), but contrary to adult studies (111), a negative association between BMI and DBP was observed. While some pediatric studies have shown a positive association between BMI and DBP (112), other studies have found no significant association (62). Sorof and Daniels suggested that obesity HTN appears to be characterized by a preponderance of isolated systolic HTN in adolescents (64). In a similar manner to adults, central body fat is more strongly related to BP than peripheral fat in children (113). It has been hypothesized that insulin resistance may play a role in the development of high BP in children and adolescents as well (114). A population-based study in children has demonstrated a relationship between serum insulin concentration and BP (115). A positive relationship has also been reported between insulin resistance and HTN in children and adolescents.(116–118).

Some authors have reported a prevalence of systolic HTN by ABPM ranging between 50 and 62% among obese children and adolescents (119, 120). Obese youths had not only higher BP levels, but also higher BP variability. Among obese youths, 6.6% had WCH, 9.2% had MH, and 5% had sustained HTN (108). Maggio et al. showed that mean ambulatory SBP and DBP are significantly higher in prepubertal obese children than in lean subjects, whereas casual BP levels are not different (96). Lurbe et al. further reported a relationship between insulin resistance and nocturnal elevations of SBP (118).

A systematic review demonstrated that interventions to promote weight loss lowered BP in adults (121). Body weight loss by diet significantly reduced BP in obese children, although the effect was greater when exercise was added (112, 122). BP has been shown to decrease with weight reduction and increased activity even among children in the general population (101, 123).

Physical Activity

The effects of physical activity in the prevention and treatment of high BP have been well described in adults (124). The effects of exercise on resting BP in children and

adolescents, however, are conflicting (125–130). Several studies reported no association, whereas others reported inverse associations, but not consistently for both SBP and DBP or in both genders. This may be partly explained by the difference in method (questionnaire or use of mechanical techniques). A meta-analysis concluded that short-term exercise does not appear to reduce resting BP in children and adolescents (131). Recent randomized controlled trials in overweight children were designed to assess the influence of combined lifestyle changes including both diet and exercise on multiple cardiovascular risk factors in overweight adolescents. Although it is difficult to interpret the influence of exercise alone on BP, most studies suggest that physical activity can effectively reduce BP in children (132). Interestingly,, BP was not reduced any further with exercise in normotensive children.

The pediatric behavioral literature suggests that sedentary activities are more than the opposite of physical activities. They are positively associated with SBP after adjustment for confounding factors (110). In obese children, the amount of time spent watching TV is associated with both HTN and the severity of obesity (133).

As for the intensity of exercise, moderate activity has been shown to be more effective than vigorous activity in reducing SBP (134). Aerobic exercise in adolescence and high-intensity exercise throughout life were associated with low DBP in adulthood (135). A recent study suggests that the volume of activity may be more important than the intensity, in lowering BP (130).

Race and Ethnicity

In adults, HTN is more common in African Americans (non-Hispanic blacks) (32%) compared with non-Hispanic whites (23%) and Mexican Americans (23%) (136). In children and adolescents, ethnic group differences in BP are not so clear. Of approximately 50 studies that examined ethnic differences in BP in children and adolescents, approximately half reported higher BP for African Americans (62, 74, 137–139). The observed differences, however, are often explained by differences in body size, fat distribution, sexual maturation, and socioeconomic status. Furthermore, 14 studies reported no consistently significant differences in BP across ethnic/racial groups (61, 138, 140–142). The ethic differences seem to become apparent at an older age (142). NHANES data indicate slightly higher levels of BP among Mexican American youth compared to their non-Hispanic white counterparts (54). A recent study that examined 8- to 17-year-old non-Hispanic blacks and whites and Mexican Americans demonstrated that non-Hispanic blacks (4.2%) and Mexican Americans (4.6%) had a greater prevalence of HTN and prehypertension than non-Hispanic whites (3.3%) (56). The trends in obesity and high BP have a greater effect on non-Hispanic blacks and Mexican-Americans, consistent with the report by Muntner et al. (54).

Higher BP in African Americans is associated with sodium intake and lower plasma rennin activity (143). Although a recent report demonstrated a higher prevalence of HTN in African American youths in parallel with an increase in obesity (56), obesity was not as closely related to BP in African American children as in white children. Thus, at lower levels of BMI, African American youths had higher SBP and DBP, whereas at higher levels of BMI, white youths had higher SBP and DBP (138, 144).

Family History

A family history of HTN is present in approximately 50% of hypertensive children (145). HTN has long been known to cluster within families (146, 147), and the reason is thought to be due to shared environmental exposures (obesity, salt intake, life style etc) and genetic susceptibility. BP concordance between spouses is greater than that between nonspouses (148) and among biological siblings than among adoptive siblings living in the same household (149, 150). Concordance is also greater among monozygotic twins than among dizygotic twins (151). Longitudinal studies have identified parental history of HTN as a risk factor for HTN in children (152–154). A recent study by Wang et al. examined the association of parental HTN with BP change and HTN risk from young adulthood through the ninth decade of life in a longitudinal cohort (155). The results showed that HTN in both mothers and fathers has a strong independent association with elevated BP levels and incident HTN over the course of adult life. Li et al. also showed that parental HTN independently predicted children's resting BP and BP reactivity along with BMI and BMI z score (156).

Genetics

The heritable portion of BP is estimated to range between 35 and 65% (147, 157). Robinson et al. performed a retrospective case-control analysis concerning the heritability of primary and secondary HTN in children (158). The study concluded that primary HTN in children and adolescents is likely due to a large number of additive

contributions of genes and that secondary HTN may be related to just a few genes.

HTN is rarely caused by monogenic disorders which include Liddle's syndrome (a mutation in the gamma subunit of the amiloride-sensitive epithelial sodium channel SCNN1G), type 1 and type 2 pseudohypoaldosteronism (mutations in the mineralocorticoid receptor gene or SCNN1G in the former and WNK kinases 1 or 4 in the latter), glucocorticoid remediable HTN (a chimeric gene formed from portions of the 11ß-hydroxylase gene and the aldosterone synthase gene), apparent mineralocorticoid excess (mutations in the gene encoding the kidney 11ß-hydroxysteroid dehydrogenase), 11ß-hydroxylase deficiency (mutations of the *CYP11B1* gene), 11α-hydroxylase deficiency (CYP17 mutation), and others (159). The rare alleles responsible for the monogenic trait do not associate with essential HTN, but more common variants of the same genes may exhibit less severe phenotypes. In fact, polymorphisms in SCNN1G have been associated with variation in SBP (160–162). WNK1 gene polymorphisms have also been associated with ambulatory BP variations in the general population (163). On the other hand, mutations of genes that cause rare recessive diseases featuring altered salt handling and reductions in BP may protect against the development of HTN. Ji et al. screened members of the Framingham Heart Study for variation in three genes, *SLC12A3* (NCCT, the thiazide-sensitive sodium-chloride cotransporter), *SLC12A1* (NKCC2, Na-K-2Cl cotransporter gene), and *KCNJ1* (ROMK, the inward rectifier K^+ channel gene) that are responsible for Gitelman's syndrome (NCCT) and Barter's syndrome (NKCC2 and ROMK) (164). Mutation carriers showed reduced BP and low prevalence of HTN compared with non-carriers. These studies show that BP variation is affected by rare alleles.

There are two other approaches to map genetic variants i.e., linkage analysis and association studies. Until recently, genome-wide scans were performed by linkage only, whereas association studies aimed at candidate genes. Linkage analyses have been effective in detecting rare monogenic HTN, whereas association studies were expected to be better for analyses of complex traits such as essential HTN. Genome-wide linkage studies using families or siblings reported significant or suggestive linkage for BP or HTN (165). The results are variable, however, probably due to different populations, small sample sizes, lack of stratification, misclassification of phenotype, and others. Association studies (case-control studies) compare frequencies of alleles of candidate genes between hypertensive patients and normotensive controls. Many association studies with candidate genes for HTN have been reported, although most positive findings failed to replicate as linkage studies. The low reproducibility may be explained by insufficient statistical power of association studies with candidate genes (166). Nevertheless, there are promising genes such as the angiotensinogen gene (*AGT*) (167), angiotensin-converting enzyme gene (168), ß2 adrenergic receptor (*ADRB2*) (169), G protein ß3 subunit (*GNB3*) (170), and adducin gene (*ADD1*) (171).

Recently, genome-wide association studies have been applied to analyze common diseases, including essential HTN. A genome-wide association study is an approach that involves rapidly scanning markers across the complete sets of DNA, or genomes, of patients and controls to find genetic variations associated with a particular disease. This approach became possible with progress in sequencing of the human genome and detection of millions of single nucleotide polymorphism (SNP) markers. In 2007, the Wellcome Trust Case Control Consortium and the Framingham Heart Study reported the results of genome-side association studies for HTN. The former found no strong association and six SNPs with moderate associations (172). None of the six association regions overlap with genes previously suggested through association studies with candidate genes. The Framingham Heart Study also failed to detect strong signals (173). Genome-wide association studies might have problems such as misclassificaiton of subjects with only single measurement of BP. Also, a common disease and common variant hypothesis, a major premise for using genotyping of common variants, may not apply to HTN. Thus HTN may have fewer common risk alleles of larger effect sizes (a statistical measure of the strength of the relationship between two variables). Furthermore, genuine common susceptibility variants of large effect size may be poorly represented on the chip used for genotyping. In support of this possibility, resequencing target regions of rare variants of responsible genes led to the identification of mutations in *SLC12A3, SLC12A1*, and *KCNJ1* associated with HTN as stated above (164). Further studies with multiple approaches are required to clarify HTN-susceptible genes.

Birth Weight

The findings of Barker et al. relating low birth weight (LBW) to increased risk of death from CVD in late adult life have led to many studies exploring this relationship (174, 175). The majority of studies that examined the relationship reported an inverse association between BP and birth weight, supporting the 'fetal origins of adult

disease' or 'programming' hypothesis (2, 176). Systematic reviews have concluded that an inverse association is present with a magnitude ranging from −1.5 to −2.0 mm Hg/kg (177, 178). In a recent meta-analysis, the magnitude of the effect of birth weight varied by study size, with a weaker association in the larger studies (175). The inverse association between birth weight and BP has been found to be independent of potential confounding factors such as socioeconomic status, maternal and participant smoking, maternal age, birth order, maternal BP, and alcohol intake (179–184).

A systematic review found that accelerated postnatal growth (either linear growth or accelerated weight gain) in LBW individuals was associated with increased BP in adulthood (178). Law et al., on the other hand, found that accelerated growth in infancy corrected for regression to the mean had no important effect on BP in early adulthood (185). Poor height gain in early childhood and shorter leg length were reported to be associated with increased adult BP (186), whereas greater growth in height around puberty may be associated with increased BP in later life (187). These studies suggest that different growth trajectories and different patterns of growth at sensitive times in the life course may affect BP in later life. The association between birth weight and childhood BP seems to vary, depending on ethnic group (188–190).

Nephron Number

Brenner et al. proposed that LBW may be associated with a congenital deficit in nephron number, which would predispose to reduced renal sodium excretion and increased susceptibility to HTN (191). This hypothesis was supported by studies that showed a relation between birth weight and nephron number (192–194). The most direct confirmation is the finding by Keller et al. They showed that hypertensive white patients had significantly fewer glomeruli per kidney than matched normotensive controls (195). The association between nephron number and BP was observed in White Europeans, White Americans and Australian Aborigines but not African Americans. Studies in additional populations are required (196).

Salt Intake

BP is positively associated with sodium intake in adults (3, 111, 197–200). In children, however, evidence for a direct relation between sodium and BP has been less conclusive. A review of 25 observational and 12 intervention studies of sodium and BP in youth by Simons-Morton and Obarzanek (201) indicated that only three included children with elevated BP (202–204). The studies that were methodologically stronger yielded conflicting results (202–209). The small or null effect of sodium on BP in most studies may be explained by poor compliance to dietary regimens, inadequate adjustment for confounding factors, variable quality in BP measurements, lack of power to detect differences, and possible differences in sodium sensitivity across groups. In a recent meta-analysis of ten trials looking at the effect of reducing salt intake on BP in infants, children, and adolescents, He and MacGregor showed that a modest reduction led to an immediate and significant fall in BP (210). Long-term and larger intervention trials are needed, however, to conclude that the observed benefits can be maintained during childhood and adolescence and have clinical relevance.

Dietary sodium intake early in life may affect BP in later life. Hofman et al. compared infants receiving a low or normal sodium-containing infant formula for the first 6 months of life (211). A small but significant decrease in BP was found at 6 months of age in infants fed the lower sodium formula. When BP was measured at 4 years, there was no BP difference between groups (212). At 15 years of age, however, BP levels were significantly lower in the low sodium group (213). The mean difference was 3.6 mm Hg in SBP and 2.2 mm Hg in DBP, an effect larger than that reported for sodium reduction in adults (198, 199, 214). Subsequent to this study, the sodium content of most formulas has been reduced (215).

Potassium supplementation is associated with a decrease in BP in adults (216, 217). A review of 12 observational and 2 intervention studies of potassium and BP in children by Simons-Morton and Obarzanek did not provide a clear relationship (201). Higher intakes of dietary potassium in children have been associated with either lower SBP (218) or DBP (219, 220) in half of the observational studies. However, results of one study indicated the opposite effect (221). Potassium supplementation at a level of 1,500 mg given for 4 weeks did not reduce BP in normotensive children (222). Longer-term supplementation trials with potassium in hypertensive children induced lower age-related BP increases in SBP and DBP, compared with nonsupplemented children (202).

The negative association of calcium with BP has been documented in several studies in children (201, 223). Calcium is a dietary component of which suboptimal intakes in children have been associated with higher DBP (224) and SBP (225), although not in all cases (201, 226, 227). Of the randomized intervention trials conducted, supplementation with calcium at a

level ranging from 600 to 1,000 mg/day resulted in either a small non-significant decrease in SBP in normotensive children (228) or a significant decrease in DBP in children with mild HTN (229).

Potassium and calcium supplementation has been shown to enhance urinary sodium excretion that is likely to result in a hypotensive effect (230, 231). At present, the evidence is too limited to support clinical recommendations for potassium and calcium supplementation in BP management in children.

Breast Feeding

Breast feeding has recently been found to be associated with reduced BP in later life (232–234), although the findings have not been consistent (235–237). Two large cohort studies prospectively examined the relation between breast feeding and BP, and found that SBP and DBP were lower in breast-fed children compared with formula-fed children (232, 233). The relation remained significant after controlling for potential confounding factors. A longer duration of breast feeding was associated with a more significant reduction in BP (233). Martin et al. conducted a meta-analysis of studies published after 1980 reporting on BP levels in breast- and bottle-fed subjects (234). Pooled estimates based on a random effects model indicated that breast feeding was associated with a 1.4 and 0.5 mm Hg reduction in SBP and DBP, respectively. The magnitude of the association is similar to those reported for salt restriction and physical activity (2). There was some evidence that the effect on BP is amplified with the increasing age at which the BP is measured (183).

The association of breast-feeding and lower BP may be explained by a hormonal effect, lower sodium intake, or a protective effect of long-chain polyunsaturated fatty acids that are not present in most formula. A recent follow-up of a randomized controlled trial found that BP at age 6 was lower among breast-fed children and formula-fed children who had a formula supplemented with a long-chain polyunsaturated fatty acid than among those randomized to an unsaturated formula (238).

Environment

Adverse socioeconomic status during childhood is associated with increased CVD in later life, independently of adult socioeconomic status (239). Children from the low socioeconomic status are reported to have higher BP in adulthood than those from high socioeconomic status (240–244). Adjustment for risk factors including birth weight, breast feeding, adult body mass index, smoking, and alcohol consumption had little effect on the association between socioeconomic status and BP. In some studies, on the other hand, the association decreased or disappeared after adjusting for body mass index in adulthood (245). Other studies do not support the association between childhood socioeconomic status and adult BP (246–249).

Sleep Disordered Breathing

Sleep disorders including sleep apnea are associated with HTN and cardiovascular morbidity in adults (250, 251). Findings from pediatric studies suggest that elevated BP is associated with the presence of sleep disorders (252, 253). Several cross-sectional studies have described trends of increasing BP with greater frequency of apnea and hypopnea during sleep in children (254, 255). Obese children with high apnea and hypopnea index had a higher prevalence of HTN than obese children with low index (255). This relationship was not found in nonobese children.

The severity of sleep-disordered breathing in children was also associated with increased BP variability, decreased nocturnal dipping, and nocturnal HTN (256–258). Amin et al. further demonstrated that sleep-disordered breathing was independently associated with an increase in morning BP surge, BP load, and 24-h ABP (259).

Two meta-analysis studies provided conflicting results. Ng et al. suggested a significant association between sleep-disordered breathing and HTN, although sleep-disordered breathing may affect BP in either direction in children (260). According to the more recent analysis by Zintzaras et al. no evidence exists that moderate to severe sleep-disordered breathing in childhood increases the risk of elevated BP (261). However, the conclusions were based on relatively small numbers of cases recruited for a few studies, and large population-based studies are needed.

Since approximately 15% of children snore and at least 1–3% have sleep-disordered breathing (252), the fourth report recommends obtaining a brief sleep history during the initial evaluation (2).

Uric Acid

In 1993, uric acid levels were suggested to be useful indicators of adolescents at risk for HTN (262). Recently,

uric acid has been proposed to play a role in essential HTN by contributing to endothelial dysfunction leading to microvascular and inflammatory injury to the kidney (263). Data from the Bogalusa Heart Study determined that childhood uric acid predicts adult BP, suggesting that early elevation in serum uric acid levels may predispose to the development of HTN (264).

Uric acid may provide the link between LBW and childhood HTN. In a retrospective chart review of 95 hypertensive children, Feig et al. showed that birth weight inversely correlated with serum uric acid (265). In 113 randomly selected children aged 8–13 years, Franco et al. confirmed uric acid levels were significantly higher in association with impaired endothelial function in children with LBW compared with those with normal birth weight (266). Uric acid levels correlated with SBP in children of the entire cohort.

Homocysteine

In adults, homocysteine (Hcy) is a well-known risk factor for CVD and was found to be related with BP regardless of the presence of signs and symptoms of CVD (267). Plasma Hcy concentrations were shown to be correlated with BP in healthy children and elevated in obese schoolchildren with HTN and dyslipidemia (268, 269). Glowinska et al. also showed that Hcy correlated with BP and that hypertensive children had the highest concentrations (270). Papandreou et al., on the other hand, reported no association of BP and Hcy in young age groups composed of normal and obese children (271). Franco et al. demonstrated that there was a significant association between the circulating levels of both Hcy and nitric oxide with BP levels and vascular function in children aged 8–13 years, born small for gestational age (272).

Sequelae of Childhood Hypertension

Tracking of Blood Pressure

Tracking of BP refers to the process by which individuals remain in the same BP percentile over time. It is well recognized that childhood BP tracks (273–277) and predicts adult BP (105, 137, 278). The tracking correlations are reported to increase with increasing age, being 0.1 between birth and age 2, 0.5 between ages 3 and 4, and 0.6 between age 9 and 10 (106, 279) reaching a maximum of 0.7 around late adolescence/early 20s and remaining constant thereafter (280). The Bogalusa Heart Study showed that 40% of individuals with SBP and 37% of individuals with DBP levels above the 80th percentile at baseline had levels above this percentile 15 years later(273). Tracking is apparent in children with higher BP, family history, obesity, lower socioeconomic status, and increased left ventricular mass (152, 243, 273, 281–283).

End-Organ Damage

High BP in children is associated with the development of atherosclerosis (50, 51, 284–286). Autopsy studies demonstrated a relationship between HTN and early development of atherosclerosis in adolescents and young adults (285, 287, 288). Nowadays, atherosclerosis can be detected by measuring carotid intima-media thickness and large artery compliance in young adults (50, 51, 289). Other markers of target organ damage include left ventricular mass, retina, urinary albumin excretion, and renal function in patients with kidney disease.

ABPM is considered superior to office BP as a predictor of hypertensive end-organ damage (290). Similar to observations in adults, studies of pediatric subjects found greater correlation of end-organ damage, left ventricular hypertrophy and left ventricular mass index, with ABPM parameters such as 24-h mean SBP (291), mean nighttime SBP (292, 293), and daytime ABP (294) than with casual BP values. Several studies in adults had associated a generally worse prognosis with "non-dipping," which is also shown in children (295).

There appears to be ethnicity difference in target organ damage. African Americans are more likely to develop target organ damage, particularly renal disease, in adulthood (296). In normotensive adolescents, microalbuminuria has been shown to be more common in African Americans compared with whites (297). In a study in African Americans and whites aged 7–30 years, it was reported that "nondipping", a marker strongly associated with higher rates of target organ damage, begins by age 10 years and that this blunted decline is exacerbated with age during the years of adolescence (298). In hypertensive children, LVH may be more prevalent in Hispanic children than in other ethnic groups (299).

Left Ventricular Hypertrophy

In adults, increased left ventricular mass is a known risk factor for CVD (300).

Among children and adolescents with borderline or established essential HTN, left ventricular hypertrophy (LVH) is present in approximately 34–47% of cases (301–305). The fourth report recommends performing echocardiography to assess LVH in children with HTN (2).

Increased left ventricular mass indexed to height to correct for body size (LVMI) seems to correlate with casual BP or systolic ABP (301, 304, 306, 307). A recent large study, however, did not demonstrate the relationship between LVH and severity of BP elevation at the initial visit of a child with confirmed HTN (308), underscoring the importance of including echocardiography in the initial examination. "Non-dipping" status and 24-h pulse pressure have been associated with higher LVMI in adolescents with essential HTN (301, 307).

Similar to adults, children with MH have increased LVMI when compared with normotensive children (88, 95). Stabouli and colleagues demonstrated that children with WCH also tended to have higher LVMI than normotensive children (88).

Carotid Artery Intima-Media Thickness

Measurement of the carotid artery's intima-media thickness (cIMT) has gained acceptance as a way to evaluate the degree of atherosclerosis in adults (309). Elevated BP is associated with increased cIMT in children and young adults also (50, 51, 289, 304, 305). On the other hands, several studies failed to show a correlation between office SBP or DBP and cIMT after adjusting for BMI (120, 305, 310). A strong correlation, however, was found between cIMT and several ABPM parameters such as daytime systolic BP load and daytime systolic BP index (310).

Only one study has assessed cIMT in children with MH (88). The study demonstrated that masked hypertensive children tended to have greater cIMT than normotensives, but lower than hypertensive subjects.

Retina

Retinal arteriolar narrowing is a recognized consequence of chronic HTN in adults and independently predicts cardiovascular mortality (311). Retinal abnormalities have been reported in infants with HTN (312) and in 50% of hypertensive children and adolescents (313). Recently, Mitchell et al. examined the relationship of retinal vascular caliber and BP levels in two population-based cohorts among children aged 6–8 years in Australia and Singapore (314). They demonstrated that higher BP is associated with retinal arteriolar narrowing in healthy children and that the effect was continuous across the range of BP. This study provides further evidence that the risk of cardiovascular disease may have its origins early in life.

Microalbuminuria

While urinary albumin excretion is a powerful marker to identify adults with a risk for CVD, data in children with HTN are limited. In children and adolescents with type 1 and type 2 diabetes, microalbuminuria was clearly linked to elevated 24-h DBP, nocturnal BP, loss of nocturnal dip, or increases in BP load (315–320). Assadi examined the relation of LVH to microalbuminuria in hypertensive subjects and documented that urinary albumin excretion was increased in children and adolescents with HTN in correlation to LVH (321). Nguyen et al. recently examined the association between cardiovascular risk factors and microalbuminuria in a nationally representative US sample and demonstrated that microalbuminuria was associated with HTN among overweight adolescents (322).

Renal Function

Renal damage other than microalbuminuria has rarely been reported in children with HTN except for those with accelerated HTN or those with renal diseases. Harshfield et al. examined the relationship between ABP patterns and renal function in healthy, normotensive African American and white youths (323). The relationship between creatinine clearance and BP was not significant for casual BP or daytime BP for either group, or with night-time BP in the Anglo-American subjects. In contrast, creatinine clearance was related negatively to both night-time SBP and night-time DBP in the African American subjects. Mitsnefes et al. examined the role of HTN in the progression of chronic renal failure in children by using the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) chronic renal insufficiency database that consists of 3,834 patients aged 2–17 years with an estimated glomerular filtration rate (GFR) less than 75 ml/min/1.73 m^2 (324). Systolic HTN proved to be a significant independent predictor of the progression of chronic renal insufficiency in children. In a study of 61 children with chronic pyelonephritis or vesicoureteral reflux, the extent of scarring was strongly correlated

with ABP values (325). Lama et al. also showed that 24-h SBP and DBP correlated with the decline of GFR (326), during a 5-year follow up of 100 normotensive children with reflux nephropathy.

ABPM provided valuable information about pediatric renal transplant recipients (327, 328). ABPM had stronger correlations than office BP with GFR in children with chronic renal failure (329). In pediatric post-renal transplant patients, first year SBP and DBP correlated positively with values at 56 months, and GFR at 1-year and at the end of study was significantly lower in patients with high BP. Moreover, patients who maintained a normal SBP throughout the study had a significantly higher final GFR than those who were hypertensive both times (330).

In the adult renal transplant population, HTN has been linked with accelerated graft failure (331, 332). The same associations have been observed among pediatric recipients. Sorof et al. reviewed NAPRTCS data and showed higher graft failure associated with the use of antihypertensive medications (333). SBP has been found to be an independent predictor of renal function at 1-year post-transplant (334) while increases in both DBP and SBP have been linked to worsening graft survival (291). Two different studies, however, failed to reveal any relationship between graft dysfunction and ABPM measures (327, 335, 336).

Conclusion

During the last decade there have been increasing interest and progress in the field of HTN in children and adolescents. Recent accomplishments include the development of normative data, updated clinical practice guidelines, knowledge of the prevalence of HTN in association with obesity, widespread use of ABPM, and newly applied techniques to detect early target organ damage. Future studies should aim at defining HTN in relation to target organ damage. For this goal, it may be necessary to establish the role of ABPM and home BP measurement in predicting early target organ damage. The efficient way of detecting children with high BP should also be sought. At present, population-based screening of HTN in the pediatric age group is not recommended (337). While routine measurement of BP in the clinic is performed in the Unite States, it is not the case in many other countries. Even in the United States, a large number of children with HTN and prehypertension are undiagnosed (5). Finally, large population-based studies are needed to investigate whether various intervention methods prevent the development of HTN.

61 Pathophysiology of Hypertension

Ikuyo Yamaguchi · Joseph T. Flynn

Introduction

Blood pressure can fundamentally be viewed as a function of cardiac output (CO) and systemic vascular resistance. Cardiac output depends on cardiac stroke volume and heart rate. Stroke volume in turn depends on myocontractility and preload. Systemic vascular resistance is dependent on vessel elasticity, myocontractility and afterload. Recent research has begun to unravel relationships at the cellular and molecular levels that exert important effects on blood pressure. The endothelium, intima, vascular smooth muscle and extracellular matrix interact with each other and with vasomotor, growth factors, transcriptional, hormonal and neuronal factors that affect signal transduction, gene transcription, ion transport, tissue remodeling and cellular response, all in the context of the patient's genetic background.

As will be discussed, derangements in any of these myriad processes can influence either cardiac output or systemic vascular resistance, thereby leading to the development of hypertension.

Mechanisms of Blood Pressure Regulation

Cardiac Output

Since the mean arterial blood pressure (MAP) is a function of cardiac output (CO) and systemic vascular resistance (SVR), hypertension is fundamentally a hemodynamic disorder indicating a disturbance in CO and/or SVR. CO is a function of stroke volume (SV) and heart rate (HR). The preload of cardiac myocytes determines SV, and HR is regulated by the sympathetic nervous system (SNS), as well as by the cardiac autonomic pacemaker. The SNS receives homeostatic feedback from baroreceptor/chemoreceptor reflexes and regulates the distribution of cardiac output over short-term. Increased SNS activity is most likely responsible for the mild tachycardia seen in many patients with primary hypertension (1).

Cardiac Index (CI) is a function of CO and body surface area (BSA). Young patients with mild hypertension have significantly higher CO, CI, and sympathetic nerve burst frequency than age-matched controls (1). Increased muscle sympathetic nerve activity also appears to be involved in development of complications of primary hypertension such as left ventricular hypertrophy (2). In borderline HTN, CI and HR are higher, and calculated SVR is normal (3). However, in nearly all forms of established HTN, SVR is increased and CO is reduced. Moreover, in progressive hypertension, a further increase in SVR occurs and CO continues to fall, indicating reduced vascular compliance (4).

However, it is clear that not all hypertensive patients start out with a state of increased cardiac output. In some patients, hypertension may develop because of an increased SVR. In addition, some patients may develop hypertension because of primary renal disease or a genetic defect that increases circulating blood volume through sodium retention.

Systemic Vascular Resistance/Vascular Wall

When the cross-sectional area of a vessel decreases, resistance to flow increases. This makes systemic vascular resistance mainly a function of small, peripheral arterioles, whose medial layer characteristically increases in response to sustained hypertension. The earliest structural change observed in the arterioles of experimental animals after the onset of hypertension is thickening of the media due to matrix deposition, smooth muscle cell hypertrophy (increase in cell size without division), and hyperplasia (increase in cell number) (5). The medial smooth muscle cells then rearrange themselves to create a smaller lumen without change in cell number or size, a process that has been termed remodeling. Later, there may be development of a neointima with appearance of smooth muscle cells inside the internal elastic lamina. There are also local areas of endothelial cell denudation and inflammatory cell infiltration, which can progress to atherosclerotic plaque formation (6). Finally, there may be resorption and loss of blood vessels in the periphery, a process termed "rarefaction," which has been described in both the early and later stages of hypertension (7).

© Springer-Verlag Berlin Heidelberg 2009

In larger vessels, the content of elastin and collagen in the media increases and the number of smooth muscle cells decreases (via medial atrophy, necrosis, or apoptosis) (8), leading to a loss of elasticity and the development of increased vessel "stiffness." Significant increases in the size and number of vasa vasorum (tiny vessels in the adventitia that supply nutrients and oxygen to the deeper layers of the media) can be observed in larger, conduit vessels, which is probably an adaptive process in the sense that the increased smooth muscle cell mass in the hypertensive vessel wall requires more oxygen and nutrients. In summary, the hypertensive vessel wall is generally characterized by increased medial thickness or an increased media/lumen ratio of the resistance arterioles. This structural change is biomechanically adaptive because wall stress is normalized as defined by Laplace's law, but functionally, this means that there is greater resistance for a given contractile stimulus (9).

Altered vascular structure in hypertension is also accompanied by functional changes in the cellular components of the vessel wall, specifically decreased relaxation and increased contraction (9). Decreased relaxation has been attributed primarily to endothelial dysfunction, and increased contraction has been attributed to enhanced smooth muscle cell vasoreactivity. Sensitivity to vasoconstrictors may also be increased (7). Decreased relaxation is an effect of impaired endothelial production of vasodilatory substances (mainly nitric oxide and prostacyclin) or increased production of vasoconstricting substances (endothelin, PDGF), or both.

Increased smooth muscle cell responsiveness is caused by alterations in the ability of vasodilating substances to exert their effects, changes in the ability of smooth muscle cells to respond to vasodilators, increased responsiveness to vasoconstrictors because of increased numbers of receptors or an augmented contractile machinery, or all of the above. Moreover, vasoconstrictors frequently stimulate smooth muscle cell growth and, conversely, many growth factors have vasoconstrictor activity (i.e., PDGF is a vasoconstrictor (10) and angiotensin II is a potent smooth muscle cell growth factor (11). These functional alterations act in concert with the structural changes discussed above to perpetuate hypertension (12), emphasizing the importance of the vasculature in the pathogenesis of hypertension.

Sympathetic Innervation/CNS

Renal vessels, tubules, and the juxtaglomerular apparatus are innervated by the renal sympathetic nerves (13). Renal sympathetic nerve activity (RSNA) influences renal hemodynamics, solute and water handling, and hormonal release. Increased RSNA is found in animal models of hypertension and also in hypertensive humans (14). Sympathetic nervous system activation, as confirmed by increased circulating noradrenaline, muscle sympathetic nerve traffic and systemic noradrenaline spillover, is almost universally present in primary hypertension (15, 16), and has been recently demonstrated in patients with renovascular hypertension (17). It appears to be particularly pronounced in younger patients (16). Renal denervation prevents or alleviates hypertension in virtually all animal models of hypertension.

Increased RSNA constricts the renal vasculature, and decreases GFR and renal blood flow (18). The hypertensive response to chronic renal adrenergic stimulation is associated with a sustained increase in plasma renin activity, and is dependent on an increase in plasma angiotensin II (ANGII) concentration (19). Sympathetic nerve activation appears to enhance the response to circulating angiotensin II (20). The renal effects of ANG II on proximal tubular chloride and water reabsorption are decreased by 75% in animals after experimental renal denervation. Thus only about 25% of ANGII effect is mediated directly via type-1 angiotensin receptors, with the majority of the effect being dependent on intact renal innervation. In experimental renal sympathetic nerve stimulation, ANG II enhanced renal venous outflow of norepinephrine, an effect that was blocked by an ANG II receptor antagonist (21). This clearly demonstrates the connection between RSNA and ANG II, and suggests that ANG II exerts a peripheral, pre-synaptic action on renal sympathetic nerve terminals in renal tubular epithelial cells and vessels to enhance the release of norepinephrine (22).

Circadian Rhythm

The circadian rhythm is an intrinsic 24-h cycle that affects numerous physiologic processes. Vascular tone, systemic vascular resistance (SVR), heart rate, and blood pressure (BP) increase in the early morning hours in both normotensive and hypertensive subjects. This rise corresponds to increased plasma renin activity and a surge in secretion of catecholamines. BP reaches its peak at approximately 9 A.M., and falls to its lowest at 3 A.M. A significant rise in BP occurs prior to awakening. Diurnal variation of BP has been clearly demonstrated in normotensive children (23); in hypertensive children, data suggest that diurnal variation is preserved in children with primary hypertension but is abnormal in those with secondary forms of

hypertension (24). Animals with disordered circadian variation due to point mutation in the circadian regulatory gene develop cardiomyopathy and renal disease (25) and human patients with blunted blood pressure dipping have increased rates of cardiovascular events such as stroke and myocardial infarction (26).

The circadian pacemaker in mammals is located in the suprachiasmatic nucleus (SCN) of the brain, which is itself located in the anterior hypothalamus, immediately above the optic chiasm (27). It receives input about light/dark cycles from the retina via the retino-hypothalamic tract, and produces several neuropeptides, including vasopressin and vasoactive intestinal peptide (VIP), that appear to have diurnal peaks of expression and release (28). Animal experiments have demonstrated that the SNC is linked to multiple sympathetic pathways that affect many components of the cardiovascular system (29). It plays a crucial role in synchronizing the peripheral oscillators that are found in all tissues, including VSMCs and the aorta, and in the execution of rhythmic behavior. The primary mediator of SCN action appears to be melatonin, which is secreted by the pineal gland under control of the SCN. Melatonin appears to transmit information about light/dark cycles from the SCN to the peripheral oscillators as well as to other centers in the hypothalamus that regulate cardiovascular activity (29, 30).

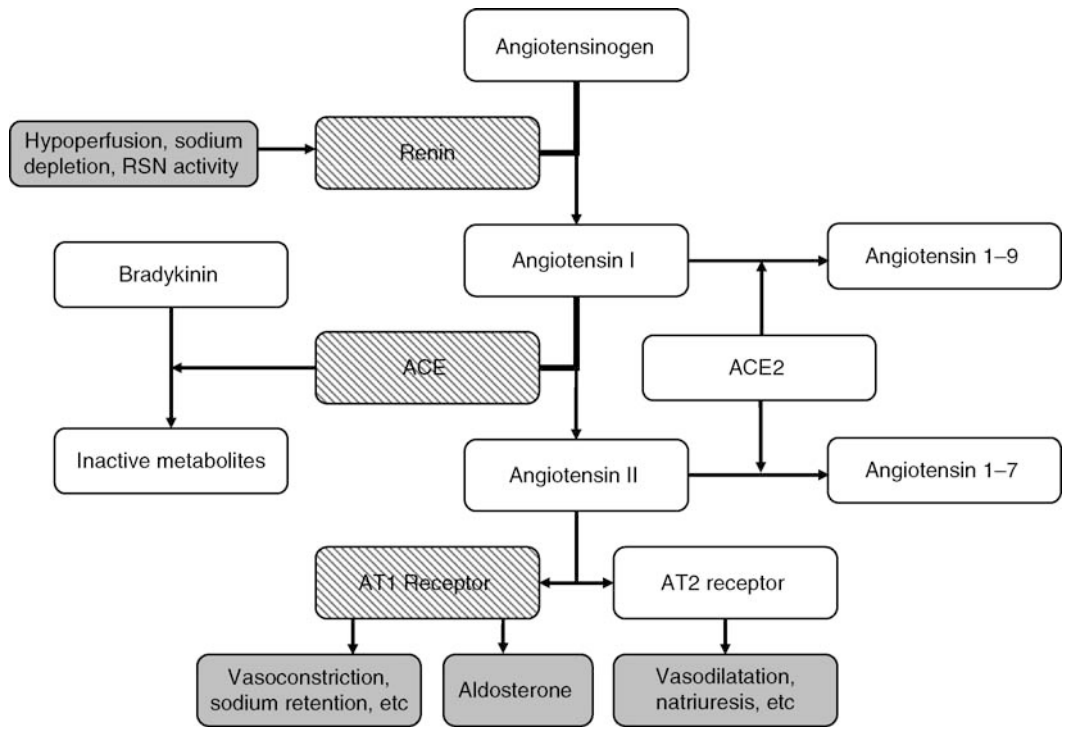
Supporting evidence for the role of the SNC and melatonin in blood pressure regulation comes from studies demonstrating that melatonin levels are decreased in hypertensive individuals, and that administration of melatonin lowers blood pressure (29). Autopsy studies of patients with primary hypertension have demonstrated that SCN neuronal populations responsible for producing vasopressin and VIP are reduced, suggesting that in at least some individuals with hypertension, normal function of the intrinsic biologic clock is impaired (31). Melatonin appears to modulate activity of the sympathetic nervous system, has antioxidant activity and may prevent endothelial dysfunction (32).

Renin–Angiotensin System

The renin–angiotensin system (RAS) (*Fig. 61-1*) is the major hormonal system affecting blood pressure. Renin, the first active molecule in the RAS, is produced in the

Figure 61-1

Renin–angiotensin system. Current targets of antihypertensive medications are indicated in *red*. *ACE* angiotensin converting enzyme; *ACE2* angiotensin converting enzyme-2; *AT1* angiotensin II type 1; *AT2* angiotensin II type 2; *RSN* renal sympathetic nerve.



juxtaglomerular cells of the afferent renal arteriole in a series of steps: following transcription of preprorenin in the cell nucleus, prorenin is further processed in the endoplasmic reticulum then packaged into secretory granules by the Golgi apparatus, where a portion appears to be converted into active renin (33, 34). Extra-renal sites of prorenin to renin conversion undoubtedly exist, as both prorenin and renin are released when the juxtaglomerular cells are stimulated. Until recently, it was thought that prorenin had no intrinsic activity. However, that view is now changing with discovery of the prorenin receptor, described below.

Major stimuli for secretion of renin from the juxtaglomerular apparatus include glomerular underperfusion or reduced sodium intake, and activity of the sympathetic nervous system. Except for renin, all the components of a local vascular wall renin–angiotensin system appear to be present in normal vessels (35), and their activity is dynamically regulated. In the classical systemic RAS, circulating renal-derived renin cleaves hepatic-derived angiotensinogen to form the decapeptide angiotensin I (ANG I), which is converted by angiotensin-converting enzyme (ACE) in the lungs to the major active component of the RAS, angiotensin II (ANG II). ACE also degrades bradykinin, a potent vasodilator, into inactive metabolites. ACE exists in plasma, in the interstitium, and intracellularly. Tissue ACE is present in all major organs, including the heart, brain, blood vessels, adrenals, kidney, liver, and reproductive organs (36), and is already functional in utero (37).

A homologue of the angiotensin converting enzyme, termed ACE2, has been recently discovered (38). ACE2 hydrolyzes ANG I to angiotensin 1–9 and ANG II to angiotensin 1–7 (*Fig. 61-1*). The functions of angiotensin 1–9 are not completely understood but angiotensin 1–7 has vasodilatory effects (39). ACE2 was initially found in heart, kidney, and testis, as well as the lungs, colon, small intestine, and ovary (40). Reduced ACE2 levels could contribute to the pathogenesis of primary hypertension via impaired degradation of ANG II, and reduced formation of vasodilator by-products at the level of the renal endothelium (41). Alterations in ACE2 activity have also been shown to have a potential role in the development of diabetic nephropathy in animal models (40).

ANG II is a potent vasoconstrictor and thus increases blood pressure. It also stimulates the release of aldosterone from the zona glomerulosa of the adrenal gland, which results in a further rise in blood pressure from aldosterone-mediated sodium and water retention. In addition, it plays an important physiologic role in the regulation of sympathetic nervous activity and the thirst response. The varied effects of ANGII in hypertension provide the physiologic foundation for the use of angiotensin converting enzyme inhibitors and angiotensin II receptor antagonists in the treatment of patients with hypertension.

ANG II effects are primarily mediated through the plasma membrane receptors AT1 and AT2 (*Fig. 61-1*). The AT1 receptor is composed of 359 amino acids and belongs to the seven-membrane-spanning G protein-coupled receptor family (42, 43). In rodents, the AT1 receptor has two functionally distinct subtypes, AT1A and AT1B, with >95% amino acid sequence homology (44). The human AT1 receptor gene has been mapped to chromosome 3 (45). Expression of the AT1 receptor is a subject to "negative feedback" by ANG II (46). AT1 receptor activation stimulates vasoconstriction, vascular cell hypertrophy and hyperplasia, sodium retention, reactive oxygen species generation via NADPH induction (47) and induction of inflammatory (48), thrombotic (49), and fibrotic processes (50). Some of the pathophysiologic effects of ANG II may be mediated through activation of the transcription factor nuclear factor-B (NF-B) (51), which participates in a variety of inflammatory responses (52).

Independently of its effect on blood pressure, ANG II via its interaction with the AT1 receptor contributes to left ventricular remodeling, alterations in the morphology and mechanical properties of the vasculature, and the development of endothelial dysfunction (53, 54). Many polymorphisms of the AT1 receptor gene have been identified, but the A1166 → C polymorphism has been the most extensively studied. It has been associated with the development of primary hypertension in various populations (55).

The AT2 receptor is a seven-transmembrane-type, G protein-coupled receptor comprising 363 amino acids. It has low amino acid sequence homology (~34%) with AT1A or AT1B receptors (42, 43). The expression of the AT2 receptor is upregulated by sodium depletion (56) and is inhibited by ANG II and growth factors such as PDGF and EGF (57). Under physiologic conditions, the AT2 receptor mainly antagonizes AT1-mediated actions (58) by inhibiting cell growth and by inducing apoptosis and vasodilatation (59, 60). Cardiovascular effects of the AT2 receptor appear to be opposite to those of the AT1 receptor (61). In the kidney, stimulation of the AT2 receptor promotes natriuresis through interactions with the renal dopaminergic system (62). It also has proinflammatory effects, via induction of NF-B (51), and trophic effects, leading to vascular (63) and cardiac (64) hypertrophy. The functions of the AT1 and AT2 receptors are summarized and compared in *Table 61-1*.

Table 61-1
Comparison of the effects of AT1 and AT2 receptors

AT1	AT2
Vasoconstriction	Vasodilatation
Tubular sodium reabsorption	Natriuresis
Aldoseterone, endothelin and vasopressin secretion	Nitric oxide production
Cellular dedifferentiation, proliferation and hypertrophy	Cellular differentiation
Sympathetic nervous system activation	Inhibition of cellular proliferation and matrix formation
Thrombosis, inflammation and fibrosis	Apoptosis
Superoxide production	Collagen synthesis
Lipid peroxidation	Suppression of renin secretion
Adhesion molecule expression Vascular matrix expansion	Anti-angiogenesis

ANG II also acts centrally on brainstem nuclei that are important in the control of peripheral sympathetic vasomotor tone, e.g., the rostral ventrolateral medulla of the hypothalamus (RVLM) (65). Since circulating ANG II is not able to cross the blood–brain barrier, it acts on circumventricular organs in which the normal blood–brain barrier is lacking. Those consist of the subfornical organ (SFO), the organum vasculosum of the lamina terminalis (OVLT), the median eminence, and the area postrema (AP) (66). Activation of the AP by circulating ANG II may in turn increase peripheral sympathetic nerve activity via a direct excitatory connection from the AP to the RVLM. Experimental microinjection of ANG II into the RVLM results in increases in arterial pressure (67) and peripheral sympathetic nerve activity (68), and facilitates arterial baroreflex modulation of RSNA (69). All those effects are blocked by AT1, but not by AT2 receptor antagonists (70). Moreover, the RVLM contains ANG II immunoreactive nerve terminals, AT1 receptor mRNA and AT1 receptor binding sites (71). This suggests that angiotensin peptides of brain origin may have a local paracrine or autocrine action on the RVLM that regulates RSNA and its arterial baroreflex control.

As mentioned earlier, both prorenin and renin are secreted by the juxtaglomerular cells. Prorenin has no intrinsic enzymatic activity due to the presence of a 43-amino acid N-terminal propeptide that covers the enzymatic cleft, obstructing access of angiotensinogen to the active site of renin (34). However, prorenin may have a role in the development of hypertension through its interactions with the prorenin receptor, which is found on the surface of vascular smooth muscle cells and the distal tubule, among other locations (72, 73). The prorenin receptor activates prorenin, resulting in generation of angiotensin I from angiotensinogen (34). Rats overexpressing the prorenin receptor develop hypertension, glomerular sclerosis and proteinuria and have elevated aldosterone concentrations (72). The prorenin receptor may explain some of the local/vascular effects of the RAS, and its existence and actions have been put forward as an explanation for the "renin escape" phenomenon seen in patients treated with agents affecting the RAS. Further research will be needed to fully define the role of prorenin and the prorenin receptor in the pathogenesis of hypertension.

Aldosterone

Aldosterone is produced from deoxycorticosterone by the mitochondrial enzyme CYP11B2 (aldosterone synthase) encoded by the CYP11B2 gene (74). As discussed later, mutations in the CYP11B2 gene lead to glucocorticoid-remediable aldosteronism, a genetic form of hypertension. Aldosterone synthase is expressed in the zona glomerulosa of the adrenal glands, aorta, endothelial cells and vascular smooth muscle cells (VSMCs), hypothalamus, hippocampus, amygdala, cerebrum, and cerebellum (75, 76). Angiotensin II and III (ANG II, ANG III) induce aldosterone synthesis and potassium, endothelin, adrenocorticotropic hormone (ACTH) and vasopressin stimulate its secretion (77). Inhibitors of aldosterone secretion include atrial natriuretic peptide, somatostatin and dopamine. Dietary sodium restriction increases aldosterone secretion in order to restore plasma volume.

Aldosterone acts via intracellular, high-affinity type I mineralocorticoid receptors that are present in the kidney, brain, heart, colon and vessel walls (78). Aldosterone induces retention of sodium and potassium excretion. It also activates the sympathetic nervous system by preventing the uptake of norepinephrine by the myocardium and causes baroreceptor dysfunction (79, 80) and eventually myocardial and vascular fibrosis (81). The importance of aldosterone in hypertension and cardiovascular disease is highlighted by recent studies demonstrating that the aldosterone receptor antagonists spironolactone and eplerenone improve endothelial dysfunction and resistance artery stiffness, increase nitric oxide bioactivity in chronic heart and renal failure, reduce cardiac fibrosis

and prevent the development of nephrosclerosis and cerebrovascular lesions (82–85).

Dopamine

Dopamine is an important modulator of systemic blood pressure with direct actions on the heart, arteries and veins. Dopamine is synthesized in noradrenergic and dopaminergic nerves, and also in non-neural tissues (e.g., kidney, gastrointestinal tract) (86). Five dopamine receptor sub-types have been identified, which can be divided in to D1-like and D2-like (87). Dopamine modulates renal epithelial transport, and gastrointestinal sodium uptake (88). It can indirectly modulate blood pressure via release of hormones and humoral agents such as aldosterone, catecholamines, endothelin, prolactin, pro-opiomelanocortin, renin, and vasopressin (89). Dopamine modulates fluid and sodium intake via "appetite" centers in the brain (90), and in addition, controls blood pressure by direct action on neuronal cardiovascular centers.

Dopamine increases cardiac output by stimulating myocardial b-adrenergic receptors, and plays an important role in modulating vascular smooth muscle tone. Stimulation of D1 and D5 dopamine receptors, which are expressed in vascular smooth muscle cells, can cause vasorelaxation, whereas stimulation of D3 receptors produces either vasodilatation or vasoconstriction, depending on the degree of renal nerve activity (87). These properties of the dopamine receptors are illustrated by the drug fenoldopam, an intravenously administered antihypertensive agent, which lowers blood pressure by stimulation of peripheral D1 receptors (91). At extremely high concentrations, dopamine produces vasoconstriction by occupation of a1-adrenergic receptors (92). Dopaminergic blockade is associated with the development of hypertension in rats and potentiates the renal effects of nitric oxide inhibition in humans (93).

Moreover, dopamine also regulates the expression of other receptors involved in BP regulation (e.g., endothelin-B, AT1). Both D1- and D2-like receptors downregulate AT1 receptor expression and function (94). Disruption of the D3 receptor gene in mice is associated with renin-dependent hypertension and a decreased ability to excrete an acute saline load (95). Aberrant dopaminergic regulation of aldosterone secretion (via D3 receptors) may be involved in some forms of hyperaldosteronism and hypertension (96, 97).

Interindividual variation in systolic blood pressure has been shown in one study to be influenced by the activity of the gene that encodes the type 1A dopamine receptor (98). A polymorphism in the noncoding region of the D1 receptor has been reported to be associated with human essential hypertension (99). Several D2 receptor polymorphisms have been reported, one of which is associated with hypertension (100). It is notable that all of the dopamine receptor subtypes identified to date have some effect on renal sodium handling (87). Recent studies have demonstrated that genetic variation in the dopamine D1 receptor promoter are correlated with renal sodium handling and blood pressure (101). These data support the concept that dopamine may result in human hypertension through altered renal sodium handling.

Atrial Natriuretic Peptide

Atrial natriuretic peptide (ANP) belongs to a family of natriuretic peptides that also includes the B-type (BNP) and the C-type (CNP) natriuretic peptides (102). The biological functions of BNP and CNP do not differ from those of ANP. ANP is involved in regulation of salt and water balance, blood pressure homeostasis, and has an antiproliferative effect at the cellular level in the cardiovascular system (103–105). ANP is primarily expressed in cardiac myocytes, but is also found in brain, vessels and kidneys. ANP has potent diuretic, natriuretic and vasorelaxant effects. In the kidney, ANP increases glomerular filtration rate (GFR) through vasodilatation of the afferent arteriole and vasoconstriction of the efferent arteriole (106), and promotes natriuresis by inhibiting tubular sodium reabsorption (107, 108) and renin and aldosterone biosynthesis (109, 110).

The combined systemic hemodynamic effects of ANP result in reduction of both preload and afterload (111, 112). Administration of endogenous ANP results in a significant decrease of blood pressure in man and in animal models of hypertension by reducing systemic vascular resistance (106, 113). At high plasma levels, ANP decreases heart rate, central venous pressure and stroke volume (114).

Mutations in the ANP gene appear to be associated with the development of hypertension in humans. A significant association has been demonstrated between an intronic variant of the ANP gene (HpaII) and salt-sensitive hypertension in African-Americans (115). A mutation located within the 5′ untranslated region of the ANP gene has been linked with the occurrence of both hypertension and left ventricular hypertrophy in a Japanese population (116). In mice, absence of corin, a transmembrane serine protease that converts pro-atrial natriuretic peptide (pro-ANP) to active ANP, results in salt-sensitive hypertension (117).

Endothelin-1

Endothelin-1 (ET-1) is an endothelial-derived, potent vasoconstrictive peptide containing 21 amino acids (118). Three isopeptides of endothelin (ET-1, ET-2, ET-3), encoded by separate genes, have been identified (119). Endothelial ET-1 synthesis is activated by vasoactive hormones, growth factors, hypoxia, shear stress, lipoproteins, free radicals, endotoxin and cyclosporine, and is inhibited by nitric oxide, natriuretic peptides, heparin and prostaglandins (120). Apart from endothelial cells, ET-1 is also produced by the heart, kidney, posterior pituitary, central nervous system, and vascular smooth muscle cells (120). ET-2 is produced in endothelial cells, heart and kidney (121), but it has not been detected in human plasma. ET-3 is selectively expressed in the endocrine, gastrointestinal and central nervous systems, but not in endothelial cells (122).

ET-1 primarily appears to be a locally acting paracrine substance. ET-1 closes membrane K^+ channels (123), which prevents efflux of K^+ from the cell, thereby favoring membrane depolarization, leading to smooth muscle cell contraction. In the kidney, ET-1 causes contraction of both afferent and efferent glomerular arterioles, thereby reducing both renal plasma flow and glomerular filtration rate (124, 125). It blocks reabsorption of sodium by inhibiting tubular Na^+/K^+-ATPase activity in the proximal tubule and collecting duct (126). Endothelin-1 inhibits release of renin from isolated rat glomeruli (127) but stimulates release of aldosterone from isolated cortical zona glomerulosa cells (128). ET-1 also stimulates production and release of atrial natriuretic peptide (ANP) by cultured atrial myocytes (129).

Endothelin signals through two receptor subtypes, ETA and ETB. The ETA receptor is preferentially activated by ET-1 but not by ET-3, whereas the ETB receptor is activated equally by ET-1 and ET-3 (130, 131). The overall cardiovascular effect of endogenous ET-1 depends on the balance between ETA- and ETB-mediated effects. Activation of vascular smooth muscle ETA receptors causes vasoconstriction and tends to elevate blood pressure, while activation of endothelial and renal ETB receptors promotes vasodilatation and natriuresis and tends to decrease blood pressure (132). ETB knockout mice have hypertension secondary to renal sodium retention and there is evidence of marked enhancement of vascular expression of ET-1 in salt-sensitive hypertensive rat models (133). ET-1 appears to potentiate sympathetically mediated vasoconstriction only in hypertensive and not normotensive subjects (134).

Hypertensive patients with normal renal function-have similar concentrations of immunoreactive E-1 as normotensive patients (135); however, plasma concentrations of ET-1 are raised in patients with accelerated hypertension, in which case they are positively correlated with creatinine clearance (136). Plasma concentrations of ET-1 in patients with chronic renal failure are 1- to 2-fold greater than normal, whereas values in those undergoing hemodialysis are 2- to 4-fold greater than normal (137). In renal transplant patients, production of ET-1 is stimulated by cyclosporine A (138), which also increases the number of renal ET-1 binding sites (139). Tacrolimus also appears to increase secretion of ET-1 in vitro (140). These findings suggest that endothelin may be involved in the pathogenesis of calcineurin-induced hypertension.

Genetic variation in ET-1 expression may be involved in the pathogenesis of essential hypertension. African-Americans with hypertension have much higher concentrations of immunoreactive endothelin than do Caucasians (141). There is also strong correlation between diastolic blood pressure and polymorphisms of the ET-1 precursor pre-proendothelin-1 between patients with essential hypertension and normotensive controls (142). Recently an association between the G/T genotype of the ET-1 gene was demonstrated in a population of obese adolescents, suggesting a possible role for polymorphisms in the ET-1 gene in the development of obesity hypertension in the young (143).

Nitric Oxide, Adenosine

Nitric oxide (NO) is an endothelium-derived gas, synthesized from the amino acid L-arginine by the endothelial isoform of nitric oxide synthase (NOS) (144). Nitric oxide is extremely labile, with a half-life of <4 s in biological solutions. It is rapidly oxidized to nitrite and then nitrate by oxygenated hemoglobin before being excreted by the kidneys (144). Synthesized nitric oxide diffuses across the endothelial cell membrane and enters vascular smooth muscle cells, activating guanylate cyclase, leading to production of the second messenger cyclic guanosine-3′,5-monophosphate (cGMP) (144). cGMP in turn mediates control of vascular tone and platelet function.

Nitric oxide is a vasodilator, and the balance between nitric oxide and various endothelium-derived vasoconstrictors and the sympathetic nervous system maintains physiologic blood vessel tone (145). In addition, nitric oxide suppresses platelet aggregation, leukocyte migration, and cellular adhesion to the endothelium. It attenuates vascular smooth muscle cell proliferation and migration, as well as inhibits activation and expression

of certain adhesion molecules, and has an influence on production of superoxide anion.

Endothelium-dependent relaxation is decreased in patients with essential hypertension (146) and appears to be related to defective L-arginine transport. Similar abnormalities have been found in normotensive subjects with a family history of hypertension (147). Treatment with inhibitors of nitric oxide synthesis induces a hypertensive response, while L-arginine treatment prevents the development of hypertension in animals prone to this disease (148), and also causes a rapid reduction in systolic and diastolic pressures when infused into healthy humans and patients with essential hypertension (149). Methylated L-arginine derivatives, including NG-NG-dimethylarginine (asymmetric dimethylarginine (ADMA)), an endogenous inhibitor of nitric oxide synthase, and symmetric dimethylarginine, its inactive isomer, are present in human plasma and urine. Elevated levels of ADMA and other markers of oxidative stress have been demonstrated in patients with primary hypertension and have been postulated to contribute to the endothelial dysfunction that accompanies hypertension (150).

Adenosine is produced from the hydrolysis of adenosine 5′-monophosphate (AMP) by 5′-nucleotidase (5′-ND) (151, 152). In the kidney, it regulates GFR, tubuloglomerular feedback (TGF), tubular reabsorption, and renin secretion. Adenosine acts via several cell surface receptors that have been designated A1, A2A, A2B, A3, A4, all of which differentially stimulate or inhibit the production of cyclic adenosine-3′,5′-monophosphate. Selective A1 antagonists lead to diuresis and natriuresis and uncouple glomerular filtration and tubular reabsorption (153). A2A and A2B receptors have been described on vascular smooth muscle cells and the endothelium, where they are associated with vasodilatation (153). A2A knockout mice have increased blood pressure and heart rate, and increased platelet aggregation (154).

Other Regulatory Hormones

Thyroid hormone plays an important role in the regulation of blood pressure. Administration of exogenous thyroid hormone results in a decrease in systemic vascular resistance, which in turn results in renin release, activation of the angiotensin–aldosterone axis, increase in renal sodium reabsorption, increase in intravascular volume, cardiac output and cardiac contractility. Thyroid hormone also stimulates erythropoietin secretion (155). Triiodothyronine (T3) acts directly on arterioles (VSMC) and promotes relaxation and vasodilatation by local heat production, and β2-receptor stimulation (156).

T3 enters the cell by a specific transporter and forms a complex with nuclear T3 receptors. This complex binds to thyroid hormone response elements of several genes and regulates their transcription. Genes upregulated by T3 include adrenergic receptors, Na^+/K^+-ATPase, and voltage-gated potassium channels, among others. Genes downregulated by T3 include those for the Na^+/Ca^{2+} exchanger, adenyl cyclase types V and VI, and the T3 nuclear receptor. In the short term, T3 modulates sodium, potassium, and calcium channels activities in the heart that leads into changes in intracellular calcium and potassium with subsequent increase in inotropy and chronotropy (157). Increased heart rate, widened pulse pressure, and increased cardiac output despite normal or low serum concentrations of catecholamines is a characteristic feature of patients with hyperthyroidism (158).

Adrenomedullin peptide (ADM), a 52-amino acid peptide, has been found in the adrenal medulla, cardiac atrium, lung and kidney. In the kidney, ADM is found in glomeruli, cortical distal tubules, and medullary collecting duct cells (159, 160). ADM is also secreted from endothelial cells and vascular smooth muscle cells (161). ADM leads to vasodilatation, natriuresis, diuresis, inhibition of aldosterone production, and enhancement of tumor cell growth (162, 163). Increased levels of ADM have been documented in patients with high-renin primary hypertension (164), and variations in the 19-repeat allele of the human ADM gene have been postulated to be involved in the pathogenesis of hypertension and diabetic nephropathy (165).

Renal Mechanisms

The kidneys have the ability to respond to changes in arterial pressure by altering the renal excretion of salt and water; increases in renal perfusion pressure lead to decreases in sodium reabsorption and increases in sodium excretion (pressure natriuresis) (166). The intrarenal mechanism of pressure natriuresis is related to medullary blood flow, renal interstitial hydrostatic pressure (RIHP), and renal autocoids (nitric oxide, prostaglandins, kinins, and angiotensin II). Increased renal perfusion pressure is associated with increases in RIHP, nitric oxide, prostaglandin E2, and kinins, and a decrease in angiotensin II (166–169). Increased blood flow to the renal medulla, which normally receives only 5–10% of the total renal blood flow, contributes to washout of the urea gradient. This results in an increase of renal interstitial fluid

pressure, which in turn reduces tubular reabsorption of sodium and water, leading to a natriuresis and diuresis, lowering blood pressure (170). Norepinephrine infused into the renal medulla results in a pressure naturesis and arterial blood pressure lowering (171). This depressor response is abolished by chemical medullectomy (172), suggesting the presence of an as-yet-to-be-characterized depressor hormone in the renal medulla (173).

Renal autoregulation, or the kidney's intrinsic ability to maintain constant renal blood flow and GFR despite changes in renal perfusion pressure, serves to protect nephron function. However, major variations in renal perfusion can still influence renal excretory functions, renin release and arterial blood pressure. Autoregulation occurs in interlobular arteries, side branches of arcuate arteries, and afferent and efferent arterioles. It depends on myogenic mechanisms present in those vessels, and is blocked by the smooth muscle relaxant papaverine (174), and by calcium channel blockade (175). Tubuloglomerular feedback (TGF) also plays an important but not essential role in autoregulation (176).

Renal autoregulation is reset in animal models of spontaneous hypertension (177). ANG II plays an important role in the resetting of the autoregulation limits (178). Higher pressures are needed to trigger the vasoconstrictive response in the afferent arteriole (179), but in the intermediate portion of the interlobular artery of the spontaneously hypertensive rat, a lower threshold pressure stimulates a greater myogenic response (180). In the Dahl salt-sensitive hypertensive rat, both the afferent arterioles and the interlobular arteries have reduced myogenic responsiveness to increases in perfusion pressure (181). Studies demonstrating that abnormalities in renal autoregulation are more pronounced in patients with severe hypertension than those with moderate hypertension (182) suggest that chronic hypertension can induce alterations in renal autoregulation. Thus, disturbed renal autoregulation may contribute to the perpetuation of blood pressure elevation in patients with established hypertension.

Finally, the kidney also controls salt and water balance through regulation of the number and function of critical renal sodium transporters and channels. For example, in an animal model of primary hypertension, the Dahl salt-sensitive hypertensive rat, AngII/AVP receptor dysfunction produces hypertension through increased tubular sodium and fluid reabsorption (183). Expression of many of these proteins is influenced by aldosterone and other hormones that affect blood pressure (184, 185). As discussed later in this chapter, all monogenic forms of human hypertension described thus far can be characterized by alterations in renal ion channels leading to either increased sodium reabsorption or decreased excretion.

Primary Hypertension

Most hypertension in adults has no identifiable underlying etiology; therefore, the term "essential hypertension" has been utilized for those individuals without secondary hypertension. However, since "essential" implies that the patient's level of blood pressure is necessary in some way to maintain normal function, this term is misleading, and should be abandoned in favor of "primary" hypertension. It is likely that as our unraveling of the human genome progresses and more genetic forms of hypertension are identified (see below), fewer and fewer patients will be diagnosed with primary hypertension; for now, however, primary hypertension remains an important entity, accounting for most human hypertension.

In children, primary hypertension has long been considered uncommon, accounting for less than 25% of hypertensive children in referral series published through the early 1990s (186). However, more recent series from referral centers have demonstrated that primary hypertension in children is likely more common than previously thought, now accounting for between 48 and 69% of children referred for evaluation of elevated blood pressure, at least in the United States (187, 188). Furthermore, survey data indicate that the prevalence of hypertension in children is increasing (189), with many children developing hypertension as a manifestation of obesity (see following discussion), which is also becoming increasingly prevalent in childhood (190).

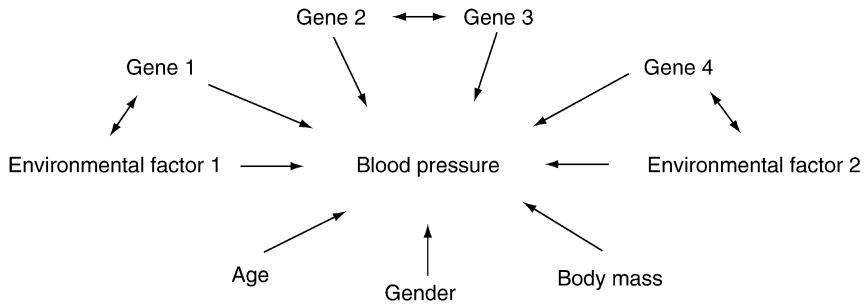
Primary hypertension is a multifactorial disorder in which elevated blood pressure is likely to be caused by different combinations of factors in different individuals (see *Fig. 61-2*). The following sections will highlight some of the more important mechanisms likely to contribute to the development of primary hypertension in children.

Genetic Influences

There is substantial evidence for genetic influence on blood pressure. Years ago, twin studies documented greater concordance of blood pressures among monozygotic than dizygotic twin (192), and population studies have demonstrated greater similarity of blood pressure within families than between families (193). Studies demonstrating a lack of correlation of blood pressure between parents

Figure 61-2

The potential interaction of these determining factors is represented by *arrows* linking different determinants. Reproduced with permission from (191).



and their adoptive children would also support the contention that blood pressure is genetically determined (194). However, despite intensive efforts over nearly three decades, the genetic basis of hypertension has not been fully elucidated thus far.

Advances in molecular genetics have led many researchers to focus on determining how genetic variation may explain blood pressure elevation in some individuals (191). Many of these studies have focused on identifying candidate genes involved in the pathogenesis of hypertension. To date, however, with the exception of the single-gene forms of hypertension discussed elsewhere in this chapter, most of these studies have failed to demonstrate how the various genetic mutations identified lead to elevated blood pressure. For example, while the studies of Jeunemaitre (195) and Inoue (196) have identified a link between polymorphisms of the angiotensinogen gene and hypertension, and while other studies have shown that angiotensinogen levels are higher in individuals with higher levels of blood pressure (197) we still do not know how these variations cause hypertension (191). The same holds true for all of the many other allelic variants identified to date in individuals with primary hypertension.

Recent studies have demonstrated that in some people, blood pressure elevation may be the result not of a single mutation, but rather the product of multiple genetic variants interacting with each other (198). Similarly, it is probable that the role of some genetic variants in the pathogenesis of primary hypertension may not be to increase blood pressure in and of themselves, but rather to increase the susceptibility of an individual to environmental factors that can elevate blood pressure (199). This would be consistent with the scheme illustrated in *Fig. 61-2*.

Clearly, although progress has been made, delineation of the pathogenesis of primary hypertension from the genetic standpoint remains incomplete. Recent mapping of the human genome, the development of new strategies and technologies in molecular genetics, including differential gene expression, expressed sequence tags and DNA biochips provide hope that the challenge of elucidating the genetic basis of primary hypertension will be met (200). However, it should be noted that although genes are likely to be involved to some extent in nearly every hypertensive individual, the genetic contribution to an individual's hypertension may not be as significant as that of other factors, such as their body habitus or their environment.

Influence of Birth Weight and Perinatal Factors

Population studies conducted by Barker and others have demonstrated an inverse correlation between birth weight and adult blood pressure (201, 202). A relationship between birth weight and coronary heart disease and type 2 diabetes has also been noted (203). Proposed explanations for these findings include deficient maternal nutrition (201, 204), possibly leading to acquisition of a reduced number of nephrons (205). Autopsy studies demonstrating a reduced number of nephrons in patients with primary hypertension (206) have added intriguing evidence to the latter hypothesis. Other investigators have demonstrated that maternal smoking during pregnancy and bottle-feeding of newborns also may lead to hypertension later in life (207, 208), thus widening the spectrum of possible influences on later blood pressure from in utero factors to postnatal factors as well.

Animal studies have generally supported the epidemiologic evidence cited above. Pregnant rats fed low protein diets bear young that are small at birth and later develop

hypertension (209). Maternal diets low in protein result in decreased nephron number as well as suppression of the renin–angiotensin system (210), leading to elevated blood pressure and reduced GFR. In addition, various pharmacologic manipulations of the fetal milieu also lead to changes in fetal renal development that promote the appearance of hypertension after birth (211), lending further credence to the theory that perinatal events have an important influence on later blood pressure.

In contradiction to the studies demonstrating an inverse relationship between birth weight and adult blood pressure, other epidemiologic studies have found that adult blood pressure is more closely related to gestational age (212) or to early childhood growth (213) than to birth weight. In addition, recent studies have shown that twins have lower systolic blood pressure than singletons despite their lower birth weights (214). These challenges to the fetal origins hypothesis indicate that further research will be needed to determine the effects of pre-and perinatal factors on future blood pressure, and also support the concept illustrated in *Fig. 61-2* that the development of primary hypertension depends on multiple factors that will vary among different individuals.

Sympathetic Nervous System Activation

The role of the sympathetic nervous system (SNS) in blood pressure regulation has been discussed in detail above. Many lines of evidence suggest that SNS activation/overactivity is the primary mechanism by which blood pressure elevation is initiated in young individuals with otherwise unexplained primary hypertension. Children with primary hypertension have been shown to have resting tachycardia compared to normotensive children (215), and resting heart rate has been found to correlate with blood pressure in large epidemiologic studies such as the Bogalusa Heart Study (216). And while this characteristic has recently been "rediscovered" in obese adolescents with primary hypertension (217), there is a large, established body of literature that links tachycardia not only with elevated blood pressure but also with increased cardiovascular risk in general (218).

Another notable manifestation of SNS activation in hypertensive children is heightened cardiovascular reactivity to stress. Early studies by Falkner demonstrated that hypertensive adolescents had significantly greater increases in heart rate, systolic BP and diastolic BP during mental stress (performance of difficult arithmetic problems) than normotensive adolescents (215). Increased cardiovascular reactivity to the cold pressor test has also been shown to predict the subsequent development of hypertension (219). An interaction between genetic factors and SNS activation is suggested by differences in the cardiovascular response to stress in children with different racial backgrounds or family histories of hypertension (220).

SNS activation in primary hypertension suggested by clinical and epidemiologic data has been confirmed experimentally. Both children and young adults with primary hypertension have elevated plasma norepinephrine levels compared to normotensives (15, 16). Elevated catecholamines are more commonly found in younger individuals with primary hypertension than older individuals (16), and in young individuals with borderline hypertension who later go on to develop more significant blood pressure elevation (221). Abnormalities in the SNS have been demonstrated in normotensive children of hypertensive parents (222), suggesting that SNS activation is not only present in prehypertensives, but may also be genetically determined.

Direct recordings of nerve activity provides additional laboratory evidence for SNS activation in primary hypertension. Increased SNS activity has been found in recordings from both peripheral and renal sympathetic nerves (223) in hypertensive individuals. Differences in patterns of sympathetic activation have been found in obese and non-obese hypertensives, with higher cardiac sympathetic activity in lean hypertensives (224). There is also evidence to suggest that SNS overactivity may be involved in the development of the vascular hypertrophy and other systemic cardiovascular effects of established hypertension (225, 226). In sum, there is strong evidence that abnormalities of SNS activity are involved in the pathogenesis of primary hypertension, especially in the early phases of blood pressure elevation, which is clearly significant as far as pediatric hypertension is concerned.

The SNS is likely also involved in the pathogenesis of white coat hypertension (WCH), in which an individual's office blood pressure readings are elevated but whose out-of-office readings are normal (227). WCH is most likely a manifestation of the "flight or fight" response; individuals with WCH are typically anxious and demonstrate a mild resting daytime tachycardia (228). There appears to be an imbalance between parasympathetic and sympathetic tone in WCH similar to that seen in established primary hypertension (229), and increased muscle sympathetic nerve activity has been demonstrated in subjects with WCH. While further investigation of the role of SNS activation in the development of WCH is needed, it is a plausible underlying mechanism.

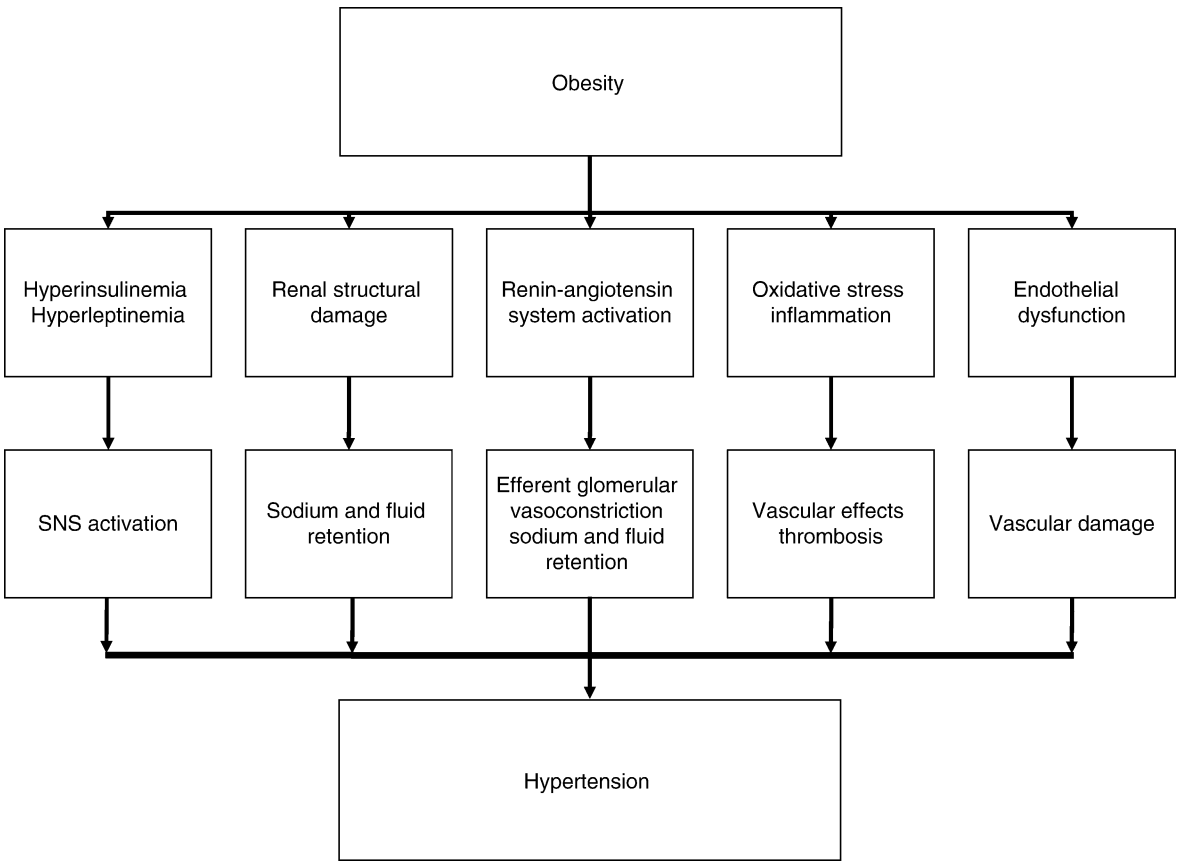
Mechanisms of Obesity Hypertension

Given the epidemic of childhood obesity (190), understanding the mechanisms of obesity hypertension is crucial for understanding the pathogenesis of hypertension in the young. While the exact mechanisms by which obesity causes hypertension remain incompletely understood, significant advances in our understanding have been made in recent years. *Fig. 61-3* presents a simplified summary of the many mechanisms of hypertension that have been demonstrated to occur in obese individuals. Selected mechanisms illustrated in the figure will be summarized in the following discussion. Others are discussed elsewhere in the chapter. Additionally, we recommend that the interested reader should consult updated reviews, as there is much active research in all of these areas.

Two major hormonal abnormalities in obesity hypertension are hyperinsulinemia, a consequence of peripheral insulin resistance, and hyperleptinemia, a consequence of the increased mass of visceral adipose tissue. Landsberg has noted that "...insulin resistance in the obese is a mechanism evolved for limiting further weight gain. Like any compensatory mechanism, however, there is a price to pay. In this situation, that price is the hyperinsulinemia and sympathetic activation which, via effects on the blood vessels, the heart and the kidneys, exerts a pro-hypertensive effect that, in susceptible individuals, causes hypertension (230)." There are several lines of evidence linking hyperinsulinemia with increased sympathetic nervous system activation and hypertension, including the finding of elevated levels of plasma catecholamines, and abrogration of hypertension after adrenergic blockade (231, 232). The hyperinsulinemia associated with insulin resistance in obese individuals probably contributes to the development of hypertension via additional mechanisms other than SNS activation, which are discussed later in the chapter.

Figure 61-3

Mechanisms of hypertension in obesity. *SNS* sympathetic nervous system.



Leptin is a peptide hormone encoded on chromosome 7 in humans and primarily produced by adipose tissue whose major function seems to be regulation of energy stores. With weight gain, leptin levels increase, leading to release of melanocyte-stimulating hormone which in turn binds to and activates the melanocortin-4 receptor which induces physiologic changes that counteract obesity (233). In obese hypertensives, leptin levels are elevated and correlate with both blood pressure and heart rate (234). The major link between hyperleptinemia and hypertension appears to be increased sympathetic nervous system activity, as demonstrated in animal studies documenting increased renal sympathetic nerve activity with intraventricular leptin infusions. Intravenous leptin infusions in animals also increase blood pressure and heart rate (234, 235). In obese humans, leptin appears to modify muscle sympathetic nerve activity as well as central SNS activity; the latter effect appears to be mediated primarily through activation of hypothalamic pathways (236, 237).

Leptin also has significant intraglomerular effects, including increased TGF-β synthesis and increased type IV collagen production by glomerular endothelial cells, and stimulation of type I collagen synthesis by mesangial cells. This, in turn, may lead to glomerular sclerosis via extracellular matrix deposition (238), perhaps contributing to or even accounting for the secondary FSGS that can be seen in obesity. Losartan treatment appears to ameliorate the renal effects of leptin in experimental animals (239).

Of the other mechanisms illustrated in *Fig. 61-3*, activation of the renin–angiotensin system and the role of inflammation and oxidative stress merit further discussion. Children with primary hypertension have been noted to have elevated plasma renin activity in single-center studies that correlate with diastolic but not systolic blood pressure (188). Similar peripheral elevations of plasma renin activity and other components of the renin–angiotensin system have been noted in obese adults (240). Elevated renin despite the presence of other mechanisms that promote volume overload (*Fig. 61-3*) point to a generalized dysregulation of the renin–angiotensin system in obesity that likely contributes not only to the development of hypertension, but also to obesity-related renal damage.

Adipose tissue is increasingly being viewed as an endocrine organ; it secretes several hormones, particularly leptin (see above) and adiponectin, and a variety of other proteins that are collectively known as adipokines. Unlike most adipokines, adiponectin expression and serum concentration are reduced in obesity (241), but there is increased expression of pro-inflammatory cytokines such as TNF-alpha and interleukin-6. This contributes to the insulin resistance seen in obesity (242), and thereby to blood pressure elevation and other adverse cardiovascular effects. Obesity is also associated with increased markers of oxidative stress such as urinary 8-epi-prostaglandin F2alpha in both experimental and population studies (243, 244).

Finally, obesity produces direct effects on the kidney that contribute to the development of hypertension (231, 245). There is compression of the kidneys by the perirenal fat, leading to increased interstitial pressure, reduced medullary blood flow and tubular compression, all of which lead to increased sodium reabsorption. Over time, hyperfiltration injury and increased glomerular transforming growth factor-beta1 expression (246) lead to glomerular sclerosis and nephron loss, further exacerbating the trend toward sodium retention, as well as activation of mechanisms operative in chronic kidney disease (CKD) such as activation of the renin–angiotensin system.

Insulin Resistance in Nonobese Hypertensives

Insulin resistance has been linked to several physiologic mechanisms that can elevate blood pressure. First and foremost among these mechanisms is likely to be an altered renal handling of sodium, leading to hypertension through an expansion of plasma volume. Insulin increases renal sodium reabsorption, possibly in the distal nephron, although this is not completely certain (247). It is likely that increased activity of renal sympathetic nerves is responsible at least in part for this effect (248). Elevated circulating levels of aldosterone, which have been demonstrated in salt-sensitive obese adolescents, may also be involved (249). Importantly, these effects of hyperinsulinemia on renal sodium handling can be reversed with weight loss (249).

The second major mechanism by which hyperinsulinemia may elevate blood pressure is through effects on vascular structure and function. Although insulin when infused directly into local vascular beds acts as a vasodilator (250), in hypertensive subjects this effect is probably offset by vasoconstriction mediated by increased sympathetic nervous activity (250, 251). In addition, impaired vasodilatation in response to insulin infusion has been demonstrated in obese individuals (252). Alternatively, insulin may act to stimulate vascular smooth muscle proliferation in resistance vessels (253), thereby leading to increased peripheral vascular resistance due to vascular medial hypertrophy. In this way, hyperinsulinemia would lead to hypertension by increasing SVR.

Not all hypertensive individuals with insulin-resistance are obese (251, 254), suggesting that insulin resistance is a primary mechanism in the development of primary hypertension. Supporting this hypothesis are studies demonstrating a significant inverse relationship between insulin-mediated glucose uptake and blood pressure levels in lean normotensive and borderline hypertensive individuals (255). The mechanisms responsible for the development of elevated blood pressure in lean individuals with insulin resistance are most likely similar to those discussed above. What remains unknown at this point is what causes insulin resistance in non-obese hypertensives (251).

Uric Acid

That serum uric acid concentrations are frequently elevated in hypertensive children and adults has been known for decades (256, 257). Serum uric acid levels have also been shown to predict the development of hypertension in community-based studies (258, 259), although other studies have failed to demonstrate that such a relationship exists (260). Given the conflicting epidemiologic data, routine measurement of uric acid levels has not been advocated in patients with hypertension, except to monitor for drug-induced hyperuricemia, which can be caused by thiazide diuretics.

However, an interesting body of work has recently emerged on a possible pathophysiologic link between uric acid and the development of hypertension. Rats given the uricase inhibitor oxonic acid developed mild hyperuricemia, elevated blood pressure, microvascular changes in the kidneys and increased expression of renin in the juxtaglomerular apparatus (261, 262). Administration of the xanthine oxidase inhibitor in the same animal model lowered serum uric acid levels and prevented the development of hypertension and vascular changes (262). The postulated mechanism for development of hypertension appears to involve endothelial dysfunction, specifically reduced levels of endothelial-derived NO (263).

Findings in this animal model appear to correlate with experimental data in humans. Uric acid levels correlate with elevated plasma renin in hypertensive adolescents (264) and with endothelial dysfunction and atherosclerosis in adults (265, 266). Lowering serum uric acid with allopurinol has been shown to improve flow-mediated dilation, an indicator of endothelial function, in patients with hyperuricemia (265), and in a recent small trial, allopurinol reduced blood pressure in adolescents with primary hypertension (267). Although further confirmatory studies are clearly required, some have speculated that uric acid-lowering strategies may find a role in the treatment and even prevention of hypertension (268).

Dietary and Environmental Influences

Numerous dietary constituents have been examined as possible contributors to the development of hypertension. Of these, the two that have received the most interest have been sodium and potassium. Population studies of sodium consumption have demonstrated that populations with lower sodium intake have lower blood pressures than those with higher sodium intake (269, 270). It is noteworthy that typically, populations with high dietary sodium intake also have lower potassium intake (269, 271), suggesting a potential pathogenic role for potassium as well. Interventional studies of sodium restriction have generally shown that reducing sodium intake lowers blood pressure in both adults (272) and children (273), whereas the data for potassium supplementation are less clear (273, 274). The "DASH" diet, which is low in sodium and saturated fats and high in potassium and calcium has been shown to be able to substantially lower blood pressure in hypertensive adults (275) as well as adolescents (276); this diet has also been advocated as a method of hypertension prevention.

However, these dietary influences on blood pressure, although present when large populations are studied, may not apply at the individual patient level (269, 277). This is because some hypertensive patients are salt-sensitive and others are not; for example, in obese hypertensives, salt sensitivity is likely present and can be reversed with weight loss (249), but lean hypertensives are less salt-sensitive. Similarly, salt sensitivity of blood pressure has been demonstrated in children with a history of low birth weight, but not in children whose birth weight was appropriate (278). The public health implications of dietary sodium restriction on a population basis cannot be ignored – a modest reduction in sodium intake resulting in a 3 mmHg reduction in systolic blood pressure has been calculated to have significant potential to reduce the incidence of stroke and other cardiovascular disease (272).

The other environmental factor felt to play a role in the development of primary hypertension is stress. Acute stress has been shown to increase blood pressure in experimental settings, most likely through activation of the sympathetic nervous system (215, 219, 220). At the population level, stress has also been advanced as an explanation for the increased incidence of hypertension among

African-Americans compared to Caucasians (279). An individual's reaction to stress may lead to other changes in their environment that are themselves related to blood pressure (280), such as obesity from increased caloric intake, which would then cause hypertension by the mechanisms discussed above.

Secondary Hypertension

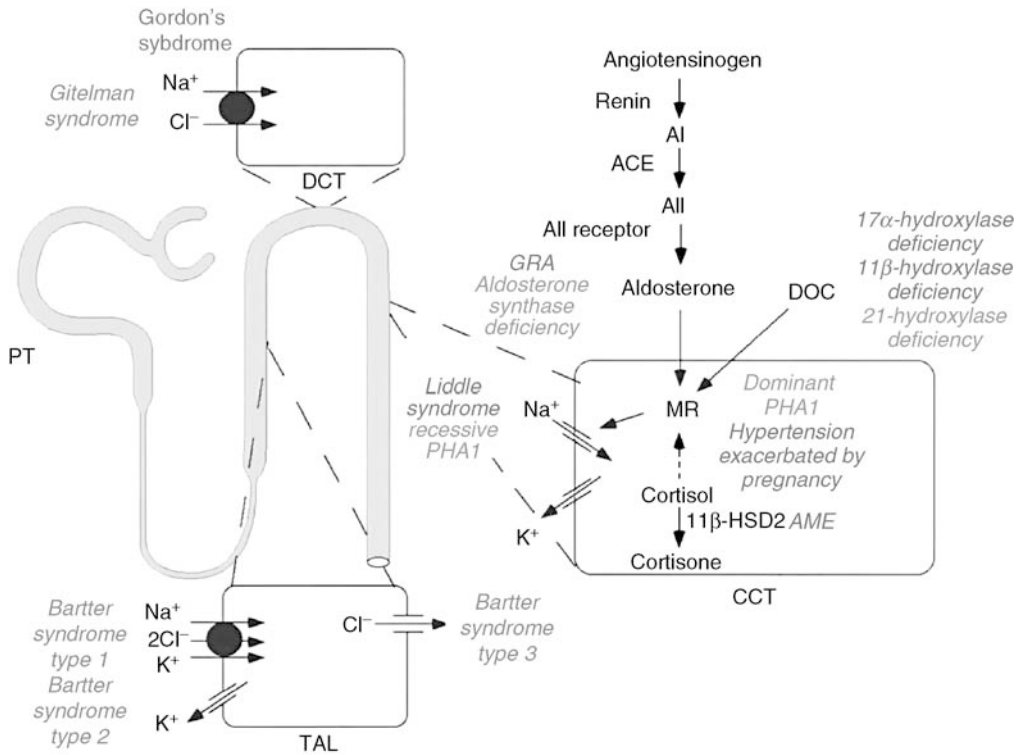
Mendelian Forms of Hypertension

Molecular genetic studies have now identified many gene mutations that affect blood pressure. Most of the mutations found to date affect sodium handling in the renal distal tubules. Below, we will mainly discuss well characterized monogenic hypertensive disorders (Fig. 61-4) (200).

Glucocorticoid-remediable aldosteronism (GRA) or *familial hyperaldosteronism type 1* (FH-I) is an autosomal dominant disease characterized by early onset of hypertension with normal or elevated aldosterone levels despite suppressed plasma renin activity (191). GRA is caused by a chimeric gene that results from unequal crossing over between the aldosterone synthase and 11β-hydroxylase genes on chromosome 8. Aldosterone synthase is the rate-limiting enzyme for aldosterone biosynthesis in the adrenal glomerulosa and 11β-hydroxylase is an enzyme involved in cortisol biosynthesis in the adrenal fasciculata whose expression is regulated by adrenocorticotropic hormone (ACTH). The resulting chimeric gene is expressed in the adrenal fasciculata and encodes a protein product with aldosterone synthase enzymatic activity whose expression is regulated by ACTH. Consequently,

Figure 61-4

Single-gene mutations altering blood pressure. A diagram of a nephron, the filtering unit of the kidney, is shown. The molecular pathways mediating NaCl reabsorption in individual renal cells in the thick ascending limb of the loop of Henle (TAL), distal convoluted tubule (DCT), and the cortical collecting tubule (CCT) are indicated, along with the pathway of the renin–angiotensin system, the major regulator of renal salt reabsorption. Inherited diseases affecting these pathways are indicated, with hypertensive disorders in *red* and hypotensive disorders in *blue*. *Abbreviations: AI* angiotensin I; *ACE* angiotensin converting enzyme; *AII* angiotensin II; *MR* mineralocorticoid receptor; *GRA* glucocorticoid-remediable aldosteronism; *PHA1* pseudohypoaldosteronism, type-1; *AME* apparent mineralocorticoid excess; *11 HSD2* 11-hydroxysteroid dehydrogenase-2; *DOC* deoxycorticosterone; *PT* proximal tubule. Reprinted and modified from (200).



aldosterone synthase activity is ectopically expressed in the adrenal fasciculata under control of ACTH rather than angiotensin II or potassium. Aldosterone secretion becomes linked to cortisol secretion, and maintenance of normal cortisol levels results in constitutive aldosterone secretion, which leads to expanded plasma volume and hypertension (281, 282). The expanded plasma volume suppresses secretion of renin, but this fails to diminish secretion of aldosterone.

Familial hyperaldosteronism type II (FH-II) is a similar to GRA (FH-I) with excess production of miniralocorticoids, but is not suppressed by dexamethasone. FH-II may be associated with a family history of adrenal hyperplasia or adenoma and appears to be more common than FH-I. FH-II is autosomal dominant, and linkage analysis suggests an association with chromosome 7 (283, 284), but the molecular basis of the disorder remains determined.

Hypertension Exacerbated in Pregnancy by mutations in the mineralocorticoid receptor is an autosomal dominant form of hypertension that is markedly accelerated in pregnancy (285). A systematic screening of patients with early-onset hypertension detected a missense mutation in the ligand-binding domain of the mineralocorticoid receptor MR S810L. MR-L810 carriers all developed hypertension before age 20, a finding absent among their unaffected relatives. Steroids lacking 21-hydroxyl groups (progesterone, spironolactone) that normally bind but do not activate MR are all potent agonists of the mutant receptor. Because progesterone levels rise 100-fold during pregnancy, all pregnancies among patients harboring this mutation have been complicated by dramatic acceleration of hypertension associated with complete suppression of the renin–angiotensin system (285).

Congenital adrenal hyperplasia from the two known defects in either 11β-hydroxylase or17α-hydroxylase activity may cause hypertension. These defects lead to overproduction of 21-hydroxylated steroids, which activate mineralocorticoid receptors, resulting in increased sodium reabsorption in distal tubules (286, 287).

Primary glucocorticoid resistance represents the partial resistance of the glucocorticoid receptor, resulting in excessive ACTH-dependent 11-deoxycortisone and corticosterone production. A cortisol level too high to be controlled by 11β-hydroxysteroid dehydrogenase type II enzyme activity activates mineralocorticoid receptors and increases sodium reabsorption in the distal tubules (286–290).

The syndrome of *apparent mineralocorticoid excess* (AME) is an autosomal recessive disease characterized by early-onset hypertension with hypokalemia and metabolic alkalosis, accompanied by suppressed plasma renin activity and the virtual absence of circulating aldosterone. In this disease, steroids other than aldosterone activate the mineralocorticoid receptor (MR). Affected patients have a lack-of-function mutation in the gene encoding the renal isoenzyme of 11-hydroxysteroid dehydrogenase (11HSD), resulting in impaired conversion of cortisol to cortisone (291). In vitro, cortisol activates MR with potency similar to aldosterone. However, in vivo almost all activation of MR is mediated by aldosterone, despite its low plasma concentration. The specificity of MR for aldosterone in vivo is mediated indirectly by 11HSD activity, "protecting" the MR from cortisol by metabolizing it to cortisone, which does not activate MR (292). In AME, the absence of this enzyme allows cortisol to activate the MR, resulting in hypertension mediated by increased sodium retention. Confirmation of the pathogenesis of AME came with the cloning of 11HSD-2. This gene, expressed in the same cells of the nephron that express ENaC, shows homozygous loss-of-function mutations in AME patients (291, 293).

Liddle's syndrome is an autosomal dominant disease characterized by severe hypertension, metabolic alkalosis, and hypokalemia with low renin and aldosterone (284). Activating mutations in the β or γ subunit of the epithelial Na channel (ENaC) are responsible for constitutively elevated renal sodium reabsorption in Liddle's syndrome (294–297). ENaC is the main sodium channel responsible for sodium reabsorption in the renal collecting ducts. Clearance of the normal channel from the membrane depends upon the sequence PPPXY in the cytoplasmic C termini of the β and γ ENaC subunits. Mutations of this sequence in either subunit prolong the cell-surface half-life (295) and increase the number of channels (297), by eliminating interaction with WW domain-containing proteins such as the ubiquitin ligase Nedd4 and thereby reducing channel ubiquitylation and internalization (294, 298–303).

Gordon's Syndrome, also known as pseudohypoaldosteronism type II, is an autosomal dominant disorder characterized by hypertension, hyperkalemia, hyperchloremic metabolic acidosis, and normal glomerular filtration rate (304–307). The WNKs ("with no lysine" (K)) are a family of serine/threonine protein kinases, and mutations of WNK1 and WNK4 genes located on human chromosomes 12 and 17, respectively, are found to be responsible for Gordon's syndrome (308–312). Deletions in the first intron of the WNK1 gene increase gene expression. This increases sodium reabsorption via ENaC and the Na^+/Cl^- cotransporter (NCC); the latter effect is caused by reducing inhibition of NCC by WNK4. Increased WNK1 expression also decreases potassium

excretion by inhibiting the renal outer medullary potassium channel (ROMK). Missense mutations of the WNK4 gene have several effects on renal ion transport. In general WNK4 inhibits NCC and prevents Na^+ reabsorption in the distal convoluted tubules. The mutated WNK4 does not inhibit NCC, leading to constitutively increased Na^+ reabsorption. WNK4 mutations also inhibit potassium excretion by ROMK, which contributes to hyperkalemia (287, 302, 313). Recent studies suggest that WNK1 may also play a role in the pathogenesis of salt-sensitive hypertension (314, 315).

Hypertension with brachydactyly features severe hypertension with abnormal skeletal development in the hand and wrist. There are no associated distinguishing biochemical features. This syndrome has been mapped to chromosome 12p12.2-11.2 (316, 317), but the responsible gene has not yet been identified.

Other Genetic Forms of Hypertension

Mutations in peroxisome proliferator-activated receptor γ (PPARγ) are dominant-negative and lead to loss of function. These mutations result in insulin resistance, type 2 diabetes, and hypertension at an early age (318). A syndrome of hypertension, hypercholesterolemia, and hypomagnesemia shows maternal inheritance of a homoplasmic mutation caused by a cytidine substitution in the mitochondrial tRNA (319).

Hypertension in Renovascular Disease

Hypertension in the one-clip, two-kidney model (analogous to unilateral renal artery stenosis in humans) is renin-dependent (320). One-clip, two-kidney animals also have increased norepinephrine release and SNS activity (321), implicating a role for the SNS in the development of renovascular hypertension. This has been disputed in animal models (320), but as mentioned previously, studies in humans with renovascular hypertension have clearly demonstrated elevated sympathetic nerve activity (17).

Renal perfusion pressure starts to be affected when renal artery stenosis reaches 50%. However, the stenosis needs to occlude at least 70% of the lumen before it begins to reduce renal blood flow and raise arterial pressure (322). In the late phase, hypertension persists despite removal of the stenosis or ischemic kidney, due to damage to the contralateral kidney (323), and probably also to systemic vascular changes as discussed elsewhere. In fact, in the one-clip, two-kidney model of renovascular hypertension, the vascular, glomerular and tubulointerstitial damage in the unclipped kidney is greater than in the clipped kidney. The clipped kidney is exposed to elevated angiotensin, but protected from hypertension (324). Activation of the renin–angiotensin system also results in an increase in oxidative stress and accelerated atherosclerosis (325).

Renovascular hypertension accounts for 5–10% of hypertension in children. The causes of renovascular hypertension are diverse, including fibromuscular dysplasia, syndromes such as neurofibromatosis type 1, tuberous sclerosis, Williams' syndrome, and Marfan syndrome, vasculitis, extrinsic compression, radiation, umbilical artery catheterization, trauma, congenital rubella syndrome, transplant renal artery stenosis, and others (326). Eleven to sixty percent of renovascular hypertension cases are familial, showing autosomal-dominant inheritance with variable penetrance (327, 328).

The renin–angiotensin system is important for not only blood pressure regulation but also for vascular remodeling and vascular smooth muscle growth. Bofinger et al. note that polymorphisms of the angiotensin-converting enzyme (ACE) allele associated with lower circulating ACE levels might predispose to defective vascular remodeling (328). In addition, elastin gene mutations in Williams' syndrome and the mutations of JAGGED 1 (JAG1) in Alagille's syndrome may be responsible for renal artery stenosis (329). Vasculitis including Takayasu disease, polyarteris nodosa, Kawasaki disease, other systemic vasculitis, and transplant renal artery stenosis are also important causes of renovascular hypertension (328).

Hypertension in Acute Kidney Injury and Chronic Kidney Disease

Hypertension resulting from renal parenchymal disease is multifactorial in origin. Acute and severe insult to the kidneys either impairs excretion of salt and water, reduces renal blood flow, or both. Dysregulation of salt and water excretion leads to volume expansion and thereby increases cardiac output. Both the reduction in renal bloodflow and the volume expansion activate the renin–angiotensin–aldosterone axis (330). For example, autosomal dominant polycystic kidney disease (ADPKD) presents with significantly increased renin, likely due to cyst expansion reducing renal blood flow, leading to ischemia (331). CKD also causes abnormal activation of the adrenergic system and baroreceptor dysfunction (332) and leads to accumulation of the NOS inhibitors (333) and endothelial dysfunction (334). There is also decreased production of vasodilators, including kinin

and prostaglandins, and increased production of the vasoconstrictor ET-1 (335). Recombinant human erythropoietin treatment induces hypertension by several mechanisms: a direct vasoconstrictive effect, diminished response to nitric oxide, increased plasma endothelin, a marked increase in intracellular calcium in vascular smooth muscle cells, arterial remodeling, and others. Abnormal parathyroid/calcium homeostasis secondary to chronic kidney diseases may increase intracellular calcium concentrations in the myocardium and platelets, which subsequently leads to hypertension (336, 337) (*Fig. 61-5*).

Hypertension in end-stage renal disease (ESRD) is primarily volume- and salt-dependent and results from impaired sodium excretion. In ESRD as well as in advanced CKD, there is expansion of the extracellular water volume, as well as in total body water (330). The renin angiotensin system is also stimulated, which in turn enhances sodium retention and produces an increase in systemic vascular resistance.

Increased sympathetic tone, as evidenced by elevations in plasma noradrenaline levels, contributes to increased systemic vascular resistance and cardiac output (338). As discussed previously, ET-1 and ANP are elevated and are associated with high blood pressure in CKD (137, 339). Administration of non-steroidal anti-inflammatory drugs in CKD increases arterial pressure and reduces renal prostaglandins (340) suggesting an important role for prostaglandins in CKD-associated hypertension. Patients with uremia secondary to impaired renal clearance also have elevated levels of the NOS inhibitors asymmetric and symmetric dimethylarginine (333, 341). Patients with ESRD are known to lose the normal nocturnal dip in blood pressure, have increased pulse pressure and isolated systolic hypertension, and may develop increased aortic stiffness (342, 343). The mechanisms of these changes have not been elucidated.

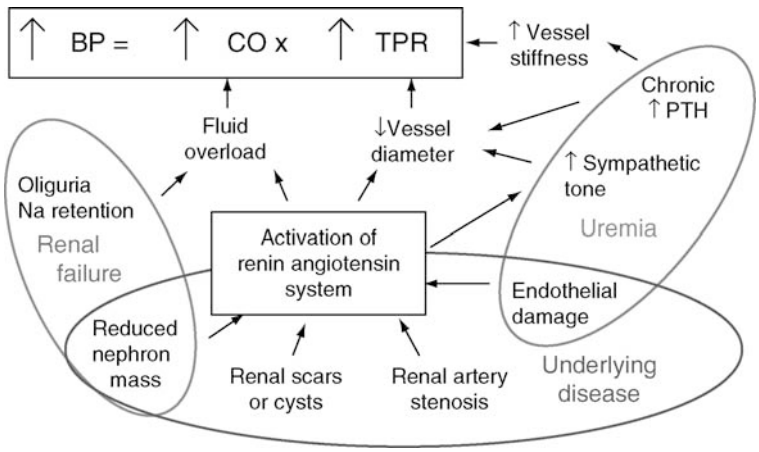
Hypertension in Dialysis Patients

Children receiving chronic dialysis have a significant incidence of hypertension: 53–65% of children receiving hemodialysis and 45–58% of children receiving peritoneal dialysis in the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) dialysis database were receiving antihypertensive medications at the time of the 2007 NAPRTCS annual report (344). It was noted that the use of antihypertensive medications among PD and HD patients decreased over 3 years (344). The major pathophysiologic mechanism in most dialysis patients seems to be volume overload related to sodium and water retention. This may be more significant in peritoneal dialysis patients than in hemodialysis patients (345). Evidence in favor of fluid overload being the major mechanism can be found in the many studies that demonstrate correction of hypertension by increased fluid removal in both peritoneal dialysis and hemodialysis patients (346, 347).

However, numerous other factors have been implicated, including overactivity of the sympathetic nervous system, activation of the renin–angiotensin system,

Figure 61-5

Interplay of different factors in the generation of hypertension in chronic kidney disease (*BP* blood pressure, *CO* cardiac output, *TPR* total peripheral resistance, *PTH* parathyroid hormone, *Na* sodium). Reprinted from (337).



erythropoietin, parathyroid hormone, and nocturnal hypoxemia (348). Recent studies have also implicated nitric oxide and endothelin as being involved in the pathogenesis of dialysis hypertension (348, 349). Endothelin and other vasoconstrictor factors have also been shown to be involved in the pathogenesis of erythropoietin-related hypertension (350). Post-dialysis hypertension in hemodialysis patients is likely renin-mediated and responds to administration of an angiotensin converting-enzyme inhibitor following dialysis (351–355).

Post-transplant Hypertension

Hypertension following renal transplantation is a common phenomenon. Eighty-five percent of deceased donor recipients and 79% of live donor recipients are receiving antihypertensive medications at the time of transplantation. The percentage receiving antihypertensives is decreased in 5 years for both deceased and live donor recipients, to 69 and 59%, respectively (344). The major contributing factors include history of pre-transplant hypertension, persistent native kidney hypertension, effects of immunosuppressive medications, transplant renal artery stenosis, and chronic allograft dysfunction (356–358).

As in hypertension of any cause, pre-transplant hypertension leads to chronic vascular changes that increase peripheral vascular resistance, perpetuating hypertension after transplantation. Although such vascular remodeling can be reversed with effective antihypertensive treatment (359), many patients come to transplant hypertensive despite therapy, so pre-existing vascular remodeling remains a significant factor following transplantation. Remaining native kidneys may also contribute to post-transplant hypertension, presumably via persistent release of renin (360).

Immunosuppressive medications, particularly glucocorticoids and calcineurin inhibitors, may both contribute to post-transplant hypertension. Although prednisone may be a significant contributing factor to the development of hypertension in the immediate post-transplant period, many current pediatric immunosuppression protocols rapidly reduce the dose of prednisone in order to maximize post-transplant growth, making prednisone a much less important contributing factor later on (360, 361). This may be even less of a problem in pediatric transplantation in the future as the use of steroid-free immunosuppression increases.

Calcineurin inhibitors affect blood pressure in a variety of ways, including increased production of the vasoconstrictor endothelin (138, 140, 362, 363), decreased production of vasodilatory substances (361), and activation of the sympathetic nervous system (364). Cyclosporine increases renal vascular resistance by stimulating afferent artery vasoconstriction. Calcineurin inhibitors also cause sodium retention (365). Many studies suggest that calcium channel blockers can minimize calcineurin-induced vasoconstriction (366, 367), thereby ameliorating hypertension and preventing chronic graft injury.

Transplant renal artery stenosis (TRAS) has been reported to occur in up to 20% of hypertensive pediatric renal transplant recipients (360), although improved surgical techniques have probably decreased its incidence more recently (361). Causes may include surgical trauma, prolonged ischemia, suturing technique or reactions to suture material, atheromatous plaques in the donor kidney, and cytomegalovirus infection (361, 368–370). Elevated renin secretion has been seen in patients with TRAS (371), suggesting that the mechanisms responsible for hypertension in TRAS are similar to those discussed elsewhere in this chapter for renovascular hypertension.

Allograft dysfunction has long been recognized as a significant cause of hypertension in both children and adults with post-transplant hypertension (360, 361). Chronic allograft nephropathy presents with a slow, progressive arteriolopathy and glomerulosclerosis. Whether resulting from the sequelae of rejection or from calcineurin nephrotoxicity, the primary mechanism of hypertension related to allograft dysfunction appears to be renal sodium retention (361, 372). Other mechanisms seen in patients with renal insufficiency of other causes may also be responsible.

Hypertension in Coarctation of the Aorta

Hypertension associated with aortic coarctation may occur in three clinical settings: prior to surgical repair, in the immediate post-operative period following surgical repair, and years after repair. Pre-repair hypertension is the result of renal hypoperfusion and activation of the renin–angiotensin system. There may also be increased activity of the sympathetic nervous system (373). In the immediate post-surgical period, paradoxical hypertension may be seen, probably resulting from increased activity of the renin–angiotensin and sympathetic nervous systems (374). This phenomenon appears to be rare following balloon angioplasty (375), which has largely replaced primary surgical repair as the initial procedure of choice.

Despite surgical repair of coarctation, many patients will later be found to have abnormal blood pressure at rest. Ambulatory blood pressure monitoring is probably

superior to casual blood pressures for detection of hypertension in this population (376). Proposed mechanisms for this late or persistent hypertension include altered baroreceptor function, thickening of blood vessels below the site of the coarctation, and elevation of plasma adrenaline and aldosterone levels (377, 378). Vascular dysfunction in patients with repaired coarctation has been demonstrated and appears to be related to the age of repair (379). Renal structural changes have also been demonstrated in animal models of coarctation (380). Recoarctation should also be investigated in any patient with the development of late post-repair hypertension.

Hypertension in Vasculitis

Because of the numerous vessels within the renal parenchyma, the kidneys are frequently targeted by systemic vasculitis. Glomerular inflammation, with cellular infiltration, proliferation, and immune complex deposition resulting in nephritis and renal failure has been well characterized in systemic lupus erythomatosus (SLE), microscopic polyarteritis, Wegener's granulomatosis, Henoch–Schonlein purpura, and cryoglobulinemic vasculitis. Takayasu's arteritis (TA), an inflammatory process associated with stenosis and obliteration of the aorta and its primary branches, induces hypertension by mechanisms that are similar to those seen in coarctation of the aorta, renovascular hypertension, or ischemic kidney disease, as discussed above. Necrotizing vasculitides, such as classic polyarteritis nodosa and Kawasaki's disease, may lead to hypertension secondary to thrombosis of inflamed major extrarenal and intrarenal arteries with resulting local (intrarenal) renin–angiotensin system activation and infarction of the renal parenchyma (381).

Hypertension in Endocrine Diseases

Hypertension can occur secondary to many hormonal derangements, including excess production of mineralocorticoids, glucocorticoids, and catecholamines. An excess of growth hormone or parthyroid hormone, hypo- or hyperthyroidism, a renin-secreting tumor, or diabetes mellitus may also lead to hypertension (382).

Primary hyperaldosteronism (PAL) or mineralocorticoid excess is now believed to be much more common than it was previously thought (382–384). PAL was first reported by Conn as aldosterone-producing adenoma (APA) (385) and more commonly results from adrenal hypertrophy ("idiopathic hyperaldosteronism" (IHA)). Rarely, pure aldosterone-producing adrenocortical carcinoma and ectopic aldostrone-secreting tumors cause PAL. Glucocorticoid-remediable aldosteronism (GRA), familial hyperaldosteronism type II (FH-II), and apparent mineralocorticoid excess (AME), which were previously described in this chapter, are also in this category.

APA and IHA both cause excess aldosterone secretion, and both produce hypertension with similar clinical features: hypokalemia, renal potassium wasting, suppressed plasma renin activity, and increased plasma and urinary levels of aldosterone (386). The blood pressure elevation due to aldosterone excess results from an increase in systemic vascular resistance (SVR) due to aldosterone-mediated increased plasma sodium concentration that leads to a rise in the intracellular calcium content. The increase in intracellular calcium leads to impaired left ventricular diastolic relaxation (387) and enhanced contractility with reduced vascular compliance (388). The increased aldosterone production in IHA reflects increased activity of a rate-limiting mitochondrial cytochrome P450 isoenzyme, the aldosterone synthase gene CYP11B2 (389). Polymorphisms of the CYP11B2 gene determine interindividual variations in aldosterone activity and response to antihypertensive treatment (390, 391).

Cushing's syndrome or glucocorticoid excess has long been known to cause hypertension, but the exact mechanism or mechanisms that result in blood pressure elevation remain unknown. Increased peripheral vascular sensitivity to adrenergic agonists may play a role in the hypertension (392). Hepatic synthesis of angiotensinogen, which stimulates the renin–angiotensin system, is activated, and phospholipase A2, which releases arachidonic acid from phospholipids and plays an important role in the synthesis of vasodilatory prostaglandins, is inhibited (393). Glucocorticoids also reduce the activity of the depressor kallikrein–kinin system, enhance pressor sensitivity to endogenous vasoconstrictors (epinephrine and angiotensin II) (394, 395), and promote sodium influx into vascular smooth muscle cells (396). High levels of cortisol exert mineralocorticoid effects, and in adrenal carcinomas, DOC and aldosterone may also be elevated (397).

Pheochromocytoma. Pheochromocytomas are catecholamine-secreting tumors of chromaffin cells that may arise from cells of neural crest origin, either in the adrenal glands or in extra-adrenal sites. Sustained or paroxysmal hypertension is the most common clinical sign, although it may be less common in children than in adults (398). Although most pheochromocytomas are sporadic, there is a familial predisposition in patients with multiple endocrine neoplasia type II (MEN II), von Hippel–Lindau disease, neurofibromatosis type 1, and

familial paraganglioma (399–401). Pheochromocytoma in MEN II is associated with a germline mutation of the proto-oncogene RET (402) and pheochromocytoma in von Hippel–Lindau disease results from germline mutation of the von Hippel–Lindau gene (403). Familial paraganglioma is an autosomal dominant disorder with catecholamine hypersecretion. Paragangliomas are mostly located in the head and neck, but can be found in the thorax, abdomen, pelvis, and bladder. Mutations of succinate dehydrogenase in subunits D, B, and C are found in most cases of familial paraganglioma (404–409).

Hypertension in pheochromocytoma results from a direct effect of high circulating levels of catecholamines primarily noradrenaline, adrenaline and dopamine (398). Some tumors produce the catecholamine precursor L-dopa. Pheochromocytomas also secrete numerous other peptide hormones, among which are renin, VIP, neuropeptide Y, somatostatin, and ET-1. These substances are responsible for many of the non-hypertensive symptoms seen in patients with pheochromocytoma, including flushing, sweating and diarrhea (398).

Acromegaly or growth hormone (GH) excess. The prevalence of hypertension in acromegaly is approximately 35% (398, 410, 411). The relationship between hypertension and growth hormone excess is not completely understood. GH causes sodium retention with volume expansion by inhibiting atrial natriuretic peptide (ANP) (412, 413). Acromegaly may also present with insulin resistance, which may impair NO production and vasodilation. GH and insulin-like growth factor-1 (IGF-1) affect growth and mitosis of endothelium and VSMC and may increase myocardial hypertrophy and contractility (414–416).

Primary hyperparathyroidism (PHPT). Whether PHPT causes hypertension is still controversial. However, potential pathogenic mechanisms of hypertension in PHPT are elevated intracellular calcium, hypomagnesemia, raised plasma renin activity, and glucose abnormalities. Impairment of endothelial vasodilation by increased intracellular calcium and vasospasm induced by neurohormonal substances due to hypomagnesemia have been reported (417, 418).

Thyroid disorders. Hypothyroidism reduces renal blood flow and glomerular filtration rate and decreases cardiac output (419). Compensatory mechanisms – primarily increased peripheral resistance mediated by increased responsiveness to adrenergic stimulation and increased SNS activity (420) – lead to diastolic hypertension. Treatment with thyroid hormone will correct the hypertension.

Hyperthyroidism, on the other hand, is associated with activation of the renin–angiotensin–aldosterone axis and increased sodium reabsorption, leading to expansion of plasma volume (154). There is also β2 receptor stimulation, which results in vasodilatation and increased cardiac output and contractility (155). These physiologic changes result in isolated systolic hypertension (157).

Renin. Juxtaglomerular cell tumors of the kidney or ectopic tumors secrete renin and induce hypertension associated with hypokalemia, hyponatremia, and other features of RAAS activation (421). This form of hypertension can often be severe and present acutely (422).

Diabetes mellitus (DM). Hypertension in patients with type I diabetes is usually correlated with the development of microalbuminuria and diabetic nephropathy. On the other hand, the majority of patients with type II diabetes have hypertension prior to the development of nephropathy. The pathogenesis of hypertension in diabetes is multifactorial, with hyperinsulinemia, sodium retention, volume expansion, and increased arterial stiffness all playing important roles. Hyperglycemia alters lipid and protein metabolism, and insulin increases sympathetic nervous system activity. DM leads to vascular changes including both macroangiopathy and microangiopathy, and autonomous neuropathy causes vascular dysfunction. Numerous studies have shown that endothelial dysfunction in DM may play a significant role in hypertension by altering vascular architecture and remodeling in response to hemodynamic changes, low NO, and prostacyclin release, increased oxygen-reactive species, and increased endothelin-1. Hyperglycemia and advanced glycosylation end-products may also be important contributing factors (423–426).

Hypertension in Pulmonary Diseases (BPD, Sleep Apnea)

Hypertension in children with chronic lung disease is most commonly seen in infants with bronchopulmonary dysplasia (BPD). Although the pathophysiology of BPD-associated hypertension is not completely understood, it is likely to be multifactorial in origin. Corticosteroids, especially dexamethasone, when used for prolonged periods will elevate blood pressure in such infants, but with withdrawal the hypertension resolves (427). Because the development of hypertension is correlated with the severity of lung disease, chronic hypoxia may also be an important mechanism (428).

Obstructive sleep apnea (OSA), characterized by episodic upper airway obstruction during sleep despite persisting respiratory efforts, leads to asphyxia, hypoxia, hypercapnea, and disruption of sleep architecture. OSA is a risk factor for systemic hypertension, myocardial infarction, stroke, and sudden death (429). Acute episodes

of hypoxia result in stimulation of peripheral chemoreceptors and increased sympathetic outflow with subsequent activation of the renin–angiotensin system. Other important contributing factors include endothelial dysfunction, oxidative stress and inflammation (430). Cardiac output may also change secondary to fluctuation of intrathoratic pressure (431, 432). Since many patients with OSA are obese, coexisting conditions such as the metabolic syndrome are probably also involved in the development of hypertension (433). Effective therapy of OSA will often result in an improvement in blood pressure in affected individuals.

Hypertension in Neurologic Disorders

Systemic hypertension can be seen in a variety of neurologic disorders, including seizures, poliomyelitis, hydrocephalus, head trauma, pseudotumor cerebri (idiopathic intracranial hypertension), Guillain–Barre syndrome, and with space-occupying lesions (tumor, bleeding, and abscess). Many of these are associated with increased SNS outflow, leading to peripheral vasoconstriction and renal sodium retention (see earlier sections).

In Guillain–Barre syndrome, for example, microneurographic studies have demonstrated increased SNS activity in the acute phase of the illness (434). Increased levels of circulating renin and catecholamines have also been reported (435). These abnormalities, and the hypertension, resolve as the neurologic abnormalities subside. Increased sympathetic activity is also seen in patients with spinal cord injury. In familial dysautonomia, HTN is caused by increased circulating catecholamines and increased responsiveness to circulating catecholamines (436).

Increased intracranial pressure (ICP) causes systemic HTN that can be quite labile. The mechanism of hypertension is believed to be the stretching of receptors located under the floor of the fourth ventricle (437). Sympathetic nervous outflow is increased in most patients, and baroreceptor function is disrupted. Circulating levels of catecholamines may be increased. Hemodynamically, HTN is primarily due to increased SVR. In many instances, especially when ICP is elevated due to trauma, systemic hypertension is an important compensatory mechanism for the maintenance of normal cerebral perfusion (438).

Pregnancy-Induced Hypertension and Pre-eclampsia

Pregnancy-induced hypertension (PIH) may affect up to 8% of all first pregnancies in the United States, and the incidence of preeclampsia has increased by 40% in recent years (439, 440). As with many of the forms of hypertension discussed in this chapter, PIH is most likely a multifactorial disorder with many contributing mechanisms. However, because the hypertension associated with pre-eclampsia develops during pregnancy and remits after delivery, the placenta is thought to play a central role in the disease development. Abnormal cytotrophoblast invasion of spiral arterioles leading to reduced uteroplacental perfusion and ischemia appears to be the initiating event (441, 442).

Placental ischemia results in activation/dysfunction of the maternal vascular endothelium that in turn increases synthesis and release of vasoactive factors such as soluble fms-like tyrosine kinase-1 (sFlt-1), cytokines, and angiotensin II type 1 receptor autoantibodies (AT_1-AA). Increased production of sFlt-1 triggers an imbalance between pro-angiogenic factors (VEGF and PlGF) and anti-angiogenic factor (sFlt-1). This imbalance reduces active angiogenesis, which is necessary for the placental vascular network. Ischemia of the placenta also increases thromboxane and AT_1-AA, leading to increased production of reactive oxygen species and ET-1, and decreases formation of vasodilators such as nitric oxide and prostacyclin (443, 444). There is also increased synthesis of inflammatory cytokines such as tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), and IL-6, which is activated by TNF-α (441). Those cytokines, in turn, induce structural and functional alterations in endothelial cells, enhance endothelin production, and reduce acetylcholine-induced vasodilatation (441, 445–447).

Another important mechanism may be defective nitric oxide (NO) production. During normal pregnancy, maternal cardiac output and blood volume increase by 40–50%, whereas SVR and BP tend to decrease. In addition, GFR and renal plasma flow increase 30–40%. There is substantial evidence that NO plays an important role in mediating those changes. Plasma and urinary levels of cGMP, the second messenger of NO, increase during pregnancy in rats, and urinary nitrate/nitrite excretion has also been reported to be increased. Chronic NOS inhibition in pregnant rats produces hypertension associated with peripheral and renal vasoconstriction, proteinuria, intrauterine growth retardation, and increased fetal morbidity, a pattern that closely resembles the symptoms of human pregnancy-induced hypertension (445–449).

Drug-Induced Hypertension

Numerous therapeutic and illicit drugs, as well as some commonly used dietary supplements, may influence

Table 61-2

Mechanisms of drug-induced hypertension

Drug	Potential mechanism(s)
Caffeine	Vasoconstriction, increased SNS activity, decreased baroreceptor sensitivity (450, 451)
Calcineurin inhibitors	SNS activation (364), increased ET-1 secretion (138–140)
Cocaine	Increased heart rate and myocardial oxygen demand, direct vasoconstriction, increased matrix synthesis, glomerular inflammation, and glomerulosclerosis (452)
Ephedra/ephedrine	Stimulation of catecholamine release, stimulation of α-, β1-, and β2-receptors, CNS excitation and stimulation (453)
Erythropoietin	Increased erythrocyte mass, changes in production of or sensitivity to endogenous vasopressors, dysregulation of production of or responsiveness to endogenous vasodilatory factors, direct vasopressor effect, arterial remodeling through stimulation of vascular cell growth (350, 454)
Ethanol	Abnormal response of blood pressure and plasma renin activity to variations in salt intake (455)
Glucocorticoids	Stimulation of the renin–angiotensin system, inhibition of phospholipase A2, reduced activity of the kallikrein–kinin system, enhanced pressor sensitivity to endogenous vasoconstrictors, mineralocorticoid effects (394–397)
NSAIDs	Prostaglandin inhibition, decreased glomerular filtration rate, salt and water retention, tubulointerstitial injury (456)
Oral contraceptives	Alteration in sodium balance and the renin–angiotensin–aldosterone system (457, 458)
Tobacco	Increased SNS outflow, attenuated endothelium-dependent vasodilatation, increased arterial wall stiffness (459–461)
Yohimbine	Presynaptic alpha-2-adrenergic blockade; increased plasma norepinephrine levels (462)

Abbreviations: ET-1 endothelin-1; *NSAID* non-steroidal anti-inflammatory drug; *SNS* sympathetic nervous system

blood pressure significantly, especially in individuals whose blood pressure regulation is already disturbed. A detailed discussion of the many substances with effects on blood pressure would be beyond the scope of this chapter. However, some of the more commonly seen drug-blood pressure effects are summarized in *Table 61-2*.

62 Evaluation of Hypertension in Childhood Diseases

Eileen D. Brewer

Introduction

Evaluation of hypertension in the pediatric age group should be guided by the age at presentation, the severity of hypertension at presentation and whether the hypertension is sustained or transient. The commonest causes of hypertension differ by age group (› *Table 62-1*). Hypertension is more likely to be secondary and sustained in the younger age groups, whereas primary (essential) hypertension and white coat hypertension are more likely to be the etiology in adolescents (1–3). The global epidemic of childhood obesity has been associated with an increased incidence of primary hypertension in adolescence (3–5), although the evidence base is not robust enough to know the full extent of this problem (5–7). Obese children have a 3-fold higher risk for developing hypertension compared to non-obese children (4). The frequent occurrence of primary hypertension in obese adolescents dictates an entirely different evaluation than for younger or non-obese children. Renal disease must be considered in every child with hypertension, because of the prevalence of renovascular and renal parenchymal disorders as the etiology in any age group. Secondary hypertension from renal disorders is more likely to be severe at presentation than primary hypertension. Endocrine causes of hypertension are rare, so special diagnostic studies for these disorders should be reserved for those patients whose history, physical examination and preliminary evaluation warrant further specific investigation. This chapter outlines the steps in evaluation of childhood hypertension, starting with the confirmation of the diagnosis and evaluation of its duration and severity.

Confirmation of the Diagnosis of Hypertension in Children and Adolescents

Recommended techniques for measuring blood pressure in children are discussed in detail in Chapter 61. A few points will be re-emphasized here because confirming the diagnosis of hypertension is the first step in evaluation. Standards for blood pressure in children and adolescents were updated in 2004 in the Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents (1) and incorporated new height percentile data and new information about normal blood pressure from the 1999–2000 National Health and Nutrition Examination Survey (NHANES). Like the previous revision in 1996 (8), the updated 2004 tables classify blood pressure by gender, age and height for children 1–17-years old, with the height assessment included to minimize misclassifying children as hypertensive, when they are very tall or very short for age. Adolescents 18 years of age and older are considered adults and addressed in the 2003 Seventh Report of the Joint National Committee (JNC 7)(9), which set the guidelines for all adults aged 18 years or older, but did not take into account their age, gender or height. The 2004 Fourth Report update for children and adolescents includes normative data for multiple blood pressure percentiles to allow classification of childhood hypertension into stages parallel to those recommended for adults in the JNC 7 Report. The JNC 7 Report set the upper limit of normal blood pressure for all adults at 120/80. Pre-hypertension was classified as blood pressure between 120/80 and 139/89; stage 1 hypertension, as between 140/90 and 159/99; and stage 2 hypertension, as greater than or equal to 160/100. The 2004 Fourth Report recommended a similar classification of childhood hypertension as follows: normal blood pressure is defined as less than the 90th percentile blood pressure from the tables, or less than 120/80 for adolescents no matter what the 90% percentile; pre-hypertension is blood pressure between the 90th and 95th percentiles, or greater than or equal to 120/80 up to less than the 95th percentile for adolescents; stage 1 hypertension is blood pressure between the 95th percentile to 5 mg Hg higher than the 99th percentile; and stage 2 hypertension is greater than 5 mm Hg higher than the 99th percentile. Adding the 99th percentiles to the tables facilitates identification of stage 2 hypertension, which is the most severe and dictates more rapid evaluation and

Table 62-1
Commonest Causes of Hypertension by Age at Presentation

Age Group	Cause
Newborn	Renal artery thrombosis or embolus (umbilical artery catheter)
	Renal vein thrombosis
	Congenital renal malformations
	Coarctation of aorta
	Renal artery stenosis
	Bronchopulmonary dysplasia
Infancy to 6 years	Renal parenchymal disease
	Renal artery stenosis
	Coarctation of the aorta
	Medications (corticosteroids, albuterol, pseudoephedrine)
	Endocrine causes
6–10 years old	Renal parenchymal disease
	Renal artery stenosis
	Primary (essential) hypertension
	Endocrine causes
Adolescence	Primary (essential) hypertension
	White coat hypertension
	Renal parenchymal disease
	Substance abuse (cocaine, amphetamines, methamphetamines, phencyclidine, methylphenidate, caffeine)
	Endocrine causes

therapy. As before, auscultation of the fifth Korotkoff sound (point at which the sound disappears) is still recommended to determine diastolic blood pressure in all age groups. In some young children no fifth sound can be heard, because sounds are still audible at 0 mm Hg, even with less pressure applied to the stethoscope head. The new recommendation for these children is to use the fourth Korotkoff sound (point at which the sound muffles) as the diastolic blood pressure (1).

The Fourth Report does not address blood pressure for infants less than 1 year of age, and very little data is available for this age group (10). The 1987 Second Task Force on Blood Pressure (11) includes standards for both systolic and diastolic blood pressure for awake infants, ages birth to 12 months, based on measurements obtained with either Doppler instruments or sphygmomanometers and the fourth Korotkoff sound to determine diastolic blood pressure. Blood pressure is lower in sleeping infants, so correction factors of 7 mm Hg for systolic and 5 mm Hg for diastolic blood pressure are recommended when using sleeping measurements to assess for hypertension.

Normal blood pressures for children and adolescents (1) or for adults (9) are based on measurements made manually with a sphygmomanometer and auscultation using a stethoscope. Even though automatic oscillometric devices, such as the Dinamap™, are in wide spread use in pediatric hospitals in North America, especially for neonates, infants and toddlers, little data and no established reference standards exist for normal blood pressure in children using these devices (12–15). In practice, values obtained with automatic oscillometric devices are often treated as if they were obtained manually and compared to the standard blood pressure tables. In the few studies comparing measurements with oscillometric devices to conventional manual sphygmomanometry in children, the blood pressures were not equivalent and the errors were not systematic for all ages (13, 14). In addition, few of the oscillometric devices on the market have actually been found to fulfill strict criteria for accuracy (15). Therefore, in cases of pre-hypertension and stage 1 hypertension, manual sphygmomanometry should be performed to confirm the diagnosis.

The conditions under which blood pressure is measured are also important, but sometimes not able to be followed precisely in a busy outpatient clinic or emergency room. The 2004 Fourth Report (1) recommends that blood pressure be taken on three separate occasions in a controlled environment, preferably in the right arm with the cubital fossa at heart level when the patient is seated, has rested quietly for 5 min, and has avoided stimulant drugs or foods. The inflatable bladder of the cuff, not the entire cuff, should be an appropriate size for the patient. The bladder width should be approximately 40% of the arm circumference midway between the acromion and olecranon; the length of the bladder should cover 80–100% of the circumference of the arm without overlapping; and the bladder width to length ratio should be at least 1:2. If the only cuffs available are either too small or a bit too large for the patient, the larger cuff should be chosen, because the error will be less than when the cuff is too small. Cuff sizes are not yet standardized as recommended by the 2004 Fourth Report (1), so determination of appropriate cuff size should be made according to the above guidelines and not by the name written on the cuff; for example, a small adult cuff might be just the right size for a tall or obese 7-year old. Measuring blood pressure accurately may be difficult in a severely

obese adolescent, unless a large adult thigh cuff is applied to the arm in a "cone" configuration. Sometimes, particularly in a small or ill child, blood pressure is most conveniently measured in the leg with an arm cuff. When abnormal, the blood pressure should be retaken in the right arm to be certain of the diagnosis of hypertension. If a patient has coarctation of the aorta, blood pressure may be greatly reduced in the legs and possibly the left arm, depending on the location of the coarctation, but will still be elevated in the right arm.

High blood pressure readings may be transient. A blood pressure reading in a crying, moving or anxious child is likely to be high, but not reliable for diagnosing hypertension. Blood pressure should be repeated several times when the child is calm. If initial values indicate pre-hypertension or stage 1 hypertension, blood pressure should be taken on repeated visits over days to weeks before diagnosing hypertension or embarking on a detailed diagnostic evaluation (1). Blood pressure tends to decrease on subsequent visits as anxiety subsides and the patient becomes more accustomed to the measurement. If white coat hypertension is suspected after focused detailed history and physical examination and minimal screening laboratory tests, ambulatory blood pressure monitoring (ABPM) is the next step in the evaluation, both for diagnosis (1, 5, 16) and cost-effectiveness (17). ABPM is measured with a wearable oscillometric blood pressure device usually placed on the non-dominant arm, which automatically measures and records blood pressure at prescribed frequent intervals (e.g., every 20 min when awake and every 30 min during sleep) over an entire 24-h period. ABPM allows evaluation of blood pressure throughout the day in the patient's own environment to reduce anxiety-induced elevations in blood pressure. Frequency of hypertension throughout the day (blood pressure load) and changes in the normal circadian pattern of blood pressure are assessed, which cannot be done by casual blood pressure measurements in the clinic or at home. In addition, ABPM sometimes uncovers masked hypertension, a condition in which the blood pressure is mostly normal in the clinic setting, but high during ABPM (5, 16). ABPM is discussed in detail in Chapter 61.

Assessment of Severity and Duration of Hypertension

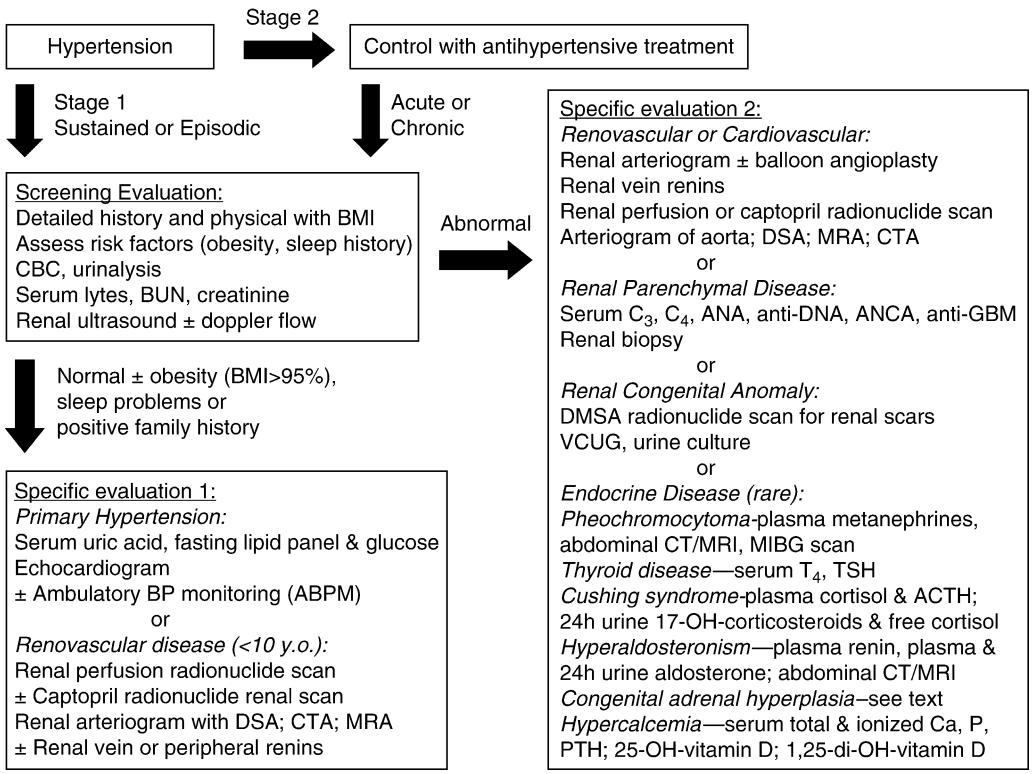
When repeated blood pressure measurements taken under appropriate conditions satisfy the definition of hypertension (1, 9), the stage, either 1 or 2, will direct further evaluation (*Fig. 62-1*). A quick guide for assessment of the stage of hypertension by age, gender and height percentile is given in *Table 62-2*. For stage 1 hypertension, diagnostic evaluation may continue before treatment is instituted. For stage 2 hypertension, emergent treatment should be undertaken to reduce the level of severe hypertension before further diagnostic evaluation (*Fig. 62-1*). If possible, laboratory tests that might be affected by treatment, such as peripheral plasma renin levels, should be drawn prior to initiating therapy.

Whether hypertension is acute or chronic, transient or sustained in duration, or episodic will help direct further evaluation. Transient or unsustained hypertension may need only clinical follow-up to be sure it does not recur. Episodic hypertension is best evaluated at the time of an occurrence, as evaluation may be unrevealing between attacks. Acute hypertension is often secondary to other diseases, which may have specific signs and symptoms to direct specific evaluation at the time of presentation.

Duration of hypertension is first assessed by a thorough hypertension-oriented history and physical examination (1). Headaches, blurred vision, seizures, chest pain and frequent epistaxis are usually associated with acute onset of hypertension. Episodic symptoms and hypertension are associated with pheochromocytoma or autonomic nervous system dysfunction. A detailed medication history for both prescription and over-the-counter medications, including herbal medicines, may help identify the etiology of acute, transient or episodic hypertension. Recent introduction of medications for which hypertension is a known side effect, like high dose corticosteroids (18) or albuterol for asthma, large (adult) doses of pseudoephedrine for cold symptoms, or phenylephrine eye or nose drops, may be the cause of new-onset, but transient hypertension. Adolescents are at risk for substance abuse and should be interviewed in private in order to maximize the chance of obtaining a history of the use of illicit drugs, tobacco or high-caffeine drinks, all of which can cause or contribute to hypertension (1, 19–21). Restless sleep, sleep apnea, irritability, anorexia and poor school performance are subtle signs of chronic hypertension and should be specifically elicited in the history. Poor growth may also be a sign of chronic hypertension or underlying chronic kidney disease. Obesity with BMI greater than the 95th percentile for age and gender is often associated with chronic primary hypertension (1, 3–5). The presence of peripheral edema, pleural effusion, rash, or swelling and tenderness of joints suggest acute onset or exacerbation of underlying renal or systemic disease. Retinal changes usually indicate long-standing, untreated hypertension and include arteriolar narrowing or tortuosity, arterio-venous nicking and hemorrhages and exudates (*Fig. 62-2*).

Figure 62-1

Algorithm for evaluation of hypertension in children and adolescents. Abbreviations: CBC, clinical blood count; BUN, blood urea nitrogen; DSA, digital subtraction angiography; MRA, magnetic resonance angiography; C_3 and C_4, complements 3 and 4; ANA, anti-nuclear antibody; anti-DNA, anti-double stranded desoxynucleic acid antibody; ANCA, anti-neutrophil cytoplasmic antibody; anti-GBM, anti-glomerular basement membrane antibody; DMSA, dimercapto-succinic acid; VCUG, voiding cystourethrogram; DSA, digital subtraction angiography CTA, computed tomographic angiography; MRA, magnetic resonance angiography; MIBG, metaiodobenzylguanidine; T_4, thyroxine; TSH, thyroid stimulating hormone; ACTH, adrenocorticotrophic hormone; OH, hydroxy; DOC, deoxycorticosterone; Ca, calcium; P, phosphorus; PTH, parathyroid hormone.



Screening Evaluation of Hypertension

Episodic or sustained, acute or chronic hypertension, whether stage 1 or stage 2, merits further screening and specific detailed evaluation as dictated by the screening. A convenient algorithm for evaluation of pediatric hypertension is shown in *Fig. 62-1*. The direction of further detailed laboratory and radiographic or biopsy evaluation of hypertension should become apparent after taking a detailed personal and family history, performing a careful physical examination and ordering a few simple laboratory tests.

The personal history should include specific questioning regarding the occurrence of headaches, sleep disturbance, visual symptoms, nosebleeds, palpitations, episodic rapid pulse, pallor or flushing, joint pains, rash, edema, gross hematuria, excessive weight gain or loss or decreased height growth. Neonatal history of low birth weight or the use of umbilical artery catheters may provide clues to the diagnosis of primary hypertension in an adolescent (22–24) or hypertension from renal artery thrombosis or emboli in an infant, respectively. Detailed dietary history may reveal excessive intake of sodium or caffeinated beverages, especially soft drinks or energy drinks (21). A medication history should include specific questions about over-the-counter drugs like pseudoephedrine or herbal preparations like ephedra, St. John's Wort or licorice (25, 26), as well as prescription drugs. Adolescents should be questioned in private to obtain a history of substance abuse or the possibility of pregnancy. Family history of hypertension, heart attacks or stroke is particularly important for children with primary hypertension.

Table 62-2

Quick Guide for Assessment of Stage of Hypertension (HTN) by Age, Gender & Height (Ht) Percentile

Age Group	Percentiles of Blood Pressure (mm Hg) for Ht Percentile			
	Stage 1 HTN[a]: 95%		Stage 2 HTN[a]: >99% + 5	
Boys	*Ht 5%*	*Ht 95%*	*Ht 5%*	*Ht 95%*

BP blood pressure; *HTN* hypertension; *Ht* height

[a]Adapted from blood pressure tables in the 2004 Fourth Report on Diagnosis, Evaluation and Treatment of High Blood Pressure in Children and Adolescents (1) for blood pressure measured by auscultation with a sphygmomanometer on at least 3 separate occasions; if systolic and diastolic categories differ, categorize by the higher value

[b]Adapted from the Report of the Second Task Force on Blood Pressure Control in Children – 1987 (11);

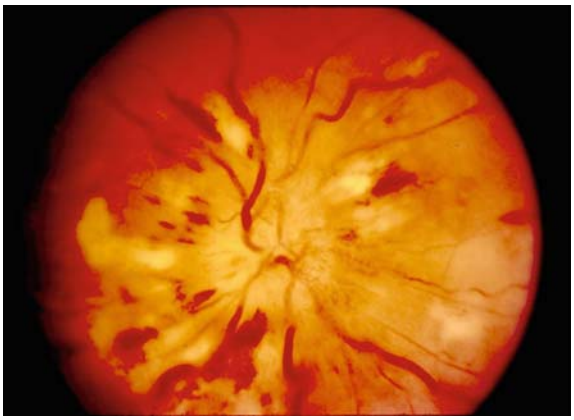
[c]Adapted from the 2003 Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (9).

A large percentage of children with primary hypertension will have a close relative with the same disease (2, 3, 8, 11).

Physical examination may reveal specific signs of genetic disease, such as the elfin facies of Williams syndrome, the café-au-lait spots and small skin neurofibromata of neurofibromatosis type I, the physical features of Cushing syndrome, or ambiguous genetalia associated with congenital adrenal hyperplasia or Denys-Drash syndrome. Rarely, unilateral facial paralysis (Bell's palsy of the seventh cranial nerve) can be the initial presentation of severe hypertension in a child (27, 28). Careful auscultation of the abdomen may reveal a bruit suggestive of renovascular disease, but a bruit is audible only about 50% of the time in these patients (29). Femoral pulses may be diminished in patients with coarctation of the aorta or middle aortic syndrome. Determination of height, weight and BMI with comparison to percentiles for age and gender should always be included as part of the screening physical examination.

Screening laboratory evaluation should be minimally invasive and cost-effective. Screening for rare endocrine causes of hypertension should not be done initially in every pediatric patient with hypertension. Screening studies for all patients should include clinical blood count, urinalysis, and serum electrolytes, creatinine and BUN (1–3). In adolescents with suspected primary hypertension and

Figure 62-2
Severe hypertensive retinopathy in a child with long-standing untreated hypertension showing arteriolar narrowing, hemorrhages and exudates and papilledema. (See color plate 38)



no suspicion for endocrine abnormalities, serum electrolytes may not be that useful. However, a low potassium concentration with metabolic alkalosis may indicate a rare, but treatable disorder, like primary or secondary hyperaldosteronism or Liddle syndrome. Elevated serum potassium in conjunction with metabolic acidosis may suggest chronic renal disease, which is confirmed by the presence of an increased serum creatinine concentration. Creatinine clearance can be estimated from serum creatinine (new Schwartz formula) (30) or measured directly with a 24-h urine collection. Since renal disease is the most common cause of hypertension in children and the kidney is also a target organ for damage from untreated hypertension, urinalysis is an important screening test. Hematuria and red cell casts with or without proteinuria suggests glomerular disease. Isolated hematuria also may be associated with dilatation of the urinary tract or trauma. Proteinuria may be seen in non-glomerular conditions such as reflux nephropathy, obstructive uropathy, or interstitial nephritis, as well as glomerular diseases like focal segmental glomerulosclerosis or membranoproliferative glomerulonephritis. Proteinuria alone may be a sign of end-organ damage from hypertension, but must be distinguished, especially in adolescents, from orthostatic (postural) proteinuria, which is a benign condition.

A renal ultrasound examination is a simple, non-invasive test that is appropriate to perform early in the evaluation of any hypertensive child (1–3). Although it may not be provide much information for the adolescent in whom primary hypertension is strongly suspected, a renal ultrasound helps exclude congenital anomalies that have previously gone undetected. The renal ultrasound provides information about the size and architecture of each kidney and the lower urinary tract. Abnormal kidneys may be small or asymmetric (renovascular disease, vesicoureteral reflux, or dysplasia); hyperechoic, symmetric and normal or large (renal parenchymal disease like glomerulonephritis); or large with or without cysts (polycystic kidney disease, multicystic dysplastic kidney). Hydronephrosis and/or hydroureters may be associated with congenital obstructive uropathy or vesicoureteral reflux.

Color-coded Doppler analysis with B-mode ultrasonography is termed duplex ultrasonography (31) and provides information about the patency and flow within the main renal vessels, including the more distal segments of the main renal artery, to help diagnose renovascular hypertension. During Doppler evaluation care should be taken to scan the entire artery from origin at the aorta to renal hilum to improve sensitivity and accuracy. Obtaining measurements in two views, both anterior and oblique, improves identification of fibromuscular dysplasia in the middle to distal segments of the main renal artery. The limited amount of body fat in many children and the proximity of renal vessels to the skin surface allow the use of high-frequency transducers to improve the technical quality (32); obese patients provide a technical challenge. Color Doppler images can demonstrate global perfusion as well as patency of flow through large renal arteries and veins. Turbulence at a stenotic site alters peak systolic and end diastolic blood flow velocities and creates a characteristic pattern of flow detected by the spectral Doppler waveform (*Fig. 62-3*). The sensitivity of the Doppler flow study is limited for detection of stenosis in accessory renal arteries, intrarenal arteries or mildly stenotic arteries (32, 33). A positive Doppler flow study is helpful in directing further evaluation, but a negative study does not rule out significant renovascular disease.

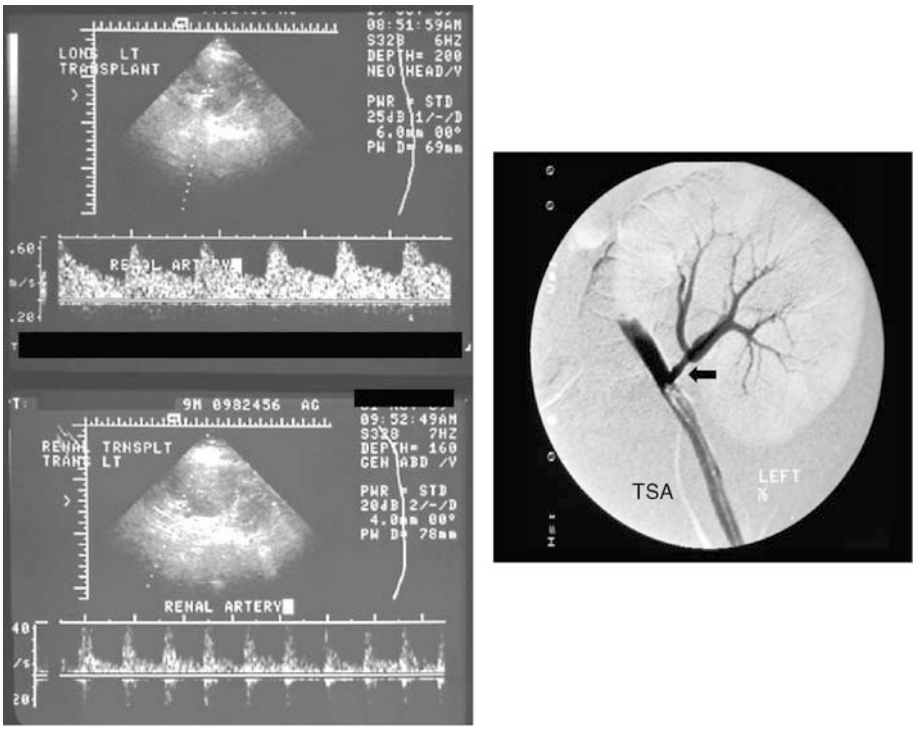
Directed Specific Evaluation of Hypertension after Screening

Specific Evaluation 1: If the screening evaluation is normal or only positive for obesity, sleep problems or a positive family history for essential hypertension, detailed evaluation should be directed toward the diagnosis of primary hypertension (*Fig. 62-1*). Since primary hypertension is largely a diagnosis of exclusion and less common in young children, renovascular disease must always be ruled out, especially if the child is less than 10-years old.

Primary hypertension: The specific evaluation of primary hypertension is designed to determine the presence

Figure 62-3

Renal transplant ultrasound with Doppler flow evaluation in a child. *Left upper panel:* The resistive index is high (0.6) and the flow pattern turbulent, suggesting transplant renal artery stenosis, which was confirmed by digital subtraction angiography (DSA) (arrow) shown in the *Right panel*. *Left lower panel:* Normalization of the Doppler flow study with resistive index lower (0.4) and no turbulence after successful balloon angioplasty of the stenosis.



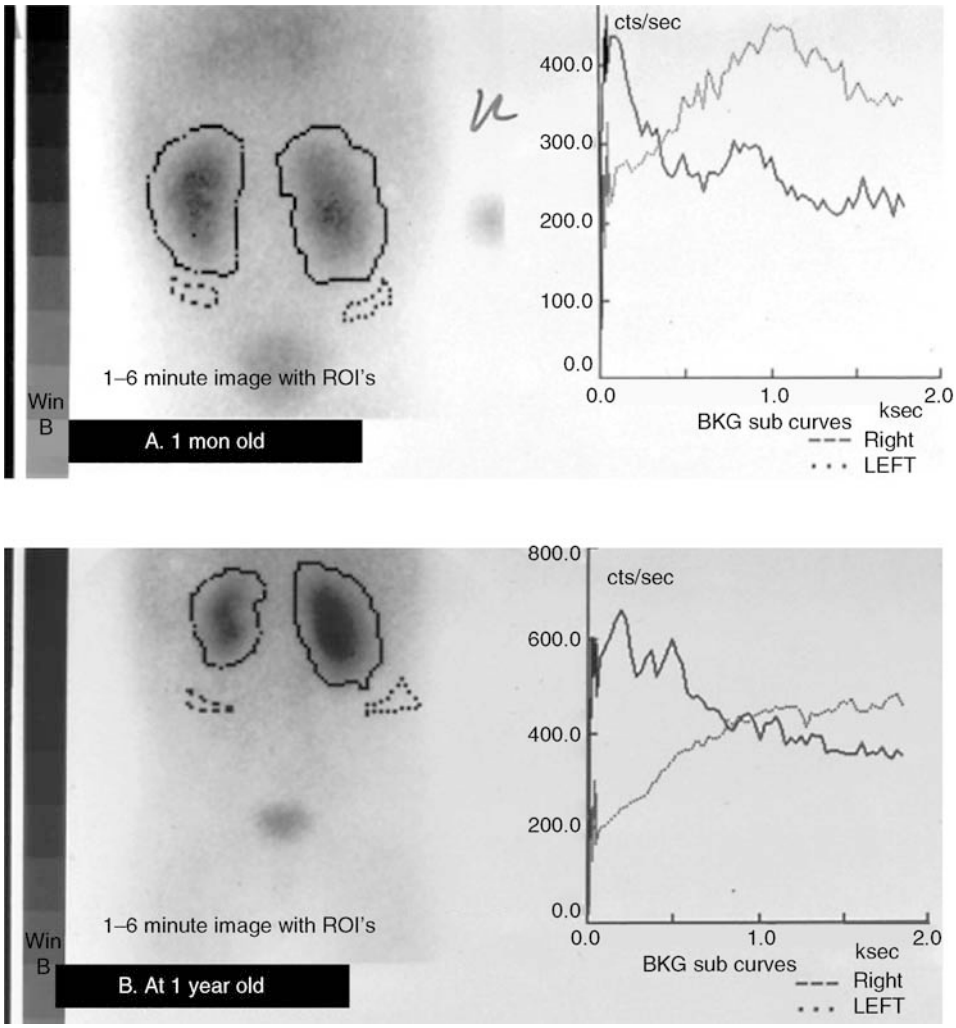
of cardiovascular risk factors, such as hyperlipidemia and insulin resistance, and to assess any end-organ damage to the heart or kidneys (1). In children elevation of serum uric acid level may help distinguish primary from secondary hypertension. Many decades ago increased serum uric acid concentrations were noted in children with primary hypertension, but largely ignored until recent reports that serum uric acid is significantly higher at presentation in children with primary hypertension compared to children with secondary hypertension (34). Elevated uric acid likely plays an early pathogenetic role in childhood hypertensives by activating cellular pathways that lead to increased renovascular tone, fibrosis and irreversible arteriolosclerosis (34). ABPM may help distinguish primary from secondary hypertension, the latter of which is more likely to have greater daytime diastolic blood pressure load, greater nocturnal systolic blood pressure load and blunted nocturnal dipping (35).

End-organ damage may already be evident at presentation of primary hypertension in adolescents. An echocardiogram is the best way to screen for left ventricular hypertrophy and will also serve as a baseline study for comparison later in the course of therapy (1). ABPM may also be useful to identify which children may be at greatest risk for developing end-organ damage from hypertension (5, 16, 36).

Renovascular disease: Renovascular disease is the cause of hypertension in about 10% of the children referred for diagnosis (37, 38). Children with renovascular hypertension are frequently asymptomatic (38). Their hypertension is often severe and may be hard to control with medication before proceeding with specific evaluation (38). An angiotensin converting enzyme inhibitor (ACEI) or angiotensin-receptor blocker (ARB) may provide the best control, but with prolonged use, can also lead to loss of function in the affected kidney from reduced arterial flow in an area of severe stenosis (*Fig. 62-4*). Patients with bilateral renal artery stenosis are at risk for developing acute renal failure at the onset of ACEI or ARB therapy. A child's response to an ACEI, such as captopril, during radionuclide imaging, with either diethylenentriamine pentaacetic acid (DTPA), mercaptoacetyltriglycine

Figure 62-4

Sequential ^{99}Tc-DTPA radionuclide renal scans in an infant with unilateral left renal artery stenosis treated medically, because body size was too small to allow transluminal balloon angioplasty. A. At diagnosis at 1 month old; 40% function left kidney, 60% function right kidney. B. At 1 year old after 11 months of oral ACEI therapy for left main renal artery stenosis; 26% function left kidney, 74% function right kidney.



(MAG3) or dimercapto-succinic acid (DMSA), can be used in the evaluation for renal artery stenosis and is referred to as a captopril renal scan (38–41). Although a captopril renal scan may help lead to a diagnosis, the test is invasive and only moderately sensitive (50–70%), especially if disease is bilateral (38–41). Since a renal arteriogram is both diagnostic and potentially therapeutic when coupled with balloon angioplasty, a captropril renal scan may not be a reasonable step in the evaluation of children with a high likelihood of renal artery stenosis at centers with skilled pediatric interventional radiologists. A renal perfusion scan with DTPA or MAG3 may be useful to identify segmental areas of hypoperfusion or infarction, especially those associated with an embolus from an umbilical artery catheter used in the neonatal period (42, 43). Intravenously administered MAG3 is initially filtered by the glomerulus, then taken up into the kidney primarily by proximal tubular secretion, so MAG3 can be used for estimation of tubular function as well as renal plasma flow.

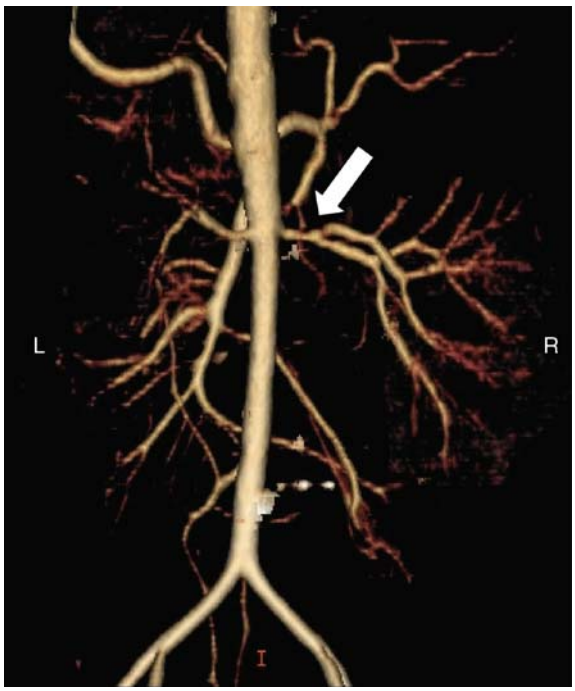
Selective renal arteriography with or without digital subtraction angiography (DSA) enhancement is the gold standard for diagnosis of renal artery stenosis. In a retrospective review of 15 years experience with renal

arteriography for pediatric hypertensive patients, Shahdadpuri and colleagues (44) showed that renal arteriography had a high positive yield of 40% of cases with diagnostic findings, when performed for the indications of severe hypertension or inability to control hypertension effectively with one drug. Renal arteriography has the added advantage that therapeutic transluminal balloon angioplasty (45–50) or placement of bridging stents (38, 49, 50) can be performed during the same procedure. Balloon angioplasty may be possible even in small children, using balloon catheters designed for coronary artery angioplasty (51). The disadvantage of renal arteriography is that it is invasive, exposes the child to nephrotoxic radiocontrast agents and usually requires general anesthesia for small or uncooperative children (39). Deep conscious sedation may be effective for cooperative older children and adolescents. If performed by an experienced interventional radiologist, the renal arteriogram can be done safely as a one-day outpatient procedure in most children. The incidence of severe complications, such as intimal tear or injury, renal artery thrombosus or branch embolus, is very low in experienced hands. Patients need to be observed for 4–6 h post-procedure for possible complications. Arterial puncture carries the risk of hematoma formation at the site and vascular compromise to the extremity.

Computed tomographic angiography (CTA) and magnetic resonance angiography (MRA) are 80–90% accurate alternatives to renal arteriogram for evaluation of renovascular disease (52–54). Stenosis of accessory renal arteries or of the more distal portions of renal arteries, as in patients with fibromuscular dysplasia, are more likely to be missed with these techniques. Both modalities allow scans of high resolution within a 10–30 s breath hold (52), so movement artifact is minimized for children, especially with the shorter 5–10 s breath hold for CTA. CTA requires only a peripheral intravenous approach, produces excellent images of the renal vasculature and allows 3-dimensional (3D) visualization with appropriate software (52, 55) (*Fig. 62-5*). A limited CT scan of the abdomen may be performed before CTA to provide additional information about the anatomy of the kidneys, adrenals and surrounding structures (31). CTA is very useful for evaluation of children and adolescents, in whom the need for invasive renal angiography is not clear-cut (55). The disadvantage of CTA is that it uses ionizing radiation and requires nephrotoxic iodinated radiocontrast agents (31, 52). MRA has the advantages of being minimally invasive and avoiding ionizing radiation, but requires the use of gadolinium contrast enhancement, which puts patients with chronic renal failure, especially those with less than 30% renal function, at risk for nephrogenic systemic fibrosis (56–58). At our center MRA has been a useful evaluation technique for infants and children too small to undergo balloon angioplasty, as well as for neonates (59), but currently we avoid MRA for any patient with even mild renal failure.

Figure 62-5

Computer reconstructed 3D CTA image from a 2.5-year old boy with failure to thrive and severe hypertension, showing mild narrowing of the distal aorta and stenosis of the right main renal artery and its proximal branches (arrow). (See color plate 39)



Plasma renin activity measured in samples from peripheral veins or especially from selective renal veins may provide additional useful information for evaluation of renovascular disease (38, 60). Selective sampling of renal vein renins may be done conveniently at the time of renal arteriogram to provide supporting evidence for unilateral or bilateral disease. The inferior vena cava above and below the renal veins should be sampled at the same time as the renal veins. If the selective renal vein renin concentration is at least 1.5 times greater than concentration in the contralateral kidney, the result is diagnostic for renin-mediated hypertension from that kidney (60). If the contralateral kidney is normal, renal vein renin concentration should actually be decreased due to down-regulation of renin production in the normal kidney from increased circulating angiotensin II (61, 62).

If the ratio between renal vein renin from the contralateral kidney and caudal inferior vena cava is <1.3, then renin production is suppressed in the contralateral kidney (60). The combination of results may be useful to determine whether a patient might benefit or be cured by surgery (60), in the event that angioplasty is only partially successful or not able to be performed.

Peripheral vein renin levels obtained before initiation of antihypertensive therapy may also be useful in evaluation of renovascular hypertension, if they are abnormal (1). Levels must be interpreted within the age-specific normals for the laboratory performing the test and in light of estimated sodium intake at the time the level was drawn. Furthermore, the levels may be adversely affected if the blood is not handled properly from the time of the blood draw. The specimen should be drawn into an EDTA tube, immediately placed on ice, spun in a refrigerated centrifuge and then kept frozen for later assay. A peripheral renin level that is elevated for age suggests renovascular or renal parenchymal hypertension. A normal level, however, does not exclude significant renovascular hypertension. Low levels of plasma renin in the presence of hypokalemia and elevated plasma and urinary aldosterone suggest primary aldosteronism or one of the forms of congenital adrenal hyperplasia as the cause of hypertension (see Endocrine section below).

Specific Evaluation 2: When the history, physical examination or screening laboratory evaluation is abnormal, further evaluation should be directed by those results. If the history, physical, urinalysis and other laboratory tests suggest renal artery stenosis or other vascular disease (*Table 62-3*) or renal parenchymal disease (*Table 62-4*), evaluation should proceed along the lines outlined in the algorithm (*Fig. 62-1*). If initial screening rules out renal disease, but suggests a rare endocrine cause (*Table 62-5*), evaluation should proceed in a different way (*Fig. 62-1*).

The need for evaluation for other causes of childhood hypertension, such as neurological abnormalities, teen pregnancy, drugs or other illnesses (*Table 62-6*), should become apparent after a detailed screening history and physical examination. The rest of the discussion in this chapter will be divided into evaluation of hypertension by disease category.

Renovascular and Cardiovascular Disease

Renovascular Disease: Multiple types of renovascular abnormalities can lead to hypertension (*Table 62-3*), but fibromuscular dysplasia is the most common, occurring in approximately 70% of pediatric cases (37, 63, 64). Most often, the medial layer of the artery is affected, although rarely the intima may be involved (65), especially in the case of neurofibromatosis type 1 (66) or Williams syndrome (67). Disease may be bilateral or unilateral, but if unilateral, may manifest itself with hypertension from the other kidney at a later date. Multiple stenotic lesions followed by post-stenotic aneurysms can resemble a string of beads on a selective angiogram (*Fig. 62-6*). Branch vessels, as well as peripheral intrarenal vessels, may be involved. Other vessels, including the abdominal aorta may be stenotic or hypoplastic, especially in association with neurofibromatosis type 1 (66) (*Fig. 62-7*) or Williams syndrome (67, 68). Typically, the lesions of

Endocrine Abnormalities Associated with Hypertension

Tumors secreting vasoactive substances (catecholamines, renin)
Pheochromocytoma, paraganglioma
Sporadic or hereditary (associated with von Hippel Lindau disease, multiple endocrine neoplasias type II, neurofibromatosis)
Neuroblastoma, ganglioneuroblastoma
Juxtaglomerular cell tumors, Wilm's tumor
Thyroid disorders
Hyperthyroidism (Grave's disease)
Hypothyroidism
Cushing syndrome
ACTH-dependent
Iatrogenic (exogenous glucocorticoid therapy)
Adrenocortical tumor (adenoma, carcinoma)
ACTH-independent
Iatrogenic (ACTH therapy)
Hypothalmic or ectopic CRH-producing tumor
Pituitary or ectopic ACTH-producing tumor
Hyperaldosteronism
Adrenal tumor (adenoma, carcinoma)
Idiopathic adrenal hyperplasia
Congenital adrenal hyperplasia
11β-hydroxylase (P450c11) deficiency
17α-hydroxylase (P450c17) deficiency
Hypercalcemia
Vitamin D intoxication
Hyperparathyroidism
Williams syndrome
Malignancy

ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; P450c11 or 17, cytochrome P450 enzyme

neurofibromatosis are near the origin of the renal arteries (*Fig. 62-7*), whereas the lesions of fibromuscular dysplasia are often more distal (37, 45) (*Fig. 62-8*). Duplex ultrasonography with color Doppler flow may suggest the diagnosis of these disorders, but renal arteriogram is needed for diagnosis and delineation of the extent of the renovascular disease. If the lesion is in the main renal artery and does not involve a long segment of the vessel, transluminal balloon angioplasty may be performed at the same time (45–50) (*Fig. 62-8*). If the child is too small for balloon angioplasty, hypertension may be controlled with medical therapy, especially ACEI or ARB. Caution should be exercised when using ACEI or ARB in the presence of bilateral disease, because of the risk for inducing renal failure. A radionuclide renal scan is a useful tool to sequentially evaluate growth and function of the affected kidney during long-term follow-up (*Fig. 62-4*).

Duplex ultrasonography with color Doppler is a good screening evaluation test for renal transplant artery stenosis (69), which usually occurs at or near the surgical anastomosis (*Fig. 62-3*). The incidence is as high as 10% in children and adults (69, 70). Confirmatory arteriography is always necessary (*Fig. 62-3*), and therapeutic balloon angioplasty may be done at the same time if indicated. Duplex ultrasonography is also useful for follow-up to determine the continued success or recurrence of stenosis after balloon angioplasty or surgical intervention (69, 70) (*Fig. 62-3*).

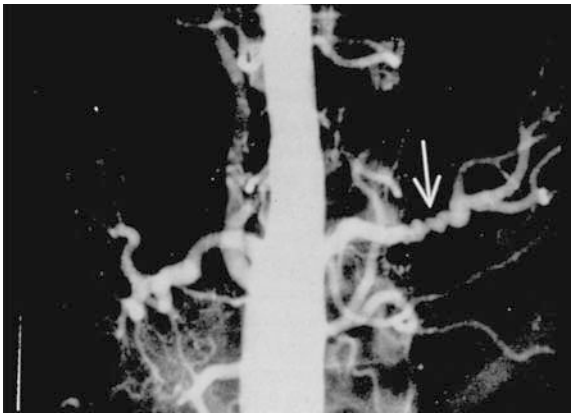
Table 62-6

Miscellaneous Causes of Hypertension

Neurologic abnormalities
Elevated intracranial pressure (associated bradycardia)
Recent seizure, status epilepticus
Familial dysautonomia (Riley-Day syndrome)
Quadriplegia with autonomic nervous system dysfunction
Femoral nerve traction
Cyclic vomiting syndrome
Polycythemia; recombinant erythropoietin therapy
Anesthetic drugs
Ketamine
Naloxone
Drug abuse
Cocaine
Amphetamines
Methamphetamines (e.g., Ecstasy)
Phencyclidine (PCP)
Methylphenidate
Oral contraceptives
Teen pregnancy

Figure 62-6

Renal arteriogram showing typical "string-of-beads" appearance (arrow) of fibromuscular dysplasia in the left main renal artery.



Mild to severe hypertension in transplant patients is associated with chronic renal allograft nephropathy, which includes chronic rejection, donor vascular disease and chronic calcineurin inhibitor nephrotoxicity, all of which lead to arterial fibrous intimal thickening, interstitial fibrosis, tubular atrophy and glomerulosclerosis late in the course after renal transplantation (71). The small arteries are affected, so imaging is not useful for diagnosis. The diagnosis is made by renal transplant biopsy.

Rarely, hypertension in a child results from extrinsic compression of a renal artery or segment by an extrinsic mass, such as a tumor or traumatic perirenal hematoma. Renal ultrasound may identify the mass, but CTA or MRA technology allows extensive 3D detail to establish the diagnosis (*Fig. 62-9*) and direct corrective therapy. More than half of patients with Wilms' tumor have concomitant hypertension secondary to either intrarenal vessel compression or renin production by the tumor (63).

Cardiovascular disease: Coarctation of the aorta accounts for 2% of secondary hypertension in childhood and adolescence, but accounts for approximately one-third of patients seen in the first year of life (72, 73). Aortic coarctation may be focal (juxtaductal), diffuse (hypoplastic aortic isthmus) or complete (aortic arch interruption) (74). Screening evaluation of the hypertensive child suggests coarctation when blood pressure is at least 10 mm Hg higher in the right arm or both arms than in the legs, and the femoral pulses are diminished. A systolic ejection murmur of low intensity may be heard over the base of the heart and precordium and radiate into the left interscapular region. The murmur may be louder over the back. The older child who has developed collateral circulation may have a continuous murmur over large collateral intercostal arteries. When coarcation is suspected on the basis of screening evaluation, the patient should be referred to a pediatric cardiologist for further evaluation.

Echocardiography with color Doppler flow may identify a characteristic wedge-shaped band of tissue to confirm the diagnosis and measure any gradient across the coarcted segment (75). The transverse aortic arch also should be imaged to evaluate for hypoplasia. MRA (74, 76–78) and multidetector CTA (79) are being used increasingly for primary evaluation of thoracic coarctation in children over 4–5 years of age or for follow-up after angioplasty or surgical correction. Echocardiography is difficult after surgical repair because of scar tissue and thorax deformities limiting the acoustic window. 3D gadolinium-enhanced MRA demonstrates excellent anatomy of the aorta, estimates pressure gradient based on peak flow velocity across the stenosis, assesses collateral aortic circulation, and allows a 3D view of the full extent of the aorta (74, 76, 78). Conventional angiography still remains the gold standard and allows direct measurement of pressure gradient across the coarctation, but MRA and multidetector CTA provide alternative non-invasive ways

Figure 62-7

Abdominal arteriogram in a child with neurofibromatosis type 1 showing long segment tubular stenosis of the aorta with collateral flow as well as severe stenosis of the left main renal artery near its origin (arrow). Post-stenotic dilatation of the renal artery and delayed uptake of contrast in the left kidney compared to the right are also present.

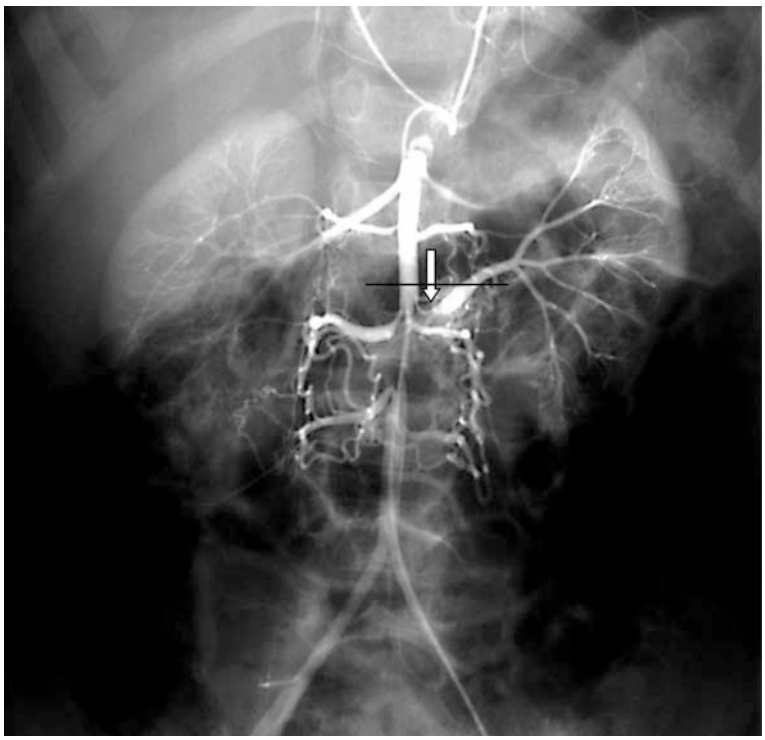


Figure 62-8

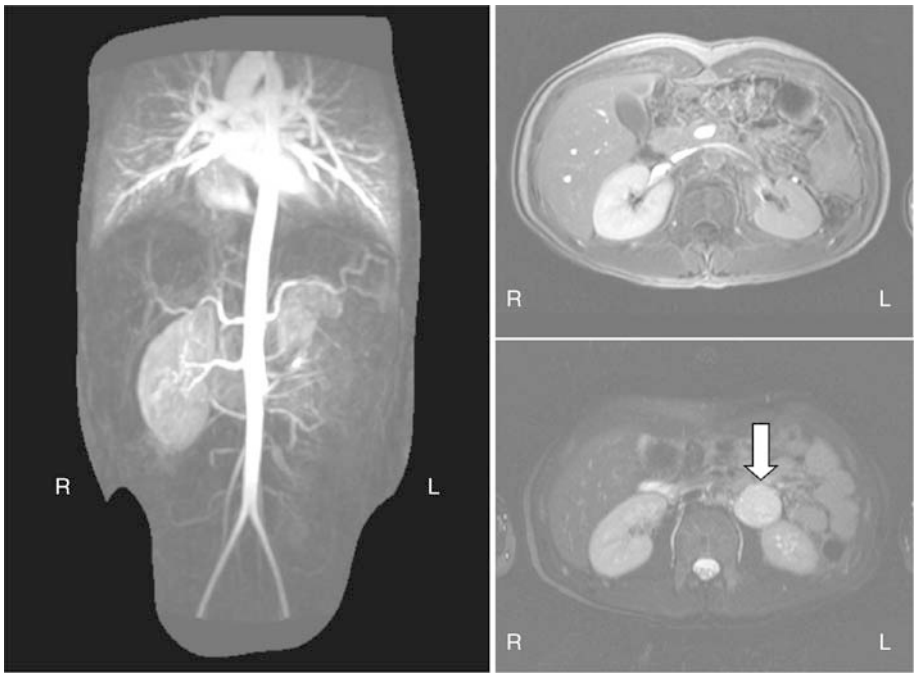
to diagnose, follow and evaluate anatomy for preoperative planning (74, 77, 79).

Other uncommon forms of cardiovascular disease lead to hypertension in infants and children (*Table 62-3*). Middle aortic syndrome, a rare entity which may be congenital, acquired from aortitis/vasculitis or associated with genetic diseases such as neurofibromatosis (*Fig. 62-7*) or Williams syndrome, may lead to severe

Figure 62-9

Images from a 3D gadolinium-enhanced MRA for a teenager with new onset severe hypertension. MRA shows that each kidney is supplied by two renal arteries (left panel). The right kidney and left upper pole kidney show prompt nephrograms, but perfusion of the lower two-thirds of the left kidney is delayed (left and right upper panel) secondary to compression of the left lower renal artery by a 4 cm paraspinal soft tissue mass (arrow, right lower panel).



life-threatening hypertension as well as lower extremity claudication and mesenteric ischemia (28, 37, 80–84). Diagnosis is made by conventional abdominal angiography showing tubular stenosis of the aorta and its visceral branches. 3D CTA is much less invasive and provides excellent detail of the aorta and its branches, but is not yet ready to replace angiography for preoperative planning of surgical therapy (81).

Williams syndrome or Turner syndrome should be suspected during screening evaluation because of typical physical findings, including the elfin facies of Williams syndrome and short stature and webbed neck of Turner syndrome. A variety of cardiovascular abnormalities that can cause hypertension are associated with Williams syndrome, including supravalvular aortic stenosis and thoracic coarctation (67, 84). Patients with Turner syndrome have a high incidence of renal anomalies (40%) and of cardiovascular malformations (20–50%), including coarctation of the aorta, bicuspid aortic valve, and aortic root dilatation (85–88). They also have a high incidence of cardiovascular disease morbidity and mortality as adults (86). Hypertension *per se* may contribute to their adult cardiovascular disease (86–88). ABPM in 75 girls with Turner syndrome revealed abnormal blood pressure circadian rhythm in 50%, suggestive of secondary hypertension (87).

Renal Parenchymal Disease

Most children with secondary hypertension (60–80%) have renal parenchymal disease (2, 89, 90). A variety of glomerular and a few tubular or interstitial renal disorders may cause hypertension in children and adolescents (*Table 62-4*). The most common renal parenchymal disorders associated with hypertension are glomerulonephritis and reflux nephropathy (90–92). Further evaluation for renal parenchymal disease is dictated by findings of the screening history and physical examination or an abnormal CBC, urinalysis, BUN, serum creatinine or electrolytes (*Fig. 62-1*). Hematuria, proteinuria, red blood cell casts on urinalysis, and edema suggest glomerulonephritis. Other systemic signs and symptoms, such as purpuric or malar rash, arthritis and abdominal pain, are suggestive of systemic vasculitis. Anemia and short stature for age in the presence of

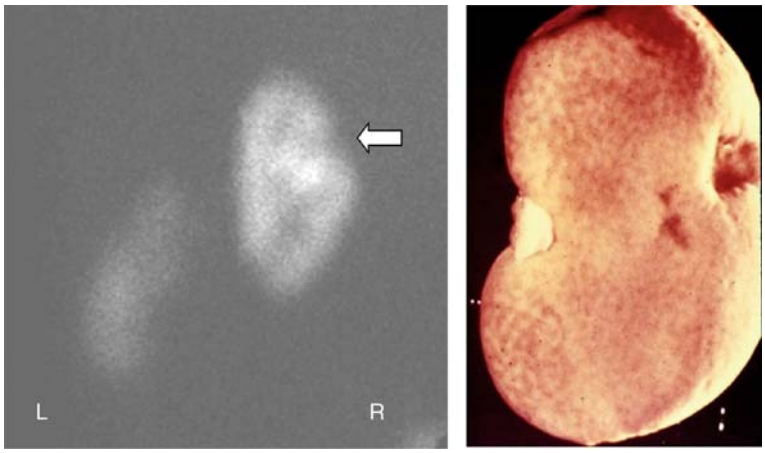
elevated BUN and serum creatinine are characteristic of chronic kidney disease with renal failure, which can result from most of these disorders. Additional laboratory studies, including serum C_3 and C_4, anti-glomerular basement membrane antibody (anti-GBM), anti-nuclear antibody (ANA), anti-double stranded desoxynucleic acid (anti-DNA), and anti-neutrophil cytoplasmic antibody, may help make the diagnosis of a specific glomerulonephritis or systemic vasculitis, but a renal biopsy is almost always needed for definitive diagnosis. The diagnosis of hemolytic uremic syndrome may be made clinically, if microangiopathic hemolytic anemia, thrombocytopenia and uremia are present. These diseases are all discussed in detail in other chapters of this book.

Some hereditary diseases are frequently associated with hypertension (*Table 62-4*). These include autosomal recessive and dominant polycystic kidney disease, medullary cystic disease, juvenile nephronophthisis, Denys-Drash syndrome and sickle cell disease. Diagnostic evaluation of these disorders is discussed in detail in other chapters of this book. Liddle syndrome (pseudoaldosteronism) is an autosomal dominant disease characterized by early onset severe hypertension, hypokalemia, metabolic alkalosis and decreased plasma renin activity and aldosterone (93–95). Originally thought to be an endocrine disorder, Liddle syndrome actually results from mutations/deletions in the gene for an epithelial sodium channel (ENaC) located in the luminal membrane of the distal convoluted tubule and collecting duct. Normal endocytosis of ENaC is impaired leading to increased numbers of ENaC channels and avid unregulated renal sodium reabsorption, volume expansion, hypertension and renal potassium wasting (93). The ENaC is sensitive to amiloride or triamterene suppression, which in combination with dietary sodium restriction forms the basis of therapy for Liddle syndrome (95).

Hypertension associated with congenital renal anomalies, especially vesicoureteral reflux, typically presents in late childhood or early adolescence and may be the first sign of disease (27, 91). Screening renal ultrasound may be diagnostic and at least will direct further specific evaluation, which should include a detailed history for undiagnosed fevers or documented urinary tract infections in early childhood and a voiding cystourethrogram (VCUG). The VCUG will both diagnose and grade reflux. Urinalysis and urine culture should be negative for urinary tract infection before proceeding with a VCUG. The absence of reflux does not negate the possibility that reflux was present in infancy and early childhood and then spontaneously resolved, but left the child with renal scars, reflux nephropathy and the potential for developing hypertension at an older age (91, 92). Unfortunately, no test is available to predict the risk for developing hypertension, so regular long-term follow-up of blood pressure is recommended (91). To detect the presence of renal scars, a DMSA radionuclide scan is preferred over conventional urography or ultrasonography (96, 97). DMSA is filtered then reabsorbed by the renal tubule to become fixed in the parenchyma, providing a static image of functional renal tissue (98). Absence of uptake is consistent with a non-functioning scar as illustrated by *Fig. 62-10*.

Figure 62-10

DMSA radionuclide scan for evaluation of renal scars. *Left panel:* ^{99m}Tc-DMSA radionuclide scan of a 9-year old, who presented with hypertension and Bell's palsy, showing right upper pole renal scar (arrow) and poorly functioning smaller left kidney (relative activity 29%) from vesicoureteral reflux. *Right panel:* Kidney from a different patient showing an upper pole scar from vesicoureteral reflux. (See color plate 40)



Segmental hypoplasia with atrophy, known as the Ask-Upmark kidney (Fig. 62-11), is a scarred, shrunken segment of the kidney characterized histologically by the presence of colloid filled tubular microcysts and few or absent glomeruli (99, 100). Whether this defect is congenital or the result of injury from vesicoureteral reflux or urinary tract infection is uncertain (100). Partial nephrectomy cures the associated hypertension. Renal arteriography with selective renal vein renin sampling is helpful to identify the exact location and extent of the hypoplastic segment before undertaking surgery (101).

Endocrine Abnormalities Associated with Hypertension

Endocrine causes of hypertension in childhood are rare, but usually treatable and often curable (102). Specific evaluation should be directed by the suspected disorder (Fig. 62-1). The combination of a good history and physical examination, accurate interpretation of screening laboratory data and sequential ordering of diagnostic tests will lead to a diagnosis and still be efficient and cost effective.

Pheochromocytoma: The incidence of pheochromocytoma is quite rare in all age groups (102, 103), and accounts for about 1% of the cases of secondary hypertension in childhood (72, 103). Children are more likely to have multiple tumors, recurrence of tumors and a positive family history for related tumors than adults (102, 103)). Pheochromocytomas are chromaffin cell tumors called paragangliomas that arise from the adrenal gland (103). When they are not adrenal in origin, but arise in the autonomic nervous system of the abdomen, thorax, neck or head, they are termed extra-adrenal paragangliomas (103). Children with pheochromocytomas

Figure 62-11

Ask-Upmark kidney. A. ^{99}Tc-DTPA radionuclide scan showing right kidney smaller than left. B. Selective right renal arteriogram showing no filling of lower pole of right kidney; left kidney with late nephrogram of previous radiocontrast injection. C. (See color plate 41)

may present with the classical clinical triad of episodic hypertension, headache and sweating, but hypertension is sustained about 80% of the time in children (102, 103). Other symptoms include anxiety, flushing, visual disturbances, abdominal pain, nausea, vomiting and weight loss. Physical examination may reveal hypertensive retinopathy, features of associated syndromes like the café-au-lait spots of neurofibromatosis, or rarely an abdominal mass, the palpation of which may lead to an abrupt increase in blood pressure and other symptoms of catecholamine release (102).

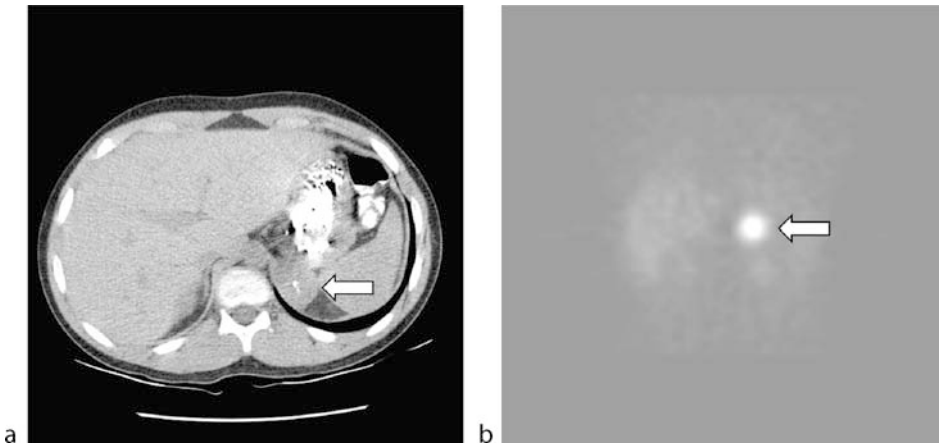
Pheochromocytomas in childhood may be sporadic, but are hereditary about 40% of the time (103). Advances in genetic mutation analysis have improved identification of familial disease, allowing detection of affected children at an early age, before typical signs and symptoms occur (103). The most common hereditary syndromes are von Hippel-Lindau disease, multiple endocrine neoplasia type 2 (MEN 2) and neurofibromatosis. If pheochromocytoma is the primary manifestation of the family disease, a von Hippel-Lindau gene mutation is the most likely cause, whereas most of the patients with MEN 2 have medullary thyroid carcinoma.

Pheochromocytoma is a potentially curable cause of severe and sometimes life-threatening bouts of hypertension (102, 104), so a thorough evaluation to make the diagnosis is important. Specific evaluation for pheochromocytoma (*Fig. 62-1*) should start with measurement of plasma metanephrine and normetanephrine, which are elevated in 80% of patients even when they are asymptomatic (105). Blood should be obtained when the child is in the supine position for better diagnostic sensitivity (103), and results compared to age and gender appropriate reference ranges, since adult normals are higher than those for children (106). Periodic screening with this test can lead to early diagnosis in children with familial disease (103). If the levels are normal, the diagnosis may be excluded. If the results are only marginally increased, further evaluation with repeat plasma metanephrines plus plasma catecholamines or a clonidine-suppression test should be performed, but only by a clinician experienced with these tests (103). Imaging studies may also be indicated for further screening in cases of known familial disease. High levels of plasma metanephrines indicate the presence of a pheochromocytoma with 100% specificity and warrant proceeding directly to imaging studies to locate the tumor (103).

The first step in imaging is usually a CT or MRI scan of the abdomen (103, 104). CT detects adrenal pheochromocytomas with 93–100% sensitivity (*Fig. 62-12*), but has only 90% sensitivity for extra-adrenal tumors. MRI has high sensitivity for detecting both. CT and MRI cannot delineate whether a mass is a pheochromocytoma versus other adrenal or soft tissue tumor. As an example, the paraspinal tumor depicted by MRA in *Fig. 62-9* was unexpectedly identified as an extra-adrenal paraganglioma histologically after surgical removal. In order to identify pheochromocytomas pre-operatively, a meta-iodobenzyl guanidine (MIBG) scan should be done (*Fig. 62-12*). MIBG, which localizes in storage granules in adrenergic tissue of neural crest origin, is very specific (95–99%) for pheochromocytoma and neuroblastoma in children (107, 108). ^{123}I-MIBG offers superior imaging quality compared to ^{131}I-MIBG (109). False-negative

Figure 62-12

Diagnostic imaging for pheochromocytoma. A. Abdominal CT scan showing a 3 cm mass with central calcifications (arrow) located superior to the left kidney in the left adrenal gland. B. ^{123}I-MIBG scan showing uptake in right adrenal mass (arrow).



MIBG results can occur, particularly if tumors are small or in the thorax, neck or head. Repeated examinations may be necessary to finally localize small tumors. Once localized, the pheochromocytoma may be surgically removed and will cure hypertension in 90% of cases (102). In series of childhood pheochromocytomas, as few as 5% up to 45% of tumors have been reported to be malignant (103).

Renin-producing tumors: The possibility of a renin-secreting tumor, such as a juxtaglomerular cell tumor (110, 111) or Wilms' tumor (112, 113), should be entertained in a hypertensive child with hypokalemia, elevated plasma renin activity and absence of other obvious renal or renovascular disease. For juxtaglomerular cell tumors, abdominal CT or MRI imaging will identify small masses better than selective renal arteriography, which is normal in about 50% of reported cases (110).

Thyroid disorders: Mild hypertension may be associated with hyperthyroidism from Grave's disease or rarely thyroid adenoma (102). Acquired hypothyroidism in adults is associated with hypertension and is reversible with thyroid replacement therapy in about 50% (114). The incidence of hypertension from hypothyroidism in children is unknown. The first step in specific evaluation of thyroid disease is assessment of serum T_4 and thyroid stimulating hormone concentration to make the diagnosis of hyper- or hypothyroidism (*Fig. 62-1*). Further evaluation is probably best made by referral to a pediatric endocrinologist.

Cushing syndrome: Exogenous glucocorticoid or adrenocorticotropic hormone (ACTH) therapy, including that used for treatment of asthma, renal disease, rheumatologic disease, neurologic disorders and cancer or transplantation immunosuppression, is the most common cause of Cushing syndrome and endocrine-associated hypertension in pediatrics (102). On the other hand, excess endogenous production of glucocorticoids or ACTH, from an adrenal or pituitary tumor, is unusual in childhood. Obvious physical changes of glucocorticoid excess, including round facies, plethora, truncal obesity, acne, easy bruisability and abdominal striae, may direct the physician to the diagnosis. If the patient is receiving no glucocorticoid medications, screening with an 8 a.m. plasma cortisol, ACTH level and 24-h urinary 17-hydroxycorticosteroids and free cortisol may be appropriate, if referral to a pediatric endocrinologist is not readily available.

Hyperaldosteronism: Hypertension associated with adrenal tumors or idiopathic adrenal hyperplasia is usually mediated by aldosterone or other compounds with mineralocorticoid effects (102). Mineralocorticoid excess leads to salt and water retention, volume expansion and renal potassium wasting. Hypertension in the presence of hypokalemia and metabolic alkalosis found on screening evaluation, should direct the specific evaluation to that for hyperaldosteronism (*Fig. 62-1*). If plasma renin activity is low, plasma and 24-h urinary aldosterone should be measured. Urinary aldosterone is elevated in the presence of high plasma aldosterone concentration and decreased in the presence of other compounds with mineralocorticoid effect. Imaging of the adrenal glands with CT or MRI should be the next step for diagnosis and localization of adrenal adenoma or carcinoma in patients with hyperaldosteronism (102).

Congenital Adrenal Hyperplasia (CAH): Only two enzyme deficiencies in the cortisol pathway are associated with hypertension, 11 β-hydroxylase (102, 115–118) and 17 α-hydroxylase (102, 117, 119, 120). 11 β-hydroxylase deficiency is the second most common cause of CAH, but only accounts for about 5% of cases (102). 11 β-hydroxylase deficiency is an autosomal recessive disorder caused by mutations of the CYP11B1 gene located on chromosome 8q21-q22 (116). 11 β-hydroxylase deficiency results in decreased conversion of 11-deoxycortisol to cortisol and 11-deoxycorticosterone (DOC) to corticosterone, and excess production of androgens from precursors more proximal in the pathway. Decreased cortisol production stimulates secretion of pituitary ACTH resulting in adrenal stimulation and excess production of DOC, which has mineralocorticoid effects in high concentration. The excess androgen production results in virilization and ambiguous genitalia in female infants and penile enlargement in males. Hypertension, hypokalemia and low plasma renin activity are present in most, but not all affected patients. Referral to a pediatric endocrinologist for more extensive laboratory evaluation is an appropriate next step. Characteristic findings are elevated plasma concentrations of 11-deoxycortisol and DOC and the androgens, dehydroepiandrosterone (DHEA) and testosterone, as well as increased urinary excretion of 17-hydroxycorticosteroids, tetrahydro-11-deoxycortisol and 17-ketosteroids (118). ACTH stimulation testing may be needed to make or confirm the diagnosis, especially in adolescents.

17 α-hydroxylase deficiency is very rare, occurring in less than 1% of cases of CAH (102). The trait is autosomal recessive and caused by mutations in the CYP17 gene on chromosome 10q24-q25 (117). This enzyme has both 17 α-hydroxylase and 17,20-lyase (desmolase) activity (119, 120). 17 α-hydroxylase normally facilitates conversion of progesterone to 17-hydroxyprogesterone and pregnenolone to 17-hydroxypregnenolone, which lead to the production of cortisol. 17,20-lyase is required for the synthesis of androgens and estrogenic C18 steroids.

Deficiency of the enzyme limits synthesis of cortisol as well as androgens and estrogens. Unlike patients with 11 β-hydroxylase deficiency, patients with 17 α-hydroxylase deficiency are not virilized, so may not be diagnosed before discovery of their hypertension, hypokalemia and hypogonadism in adolescence. Girls have primary amenorrhea and absent secondary sexual characteristics. Boys usually have complete male pseudohermaphroditism with female external genitalia, a blind vagina, absent uterus and intrabdominal testes. Laboratory evaluation reveals increased serum progesterone and DOC and reduced plasma cortisol, 11-deoxycortisol, DHEA, testoterone and estradiol concentrations. These cases are very rare and best evaluated by referral to a pediatric endocrinologist.

Hypercalcemia: Hypercalcemia is well-known to cause hypertension as well as polyuria, constipation, abdominal pain, anorexia and mental status changes. In pediatric cases, the etiology is most often vitamin D intoxication, Williams syndrome or malignancy and rarely primary hyperparathyroidism (102). Evaluation should include measurement of serum total and ionized calcium, phosphorus, parathyroid hormone, 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D (*Fig. 62-1*).

Miscellaneous Causes of Hypertension

Table 62-6 lists a number of miscellaneous causes of hypertension, including some drugs that should be considered in the evaluation of the hypertensive child. In adolescents or younger children at high risk for drug abuse, a urine drug screen should always be obtained as part of the initial evaluation. A few of the other causes of hypertension in children will be discussed in more detail here.

Neurologic abnormalities: A variety of neurologic disorders give rise to hypertension (*Table 62-6*). In the critically ill child with rising blood pressure and falling heart rate, evolving increased intracranial pressure (ICP) should always be suspected. The incidence of ICP is especially high with acute meningitis or encephalitis (121). Children with seizures and status epilepticus may present with hypertension (122). If blood pressure in the postictal period is high, but less than 4 standard deviations above the mean, hypertension is more likely to be transient and seizure-induced rather than caused by hypertensive encephalopathy with seizures (122). Disorders of the autonomic nervous system may also lead to hypertension. Familial dysautonomia is the best know of these disorders (123–125). Clinical features include paroxysmal hypertension, swallowing difficulties, speech and motor incoordination, and pain insensitivity. Clinical diagnosis is based on Ashkenazi Jewish heritage, diminished tear production, lack of an axon flare after intradermal histamine, lack of lingual fungiform papillae and decreased deep tendon reflexes. The gene for this disorder, IKBKAP, has been isolated and mapped to chromosome 9q31.

Teen pregnancy: Pregnant teenagers are at high risk for developing hypertension, which increases their risk for poor outcomes for the baby, including low birth weight, pre-term delivery and congenital malformations (126–128). When hypertension occurs early in gestation, hospitalization with strict supervision and control of blood pressure may be required. Ultrasound imaging for evaluation of hypertension is acceptable, but conventional radiographic studies and radioisotopic scans should be avoided because of potential adverse effects on the fetus. ACEI and ARB are teratogenic and their use in pregnancy is contraindicated (129, 130). Pubertal and post-pubertal girls with antecedent hypertension should be advised to protect against pregnancy while taking these medications for control of hypertension (130). When preeclampsia or severe hypertension occurs after 36 weeks' gestation, delivery is the therapy of choice. If a teenager with known hypertension becomes pregnant, evaluation should always include serial reassessment of maternal renal function throughout pregnancy.

63 Management of the Hypertensive Child

Demetrius Ellis

Overview

There has been a marked rise in the prevalence of childhood hypertension (HTN) over the last 10–15 years. This has mirrored the rise in obesity and sleep disorders in children (1–4). With an increasing number of children becoming candidates for management of HTN, pediatricians must become much more familiar especially with the pharmacologic management of this important disorder. The extent of interventions to treat HTN will depend greatly upon the demonstration of a link between blood pressure (BP) values and the pathophysiological changes observed in target organs of HTN. Thus, longitudinal investigations are needed in hypertensive children to determine the benefits and risks of lifestyle and/or pharmacologic interventions in preventing cardiovascular and other short and long-term end-organ injury resulting from any level of BP.

In children with HTN, as many as 90% of hypertensive preadolescent children have secondary HTN where as the majority of adolescents have primary (essential) HTN (5–7). Despite the relatively low prevalence of HTN especially in the preadolescent population, there are multiple and unique hereditary or acquired renal and urologic causes of HTN. This underscores the need to develop a therapeutic plan tailored for each child. The age, size, and lifestyle of the child are just a few of the considerations in selecting pharmacologic agents to manage the HTN. Careful attention must also be given to the means of administration, dosage guidelines, and adverse effects of antihypertensive agents.

In addition to providing a general approach to the management of the hypertensive child, including nonpharmacologic measures and a review of the major classes of antihypertensive agents, a major objective of the current treatise is to provide a framework for the rational use of antihypertensive agents based on an understanding of causality and of the pathophysiologic mechanisms. The ultimate aim of such targeted approach to therapy is to provide efficient and effective control of HTN and to minimize adverse effects.

© Springer-Verlag Berlin Heidelberg 2009

Recommendations for Treatment

Pediatricians are at the forefront for detecting risk factors for HTN through regular and proper measurement of BP and through assessment body mass index, dietary, and exercise habits, prescribed or over-the-counter medications and drugs, and lifestyle measures in general, that may impact BP. Such evaluation followed by counseling on healthy habits is essential in preempting the potentially devastating consequences of HTN. This is particularly important in the prehypertensive population with BP between the 90th and <95th BP percentiles in whom BP may be measured more frequently. Tables listing BP by age, gender, and height percentiles must be consulted in order to define the level of BP that should raise concern (8).

The current guidelines for managing childhood HTN are summarized in the fourth report of the National High Blood Pressure Education Program (NHBPEP) Group on High Blood Pressure in Children and Adolescents (8). In brief, all asymptomatic hypertensive children may benefit from nonpharmacologic management. Pharmacologic treatment is indicated in children with BP ≥95th percentile, i.e., Stage I HTN (95th–99th percentile) plus 5 mm Hg who are unresponsive to changes in life style, and in those with Stage II HTN (≥99th percentile) plus 5 mm Hg. Also, children with secondary hypertension, and those with end-organ injury are candidates for pharmacotherapy.

Goal of Therapy

In asymptomatic children, the NHBPEP (8) recommends achieving target BP of:

1. Less than the 95th percentile if there is no other coexisting disorder.
2. Less than the 90th percentile in children with evidence of coexisting cardiovascular risk factors, diabetes or end-organ damage. HTN in children with overt proteinuria or progressive renal insufficiency is also an indication for lowering BP below the 90th percentile.

Of immediate concern is the management of acute symptoms of HTN. For example, aggressive and immediate pharmacologic control of BP is often required in hypertensive children with overt evidence of end-organ injury in the form of encephalopathy, seizures, Bell's palsy, cerebrovascular accident, congestive heart failure, or hypertensive retinopathy.

The long-term objective of HTN control is the prevention of cardiovascular disease and heart failure which remain to be the leading causes of morbidity and mortality in adults in the USA. Currently there are no longitudinal studies in children assessing the relationship of the level and the duration of HTN, and cardiovascular risk. While numerical goals are often used to assess the efficacy of therapy, isolated BP values obtained at clinic settings may be unreliable. Thus, many experts recommend more reliable means of predicting cardiovascular complications, including ambulatory BP monitoring (ABPM) (9–11) which requires special authorization for reimbursement by health care insurers in the USA, or, home blood BP monitoring (12).

Reversal of the symptoms and signs of HTN and of markers of HTN is an even more important goal of therapy. Left ventricular hypertrophy (LVH) on echocardiography is perhaps the most sensitive means for detecting end-organ injury in children with well-established HTN. LVH is detected in 40% of such children (13–15). Microalbuminuria, as a marker of microvascular disease, is another early clinical indicator of end-organ damage in adults with HTN, but its importance has not been investigated in children except as it relates to type 1 diabetes.

Lifestyle Measures and Nonpharmacologic Management of HTN (See *Table 63-1*)

While many children present with established HTN, prevention of HTN and its complications is highly desirable and also plausible. A heightened awareness of environmental or medical factors, such as obesity, and renal disorders may indicate a need for close monitoring to detect HTN such that timely intervention can be implemented. Thus, the pediatrician and other health care providers must inquire about environmental or modifiable risk factors as well as to assess genetic risks. It is essential that education and counseling must then be provided to the family and not just the child so as to enhance motivation and compliance with the proposed treatment strategy. Intervention may be needed in the management of overweight, sleep disorders, in intake of exogenous agents that may provoke HTN, and in limiting psychobehavioral factors including school stress and excessive use of computer games. Attention must be given to the sodium content of processed food along with the amount of fat in the diet, as well as the amount of vegetables and fruits consumed by the child. An overview of the amount and type of exercise and activity may also be part of the medical history.

Table 63-1

Lifestyle modifications and approximate range of systolic BP reduction (mm Hg)[a]

Exercise/limit TV and other sedentary activities (4–9)
Weight reduction (smaller portions/exercise) (5–20/10 kg weight loss)
Consume more fresh vegetables and fruits, low-fat dairy products and low content of saturated fats (2–8)
Reduce Na intake (2–8)
Avoid alcohol (2–4)
Limit caffeine
Avoid tobacco (cigarettes/chewing)

[a]Obtained from adult studies

Lifestyle changes are essential in managing all children with HTN. An initial conservative, nonpharmacologic treatment approach is also recommended in children with Stage 1 HTN and no end-organ injury. The aim of treatment is not only to lower blood pressure but to also diminish other consequences of unhealthy lifestyle which may impact cardiovascular disease such as obesity and hyperlipidemia, and to reduce the use of caffeine, drugs, alcohol, tobacco, and high salt intake, as well as to balance food intake and exercise.

Setting realistic and measurable goals over specified periods of time for achieving weight reduction, correction of metabolic disturbances, and numerical targets of BP, are useful adjuncts in managing the hypertensive child.

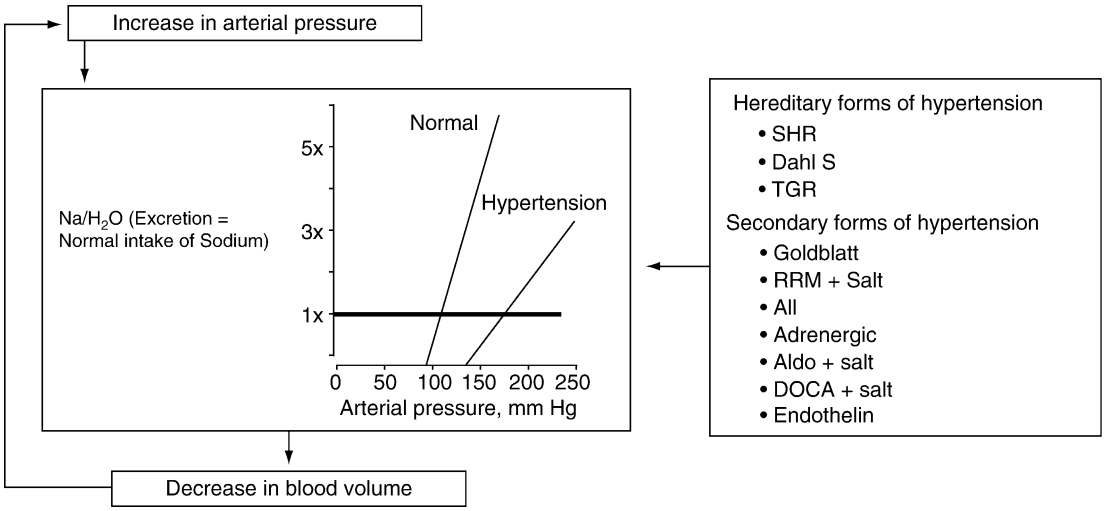
Diet

Salt Restriction

The link between a high salt intake and HTN is indisputable (16–18) *Fig. 63-1* shows the mechanisms implicated in salt-sensitive HTN (19). Several epidemiologic studies as well as a well-controlled study, the INTERSALT study (20), confirmed the relationship between salt and HTN. Also, a meta-analysis of multiple studies indicates that salt reduction lowers BP in individuals with HTN (21). More importantly, the randomized Dietary Approaches to Stop Hypertension (DASH) study showed that the lower the salt intake the greater the BP reduction

Figure 63-1

Etiopathogenesis of salt-sensitive hypertension. Schematic representation of the pressure-natriuresis hypothesis for the long-term control of arterial pressure. In normal animals, any elevation in arterial pressure would be expected to increase sodium and water excretion via pressure natriuresis. Because sodium and water intake is habitually determined and remains relatively fixed, the increase in sodium and water excretion slowly lowers blood volume sufficiently until arterial pressure returns exactly to control. The pressure-natriuresis relationship either exhibits a reduced sensitivity (slope reduction) or is shifted in a parallel manner toward a higher set point, or in every experimental model of hypertension studied to date. Thus, sodium and water are retained until arterial pressure is elevated sufficiently to restore sodium and water balance. SHR indicates spontaneously hypertensive rats; Dahi S, Dahi salt-sensitive rats; TGR, transgenic renin gene rats; RRM, reduce renal mass; Aldo, long-term administration of aldosterone; DOCA, long-term administration of deoxycorticosterone acetate; and gray bar, normal level of sodium intake.



in both normotensive and hypertensive individuals on a normal North American diet. Also, this study demonstrated the benefit of a diet rich in fruits and vegetables and low in saturated fats in lowering BP (22).

North American children have a high intake of salt derived mainly from processed food rather than salt added to food by the individual. Sodium restriction is particularly useful in African–Americans with salt-sensitive HTN. This is because such individuals have an inheritable impairment in sodium excretion at any level of renal perfusion pressure. When combined with an acquired taste for salt leading to ever increasing salt intake, this eventually leads to sustained HTN. For any level of sodium intake, salt-sensitive individuals may experience a 16-fold increase in systolic blood pressure (SBP).

The NHBPEP recommends a 1.2 g/day sodium intake for 4–8 year-olds and 1.5 g/day for older children (8). These limits may be difficult to implement. A daily intake of 1.5–2.0 g of sodium (4.25–5.0 g of salt)/m^2 body surface area may be more realistic compared to an average salt intake that is double this amount among children in North America. The DASH study recommends no added salt, as well as increased fruits, vegetables, and low fat and low dairy intake (22). This is a more palatable diet and more likely to succeed in the long term.

Potassium/Calcium/Magnesium

A higher intake of potassium, calcium, and magnesium has been shown to have an ameliorating effect on BP in both experimental models of HTN, as well as in human epidemiologic studies (17). No specific requirements for supplemental amounts of potassium, calcium, and magnesium are available for hypertensive children.

Caffeine

Acute caffeine intake may increase "central" BP which may not be evident by measuring peripheral BP, by increasing catecholamine release and thereby raising vascular resistance (23, 24). Caffeine intake has risen in children in North America in parallel to obesity. "Super-sizing" of portions by many food providers have included large

volumes of high calorie and high caffeine soft beverages, as well as less well known amounts of caffeine found in iced tea (70 mg of caffeine/12 ounces of tea compared to 55 mg/12 ounces of Mountain Dew and most Coke/Pepsi products). Caffeine-sensitive individuals may develop tachycardia that initially raises SBP independent of obesity.

Weight Loss

There are several studies linking obesity and HTN in children (3, 4). The causes of hypertension in obesity are multifactorial, complex and poorly understood. Several mechanisms are reviewed under Sect. "Obesity/Metabolic Syndrome/Sleep Apnea".

The body mass index (BMI = weight (kg)/height $(m)^2$) chart should be consulted to determine if the child is overweight (BMI > 85 percentile) or obese (BMI > 95 percentile) for age and gender. A plan for management may include modifications in diet and exercise as outlined by Rocchini (25). Participation in a formal weight management program to review and to monitor for complications of obesity, and to reenforce the need for weight control with the child and his family, is strongly recommended by the author.

Hyperlipidemia is an independent risk factor for cardiovascular disease associated with HTN. However, hyperlipidemia is also more prevalent in obese children with or without HTN. The coexistence of the two disorders is more conducive to cardiovascular injury. The American Heart Association recommends Step 1 or Step 2 diet to control hyperlipidemia (26). Exercise may also be helpful not only in reducing body weight but also by lowering triglycerides in particular.

Exercise (See Sect. "Hypertension in Athletes")

A 10 mmHg reduction in mean arterial BP may be achieved through regular exercise. The American College of Sports Medicine recommends aerobic exercise three to four times per week with the goal of achieving 60–85% of maximal heart rate (26). A daily aerobic activity lasting 30–60 min is highly recommended. Static exercises are less useful for weight control while excessive weightlifting (more than 30 min/day for more than 3 days/week) may contribute to HTN.

Drug Intake and HTN

In addition to nicotine (tobacco) and alcohol use, there is an expanding list of prescribed and illicit drugs that may either cause HTN or exacerbate preexisting HTN (*Table 63-2*). A careful medical history for such drug intake may lead to appropriate education and counseling.

Table 63-2
Exogenous substances that raise the blood pressure

Substance	Raise blood pressure	Interfere with therapy	Source of substance
Anabolic steroids	Yes	No	Patient
Caffeine	Yes	No	Patient
Cocaine	Yes	Yes	Patient
Ethanol	Yes	No	Patient
Nicotine	Yes	No	Patient
Sodium chloride	Yes	Yes	Patient
Sympathomimetic agents	Yes	No	Patient or clinician
Nonsteroidal antiinflammatory agents	Yes	Yes	Patient or clinician
Chlorpromazine	Yes	No	Clinician
Corticosteroids	Yes	Yes	Clinician
Cyclosporine	Yes	No	Clinician
Tacrolimus	Yes	No	Clinician
Erythropoietin	Yes	No	Clinician
Monoamine oxidase inhibitors	Yes	No	Clinician
Oral contraceptives	Yes	No	Clinician

Behavioral Modification/Stress Management/Biofeedback

These are techniques that may be used to complement other treatment modalities. They may be especially useful in individuals with white coat HTN evident on ABPM, or those with systolic HTN.

Pharmacologic Agents Used to Manage Hypertension

Introduction

Important recent legislative initiatives such as the Food and Drug Administration Modernization Act of 1997 (FDAMA) (27) followed by the Better Drugs Act of 2002 (28), have enabled trials of antihypertensive agents in children and refined the investigative guidelines to include data on the long-term effects of antihypertensive agents on cognitive function and body growth. These legislations have been very instrumental in obtaining evidence-based data on dosing, efficacy and safety for many antihypertensive agents currently utilized in children. In return for sponsoring pediatric clinical trials, pharmaceutical companies receive labeling or exclusivity for approved indication of their agent as well as an extension of the drug patent.

Based on clinical trials, an increasing number of antihypertensive drugs have received FDA approval for pediatric use. An updated list of these drugs that received label change based on pediatric studies is maintained on the internet (29) and is summarized in *Table 63-3*. However, at best, antihypertensive trials in children are limited in scope, partly because of the relatively small number of children with specific disorders. Also, there is a large variability in the bioavailability of drugs based on the child's age and body size. A number of other areas remain problematic and include a limited number and uniformity of liquid preparations for use in younger children, the lack of information on the stability of such suspensions, and a dearth of pharmacokinetic data of antihypertensive agents in general. Thus, certain agents may not be uniformly effective despite adjustment in dosage, or the child may require more than one agent to achieve optimal BP control. Also, long-term effects of antihypertensive agents on linear growth and cognitive function remain to be assessed in longitudinal studies.

Table 63-3

FDAMA-related written requests for antihypertensive medication studies and exclusivity status in children (as of 3/2008)

Compound	Study status	Exclusivity granted
Amlodipine	Completed	Yes
Benazepril	Completed	Yes
Betaxolol	Completed	Yes
Bisoprolol/HCTZ	Completed	Yes
Candesartan	Unknown	–
Carvedilol	Completed	Yes
Enalapril	Completed	Yes

Indications for Pharmacologic Treatment of HTN

The pharmacologic management of HTN is multifaceted and individualized based on the pathophysiology and on the classification of HTN. Criteria for pharmacologic management have been outlined by the NHBPEP (8). Accordingly, one of the following criteria must be present before drug therapy is initiated:

1. *Stage I* HTN (95th–99th percentile) plus 5 mm Hg who are unresponsive to changes in life style, and in those with *Stage II* HTN (>99th percentile) plus 5 mm Hg.
2. Symptomatic hypertension including headaches, changes in mental process or consciousness, increased urination, or irritability.
3. Secondary HTN.
4. Evidence that the high blood pressure is causing end-organ damage. This may be evident by left ventricular hypertrophy or increased left ventricular mass index, or by hypertensive alterations of the retinal vessels as described by Keith-Wagener.
5. Coexisting diabetes. All children with HTN and diabetes should be considered for pharmacologic therapy, independent of albuminuria status.

6. The presence of additional cardiovascular risks including elevated serum cholesterol, known heart disorders, severe obesity, etc.

General Approach to Pharmacotherapy of HTN

In general, the use of fewer medications with fewer adverse effects leads to better compliance. Single medications with extended release or long-action, or combination drugs may also enhance compliance, particularly in adolescents. It should be noted, however, that even among the best conceived studies, target BP may be achieved in only 45–63% of the children (30).

As a rule, one should start with one medication at a time using the lower dosage range. BP should be closely monitored at home, school or at the primary care physician's office. If the child is asymptomatic and BP fails to improve within 2–3 days after using the agent at the mid-range dosage, there are three general guidelines:

1. Further increase the dosage gradually to the maximum tolerable dose ("stepped" or "step-up" care), or,
2. Replace the initial agent with that of another class ("sequential monotherapy") on the assumption that it is not possible to predict how all children with a given disorder will respond to any individual agent. or,
3. Add another agent ("add-on" care).

Many clinicians are now deviating from the current paradigm of step-up care because of the higher risk of dose-dependent adverse effects, and also because adding drugs with complimentary mechanisms of action administered at mid-range dosages lowers such risks while providing an additive effect (31).

Choice of Antihypertensive Medications

Because renal disease comprises 60–70% of the etiology of HTN in preadolescent children (5, 7), the use of angiotensin converting enzyme inhibitor (ACEI) and angiotensin recptor blocker (ARB) is more prevalent in children than in adults while other classes of medications may also be effective. A survey of pediatric nephrologists noted that 47% used ACEI, 37% used CCB, and 7.6% used a beta blocker as first-line drugs to manage primary HTN (32). Pediatric nephrologists utilize ACEI as first-line drugs in 84% of children with HTN associated with renal disorders. Primary or essential hypertension is much more prevalent in adolescents. In this population the initial medication choice may be much wider (see Sect. "Primary (PH) or Essential HTN"). In general, the use of beta blockers is discouraged as an initial agent except for special circumstances, which will be discussed below. The special needs of hypertensive children participating in competitive sports must also be addressed (see Sect. "Hypertension in Athletes").

In choosing antihypertensive agents for any indication, one must always consider the presence of other medical conditions. For instance, thiazide diuretics should be avoided in individuals with gout, diabetes or hyperlipidemia; beta blockers are relatively contraindicated in individuals with bronchospasm, asthma or peripheral vascular disease; CCB should be avoided in individuals with certain cardiovascular disorders; and ACEI must be avoided throughout pregnancy.

In addition, the choice of medication within a particular class may depend on cost because insurance providers may not reimburse for certain medications, even if these have been tested in children. In addition, the psychological effects of labeling a child as "hypertensive" and in need of antihypertensive medications should be addressed with the child and the family.

Classes of Antihypertensive Agents

The author employs three essential steps to aid the decision to choose a specific class of antihypertensive medication and which agent within a class for a particular child:

Step 1. Formulate a hypothesis of the pathophysiology of HTN and of contributing factors. This will aid the selection of one or more agents with a mechanism of action that may counteract or oppose such pathophysiologic mechanisms. *Table 63-4* provides pediatric dosage guidelines for agents that are widely utilized in hypertensive children.

Step 2. Identify comorbid conditions such as diabetes and other metabolic disorders, heart disease, pulmonary or kidney disorders and consider whether or not these disorders may be negatively impacted by the proposed agent(s).

Step 3. Monitor for adverse effects associated with specific antihypertensive agents.

Diuretics

These agents promote urine production (diuresis) by reducing renal tubular sodium reabsorption (termed

Table 63-4

Antihypertensive drugs for management of hypertension in children

Diuretic		
Drug	**Dose**	**Comments**
Hydrochlorothiazide (HCTZ)	Initial: 1 mg/kg per day (q.d.; bid)	All patients treated with diuretics should have electrolytes monitored shortly after initiating therapy and periodically thereafter. Avoid thiazides in newborns with hyperbilirubinemia
	Maximum: 3 mg/kg per day upto 50 mg/day	
Chlorothiazide	Initial: 10–20 mg/kg per day	
	Maximum: 375 mg if age <2-years; 1,000 mg if age 2–12-years with 0.2–0.4 mg/kg/day	
Metolazone		Especially useful in combination with loop diuretics
Chlorthalidone	Initial: 0.3 mg/kg per day (q.d.)	May precipitate azotemia. Use with extreme cation in children with renal impairment
	Maximum 2 mg/kg per day up to 50 mg/day nephrocalcinosis	
Furosemide	Initial: 0.5–4.0 mg/kg per dose (q.d.-bid)	Avoid loop diuretics in children with hypercalciuria or nephrocalcinosis. May cause hypocalemia, hypocalcemia, hypomagnesemia. may be useful as add-on therapy in children with resistant HTN in association with renal failure
	Maximum: 6 mg/kg per day	
Bumetanide	0.015–0.06 mg/kg/day (daily or bid)	
Spironolactone	Initial: 1 mg/kg per day (q.d.-bid)	
	Maximum: 3.3 mg/kg per day up to 100 mg/day	
Triamterene	Initial: 1–2 mg/kg per day (bid)	Spironolactone, riamterence and amiloride may cause severe hyperkalemia, especially if given with ACE inhibitor or ARB
	Maximum: 3–4 mg/kg per day up to 300 mg/day	
Amiloride	Initial: 0.4–0.625 mg/kg per day (q.d.)	
	Maximum: 20 mg/day	
Epleronone	0.5–1 mg/kg per day (q.d.)	
Central α-agonist		
Clonidine*	Children ≥12 years (bid)	May cause dry mouth and/or sedation
	Initial: 0.2 mg/day	Transdermal preparation also available
	Maximum: 2.4 mg/day	Sudden cessation of therapy can lead to rebound HTN
α-metyldopa	Initial: 10 mg/kg per day (bid-qid)	Sedation is common
	Maximum: 60 mg/kg per day	
Peripheral α-agonist		
Doxazosin	Initial: 1 mg/day (q.d.)	May cause hypotension and syncope, especially after the first dose
	Maximum: 4 mg/day	
Prazosin	Initial: 0.05–0.1 mg/kg per day (tid)	
	Maximum: 0.1 mg/kg per day	
Terazosin	Initial: 1 mg/day (q.d.)	
	Maximum: 20 mg/day	
α- and β-Blocker		
Labetalol	Initial: 1–3 mg/kg per day (bid)	Should not be used in insulin-dependent diabetics
	Maximum: 10–12 mg/kg per day up to 1,200 mg/day	Asthma and heart failure are relative contraindications for all drugs in this classes

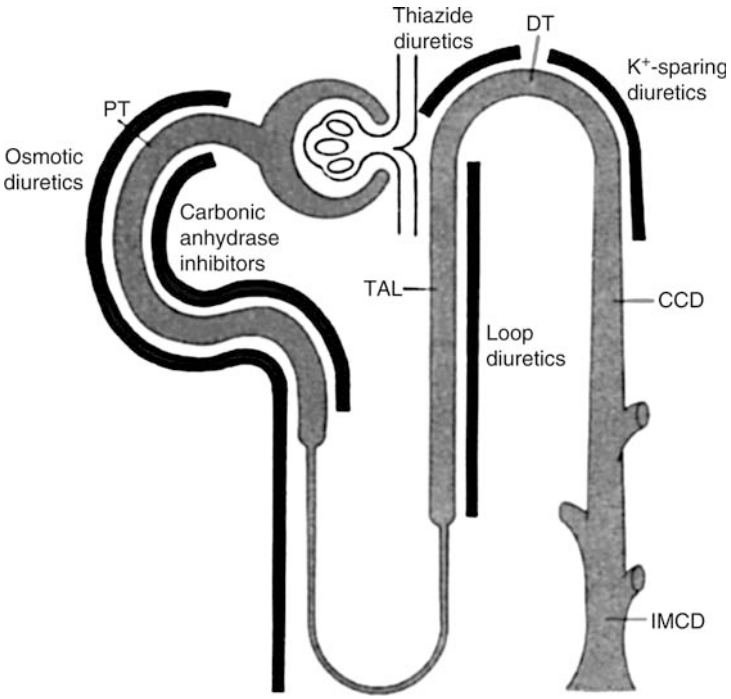
Table 63-4 (Continued)

Diuretic		
Drug	**Dose**	**Comments**
Carvedilol	Initial 0.15 mg/kg/day (bid)	Heart rate is dose limiting for all drugs in this classes
	Maximum: 0.5 mg/kg/day (bid)	All drugs in this classes may impair athletic performance
β-Blocker		
Atenolol	Initial: 0.5–1 mg/kg per day (q.d.-bid)	
	Maximum: 2 mg/kg per day up to 100 mg/day	
Bisoprolol/HCTZ	Initial: 2.5/6.25 mg/day (q.d.) (0.04 mg/kg per day is the bisoprostol component in Ziac)	
	Maximum: 10/6.25 mg/day	
Metoprolol	Initial: 1–2 mg/kg/per day (bid)	
	Maximum: 6 mg/kg per day up to 200 mg/day	
Propranolol	Initial: 1–2 mg/kg per day (bid-tid)	
	Maximum: 4 mg/kg per day up to 640 mg/day	
Vasodilators		
Hydralazine	Initial: 0.75 mg/kg per day (qid)	Tachycardia and fluid retention are common side effects
	Maximum: 7.5 mg/kg per day up to 200 mg/day	Hydralazine can cause a lupus-like syndrome in slow acetylators
		Avoid both agents in coronary artery disease, head trauma, intracranial hemorrhage and other cerebrovascular disorders
Minoxidil	Children $<$12 years: (q.d.-tid)	Prolonged use of minoxidil can cause hypertrichosis
	Initial: 0.2 mg/kg per day	Minoxidil is usually reserved for patients with resistant to multiple drugs
	Maximum: 50 mg/day	
	Children $\geq$12 years	
	Initial: 5 mg/day	
	Maximum 100 mg/day	
Calcium channel blocker		
Amlodipine (Norvasc)	0.06 mg/kg/day	Amolodipine and isradipine can be compounded into stable extemporaneous suspension
	Children 6–17 years: 2.5–5 mg once/day	
Felodipine (Plendil)	Initial: 2.5 mg/day (q.d.)	Felodipine and extended-release nifedipine tablets must be swallowed whole
	Maximum: 10 mg/day	
Isradipine (Dinacirc)	Initial: 0.15–0.2 mg/kg per day (tid-qid)	Isradipine may cause tachycardia
	Maximum: 0.8 mg/kg per day up to 20 mg/day	
Short-acting nifedipine	Initial: 0.2–0.25 mg/kg per dose	See Section VII. 12
	Maximum: 0.5 mg/kg per dose	

Table 63-4 (Continued)

Diuretic		
Drug	**Dose**	**Comments**
Extended-release nifedipine (Procardia XL, Adalat-CC, Nifedipine-ER)	Initial: 0.25–0.5 mg/kg per day (q.d.-bid)	
	Maximum: 3 mg/kg per day up to 120 mg/day	
Diltiazem (Cardizem)	1.5–2 mg/kg/day divided tid	Avoid in children with left ventricular dysfunction. Avoid in neonates and infants, or in those with sick sinus syndrome or A-V block
Verapamil (Calan-SR)	3–8 mg/kg/day divided tid	Same as for diltiazem
ACE inhibitor		
Benazepril (Lotensin)	Initial: 0.2 mg/kg per day upto 10 mg/day (q.d.)	All ACE inhibitors are contraindicated in pregnancy; females of childbearing age should use reliable
	Maximum: 0.6 mg/kg per day up to 40 mg/day	
Captopril (Capoten)	Initial: 0.3–0.5 mg/kg/dose (tid)	Cough and angioedema are reportedly less common with newer members of this class then with captopril
	Maximum: 6 mg/kg/per day	
Enalapril (Vasotec)	Initial: 0.08 mg/kg/per day up to 5 mg/day (bid)	Benazepril, captopril, enalapril, and lisinopril labels contain information on the preparation of a suspension
	Maximum: 0.6 mg/kg per day up to 40 mg/day	
Fosinopril (Monopril)	Children >50 kg: (q.d.)	Check serum potassium, creatinine periodically to monitor for hyperkalemia and renal dysfunction
	Initial: 5–10 mg/day	
Lisinopril (Prinivil, Zestril)	Initial: 0.07 mg/kg per day upto 5 mg/day (q.d.)	
	Maximum: 0.6 mg/kg per day upto 40 mg/day	
Quinapril (Accupril)	Initial: 5–10 mg/day (q.d.)	
	Maximum: 80 mg/day	
Ramipril ((Altace)	6 mg/m^2/day	
	Maximum: 20 mg/day	
Angiotensin-receptor blocker		
Irbesartan (Avapro)	6–12 years: 75–150 mg/day (q.d.)	All ARBs are contraindicated in pregnancy; females of childbearing age should use reliable contraception
	>13 years: 150–300 mg/day	
Losartan (Cozaar)	Initial: 0.7 mg/kg per day up to 50 mg/day (q.d.)	Check serum potassium, creatinine periodically to monitor for hyperkalemia and renal dysfunction
	Maximum: 1.4 mg/kg per day up to 100 mg/day	
Candesartan (Atacand)	0.23–0.35 mg/kg per day (q.d.)	
Valsartan (Diovan)	1.3 mg/kg/day (q.d.)	
	Maximum: 40 mg/day (q.d.)	
Olmesartan (Benicar)	1–5 years: 0.3 mg/kg per day (q.d.)	
	16 years: 0.3–0.6 mg/kg per day (q.d.)	

Figure 63-2
Nephron site of diuretic action.



saluresis or natriuresis). Hence, these agents are frequently prescribed for the management of HTN associated with edema or salt retaining disorders. *Fig. 63-2* shows the nephron site of diuretic action. *Table 63-5* summarizes the mechanism and duration of action as well as dosage of diuretics in children (33–35). Diuretics have a wide range of adverse effects and are often misused.

All diuretics, except spironolactone and amiloride, exert their action at the intraluminal side of the tubular epithelium. Nearly all diuretics other than mannitol are highly bound to plasma proteins; hence, they are not filtered at the glomerulus and must be secreted by tubular organic acid or organic-base secretory pathways. The site and mechanism of action determines if electrolytes other than sodium (example potassium) will be lost in the urine. Several agents acting in the late distal convoluted tubule induce limited diuresis, but may be useful as potassium sparing drugs, or they may be indicated for the management of specific monogenic hypertensive disorders.

In salt-sensitive hypertensive individuals with disturbed BP/natriuresis, diuretics such as hydrochlorothiazide may be of special benefit. Blacks and children with low birth weight and a decreased number of nephrons may also benefit from use of thiazides, especially when HTN is associated with a high body mass index.

Unlike the widespread use of diuretics in adults, such agents are utilized less frequently in the management of childhood HTN. In general, they are used as second or third line drugs to manage HTN associated with renal disorders, and loop diuretics are preferred over other classes, particularly in the setting of renal insufficiency. Diuretics have an additive and occasionally synergistic effect when used with other classes of antihypertensive agents. There are multiple antihypertensive combinations that contain thiazide diuretics so as to facilitate compliance. Osmotic diuretics, such as the nonmetabolizable sugar mannitol, expand the extracellular fluid compartment and are not utilized in the management of HTN.

Loop Diuretics

These include *furosemide*, *ethacrynic* acid, and *bumetanide*. By blocking the $Na^+/K^+/2\ Cl^-$ (NKCC2) electroneutral cotransporter in the luminal membrane of the medullary and the cortical segments of the ascending limb of the loop of Henle, these agents may increase the fractional excretion of sodium (FENa) by inhibiting the reabsorption of as much as 20% of the filtered sodium, and thereby lead to dramatic diuresis. Potassium, calcium, and magnesium depletion is also enhanced by these

Table 63-5

Site, mechanism, duration of action, and dose of diuretics used to manage hypertension

Site of action	Diuretic	Mechanism of action
Ascending loop of Henle	Fursemide (Lasix)	Inhibition of chloride reabsorption
	Bumetanide (Bumex)	
	Ethacrynic Acid (Edecrin)	
Distal convoluted tubule (early) and cortical thick ascending limb	Hydrochlorothiazide (Hydrodiuril)	Inhibition of sodium reabsorption
	Chlorothiazide (Diuril)	
	Metolazone (Zaroxolyn)	
Distal convoluted tubule (late) and collecting duct	Spironolactone (Aldactone)	Competitive inhibitor of aldosterone
	Triamterene (Dyrenium)	Direct effect by reducing electrical potential between cell and lumen
	Amiloride (Midamor)	Direct effect by reducing electrical between cell and lumen

rapidly acting agents. These agents are contraindicated in children with hypecalciuria or nephrocalcinosis. Metabolic alkalosis and volume contraction may result, especially if hypokalemia is not corrected. Loop diuretics may serve as first or second line agents in the management of HTN in disorders leading to sodium and fluid retention and HTN, such as acute poststreptococcal glomerulonephritis or other edema-forming states.

Thiazide Diuretics (Hydrochlorothiazide, Chlorothiazide, Metolazone)

Thiazide diuretics (*hydrochlorothiazide, chlorothiazide, metolazone*) directly inhibit the Na^+/Cl^- cotransporter in the cortical thick ascending limb and in the early distal tubule. The resultant increased delivery of sodium to the cortical collecting duct induces a kaliuresis similar to that seen with loop diuretics. However, the overall diuretic effect is more gentle than with loop diuretics. While thiazide diuretics are widely described as add-on or in combination with other antihypertensive agents, usually they are not effective in individuals with low GFR and low urinary flow rates. Because thiazides often cause volume contraction, more reabsorbtion of solutes such as glucose, calcium, and uric acid, as well as fluid can take place in the proximal tubule. Thus, hyperglycemia, hypercalcemia and hyperuricemia (gout) may occur, while serum potassium and magnesium concentrations may fall. These agents are contraindicated in individuals with high bilirubin concentrations, particularly newborns with hypebilirubinemia. *Chlorothiazide* may be given intravenously and has an additive effect when used concurrently with loop diuretics. This may also be further augmented by the addition of *aminophylline* infusion in children exhibiting diuretic resistance. *Metolazone* is the most powerful thiazide diuretic. It is especially effective in individuals with renal insufficiency when combined with loop diuretics. It can be given orally or enterally and has a longer duration of action than other agents in this class. Hence, once per day dosing is often adequate.

Potassium-Sparing Diuretics

Spironolactone, canrenone, and epleronone are aldosterone receptor antagonists and inhibit potassium excretion by the principle cells located at the cortical collecting duct, and to a lesser degree at the connecting tubule. Spironolactone is mainly used as a potassium-sparing diuretic and has a slow onset of action (about two days) and a relatively long half-life (20 h). All potassium sparing diuretics are relatively contraindicated in hyperkalemic disorders unless combined with another diuretic such as spironolactone/thiazide (Aldactazide). Both spironolactone and canrenone cause gynecomastia and amenorrhea and prolonged use of these agents is not recommended in children. Eplerone is a newer potassium-sparing diuretic that is relatively devoid of such side-effects and is gaining wider use in the pediatric population (see Sects. "Newer Antihypertensive Agents" and "Congenital Adrenal Hyperplasia (CAH)").

Triamterene and *amiloride* both inhibit the ENaC in the late distal tubule and collecting duct, thereby producing an electropositive change in the lumen which inhibits potassium and hydrogen secretion by transporters in principle cells which are dependent on such electrochemical gradient. These agents are often combined with loop or thiazide diuretics and may also cause hyperkalemia. They may also have a special role in the management of certain monogenic forms of HTN population (see Sect. "Monogenic Forms of HTN").

Resistance to diuretics used in the setting of HTN may be caused by several factors including a high salt intake,

progressive renal insufficiency, and use of nonsteroidal antiinflammatory agents which inhibit renal synthesis of vasodilatory and natriuretic prostaglandins.

Centrally Acting Agents

After crossing the blood-brain barrier, agents in this class stimulate alpha and/or beta imidazoline receptors in neurons of the nucleus tractus solitarius and other areas of the ventral lateral medulla. This results in inhibition of central sympathetic outflow to peripheral vessels and hence, lowers peripheral vascular resistance. Because of concurrent sympathoinhibition to the heart, vasodilation is not accompanied by reflex tachycardia. Also, cardiac output and renal blood flow, as well as glomerular filtration rate (GFR), are not affected by these agents (36). Hence, agents such as clonidine are often utilized as second or third line medications in the management of sustained HTN, particularly in children with renal disorders. Also, such agents are useful in managing disorders in which sympathetic overactivity may be playing a role, such as pheochromocytoma, diabetes, or the metabolic syndrome.

Clonidine is the most commonly utilized centrally acting agent in children. It is well-absorbed when given enterally or via the transdermal route and requires no adjustment in dosage in renal failure. It is also minimally removed by dialysis. Clonidine is especially effective in lowering BP when used adjunctively with vasodilators that cause reflex tachycardia including hydralazine and minoxidil. Because of a rapid onset of action (30–60 min), clonidine may be used to manage hypertensive urgencies, particularly if anxiety is contributing to HTN. However, transdermal delivery is not useful in this setting because the peak action occurs after 1–2 days, although effectiveness lasts for upto seven days.

Like other agents in this class, somnolence and dry mouth are the most common adverse effects of clonidine. Postural hypotension, muscular weakness and gastrointestinal symptoms are less frequent side effects. These adverse effects may particularly affect the lifestyle of children participating in competitive sports. Also, sudden withdrawal of clonidine may result in rebound HTN particularly when high dosages are utilized. With prolonged use, and particularly with high dosages of clonidine, vasodilation may occur and result in salt and water retention. This may be offset by the addition of a diuretic. Allergic dermatitis at the application site of transdermal clonidine is often encountered.

Alpha-methyldopa must be converted to the "false neurotransmitter" alpha-methylnorepinephrine, which then prevents norepinephrine from reacting with the alpha-adrenergic receptors. Because it can cause Coombs-positive hemolytic anemia and greater somnolence and depression compared to clonidine, this agent has limited use in the pediatric population. Its use in renal disorders and in dialyzed individuals is more problematic than with clonidine. It should not be used in children with hepatitis or other active liver disorders. However, alpha-methyldopa may be useful in agitated children with HTN following brain injury, and may also be utilized to manage pregnancy associated HTN because it does not interfere with placental blood flow and it is not teratogenic.

There is no appreciable experience with the use of *guanabenz* or *guanfacine* in children with HTN.

Alpha Agonists

These are fourth or fifth line drugs in children with chronic HTN. Among the drugs in this class noted in *Table 63-4*, only prazocin has had any notable use in children. However, phenoxybenzamine has specific utility in the management of pheochromocytoma (see Sect. "Pheochromocytoma/Paraganglioma, Neuroblastoma and Neuroendocrine HTN").

Beta Blockers

These agents reduce BP by several mechanisms. By binding to beta 1-adrenoceptors that predominate in cardiac myosites, they prevent epinephrine binding, thereby lowering heart rate and cardiac output. Beta blockers also decrease sympathetic outflow leading to reduced catecholamine-renin release. Peripheral vascular resistance is not greatly affected as vascular myosites possess mainly beta 2-adrenoceptors. Cardioselective beta blockers (high beta 1/beta 2 ratio) tend to lower the risk of bronchoconstriction.

Table 63-6 compares the hemodynamic and metabolic effects of beta blockers (37). There are no pediatric clinical trials comparing the hemodynamic and adverse effects of various beta blockers.

Metoprolol and *atenolol* are among the most currently utilized beta blockers. The cardioselective beta blocker, metoprolol, has shown safety and efficacy in both regular form and its extended release form (Toprol-XL) in children (38, 39). Bisoprolol in combination with hydrochlorothiazide (Ziac) is also effective in managing pediatric HTN (40).

In addition to having heterogeneous hemodynamic effects, beta blockers have very diverse effects on lipid

Table 63-6

Effects of selective antihypertensive drugs in patients with hypertension

Parameter	Ideal drug	Traditional β-blockers	Carvedilol	α1-Adrenoceptor blocker	ACE inhibitor or ARB	DHP calcium channel blocker	Thiazide diuretic

ACE, angiotensin-converting enzyme; *ARB*, angiotensin receptor blocker; *DHP*, dihydropyridine; ↓, decreased (inhibition); ↑, increased (activation); *0*, no effect; +, positive effect; and ( ), predominantly after acute administration (adapted from (143))

and glucose metabolism and other adverse effects that may reduce their cardiovascular benefit. Such negative findings reported with atenolol (41–43) have led to an increasing trend towards use of beta-adrenergic blockers which also possess alpha-blocking effects and therefore, are also capable of vasodilation. Such agents include the noncardioselective alpha/beta blockers *carvedilol* and it's once per day dosing controlled release formulation (Carvedilol CR) (44), and *labetalol*. An added advantage of these agents is that they are largely devoid of metabolic disturbances. Thus, carvedilol may be advantageous in individuals with diabetes.

Pediatric use of beta blockers is largely limited to children with compelling indications or as add-on second or third line agents. With the exception of their use to manage systolic HTN or HTN associated with obesity (45), beta blockers have limited utility as initial agents in primary HTN (40). Also, the general concept of using beta blockers to manage hypertensive children has been questioned (46). This contrasts with the frequent use of beta blockers as first line agents in the managements of adults with primary HTN (47). Beta blockers do have a special role in managing hypertensive disorders such as pheochromocytoma and postcoarctectomy HTN. Intravenous esmolol is also useful in managing hypertensive crisis (see Sect. "Management of Hypertensive Emergencies"). Beta blockers are also indicated for the management of myocardial infarction and heart failure in adults. However, these disorders are uncommon in hypertensive children, further limiting the use of beta blockers in the pediatric population, particularly as monotherapy.

Class adverse effects of beta blockers, include fatigue, nightmares, anxiety, dizziness, and bronchospasm, as well as hyperlipidemia and hyperglycemia. Thus, they are relatively contraindicated in children with asthma or diabetes, although alpha/beta blockers may be used in diabetics.

The use of beta blockers, including metoprolol, is discouraged in competitive athletes or runners with HTN because they prevent the compensatory rise in pulse rate which is necessary to maintain a higher BP during strenuous activity.

Direct Vasodilators

This class includes *hydralazine*, *minoxidil*, and *diazoxide*. The specific mechanism of action is not well understood. Hyperpolarization of arterial smooth muscle may result from opening of the K^+ channel. This leads to inhibition of IP_3-induced release of calcium from the sarcoplasmic reticulum thus preventing muscle contraction. Among drugs in this class, *hydralazine* is currently widely utilized intravenously to manage severe HTN in the Emergency Department setting particularly if the specific etiology of the HTN is not known. Common side effects include skin flushing and tachycardia which currently limit

maintenance use of oral hydralazine to manage chronic HTN. Minoxidil is a very effective vasodilator but hirsutism is a common and prominent drawback that prevents its use as a maintenance agent in children. Diazoxide can cause a precipitous fall in BP and its use has been supplanted by newer safer medications.

Sodium nitroprusside is a potent direct vasodilator which is very useful in managing hypertensive emergencies (see Sect. "Management of Hypertensive Emergencies").

Calcium Channel Blockers (CCB)

CCB antagonize the L-type calcium channels located in vascular smooth muscle. By blocking the influx of calcium into the cell CCB decrease smooth muscle contraction thus causing direct vasodilation. Several CCB also exert an important effect on cardiac muscle, sinoatrial, and atrioventricular nodes, and, hence, they may be potentially detrimental in individuals with preexisting cardiac disorders. By far, most of the CCB utilized in children belong to the more cardioselective dihydropyridine class which includes *amlodipine, nifedipine, nicardipine, isradipine, and felodipine.* The negative effect on cardiac conduction of CCB belonging to the phenylalkylamine (*verapamil)* and benzothazepine (*diltiazem*) classes limits their use in pediatric HTN.

It should be noted that the dihydropyridine CCB should not be taken together with meals that have a high fat content or with grapefruit or grapefruit juice. Such foods inhibit the enterocyte CYP3A4 system which degrades CCB and may increase their bioavailability by as much as a factor of two- to fourfold (48).

Table 63-7 highlights the hemodynamic and cardiovascular heterogeneity of CCB (49). CCBs should not be given to children with heart failure or actual damage of the myocardium. These agents may be more effective in lowering BP in African–American adults than ACEI or ARB (50) but such benefit has not been investigated in the pediatric population.

CCB are perhaps only second to ACEI and ARB in frequency of use in pediatric HTN. Most CCB are typically given twice daily. Extended release and long acting CCB formulations (*Procardia XL, Nicardipine SR, Isradipine CR, Felodipine SR, Verapamil SR*) are often dosed once daily. Generally long-acting formulations tend to produce less abrupt reductions in BP compared to agents requiring more frequent dosing. Newer preparations which combine CCB with a diuretic (example, Nifedical) may aid compliance in children requiring the use of both of these agents.

Amlodipine is very widely utilized in hypertensive children. It is inherently long-acting and probably has the least negative inotropic cardiac effects (*Table 63-7*). Studies indicate that amlodipine is equally effective to nifedipine in lowering blood pressure in children with essential HTN or in those with renal disorders (51). Pharmacokinetic studies suggest that once-daily administration may suffice in older children. Children under 13-years of age may require double the daily dosage used in older children (0.30 ± 0.16 mg/kg/day vs. 0.16 ± 0.12 mg/kg/day) and often need twice daily dosing for optimal BP control (52). It is available in tablet and in extemporaneously prepared liquid forms allowing dosage titration in small sized children. Compared with nifedipine, amlodipine use is associated with less gingival hyperplasia which occurs frequently in children with transplants managed with cyclosporine-based immunosuppressive regimens (53).

Extended release nifedipine (Procardia XL) is widely used in pediatric HTN because of its effectiveness and once or twice daily dosing. It lowers BP within 2 h.

Short-acting nifedipine is used primarily in the management of acute HTN, or in children with impaired gastrointestinal absorption, or in those who are unable to swallow medications. It lowers BP within 20 min of oral or sublingual administration. The use of short acting nifedine has declined over the past decade in large part because of safety concerns including rapid hypotension, syncope, and other cardiovascular risks mainly reported in adults, and because of the availability of newer agents thought to be safer. However, short acting nifedipine appears to be safe in children (54) and it remains to be a valuable agent for managing refractory or acute HTN in children, thus preventing the need to transfer such patients to the intensive care unit. The risk to safety ratio of short acting nifedipine may be optimized by proper selection of patients and adherence to several guidelines (see Sect. "Management of Hypertensive Emergencies").

Nicardipine also has relatively few adverse effects on the myocardium. It is especially useful in managing children with renal insufficiency who develop hypertensive emergencies (see Sect. "Management of Hypertensive Emergencies), in which the use of sodium nitroprusside is avoided because of an increased risk for cyanide/thiocyanate toxicity. The initial dosage is 1 mcg/kg/min by continuous infusion. The drug is highly effective and the dosage is readily titratable. Children should be closely monitored in the intensive care unit for hypotension and palpitations which are uncommon in the author's experience. Also, among CCB, nicardipine inhibits the metabolism of tacrolimus and cyclosporine more effectively and can lead to toxic blood levels of these drugs. Thus, close monitoring of such levels are needed if nicardipine is used to manage posttransplant HTN.

Because short acting liquid nifedipine is somewhat difficult to withdraw from the capsule and deliver

Table 63-7

Summary of CCB pharmacokinetics parameters

		Verapamil	Nifedipine	Nicardipine	Isradipine	Amlodipine	Diltiazem	Comments

accurately, *isradipine*, which is a second generation dihydropyridine, is often preferred in small children who cannot receive standard dosing of nifedipine. This agent is available in both tablet form as well as an extemporaneously prepared suspension formulation, and has a rapid onset of action. Because of its short half-life (3–8 h), isradipine permits smoother BP control but often requires dosing 3–4 times daily (55, 56). It is a useful agent particularly in younger children with HTN associated with renal disorders in general (see Sect. "Renal Disorders").

Common adverse effects of all CCB (about 10% each) include headache, dizziness, skin flushing, and fatigue associated with vasodilation. Lower extremity edema is also linked to vasodilation and is unresponsive to diuretics. Such edema, and tachycardia which occurs more frequently in infants and younger children receiving isradipine, are leading causes for discontinuing CCB. Nifedipine, as well as diltiazem, are associated with a higher incidence of gingival hyperplasia, particularly when used concurrently with cyclosporine.

Angiotensin Converting Enzyme Inhibitors (ACEI) and Angiotensin Receptor Blockers (ARBs)

By blocking angiotensin converting enzyme (ACE) in lungs and in vascular endothelium, ACEI inhibit the conversion of angiotensin I to angiotensin II (AT-II) thereby blunting the renin-angiotensin-aldosterone system *(RAAS)*. *Figs. 63-3* and *63-4* demonstrate the multiple renal and extra-renal actions of AT-II (57, 58). ACEI lower BP by reducing the vasoconstrictor effect of AT-II after it's binding to vascular smooth muscle AT-II type 1 receptors, and by decreasing salt and water retention through lowering of aldosterone biosynthesis. The latter effect may be much more pronounced in hypertensive individuals with reduced GFR. ACEI also block kininase thereby decreasing the degradation of bradykinin; the latter enhances the antihypertensive action of ACEI. Moreover, ACEI exert a beneficial effect on HTN by direct affects on atrial natriuretic peptide, vasopressin, and prostaglandins, and by down-regulation of adrenergic sympathetic activity (57). In addition to their effects on all arterial vessels, both ACEI and ARB lower intra-glomerular pressure by their preferential dilation of the efferent arteriole and by reducing the vasoconstrictive effect of angiotensin II (AT-II) (57–59). ARB have a more targeted action than ACEI by blocking the AT-II type I receptor. This may limit the adverse effects of ACEI related to higher bradykinin and lower plasma aldosterone concentrations, including hyperkalemia, chronic dry cough, and angioedema. Thus, ARB use is often preferred in managing HTN caused by diverse renal disorders (see Sect. "Renal Disorders") (60).

The addition of antialdosterone agents, such as spironolactone, to augment the antihypertensive action of ACEI

Figure 63-3

The renin-angiotensin system. *ACE* angiotensin-converting enzyme; *Ang* angiotensin.

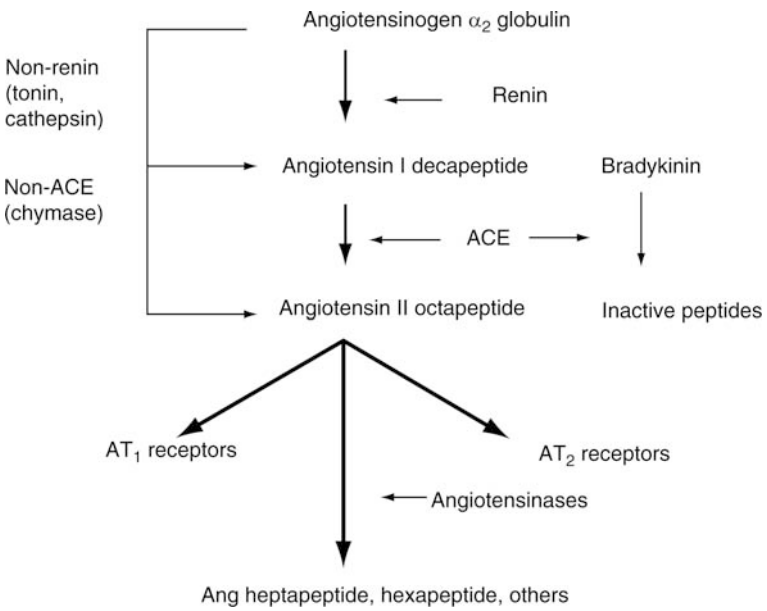

Figure 63-4

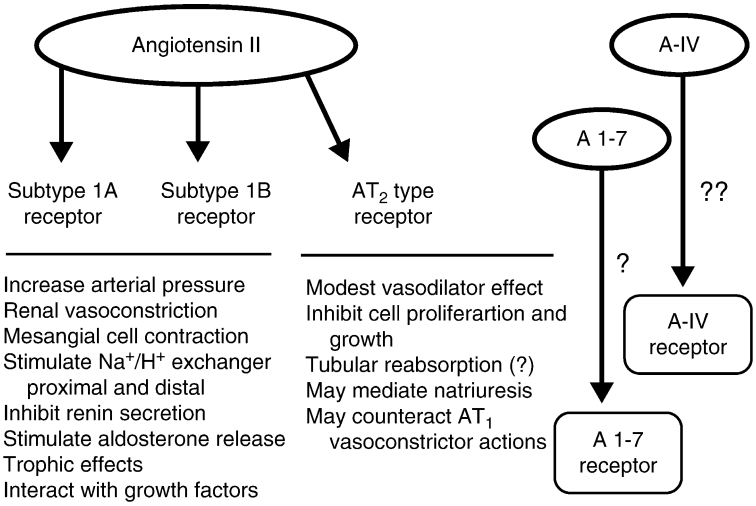
Types of angiotensin II receptor and their demonstrated or postulated actions.



and ARB in disorders associated with RAAS activation offers theoretical advantages (61). This drug combination may afford synergism and may be more nephroprotective than when either agent used alone. However, aldosterone blockade often potentiates the hyperkalemic and, possibly, the hyponatremic effects of ACEI. Thus, the combined use of spironolactone and ACEI should be avoided especially in children with reduced GFR.

Individuals with ACEDD genetic polymorphism have higher RAAS activity and may obtain a greater benefit from use of these agents (62, 63). Individuals with angiotensinogen polymorphisms may also benefit from use of the newer antirenin agents such as aliskiren (see Sect. "Newer Antihypertensive Agents"), while those with certain AT-II type 1 receptor polymorphisms may benefit from the use of ARB.

Among widely employed ACEI, the longest and more informative experience has been gained with *captopril*, *enalapril*, and *lisinopril*. When compounded into liquid formulations these agents are easier to dose and deliver in infants and younger children. *Captopril* is the only ACEI containing a disulfhydril moiety that has been credited with antioxidant and antiinflamatory action. Thus, captopril may be of special value in hypertensive children with lupus or other renal disorders. It has a short-duration of action and it usually requires three daily dosages. Titration should take place slowly over several days, particularly if it is utilized in hypertensive neonates. This is because neonates have physiologically higher renin activity which helps to maintain constant renal blood flow and GFR at a relatively low prevailing mean arterial BP in neonates. *Enalapril* and *lisinopril* have a more prolonged action enabling single or as twice daily dosing. This advantage makes these agents more suitable for use in older children and adolescents (64). Lisinopril is also available in combination with hydrochlorothiazide (*Zestoretic*). Enalapril is the only ACEI that can be administered intravenously, but it should be carefully titrated in neonates in order to lower the risk of acute renal failure.

Table 63-8 compares the pharmacologic characteristics of several ARBs. They vary greatly in their affinity for the AT-II type 1 receptor, in their half life and in bioavailability; all are highly protein-bound and therefore not easily removed by dialysis (65). *Losartan* (Cozaar) is the prototype ARB and has the widest experience of pediatric use (60). The drug is excreted by the kidneys and in bile, and is not dialyzed. *Valsartan* is also relatively short-acting and is excreted by the kidneys (30%) and bile (70%); absorption is decreased by 40% when taken with food. *Irbesartan* (Avapro) is longer acting than losartan or valsartan due to its high affinity for the AT-II type 1 receptor and is excreted mainly in bile (80%) and by the kidney (20%). *Candesartan* (Atacand) is also a long-acting AT-II receptor 1 antagonist and has 60% renal and 40% bile excretion and, therefore, may accumulate more readily than other ARB in individuals with severe renal dysfunction.

In order to offset hyperkalemia or salt and water retention associated with excessive aldosterone secretion in many renal disorders, several fixed combinations of ACEI or ARB with hydrochlorothiazide are now available (example: *Hyzaar, Diovan HCT, Avalide, Atacan HCT,* etc.).

Table 63-8

Pharmacologic characteristics of clinically available AT_1 receptor blockers

Drug/active metabolite	Compound	Relative AT_1 receptor affinity	Bioavailability (%)	Plasma half-life (h)	Protein binding (%)	Usual dosage (mg)
Losartan/*EXP 3174*	DUP-753, MK-954	50	33	2	98.7	50–100, optimal dose
		10		*6 to 9*	*99.8*	
Valsartan	CGP-48933	10	25	6	95.0	80–320, optimal dose
Candesartan/*CV 11974*	TCV-116	280	42	4	99.5	4–32, optimal dose
		1		*3 to 11*		
Irbesartan	SR-47436, BMS-186295	5	70	12	90.0	150–300, optimal dose
Eprosartan	SKF 108566	100			97.0	200– 400, twice a day
Telmisartan	BIBR 0277	10		24		40– 120, optimal dose

Common class adverse effects of ACEI include hyperkalemia and persistent nonproductive cough, while angioedema, neutropenia, and anemia are other less common adverse effects. In general, ARB have a more favorable adverse effect profile but are more expensive than ACEI. Both ACEI and ARB may cause renal functional impairment particularly in individuals with initial GFR below 60 mL/min/1.73 m^2 or in those with severe renal artery stenosis. Periodic monitoring of serum creatinine, potassium, and sodium concentrations is needed to identify important changes that may require modification in drug dosage. Also, a complete blood count may be done every 4–6 months to detect neutropenia or anemia with chronic use of these agents. These adverse effects typically resolve after lowering of dosage or discontinuing these agents. Also, both ACEI and ARB are teratogenic and their use is contraindicated during pregnancy.

Newer Antihypertensive Agents

Vasopressin Receptor Antagonists (*Table 63-9*)

Although traditionally vasopressin is not regarded as a "hypertensive hormone," it may exert a hypertensive action in African–Americans or other individuals with a blunted renin-angiotensin system. Vasopressin receptor antagonists exert their action mainly in tissues rich in V2 receptors (vascular endothelium and principal cells of the renal collecting and connecting tubules) thereby markedly increasing urine output, lowering urine osmolality, and raising serum sodium levels (64). Thus, such agents may be especially useful for managing hyponatremic euvolemic disorders such as SIADH, and hypovolemic or edema-forming hyponatremic disorders such as congestive heart failure, which are traditionally resistant to conventional diuretics. These agents do not lower blood pressure or GFR and as a rule, do not cause orthostatic hypotension, hypokalemia, hyponatremia, or reduced renal blood flow and lowering in GFR. They are also well tolerated. Such advantages over presently employed diuretic agents may make these vasopressin receptor antagonists useful adjunct agents in the management of hypertension as well. Only the intravenous agent *conivaptan* (Astellas Pharmaceuticals) has been approved by the FDA while several oral V2-selective antagonists are currently undergoing phase III trials.

Beta Blockers

Nebivolol is a beta I-selective, third generation beta blocker that received FDA approval in December 2007 for use in adults. This agent uniquely stimulates release of the potent vasodilator nitric oxide (66, 67). Its use is associated with less erectile dysfunction or impairment with lipid and glucose metabolism compared to agents such as metoprolol. Nebivolol is effective in dosages corresponding to one-tenth of dose of atenolol. There are no data of its use in children.

Table 63-9
Vasopressin receptor antagonists undergoing commercial development.

Compound	Receptor	Route	Manufacturer
Conivaptan (YM-087)	$V1_a$/V2	Intravenous	Astellas (Tokyo, Japan)
Lixivaptan (VPA-985)	V2	Oral	CardioKine (Philadelphia, PA)
Tolvaptan (OPC-41061)	V2	Oral	Otsuka (Tokyo, Japan)
Satavaptan (SR-121463)	V2	Oral	Sanofi-Aventis (Paris, France)

Aldosterone Antagonists

Eplerenone is a newer mineralocorticoid receptor blocker with less antiandrogenic and antiprogesteronic properties than spironolactone or canrenone. Thus, eplerenone may be of particular benefit to children because of less interference with sexual maturation. It is especially useful in managing HTN caused by glucocorticoid-remediable hyperaldosteronism (see Sect. "Congenital Adrenal Hyperplasia (CAH)")

Renin Inhibitors

Although ACEI are effective in lowering BP in several hypereninemic disorders leading to increased circulating angiotensin II concentrations, such agents stimulate renin release by interfering with angiotensin II type 1 receptor-induced inhibition of renin release. Ultimately, this leads to reduced sustained antihypertensive effectiveness. *Aliskiren* is the prototype of a new class of drugs that directly inhibit renin. Several randomized human trials showed that orally administered aliskiren at 75 or 150 mg once daily was not only extremely safe but also very effective in lowering BP in adults with mild-to-moderate HTN (68, 69). Its antihypertensive action was additive when combined with ramipril, amlodipine, or hydrochlorothiazide. There is limited information of the use and safety of this agent in hypertensive adults with renal disorders and there are no pediatric studies using this agent.

Vasopeptidase Inhibitors

This class of agents is capable of blocking both angiotensin converting enzyme and neutral endopeptidase (NEP) (70). NEP degrades several peptides including atrial and brain natriuretic peptides, adrenomedullin, and bradykinin. Thus, inhibition of NEP potentiates the action of these peptides resulting in more salt and water excretion, inhibition of RAAS, and peripheral vascular dilation. *Omapatrilat* is a prototype agent in this class that is undergoing extensive human clinical trials (71, 72). Despite its effectiveness in lowering BP, FDA approval has been delayed because of a relatively high incidence of angioedema and dry cough attributed to higher bradykinin levels than those encountered with ACEI.

Endothelin-1 Receptor Antagonists

Endothelin-1 receptor antagonists such as *bosentan* and *avosentan* are quite effective in lowering BP associated with endothelin release which commonly occurs in the post-transplant setting (see Sect. "Posttransplant HTN"). However, endothelin antagonists are difficult to administer and are not currently indicated for treatment of systemic HTN.

Dopamine Antagonists

Fenoldopan is a newer dopamine 1 receptor agonist which promotes smooth muscle relaxation particularly within renal and splanchnic vessels. It may be particularly valuable in managing hypertensive crisis (see Sect. "Management of Hypertensive Emergencies").

Management of Specific Disorders

Primary (PH) or Essential HTN

Over the past decade the incidence of PH has increased markedly particularly among adolescents, in large part because of the obesity epidemic and lifestyle changes (2). This underscores the need to identify and implement lifestyle measures which may lead to prevention of PH at a younger age.

There are no large, longitudinal studies to provide evidence-based guidelines for the management of PH in children (30). Because beta blockers may inhibit reflex tachycardia in children involved in vigorous activities such agents may cause syncope and other adverse cardiovascular events. Thus, unlike the JNCC guidelines for managing HTN in adults (47), diuretics and beta blockers are not commonly employed as initial agents in the control of PH in children.

The combined use of beta blocker/thiazide was associated with suboptimal BP control in one pediatric study

of PH (40). However, cardioselective beta blockers may be used selectively in children with PH resulting mainly in systolic HTN. For such purposes, atenolol or carvedilol may be used. CCB and ACEI use was examined in a retrospective study of childhood PH (64). Both classes of agents lowered systolic BP while only ACEI also lowered diastolic BP. However, when the 95th percentile for age, gender, and height was the "target value," only 45% achieved systolic BP control while 62.7% achieved diastolic BP below the 95th percentile (64).

ACEI have been shown to be as effective as beta blockers and diuretics in adults with PH. ACEI may also have greater cardioprotective benefits which extend beyond BP lowering whereas several studies indicate an increase in coronary artery disease and heart failure with use of CCB. Although, such adverse outcomes are uncommon in children managed with CCB, the author prefers starting with an ACEI or ARB for pharmacologic management of PH. In obese or other children with isolated systolic HTN, carvedilol or labetalol may be indicated. Close monitoring of BP is essential in modifying the dosages of antihypertensive agents especially in children with PH in whom improvements in lifestyle may have a drastic effect in lowering BP.

Important outcome measures of managing PH in adults include a reduction in coronary heart disease, stroke, and cardiovascular death. Such data are not available in children.

Obesity/Metabolic Syndrome/Sleep Apnea

The metabolic syndrome is almost always encountered in obese children and is associated with hyperlipidemia, insulin resistance and HTN. Sleep apnea is also nearly always associated with obesity in children. Thus, the mechanisms of HTN in both of these disorders are complex and appear to overlap.

Obesity is associated with sustained sympathetic nerve activity causing an increased heart rate, and with higher endothelin-1 expression leading to impaired vasodilation and increased systemic vascular resistance (73). Circulating insulin and leptin concentrations are often high in obese children and both of these are known to aid sodium retention (74). In addition, autonomous synthesis of aldosterone by adipocytes has been demonstrated in individuals with central obesity (75, 76). Hyperaldosteronism may be confirmed by urine aldosterone exceeding 12 mcg/24 h despite sodium loading, and a plasma aldosterone to peripheral renin activity ratio greater than 20–30 when aldosterone is measured in ng/dL and PRA in ng/mL/h. These mechanisms of HTN suggest a greater potential amelioratery effect on BP of lifestyle measures or even surgical means, such as gastric bypass, in order to maintain a sustained weight loss. In addition, the preferential use of beta blockers and antialdosterone agents may be of greater but yet unproven antihypertensive benefit in obese children. There is also recent evidence indicating that ARBs may lower the incidence of type 2 diabetes in obese hypertensive individuals with metabolic syndrome by improvement in metabolic parameters (77). Thus, carvedilol or labetalol, or an ARB may be the initial pharmacologic agent in these disorders while thiazide diuretics should be avoided (see Sect "Thiazide Diuretics").

Renovascular HTN

This category of HTN includes renal microvascular disease, renal artery stenosis due to multiple etiologies, and renal focal ischemia due to renal microthrombi or scarring after pyelonephritis. This type of HTN associated with these disorders is often resistant to antihypertensive agents that do not inhibit the renin-angiotensin-aldosterone system. A "critical" fall in perfusion to a part or to the entire kidney in these disorders stimulates renin release and AT-II, and other mechanisms tending to restore renal perfusion but in the process also raise systemic BP (78–80). Because angiotensin II plays a major role in renovascular HTN, it is targeted for pharmacologic blockade.

An example of this is *renal artery stenosis* (RAS). There are no comparisons of the complications of revascularization procedures and medical management of RAS in children. While nonmedical approaches have an associated risk for hemorrhage, vessel or renal perforation, and thrombosis leading to loss of renal function, this approach is often preferred in children as it offers the possibility of a permanent cure, particularly in children having stenosis at the ostium or abdominal aorta syndrome. Conversely, ACEI or ARB use may lead to acute renal failure in children with bilateral severe or critical RAS (greater than 80% narrowing), or in those managed with diuretics and salt restriction leading to diminished circulatory volume.

Once the location and severity of the stenosis is established by imaging studies, a decision may be made to administer oral ACEI, intravenous enalaprilat, or ARB. As a caveat, the medical management of RAS should take place with great caution so as to avoid rapid lowering of systemic BP. Salt restriction should be moderate, and diuretics should be avoided. For pharmacologic management of renovascular HTN other than bilateral RAS, in infants the author recommends starting with

low-dose captopril and titrating upwards as needed. Older children may receive labetalol or carvedilol as the initial agent, and an ACEI or ARB may then be added depending on BP response. Sodium nitroprusside or fenoldopam infusion may be administered in children with hypertensive emergency (example: vessel dissection, cerebrovascular accident, seizures, retinal hemorrhage or Bell's palsy) (see Sect. "Management of Hypertensive Emergencies"). In all instances erum creatinine concentration should be carefully monitored. If it rises by more than 20% above baseline levels, ACEI or ARB may be stopped, reduced in dosage, or substituted with intravenous nitroprusside or labetalol, until a revascularization procedure is performed.

Renal Parenchymal Disorders

Activation of the renin-angiotensin-aldosterone system (RAAS) plays a major role in the regulation of BP in humans. Classically, RAAS activation occurs with hypotension; conversely RAAS is suppressed in states associated with systemic HTN. It has been demonstrated that after initial nephron injury caused by a variety of renal disorders, the RAAS becomes inappropriately activated and often remains active, rather than become suppressed, despite persistent systemic HTN (57, 81). Chronic or persistent activation of RAAS may accelerate renal parenchymal injury by several mechanisms: (1) direct vasoconstriction by angiotensin II raising systemic and/or intraglomerular BP leading to hyperfiltration injury, (2) aldosterone-mediated increase in salt and water retention and other deleterious effects of sustained elevations in plasma aldosterone concentration, and (3) elaboration of TGF beta, plasminogen activator inhibitor-1, and vascular endothelial growth factor (VEGF-A) as well as other mediators of renal fibrosis and hypertrophy which promote arteriolar wall thickening (57, 59, 82–87).

Intrarenal activation of RAAS without systemic HTN, has also been implicated in progressive renal injury associated with diabetic nephropathy, autosomal dominant polycystic kidney disease, or multicystic dysplasia.

Expansion of the circulatory volume is a major cause of HTN in disorders such as acute poststreptococcal glomerulonephritis and other acute nephritides. In this setting the use of diuretics with or without a CCB is generally preferred because GFR is often reduced on initial presentation and may become further compromised by adding ACEI/ARB to the diuretic regimen. In contrast, in chronic kidney disease (CKD)/dialysis, HTN due to circulatory volume expansion is common and may be challenging to control especially in individuals with advanced renal insufficiency. The specificity of renal protection afforded by ACEI or ARB in the setting of HTN in CKD may be overemphasized. However, these agents are still preferentially utilized because the antihypertensive synergism afforded by RAAS blockade coupled with diuretics is often effective as both classes of drugs promote salt and water excretion. Diuretics may also reduce the risk of hyperkalemia associated with concurrent ACEI use in this setting.

Although systemic hypertension may be due to multiple etiologies, the final common pathway for hypertensive renal injury involves transmission of the elevated blood BP to the renal microvasculature. The latter is physiologically opposed by intricate autoregulatory mechanisms of renal blood flow which become impaired with sustained increases in systolic BP exceeding 180 mm Hg in adults (this value is unknown for children). Autoregulation of renal blood flow is also compromised by reduced renal mass (example: fewer nephrons at birth or after nephrectomy due to tumor), and by acquired glomerulopathies. In these disorders systolic HTN tends to correlate better with progressive renal damage. Under these circumstances vascular or glomerular disruption may occur with only modest or even transient elevations in systemic BP, which may be underestimated by BP levels obtained by casual peripheral BP measurements. Ultimately, the loss of autoregulation of renal blood flow associated with renal injury renders damaged glomeruli more susceptible to the hydraulic affects of HTN, leading to progressive glomerulosclerosis (85).

Newer investigations have uncovered multiple biological functions of aldosterone beyond its well established role in potassium and volume/BP homeostasis. The unregulated stimulation of aldosterone in many renal disorders has been implicated in progressive tubulointerstitial fibrosis and dysfunctional cardiac remodeling associated with chronic HTN. Aldosterone receptor antagonists are often helpful as add-on second or third line drugs in individuals with HTN resistant to other agents (88). Use of this class of agents may reduce BP by their diuretic action, as well as by nonvolume mediated effects (89–94). Antialdosterone agents may also offset the rebound elevation in plasma aldosterone concentrations ("aldosterone escape") noted after an initial fall in plasma aldosterone concentrations evident after starting ACEI (90). Higher serum potassium concentrations particularly in individuals with GFR below 60 mL/min/1.73 m^2 managed with ACEI may be partly responsible for stimulating aldosterone biosynthesis in this setting. Hence, in theory, with proper monitoring and prevention of hyperkalemia, the combined use of spironolactone or eplerenone together with ACEI or ARB may afford more optimal nephroprotection in children with HTN and/or proteinuria (91).

Oligonephronia or, reduced nephron number, is another important and, perhaps, underappreciated cause of HTN both in children as well as in adults suspected of having primary HTN. The number of nephrons in healthy individuals is quite variable ranging from 0.8 to 1.8 million. Infants with low birth weight or intrauterine growth retardation may be susceptible to HTN during early childhood because of an impaired ability to excrete salt and water (95–98). Thus, early detection and management of such HTN may be useful in preventing renal dysfunction and other end-organ injury in early adulthood.

In conclusion, several studies have shown that suppression of the RAAS improves the rate of progression of renal injury (99). Because of their ability to lower both systemic as well as intraglomerular HTN, ACEI/ARB are recommended as first-line agents in managing HTN in children with diverse chronic renal disorders (32, 100). These agents may also have an antifibrotic and antiinflammatory benefit which may also enhance their nephroprotective properties (59, 101) which are not observed with the use of other classes of antihypertensive agents that are equally effective in lowering systemic BP. Because proteinuria is another important marker of renal disease progression, the greater antiproteinuric action afforded by ACEI and ARB has led to wider use of these drugs in hypertensive individuals who also have proteinuria. The combination of ACEI and ARB to block RAAS more completely has also been advocated, particularly in hypertensive individuals with proteinuric disorders. In children with refractory HTN associated with circulatory volume expansion, a large array of combination formulations of ACEI or ARB with hydrochlorothiazide may be more effective (47). If BP is not optimally controlled, clonidine, labetalol or carvedilol may be added as a second line agents (in place of a diuretic), or, these drugs may serve as third line agents. Provided that renal function is relatively well preserved, an antialdosterone agent may also be used as a third or fourth line agent. In children with more advanced renal failure (CKD stages 3–5), CCB may be the first line agents with clonidine, a loop diuretic, labetalol or carvedilol, and clonidine serving as second or third line agents. Minoxidil is effective for HTN refractory to these agents but its adverse effects, particularly hirsutism, makes long term use untenable.

Posttransplant HTN

Roughly two-thirds of children with kidney and other solid organ or bone marrow transplants managed with calcineurin-based regimens that include glucocorticoids develop chronic, iatrogenic HTN (102). The transplant population may, perhaps be only second in prevalence of secondary HTN to the sum of all children with renal disorders. Steroids are the main culprit since de novo HTN after transplantation is very uncommon with tacrolimus monotherapy (103). However, cyclosporine and, to a much lesser degree, tacrolimus may potentate the effect of steroid by inducing endothelial and proximal tubular cell synthesis of endothelin- 1. This potent vasoconstrictor preferentially constricts the afferent glomerular capillary thereby promoting renin-mediated systemic HTN (104). Endothelin-1 receptor antagonists such as bosentan and avosentan are quite effective in lowering BP associated with endothelin release. Also their combined use with ACEI/ARB may be of special value in disorders associated with both HTN and proteinuria. However, endothelin antagonists are difficult to deliver and have other potential hazards that have hindered their clinical use outside of pulmonary HTN (105).

Because CCB have a preferential affect in vasodilating the afferent glomerular arteriole they are often recommended. Because nifedipine, amlodipine, and isradipine do not alter metabolism of cyclosporine or tacrolimus, and because their clearance is not influenced by renal dysfunction, they are often used to manage HTN in the posttransplant setting or in children with renal disorders. In younger children, isradipine may be easier to dose; mean dosages of 0.38 ± 0.22 mg/kg/day divided in three daily dosages proved effective in a series of children mostly under 10 years old having renal disorders or various transplants (55). These dosages were generally higher compared to those utilized in adults. Another large series comprised of children of all ages with HTN associated with glomerulonephritis or solid organ transplants, found that similar dosages were effective and well tolerated (56). CCB use in the posttransplant setting may be complicated by a high rate of dependent edema due to peripheral vasodilation, and by posttransplant erythrocytosis.

Glucocorticoids may also contribute to salt and water retention, expansion of the intravascular volume, and HTN (106). In such individuals, reduction in salt intake together with use of a diuretic may be useful in lowering BP. While loop diuretics are preferred for use in the setting of posttransplant HTN, these agents should be used with caution in children with hypercalciuria or nephrocalcinosis.

ACEI and ARB are also efficacious in the management of posttransplant HTN with or without concurrent proteinuria (107). However, caution should be taken in using ACEI/ARB. ACEI, in particular, may exaggerate hyperkalemia which occurs frequently in the posttransplant

setting because calcineurin inhibitors suppress aldosterone secretion which is a key mechanism for the elimination of potassium. Also, both of these agents may lower intraglomerular pressure and GFR leading to the mistaken diagnosis of rejection. In addition, these agents may contribute to anemia that persists after successful transplantation.

Because hydration is very important after renal transplantation diuretic use is usually avoided in the management of posttransplant HTN even when hyperkalemia is present. Fludrocortisone (Florinef) is often utilized for control of such hyperkalemia. However this mineralocorticoid may also contribute to hypertension.

The finding of a bruit over the allograft artery or the presence of abnormal blood flow by Doppler ultrasonography may suggest renal artery stenosis as the etiology of HTN. In such disorders, a pharmacologic trial with ARB may precede the use of intraluminal angioplasty of the affected artery.

Monogenic Forms of HTN (*Table 63-10*)

These disorders are detailed in several recent reviews (108–115). *Table 63-10* provides an excellent summary of the causes evaluation and management of monogenic HTN (108). Although some of these conditions are rare, they often manifest with HTN during childhood and they provide an excellent insight into the pathophysiology of HTN. The majority of these forms of HTN stimulate sodium reabsorption at different sites along the nephron and tend to be associated with metabolic alkalosis and hypokalemia.

Glucocorticoid Remediable Hyperaldosteronism (Also Known as Familial Hyperaldosteronism Type I)

This is an autosomal dominant disorder resulting from a chimeric gene in which the 11 beta-hydroxylase promoter sequence is spliced to the coding region of the aldosterone synthase gene. This chimeric gene is located in the zona fasciculata, rather than in the zona glomerulosa of the adrenal gland where aldosterone synthesis normally occurs, and the 11 beta-hydroxylase promoter is under the control of ACTH. This results in a salt-sensitive HTN at a young age with low plasma renin activity but high or normal plasma aldosterone concentrations, and secondary hypokalemia and metabolic alkalosis. This form of HTN responds to exogenous glucocorticoids which suppress ACTH release. However, prolonged treatment with such agents has unacceptable adverse effects especially in growing children. Alternative agents include amiloride and spironolactone. The latter is effective in opposing the aldosterone-mediated salt retention but it frequently causes gynecomastia and sexual dysfunction. A newer agent, eplerenone, is currently recommended because it also antagonizes the effect of aldosterone but has less interference with sexual maturation than spironolactone.

Table 63-10
Features of inherited hypertension

	Inheritance pattern	Age	K	PRA	Aldo	Aldo: PRA	GC resp.	MR-A resp.	Rx
Liddle's	AD	C,A	N or ↓	↓	↓		–	–	A,Tr
Gordon's	AD	A (C)	N or ↑	↓	N or ↑	↑	–	–	T
AME	AR	I,C,A	↓ (N)	↓	↓		–		MR-A
H-P	AD	C,A	N or ↓	↓	↓		–	reversed	A,Tr,T
GRA	AD	I,C	N or ↓	↓	↑ (N)	↑			G,A,Tr
FH II	AD	A	N or ↓	↓	↑	↑	–		MR-A
CAH	AR	I	N or ↓	↓	↓		–		MR-A
FGR	AR/AD	I	N or ↓	↓	↓		–		MR-A

AME, apparent mineralocorticoid excess; *H-P*, hypertension exacerbated by pregnancy; *GRA*, glucocorticoid-remediable aldosteronism; *FH II*, familial hyperaldosteronism type II; *CAH*, congenital adrenal hyperplasia with 11- or 17-hydroxylase deficiency; *FGR*, familial glucocorticoid resistance; *AD*, autosomal dominant; *AR*, autosomal recessive; *Age*, typical age at presentation; *I*, infancy; *C*, Childhood; *A*, adulthood; *K*, potassium; *N*, normal; ↓, decrease; ↑, increase; *PRA*, plasma rennin activity; *Aldo*, aldosterone; *Aldo: PRA*, ratio of aldosterone to PRA (<30 diagnostic if Aldo, in ng/dL, PRA in ng/mL/h); *GC resp.*, response to glucocorticoids; –, negative; +, positive; *MRA resp.*, response to mineralocorticoid receptor antagonists; R_x, treatment; *A*, anciloride; *Tr*, triamterene, *T*, thiazides

Apparent Mineralocorticoid Excess (AME) (116–119)

Mutations in the 11 beta-hydroxysteroid dehydrogenase type 2 (11 beta-HSD2) leads to loss of enzyme function resulting in decreased conversion of cortisol to cortisone in the principle cells located in the cortical collecting duct and connecting tubule. Cortisol, unlike cortisone, binds to the mineralocorticoid receptor and activates the basolateral sodium-potassium ATPase leading to sodium reabsorption, potassium wasting, hypokalemia, metabolic alkalosis, and hypertension. Plasma renin activity and aldosterone concentrations are suppressed secondary to HTN. The licorice-derived moieties, glycyrrizic acid and carbenoxolone (used to treat gastric ulcer disease), inhibit the action of 11 beta-HSD2 and can also cause HTN by the same mechanism. Individuals with apparent mineralocorticoid excess respond well to dietary sodium restriction, thiazides and mineralocorticoid receptor blockers including spironolactone, canrenone, and epleronone.

Genetic polymorhisms in the gene encoding for 11 beta-HSD2 may play a role in the development of low renin primary HTN in about 40% of individuals in the USA.

Gain of Function Mutation of the Epithelial Sodium Channel (ENaC) (Liddle's Syndrome) (120)

ENaC is the rate limiting step in sodium reabsorption. In Liddle's syndrome the mutated ENaC channels of the principle cells of the cortical collecting duct remain in the plasma membrane for a prolonged time period. This effectively increases the number of such channels, leading to increased sodium reabsorption and HTN. The clinical presentation is similar to apparent mineralocorticoid excess (infra supra). Thiazides, amiloride, and triamterene antagonize the ENaC directly and thereby lower BP in such individuals. Spironolactone does not affect the ENaC and does not reduce BP in Liddle's syndrome.

Gain of Function Mutation of the Mineralocorticoid Receptor (121)

This is a rare disorder in which a single amino acid substitution of the mineralocorticoid receptor gene in principal cells results in pathologic increases in sodium retention, volume expansion, and HTN. Such volume expansion may be enhanced by aldosterone, cortisol or progesterone. This disorder has been implicated in adults with primary HTN characterized by low plasma renin activity and low plasma aldosterone concentrations which are physiologically suppressed by the HTN. Also, women with preeclampsia or eclampsia may have a similar genetic predisposition to HTN which manifests only during pregnancy because of high plasma concentrations of progesterone prevailing during pregnancy. This is because progesterone tends to activate rather than suppress the mutant receptor. Similarly, spironolactone inhibits thewild type mineralocorticoid receptor but tends to activate the mutant receptor and may promote HTN in this disorder.

Congenital Adrenal Hyperplasia (CAH) (122)

Two forms of CAH are associated with HTN. The common form is caused by a mutation in the CYP11B1 gene encoding for 11 beta-hydroxylase. This leads to loss of feedback inhibition of adrenocorticotrophic hormone and stimulation of adrenal mineralocorticoid synthesis resulting in HTN. The rare form is caused by a mutation in the gene encoding for 17 alpha-hydroxylase. Both of the disorders lead to loss of function of these enzymes that are very important in the proper synthesis of cortisol and gonadal hormones. As a result, plasma 11-deoxycortisol and deoxycorticosterone concentrations rise resulting in sodium retention, volume expansion, and HTN.

Pseudohypoaldosteronism Type II (Gordon's Syndrome)

Several genes encoding aberrant kinases have been linked to this familial disorder which manifests clinically with HTN and hyperkalemia with associated muscle weakness. Peripheral plasma renin activity is suppressed while plasma aldosterone concentrations are inappropriately normal. Thiazides are highly effective in managing both the hyperkalemia and HTN.

Autosomal Dominant HTN with Brachydactyly (123)

Severe HTN starting in childhood, and death before age 50 due to stroke are common manifestations of this disorder. This disorder is not caused by salt sensitivity. No specific gene locus has yet been identified, but the sulfonylurea receptor-2 gene has been implicated. Such individuals have normal plasma renin and aldosterone concentrations. HTN is believed to be of neurogenic

origin. It is postulated that these individuals have a "neurovascular control anomaly" on magnetic resonance angiography demonstrating abnormalities of the posterior fossa of the brain causing compression of the ventrolateral medulla and of cranial nerves IX and X, resulting in a high peripheral vascular resistance. There is no satisfactory response of the HTN to any particular agent. However, HTN improves following decompression surgery of the affected brain area.

Pheochromocytoma/Paraganglioma, Neuroblastoma and Neuroendocrine HTN

Pheochromocytoma may be entertained in the etiology of HTN on the basis of classical symptoms of paroxysmal headache, palpitations, and skin flushing. However, younger children tend to have more sustained HTN as well as visual disturbances, emesis, sweating, tremors and anxiety. Several antihypertensive agents may stimulate catecholamine secretion and lead to false diagnosis of pheochromocytoma. Assuming that neurological symptoms are absent, funduscopic exam is normal and there are no seizures or severe encephalopathy to indicate an impending medical emergency, management of the HTN may be delayed until the appropriate plasma and urinary studies are obtained to establish the diagnosis of pheochromocytoma or other neuroendocrine disorders with similar presentation. Disorders mimicking catecholamine secreting tumors include essential HTN, diencephalic syndrome, and severe anxiety.

Catecholamine secreting tumors such as pheochromocytoma, neuroblastoma, and ganglioneuroblastoma result in a hyperadrenergic state. Thus, skin flushing and tachycardia may be signs of a high cardiac output state. Such sympathetic stimulation along with vasoconstriction and systemic HTN lead to diuresis and volume depletion. As a result, hemoconcentration and hypokalemia may ensue.

Preoperative medical management of the HTN is of great value in avoiding major intraoperative complications including hypotension, hypertensive crisis, and tachyarrhythmias associated with surges of catecholamine secretion during tumor manipulation and removal (124–128).

In the setting of tachyarrhythmias, initial management is aimed at inhibiting the release of catecholamines and chronic vasoconstriction utilizing phenoxybenzamine or alpha-2 adrenergic agonists with shorter duration of action such as clonidine or prazosin. Because of potentially rapid and profound fall in BP, the author does not endorse the use of phentolamine as a diagnostic tool or for treatment of pheochromocytoma. Instead, treatment may begin with oral *phenoxybenzamine* (Dibenzyline) at an initial dosage of 0.3 mg/kg/day divided in two daily dosages. The drug may be titrated by 25% every 48 h to an average dose of 1.2 mg/kg/day (maximal dosages may be as high as 4 mg/kg/day but are not recommended by the author), until BP slowly falls into the normal range for age, gender, and height. Precaution must be taken to prevent orthostatic hypotension especially during the early or acute phase of volume repletion. Salt restriction or high salt intake is not recommended. Beta blockers may be started about 48 h after the start of alpha-adrenergic agonists in order to reduce the risk of tachyarrhythmias or epinephrine-induced vasoconstriction from unopposed beta-adrenergic stimulation in individuals with epinephrine secreting tumors. For this purpose, carvedilol, a noncardioselective alpha/beta blocker, may be started at a dosage of 0.15 mg/kg/day divided in two dosages, with an increase in dose to 0.5 mg/kg/day divided in two dosages, as needed. Also, atenolol or metoprolol may be equally effective to carvedilol in improving the high cardiac output state.

Drugs that decrease synthesis of catecholamines such as the tyrosine analog alpha-methyl tyrosine or metyrasone (tyrosine hydroxylase inhibitor) are not utilized extensively in the population but have been shown to be helpful adjuncts in the management of adults with pheochromocytoma.

Agents known to release histamine and thereby stimulate sympathetic affects, including morphine, succinylcholine, atracurium, and related compounds should be avoided. In addition, drugs that provoke catecholamine release should be avoided along with foods containing tyramine which may displace catecholamines from storage vesicles. Alpha-1-adrenergic antagonists with shorter half-life than phenoxybenzamine may be substituted for about two days prior to surgery.

Resection of the tumor may be done safely when the child's BP, tachycardia, and cardiac dysfunction resolve, and other symptoms and signs subside or improve. This typically occurs 2–3 weeks after initiating treatment.

Endocrine Disorders

Conns Syndrome

In this disorder HTN often results from a benign aldosterone-secreting adrenal adenoma. This is an uncommon condition in childhood and presents with HTN in association with high aldosterone levels but suppressed peripheral

renin activity. The management of this disorder includes antialdosterone drugs, such as spironolactone and other less specific antihypertensive agents. Tumor removal may be useful if HTN becomes resistant to medical therapy.

Cushing Syndrome

This disorder results from prolonged exposure of body tissues to cortisol. A primary pituitary or adrenal etiology leading to overproduction of cortisol is uncommon in children. However, exogenous administration of corticosteroids for managing inflammatory disorders or to prevent transplant rejection are common causes of this condition. HTN and changes in body habitus are manifestations of this disorder. The mechanisms of HTN and its treatment are discussed in Sect. "Posttransplant HTN".

Hyperthyroidism

Hyperthyroidism raises BP through a high cardiac output state secondary to high serum thyroxine levels associated with Grave's disease or other disorders which stimulate an increase in oxidative metabolism. This disorder is uncommon in children and is managed with beta blockers to decrease the heart rate.

Hypertension in Athletes

HTN in athletes may be caused by any of the known etiologies of HTN affecting children. In addition, performance enhancing drugs such as growth hormone, anabolic steroids, erythropoietin, protein cocktails, as well as high caffeine and high salt intake, may be more frequently abused or utilized by athletes and may contribute to HTN. Excessive weightlifting and other isometric activities done repetitiously and for prolonged periods of time may result in behavioral modification that perpetuates the known exaggerated BP response to such activities, even hours after the activity has terminated. Hypertensive athletes should minimize static activities and should only perform these in combination with aerobic activities (129, 130). Thus, a detailed history to discover known inciting influences of HTN followed by proper counseling is very important.

Participation in sports should be encouraged in competitive athletes with well-controlled HTN unless there is evidence of ongoing end-organ injury or a known structural cardiovascular disorder or arrhythmia. The American Academy of Pediatrics Committee on Sports Medicine and Fitness currently encourages dynamic exercises and participation in competitive sports in children with mild or well-controlled HTN, but not in those with severe HTN (8, 130). Other recommendations of this Committee are listed in *Table 63-11*. The risk for sudden death related to HTN per se is extremely low. An echocardiogram and standardized exercise testing may be useful in identifying athletes who are at high risk for such catastrophic events.

In general, most pharmacologic agents may be utilized to manage HTN in competitive athletes. However, diuretics should be avoided. Also, the use of beta blockers are generally contraindicated as these may limit the normal compensatory tachycardia associated with dynamic exercise and may result in syncope or other consequences of hemodynamic insufficiency. Moreover, alpha adrenergic agonists, such as clonidine and other centrally acting agents, should be used with caution in athletes because sympathoihinbition may also prevent compensatory tachycardia related to exercise and thereby result in postural hypotension and muscle weakness.

A combination of aerobic and static exercises should also be encouraged. Weightlifting may start with a low

Table 63-11

Recommendations for participation in competitive sports for the hypertensive pediatric patient

1.	Patients with mild to moderate hypertension (90th to 99th percentile for age and height; 1996 Task Force) and no evidence of end-organ involvement or other cardiovascular disease can participate in all competitive sports. Blood pressures should be monitored every 2 mo to monitor the impact of participation
2.	Patients with severe hypertension (>99th percentile for age and height; 1996 Task Force) but with no evidence of end-organ involvement or other cardiovascular disease should be restricted, particularly from high-static sports, until blood pressure is controlled. They may then participate as in number 1. For those patients with severe hypertension and evidence of end-organ involvement, the same recommendation may be followed as long as sports participation does not exacerbate the end-organ involvement or place the patient at risk
3.	Patients with hypertension and coexisting cardiovascular disease may require additional restrictions based on the nature of the cardiovascular disease and associated risks

From American Academy of Pediatrics Committee on Sports Medicine and Fitness. Athletic participation by children and adolescents who have systemic hypertension. *Pediatrics* 1997;99:637–638, with permission. (ref (130))

weight and multiple repetitions and slowly advance to greater amounts of weightlifting and fewer repetitions.

HTN During Pregnancy (131, 132)

Over one million adolescents become pregnant in the USA each year. Adolescents have a significant higher risk for pregnancy associated HTN, and for having small for gestational age offspring who may also be at susceptible to HTN. Gestational HTN in adolescents may also be a forerunner for development of sustained maternal HTN 6–9 years after pregnancy.

The spectrum of HTN during pregnancy includes the common disorder, preeclampsia (associated with proteinuria), and the much less common conditions of eclampsia (proteinuria and seizures) and gestational HTN (no proteinuria). Collectively these disorders occur in 10% of all pregnancies and cause considerable maternal and infant mortality. Preexisting HTN and renal disease are important risk factors in 30% of women who develop preeclampsia.The pathogenesis of these disorders is unclear. Individuals with a gain of function mutation of the mineralocorticoid receptor may be at risk for developing preeclampsia (see Sect. "Gain of Function Mutation of the Mineralocorticoid Receptor").

Although preeclampsia usually resolves after delivery of the infant, it is desirable to manage the HTN until at least 32 weeks of gestation so as to limit the complications of prematurity to the fetus. Provided that there is no end organ damage, as a general rule, a higher threshold for treatment may be used (usually diastolic BP $>$ 100 and/or systolic BP $>$ 160 mm Hg) because lower placental blood flow may compromise growth and overall safety of the infant. The goal of therapy is a diastolic BP below 90 mm Hg. Drugs that do not affect placental blood flow are recommended (132). Alpha methyldopa may be an initial agent; hydralazine is another such agent.

In individuals nearing delivery, prophylaxis against seizures (eclampsia) is essential during labor and for 1–2 days after delivery. This consists of intravenous magnesium sulfate starting with a 4 g loading dose (over 15–20 min), followed by 2 g/h by continuous infusion thereafter. The goal is to achieve a blood magnesium level of 6 mg/dL. Serum magnesium levels must be monitored frequently as concentrations above 8–9 mg/dL may cause symptoms of magnesium toxicity.

Because both ACEI and ARB are teratogenic, their use is contraindicated during pregnancy. Birth defects have been noted as early as the first trimester of pregnancy that was previously thought to be a safe period (131). Birth defects include cardiovascular and neurologic complications, craniofacial deformities, and renal dysplasia leading to renal insufficiency and oligohydramnios.

Neonatal HTN (133)

Renovascular causes of HTN predominate in this population. Common etiologies include renal thromboemboli secondary to umbilical vascular access and right-to-left shunts due to ventricular septal defect or patent ductus arteriosus. Other causes include acute cortical necrosis associated with asphyxia, sepsis or circulatory shock leading to renal venous thrombosis or kidney injury, along with hypercarbia related to bronchopulmonary dysplasia leading to sodium and fluid retention, and HTN. Intracranial hemorrhage leading to neurogenic or "central" HTN, polycystic kidney disease, coarctation of the aorta and iatrogenic causes such as use of glucocorticoids, caffeine, dopamine, and inadequate pain control may be less common causes.

The management of neonatal HTN is highly individualized. The benefit of specific antihypertensive agents in preventing cardiac dysfunction, pulmonary insufficiency, and intracranial hemorrhage should be balanced against the risks of developing renal dysfunction or hypoperfusion of brain and viscera as BP is being lowered. *Table 63-12* shows the dosages of antihypertensive medications utilized in neonates. Gradual titration of such medications is particularly important in neonates. In the absence of renal artery stenosis, captopril at 0.01–0.1 mg/kg/dose given every 8-h is usually effective in newborns suspected of having other forms of renovascular HTN. Isradipine given at a dosage of 0.1 mg/kg/dose every 6–8 h is another useful agent particularly in newborns with bronchopulmonary dysplasia or steroid-induced HTN. Intravenous hydralazine (at 0.1–0.2 mg/kg/dose), or esmolol, are reserved for more refractory HTN in this population. Diuretics are generally avoided but may be used with caution in infants with bronchopulmonary dysplasia.

Many causes of HTN that start in the newborn period resolve spontaneously by 1-year of age. Thus, "step-down" care should be anticipated. Also, most infants tend to outgrow their medication dosages due to rapid body growth during infancy.

Management of Hypertensive Emergencies

Hypertensive emergency is defined by the presence of acute end-organ injury. The implication is that immediate

Table 63-12

Pharmacologic therapy of neonatal hypertension

Angiotensin-converting enzyme inhibitors	
Captopril	0.05–2.0 mg/kg/day PO (÷q6–12 h)
Enalaprilat	5–10 μg/kg/dose IV (q8–24 h)
Beta-adrenergic antagonists	
Esmolol	100–500 μ/kg IV load over 1–2 min, then 50–500 μg/kg/min IV continuous infusion
Labetalol	1–20 mg/kg/day PO (÷q8–12 h)
	0.2–1.0 mg/kg/dose IV bolus or 0.25–3.0 mg/kg/h IV continuous infusion
Propranolol	0.5–5.0 mg/kg/day PO (÷q6–12 h)
Calcium-channel antagonists	
Amlodipine	0.1–0.6 mg/kg/day PO (÷q12 h)
Isradipine	0.05–0.15 mg/kg/dose PO (q6 h)
Nifedipine	0.125–0.5 mg/kg/dose PO (÷q6–8 h) (max dose = 3 mg/kg/day)
Nicardipine	0.5–3.0 μg/kg/min IV continuous infusion
Diuretics	
Bumetanide	??
Chlorothiazide	20–30 mg/kg/day PO (÷q12 h)
Furosemide	0.5–4.0 mg/kg/dose IV/PO (÷q6–8 h) (max dose = 4 mg/kg/day)
Hydrochlorothiazide	2–3 mg/kg/day PO (÷q12 h)
Vasodilator	
Hydralazine	0.1–0.6 mg/kg/dose IM/IV q4–6h OR 0.75–5.0 μg/kg/min IV continuous infusion
Sodium nitroprusside	0.5–8.0 μg/kg/min IV continuous infusion

÷, divided

reduction in BP is needed. Although a large majority of children who present to the emergency department with hypertensive emergency have BP above the 99th percentile, hypertensive emergency is not strictly defined by numerical BP values.

Symptoms and Signs

Unlike adults in whom hypertensive emergencies usually occur in individuals with known and often severe pre-existing HTN, in children the discovery of HTN is often made at the time of presentation with symptomatic HTN. The severity of manifestations in children with hypertensive emergency often depends on the chronicity of HTN as well as on the magnitude of the BP elevation. In general chronic Stage I or Stage II HTN is usually well tolerated whereas the same BP level may be associated with severe headache or seizures in children with acute glomerulonephritis. Similarly children with cardiac outlet obstruction or cardiomyopathy may become symptomatic despite mild HTN.

Perhaps the most common symptoms of HTN in the majority of older children who present to the emergency department are those of hypertensive encephalopathy manifest by headache, nausea, vomiting, mental confusion, blurred vision, agitation or frank seizures. Other manifestations may include cerebral infarction, intercerebral or retinal hemorrhage, congestive heart failure, acute pulmonary edema (and shortness of breath), acute renal insufficiency, or microangiopathic hemolytic anemia. Uncommon sequelae of hypertensive emergencies in children include myocardial infarction or aortic dissection. Newborns and infants with severe HTN may present with congestive heart failure, hypertensive retinopathy, respiratory distress, apnea or cyanosis, extreme irritability, hypotonia, convulsions or coma. Vomiting or diarrhea as well as failure to thrive may be among the global chronic manifestations of HTN in this younger age group.

In the absence of renal disorders which often predispose to hypertensive emergency one must be aware of previously unrecognized cardiac and endocrinologic etiologies of HTN which may influence the therapeutic strategy.

Pathophysiology of Hypertensive Emergencies

Chronic HTN leads to compensatory, functional and structural changes in arterial vessels which tend to maintain perfusion to brain and kidneys in particular, while protecting against injury which may otherwise result from organ hyper-perfusion due to HTN (134). When systemic BP surpasses the compensatory limits of autoregulation, of blood flow arterial injury such as fibrinoid necrosis and organ ischemia may follow (135, 136). Conversely when BP is suddenly reduced below the new steady state limits of compensation, ischemic injury may be enhanced particularly in individuals with atherosclerotic or other structural hypertensive arterial changes. Many children with hypertensive emergencies do not have structural vascular lesions and are, therefore, less susceptible to organ ischemia after BP lowering. Conversely, the lack of adaptive responses in children with acute and rapid rise in BP may predispose to symptoms at BP levels

which may not be gauged as being sufficiently high to produce such symptoms.

General Principles of Management

Assuming that the clinical setting permits it, the diagnostic plasma and urinary studies shown in *Fig. 63-5* should be done prior to pharmacologic treatment because the latter my confound several of these studies.

There are no controlled clinical trials of treatment of hypertensive emergencies in children. Only a few reports address this topic in the pediatric age group (137–139). A review of multiple adult studies failed to produce statistical superiority of any single agent and the outcome was not uniform between studies (140). As a general rule, agents with short duration of action are preferred such that when BP reduction is gauged as excessive, the effect can be quickly reversed by stopping the agent and/or administering normal saline. A major long-term objective is to assure compliance with maintenance antihypertensive therapy during follow-up (141, 142).

The goal of emergency therapy is to achieve a gradual decrease in systolic and diastolic BP to near the 99th percentile, or, to reduce the mean arterial pressure (one third of the pulse pressure difference added to the diastolic BP) by 25%. With such reduction in BP over a period of minutes or hours, the symptoms and signs of HTN tend to improve or resolve. Further lowering in BP may then take place more slowly over several days or weeks such that the BP falls below the 90th percentile for age, gender, and height percentile (8).

Figure 63-5

Evaluation and guidelines for use of intravenous agents in the management of hypertensive emergenciest (Do not use hydralazine or nieardipine in children with head trauma or intracranial hemorrhage).

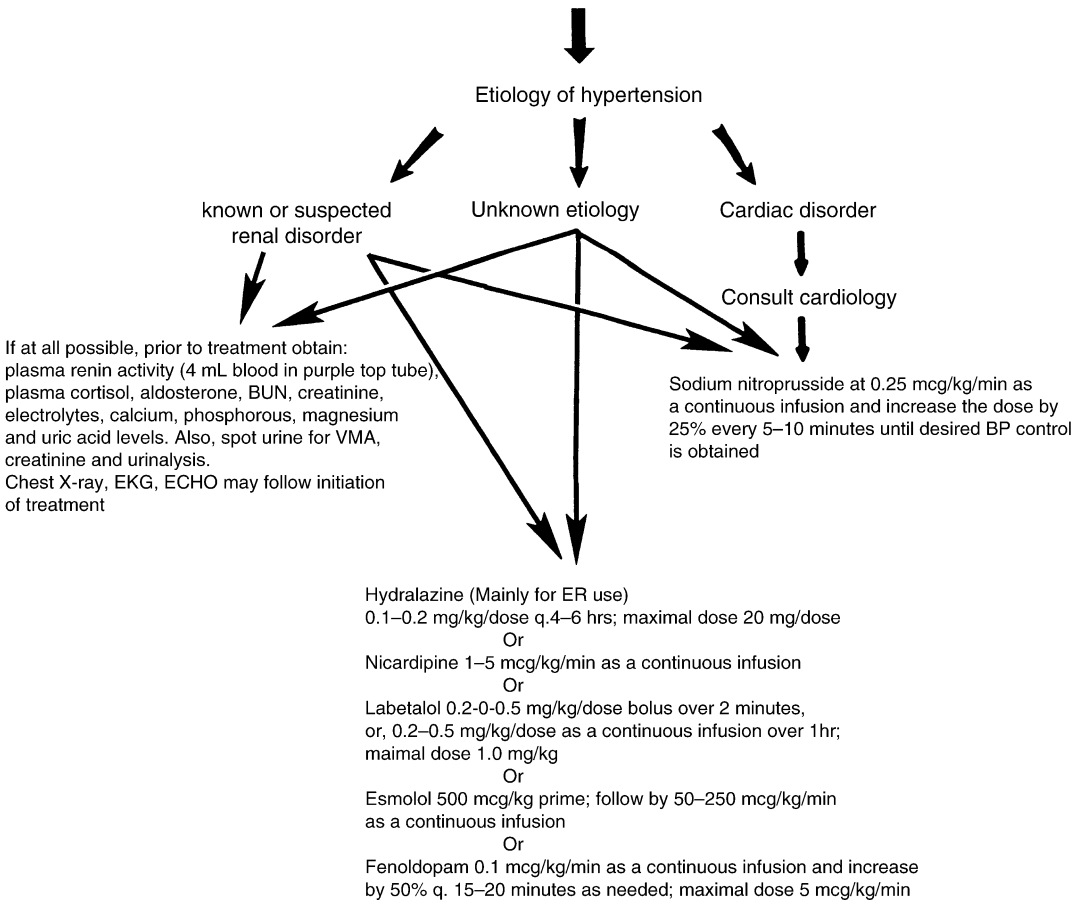


Table 63-13

Pharmacologic management of hypertensive emergencies and urgencies in infants and in children

Action	Agents (trade names)	Dose	Route	Comments
Vasodilator	Hydralazine (Apresoline, others)	0.1–0.2 mg/kg (maximum 20 mg/dose)	IV	Administer at < 0.2 mg/kg/minute; onset 5–20 minutes; lower dose can be repeated after 5–20 minutes. Duration is 2–6 hours. Can cause reflex tachycardia. Available in 20 mg/ml ampoule.
	Minoxidil (Loniten)	0.1–0.2 mg/kg (maximum 50 mg/day)	Oral	Onset ≤ 30 minutes; maximum effect @ 2–8 hours; long duration of effect, once daily dosing, contraindicated in pheochromocytoma.
	Diazoxide (Hyperstat)	1–3 mg/kg (maximum 150 mg dose)	IV push	Administer IV push over 10–30 seconds, maximum effect within 5 minutes, can be repeated after 5 minutes, duration of effect 3–12 hours. Available in 300 mg/30 ml ampoule. Alternative dosing is 1 mg/kg every 5–15 minutes until blood pressure control is achieved.
	Sodium nitroprusside (Nipride)	0.25–8 mcg/kg/min	IV drip	Administer by continuous infusion only; onset within 2 minutes, duration < 10 minutes. Start at 0.25 mcg/kg/minute and increase the dose by 25% every 5–10 minutes until blood pressure control is obtained. Obtain thiocyanate levels if used for more than 48 hours; protect from light. Available in 50 mg/5 ml vial.
Adrenergic alpha and beta blocking agents	Labetalol (Normodyne, Trandate)	0.2–0.5 mg/kg/dose (maximum 1mg/kg)	IV	Administer IV over 2–3 minutes; onset 2–5 minutes; maximum effect in 5–15 minutes, duration 2–4 hours; lower dose can be doubled and repeated at 15 minute intervals x 2; can also be given at same dose by IV infusion over 1 hr. Avoid if child has a history of asthma / bronchospasm. Contraindicated in congestive heart failure, sinus tachycardia, heart block. Available as 5 mg/ml.
	Clonidine (Catapres)	5–10 mcg/kg/day (maximum 25 mcg/kg/day)	Oral	Divide dose and administer q 6–12 hours. Also available in transdermal formulation. Avoid in cerebrovascular disorders. May cause agitation, insomnia, drowsiness, rebound hypertension after rapid withdrawal
	Esmolol (Brevibloc)	Loading dose: 500 mcg/kg IV, then use as continuous infusion 50–250 mcg/kg/min.	IV drip	Use for postoperative hypertension; administer loading dose over 1 minute; followed by continuous infusion; onset: beta blockade occurs in 2–10 minutes; duration 10–30 minutes (short). Contraindicated in congestive heart failure, sinus tachycardia, heart block.
	Isradipine (DynaCirc)	0.2–0.9 mg/kg/day (maximum 0.6 mg/kg/day)	Oral	Available in capsules (2.5 and 5 mg) and in liquid formulation (1 mg/mL). May cause tachycardia or congestive heart failure.

Table 63-13 (Continued)

Action	Agents (trade names)	Dose	Route	Comments
Calcium-channel blocking agents	Nifedipine (Procardia, others)	0.2–0.5 mg/kg (Initial dose should not exceed 0.25 mg/kg)	Oral	Swallow whole or bite capsule and swallow, or remove liquid from capsule with syringe; not effective by sublingual route (actual effect due to swallowing the drug with subsequent rapid oral absorption); initial dose can be repeated once within 30 minutes. Onset of effect within 1–5 minutes after bite and swallow dosing, contraindicated in patients with heart disease; available in 10 and 20 mg capsules.
	Nicardipine (Cardene IV)	1 mcg/kg/min (maximum 5 mcg/kg/min)	IV drip	Onset 10 minutes; duration 2–6 hours; available as 2.5mg/ml
Alpha-adrenergic blocker	Phentolamine (Regitine)	0.05–0.1 mg/kg/dose (maximum 5 mg)	IV	Diagnostic test for pheochromocytoma. Onset is immediate; maximum effect in 2 minutes, duration 30 minutes; available in 5 mg vial.
ACE inhibitors	Enalaprilat	5–10 mcg/kg/dose	IV	Administer undiluted over 5 minutes; onset ≤ 15 minutes; maximum effect @ 1 hour; duration 4–6 hours. Severe hypotension can occur in sodium or volume depleted patients. Use lower dosages in neonates.
Dopamine receptor agonist	Fenoldopam	0.1 mcg/kg/min (maximum 5 mcg/kg/min)	IV	Administer as a continuous infusion; onset ≤ 15 minutes. Especially useful in children with severe renal dysfunction.

Management of Hypertensive Emergencies

A list of antihypertensive agents and the recommended dosages in children with hypertensive emergencies is shown in *Table 63-13*. An algorithm for managing hypertensive emergencies with intravenous agents is shown in *Fig. 63-5*. Oral agents, such as nifedipine, have a limited and often controversial role in the management of hypertensive emergencies (see below). In most other children with symptoms and signs of hypertensive emergency, or in those with cardiovascular or other disorders associated with HTN in whom CCB or beta blockade may be harmful, the initial agent may include intravenous hydralazine (see *Fig. 63-5*). If HTN persists, the child may be managed in the intensive care unit where more powerful parenteral agents may be administered (see *Fig. 63-5*), and BP may be monitored continuously and directly through an intra-arterial transducer.

Not shown in *Fig. 63-5*, is the management of drug-induced HTN due to catecholamine excess (cocaine intoxication, monoamine oxidase inhibitor crisis). This disorder may be controlled with an alpha adrenergic blocker while avoiding initial use of β-blockers which may potentiate the alpha adrenergic action of catecholamines. This resembles the management of pheochromocytoma-associated HTN (see Sect. "Pheochromocytoma/Paraganglioma, Neuroblastoma and Neuroendocrine HTN"). Also, intravenous diuretics may be very useful as adjunctive agents in the setting of congestive heart failure in disorders accompanied by fluid overload, such as acute glomerulonephritis.

Oral Agents

In general, oral agents may be used in a minority of children with mild manifestations of hypertensive emergency secondary to renal etiologies, such as mild headache or other symptoms of impending organ injury, rather than those with evidence of active organ injury. In this setting, the initial therapy may consist of oral agents, and, frequently, short acting *nifedipine*. Unlike studies in adults showing that the use of this agent may be associated with precipitous fall in BP and an increased risk for myocardial infraction, stroke, and death (143), pediatric use of this agent is safe and effective (54, 144). However, both the clinical setting and the initial dose may influence safety. Guidelines for avoidance of the use of short acting nifedipine in children may include:

1. Congestive heart failure, presence of myocardial ischemia, post cardiac arrest, severe left ventricular

hypertrophy, left ventricular outflow obstruction, or cardiac arrhythmia.
2. Acute hypertension with high cardiac output states such as sickle cell crisis or other chronic anemia.
3. Cyanotic heart disease
4. Hypovolemic states including children undergoing acute diuresis, or those with acute hemorrhage.
5. Acute hypertension associated with severe pain. BP should be reassessed after administration of appropriate analgesics such as morphine.
6. Acute central nervous system injury
7. Children receiving large dosages of beta blockers, such as atenolol or labetolol.
8. Infants less than 1 year of age in whom dosing of nifedipine may be inaccurate.

In the absence of such disorders, orthostatic hypotension is usually avoided when the starting dose of nifedipine is 0.2 to 0.25 mg/kg/dose. Although it is often given sublingually, very little of the agent is actually absorbed via the oral mucosa. Thus, if the entire 10 mg nifedipine capsule is to be used, the author recommends the "bite and swallow" method. If lesser amounts are needed, the 10 mg capsule contents is drawn into a 1 mL graded syringe (0.034 mL = 1 mg) and the portion needed may be administered orally so as to speed up gastrointestinal uptake and onset of action. If needed, this dose may be repeated once within 30 min. All subsequent dosages should not exceed 0.5 mg/kg/dose with a maximum total dose of 10 mg, and the frequency of administration may be every 4–6 h. Close BP monitoring is mandatory and such children should not ambulate after receiving the medication unless they are completely free of orthostatic hypotensive symptoms and signs such as headache, dizziness or mental disturbances.

Minoxidil is an alternative oral agent with properties of smooth arterial muscle relaxation (leading to vasodilation) which may be effective in preventing the development of a full hypertensive emergency. Close BP monitoring and avoidance of ambulation is also recommended after its use.

Intravenous Agents (*Fig. 63-5*)

The majority of children with hypertensive emergencies require intravenous antihypertensive medications. Nowadays, diazoxide is rarely used for this purpose because of unpredictable or precipitous fall in BP. Also, hydralazine has become less popular because of the common occurrence of flushing, tachycardia, nausea, and headache. However, hydralazine may be useful in the Emergency Department setting, particularly if the etiology of the HTN has not been established. With more severe or refractory symptomatic hypertension more potent intravenous medications are indicated. Coadministered antihypertensive and other medications may be reviewed for possible synergism or drug interaction which may exacerbate adverse effects of the intravenous agents.

In the author's experience, the most useful parenteral agents in children include sodium nitroprusside (137, 145, 146), nicardipine (147–149), and labetalol (150, 151); esmolol may be a preferred drug in infants (137, 152–154) along with labetalol and enlaprilat (141, 155). As shown in *Table 63-13* some of these agents may be given as a constant infusion and have an onset of action of less than 5 min. Generally, one should start with the lower dosage range with stepwise increase in dosage by 25% every 5–10 min until the desired BP is reached.

Sodium nitroprusside may be the initial intravenous agent in any child presenting with hypertensive emergency with the exception of coarctation of the aorta, closed head injury or suspected high intracranial pressure. This agent along with hydralazine, and diazoxide should also be avoided in children with intracranial hemorrhage. With chronic use of this agent accumulation of its metabolic end products comprised of cyanide and thiocyanate, may cause nausea, vomiting, neurological symptoms, hypothyroidism, dyspnea and lactic acidosis. *Nicardipine* may be more suitable for children with renal insufficiency who are unable to effectively excrete these metabolites. Less frequently, nicardipine may also be given as mini-boluses. *Fenoldopam*, a vascular dopamine receptor agonist (DA1), is also effective and may be uniquely suitable for managing hypertensive emergencies in the setting of renal insufficiency (136, 140, 156). *Esmolol* may be given by constant infusion. However, esmolol, labetalol, and enalaprilat (IV enalapril) may also be administered on an intermittent basis. Intravenous labetalol or nicardipine may be particularly useful in the management of hypertension after transplantation. As with esmolol and other beta-blockers, labetalol should be avoided or used with caution in children with reactive airway disease and one should be aware of other contraindications to their use (see Sect. "Newer Antihypertensive Agents"). Infants are particularly susceptible to enalaprilat-induced inhibition of angiotensin II, and may develop significant reduction in renal blood flow and glomerular filtration rate. Hence, enalaprilat should be used with caution in infants with known or suspected renal artery stenosis. However, this agent may be useful in managing renovascular HTN due to focal renal scarring or microthrombi associated or intubation of the umbilical vessels.

Acute Renal Failure

64 Pathogenesis of Acute Renal Failure

Rajasree Sreedharan · Prasad Devarajan · Scott K. Van Why

Introduction

Acute renal failure (ARF) is defined clinically as the sudden loss of renal function that may result from inadequate renal perfusion associated with a decrease in effective circulation, arterial or venous obstruction, renal cell injury, or obstruction to urine flow as occurs in obstructive uropathy. Renal cell injury, commonly termed intrinsic ARF, results from an ischemic or toxicant insult that causes acute tubular damage with accompanying loss of ability to reabsorb filtered solute. The resulting decrease in glomerular filtration rate (GFR), an invariable component of ARF, is then a successful adaptive response, since continued filtration of plasma across the glomerular basement membrane without reabsorption of the filtrate by injured renal tubules would result in massive losses of salt and water (1). Thus, the decreased GFR associated with ARF prevents severe depletion of extracellular fluid.

Many definitions for ARF have been employed, ranging from dialysis requirement to subtle increases in serum creatinine (2). The term acute kidney injury (AKI) has been proposed to replace the term ARF and is garnering wide usage (3). The intent of the change in terms is to standardize the definition and to reflect both the entire spectrum of the condition as well as the understanding of mechanisms that underlie the renal dysfunction. AKI refers to a complex disorder from multiple causes with varied clinical manifestations ranging from a minimal but sustained elevation in serum creatinine to anuric renal failure. Rapidly and fully reversible causes of acute renal insufficiency, such as volume depletion, are specifically excluded from the spectrum of AKI. The unifying feature of AKI is renal cell injury, so AKI and intrinsic ARF, in a sense, can be used interchangeably.

Renal ischemia is both the most common isolated cause of AKI and most common contributor to multifactorial AKI. For decades, then, studies of ARF have focused on models of ischemic renal cell injury. From these studies it is clear that AKI manifestations can range from mild, sublethal cell injury with disrupted renal cell architecture and function to fulminant necrotic cell death. Furthermore, both extremes, along with the full spectrum of intervening cell injury features, can be present simultaneously or sequentially after the insult (*Fig. 64-1*)

This chapter, then, describes the pathophysiology of ARF, as revealed in experimental models, both *in vivo* and *in vitro*, of ischemia induced AKI. Included are classical concepts of ARF as well as a contemporary understanding of vascular, cellular, molecular, and metabolic alterations that are associated with renal cell injury. Mechanisms that lead to cell injury and death will be addressed along with processes that can result in cellular repair and renal recovery.

Renal Hemodynamics

Renal vasoconstriction in experimental and clinical ARF is intense (4). Because vasoconstriction was considered to be the dominant factor, it was suggested once that the term "vasomotor nephropathy" might be more appropriate than ARF to describe this condition (5). The hypothesis was that an insult to the renal tubular epithelium results in release of vasoactive compounds that increase cortical vascular resistance causing decreased renal blood flow (RBF), thus perpetuating injury to the tubule and furthering the cycle. Release of vasoconstrictive compounds may then diminish GFR by constricting afferent and efferent arterioles, thereby causing diminished urine output, or oliguria. Therefore, emphasis has been placed on identifying vasoactive compounds that are stimulated by an ischemic or toxic insult. Candidate systems for the vasoconstriction and vascular components of AKI include angiotensin, prostaglandins, adenosine, endothelin and nitric oxide.

Renin-Angiotensin System

The renin-angiotensin system functions in a manner consistent with the renal vasoconstriction hypothesis (6). An injury to the more proximal portion of the nephron, a typical feature of ischemic AKI, impairs reabsorption resulting in delivery of more solute and water to the distal

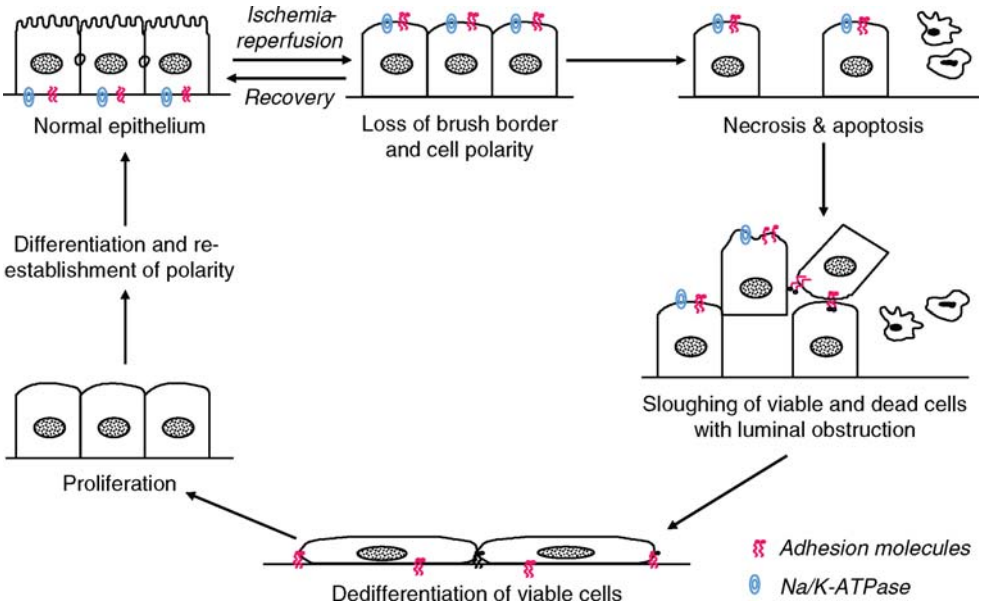
Figure 64-1

Disruption and recovery of renal tubule architecture **Ischemia disrupts normal polar distribution of membrane transport proteins and adhesion molecules, causing loss respectively of reabsorptive function and tubule integrity. Sublethally injured cells can recover normal structure and function. More severely injured cells die of apoptosis or necrosis, resulting in denudation and obstruction of the tubule. Restoration of tubule structure proceeds through dedifferentiation, proliferation, and redifferentiation processes likely mediated by growth factors and stem cells.**



nephron. This increased solute load in the distal nephron perfuses the macula densa of the juxtaglomerular apparatus, stimulating the release of renin with the subsequent generation of angiotensin II, a potent renal vasoconstrictor.

Several findings suggest that this system may have a role in the pathogenesis of ARF: (*a*) hyperplasia of the juxtaglomerular apparatus with increased renin granules is found both in patients and in experimental animals with ARF; (*b*) plasma renin activity is increased in patients with ARF; and (*c*) changing intrarenal renin content modifies the degree of renal functional impairment. For example, feeding animals a high-salt diet, which suppresses renin production, prior to a renal injury preserves renal function compared with animals fed a low-salt diet, which stimulates renin production.

However, other findings suggest that the renin-angiotensin system is not fully responsible for the changes in renal hemodynamics and function in ARF. For example, amelioration of experimental ischemic AKI also follows the induction of a solute diuresis with either mannitol or loop diuretics, neither which affect intrarenal renin. Furthermore, the degree of renal injury is not changed by immunizing animals against renin-angiotensin, treating with angiotensin converting enzyme inhibitors, or infusing with a competitive antagonist to angiotensin II. Therefore, the role of the renin-angiotensin system as the modulator of renal injury in ARF is uncertain.

Nevertheless, recent findings have renewed interest in this pathway, since it appears that a hormone downstream from renin and angiotensin, aldosterone, may play a central role in ischemia induced AKI (7). Prior mineralocorticoid receptor (MR) blockade with spironolactone was found to prevent several structural and functional manifestations of ischemia-reperfusion injury. Spironolactone administration prior to induction of renal ischemia prevented the typical reductions in RBF and GFR during reperfusion, and substantially reduced accompanying renal histomorphologic damage and tubule apoptosis. The protection conferred by MR blockade correlated with changes in other pathways that have been implicated in AKI. Primarily, it appeared that MR blockade decreased oxidative stress present during reperfusion after renal ischemia.

Prostaglandins

Prostaglandins are potent renal vasodilators. While inhibition of prostaglandin production is associated with

decreased RBF and can affect the severity of ARF, the precise role of prostaglandins in the induction and maintenance of ARF is not established (6). However, prostaglandin inhibitors, such as non-steroidal anti-inflammatory drugs, increase the risk for development of ARF and may act synergistically with other insults.

Adenosine

Adenosine, which results from catabolism of adenine nucleotides, is a potent vacoconstrictor of renal vasculature, whereas it is a vasodilator of peripheral vasculature (8). The infusion of methylxanthines, which block adenosine receptors, inhibits the tubuloglomerular feedback mechanism and the decrease in GFR that accompanies reduced tubular absorption, suggesting that adenosine may be involved in the modulation of renal vascular resistance in ARF. In some experimental models, the infusion of methylxanthines has been associated with diminished functional impairment. The proposal that adenosine is an important vasoactive compound following an acute tubule insult is attractive, because it would link alterations in cell metabolism with hemodynamic changes.

However, the evidence that adenosine is a major factor in the vasoconstrictive response is inconclusive because: (a) methylxanthines have a variety of effects in addition to the inhibition of adenosine receptors; (b) while adenosine is produced following the initiation of adenine nucleotide catabolism, it is rapidly catabolized by adenosine deaminase when released into extracellular fluid; (c) intrarenal levels of adenosine diminish very rapidly upon the establishment of reflow to the kidney, while renal vasoconstriction is continued through the early phases of reperfusion following an ischemic injury; and (d) when tissue adenosine levels are increased by inhibition of adenosine deaminase during ischemia, post-ischemic recovery of renal function is enhanced (9).

A recent study in the A1 adenosine receptor (A1AR) mouse knockout model may help reconcile these apparent discrepant effects of adenosine on renal blood flow and AKI. The increased delivery of sodium chloride to the macula densa due to dysfunction of the ischemic proximal tubule would be expected to cause afferent arteriolar constriction via A1AR activation, and thereby decrease GFR (10). However, knock out of the A1AR resulted in a paradoxical worsening of ischemic renal injury, and exogenous activation of A1AR was protective (11). Thus, tubuloglomerular feedback following ischemic injury, contributed to by activation of adenosine receptors, may be an adaptive response that limits delivery of solute to damaged proximal tubules, thereby reducing the demand for ATP-dependent resorptive processes. The effect of exogenous A1AR activation in human AKI is not known.

Endothelin

Endothelin, a 21-amino acid peptide, is a potent renal vasoconstrictor that has other important biological activities as well (12–14). It contributes to the vasoconstriction that occurs in a variety of tissues as a response to hypoxia. Raised endothelin levels in plasma and in both the cortex and medulla of the kidney have been demonstrated in experimental animals after the induction of renal ischemia (12). The post-ischemic infusion of anti-endothelin antibody or endothelin receptor antagonists provides protection from ischemic injury in animal models, but there is a lack of human data (12–15).

Nitric Oxide

Nitric oxide (NO) is a potent renal vasodilator, which is widely distributed in the kidney, and is produced by constitutive and inducible synthetases located in endothelial cells and renal tubules (16). While a specific role for these compounds in cerebral ischemia has been established (17), the effect of either stimulation or inhibition of nitric oxide synthetase (NOS) on ischemic or toxic ARF is confusing and, at times, contradictory. The apparent contradictory effects are likely attributable to the differential distribution and specific effects of each isoform on renal vasculature and tubules.

The rat kidney is protected from ischemic injury when inducible NOS is targeted with antisense oligonucleotides, suggesting that NO has a direct cytotoxic effect on renal epithelia (18). A similar cytotoxic effect of NO is found in isolated proximal tubule cells subjected to hypoxia (19). However, it has been postulated that production of NO following ischemia should help alleviate the vasoconstriction which characterizes ARF. In that regard, non-selective NOS inhibition has been found to worsen renal function and cause profound renal vasoconstriction (17). Hence the dilemma: stimulation of NO in the renal vasculature via NOS could modulate vasoconstriction and potentially lessen AKI; induction of NO via NOS in renal tubules is cytotoxic (16–18). So, this complex biological system may indeed play a role in the pathogenesis of ARF, but the specificity of action remains to be determined and may depend on whether vascular or tubular effects of NOS predominate in a particular setting.

All things considered, persistent renal vasoconstriction is a well-documented event during reperfusion following renal ischemia, but vasodilation does not consistently result in amelioration of an acute renal insult. Once AKI has been established, the infusion of potent vasodilators such as prostaglandins or dopamine does not lead to sustained improvement in GFR (20, 21). The early recovery phase of ARF is associated with an increase in renal blood flow while GFR increases more slowly (22). Confirming the findings of animal studies, several human trials of renal vasodilators such as dopamine have failed to demonstrate improvement in GFR in established ARF despite augmentation of total renal blood flow (23). Although renal hemodynamic factors play an important role in initiating ARF, alterations in renal vascular resistance and renal perfusion on a macroscopic scale may not be dominant determinants of renal epithelial cell injury. They may, in fact, be an adaptive response to ameliorate further cellular injury during reperfusion. On the other hand, microvascular alterations are now recognized to play a major role, as discussed below.

Alterations in Microvasculature

Medullary vascular congestion is a consistent observation following experimentally induced ischemic renal injury. Advances in recent years, including application of *in vivo* microscopy, has given substantial credence to the concept that injury to the vascular endothelium is central to the initiation and extension of AKI. The microvascular endothelium undergoes direct structural alterations after an ischemic insult, and is both a source of and a target for inflammatory injury (24–28).

Similar to features described years earlier in tubule epithelial cells, an ischemic insult has been found to disrupt the structural integrity of both the actin cytoskeleton within endothelial cells and the junctional complexes between endothelial cells (29, 30). Consequent endothelial cell swelling, blebbing, and cell death or detachment of viable cells occurs, and circulating endothelial cells have been found in humans with septic shock (31). Sites of endothelial denudation may be prone to prolonged vasoconstriction. Minimally invasive intravital microscopy in animals has revealed sporadic cessation and even reversal of blood flow in peritubular capillaries in the renal cortex during reperfusion (32, 33). Systemic or intra-renal administration of fully differentiated endothelial cells into post-ischemic rat kidneys has resulted in significant functional protection (33). Similar, but less impressive amelioration of AKI can be achieved using surrogate cells expressing endothelial nitric oxide synthase (eNOS). Furthermore, ischemic injury markedly increases expression of angiostatin, a well known anti-angiogenic factor that induces apoptosis of endothelial cells (34).

Ischemic AKI also increases endothelial expression of a variety of adhesion molecules that promote endothelial-leukocyte interactions. These include intercellular adhesion molecule-1 (ICAM-1), P-selectin, and E-selectin (25, 35). Ablation of the ICAM-1 gene or pre-treatment with ICAM-1 antibody rendered mice resistant to ischemic AKI, raising the promise of the latter approach in humans. However, trials with anti-ICAM-1 monoclonal antibody administered post-ischemia did not prevent AKI manifested as delayed graft function in deceased donor kidney transplant recipients (25). Similarly, initial studies of animals with gene knock-outs and treatment with monoclonal antibodies or pharmacologic inhibitor have suggested a role for endothelial E- and P-selectins in the microvascular injury (35–37). Subsequent studies, though, demonstrated that platelet P-selectin, not endothelial P-selectin, is the key contributor to AKI (38). Proposed mechanisms include initial adhesion of platelets to the endothelium with subsequent recruitment of leukocytes, or adhesion of platelets to neutrophils with consequent intra-luminal cell aggregate formation and trapping in narrow peritubular capillaries (35). Furthermore, derangements in the coagulation cascade, such as alterations in tissue-type plasminogen activator and plasminogen activator inhibitor-1 in the kidney (39), may combine with the alterations in adhesion molecules to cause the fibrin deposits characteristically found in the renal microvasculature following ischemic injury.

Despite the lack of apparent benefit from the trial of anti- ICAM-1 in limiting ARF in transplant recipients, the series of investigations in the past several years that have highlighted the important role that microvascular injury plays in ischemia induced AKI provide rationale for additional trials of pro-angiogenic agents in ARF. These may include agents that can mobilize or increase the pool of endothelial progenitor cells, such as erythropoietin, bone morphogenic protein, Vascular Endothelial Growth Factor, and statins (28).

Nephronal Factors

The term 'nephronal factors' refers to the unique susceptibilities of specific nephron segments to injury. Best studied following ischemia are the S_3 segment of the proximal tubule and the medullary thick ascending limb (mTAL). There has been controversy over the relative importance

of each of these segments in ARF (40). What is clear, though, is that studies of cellular injury and repair in both segments have provided important insights into the pathophysiology of tubule cell injury.

Tubule Segment Susceptibility to Injury

Medullary Thick Ascending Limb: The mTAL appears to be particularly vulnerable to hypoxia because oxygen tension in the medulla is low and the mTAL segment has a high rate of oxygen consumption (41). Initial observations that established this relationship were made in isolated kidneys that were perfused with cell-free perfusate. Injury to the mTAL is prevented or reversed by increased oxygen delivery through addition of red blood cells or hemoglobin to the perfusion media. The degree of mTAL necrosis in this model was modified by the work load imposed on this segment. Decreasing the work load by inhibiting mTAL solute transport with furosemide or ouabain markedly diminished the severity of injury; increasing the work load had the opposite effect.

The relationship of these observations to the pathogenesis of ischemia induced AKI in man is controversial. Reducing oxygenation in experimental animals does not reproduce the lesions seen in the isolated-perfused kidney model. The experimental models where the lesions are predominantly in the mTAL involve combining severe reductions in renal blood flow with the administration of a nephrotoxin. Nevertheless, studies of the unique vulnerability of this nephron segment to hypoxia have provided insight into the relationship between oxygen supply, work load, and the cellular targets of ischemic, hypoxic, or anoxic injury (40). They may, in fact, be most pertinent to the understanding of synergistic effects of various cellular insults that alone would not produce AKI.

Straight Segment of the Proximal Tubule: The straight segment of the proximal tubule (S_3 segment) is highly dependent on oxidative phosphorylation to supply the energy necessary for its bulk transport functions. It is particularly susceptible to ischemia and to nephrotoxins that disrupt energy supply or mitochondrial function (6, 42). The earliest alterations in the S_3 segment, after mild or brief ischemia, are found in the brush border and consist of blebbing and internalization of the luminal membrane. With more prolonged ischemia, these changes progress to a more severe form of sublethal injury characterized by cell swelling, mitochondrial condensation, and broader disruption of cellular morphology. Simultaneous with these changes in sublethally injured cells, other cells in this segment may progress to a lethal injury such that the tubule epithelium is denuded from the basement membrane (*Fig. 64-1*). These changes in the S_3 segment result in two important pathophysiologic events, intratubular obstruction and backleak.

Intratubular Obstruction and Backleak

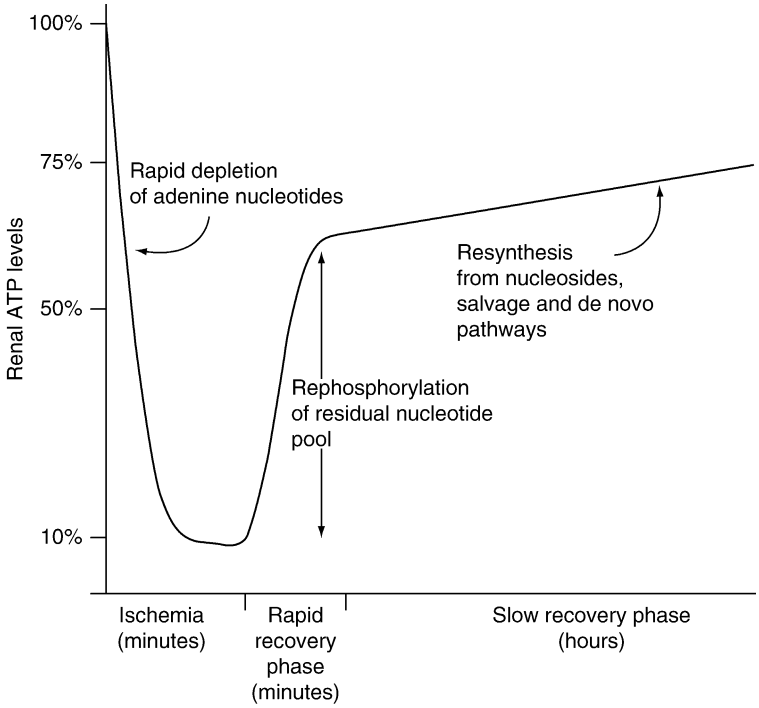
Cell and brush-border debris become impacted in the hairpin turn of the loop of Henle causing obstruction and backleak of tubular fluid in some nephron segments. Intratubular obstruction following ischemic injury has been demonstrated by histomorphology and by finding elevated proximal tubular pressure (42–44).

The backleak of tubular fluid that accompanies the loss of tubular integrity in AKI has been demonstrated in both experimental animals and patients (42–45). In animals, microinjection of inulin or horseradish peroxidase into normal nephrons results in the inulin being collected only from that kidney and the staining of horseradish peroxidase only within that tubule lumen. In contrast, inulin is found to be excreted by the contralateral kidney and horseradish peroxidase is found in both intra-and peritubular loci after microinjection into an injured nephron. In patients with ARF, backleak has been demonstrated by the differential clearance of graded dextrans (45). Since filtration is preserved and inulin, urea, and creatinine leak back into the circulation, the renal clearances of these solutes no longer represent GFR in patients with ARF. They nevertheless retain clinical utility in the global assessment of renal clearance ability.

The cellular and molecular mechanisms of tubule obstruction and backleak have been nicely defined (46, 47). Integrins are outer membrane proteins, basolaterally located in epithelial cells that attach the cell to the extracellular matrix. Following ischemia or ATP depletion, these adhesion molecules become detached from the extracellular matrix, allowing both dying and viable cells to leave the tubule basement membrane and float into the tubule lumen. In addition, these integrins become displaced from the basal to the luminal domain, which allows intraluminal sloughed cells to attach to cells that remain in place, thus contributing to tubule obstruction (*Fig. 64-1*). The integrin attachment occurs via an arginine-glycine-aspartic acid (RGD) sequence (46). This same RGD sequence may also promote binding of sloughed tubule cells to Tamm Horsfall protein produced in the mTAL and distal convoluted tubule (47). The infusion of RGD peptide abolished the characteristic increase in proximal tubule pressure and substantially improved renal function following ischemia, thus confirming the

Figure 64-2

Renal ATP depletion and recovery during ischemia and reperfusion **The initial rapid phase of ATP recovery occurs via phosphorylation of residual renal AMP and ADP. Slow phase recovery represents resynthesis and phosphorylation of adenine nucleotides.**



central role of integrin disruption to the processes of intratubular obstruction and backleak in AKI (48, 49).

Cellular and Metabolic Alterations

Adenine Nucleotide Metabolism

Energy depletion and restoration play a pivotal role in renal cell injury (50). *in vivo*, renal ischemia causes a profound fall in ATP; *in vitro*, metabolic inhibition of ATP production is used to induce cellular injury similar to the *in vivo* ischemia model. Within 5 to 10 minutes of inducing ischemia, nearly 90% of renal ATP has been consumed (9). With reperfusion, renal ATP levels recover in a bimodal fashion (*Fig. 64-2*). In the first few minutes of reperfusion, there is rapid, though incomplete, recovery of ATP to 50 to 70% of normal levels, depending on the duration of ischemia (51, 52). The longer the interval of ischemia, the less is renal ATP recovery during the initial, rapid phase. ATP recovery during the initial phase correlates highly with the total pool of adenine nucleotides (ATP + ADP + AMP) present in the kidney at the end of the ischemic interval. The total adenine nucleotide pool, mainly composed of AMP, decreases as the duration of ischemia increases. The catabolism of adenosine by adenosine deaminase results in progressive depletion of the adenine nucleotide pool with extended duration of ischemia (*Fig. 64-3*). Thus, ATP recovery during the initial period of reoxygenation is accomplished predominantly by oxidative phosphorylation of the residual cellular nucleotides (AMP and ADP).

A second, slow phase of ATP recovery occurs over hours following the initial rapid phase. The ATP recovery rate in the second phase also is a function of the preceding duration of ischemia; longer ischemic intervals result in slower recovery rates. The second phase requires resynthesis of ATP from purine nucleotide degradation products and salvage pathways, or from precursors provided during reperfusion (*Fig. 64-3*). A primary role for ATP depletion in ischemia induced epithelial cell injury is supported by several findings. (1) When ATP catabolism is inhibited during renal ischemia, the structural and functional manifestations of AKI are significantly ameliorated

Figure 64-3

(22, 42, 50). Graded reductions in cellular ATP, either *in vivo* or *in vitro*, determine the severity of cellular disruption (53, 54). Finally, augmentation of ATP recovery during reperfusion substantially enhances recovery of renal structure and function (50). Consequently, alterations in adenine nucleotide metabolism are both a consequence and predictor of renal cell injury. Furthermore, altered ATP metabolism triggers several pathways that lead to deranged epithelia structure and function: reactive oxygen molecules, increased intracellular calcium, activation of phospholipases, and disruption of tubule cell architecture.

Reactive Oxygen Molecules

Reactive oxygen molecules (ROM) have been implicated in a variety of kidney diseases, including reperfusion injury after ischemia (55). The most highly reactive oxygen molecules are free radicals such as hydroxyl radical (OH) or superoxide anion (O_2^-). The high reactivity and brief existence of these molecules result in injury close to the site of free radical generation. Other oxygen species such as hydrogen peroxide (H_2O_2) and hypochlorous acid (HOCl), not being free radicals, are less reactive. However they have longer half-lives than free radicals and may cross cell membranes to cause injury distant from their site of origin.

ROM are generated during reperfusion of kidneys (55). Ischemia induces metabolism of the adenine nucleotides to adenosine, inosine, and hypoxanthine (*Fig. 64-3*). Ischemia also may cause a conformational change in xanthine dehydrogenase (which uses NAD as an electron receptor) to xanthine oxidase, which uses oxygen (56). Once perfusion and oxygen delivery are returned, xanthine oxidase can metabolize hypoxanthine to xanthine and uric acid, generating hydrogen peroxide and superoxide anion (*Fig. 64-3*). Mitochondria, which produce reactive species though electron transport systems, when damaged by ischemia, may leak the injurious oxygen metabolites. The respiratory burst and myeloperoxidase released from activated PMNs produce superoxide anion, hydrogen peroxide, and hypochlorous acid (55). Prostaglandin metabolism may also provide reactive molecules. Iron can play a significant part by donating electrons to hydrogen peroxide to form the highly damaging hydroxyl radical (57). In this way, iron release may be responsible for the injury resulting in hemoglobin- or myoglobin-induced ARF (58).

Once generated, ROM damage cellular components and extracellular matrix (50). Intracellular proteins can be oxidized, resulting in conformational changes with loss of enzymatic activity or compromised integrity of structural proteins. Membrane lipids and lipoproteins undergo peroxidation by free radicals; these propagate and result in progressive membrane damage. Hydroxyl radicals damage DNA and oxidize matrix proteins. Reactive oxygen metabolites may contribute to ischemia by deleterious interactions with nitric oxide synthetases or with NO itself. NO can combine with superoxide to form peroxynitrate, a potent oxidant.

Because of these putative actions, much attention has focused on the role of ROM in ischemia-reperfusion injury (51, 55). While many studies have shown reactive oxygen species involved in the pathogenesis of AKI in animal models, it has long been questioned whether they play a significant role in human AKI. However, a recent study found a significant increase in oxidative stress in humans with ARF, as evidenced by depletion of plasma protein thiols and increased carbonyl formation (59).

The effects of enhancing endogenous antioxidants (superoxide dismutase, glutathione, catalase, apotransferrin,

or neutrophil gelatinase-associated lipocalin, NGAL) or administering exogenous free radical scavengers (*N*-acetylcysteine, deferoxamine, or edaravone) have been examined (60–63). Many of the animal studies have shown benefit from treatment with the anti-oxidants or free radical scavengers, but studies of humans using this approach, so far, have been at best inconclusive or have shown no benefit. So, despite the large number of studies on this topic, no final conclusion can be made as to the importance of reactive oxygen species in the pathogenesis of AKI, since strong evidence exists both for and against these compounds having a dominant role.

Intracellular Calcium

Under normal circumstances, extracellular fluid calcium concentration exceeds that of intracellular free calcium (Ca_i) by a factor of 10^4. The remarkably low Ca_i is maintained by a variety of mechanisms that exclude calcium from the cell or sequester it within intracellular compartments. Calcium is extruded from cells by plasma membrane Ca-ATPase and the Na/Ca-exchanger. Intracellular sequestration is mediated by Ca-ATPase in the endoplasmic reticulum and by calcium uptake into mitochondria. A fall in cellular ATP would be expected to reduce the activity not only of Ca-ATPase, but also Na/K-ATPase and thereby affect the Na/Ca-transporter. The net effect of cellular ATP depletion on extrusion of Ca from the cell and sequestration in the endoplasmic reticulum, then, would be to decrease calcium transport contributing to a rise in Ca_i. In addition, release of Ca from cellular organelles may contribute substantially to the rise in cytosolic Ca.

The contribution of mitochondrial damage to the observed rise in cytosolic calcium after ischemic or hypoxic injury appears to be minimal, because even damaged mitochondria are able to sequester calcium actively (51). However, the converse effect may be a mechanism in lethal cell injury. That is, the increases in cytosolic Ca that occur through the mechanisms outlined above can lead to unrestricted uptake by mitochondria. A substantial rise in mitochondrial calcium levels, then, usually occurs after cell injury is lethal.

There has been controversy whether high Ca_i levels play a central role in the pathophysiology of cell injury or whether the intracellular Ca changes are merely secondary to cell death. Increased cell and mitochondrial Ca levels are linked to cell death; but were thought not to increase until irreversible changes had occurred (64, 65). Later studies, however, have demonstrated a reversible increase in Ca_i early in the course of cell injury. After 5 minutes of hypoxia, rat proximal tubules develope a significant rise in Ca_i prior to evidence of membrane damage, and the increase in Ca_i is reversed with reoxygenation (66). In an *in vitro* model of renal cell injury from ATP depletion, graded levels of ATP depletion cause significant, early increases in Ca_i, but do not cause cell death. Furthermore, the increases in Ca_i are tightly and inversely correlated to the level of ATP depletion, and precede disruption of membrane protein-cytoskeleton interactions and induction of putative recovery mechanisms through activation of heat shock transcription factor and the stress response (54).

Therefore, alterations in intracellular Ca appear not to be merely a terminal manifestation of lethally injured cells. Increases in Ca_i may play an early role in AKI by mediating several aspects of sublethal injury, and a later role in a subsequent transition to lethal injury after a more severe insult. An increase in Ca_i may contribute to renal cell injury in several ways. It could activate calpain, contributing to degradation of the cytoskeleton; it could increase activity of other proteases and phospholipases that are active in mechanisms leading to either sublethal cell disruption or cell death; and it could inhibit mitochondrial oxidative phosphorylation. The latter effect would lead to a vicious cycle of progressive cell energy depletion, further cell injury, and eventual cell death. However, alterations in intracellular calcium also could activate recovery mechanisms, such as induction of the stress response (54). Furthermore, increased cytosolic calcium dramatically induces calcium binding proteins such as annexin A2 and S100A6, which play an important role in cell proliferation during recovery from AKI in animal models (67). Nonetheless, the relative contribution that changes in Ca_i make to specific pathophysiologic versus recovery mechanisms in AKI is yet to be defined.

Phospholipids and Lipases

The striking morphologic changes that occur in proximal tubules after ischemia, especially brush border membrane blebbing and the release of intracellular enzymes such as lactate dehydrogenase, suggest that significant membrane alterations may be part of the cellular injury in AKI. Changes in intracellular calcium flux have been shown to activate endogenous phospholipase, and some phospholipase may be activated by decreased cellular ATP. Phospholipase activation results in breakdown of membrane phospholipids into products including free fatty acids and lysophospholipids, which can disrupt

membranes and can be precursors of active metabolites that promote inflammation and further activate phospholipases. Moreover, the lack of ATP during ischemia may prevent the synthesis of new phospholipids to replenish membranes. The result would be a generalized loss of membrane phospholipids with an accumulation of degradative products that by their detergent activities would further disrupt cell membranes and eventually lead to loss of membrane integrity and cell death (68).

As discussed earlier, another mechanism that appears to contribute significantly to progressive membrane deterioration is injury by oxygen free radicals. ROM generated during reperfusion peroxidate lipids, which can propagate through other membrane lipids causing widespread membrane damage. In fact, signs of lipid peroxidation provide significant evidence for free radical generation during reperfusion. Certain phospholipase isoforms may limit, rather than enhance, membrane injury by hydrolyzing phospholipids oxidized by ROM (68). Removal of the damaged, oxidized lipids are thereby facilitated, limiting progressive membrane damage from these toxic metabolites.

Renal ischemia indeed causes activation of phospholipase (PLA_2) and a rapid fall in cortical phospholipid levels (69). The detrimental effects of PLA_2 can be offset by unsaturated free fatty acids (70) and suggest that PLA_2 may be cytotoxic by degradation of phospholipids in cell membranes or through accumulation of lysophospholipids (71). It appears, though, that the role PLA_2 plays in renal cell injury depends on both the particular isoform of PLA_2 as well as the insult applied to cause AKI (68). For example, cytosolic calcium dependent PLA_2 is implicated in mediating oxidant induced renal cell injury. On the other hand, inhibition of endoplasmic reticulum Ca-independent PLA_2 potentiates oxidant induced lipid peroxidation and necrosis in renal proximal tubule cells, suggesting that this particular isoform has a role in phospholipid repair (72). The effect, however, is specific to injury from oxidants since injury from mitochondrial inhibition (antimycin A) is not potentiated by inhibiting that PLA_2 isoform.

Just as phospholipase activity may vary according to the stimulus and domain, and either contributes to or limits the injury depending on the context, the role of lipid alterations similarly can differ in AKI (73). While free fatty acid and lysophospholipid accumulation may contribute to membrane damage, cholesterol accumulation appears to stabilize plasma membranes and limit renal cell injury in models of AKI. Acute tubule injury initially lowers, then increases, cholesterol content in renal tubule cells (74). When renal cells were treated with a variety of agents to reduce cholesterol content, including cholesterol synthesis inhibitor or stripping agent, cell susceptibility to injury from ATP depletion is substantially increased, suggesting that cholesterol is a cytoprotectant in the context of ischemic AKI (75).

So, while the understanding of lipid alterations in AKI has become more complex, the story is similar to that of changes in Ca_i. The role of these alterations may be pathologic or adaptive, depending on the type and severity of the insult, on the location of the intracellular perturbations, and on the particular isoforms active in the affected areas.

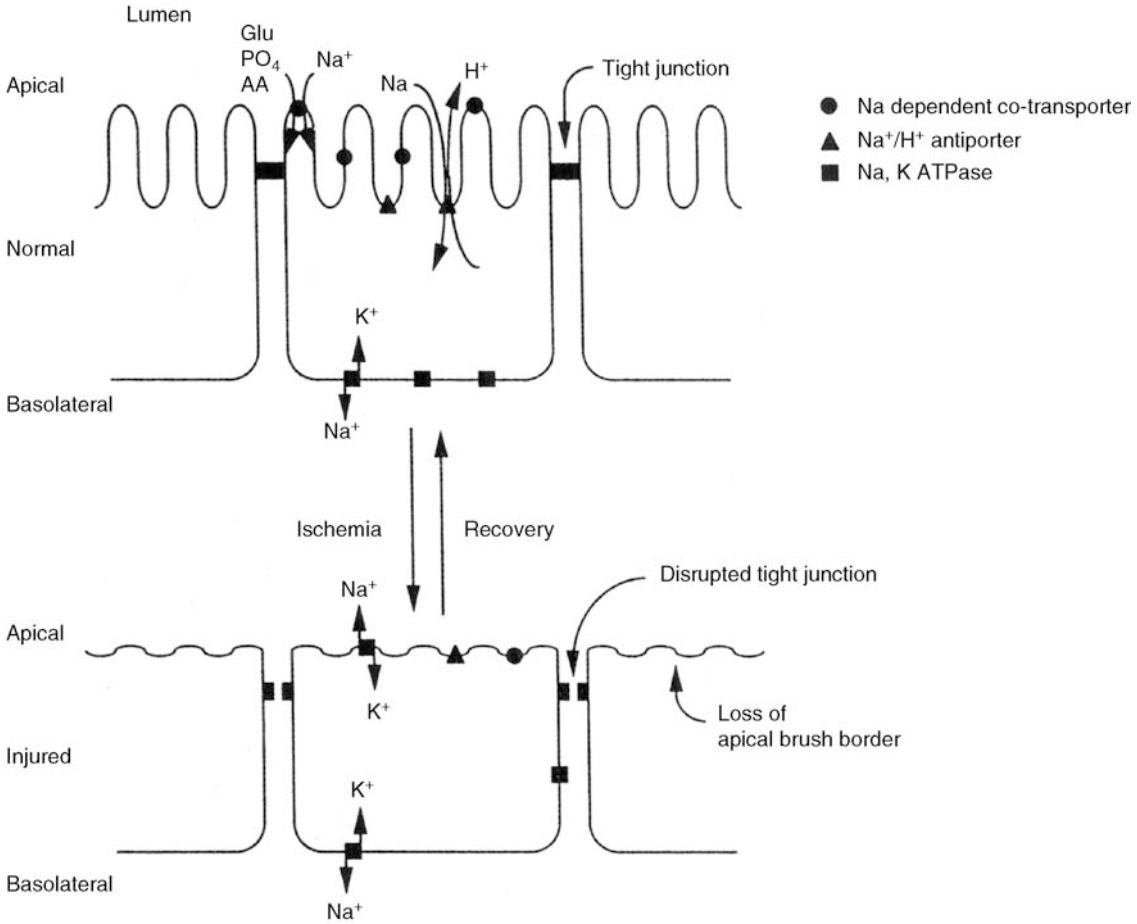
Disruption of Tubule Cell Architecture

Renal tubules are composed of highly specialized cells whose primary function of transport depends on their polar structure (*Fig. 64-4*). Changes in cell polarity that occur during acute renal failure have important effects on these functions (76). The plasma membrane of proximal tubule cells is divided into apical and basolateral domains by the tight junction that it shares with neighboring cells. The apical membrane, which faces the tubule lumen, differs from the basolateral membrane both in lipid composition and in the type of membrane proteins present. The microvilli of the apical domain are rich in sodium-dependent cotransporters and Na/H-antiporters, which effect reabsorption of glucose, amino acids, phosphate, and bicarbonate along with sodium. The sodium gradient across the apical membrane, which drives the resorption of these compounds, is established and maintained by Na/K-ATPase located on the basolateral membrane. Plasma membrane polarity is maintained by the tight junctions that prevent lateral diffusion of membrane phospholipids and proteins into the opposite domain. In addition, the cortical cytoskeleton anchors membrane proteins, such as Na/K-ATPase, in specific domains through an intricate sequence of linked proteins. The actin based cytoskeleton is a dynamic structure that maintains cellular polarity and mediates a number of processes necessary to sustain both structure and function of renal epithelia (77). Interactions between cytoskeletal proteins and plasma membrane proteins are responsible for functions that include cell adhesion, endocytosis, signal transduction and activity of ion channels.

The loss of cellular polarity is a fundamental alteration in renal epithelial injury and results in reduction of transepithelial sodium reabsorption. Renal ischemia alters this polarity in that membrane lipids and proteins, which are highly mobile, redistribute between apical and basolateral

Figure 64-4

Disruption of proximal tubule cell polarity **Ischemia causes loss of apical brush border, opening of tight junctions, and loss of cell polarity that impairs transepithelial solute reabsorption. Recovery of function parallels recovery of cell architecture.**



domains (*Fig. 64-4*). After as little as 5 minutes of renal ischemia there is blebbing, loss, and internalization of brush border membranes and, shortly thereafter, basolateral Na/K-ATPase migrates to apical membranes (76). With longer ischemia, the loss of polarity worsens. Proximal tubule tight junction integrity, an obstacle to diffusion of membrane components across domains, is lost. Membrane proteins such as Na/K-ATPase, which normally are anchored to the actin cortical cytoskeleton, can then migrate when this attachment is disrupted.

The actin cytoskeleton plays an important role in both processes. Disruption of actin microfilaments and polymerization follows ischemia and is dependent on the severity of the insult (77, 78). Actin disruption itself results in opening of tight junctions and loss of the polar distribution of those proteins that anchor Na/K-ATPase to the plasma membrane (52, 79–81). Ankyrin, which links fodrin to Na/K-ATPase, normally is limited to the basolateral domain. After ischemia, ankyrin migrates along with Na/K-ATPase to the apical domain while fodrin, which normally links actin to ankyrin and Na/K-ATPase, becomes dissociated and solubilized throughout the cytosol (81, 82).

Actin depolymerizing factor (ADF, also known as cofilin) participates in ischemia-induced actin cytoskeletal alterations and determines the rate and extent of these ATP depletion-induced cellular alterations (83). ADF/cofilin is a cytosolic protein that is normally maintained in the inactive phosphorylated form by Rho GTPases. ATP depletion inactivates Rho GTPase, which results in activation and relocalization of ADF/cofilin to the surface membrane (83, 84). Concomitantly, ATP depletion dissociates the actin stabilizing proteins tropomyosin and ezrin, allowing the activated ADF/cofilin to bind

and cleave actin, leading to microvillar breakdown (85). Finally, atypical protein kinase (aPKC) signaling, impaired during ATP depletion, participates in tight junction disassembly during cell injury. Furthermore, aPKC function is important for tight junction reassembly during recovery, a feature necessary for restoration of cell polarity and tubule integrity (86).

The reduction in transepithelial sodium reabsorption that follows renal ischemia, a hallmark of AKI and manifested clinically as increased fractional excretion of sodium is thus a function of this disruption of renal tubule cell architecture. Recovery of normal sodium reabsorption does not occur until these renal cell structural changes and membrane polarity, in sublethally injured cells, is reestablished during recovery from AKI.

Cell Death: Necrosis and Apoptosis

After an ischemic or toxic insult, cells can proceed down one of several pathways: recovery from sublethal injury or death by necrosis or apoptosis. Indeed, individual cells can simultaneously be moving through each of these pathways in AKI (*Fig. 64-5*). The hierarchy of injury that results depends on the cell type, location, and on the severity and duration of the insult (54, 87, 88). Cell death by necrosis tends to follow a severe insult that leads to metabolic collapse of the cell. Necrosis, then, is massive, rapid, and near synchronous leading to cell lysis with secondary injury to surrounding tissue. Typical features of necrosis include cytoplasmic swelling, loss of membrane integrity, and nuclear and cellular fragmentation. Cell death from apoptosis is a more organized, regulated process that leads to cytoplasmic and nuclear shrinkage, DNA condensation and fragmentation, and eventual cell breakdown into membrane-bound apoptotic bodies. These apoptotic bodies *in vivo* are cleared rapidly by other cells, which has made the assessment of how much apoptosis occurs following a renal injury difficult.

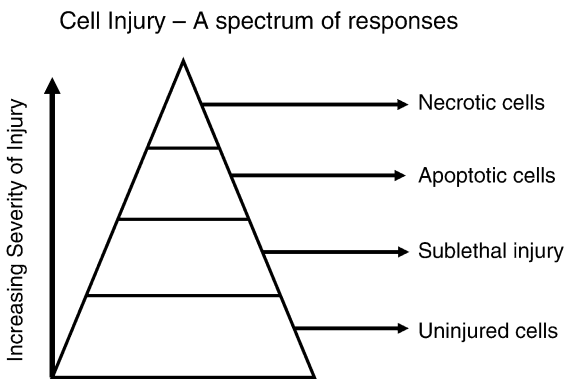
While clinical acute renal failure from ischemic or toxic injury has long been called acute tubular necrosis (ATN), this term has been questioned since biopsy of patients with ARF rarely show necrotic features. However, biopsies of patients typically are late in the course of ARF and may miss earlier signs of necrosis. Animal models of ischemic or toxic injury clearly show at least focal areas of necrosis early during reflow. Nevertheless, the current understanding that a renal insult can leads to simultaneous sublethal and lethal injury, both necrosis and apoptosis, in cells in different areas of the kidney has lead to the change in terminology from ARF or ATN to acute kidney injury (AKI) (3).

Measuring apoptotic cell death *in vivo* has been problematic, leading to controversy over whether this is an important pathway in AKI. This is an important issue since the same type of insult *in vivo* or *in vitro* can cause either necrosis or apoptosis (89). Definitive morphologic criteria have established apoptosis as a pathway to cell death in renal epithelia both *in vivo* and *in vitro* (90, 91), and apoptosis is now recognized as an important feature of human AKI (92, 93).

Biochemical assays can be helpful in quantifying apoptosis, but they are not uniformly reliable measures of apoptosis *in vivo* or *in vitro,* unless traditional cell morphology criteria are also applied in the particular setting being studied. For example, neither endonuclease activation nor DNA laddering, previously thought to be features unique to apoptosis, consistently discriminate between necrosis and apoptosis in injured renal epithelia (94, 95). Thus, the specificity of traditional *in vivo* assays for apoptosis such as the TUNEL assay, based on endonuclease activation, has been questioned. However, the specificity of TUNEL staining for apoptosis in several forms of *in vivo* renal cell injury has been determined using accepted morphological criteria (96). While not specific for apoptosis in some forms of renal injury (e.g., H_20_2), TUNEL is 99% specific for apoptosis in *in vivo* ischemic renal injury. Studies such as these have shown that apoptosis is an important mechanism of cell death in AKI, and have allowed for exploration of apoptotic pathways that might be active after a renal injury.

Figure 64-5

The spectrum of cellular outcomes in acute kidney injury **The particular outcome of an injured cell depends on the severity, duration and specificity of the insult, and on the type of cell and location. In acute kidney injury, the entire spectrum of responses can occur in different cells simultaneously (adapted from (265)).**



The process of apoptosis has been separated into three sequential phases: initiation, commitment, and execution phases. Membrane receptors and the Fas pathway can contribute to the initiation phase of apoptosis in ischemia, and interference with this pathway can ameliorate In vivo AKI (97–100). The series of intracellular derangements in cell architecture, metabolism, and function during ischemia are likely a major trigger to the initiation of apoptosis following ischemia.

Central to the commitment phase of apoptosis are several changes in mitochondria. Loss of mitochondrial transmembrane potential is pivotal to the apoptotic cascade; interventions that prevent the mitochondrial permeability transition event prevent apoptotic nuclear and cell membrane alterations (101–104). Bax translocation from its cytoplasmic pool to mitochondria contributes to opening of mitochondrial pores and the mitochondrial permeability transition with subsequent release of cytochrome C (105–107). That Bax mediated apoptosis occurs in ATP depletion injury has been demonstrated in cultured proximal tubule cells (107). There is growing evidence implicating an imbalance between the pro-apoptotic (Bax, Bid) and anti-apoptotic (Bcl-2, Bcl-xL) members of the Bcl-2 family of proteins, as well as the pro-apoptotic protein p53, that are active in the commitment phase of apoptosis in both animal (108–110) and human (92, 111, 112) conditions of ischemia induced AKI. Though cytochrome C release from mitochondria is not specific for apoptosis, it follows the mitochondrial permeability transition that is modulated by the Bcl-2 protein family, and indicates commitment to cell death. Its release is an essential factor in causing downstream activation of the effector proteins for apoptosis (88, 101, 107).

Caspase 3 is the effector protein that lies at a critical juncture in apoptosis pathways. Activation of Caspase 3 begins the execution phase of apoptosis (113–115). A series of additional caspases are activated in the execution phase that cleave multiple cellular proteins, including cytoskeletal-associated proteins and endonuclease inhibitors, resulting in the characteristic morphology of apoptosis – cell shrinkage, membrane blebbing, nuclear condensation and fragmentation (88).

Defining the relative importance of apoptosis in a particular form of AKI, and determining which portion of initiation and effector phase pathways are active after a specific renal insult, provide the hope that targeting specific sites in these apoptotic pathways for therapeutic intervention could limit renal injury in patients at risk to develop severe ARF.

Inflammatory Response

Although studies many years ago suggested that the immune system had no role at all in ischemia induced ARF, a growing body of evidence in the past several years indicates that the inflammatory response plays a major role in AKI. Inflammatory cascades initiated by endothelial dysfunction can be augmented by potent mediators generated by the ischemic proximal tubule. Both pro-inflammatory cytokines (TNF-α, IL-6, IL-1β, TGF- β) and chemotactic cytokines (MCP-1, IL-8, RANTES) are generated following renal ischemia and can enhance inflammation (24, 25, 116, 117). Toll-like receptor 2 (TLR-2), a pro-inflammatory molecule, is upregulated in renal tubules following ischemic kidney injury. Inhibition of TLR-2 by gene knock out or antisense treatment prevents ischemia induced renal dysfunction and suppress some of the cytokines in cultured proximal tubule cells (118, 119). Some of these cytokines, measured in the urine and plasma, have been found to be predictive of kidney injury or mortality in patients (120, 121).

Leukocyte infiltration into injured kidneys has been documented following ischemia; neutrophils being the first, followed closely by macrophages (25, 122). The significance of these events is not clear because (a) neutrophil depletion or blockade of function provides only partial functional protection and only in some animal models, (b) neutrophil infiltration appears not to be a prominent feature of ischemic renal injury in humans, and (c) although selective macrophage depletion ameliorates ischemic kidney injury, macrophages are dependent on coordinated action of T cells and neutrophils (123). The role of T cells has also been evaluated; they have been found in the kidney in both animal and human ischemic AKI models (25, 124, 125). Protection against injury from ischemia is observed in mice subjected to T-cell depletion as well as in mice with a double knockout of CD4/CD8 (126, 127). Reversal of protection in the latter model occurs with adoptive transfer of wild-type T cells into the knockout mice.

On the other hand, animals deficient in both T and B cells are not protected from ischemic injury (128) and depletion of peripheral CD4 T cells does not confer resistance against ischemic renal injury (129). Complicating the T cell picture further is identification of both protective (Th2 phenotype) as well as deleterious (Th1 phenotype) subtypes of T cells (130). Compared with wild type animals, B-cell deficient mice kidneys, with comparable T cell and neutrophil infiltration following ischemic renal injury, are partially protected both structurally and

functionally (131). Wild type serum transfer, but not B cell transfer, into these B-cell deficient mice restores susceptibility to ischemic AKI, implicating a soluble serum factor as a mechanism by which B cell deficiency confers renal protection (131).

Ischemia-reperfusion injury in most organs activates the classical pathway of the complement cascade. However, the alternative pathway, along with the mannose-binding lectin pathway of complement activation, appears to predominate in ischemic AKI in animals and humans (132–134). Recent studies have focused on C5a, a powerful chemoattractant for inflammatory cells, and its antagonists (135). C5a receptor is expressed in tubule epithelial cells and interstitial macrophages and is upregulated following ischemia-perfusion injury and sepsis (136–138). Inhibition of C5a generation using monoclonal antibodies prevents neutrophil and macrophage influx and protects against renal dysfunction after ischemia, and pretreatment with orally active C5a receptor antagonists in animals conferred histologic and functional protection against ischemic renal injury (137, 139, 140).

Strategies to modulate the inflammatory response by altering cytokine action have also been tried in AKI. IL-10 is a potent anti-inflammatory cytokine that provides protection against ischemic AKI by inhibiting maladaptive cytokine production by Th1 cells (141). Administration of a monoclonal antibody against the pro-inflammatory cytokine IL-6 reduces pro-inflammatory cytokine production, decreases neutrophil infiltration, and ameliorates structural and functional consequences of ischemic AKI (142). Furthermore, several agents with generalized anti-inflammatory effects are being studied as candidates to prevent or treat acute kidney injury. These include Bimosiamose (a pan-selectin inhibitor), statins and erythropoietin (with anti-inflammatory actions separate from their better known cholesterol lowering and erythropoetic effects respectively), and alpha-melanocyte stimulating hormone (143–148).

The clear involvement of the immune system in ischemic AKI suggests a mechanism underlying the consistent observation that development of acute renal failure substantially increases overall morbidity and mortality in patients suffering from a variety of diseases, including isolated cardiac disease, sepsis, and multi-organ dysfunction (149–153). In that context, it has been intriguing to see animal studies documenting distant organ effects and dysfunction in the heart, lungs, and brain after isolated ischemic AKI (154, 155). These distant effects of renal ischemia may be mediated by inflammatory signals generated in the injured kidney (156, 157).

Genetic Susceptibility, Gene Expression, and Biomarkers

In the clinical realm, it has long been observed that the incidence or severity of ARF varies widely between patients who have apparently been subjected to the same renal insult. While unrecognized environmental factors may certainly play a role, this observation has led clinicians to suspect that individual patients may have an inherent genetic susceptibility or resistance to developing ARF. A recent study of different rat strains has given credence to this concept that genetic background can substantially influence vulnerability to AKI. In that study, the inbred Brown-Norway rat strain, from two separate sources, was profoundly resistant to developing ARF following ischemia when compared with other inbred and outbred rat strains, all of which develop similar levels of renal failure (158). The rat strain specific protection appears to be on a cellular level since immediate cellular manifestations of ischemic AKI are limited, and the protection is sustained. The specific mechanism providing this protection is yet to be determined, but that it is related to differential gene expression is indicated by the finding of increased constitutive expression of inducible heat shock proteins, putative cytoprotectants, in the protected strain.

Specific human genetic polymorphisms have been linked, by several separate groups, alternately to either resistance or susceptibility to develop ARF (149). These human studies have implicated genetic polymorphisms of pro- and anti-inflammatory cytokines as well as heme oxygenase-1 (HO-1) as potential determinants of susceptibility to ischemic renal injury (149). Recent studies in pediatric patients have further supported a genetic basis underlying either resistance or susceptibility to develop ischemic ARF.

Genetic polymorphisms of the 70 kD stress protein Hsp72 appear to play a role in neonatal susceptibility to both ARF and its risk factors (159, 160). The Hsp72 (1267) GG allele has associated low inducibility of the Hsp72 protein. Very low birth weight neonates have increased prevalence of Hsp72 (1267) GG allele, and neonates in general carrying the Hsp72 (1267) GG genetic variation have increased risk of ARF (159, 160). Furthermore, an association was found between several maternal and fetal cytokine genetic polymorphisms, which increase the inflammatory response in preterm infants, and the incidence and severity of sepsis, necrotizing enterocolitis, and eventual ARF (159). Although genetic polymorphisms of the renin-angiotensin-aldosterone system have not been shown to influence directly the risk for ARF, they may

be associated with patent ductus arteriosus, poor postnatal adaptation, and heart failure, all prevalent risk factors for ARF (159, 161). A combination of high tumor necrosis factor-alpha producer and low interleukin-6 producer genotypes has been shown to increase the risk of acute renal failure in neonates as well as increase the mortality of adults in renal failure (162, 163).

Recent advances in functional genomics and cDNA microarray-based technologies have provided the opportunity to see the landscape of the numerous and intricate pathways activated by a complex process such as acute kidney injury (164–168). In combination with bioinformatic tools, these studies have identified novel genes with altered expression, new signal transduction pathways, and biomarkers of AKI. Kidney injury molecule-1 (KIM-1) protein, upregulated following ischemia on the apical membranes of proximal tubule cells, may be involved in renal tubule regeneration and is a promising non-invasive urinary biomarker of ischemic kidney injury (169) (170–173). The NGAL gene and protein is highly induced early in post ischemic kidney both in animals and humans; increased expression of this protein is found early in tubule cells undergoing proliferation, suggesting a protective role in AKI (164, 174–177). In addition, the finding that NGAL is rapidly excreted in the urine following a variety of renal insults suggests that NGAL is a novel, sensitive and early urinary biomarker of ischemic renal injury in patients (178–180). Furthermore, the demonstration in animal studies of protective effect against injury when exogenously administered makes it a potential therapeutic target (63, 181–184). Additional pathophysiologic pathways identified using these techniques include Zf9, a Kruppel-like transcription factor, which is strongly expressed during kidney development and markedly upregulated in post-ischemic tubule cells, along with its major trans-activating factor, TGF-β1(185). Thrombospondin 1 (TSP-1), a known p53-dependent pro-apoptotic and antiangiogenic molecule in malignant cells, is upregulated in postischemic proximal tubule cells, and TSP-1 null mice are partially protected from ischemia (169). Finally, microarray analyses have identified alterations in C4 complement, calcium binding protein S100A4, and matrix Gla protein, which may be involved in the long term outcome of ischemic acute renal injury (186).

Repair Mechanisms

Just as multiple pathways to cell injury are activated in AKI, the repair processes necessary to restore kidney structure and function would be expected to be multifaceted. The mechanisms to renal recovery, then, might include (1) endogenous repair of sublethally injured cells, (2) proliferation of surviving renal tubular cells, and (3) replacement of dead renal cells either by circulating stem cells or inherent stem cells within the kidney, with subsequent differentiation into tubule segment specific renal cells. The rapid initiation of repair in injured tubules supports the theory of endogenous repair of sublethally injured cells, with replacement of denuded segments of tubules with cells of either proximal or distal tubule origin (187–189). An understanding of factors that influence the recovery process would identify potential therapeutic interventions that could modulate injury or augment cellular repair to restore kidney function more quickly and fully following injury.

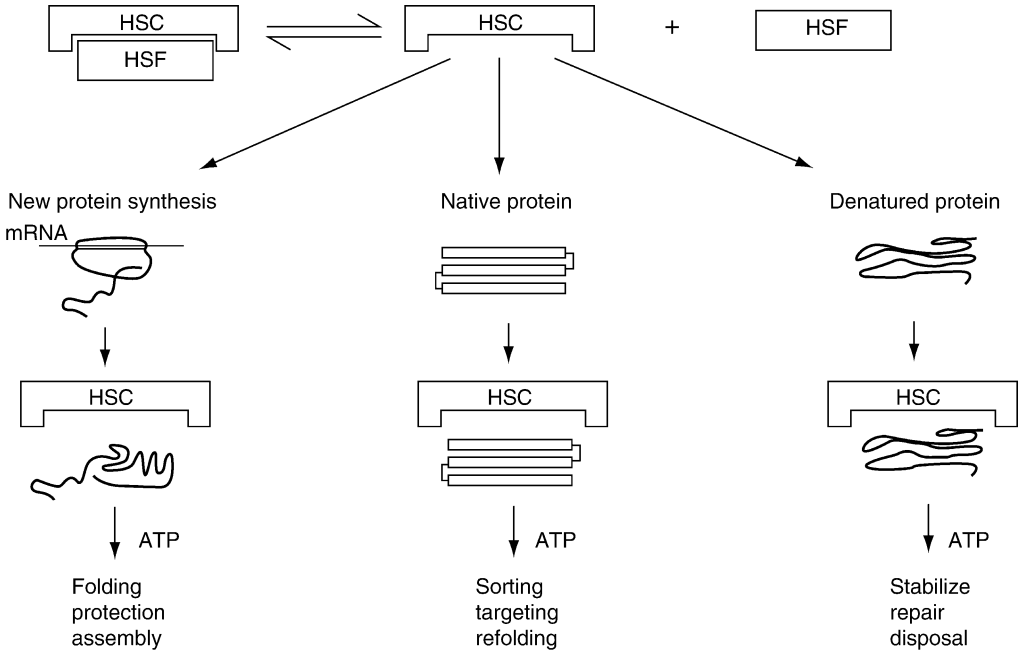
Heat Shock Proteins

Heat-shock proteins (Hsps), also called stress proteins, are highly conserved across species, being present in nearly every organism studied. They are elaborated in cells in response to injury caused by heat, anoxia, and a number of toxic agents. Hsps appear to be essential to basic cell function and survival by providing routine assistance in intracellular protein handling and trafficking (see *Fig. 64-6*) (190). These stress proteins are grouped into families according to size and apparent function. The two stress protein families most studied in AKI are the 70-kDa (Hsp70) and the small Hsp 25/27 class. Both of these Hsps act as chaperones to newly formed proteins, allowing proper folding and preventing inappropriate peptide interactions or aggregation. In like manner, these Hsps assist in the translocation of proteins across intracellular membranes and assist denatured proteins in refolding or reassembling into normal configuration as part of the process of repair (*Fig. 64-6*). Heat shock transcription factor (HSF) activation, the most proximal component of the stress response, is rapid after onset of renal ischemia, and significant Hsp induction in the kidney soon follows (53, 191, 192). The particular functions of these stress proteins in the kidney appear to have multiple aspects in AKI.

Renal tubule cells, which have suffered loss of structural integrity following injury, regain their normal architecture and polarity through remodeling (76). The recycling of cytoskeletal and plasma-membrane proteins is a primary mechanism of cellular repair following ischemia or ATP depletion (81, 193). The chaperone capacity of Hsps makes them likely candidates to be involved in the repair process. Indeed, among many potential functions

Figure 64-6

Heat shock protein functions **Shown are known actions of constitutively expressed Hsps, primarily of the 70 kD family (Hsp 70) called heat-shock cognates (HSC), in processing cellular proteins. Cell stress increases denatured protein, causing increased demand for HSC. Heat Shock Transcription Factor (HSF), reversibly bound to HSC, is released with the increased demand for HSC. HSF then rapidly initiates transcription for all inducible Hsps, including Hsp72 and Hsp25/27 (see text).**



during the recovery process, it has been found that Hsp72 and Hsp25/27 bind specifically to cellular proteins disrupted by ischemia or ATP depletion. Following renal ischemia, Hsp72 binds to aggregated cellular proteins, which include Na/K-ATPase, and is released from the aggregated proteins upon addition of ATP, a feature typical of its chaperone function (194). Furthermore, Hsp72 binds specifically to Na/K-ATPase during ATP depletion injury in renal cells (195). On the other hand, Hsp 25/27 is induced and moves from a soluble cytosolic distribution to an insoluble actin-associated state rapidly after renal ischemia, and binds specifically to disrupted actin during ATP depletion injury (196, 197).

These dynamic actions of different classes of Hsp, each with its specific function, may be essential to reestablish cellular polarity and integrity and may also provide insight into mechanisms of protection afforded by Hsps. In fact, separate overexpression of either Hsp72 or Hsp 25/27 limits the disruption of renal cell architecture that occurs with energy deprivation (195, 197). Furthermore, Hsp72 and 25/27 appear to work synergistically to preserve renal cell structure in the *in vivo* model of ischemic preconditioning (198).

Because of their well known characterization as cytoprotectants in a variety of cell types, Hsps have been examined by several groups as potential renal cytoprotectants (199). Studies of cultured renal epithelia have clearly demonstrated that stress proteins can mediate protection against specific manifestations of injury that result from specific insults (195, 197, 199–201). Whether heat shock proteins provide significant protection to the intact kidney has been controversial. Important initial studies clearly showed that stress proteins, when induced by a prior insult, do not uniformly and broadly protect the kidney against subsequent ischemic injury (199, 202, 203). However, recent studies of *in vivo* renal ischemia by several separate groups have supported a role for either Hsp72 or Hsp25/27 in providing resistance against ischemic renal injury (198, 204–206).

Furthermore, a more actively primed stress response may contribute to the phenomenon, long recognized by clinicians, that the immature kidney appears to be resistant to insults that would be expected to produce profound ARF in older patients. As observed in patients, immature rat kidneys are more resistant to ischemic injury than their mature counterparts. The neonatal

rat kidney has increased constitutive activity of HSF compared with mature animals, which translates into increased expression and induction of Hsp72 both prior and subsequent to an hypoxic or ischemic insult (207, 208). Not only does increased HSF activity and Hsp expression in the neonatal kidney correlate with resistance to hypoxia and ischemia, blocking HSF function reduces both Hsp72 expression and the tolerance of the immature renal tubules to anoxia (207–209). Heat shock proteins, then, may play a fundamental role in the tolerance of immature kidneys to ischemic or anoxic injury. So, while broad Hsp protection against all forms and severity of injury in the kidney clearly is not a fact, evidence continues to mount that these stress proteins contribute, along with other mediators of cytoprotection, to resistance against renal injury from ischemia.

Growth Factors

It has long been suspected that growth factors, either produced locally or exogenous to the kidney, are involved with the dedifferentiation, cellular proliferation, and redifferentiation of the tubule epithelial cell following AKI (*Fig. 64-1*). In the past two decades many studies have demonstrated the activity of a variety of growth factors on these aspects of cellular proliferation and differentiation following AKI. These include epidermal growth factor (EGF), insulin like growth factor-1 (IGF-1), hepatocyte growth factor (HGF), parathyroid hormone related peptide (PTHrP), basic fibroblast growth factor, osteopontin, neural cell adhesion molecule, and transforming growth factor – beta 1 (TGF-β) (188, 210–212).

Growth factor function may be intimately linked to processes involved in regulated, apoptotic cell death. In the rat model of AKI, expression of pro- and anti-apoptotic members of the Bcl-2 gene family (Bcl-2, Bcl-X(L), Bax) are temporally and spatially related to tubule expression of EGF, IGF-1, and TGF-β, all growth factors that are thought to be reparative in ARF (212). The study suggested that the distal tubule is adaptively resistant to ischemic injury through anti-apoptotic effects of Bcl-2 genes, and its survival allows expression of growth factors critical not only to the survival and regeneration of its own cell population (autocrine action), but also to the adjacent ischemia-sensitive proximal tubule cells (paracrine action).

Acute kidney injury in rats increases expression of transcription factors Ets-1 and Wnt-4 that are in pathways involved in cell cycle progression (213). Nephrogenic proteins basic fibroblast growth factor (bFGF), vimentin, neural cell adhesion molecules, paired homeobox-2, bone morphogene protein-7, Noggin, Lim-1, Engrailed, Smad, phospho-Smad, hypoxia-inducible factor-1 alpha (HIF-1 alpha), vascular endothelial growth factor (VEGF), and Tie-2 are all induced by renal ischemia in a pattern similar to that seen in normal renal development, and administration of bFGF accelerated induction of many of those nephrogenic proteins during recovery (214, 215). HIF-1 alpha is rapidly activated by renal ischemia and growth factor genes regulated by this transcription factor, VEGF and erythropoietin, appear to have important effects on renal epithelial cells, as well as endothelial cells in the renal microvasculature. Erythropoietin administration prior to renal ischemia protects the kidney against the injury through mechanisms that limit apoptosis (216).

The relative importance of the many growth factors identified to be active in AKI has rarely been addressed. One study, however, directly compared the effect of two of these growth factors in AKI using a transgenic mouse model with targeted over expression in the proximal tubule of HGF in one strain, and PTHrP in another strain. It was found that the strain with increased HGF in the proximal tubule had a fourfold increase in tubule cell proliferation and a threefold decrease in apoptotic tubule cell death along with rapid recovery from ischemic injury compared with either the mice with targeted proximal tubule over expression of PTHrP or background strain control mice (217). This study confirmed the importance of HGF during the recovery process, but raises questions about the role of the rapid induction of PTHrP observed in the proximal tubule after renal ischemia. By extension, it also raises questions about all of the growth factors identified as being induced by renal ischemia whose functional effects are yet to be defined. Some may be beneficial. Some, such as TGF-β, may have detrimental effects in the long term. A complex interaction between the growth factors and various chemokines that is dependent on the local context of the affected cells likely determines the outcome following AKI. A delicate balance of these factors may determine whether tissue remodeling following renal injury results in restitution of normal architecture or proceeds to a dead-end of irreversible fibrosis.

Stem Cells

With the advent of stem cell research, the possibility that some form of stem cell might be integral to kidney repair after AKI rapidly came to the fore. Along with the well-known embryonic stem cells, non-embryonic/adult stem cells that can differentiate into more than one type of

specialized cell come from several sources. Best characterized are hematopoetic stem cells that can differentiate into any of the blood cell lines. Mesenchymal stem cells reside in the bone marrow and can differentiate into a variety of mesenchymal tissues *in vitro* and *in vivo*. Tissue specific progenitor cells may reside in any organ and be able to differentiate into a range of cells as the need arises. Each of these potential sources of stem cells is actively being studied to determine the contribution to renal repair following acute kidney injury (218).

Both categories of bone marrow derived stem cells (BMDSC), hematopoetic stem cells (HSC) and mesenchymal stem cell/stromal cells (MSC), have been evaluated in AKI. Although, some have reported differentiation and incorporation of BMDSC into other cell types and tissues, including lungs, hepatocytes, pancreatic islet cells, endothelial cells and cardiac myocytes, not all studies have supported those findings (219–225). Biopsies of kidney transplants from a female donor to a male recipient, after acute injury to the transplant, have demonstrated the presence of Y chromosome positive tubule cells in the graft, indicating homing and differentiation of non-inflammatory bone marrow derived cells into renal tubule cells following injury (226). However, transplantation of male bone marrow into lethally irradiated female mice have demonstrated that bone marrow derived cells contribute minimally to the repair of the renal tubule and that most cells involved in repair are of endogenous tubule origin (227–230). Studies using bacterial β – galactosidase expressing BMDSC support the concept of these cells being incorporated into renal tubules after AKI, but the specificity of this technique has been questioned since injured endogenous tubule cells are able to incorporate and express this marker (231, 232). Hence, whether bone marrow derived cells participate significantly in tubule regeneration through incorporation and differentiation remains an open question.

Evidence that BMDSC have a functional role in the repair process is more consistent. The severity of renal injury in mice whose bone marrow has been ablated is worse than those without ablation and is reversible with infusion of lineage negative bone marrow cells (231). Studies designed to differentiate the function of MSCs from HSCs found MSC incorporation into regenerating tubules associated with protection from injury, but no such findings with HSCs (233, 234). Although other studies have not confirmed that MSCs engraft into renal tubules, they have found functional effects attributable to MSCs such as blunted rise in serum creatinine and alteration in pro-inflammatory cytokine and growth factor expression (230, 235). Similar findings in other reports suggest that protection by MSC may be mediated by paracrine or endocrine effects (235, 236). The number of MSCs infused appears to be a critical determinant of their protective function (229–231, 233). Recent studies suggest further that mobilizing endogenous BMDSCs is a therapeutic option in AKI using stem cell factor or colony-stimulating factors (macrophage-CSF or granulocyte-CSF) (237, 238). The mechanisms underlying the observed renal protection using these agents might be through ameliorating injury pathways detailed earlier in this chapter, along with affecting recovery pathways through BMDSC mobilization.

Since developmental biology has found that most renal epithelial cells proximal to the collecting duct originate from mesenchymal cells that transform into the specialized cells of the glomeruli and renal tubules, it is possible that these mesenchymal stem cells may persist in the adult renal interstitium, providing a reservoir of tubule cell progenitors (218, 239). Evidence for this concept comes from using the cell proliferation marker BrdU to identify slow cycling stem cells in rodent renal interstitium during late organogenesis that disappear following transient ischemia (240). Stem cells can be isolated from adult renal interstitium with help of surface markers and they express endothelial or epithelial cell markers when cultured under the influence of specific growth factors (241, 242). Called side population (SP) cells, the stem cells isolated from renal interstitium have been shown in mice to differentiate toward epithelial lineage, supporting the possibility of their involvement in the repair process. Furthermore, infusion of SP cells in rodents ameliorates renal injury induced by cisplatin (243, 244). These SP cells, following injury, have increased expression of several growth factors that appear to play a role in renal repair (as discussed earlier). So, while the relative contribution that stems cells make through direct repopulation of the nephron is unclear, evidence is growing that stems cells make an important contribution to the overall repair of the tubule after AKI via several pathways.

Long-Term Sequelae

The focus in the clinical realm, and in experimental models of ARF, typically is on the severity of the acute renal manifestations and the speed and completeness of early recovery. Little attention commonly is given to long-term sequelae in the kidney following an episode of ARF, particularly since many, if not most, patients who survive the triggering event appear to recover renal function completely in the short term. However, this aspect of

AKI is garnering progressively increased recognition. Decades ago it was found that many adult patients who suffer ARF never recover renal function completely, manifested by decrements in GFR and urinary concentrating ability months to years later (245–249). More recent reports in young pediatric patients have documented late renal insufficiency after recovery from an episode of ARF (250–253). The finding of significant and progressive renal insufficiency in adolescence and early adulthood after recovery from ARF as a neonate is of particular interest. Though the neonatal kidney may be more resistant to AKI, it may be more prone to develop late sequelae once AKI has been established.

The rat model of AKI has revealed how a late decline in renal function may follow apparent complete initial recovery as measured by GFR. One mechanism may be that many nephrons may not be able to regenerate completely after the injury, leading to disconnection of intact glomeruli from residual tubule segments with eventual later decline in overall renal function (254, 255). Another is that inflammatory mediators of renal injury, initiated by AKI, may persist and cause progressive renal dysfunction (256).

Finally, the early alterations in the renal microvasculature that accompany ischemia induced AKI appear to have substantial long term consequences (257). It has been found that peritubule microvessel density is reduced by half, weeks after uncomplicated recovery from ischemic AKI (258). The renal microvascular system, then, seems to lack the profound regenerative ability of the renal tubule system. The peritubular capillary dropout has the accompanying functional effect of reduced renal oxygenation, particularly in the outer medulla, the region of the kidney most susceptible to an ischemic insult (259). That chronic renal hypoxia may contribute to progressive renal dysfunction in patients is suggested by finding impaired renal oxygenation in kidney transplants affected by chronic allograft dysfunction (260).

The principal cause of the renal microvascular dropout after AKI, whether it be endothelial cell necrosis or apoptosis, lack of regenerative potential, endothelial-mesenchymal transition, or progressive interstitial fibrosis is yet to be defined. TGF-β, though, may be a central player in the initial injury as well as in potentiating the later progressive renal injury. Blockade of TGF-β, which is highly expressed after AKI, preserves microvascular density (261). TGF-β may be pivotal in a vicious cycle triggered by AKI, since it can stimulate apoptosis in endothelial cells (262), stimulate endothelial-mesenchymal transition (263), and is itself a fibrinogenic factor that is triggered by hypoxia (264). Blocking TGF-β, then, could intervene on several processes that may contribute to chronic, progressive renal injury after AKI.

Conclusion

The study of acute kidney injury that leads to clinical acute renal failure continues to advance rapidly. The progressive discovery of the many facets in the pathogenesis of the injury, markers of the injury, and potential recovery mechanisms provides hope that therapy targeted to the kidney injury specifically, along with ongoing advances in supportive therapy, will substantially improve survival and wellness of patients affected by acute kidney injury. Suggested by the many interactive pathways active in AKI outlined here, no single intervention alone is likely to alter outcome substantially. An integrated approach may be required to limit injury or facilitate renal recovery. Having a clear understanding of the pathogenesis of acute kidney injury from a particular renal insult should help direct when to intervene with a specific therapy, and which intervention would be most likely to benefit the patient.

Acknowledgment

The authors, separately and together, are profoundly indebted to Norman Siegel (1943–2006), a good friend who formed our careers, understanding of medicine and nephrology, and thoughts on this particular topic.

65 Clinical Evaluation of Acute Kidney Injury in Children

Sharon P. Andreoli

Introduction

The incidence of acute kidney injury (AKI) (previously called acute renal failure) has increased over the past several years and AKI leads to substantial morbidity and a high mortality rate (1–4). The epidemiology of AKI has changed to multifactorial causes particularly in hospitalized patient and many forms of AKI such as ischemic/hypoxic AKI which were thought to be reversible are now known to be significant contributors to chronic kidney disease (CKD) (1–4). There are many causes of AKI and the more common etiologies are listed in *Table 65-1*. Some diseases, such as the tumor lysis syndrome, drug-induced interstitial nephritis, aminoglycoside nephrotoxicity, and other toxic nephropathies, usually present as AKI and recovery is usually complete while other diseases, such as rapidly progressive glomerulonephritis (RPGN), may present as AKI but rapidly evolve into chronic kidney disease (CKD). Several renal diseases, such as the hemolytic-uremic syndrome (HUS), Henoch-Schönlein purpura, and obstructive uropathy with associated renal dysplasia, may present as AKI with improvement of renal function to normal or near-normal levels, but the child's renal function may slowly deteriorate, leading to CKD several months to years later.

Children with AKI due to hypoxic/ischemic insults, HUS, acute nephritis as well as other causes are more likely to demonstrate oliguria or anuria (urine output less than 500 ml/24 h in older children or urine output less than 0.5–1.0 ml/kg/h in younger children and infants). Children with acute interstitial nephritis, nephrotoxic renal insults including aminoglycoside nephrotoxicity, and contrast nephropathy are more likely to have AKI with normal urine output. The morbidity and mortality of nonoliguric AKI are substantially less than oliguric renal injury (5, 6). This chapter will review the common causes of AKI, evaluation of AKI and potential future therapies. The previous chapter discussed the pathophysiology of AKI while the next chapter focuses on medical management and renal replacement therapy for AKI.

Definition

Currently, there is not a uniform definition of AKI in adult or pediatric patients and AKI is defined in multiple ways but the majority of definitions of AKI currently in use involve a change in the serum creatinine level. Increases in the serum creatinine and blood urea nitrogen are typical in AKI but each may be affected by factors other than a decline in the glomerular filtration rate. Since the serum creatinine is a reflection of muscle mass, children with decreased muscle mass may have substantial decreases in their glomerular filtration rate with minimal to modest changes in the serum creatinine concentration. The blood urea nitrogen (BUN) is affected by multiple factors including the state of hydration of the child, gastrointestinal bleeding, protein intake, a hypermetabolic state and the administration of catabolic medications such as corticosteroids each of which tend to increase the BUN irregardless of renal function. In contrast, the BUN may be lower than expected in AKI in a child with severe liver disease or in a child with protein malnutrition.

It is accepted that the serum creatinine is an insensitive and delayed measure of decreased kidney function following AKI (7–14). Multiple studies have focused on the development of sensitive and specific biomarkers of AKI; biomarkers under investigation include changes in plasma Neutrophil Gelatinase-Associated Lipocalin (NGAL) and cystatin C levels and urinary changes in NGAL, Interleukin-18 (IL-18) and Kidney Injury Molecule-1 (KIM-1) (7). NGAL was found to be one of the most rapidly induced proteins in the kidney following experimental AKI and NGAL appeared in the urine of animals before other biomarkers (8, 9). In a prospective study of children undergoing cardiac surgery, plasma and urine NGAL measurements increased hours after surgery in those who developed AKI compared to 2–4 days for an increase in serum creatinine to occur (9). NGAL was also shown to be an early predictor of contrast induced nephropathy in children (10). Other biomarkers that have shown promise to detect AKI at an early stage include

Table 65-1
Common causes of acute kidney injury

Pre-renal failure
Decreased true intravascular volume
Decreased effective intravascular volume
Intrinsic renal disease
Acute tubular necrosis (vasomotor nephropathy)
Hypoxic/ischemic insults
Drug induced
Toxin mediated
Endogenous toxins - hemoglobin, myoglobin
Exogenous toxins - ethylene glycol, methanol
Uric acid nephropathy and tumor lysis syndrome
Interstitial nephritis
Drug induced
Idiopathic
Glomerulonephritis
Vascular lesions
Renal artery thrombosis
Renal vein thrombosis
Cortical necrosis
Hemolytic Uremic Syndrome
Hypoplasia/dysplasia with or without obstructive uropathy
Idiopathic
Exposure to nephrotoxic drugs in utero
Hereditary renal disease
Autosomal dominate polycystic kidney disease
Autosomal recessive polycystic kidney disease
Alport's syndrome
Sickle cell nephropathy
Juvenile nephronophthisis
Obstructive uropathy/lower tract lesions
Obstruction in a solitary kidney
Bilateral ureteral obstruction
Urethral obstruction
Blaldder rupture

KIM-1 and urinary cystatin C in adult and pediatric patients undergoing cardiac surgery (11, 12). Recently, liver fatty acid-binding protein (L-FABP) has also been shown to be a sensitive and early predictor of AKI in pediatric patients undergoing cardiac surgery (13). As described later the development, testing and successful implementation of therapeutic strategies in AKI is going to require the development of sensitive biomarkers so that therapy can be initiated in a timely manner. Reliable biomarker(s) for early detection of AKI should facilitate early identification, help stratify risk and contribute to informative diagnostic classification so interventions to improve outcome of AKI can be developed (14).

As described above, the definition of AKI in adults and pediatric patients has been quite variable. A new classification system entitled the RIFLE criteria (R = Risk for renal dysfunction, I = Injury to the kidney, F = failure of kidney function, L = loss of kidney function, and E = end stage renal disease) has been proposed as a standardized classification of acute kidney injury in adults (15) and has been adapted for pediatric patients (16). The pediatric RIFLE was found to better classify pediatric AKI and to reflect the course of AKI in children admitted to the ICU (16). The pediatric RIFLE criteria have been validated in children and appears quite promising for better characterization of AKI (16). The RIFLE criteria have been used by the Acute Kidney Injury Network (AKIN) which is a group of adult nephrologists, pediatric nephrologists, critical care physicians and societal organizations interested in AKI research; the focus of AKIN is to facilitate international, interdisciplinary and intersociety collaborations to ensure progress in the field of AKI (17). In addition, the definition of AKI has a substantial impact on studies to determine the incidence and epidemiology of AKI in adult and pediatric patients (18).

Some definitions of AKI include a decline in urine output. While a decline in urine output is a common clinical manifestation of acute kidney injury, many forms of acute kidney injury are associated with normal urine output. Children with acute kidney injury due to hypoxic/ischemic insults, hemolytic uremic syndrome, acute glomerulonephritis, rapidly progressive glomerulonephritis as well as other causes are more likely to demonstrate oligo/anuria (urine output less than 400–500 cc/24 h in older children or urine output less than 0.5–1.0 cc/kg/h in younger children and infants). Children with acute interstitial nephritis, nephrotoxic renal insults including aminoglycoside nephrotoxicity and contrast nephropathy are more likely to have acute kidney injury with normal urine output. Studies have shown that the morbidity and mortality of nonoliguric acute kidney injury is substantially less than oliguric renal injury (19, 20).

Epidemiology of Acute Kidney Injury

The epidemiology of AKI is quite different in developed and developing countries. AKI has become increasingly prevalent in both developed and in developing countries with

significant morbidity and mortality (21). In developed countries, AKI was more common in intensive care units in older individuals with multi-organ failure, sepsis and multiple co-morbid conditions. In urban areas of developing counties, AKI occurred under similar epidemiology conditions as in developed counties. In contrast, AKI in rural areas of developing countries is usually a result of a single disease or infection such as gastroenteritis, malaria, leptospirosis or hemolytic uremic syndrome in younger other wise healthy individuals (21). Due to the limited resources to treat AKI in rural area and the high mortality of AKI, strategies for the prevention of AKI in rural areas is paramount to decrease morbidity and mortality.

While the precise incidence and causes of AKI in pediatric patients is unknown, recent studies suggest that the incidence of AKI in hospitalized children is increasing (22–27). An important cause of AKI in hospitalized children is in the setting of post cardiac surgery and in children undergoing stem cell transplantation. AKI in such children is frequently multifactorial with ischemic/hypoxic injury and nephrotoxic insults being important contributors. No epidemiology studies using an established definition of AKI have been conducted in pediatric patients. In a large study of adult patients, the incidence of AKI was 209 per million population and the most common cause of AKI was prerenal in 21% of patients and acute tubular necrosis in 45% of patients (28). Similar epidemiologic studies have not been performed in pediatric patients but hypoxic/ischemic and nephrotoxic induced AKI has been shown to be an important cause of AKI in neonates, children and adolescents (5, 21–27). In a study of pediatric patients in a tertiary care center, 227 children received dialysis therapy during an eight-year interval for an overall incidence of 0.8 per 100,000 total population (6). In a study of neonates, the incidence of AKI ranged from 8 to 24% of newborns and AKI was particularly common in neonates who had undergone cardiac surgery (29). Other studies have demonstrated that very low birth weight (less than 1,500 g), a low Apgar Score, a patent ductus arteriosis and maternal administration of antibiotics and nonsteroidal anti-inflammatory drugs was associated with the development of AKI (23). A low Apgar score and maternal ingestion of non-steroidal anti-inflammatory drugs has been associated with decreased renal function in preterm infants (23, 30). The incidence of AKI in newborns in a developing county was 3.9/1,000 live births and 34.5/1,000 newborns admitted to the neonatal unit (24).

Several studies have demonstrated that newborns and children may have genetic risks factors for AKI independent of environmental risk factors (31–35). Several candidate polymorphisms have not been associated with AKI while other polymorphisms have been found to be associated with AKI. Polymorphism of the ACE gene or the angiotensin receptor gene with resultant alterations in activity of the renin angiotensin system does not appear to play a role in the development of AKI (31). In studies in newborns, polymorphisms of tumor necrosis factor alpha, interleukin 1b, interleukin 6 and interleukin 10 genes were investigated in newborns to determine if polymorphisms of these genes would lead to a more intense inflammatory response and predispose newborns to AKI (32). The allelic frequency of the individual genes did not differ between newborns with AKI and those without AKI but the TNFa/IL-6 AG/GC haplotype was present in 26% of newborns who developed AKI compared to 6% of newborns who did not develop AKI. The investigators suggested that the combination of these polymorphisms might lead to a greater inflammatory response and the development of AKI in neonates with infection (32). As described later, future therapies for AKI might involve strategies to interrupt the inflammatory response. In other studies, the incidence of ACE I/D allele genotypes or the variants of the angiotensin I receptor gene did not differ in neonates with AKI compared to neonates without AKI but they may be associated with patent ductus arteriosis and heart failure and indirectly contribute to CKD (31–34). AKI occurred more commonly in very low birth weight neonates carrying the heat shock protein 72 (1267) GG genetic variation which is associated with low inducibility of heat shock protein 72 (33). Given the important role of heat shock proteins in ischemic renal injury, these findings suggest that some neonates are more susceptible to ischemic injury (34). Another very interesting study of demonstrated that NADPH oxidase p22phos and catalase gene variants are associated with biomarkers of oxidative stress and adverse outcomes in acute renal failure (35). Since oxidant stress plays a role in the pathophysiology of AKI, it is interesting that genetic variants of pro-oxidant and anti-oxidant molecules are associated with susceptibility to AKI (35, 36). Future studies of the genetic background of the child at risk for AKI due to medication exposure, toxin exposure, ischemic hypoxic insults or other insults will likely impact the management of the child at risk for AKI and the management of AKI.

Etiology of Acute Kidney Injury in Children

AKI can be divided into prerenal injury, intrinsic renal disease including vascular insults, and obstructive uropathies

(see *Table 65-1*). Some causes of AKI, such as cortical necrosis and renal vein thrombosis, occur more commonly in neonates, whereas HUS is more common in young children, and RPGN generally occurs in older children and adolescents (*Table 65-2*). Hypoxic ischemic injury is an important cause of AKI at all ages (*Table 65-2*). An important cause of AKI in neonates is exposure to maternal drugs in utero that interfere with nephrogenesis such as angtiotensin converting enzyme inhibitors, angiotensin receptor blockers and non steroidal anti-inflammatory drugs (37–41). The history, physical examination, and laboratory studies including a urinalysis and radiographic studies can establish the likely cause(s) of AKI. In many instances, such as AKI occurring in hospitalized children, multiple factors are likely to be implicated in the etiology of AKI.

Prerenal Injury

In prerenal failure, renal function is decreased due to decreased renal perfusion and the kidney is intrinsically normal. Restoration of renal perfusion results in a prompt return of renal function to normal while acute tubular necrosis as described below implies that the kidney has suffered intrinsic damage. However, the evolution of prerenal injury to intrinsic renal injury is not sudden and a number of compensatory mechanisms work together to maintain renal perfusion in the face of adverse renal hemodynamic conditions (42). When renal perfusion is compromised, the afferent arteriole relaxes its vascular tone to decrease renal vascular resistance and maintain renal blood flow. Decreased renal perfusion results in increased catecholamine secretion, activation of the renin angiotensin system and the generation of prostaglandins. During renal hypoperfusion, the intrarenal generation of vasodilatory prostaglandins including prostacyclin mediates vasodilatation of the renal microvasculature to maintain renal perfusion (42). Administration of aspirin or non-steroidal anti-inflammatory drugs can inhibit this compensatory mechanism and precipitate acute renal insufficiency during renal hypoperfusion. Similarly, when renal perfusion pressure is low as in renal artery stenosis, the intraglomerular pressure necessary to drive filtration is in part mediated by increased intrarenal generation of angiotensin II to increase efferent arteriolar resistance (42). Administration of angiotensin converting enzyme inhibitors in these conditions can eliminate the pressure

Table 65-2

Common causes of acute kidney injury according to age group

Age	Glomerular diseases	Vascular diseases	Developmental/tubulointerstitial
<2 years		Cortical Necrosis	In utero exposure to ACEI, ARBs, NSAID
		Renal Artery Thrombosis	Obstructive Uropathy
		Renal Vein Thrombosis	Dysplastic Kidneys
		Hypoxic/ischemic AKI	Hypoxic/ischmeic AKI
			Nephrotoxic AKI
2–6 years	Post-infectious glomerulonephritis	Hemolytic Uremic Syndrome	Obstructive Uropathy
	Henoch Scholein Purpura	Hypoxic/ischemic AKI	Hypoxic/ischemic AKI
			Nephrotoic AKI
			Tumor lysis syndrome
6–12 years	Post-infectious glomerulonephritis	Hemolytic Uremic Syndrome	Obstructive Uropathy
	Henoch Scholein Purpura	Hypoxic/ischemic AKI	Hypoxic/ischemic AKI
	RPGN		Nephrotoxic AKI
			Tumor lysis syndrome
			Interstial Nephritis
12–18 years	RPGN		Obstructive Uropathy
	Systemic Lupus Erythematosis		Hypoxic/ischemic AKI
	Henoch Schonlein Purpura		Nephrotoxic AKI
			Interstitial Nephritis

gradient needed to drive filtration and precipitate acute kidney injury (43, 44). It was originally thought that selective COX-2 inhibitors would be renal sparing but it has been recognized that the selective COX-2 inhibitors can adversely affect renal hemodymanics similar to the effects of non selective COX inhibitors (45). In addition, clinical use of selective COX-2 inhibitors has been associated with acute kidney injury (45). Thus, administration of medications that can interfere with compensatory mechanisms to maintain renal perfusion can precipitate acute kidney injury in certain clinical circumstances.

Prerenal injury results from renal hypoperfusion due to true volume contraction or from a decreased "effective" blood volume. True volume contractions results from hemorrhage, dehydration due to gastrointestinal losses, salt wasting renal or adrenal diseases, central or nephrogenic diabetes insipidus, increased insensible losses as occurs in burns, and in disease states associated with third spaces losses such as sepsis, nephrotic syndrome, traumatized tissue and capillary leak syndrome. Decreased effective blood volume occurs when the true blood volume is normal or increased but renal perfusion is decreased due to diseases such as congestive heart failure, cardiac tamponade, and hepatorenal syndrome. Whether prerenal injury is caused by true volume depletion or decreased effective blood volume, correction of the underlying disturbance will return renal function to normal.

The urinalysis can help differentiate ATN from prerenal injury; the presence of casts and renal tubular epithelial cells was found to highly correlate with ATN while the absence of such findings was associated with prerenal disease (46). The urine osmolality, urine sodium concentration, the fractional excretion of sodium, and the kidney failure index have all been proposed to be used to help differentiate prerenal injury from vasomotor nephropathy (ATN). This differentiation is based on the concept that the tubules are working appropriately in pre-renal injury and are therefore able to conserve salt and water appropriately while in vasomotor nephropathy tubules have progressed to irreversible injury and are unable to appropriately conserve sodium (47, 48). During prerenal failure, the tubules are able to respond to decreased renal perfusion by appropriately conserving sodium and water such that the urine osmolality is greater than 400–500 mOsm/L, the urine sodium is less than 10–20 meq/L, and the fractional excretion of sodium is less than 1%. The fractional excretion of sodium is calculated by the formula urine sodium/plasma sodium divided by urine creatinine/plasma creatinine. Since the renal tubules in newborns and premature infants are relatively immature compared to older infants and children, the corresponding values suggestive of renal hypoperfusion are urine osmolality greater than 350 mOsm/L, urine sodium less than 20–30 meq/L, and a fractional excretion of sodium of less than 2.5% (47, 48). When the renal tubules have sustained injury as occurs in acute tubular necrosis, they cannot appropriately conserve sodium and water such that the urine osmolality is less than 350 mOsm/L, the urine sodium is greater than 30–40 meq/L and the fractional excretion of sodium is greater than 2.0%. However, the use of these numbers to differentiate prerenal injury from acute tubular necrosis requires that the patient has normal tubular function initially. While this may be the case in some children, newborns with immature tubules, children with pre-existing renal disease or salt wasting renal adrenal disease as well as other diseases may have renal injury with urinary indices suggestive of ATN. Therefore, it is essential to consider the state of the function of the tubules prior to the potential onset that might precipitate vasomotor nephropathy/ATN.

In adult patients it has been shown that calculation of the fractional excretion of urea nitrogen is a more sensitive test to differentiate prerenal injury from acute tubular necrosis than the fractional excretion of sodium particularly in patients who have received diuretic therapy (49). The fractional excretion of urea nitrogen was found to be at least as sensitive and specific as the fractional excretion of sodium in prerenal azotemia but the fractional excretion of urea nitrogen did not lose its sensitivity or specificity in differentiation prerenal injury and ATN when patients had received diuretic therapy. Weather the fractional excretion of urea will be more sensitive or specific compared to the fractional excretion of sodium in pediatric patients is unknown and such studies need to be performed to determine if this is a more sensitive measure of tubular function in children.

Intrinsic Renal Disease

Acute Tubular Necrosis

Acute tubular necrosis (ATN) can evolve from prerenal injury if the insult is severe and sufficient enough to result in vasoconstriction and acute tubular necrosis. The pathophysiology of ischemic/hypoxic ATN is thought to be related to early vasoconstriction followed by patchy tubular necrosis. ATN may also result from injury of tubular epithelial cells from drugs including aminoglycoside antibiotics, cisplatin, ifosfamide, amphotericin B,

acetaminophen and radiocontrast dye and exogenous toxins such as ethylene glycol, methanol, bromate, or endogenous toxins such as myoglobinuria and hemoglobinuria (*Table 65-1*).

Hypoxic/ischemic ATN

Hypoxic/ischemic acute tubular necrosis evolves from prolonged prerenal injury or following severe hypoxic insults. The urinalysis is likely to demonstrate casts and renal tubular epithelial cells and casts with or without low grade proteinuria casts while urine indices of tubular function demonstrate an inability to conserve sodium and water (46). The serum creatinine typically increases by about 0.5–2.0 mg/dl per day depending on the severity of the insult. Radiographic studies demonstrate kidneys of normal size with loss of corticomedullary differentiation while a radionucleotide renal scan with technetium−99-MAG3 or technetium−99-DTPA will demonstrate normal or slightly decreased renal blood flow with poor function and delayed accumulation of the radioisotope in the renal parenchyma without excretion of the isotope in the collecting system (*Fig. 65-1a*).

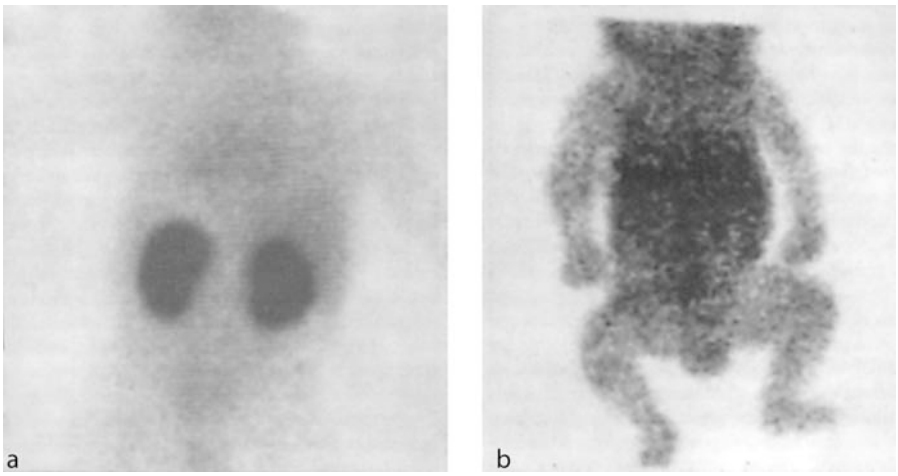
In the past it was thought that the prognosis of ATN was good except in cases when the insult is of sufficient severity to lead to vasculature injury and microthrombi formation with the subsequent development of cortical necrosis. However, it is now recognized that AKI from any cause including hypoxic ischemic can lead to chronic kidney disease (1–4, 50). The recovery of the child and the recovery of renal function depend upon the underlying events which precipitated the ischemic/hypoxic insults. The mortality and morbidity of children with acute kidney injury is much worse in children and neonates with multiorgan failure. Typically, the child does not succumb of renal injury but rather the child succumbs with renal injury and the associated conditions that precipitated the multi-organ injury (51–54). In children who recover from ATN, renal function generally returns but the length of time before recovery is quite variable. Some children will begin to recover renal function within days of the onset of renal injury while recovery may not occur for several weeks in other children. Return of renal function may be accompanied by a diuretic phase with excessive urine output at a time when the tubules have begun to recover from the insult but have not recovered sufficiently to appropriately reabsorb solute and water. When the diuretic phase occurs during recovery, close attention to fluid and electrolyte balance is very important to ensure adequate fluid management to promote recovery from acute tubular necrosis and prevent additional renal injury.

Nephrotoxic Acute Renal Failure

Many different drugs and agents may result in nephrotoxic acute kidney injury (55). Nephrotoxic acute renal

Figure 65-1

Mag-3 renal scan in a one year old with ATN (1a) and in a newborn with cortical necrosis (1b). Each scan is at 4 h after injection of isotope. Figure 1a shows delayed uptake of isotope with parenchymal accumulation of isotope with little to no excretion of isotope into the collecting system. In contrast, 1b demonstrates no renal parenchymal uptake of isotope in a neonate with cortical necrosis.



injury may result from the administration of a number of different medications as well as the ingestion of poisons or due to a nephrotoxic insult from indigenous compounds such as hemoglobinuria or myoglobinuria.

Drug Induced Acute Kidney Failure

Medications which are associated with acute kidney injury at least in part due to toxic tubular injury include aminoglycoside antibiotics, intravascular contrast media, amphotericin B, chemotherapeutic agents such as ifosfamide and cisplatin, acyclovir, and acetaminophen while other medications have been implicated less commonly (55). Aminoglycoside nephrotoxicity usually presents with nonoliguric acute kidney injury with a urinalysis showing minimal urinary abnormalities. The incidence of aminoglycoside antibiotic nephrotoxicity is related to the dose and duration of the antibiotic therapy as well as the level of renal function prior to the initiation of aminoglycoside therapy. The etiology of aminoglycoside nephrotoxicity is thought to be related to the lysosomal dysfunction of proximal tubules and is reversible once the aminoglycoside antibiotics have been discontinued. However, after the aminoglycoside is discontinued, the serum creatinine may continue to increase for several days due to ongoing tubular injury from continued high parenchymal levels of the aminoglycoside. Studies have demonstrated that once daily dosing of aminoglycoside antibiotics is associated with a slightly decreased incidence of nephrotoxicity without compromising efficacy (56).

Intravascular contrast media may also precipitate acute kidney injury particularly in patients who are at higher risk for contrast nephropathy including patients with dehydration, diabetes, or pre-existing renal disease and patients with hypergammaglobulinemia. The incidence of contrast nephropathy can be reduced with the use of nonionic, low osmolality contrast media. The prophylactic administration of N-acetylcysteine may decrease the decline in glomerular filtration rate associated with the administration of intravascular contrast in adults at risk for contrast nephropathy (57, 58). Similar studies have not been performed in pediatric patients and the potential risks and benefits of N-acetylcysteine in pediatric patients at risk for contrast nephropathy are unknown.

Non-steroidal anti-inflammatory drugs may also precipitate acute kidney injury by their effect on intrarenal hemodynamics. Cisplatin, ifosfamide, acyclovir, amphotericin B, and acetaminophen are also nephrotoxic and may precipitate acute kidney injury (55). The combination of a cephalosporin and acyclovir may be particularly nephrotoxic (59). Several other drugs have also been associated with acute kidney failure, but the incidence of acute kidney injury with other drugs is less common.

Exogenous Toxin Induced Acute Kidney Failure

The ingestion of toxic compounds either in their native state or once they are metabolized may precipitate acute kidney failure. Ethylene glycol and methanol are not toxic until they are metabolized by alcohol dehydrogenase to organic acids and oxalate for ethylene glycol while methanol is metabolized to formic acid and formaldehyde. Once sufficient quantities of the metabolites have been generated, the patient will present with severe metabolic acidosis with a large anion gap. Ethylene glycol intoxication may also be characterized by calcium oxalate crystalluria and hematuria on a urinalysis; other laboratory findings may include hypocalcemia. Both ethylene glycol and methanol intoxications can result from the accidental ingestion of antifreeze or transmission fluid or as a suicide attempt in older children. In the past ethylene glycol and methanol intoxication was best treated with an ethanol drip to competitively inhibit ethanol dehydrogenase and decrease the metabolism of ethylene glycol and methanol to their toxic metabolites. In addition, for patients for moderate to severe intoxication as indicated by a substantial metabolic acidosis and/or an initial ethylene glycol or methanol level greater than 50 mg/dl, the patient should be urgently treated with bicarbonate hemodialysis. This will allow for removal of ethylene glycol and methanol before it is metabolized to its toxic compounds and will also treat the acidosis as well. Fomepizole (4-methylpyrazole), a recently developed inhibitor of alcohol dehydrogenase, has been shown to be effective in the therapy of ethylene glycol intoxication in adults and in pediatric patients (60, 61). Femopizole does not have the adverse effects of ethanol infusion in pediatric patients and has been successfully used in pediatric patients (60, 61).

Endogenous Toxin Induced AKI

Hemolysis and rhabdomyolysis from any cause can result in sufficient hemoglobinuria or myoglobinuria to induce tubular injury and precipitate acute kidney injury (62, 63). Risk factors for acute kidney injury during an episode of rhabdomyolysis n children include dehydration, the serum concentration of myoglobin, the presence of other organ failure, and the presence of the systemic

inflammatory response syndrome (61). The mechanisms of injury is complex but may be related to vasoconstriction, precipitation of the pigments in the tubular lumen and/or heme-protein induced oxidant stress (62, 63). If the rhabdomyolysis is a result of tissue injury with substantial third space fluid losses as occurs in a crush injury, rapid fluid resuscitation can prevent or limit the renal injury. Once intravascular volume has been established, diuretic therapy with mannitol or other loop diuretics to promote flow and prevent precipitation of the heme proteins in the tubules and alkalization of the urine to potentially increase the solubility of hemoglobin and myoglobin have been proposed to decrease tubular injury (62, 63). Hyperkalemia, acidosis and other electrolyte abnormalities may develop rapidly and requires prompt therapy (*Table 65-3*). In children with AKI secondary to rhabdomyolysis, risk factors for the need for renal replacement therapy were a history of fever, persistent oliguria, and the degree of renal insufficiency at the time of admission (63).

Uric Acid Nephropathy and Tumor Lysis Syndrome

Acute kidney injury may be detected at the time of diagnosis of leukemia or lymphoma due to infiltration of tumor cells in the kidney or due to uric acid nephropathy. Radiographic studies demonstrate either mass lesions in the kidney in the case of lymphoma or diffuse infiltrative disease in leukemia. Children with acute lymphocytic leukemia and B-cell lymphoma are at the highest risk for uric acid nephropathy and tumor lysis syndrome (64, 65). Although the pathogenesis of uric acid nephropathy is complex, a potential important mechanism of injury is related to the precipitation of uric acid crystals in the tubules to obstruct urine flow or in the renal microvasculature to obstruct renal blood flow (64–68). A more common cause of acute kidney injury in leukemia is the development of the tumor lysis syndrome during chemotherapy (64–68). Therapy with allopurinol will limit the increased excretion of uric acid with chemotherapy but allopurinol therapy will result in a markedly increased excretion of uric acid precursors including hypoxanthine and xanthine (65, 68). Xanthine is less soluble than uric acid and precipitation of hypoxanthine and xanthine may play a role in the development of acute kidney injury during tumor lysis syndrome. Tumor lysis syndrome results in rapid increases in the serum potassium, BUN, purine metabolite products and phosphorus with a reciprocal decrease in the serum calcium as tumor cells are lysed. Rasburicase is a recombinant form of urate oxidase that catalyzes uric acid to allantion which is five times more soluble than uric acid (69). Rasburicase has been shown to be effective and well tolerated in pediatric patient with tumor lysis syndrome to prevent renal failure (69). AKI during tumor lysis syndrome can also result from extreme hyperphosphatemia from rapid breakdown of tumor cells and the precipitation of calcium phosphate crystals (70). Acute kidney injury due to tumor lysis syndrome is transient and the patient will eventually recover renal function once tumor lysis is complete. However, frequent hemodialysis may be necessary to control hyperkalemia and other metabolic abnormalities resulting

Table 65-3

Treatment of Hyperkalemia

Agent	Mechanism	Dose	Onset	Complications
Sodium bicarbonate	Shifts K+ into cells	1 meq/kg IV over 10–30 min	15–30 min	Hypernatremia, change in ionized calcium
Albuterol	Shifts K+ into cells	400 μg by nebulizer	30 min	Tachycardia, Hypertension
Glucose and insulin	Shilfts K+ into cells	Glucose 0.5 gm/kg	30–120 min	Hypoglycemia
		Insulin 0.1 U/kg IV over 30 min		
Calcium gluconate 10%	Stabilizes membrane potential	0.5–1 ml/kg IV over 5–15 min	Immediate	Bradycardia, arrhythymias, hypercalcemia
Kayexalate	Exchanges Na+ for K+ across the colonic mucosa	1 g/kg PO or PR in sorbitiol	30–60 min	Hypernatremia, constipation colonic membrane irritation if given PR

from the rapid lysis of tumor cells (66). Alternatively, continuous hemofiltration has been used to successfully control metabolic derangement associated with tumor lysis syndrome (66).

Acute Interstitial Nephritis

Acute interstitial nephritis may cause acute kidney injury as a result of a reaction to a drug or due to idiopathic acute interstitial nephritis. Children with acute interstitial nephritis may have rash, fever, arthralgias, eosinophilia and pyuria with or without eosinophiluria (71, 72). Uveitis has been reported in several cases of acute interstitial nephritis is important to recognize as therapy with tropical steroids may be indicated for the uveitis (71, 72). Radiographic studies demonstrate large echogenic kidneys while a kidney biopsy demonstrates interstitial infiltrate with many eosinophils. The pathogenesis of drug induced acute interstitial nephritis is thought to be related to a hypersensitivity reaction with the development of antitubular basement membrane antibodies in some cases (71, 72). Medications commonly associated with acute interstitial nephritis include methicillin and other penicillin analogues, cimetidine, sulfonamides, rifampin, non-steroidal anti-inflammatory drugs while other drugs have been associated with acute interstitial nephritis less commonly. Acute interstitial nephritis associated with non-steroidal anti−inflammatory drugs may also present with high grade proteinuria and nephrotic syndrome. Specific therapy for acute interstitial nephritis includes withdrawal of the drug implicated in causing the acute interstitial nephritis. In addition, corticosteroids may aid in the resolution of the renal failure (73).

Rapidly Progressive Glomerulonephritis

Any form of glomerulonephritis in its most severe degree can present with acute kidney injury and rapidly progressive glomerulonephritis. The clinical features include hypertension, edema, hematuria which is frequently gross, and a rapidly rising BUN and creatinine. The characteristic pathologic finding in rapidly progressive glomerulonephritis is extensive crescent formation. Some glomerulonephritides such as post-infectious glomerulonephritis, membranoproliferative glomerulonephritis, HSP nephritis and lupus nephritis present with a rapidly progressive course in a minority of cases. However, other glomerulonephritis such as anti-neutrophil cytoplasmic antibody (ANCA) positive glomerulonephritis, Goodpasture's syndrome, and idiopathic rapidly progressive glomerulonephritis typically presents with acute kidney injury (74–76). Serologic tests including an ANA, ANCA, anti-GBM titers and complement studies are required to evaluate the etiology of the rapidly progressive glomerulonephritis. Active lesions on biopsy are associated with recovery of renal function and may be reversible with immunosuppressive therapy (74–76). Since specific therapy will depend upon the pathologic findings, a biopsy should be preformed quite promptly when a child presents with clinical characteristics suggestive of rapidly progressive glomerulonephritis so that specific therapy can be initiated promptly.

Vascular Insults

Large vessel insults such as renal artery thrombosis and renal vein thrombosis will present with acute kidney injury only if bilateral or if they occur in a solitary kidney. Microvascular insults occur in cortical necrosis, in typical (diarrhea positive) and atypical (diarrhea negative) hemolytic uremic syndrome (HUS), and in HUS following bone marrow transplantation.

Renal Artery Thrombosis and Renal Venous Thrombosis

Renal artery thrombosis, cortical necrosis and renal venous thrombosis occur much more commonly in newborns and small children. Renal artery thrombosis is strongly associated with an umbilical artery line and a patent ductus arteriosus (77, 78). In addition to acute kidney failure, children may demonstrate hypertension, gross or microscopic hematuria, thrombocytopenia and oliguria. In renal artery thrombosis, the initial ultrasound may appear normal or demonstrate minor abnormalities while a renal scan will demonstrate little to no blood flow. Renal vein thrombosis begins in the intrarenal venous circulation and may spread to the main renal vein and the inferior vena cava. Thrombus formation is mediated by endothelial cell injury resulting from hypoxia, sepsis, or other insults (79, 80). The early findings in renal vein thrombosis include either no renal enlargement or minimal renal enlargement with perivascular streaks while later ultrasound findings demonstrates an enlarged, swollen kidney. The renal scan typically demonstrates decreased blood flow and function in the involved kidney(s). Risk factors for renal vein thrombosis include dehydration, asphyxia, maternal diabetes, low renal blood

flow, polycythemia, cyanotic heart disease, and low Apgar scores (80). Therapy for renal artery thrombosis and renal vein thrombosis should be aimed at limiting extension of the clot by treating the underlying risk factor such as removal of the umbilical arterial catheter for renal artery thrombosis. Anticoagulant or fibrinolytic therapy has been used in cases where the clot was particularly large (78).

Cortical Necrosis

Cortical necrosis as a cause of acute kidney injury is much more common in young children, particularly in the neonate. Cortical necrosis is associated with hypoxic/ischemic insults due to perinatal anoxia, placenta abruption and twin-twin or twin-maternal transfusions with resultant activation of the coagulation cascade. Children and newborns with cortical necrosis usually have gross or microscopic hematuria, oliguria and may have hypertension as well (5). In addition to laboratory features of an elevated BUN and creatinine, thrombocytopenia may also be present due to the microvascular injury. Radiographic features include a normal renal ultrasound in the early phase while ultrasound in the later phases may show that the kidney has undergone atrophy and has substantially decreased in size. A radionucleotide renal scan will show decreased to no perfusion with delayed or no function (*Fig. 65-1b*) in contrast to delayed uptake of the radioisotope which is observed in ATN (*Fig. 65-1a*). The prognosis of cortical necrosis is much worse than that of acute tubular necrosis. Children with cortical necrosis may have partial recovery or no recovery at all. Typically, children with cortical necrosis will need short or long-term dialysis therapy but children who do recover sufficient renal function are at risk for the late development of chronic kidney disease.

Hemolytic Uremic Syndrome

HUS is a common cause of intrinsic acute kidney injury in children and leads to substantial morbidity and mortality as well as long term complications which may not become apparent until adulthood (81–90). Typical HUS usually follows a gastrointestinal illness characterized by hemorrhagic colitis associated with verotoxin producing E. coli infection of which 0157:H7 is the most common serotype. Shiga toxin-producing *E. coli* (STEC) were first linked to human disease in the early 1980s (81–84). Several well-publicized outbreaks of hemorrhagic colitis and HUS have highlighted the morbidity and mortality of infection with verocytotoxin producing E. coli (81–90). While undercooked hamburger is the most common vector for 0157:H7 infection, apple juice, radish sprouts, sausages as well as other food sources have been implicated in the spread of verocytotoxin producing E. coli infections. In the US and Europe, the O157:H7 serotype is the serotype most commonly implicated in verocytotoxin producing infection but in other areas of the world non-0157:H7 strains are emerging as important pathogens (90, 91). E. coli O111:H^- caused a large outbreak of hemorrhagic colitis and HUS in Australia and other serotypes have been associated with hemorrhagic colitis and HUS as well (90, 91).

Once a person is infected with verocytotoxin producing E. coli, the percentage of patients who progress to HUS ranges from approximately 5 to 5%. In children under 5 years of age, the attack rate of hemolytic anemia or HUS is 12.9% compared to an attack rate of 6.8% and 8% for children aged 5–9.9 years and over 10 years of age, respectively (92). In another separate study, children with a white blood cell count greater than 13,000/mm^3 during the initial 3 days of illness with verocytotoxin producing E. coli infection, had a sevenfold increase in the risk of developing HUS compared to age matched children with a white blood cell count less than 13,000/mm^3. The use of anti-motility agents was also associated with a higher risk for the development of HUS (92). A recent study demonstrated that children with hemorrhagic colitis associated with shiga toxin producing E. coli who received antibiotic therapy were much more likely to progress to HUS (93). Environmental or genetic factors that might predispose to the progression of hemorrhagic colitis associated with shiga toxin producing E. coli to HUS are currently unknown. It has been suggested that alterations in the gene for Factor H recently described in patients with atypical HUS may also be relevant to epidemic diarrhea positive HUS (88).

At the time the diarrhea is subsiding, the child appears pale and lethargic due to the hemolytic anemia. Irritability is very common while some children may also develop petechia due to the thrombocytopenia. Oligo/anuria occurs in about 30–50% of children and about 40–75% of children will need dialysis therapy. The kidney and gastrointestinal tract are the organs most commonly affected in HUS while evidence of central nervous system, pancreatic, skeletal, and myocardial involvement may also be present (94–97). Gastrointestinal involvement may lead to rectal prolapse, ischemic colitis and transmural colonic necrosis requiring surgical intervention. Pancreatic involvement manifested as elevated pancreatic enzymes

occurs in 10–20% of children while glucose intolerance due to pancreatic islet cell involvement occurs in less than 10% of children (95). Central nervous system disease may present as seizures, coma, lethargy, and irritability.

Management of HUS requires appropriate attention to fluid and electrolyte balance, nutritional status and careful attention to the extrarenal complications of HUS. Hemolysis may be brisk and require frequent transfusions of packed red blood cells. Platelet transfusions are reserved for patients with active bleeding or for children with severe thrombocytopenia who need to undergo a surgical procedure such as placement of a dialysis catheter or a central line. In general, antibiotic therapy is not indicated since antibiotic therapy has the theoretical potential to alter the bacteria production of toxin resulting in the increased release of toxin. Similarly, anti-motility agents are also not indicated as they may increase the systemic absorption of toxin due the slower gastrointestinal transit time. Some studies have demonstrated a harmful effect of antibiotic therapy in hemorrhagic colitis. Children with hemorrhagic colitis associated with shiga toxin producing E. coli who received antibiotic therapy were more likely to develop HUS compared to children who did not receive antibiotic therapy (93). Other studies have not demonstrated such an association and a recent meta analysis concluded that administration of antibiotics in people infected with shiga toxin producing E. coli was not associated with the development of HUS (98, 99). While there is not a consensus on the benefit versus harm of antibiotic therapy for shiga toxin producing Escherichia coli infection, in vitro studies have shown that sub-inhibitory concentrations of several antimicrobial agents promotes and increases the release of verotoxins (100). Plasmapheresis has not been definitively shown to alter the natural history of diarrhea associated HUS (101).

A diatomaceous silicon diamide compound linked to an oligosaccharide chain (Synsorb Pk) has been developed and has been shown to avidly bind and neutralizes shiga toxin. A clinical trial has recently been completed to determine if oral administration of Synsorb Pk can decrease the rate of progression of hemorrhagic colitis to HUS or if it can decrease the need for dialysis or extrarenal complications in children who have developed HUS (102, 103). Unfortunately, the Synsorb Pk was not found to be beneficial in preventing extra renal complications or in decreasing the duration of dialysis in children with new onset HUS (103). Starfish is a new compound that has recently been developed and has been shown to bind to shiga toxin 1,000 times more efficiently than Synsorb Pk. Starfish is a pentamader that bind shiga toxin and has the potential to be administered intravenously (104). Other studies have demonstrated that vaccination with a plant lased oral vaccine protected mice against a lethal systemic intoxication with shiga toxin-2 (105).

Atypical HUS is not associated with diarrhea and is much less frequent in children. Atypical HUS may be associated with a number of immunologic diseases including systemic lupus erythematosus, with infections such as Streptococcus pneumonia or with the administration of medications such as cyclosporin, birth control pills, or chemotherapeutic agents such as mitomycin (83, 106). Acute kidney injury may also occur following bone marrow transplantation and the etiology is likely to be multifactorial but a high incidence of microvascular disease resembling HUS has been observed usually in association with veno-occlusive disease (106). Acute kidney injury following bone marrow transplantation in children is usually multifactorial and may be associated with long term renal insufficiently in some children (106).

Obstructive Uropathy and Lower Tract Lesions

Obstruction of the urinary tract can cause acute kidney injury if the obstruction occurs in a solitary kidney, if it involves the ureters bilaterally or if there is urethral obstruction. Obstruction can result from congenital malformations such as posterior urethral valves, bilateral ureteropelvic junction obstruction or bilateral obstructive ureteroceles. Acquired urinary tract obstruction can result from passage of kidney stones or rarely tumors. It is important to evaluate for obstruction since the management is to promptly relieve the obstruction. An unusual cause of acute kidney injury associated with ascites is bladder rupture; bladder rupture in children is typically due to trauma while other causes include infection, chemotherapy or post radiation therapy (107, 108).

Potential Strategies to Decrease Injury

Therapies for specific causes of AKI such as solumedrol for rapidly progressive glomerulonephritis, rasburicase for tumor lysis syndrome and preventive measures have been previously described. Therapies to prevent, limit or promote recovery for hypoxic/ischemic AKI have been the study of intense investigation for many years. Advances in understanding the cellular and molecular events that precipitate acute kidney injury has allowed for the development of strategies to potentially decrease injury and/or promote recovery from acute kidney injury. While there is

not a current specific therapy to prevent renal injury or promote recovery in human hypoxic/ischemic AKI, several potential therapies are being studied and future management of AKI may also include antioxidant, anti-adhesion molecule therapy, the administration of vascular mediators or mesenchymal stem cells to prevent injury and/or promote recovery (109–116).

Several different therapies have been shown to prevent, decrease or promote recovery in animal models of AKI. Melanocyte stimulating hormone (MSH) has anti-inflammatory activity and has been shown to protect renal tubules from injury (116). Recently, an analogue of alpha-MSA was found to ameliorate sepsis induced acute kidney injury and mortality in an animal model (115). Scavengers of free radicals and reactive oxygen and nitrogen molecules as well as anti-adhesion molecules have been shown to decrease the degree of injury in animal models of AKI (112). Recently very interesting studies have also demonstrated that multipotent mesenchymal stem cells (MSC) may have a role in promoting recovery in animal models of AKI (113, 114).

In children in the intensive care unit with multi-organ dysfunction, the systemic inflammatory response is thought to contribute to renal injury and multi-organ failure by activation of the inflammatory cascade with the participation of cytokines, reactive oxygen species, proteolytic enzymes and adhesion molecules. Ischemic injury stimulates the activation of neutrophils and the expression of adhesion molecules with resultant tissue injury. Activated neutrophils generate reactive oxygen molecules including superoxide anion, hydrogen peroxide, hydroxyl radical hypochlorus acid, and peroxyntirate. In addition, activated neutrophils release proteolytic enzymes that can results in substantial tissue injury (36, 117, 118). Pediatric patients with acute renal failure have been found to have biochemical evidence of oxidant stress as demonstrated by elevated levels of lipid peroxidation products (119). Infusion of the membrane permeable scavenger of reactive oxygen molecules resulted in significantly reduced BUN, creatinine, kidney myeloperoxidase activity and decreased lipid peroxidation in rats undergoing bilateral clamping of the renal pedicle (120). Other studies suggest that inhibition of the inflammatory cascade with adenosine 2A agonist will ameliorate ischemic/hypoxic AKI (121). While multiple interventions decrease the severity and promote recovery of acute kidney injury in animal models, interventional studies in patients with acute kidney injury have been disappointing (122, 123). As previously discussed, the development and testing of interventions for AKI will require the development of early biomarker(s) of injury that are much more sensitive than serum creatinine so that therapeutic interventions can be initiated in a timely manner.

Outcome and Prognosis

The prognosis of AKI is highly dependent on the underlying etiology of the AKI. Children who have AKI as a component of multisystem failure have a much higher mortality rate than children with intrinsic renal disease such as HUS, RPGN, and AIN. Recovery from intrinsic renal disease is also highly dependent on the underlying etiology of the AKI. Children with nephrotoxic AKI and hypoxic/ischemic AKI usually recover normal renal function. In the past it has been thought that such patients are low risk for late complications but several recent studies have demonstrated that chronic kidney disease can evolve from AKI (1–4, 124–130). Children who have suffered substantial loss of nephrons, as in the HUS or RPGN, are at risk for late development of renal failure long after the initial insult. Several studies in animal models have documented that hyperfiltration of the remnant nephron may eventually lead to progressive glomerulosclerosis of the remaining nephrons. Thus, children who have had cortical necrosis during the neonatal period and recovered renal function or children with an episode of severe Henoch-Schönlein purpura or HUS are clearly at risk for the late development of renal complications. Such children need life-long monitoring of their renal function, blood pressure, and urinalysis.

As described above, it has been thought that acute kidney injury due to hypoxic/ischemic and nephrotoxic insults were reversible with return of renal function to normal. However, recent studies have demonstrated that hypoxic/ischemic and nephrotoxic insults can lead to physiologic and morphologic alterations in the kidney that may lead to kidney disease at a later time (50, 131). Studies in adults demonstrate that CKD may evolve from AKI [12662 (128)]. Thus, acute kidney injury from any cause can be a concern for later kidney disease. Importantly, acute kidney injury is likely to be especially deleterious when the kidney is not yet grown to adult size and/or before the full complement of nephrons have been developed. Since nephrogenesis is not complete until approximately 34 weeks gestation, acute kidney injury during this interval might lead to a decreased nephron number and indeed studies have suggested that acute kidney injury during nephrogenesis results in decreased nephron number and subsequent glomerulomegaly (127). Acute kidney injury in the full term neonate is also associated with later kidney disease (129). In one study

of 6 older children with a history of AKI not requiring dialysis in the neonatal period, only two were normal, three had chronic renal failure and one was on dialysis. Studies in older children have also shown that AKI leads to CKD in a higher percentage of children than previously appreciated (126). In a prospective study of renal insufficiency in children undergoing bone marrow transplantation, the incidence acute renal insufficiency was high and was predictive of chronic renal insufficiency (130). Of those who survived 11% developed chronic kidney disease and AKI was the sole predictor of chronic kidney disease (130). Thus, children with a history of AKI from any cause need long-term follow-up.

66 Management of Acute Kidney Failure

Michael Zappitelli · Stuart L. Goldstein

Introduction

No uniform acute kidney injury (AKI) treatment strategies exist currently. Lack of consensus results from the inability to detect AKI early enough to prevent the cascade of cellular events leading to renal tubular cell death, since current diagnosis relies on serum creatinine changes. The recent discovery of early biomarkers of AKI may allow for detection prior to serum creatinine changes and interventional trials to prevent AKI development. Until then, AKI management, summarized in *Table 66-1*, remains supportive, aimed at maintaining fluid and electrolyte homeostasis, preventing life-threatening complications, avoiding further kidney injury, providing appropriate nutrition and renal replacement therapy (RRT) in the most severe forms of AKI. The current chapter outlines these management concepts with a focus on RRT – in particular continuous renal replacement therapy (CRRT).

Non-Dialytic Management

Prevention

In the past, AKI etiology most often resulted from primary renal disease (1). Today, most common causes are secondary AKI due to systemic illnesses or their treatments, such as renal ischemia (associated with sepsis, multiple organ dysfunction syndrome, and post-operative complications) or nephrotoxic medication use (2). Measures to prevent further kidney injury by these mechanisms are also important and include avoidance of (1) hypotension by providing appropriate inotropic support and (2) nephrotoxic medication use, with re-evaluation of the need for nephrotoxins and closely following serum concentrations. Careful evaluation of intravascular volume status is important to determine if AKI is reversible by fluid administration. Maintaining intravascular volume status can prevent progression of "pre-renal AKI" to acute tubular necrosis (ATN).

Fluid Management

Careful attention to fluid management is critical to mitigate AKI complications and is dependent on an accurate assessment of the underlying cause of AKI. Patients with pre-renal azotemia will often respond to fluid resuscitation, whereas patients with acute tubular necrosis should be treated with volume restriction, to prevent development of worsening fluid overload. Patients with AKI secondary to nephrotoxic medications or interstitial nephritis often demonstrate polyuria, placing them at risk for severe fluid and electrolyte losses.

Fluid prescription for children with AKI is directed by individual clinical situation. Generally, a safe starting point is to provide insensible losses (400 ml/m^2 of body surface area in patients with normal basal metabolic rate, higher in febrile patients and lower for ventilated patients who have lower respiratory losses), plus replacement of ongoing losses (urinary, gastrointestinal, chest tubes). Such fluid prescription will generally be appropriate in either patients who require fluid restriction or those with polyuria, but may not be appropriate in the setting of acute volume depletion. To promote achievement of negative balance in patients exhibiting fluid overload, less than the total urine output may be replaced.

While fluid resuscitation is essential for patients with acute hypovolemia and septic shock (3), growing evidence suggests that fluid overload development contributes to poor outcome in critically ill patients. Adult surgical patients with fluid retention had increased blood product requirements, prolonged dependency on pressors and a two-fold increase in death (4). Fluid overload has also been associated with decreased survival in adults with ARDS (5, 6) and more conservative fluid management in adults with acute lung injury was associated with improved lung function (7). Recent data from adults with septic shock demonstrates that early goal-directed fluid therapy, referring to fluid resuscitation targeted to achieve specific physiologic endpoints, may significantly improve patient survival (8, 9).

There are increasing number of studies in children supporting the negative effects of fluid overload development.

Drug dosing for renal function
Renal replacement therapy

Single center data (10–12) and a multicenter effort, the Prospective Pediatric Continuous Renal Replacement Therapy Registry Group (13, 14), demonstrate that worse fluid overload is an independent risk factor for mortality, irrespective of severity of illness, in patients who receive CRRT. Aggressive fluid control with early initiation of diuretics and CRRT to prevent >10% fluid overload may lead to improved survival in children with stem cell transplantation and AKI (15), a pediatric population where outcome is particularly poor once mechanical ventilation is initiated. The predilection for early multi-organ system failure and death in critically ill children with AKI (16, 17), may argue for early and aggressive initiation of RRT in association with an early goal-directed fluid repletion strategy in critically ill children. A very recent study in children with septic shock applied such goal-directed therapy using superior vena cava oxygen saturation as the main physiologic end-point, and found reduced need for blood transfusions and inotrope use and decreased mortality (18).

Different methods for fluid overload assessment based on calculating changes of daily weights and fluid balance as a percentage of estimated dry weight have been proposed (12, 13, 19). For critically ill children, the most commonly reported formula uses the difference in fluid output from fluid intake since PICU admission,as a percentage of the patient's estimated dry weight, using the following formula to quantify the degree of fluid overload:

$$\text{Fluid overload}(\%) = (\text{fluid in liters} - \text{fluid out liters}) / \text{weight in kg} \times 100\% \quad (12)$$

Data from the ppCRRT Registry demonstrates significant better patient survival when CRRT is initiated at <20% fluid overload versus >20% fluid overload (59% vs 40%) using this calculation in critically ill children with multi-organ dysfunction syndrome. Thus, CRRT should be considered for critically ill patients with AKI with >10% fluid overload and who are not expected to recover kidney function expeditiously to allow for appropriate nutrition, blood product and medication administration without development of worsening fluid overload status.

Electrolyte Management

Electrolyte management in AKI includes both acute and subacute management and is also dependent on the cause of AKI. Patients with oligo-aneuric kidney failure or acute tubular necrosis should not receive potassium or phosphorus unless they exhibit hypokalemia or hypophosphatemia. Even then, they must be administered with great caution. Sodium intake should be restricted to 2–3 mEq/kg body weight per day, together with fluid restriction, to prevent sodium and fluid retention with resultant hypertension. Conversely, patients with AKI secondary to nephrotoxic medications or interstitial nephritis often demonstrate polyuria, placing them at risk for severe fluid and electrolyte losses. Polyuria in this setting may lead to wastage of salt or other electrolytes, and may require higher administration than normal. In order to safely achieve these goals, it is ideal to request insertion of a urinary catheter and obtain weights and serum electrolyte levels at least daily.

Acute non-dialytic management of electrolyte problems due to AKI includes management of severe acute hyperkalemia which can lead to potentially fatal cardiac arrhythmias. Intravenous calcium may mitigate these effects, and measures to increase potassium entry into the cells, such as sodium bicarbonate (if the patient is acidotic), beta-2 agonists or insulin with dextrose, are effective in the short-term. Severe hypocalcemia may also cause cardiac conduction defects and should be corrected judiciously, especially in the setting of severe hyperphosphatemia, to avoid crystal formation. Moreover, administration of sodium bicarbonate for correction of hyperkalemia may exacerbate ionized hypocalcemia. Hyperphosphatemia, if not severe and not associated with severe hypocalcemia, may be managed with phosphate binders and restriction.

Pharmacologic Therapy

There is no proven specific pharmacologic treatment for AKI. However, preservation of renal perfusion with appropriate inotropic agents is essential in critically ill patients not responsive to volume repletion (20). The effects of dopamine, a commonly used inotropic agent in children, are varied and complex, leading to controversy with respect to its utility in the setting of AKI. At low or so-called "renal doses" (0.5–2 mcg/kg/min), dopamine

increases renal plasma flow and sodium excretion. However, these effects are short-lived (21). At increasing doses, dopamine binds beta- and then alpha-adrenergic receptors, rendering it difficult to ascertain whether any observed renal benefit from dopamine occurs as a result of its dopaminergic or intropic effect. Well-designed prospective randomized studies of adult patients at risk of acute tubular necrosis have seriously questioned the utility of "renal-dose" dopamine in reversing oliguria (22, 23), and many centers have abandoned its use for this purpose (22, 24).

The benefits of dobutamine and norepinephrine for patients with AKI reside in the ability to increase cardiac output, leading to an increase in renal blood flow (25). Vasopressin increases systemic vascular resistance by direct action on the vascular smooth muscle cells. Vasopressin has been shown to be especially effective in maintaining renal perfusion in patients with septic shock who were unresponsive to catecholamines (26).

Prospective randomized studies of adult patients at risk for acute tubular necrosis have shown that intravenous furosemide is unlikely to reverse oliguria (27, 28). However, the practice of providing furosemide, either as an intermittent bolus or as a continuous infusion (0.1–0.3 mg/kg/h) in combination with a thiazide diuretic has potential to maintain urine output in patients at risk of developing anuria, and allow for appropriate nutrition delivery.

Other pharmacologic agents, such as calcium channel-blockers and N-acetyl cysteine have been studied in adults but have shown no substantial benefit on mortality or renal outcomes (29, 30). Selective dopamine A-1 antagonist fenoldapam may improve urine output in children undergoing cardiopulmonary bypass surgery (31). Some studies suggest that nesiritide (a human natriuretic peptide) may have favorable renal hemodynamic effects and increase urine output after cardiac surgery (32–34). However, randomized controlled trials are lacking in children for each of these medications. Several other potential therapies such as growth factors (35), erythropoeitin (36), and free radical scavengers (37, 38) are being investigated in animal models from which AKI pathophysiologic mechanisms were originally delineated.

Renal Replacement Therapy

When fluid or electrolyte abnormalities are severe, RRT becomes the main supportive treatment of choice for AKI. Traditional indications for RRT in AKI are hyperkalemia, severe hyperphosphatemia (especially if accompanied by hypocalcemia), severe metabolic acidosis or fluid overload, and symptoms of uremia. Non-renal indications include prevention or treatment of tumor lysis syndrome, and removal of toxins (ingestions or inborn errors of metabolism). While little has changed in terms of acute indications, prevention or early treatment of fluid using RRT has become more prevalent, as discussed above. Acute RRT can be provided as intermittent hemodialysis (IHD), peritoneal dialysis (PD), or continuous renal replacement therapy (CRRT). There are advantages and disadvantages to each of these modalities.

Modality Choice

Several factors including dialysis indication and factors related to the patient's clinical status determine optimal RRT modality. These factors have been recently reviewed by North American and European authors (39, 40). In general, factors determining optimal modality include patient size, hemodynamic stability, and institutional expertise. *Table 66-2* outlines various advantages and disadvantages of different acute RRT modalities. PD and CRRT are better suited for patients with hemodynamic instability, since daily total ultrafiltration goals can be achieved over a 24 h period instead of a 3–4 h IHD treatment. In patients with disrupted or severely scarred peritoneal membrane, PD may not be possible. Acute drug intoxications and hyperammonemia secondary to inborn errors of metabolism are treated most efficiently with IHD, since rapid drug removal is important to prevent morbidity and IHD is the most efficient RRT modality (41, 42). However, recent studies demonstrate CRRT to be very effective in protein bound drug removal and hyperammonemia (43–45). Finally, the particular center's expertise and nursing support availability should play a major role in determining the optimal RRT modality.

Polls of US pediatric nephrologists demonstrate increased CRRT use over peritoneal dialysis as the preferred modality for treating pediatric AKI. In 1995, 45% of pediatric centers ranked PD and 18% ranked CRRT as the most common modality used for initial AKI treatment. In 1999, 31% of centers chose PD versus 36% of centers who reported CRRT as their primary initial modality for AKI treatment (46).

Acute Intermittent Hemodialysis

IHD is only briefly discussed here, as most details on materials, procedures, and prescription are discussed in the chapter covering maintenance chronic HD. Vascular access issues are similar to what is discussed below in the section on CRRT. Acute IHD can be performed using similar machinery and dialysis solutions as in chronic HD, which

Table 66-2

Advantages and disadvantages of different acute renal replacement therapy modalities

Modality	Advantages	Disadvantages
Intermittent HD	Short treatment times	Vascular access necessary
		Hemodynamic instability
	Accurate UF	Heparin anticoagulation
Peritoneal dialysis	No need for vascular access	Less efficient than HD/CRRT
	Minimal equipment needs	Variable UF dependent on BP, catheter placement and function.
	Minimal training needs	
	Feasible in small infants	
	Continuous treatment	
CRRT	Accurate UF that can be altered to account for changes in intake/patient BP	Vascular access necessary
	Smaller circuit volumes	
	Citrate anticoagulation	

means the need for a portable reverse osmosis device, purified water, and nurses specialized in performing HD. In hemodynamically stable patients with primary renal disease (e.g., acute glomerulonephritis, hemolytic-uremic syndrome), or in patients with inborn errors of metabolism or intoxications, IHD is preferred because very efficient small solute clearance can be obtained within a short period and these patients will generally tolerate the procedure well. In patients with severe uremia, who are being treated with IHD for the first time, a relatively low clearance (aiming at a urea reduction ration $\approx$ 30%) should be prescribed, in order to avoid the dialysis disequilibrium syndrome. If blood urea nitrogen is very high, intravenous mannitol or ultrafiltration profiling during dialysis may be helpful to avoid this complication. Heparin anticoagulation is generally used in IHD, which may complicate the clinical picture for patients with coagulopathy. Heparin-free IHD can be achieved by performing frequent (approximately every 20–30 min) flushes with normal saline to the hemodialysis circuit. Hemodynamically unstable patients will often not tolerate a session of IHD, and very strict fluid control will be necessary in between dialysis sessions, which may impair ability to provide adequate amounts of nutrition. In these types of patients, continuous modalities are preferable.

Acute Peritoneal Dialysis

Acute peritoneal dialysis is a continuous dialytic therapy which requires much less technical expertise, expense, and equipment compared to IHD and CRRT. PD catheters can be placed quickly and easily. In centers with expertise, a non-tunneled PD catheter can be placed percutaneously at the bedside, but these have a high tendency to leak. Placing catheters surgically is preferable, similar to chronic PD catheter placement, and may avoid problems with peritoneal leak and resultant risk of infection (47).

A recent trend toward providing PD therapy earlier in the post-cardiopulmonary bypass course has been reported, with one study of 20 patients demonstrating 80% patient survival (48). While improved survival with early PD initiation may result from prevention of fluid overload, some posit improved survival with early PD initiation results from increased clearance of cardiopulmonary bypass-induced pro-inflammatory cytokines. Further study however is required to support this hypothesis (49).

Standard PD equipment (including cyclers, or manual setups and solutions) can be used to perform dwells. Initial dwell volumes should be limited to 10 cc/kg of patient body weight in order to minimize intra-abdominal pressure, especially in patients with severe pulmonary dysfunction, and potential for fluid leakage along the catheter tunnel. Perioperative prophylactic antibiotics (cefazolin 15–20 mg/kg) are advisable, and post insertion intradialysate cefazolin and heparin are typically instilled to prevent infection and fibrin formation, respectively for 48–72 h (40). In patients for whom higher clearance is desired, increasing cycle frequency dwell volumes or dextrose concentration will help. However, in patients who cannot tolerate increasing volumes, increasing cycle frequency and dextrose may be the only

options. Although PD may deliver less efficient solute removal than hemodialysis or CRRT, its relative simplicity and minimal associated side effects allow for RRT provision in settings lacking pediatric dialysis specific support and personnel. Complications include peritonitis, leakage around the tunnel or poor catheter "function", referring to blockage or inability to drain.

Continuous Renal Replacement Therapy

Various CRRT aspects including dose, dialysis/hemofiltration fluid composition, and anticoagulation methods have been studied in recent years.

The term CRRT generally refers to one of three treatment modalities: continuous venovenous hemodialysis (CVVHD), continuous venovenous hemofiltration (CVVH), or continuous venovenous hemodiafiltration (CVVHDF), but applies to any modality which is continuous (such as PD). In CVVHD, just as with IHD, physiologic dialysis solution is run countercurrent to blood flow through the hemofilter. The mode of solute removal is by diffusion and small solutes (like urea) are removed effectively. With CVVH, replacement solution, which is typically the same or similar solution as that used for dialysis, is infused into the CRRT circuit either pre-hemofilter ("pre-dilution") or post-hemofilter ("post-dilution"). Simultaneous to the infusion of replacement solution, the same amount of fluid is removed by ultrafiltration through the hemofilter in order to achieve solute removal by convection (solute drag). Small solute removal is similar to CVVHD, but larger "middle molecules" are removed. In CVVHDF, both dialysis and replacement solutions are used to achieve solute removal. In all forms of CRRT, additional fluid is removed by ultrafiltration with the goal of achieving a negative balance.

Vascular Access

Well-functioning vascular access is absolutely essential to the success of IHD or CRRT. The most common sites for acute catheter placement are the internal jugular, subclavian and femoral veins. Avoiding the subclavian vein is preferable to prevent subclavian vein stenosis in patients who may need permanent vascular access in the ipsilateral upper extremity. The femoral vein provides advantage of relatively easy and prompt access. However, with the availability of skilled surgeons or intensivists, internal jugular venous placement is also easily attainable. Patient characteristics may also influence the choice of catheter placement. For example, in patients with severe ascites or with suspected need for a future kidney transplant, internal jugular placement may be preferable, whereas in patients receiving high-frequency oscillatory ventilation, femoral placement will be technically easier and reduce the risk of pneumothorax associated with internal jugular venous access. *Table 66-3* displays suggested options for catheter size and location by patient size.

A study of adult patients reported increased recirculation and worse performance in catheters placed in the femoral vein versus subclavian or jugular veins (50). Substantial pediatric data suggests that internal jugular access is associated with longer access survival than femoral or subclavian access, independent of anticoagulation method (51) even though the femoral vein was most commonly used (69%), followed by subclavian and internal jugular access (51). Catheter size should also be matched to patient size. However, smaller catheters (5 French) are associated with worse access survival due to clotting and poor blood flow (51). *Table 66-3* lists catheter configurations and patient size combinations. Ultimately, access placement will also be largely determined by technical expertise of the individual placing the catheter. Maintaining access

Table 66-3

Acute catheter configuration and patient size combination

Patient size	Catheter size & source	Site of insertion
NEONATE		
	Dual-Lumen 7.0 French (COOK/MEDCOMP)	Femoral or Internal Jugular vein
3–6 KG	Dual-Lumen 7.0 French (COOK/MEDCOMP)	Internal/External-Jugular, Subclavian or Femoral vein
	Triple-Lumen 7.0 Fr (MEDCOMP)	Internal/External-Jugular, Subclavian or Femoral vein

patency between dialysis sessions using heparin or citrate catheter locks is essential to prevent access clotting.

Machine and Hemofilter

Modern CRRT machines are generally user-friendly and consist of computer modules from which physicians may choose the CRRT modality. Accurate ultrafiltration with volumetric/gravimetric control incorporated into machines and disposable lines, circuits and dialyzers, sized for the pediatric weight spectrum have made CRRT safer in children (52). Accurate UF and blood flow rates are crucial for pediatric RRT since the extracorporeal circuit volume can comprise more than 15% of a small pediatric patients' total blood volume, and small UF inaccuracies may represent a large percentage of a small pediatric patient's total body water. All these machines also contain blood air leak detectors, a blood pump, dialysis fluid, and replacement fluid pumps.

Membranes or hemofilters come in different sizes, as measured by surface area – from as low as approximately 0.1 m^2 to over 1 m^2 – ranging from 15 to over 100 ml of blood. Some machines have specific hemofilters associated with them, whereas others are more versatile and can accommodate different hemofilters. CRRT hemofilters are made of polysulfone or acrilonitrile (such as the AN69). Thus, membranes are chosen based on the type of machine being used and the size of the patient.

Despite the smaller sizes of some hemofilters, delivery of IHD or CRRT to infants or small patients entails a significant portion of their blood volume to be pumped through the extracorporeal circuit. Therefore, extracorporeal circuit volumes which comprise more than 10–15% of patient blood volume (or even less, if the patient is hemodynamically unstable) should be primed with whole blood to prevent hypotension and anemia. Since the prime volume is not discarded, it is important to not re-infuse the blood into the patient at the end of the treatment in order to prevent volume overload and hypertension.

Solutions

Dialysis and replacement solutions must contain an acid buffer. Until recently, most CRRT solutions used lactate as a buffer. A crossover study in adult patients receiving CRRT revealed that lactate based solutions could lead to rising serum lactate level in patients (53), a phenomenon that could lead to unnecessary investigation for tissue ischemia. Bicarbonate buffered solutions can be made by hospital pharmacies, but are also now available from industry sources (54). A recent pediatric study has highlighted the potential adverse patient safety implications with pharmacy prepared solutions that can arise from compounding errors (55). Thus, a solution composition validation program should exist in centers that opt to use pharmacy-made solutions for CRRT.

Anti-Coagulation

Anticoagulation of the CRRT circuit is essential to provide therapy. Heparin and citrate are the two most common forms of anticoagulation. Heparin anticoagulation is achieved by continuous infusion of heparin to the CRRT machine circuit. Side effects of heparin include systemic anticoagulation and rare occurrence of induction of heparin induced thrombocytopenia. Regional (restricted to the CRRT circuit) citrate anticoagulation is performed by continuous infusion of citrate solution through a stopcock at the access ("arterial") portion of the dialysis catheter. Anticoagulation is achieved by binding to and decreasing ionized calcium in the blood required for the clotting cascade. Calcium is infused into a separate systemic central venous line or at the return ("venous") portion of the dialysis catheter to maintain physiologic ionized calcium in the patient. Potential complications of regional citrate anticoagulation include metabolic alkalosis (especially if used in combination with bicarbonate buffered CRRT replacement/dialysis solutions) and citrate lock. Citrate lock is a phenomenon where the delivery of citrate exceeds the patient's hepatic clearance and the clearance of citrate through the hemofilter. As a result, citrate concentrations increase in the blood and bind calcium. Citrate lock is identified by decreasing serum ionized calcium in the presence of rising total calcium. The treatment for citrate lock is to discontinue citrate for one to four hours and then restart at a lower citrate delivery rate. Recent pediatric studies have reported practical and safe citrate anticoagulation protocols (56, 57).

Complications

Patients who receive CRRT with an AN-69 membrane are at risk of the bradykinin release syndrome (BRS) when circuits require blood priming. BRS leads to a range of mild to profound hypotension. Several methods of mitigating BRS in children have been published, including normalizing the blood pH and administering a calcium bolus to the patient to counter the citrate in the blood

unit (58) as well as performing pre-dialysis of blood used to prime the circuit in smaller children (59).

Another complication of CRRT is hypothermia, particularly in infants. This can be avoided by the use of heat lamps, dialysis fluid warming, and blood tube warmers. Electrolyte disturbances can occur – particularly hypophosphatemia, hypomagnesemia, and hypokalemia, – due to clearance and is avoided by frequent electrolyte monitoring and appropriate adjustment of dialysis and/or replacement of solution composition. Excessive ultrafiltration is a problem that may occur, but can be avoided by careful patient monitoring with hourly fluid balance, and frequent reassessment of the day's goals by the pediatric nephrologist. Nutritional losses also occur through the hemofilter, necessitating increase in intake.

Other Types of Continuous Therapies

With increase in the level of critical illness in children admitted to the critical care unit and with a widening of the spectrum of diseases seen today, the role of the pediatric nephrologist has extended greatly from not only providing RRT through IHD, CRRT, or PD.

A modification to CRRT is SLED or sustained low-efficiency daily dialysis, in which a standard hemodialysis machine is used for more prolonged periods than a standard IHD session (generally 8–12 h) (60). While there may be some potential advantages in the use of SLED in institutions that do not perform standard CRRT, this procedure requires staffing with highly specialized nephrology nurses. Moreover, SLED has not been adequately described in children.

The pediatric nephrologist may also need to combine CRRT with other continuous or intermittent extracorporeal therapies. The performance of CRRT in patients treated with extracorporeal membrane oxygenation (ECMO) is becoming more common. In this setting, a hemofilter can be placed in series along the ECMO circuit to perform either ultrafiltration alone or with countercurrent infusion of dialysis fluid to perform solute removal (dialysis). A CRRT machine can also be attached to the ECMO circuit to perform CVVHD, CVVH, or CVVHDF, which may offer more accurate ultrafiltration control (61).

Patients with AKI requiring RRT may also require other forms of extracorporeal therapy for non-primary renal diseases, using plasmapheresis or immunoadsoprtion procedures (62, 63). These may be performed simultaneous to CRRT therapy using a separate machine attached via stopcocks to the CRRT machine or intermittently between dialysis sessions. Clearly, these procedures require expertise and good overall knowledge of extracorporeal therapy and the role of pediatric nephrologists in performing these treatments is likely to increase.

Nutritional Management

Adequate nutrition in critically ill children with AKI is a crucial component of their treatment, as they are at increased risk of developing protein-energy malnutrition (64). Presence of renal replacement therapy (RRT) contributes to nutritional losses, especially amino acids and water-soluble vitamins. Similar to what has been found in adults, amino acid losses by continuous venovenous hemofiltration (CVVH) (65, 66), continuous venovenous hemodiafiltration, (CVVHDF) (66) and continuous venovenous hemodialysis (CVVHD (67)) can be anywhere from 10 to 20% of the amount provided in the parenteral nutrition (PN), which is associated with the development of negative nitrogen balance (66). Given the age-associated baseline elevated protein needs of children and the presence of abnormal amino acid synthesis and increased protein catabolism in critical illness and AKI, daily protein intake should be in the order of at least 2–3 g/kg/day in children with AKI. During RRT, commensurate adjustment of protein intake must be made to account for losses (10–20% of amino acid intake). Some programs aim at serum urea nitrogen levels in the range of 40–80 mg/dL as a guide to determining whether protein alimentation intake is sufficient during RRT (68).

Drug Dosing

Drug dosing must often be altered for patients with AKI, not so much for avoiding kidney injury, but to avoid toxic accumulation of drugs and their metabolites which should be excreted by the kidney. When glomerular filtration rate is estimated to be less than 50% of normal, most drugs excreted by the kidney will require modifications in scheduled dosing. For patients receiving CRRT, drug dosing can be quite challenging. However, understanding the size, volume of distribution, and protein binding of the drug (for each of which, if high, leads to less clearance through the hemofilter), can lead to a fairly good estimate and appropriate drug dosing can be made. Several recent excellent review articles discuss how to specifically dose different drugs during CRRT or with AKI, based on these biochemical properties (69, 70).

Outcome

The mortality of children with AKI who receive acute RRT is high, ranging from about 40–70% (71–73) and unchanged from the past. Despite advances in technology, children who now receive AKI supportive therapy have concomitant increasing severity of illness, so the impact leading to improved survival is not readily apparent. Survival rates stratified by RRT modality have also been stable; survival rates for patients receiving IHD (73–89%) are higher than those receiving PD (49–64%) or CRRT (34–42%) (72). Better survival in patients who receive IHD likely results from improved hemodynamic stability, but no prospective pediatric study that controls for patients illness severity has compared survival across modalities. Children receiving CRRT with non-renal organ disease or multiple organ system dysfunction syndrome (MODS) have higher mortality rate (>50%) compared to other diagnoses (<30%) (74). Infants demonstrate even higher mortality when compared to older children (2, 74). Few studies have examined long-term outcome of children with AKI, but a substantial portion may not have normal renal function by discharge (2). Recent data demonstrates that long – term kidney injury is prevalent in survivors of an AKI episode (75, 76). In summary, hospital mortality of patients with AKI is related to the level of illness severity. In those who survive, there appears to be a definite risk of long term negative effects on renal function and potentially increased risk of chronic kidney disease.

Chronic Renal Failure

67 Pathophysiology of Progressive Renal Disease

Allison Eddy

Clinical Overview

The high and increasing prevalence of end-stage kidney disease (ESRD) is consuming a major portion of healthcare resources for both pediatric and adult populations (*Fig. 67-1*). While the incidence rates for pediatric ESRD have remained relatively constant at 14 per million children under the age of 19 years, many adults with ERSD suffer from a kidney disease that began as chronic kidney disease (CKD) during childhood (*Fig. 67-2*) (1). Pediatricians and pediatric nephrologists are challenged to become more involved in the prevention, early diagnosis and optimal management of childhood-onset CKD. The rapidly increasing number of overweight and hypertensive children and adolescents highlights the challenges ahead. In addition to the obvious measures, including changes in diet, exercise and lifestyle, new medical interventions are also needed. An understanding of the basic cellular, molecular, genetic, and environmental pathogenetic mechanisms that will be reviewed in this chapter will provide an essential framework for developing and testing new therapies. For patients with established CKD that is predicted to progress, a therapeutic protocol comprising multiple agents that target different pathogenetic pathways will likely become standard treatment in the future. Currently available therapies can be effective but in general they have only a modest effect on the rate of renal functional decline. An important advance in recent years has been the recognition that most patients with CKD (now estimated to be one in eight adults) never reach ESRD and the need for renal replacement therapy (2). This is because CKD patients are at risk for accelerated cardiovascular disease and are more likely to die prematurely due to cardiovascular or cerebrovascular disease. Thus clinical management of all patients with CKD must consider measures to reduce cardiovascular risk factors, even in the pediatric population.

The underlying renal diseases that lead to ESRD in childhood (*Fig. 67-2a*) are dominated by congenital structural disorders (especially dysplasia with/without reflux or obstruction) during the first decade, while acquired diseases, especially glomerular disorders such as FSGS, become more important in the second decade (3). Diabetic and hypertensive nephropathy dominate in adults, but may begin in childhood (*Fig. 67-2b*).

Crossing the GFR Threshold

Individuals with normal kidneys have considerable renal functional reserve that may be compromised in congenital and developmental anomalies and in acquired disorders that are not completely reversible. There is a critical set-point beyond which progressive renal functional decline is inevitable, even after the primary disease process becomes quiescent. For many, the threshold appears to be in the GFR range of 60 ml/min/1.73 m^2, but there is considerable variability. Relevant factors are the age of the patient and the ability of their kidneys to grow in parallel with postural growth. For this reason the risk of progressive renal failure may not be clear until after the adolescent growth spurt. Another important variable is nephron number. Once estimated to average 1×10^6 nephrons per kidney, it is now evident that for normal individuals this number may vary between 0.2 and 2.0×10^6 per kidney (4). Even if the primary disease process is no longer a factor, secondary factors reviewed in the next section may modify the natural history of the disease (*Fig. 67-3*).

The underlying process shared in common by all chronic progressive kidney diseases is one of kidney scarring or fibrosis. This process leads to glomerular obsolesce as a consequence of glomerulosclerosis and tubular atrophy (often accompanied by atubular glomeruli formation) due to interstitial fibrosis. Because the tubulointerstitium accounts for the largest kidney compartment (approximately 85% by volume), progressive interstitial fibrosis has become synonymous with kidney disease progression; interstitial fibrosis is considered the final common pathway to renal failure shared by all primary kidney disorders. This fact also explains why the degree of interstitial fibrosis is the best histological

Figure 67-1

End-stage kidney disease (ESRD): Prevalence and Incidence. While the incidence of ESRD has remained constant in the pediatric age group and has not increased in adults since the early 2000s (not shown) the cumulative ESRD prevalence continues to increase (1).

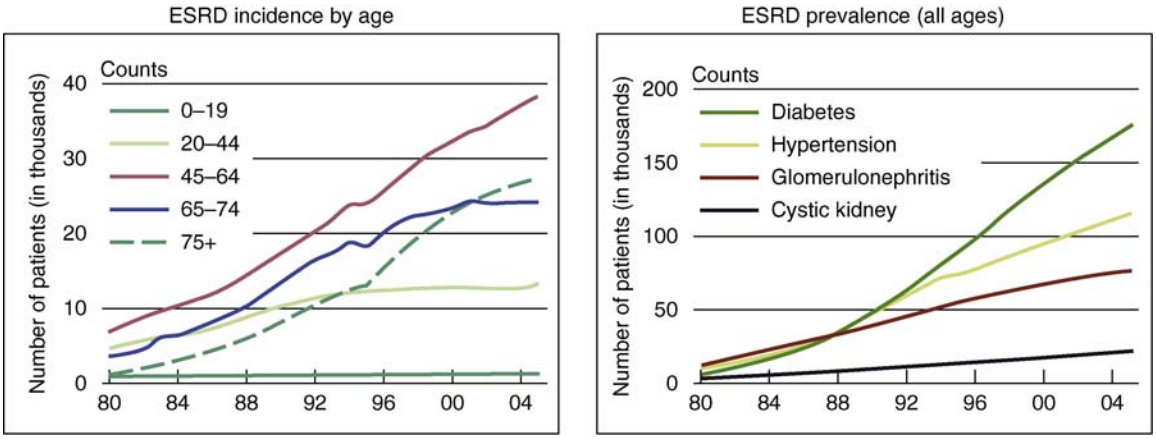

Figure 67-2

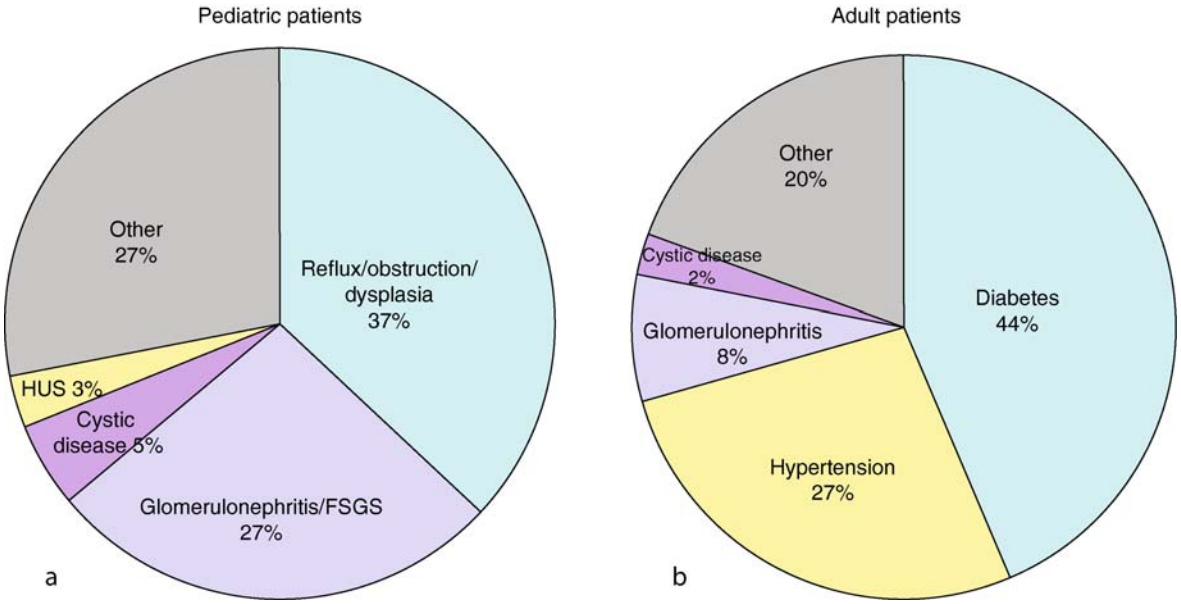
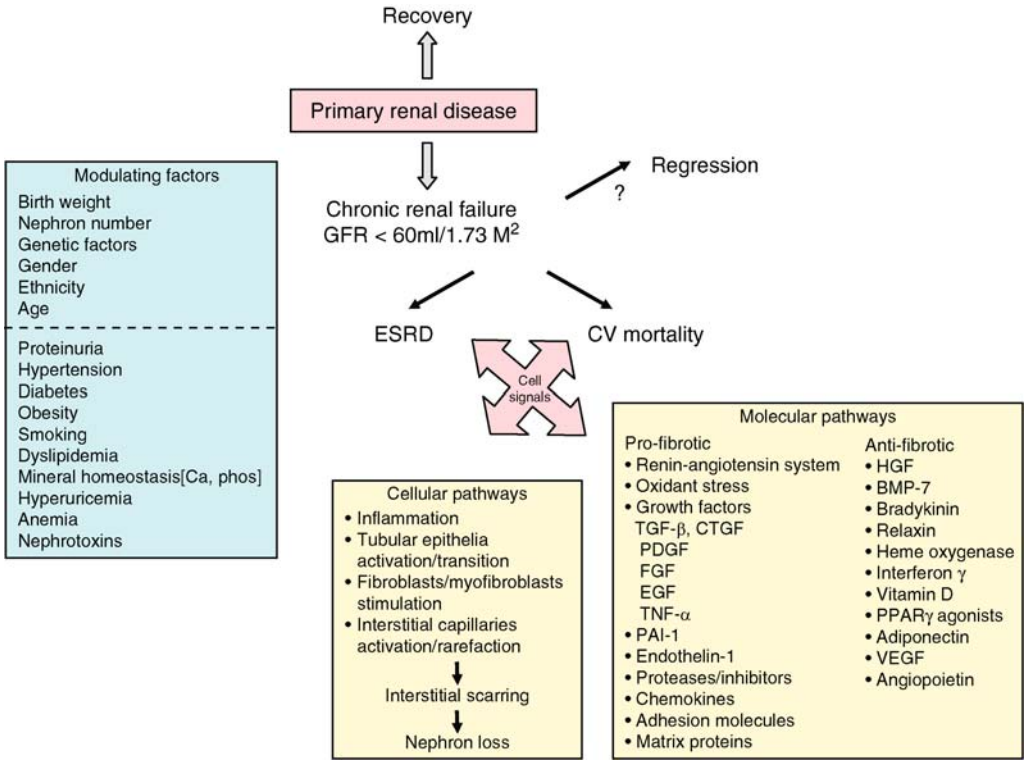
Primary cause of ESRD. The etiology of the primary kidney disease differs between adult and children. Pediatric data are from the North American Pediatric Renal Transplant Cooperative Study (https://web.emmes.com/study/ped/index.htm); adult data are from the 2008 USRDS report (1).



correlate of renal functional decline (*Fig. 67-4*) and long-term prognosis. In general, the pathogenetic mechanisms that lead to glomerulosclerosis and interstitial fibrosis share many similarities, but there are certain unique features that will be considered in the sections that follow. The fundamental process of CKD is essentially a process of accelerated aging as a consequence of an injurious process that diminished renal functional reserve. In the absence of known renal pathological events, renal function declines progressively with advancing age due progressive glomerulosclerosis and interstitial fibrosis (*Fig. 67-5*).

Figure 67-3

Chronic kidney disease (CKD) mechanisms schematic summary. Patients with glomerular filtration rates less than 60 ml/min/1.73 m^2 have CKD and a significantly increased risk of premature cardiovascular death and end-stage kidney disease. Several factors modify these risks. The pathophysiological mechanisms of CKD progression involve an integrated network of cellular events and molecular pathways. Early renal scarring characteristic of CKD may be reversible. The figure is modified from (5).



Factors that Influence Renal Failure Progression Rates

Chronic Kidney Disease Progression in Patients

Non-Modifiable Risk Factors

Fetal Programming

Low birth weight (even after correction for gestational age) is associated with an increased risk of chronic and end-stage kidney disease. Early work by Brenner, Barker, Law and others proposed an association with birth weight, renal filtration surface area and the risk of hypertension. Although the mechanisms have not been fully elucidated, a congenital defect in nephron number appears to be important. Careful stereological studies such as those performed by Hughson et al. (*Fig. 67-6*) determined a mean of 923,377 ± 256,391 nephrons in adult white patients while the mean was reduced to 754,320 ± 329,506 when the data for white hypertensive patients were examined (9). These data are similar to the findings of others. Proposed mechanisms linking nephron number and CKD risk revolve around the increased hypertension risk due to associated changes in natriuresis and glomerulosclerosis caused by intraglomerular hyperfiltration. Systemic hypertension and/or microalbuminuria may be an early indicator of low nephron number.

Ethnicity

For reasons that may pertain to genetic, environmental and/or socioeconomic factors, certain races are more likely to develop end-stage kidney disease (ESRD). Risks may be due to a higher incidence of certain diseases or a more aggressive clinical course for specific diseases entities. African Americans have a higher incidence of

Figure 67-4

Renal interstitial fibrosis: the CKD histological hallmark. Quantitative histological studies of human kidney biopsies demonstrate an inverse correlation between the scarred interstitium and renal function. The photomicrographs illustrate interstitial inflammation and fibrosis and tubular atrophy, the histological features of CKD that are not present in a normal kidney. The graph is from (6). (See color plate 42)

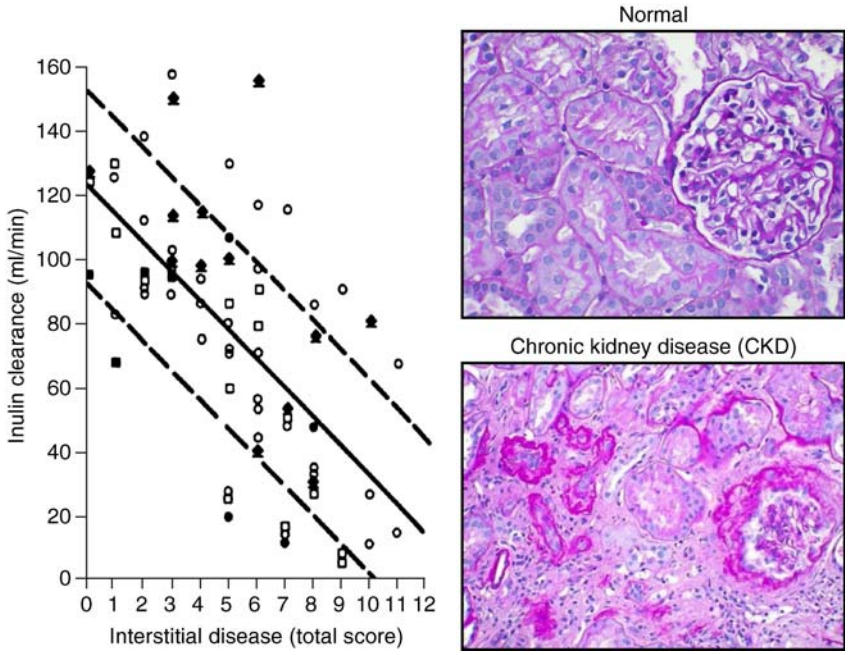


Figure 67-5

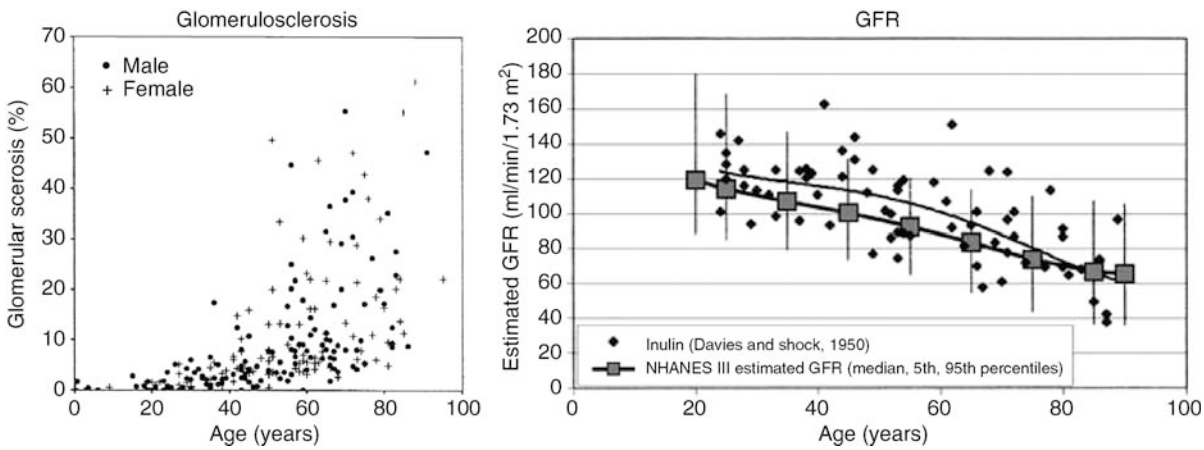
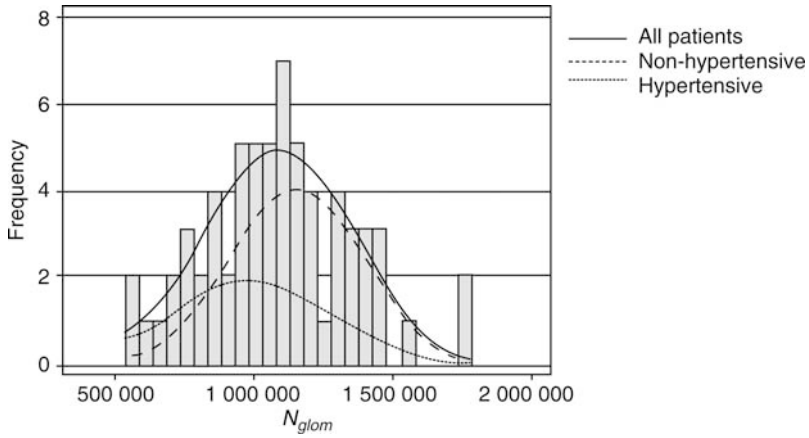
Progressive glomerulosclerosis and declining GFR characterize aging kidneys. Normal human aging is characterized by renal scarring and a progressive decline in kidney function. These figures are reproduced from (7, 8).



hypertensive nephrosclerosis and idiopathic focal segmental glomerulosclerosis. These diseases, together with lupus nephritis and HIV nephropathy, are also more aggressive in African Americans (10). Hispanic patients also have a worse prognosis than Caucasians. In a study of lupus nephritis by Contreras et al. (11), the end point of a doubling of serum creatinine or ESRD was reached by 31% of African Americans, 18% of Hispanics and 10% of

Figure 67-6

Low nephron number is a risk for hypertension. Increasing evidence supports an association between low nephron numbers (Nglom) and the risk of developing hypertension as shown by this study of white females. Data are from (9).



Caucasians. The escalating incidence of obesity and the metabolic syndrome also has significant racial differences. African Americans with the metabolic syndrome have a 31% increased risk of developing proteinuria. Certain indigenous populations, such as the Zuni Indians of New Mexico and the Australian Aborigines, have a significantly increased risk of chronic kidney disease, both diabetic and non-diabetic (12, 13). The metabolic syndrome is highly prevalent in these populations.

Age

It is not clear that age per se is an independent risk factor for CKD progression rates in the pediatric population, although it is commonly perceived that renal function deteriorates more rapidly around the time of puberty. Gonzalez et al. (14) investigated the natural history of CKD in a group of children with renal hypodysplasia and suggested three discrete phases: (1) initial improvement in GFR after birth until a median age of 3.2 years; (2) a second pre-pubertal phase characterized by stable renal function for several years in half of the patients, while the remainder had progressively declining renal function (−1.7 ml/min/1.73 m^2/year median); (3) the pubertal period when 43% with previously stable renal function began to deteriorate (−4.0 ml/min/1.73 m^2/year median) beginning at a median age of 11.4 years. Increased body mass at puberty was thought to be associated with systemic and intrarenal hemodynamics that accelerated glomerular and interstitial fibrosis. Baseline GFR, albuminuria, hypertension and recurrent febrile urinary tract infections were predictors of more rapid renal functional decline.

Other Genetic Risk Factors

Naturally occurring polymorphisms in several genes have been associated with differences in biological activity of the proteins that they encode. A field of active investigation seeks to determine if polymorphic genetic variants can be used to predict progression rates in patients with CKD (15). Most extensively investigated is the angiotensin converting enzyme (ACE) gene, known to have insertion (I) and deletion (D) variants; D is associated with increased ACE activity. The homozygous ACE D/D genotype has been associated with more aggressive renal disease in some but not all studies of patients with IgA nephropathy and diabetic nephropathy. Other polymorphisms of interest include additional genes of the renin-angiotensin system such as angiotensinogen; pro-inflammatory molecules: monocyte chemoattractant protein-1, interleukin-1, interleukin-10; pro-fibrotic molecules: transforming growth factor beta; angiogenic factors: vascular endothelial growth factor; and others: vitamin D receptor, endothelial nitric acid synthase. This list will undoubtedly expand.

Modifiable Risk Factors

Hypertension and proteinuria have been identified in numerous studies as independent determinants of the rate of renal functional deterioration that can be modified with therapy. Other factors play a role, although it is not always clear if their effects are direct or indirect, ultimately mediated through their influence on blood pressure and urinary protein excretion rates.

Hypertension

Although CKD as a consequence of primary hypertension is extremely rare in children, hypertension is a common manifestation of many pediatric chronic kidney diseases. In the 2004 annual report of the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS), 38% of children with CKD were on antihypertensive medication (16). Stratified by primary kidney disease rates ranged from 83% for polycystic kidney disease to 19% for patients with structural kidney disease. Hypertension is one of the most critical determinants of progression rates in children as well as adults (*Fig. 67-7*) (17). The pathophysiology is complex but alterations in the activity of the renin-angiotensin system play a central role while impaired renal arteriolar autoregulation makes the kidney an especially vulnerable target organ. The ensuing glomerular hyperfiltration is implicated in the genesis of glomerulosclerosis and proteinuria which is thought to induce inflammation and fibrosis within the interstitial compartment. Whether hypertension directly causes interstitial damage via effects on interstitial arterioles and peritubular capillaries is unclear. Current treatment guidelines recommend treating CKD patients with ACE and/or ARB drugs to achieve blood pressure targets of less than the 90th percentile for age, gender and height (18). Whether lower blood pressure goals will reduce progression rates is unclear. Optimal blood pressure control is also critical for cardiovascular protection, noting that cardiac disease is the second most common cause of death in children with ESRD.

Proteinuria

In virtually every epidemiological study the degree of proteinuria emerges as a significant independent predictor of CKD progression rate. This correlation is even true for non-glomerular diseases such as reflex nephropathy as shown in the ItalKid project cohort of 343 patients where urinary protein/creatinine ratios greater than 0.8 (0.2 upper normal) were associated with faster deterioration (*Fig. 67-8*) (19). There is increasing evidence that treatment designed to lower urinary protein excretion rates is beneficial. In an analysis of 542 patients with primary IgA nephropathy in the Toronto Glomerulonephritis Registry, multivariate analysis determined that proteinuria during follow-up was the most important predictor of the rate of GFR decline (*Fig. 67-9*) (20). Reducing proteinuria is especially beneficial in patients with nephrotic syndrome. Achieving proteinuria levels less than 300 mg/day has been proposed as the ideal goal for adults. Even in normotensive adults with renal disease, the use of ACE drugs to reduce albuminuria has been shown to be renoprotective (21, 22). Proteinuria is also a strong predictor of cardiovascular disease (23).

Proteinuria may be a marker of glomerular damage. While pediatric evidence is still evolving, three large adult studies have shown that controlling hypertension

Figure 67-7

Hypertension increases the rate of CKD progression. In a study of 3,834 children with chronic kidney disease, hypertension was shown to increase the rate of progression to end-stage kidney disease. Data are from (17).

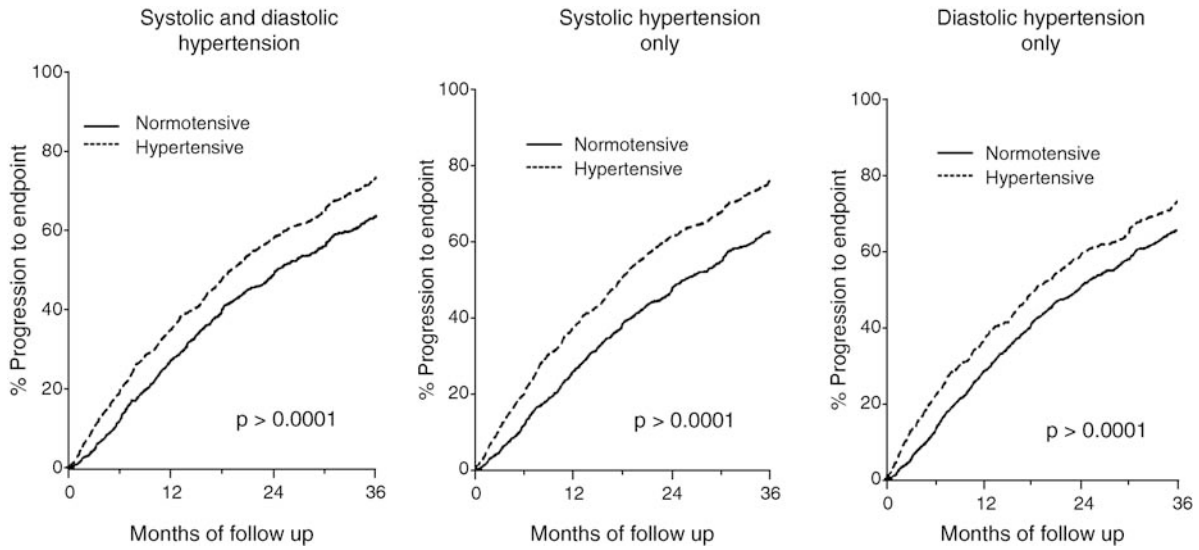


Figure 67-8

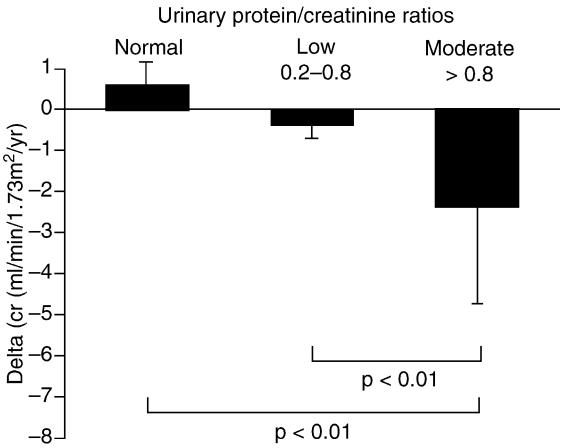
Proteinuria is an outcome predictor even in primary non-glomerular diseases. In a study of 343 children with vesicoureteral reflux, moderately elevated urinary protein/creatinine ratios showed a faster rate of decline in renal function. Data are from (19).



had important proteinuria-reducing effects (24). In the ESCAPE trial (Effect of Strict Blood Pressure Control and ACE Inhibition on CRF Progression in Pediatric Patients) use of ramipril to control hypertension was shown to reduced proteinuria in children (25). Data from experimental studies support the hypothesis that proteinuria has direct damaging effects on the tubulointerstitium (26). Through breaks in Bowman's capsule or disruptions in glomerulo-tubular junctions, biologically active proteins within the glomerular ultrafiltrate may gain access to the interstitial compartment and cause damage. Similar molecules reaching peritubular capillaries via the post-glomerular arterioles may increase permeability and/or promote inflammatory cell recruitment. In addition, direct effects on proximal tubules have been increasingly documented (*Fig. 67-10*). Interactions with the endocytic receptor complex megalin-cubulin-amnionless are likely to be involved, but the receptor-dependent pathways have not been fully elucidated. Similarly, the molecular composition of the offensive urinary proteins remains unclear. Albumin modified by lipids, transferrin

Figure 67-9

Proteinuria severity in glomerular disease predicts renal outcome. In most glomerular diseases except steroid-responsive nephrotic syndrome, the risk of renal failure increases with urinary protein excretion rates as shown in this study of patients with IgA nephropathy. Data are from (20).

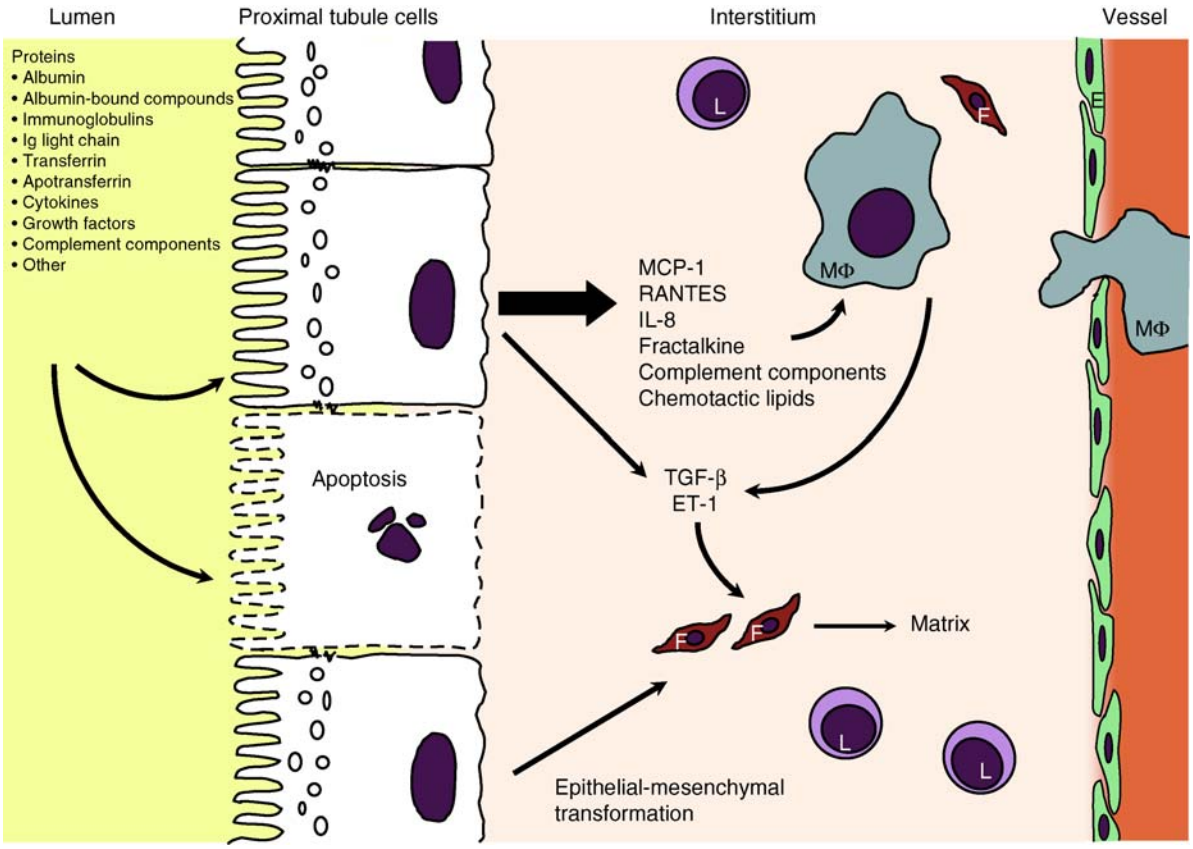
>3 g/day	120	44	13	6

Figure 67-10

Mechanistic links between proteinuria and tubulointerstitial disease. Various proteins that are filtered into the urine during glomerular proteinuria may interact with tubular epithelial cells to trigger the release of proinflammatory and profibrotic molecules, to initiate epithelial-to-mesenchymal transdifferentiation and/or apoptosis. The figure is reproduced from (26).



and complement proteins have been of particular interest. These interactions may induce profound changes in tubular epithelial cells, including synthesis of pro-fibrotic factors such as TGF-β, endothelin-1, angiotensin II; proinflammatory chemokines and cytokines such as MCP-1 and interleukin-8; and they may promote oxidative stress, tubular transdifferentiation and tubular apoptosis.

Obesity

Morbid obesity itself is associated with a significant risk of glomerulomegaly and glomerular pathological changes. Based on pre-operative studies in patients undergoing bariatric surgery, focal segmental glomerulosclerosis may even be present without proteinuria (27). Epidemiological studies have reported a strong positive correlation between excess body fat and relative risk of ESRD, ranging from 1.9 for overweight individuals to 7.1 for those who are morbidly obese (28). The pathogenesis of the renal disease appears to involve hemodynamic and other factors that develop as a consequence of associated features of the metabolic even in the absence of overt diabetes.

Dyslipidemia

Lipoprotein abnormalities are common in patients with CKD; the specific profile varies depending upon the nature of the primary kidney disease and the use of certain medications. In animal models, hypercholesterolemia is associated with accelerated CKD progression. Human epidemiological data support an association between dyslipidemia, cardiovascular disease and faster rates of renal functional decline (29). A recent study identified hyperlipidemia as a predictor of more rapid renal deterioration after lung transplantation (30). In experimental studies, statin drugs have been shown to confer significant

renoprotection that appears to extend beyond its cholesterol-lowering effects. Amongst their recognized pleotrophic effects, inhibitors of inflammatory pathway signaling molecules are important. Evidence that statins delay CKD progression in humans is less compelling. A meta-analysis by Sandhu concluded that the intrinsic anti-proteinuria and renoprotective effects of statins reached statistical significance but differences were quantitatively small (29). A more recent meta-analysis by Strippoli et al. (31) concluded that statins reduced cholesterol levels and proteinuria but did not improve GFR or all cause mortality. After initial concerns about their safety for use in children, several statin drugs are now approved for use in children over 10 years of age, but data are not yet available to address their renoprotective efficacy and safety in this age group.

Mineral Homeostasis

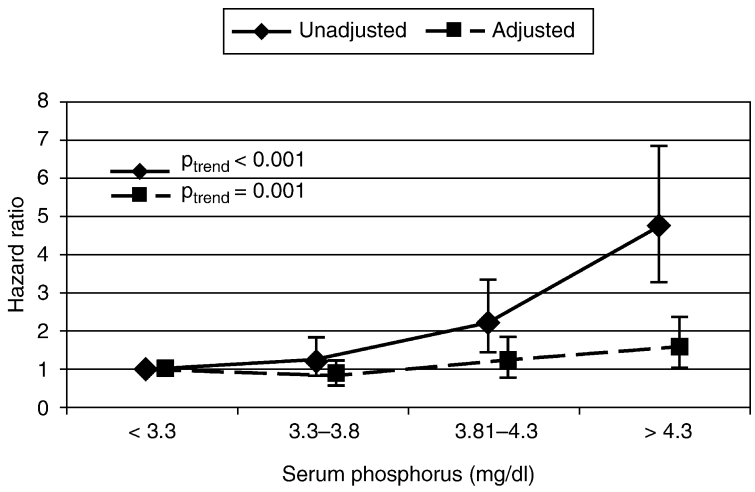
Dystrophic calcification is an important pathogenetic mechanism leading to vascular and bone disease associated and significant morbidity and mortality in CKD patients. There is reasonable evidence from both animal models and human epidemiological studies that hyperphosphatemia is an independent risk factor for more rapid renal functional decline. In a study of adult male veterans, every 1 mg/dl increase in serum phosphorous above normal was associated with an adjusted hazard ratio of 1.29 for the composite renal end-point of dialysis or serum creatinine doubling (*Fig. 67-11*) (32). Suggested mechanisms include metastatic calcification due to calcium phosphorous crystal deposition in tubular mitochondria and the renal interstitium. Recent studies by Giachelli et al. (33) have shown that hyperphosphatemia directly induces smooth muscle cell mineralization via a process that involves the type III sodium-dependent phosphate co-transporter Pit-1. These effects of phosphorous are believed to contribute to uremic vascular calcification and accelerated atherosclerosis. It is possible that similar effects on renal parenchymal cells also contribute to CKD progression.

Hyperuricemia

Elevated uric acid levels may be present in patients with CKD, but whether this is a primary or secondary event is unclear. Recent studies suggest a potential pathogenetic link between hyperuricemia and essential hypertension. Although studies in animal models support an association between hyperuricemia and renal structural damage, human data are conflicting. In a study of IgA nephropathy patients, hyperuricemia at the time of biopsy was identified as a risk factor for disease progression (34). In a cohort of Japanese patients, hyperuricemia was an independent predictor of ESRD in females (adjust hazard ratio 5.8) but not males (35). Large adults studies have reported a significant but weak association between hyperuricemia and CKD prevalence (36, 37) while a recent study of 177 adults with non-diabetic CKD by Sturm

Figure 67-11

Hyperphosphatemia increases the risk of renal functional decline. When serum phosphorus levels were divided into quartiles in a group of males with CKD, higher phosphorus trends (P_{trend}) were associated with a greater risk of renal functional deterioration (ESRD or serum creatinine doubling) even after adjusting for 15 known progression risks factors (Adjusted). The data are reproduced from (32).



et al. (38) did not identify uric acid levels as an independent predictor for CKD progression. Experimental studies suggest that in addition to urate nephropathy due to intratubular crystal deposition, uric acid may have damaging effects on smooth muscle and vascular endothelial cells that contribute to renal dysfunction (39).

Smoking

Limited experimental evidence suggests that smoking may be an additional risk factor for functional deterioration. Smoke exposure induces glomerulosclerosis in aging estrogen-deficient mice (40). Mesangial cells are known to express nicotinic acetylcholine receptors and to undergo mitosis and increased fibronectin synthesis in response to nicotine (41). Clinical data support a potential association between smoking and declining renal function, but it is unclear if smoking is an independent risk factor or if its effects are mediated indirectly via vascular or oxygen-dependent effects (42).

Anemia

Hypoxia and oxidant stress are recognized as fundamental pathways contributing to renal fibrosis, as discussed further below. It therefore seems reasonable to suggest the degree of anemia may influence these pathways. Clinical trials with erythropoietin have begun to address the relative importance of anemia as an independent progression factor. Comparing outcomes in patients with mild to moderate CKD, recombinant erythropoietin has been found to significantly slow renal disease progression in some but not all studies. Data from pediatric clinical trials are not yet available. Interpretation of the results is complicated by the fact that in addition to erythroid progenitor cells, erythropoietin receptors are expressed in several tissues including the kidney (43). Erythropoietin is now known to have cytoprotective effects in several organs suggesting a potential for renal protection that may extend beyond anemia correction.

Mechanisms of Renal Fibrosis: Insights from experimental studies

Overview

The fundamental process of renal fibrosis recapitulates wound healing at the cellular and molecular levels. Like superficial cutaneous wounds, minor kidney injury can completely resolve if the inciting event is short-lived; while severe and/or sustained damage typically leaves a scar. Recent evidence supports the view that the loose scaffold of extracellular matrix proteins that constitutes the early scar may be remodeled allowing fibrosis to regress. Evidence of at least partial reversible renal fibrosis comes from experimental studies of the tubulointerstitium in acute tubular necrosis, puromycin-induced reversible nephrotic syndrome and reversible ureteral obstruction; and glomerular studies of human and experimental diabetic nephropathy and pharmacological inhibition of the renin-angiotensin-albosterone system, especially in the remnant kidney model (44–47). Well-organized advanced scars may contract but there is no evidence that they can be degraded. Preservation of intact and functional nephrons to maintain glomerular filtration is more relevant than fibrosis reversibility. An advanced understanding of pathways of renal inflammation, fibrogenesis and tissue regeneration will most certainly lead to innovative and more effective therapies for CKD in the future.

Mechanisms of Renal Fibrosis: Cellular Pathways

Macrophages All chronic kidney diseases are characterized by an interstitial infiltrate of mononuclear cells. Although there is a population of resident interstitial macrophages in normal kidneys, these cells are considered terminally differentiated; their expansion by proliferation has been reported but is considered unusual. Interstitial inflammation associated with CKD is primarily a consequence of monocyte recruitment from the circulation, entering via the peritubular capillary microcirculation. There is also a well-developed and continuous network of dendritic cells that process antigens and regulate local immune responses (48, 49). Whether dendritic cells are mediators of progressive kidney damage in unclear. Although exposure of "neoantigens" during the primary disease process could conceivably activate an adaptive immune response and perpetrate injury, such a pathway has not yet been clearly identified during the common phase of progressive chronic damage.

Two classes of molecules have important roles during active interstitial inflammation: endothelial-cell associated leucocyte adhesion molecules (integrins and selectins) and a variety of soluble molecules that serve as chemical attractants (cytokines, chemokines, other chemoattractants). Each functions through monocyte membrane receptors that serve to direct inflammatory cell migration. In addition, these ligand-receptor interactions may initiate intracellular signals that regulate other mononuclear cell functions. Since interstitial macrophages in particular are thought to contribute to renal fibrosis, several experimental interventions have been devised to block monocyte recruitment. Targeting various adhesion molecules (ICAM-1, VCAM-1, VLA-1), chemokines or their

receptors (MCP-1, RANTES, MIP-1, fractalkine) and chemoattractants (complement proteins, osteopontin, lipids) has been shown to reduce renal fibrosis.

Macrophages produce several soluble secreted products that may directly promote fibrosis (fibrogenic growth factors such as transforming growth factor-beta [TGF-β], connective tissue growth factor [CTGF], platelet-derived growth factor [PDGF], fibroblast growth factor [FGF], tumor necrosis factor alpha [TNFα]) and certain matrix proteins such as collagen, fibronectin and thrombospondin. They also have the potential to synthesize proteins that may amplify and propagate renal injury such as plasminogen activator inhibitor-1 [PAI-1], angiotensin converting-enzyme inhibitor [ACE], matrix metalloproteinases [MMPs], endothelin-1, complement proteins and reactive oxygen species. Many of these products are also produced by other cells participating in the fibrogenic response.

It has long been known that macrophages also serve alternative roles with the potential to limit the degree of tissue damage and promote healing. These effects often pertain to their ability to serve as scavengers due to their expression of certain membrane receptors that bind, internalize and degrade participants in tissue injury. For example, macrophages are involved in eliminating apoptotic cells. The angiotensin I receptor (ATR1) and the urokinase receptor (uPAR) are examples of scavenging receptors expressed by macrophages that have been shown to attenuate renal fibrosis in mice (50, 51).

The molecular basis of macrophage functional heterogeneity is beginning to be deciphered with the recognition of two distinct activation pathways that are associated with unique functions. These have been labeled as classically activated or M1 macrophages and alternatively activated or M2 macrophages (*Fig. 67-12*) (53, 54). In vitro M1 macrophages can be generated by exposure to interferon gamma or tumor necrosis factor alpha while M2 macrophages are generated by exposure to interleukins -4 and -13. M1 macrophages are typically present during acute tissue damage while M2 macrophages appear during stages of tissue repair and fibrosis. The phenotype of interstitial macrophages associated with renal fibrosis has not been carefully examined, but the recent identification of cell surface markers unique to the M1 and M2 subsets in mice should help to address this question. It is not yet clear if M1 and M2 macrophages derive from a common precursor cell or if one phenotype can transform into another. The differential function of macrophages has been established in a study of reversible liver injury performed by Duffield et al. (55). When macrophages were depleted during the acute injury phase, liver fibrosis was attenuated. If depletion was delayed until the recovery phase, liver fibrosis was more severe. In a crescentic glomerulonephritis model these authors also demonstrated that conditional macrophage ablation on days 15–20 prevented disease progression (56). Differential macrophage function has also been established in a model of persistent nephrotic syndrome in immunodeficient mice. Following ex vivo priming, infusion of M1 macrophages exacerbated while M2 macrophages attenuated disease severity including the degree of interstitial fibrosis (57).

Immunosuppressive medications already in clinical use may help to preserve renal function through macrophage inhibition, even when the primary kidney disease is not immunologically mediated. For example methylprednisone has been shown to reduce interstitial inflammation and preserve renal function in rodent models of polycystic kidney disease while mycophenolate mofetil attenuated interstitial inflammation and fibrosis and lowered serum creatinine levels in the remnant kidney model (58, 59).

Fibroblasts/Myofibroblasts A key event in progressive kidney disease is fibrosis or the progressive accumulation of extracellular matrix (ECM) proteins, especially in the renal interstitium. The primary source of the ECM is a unique population of activated mesenchymal cells that appear to be fibroblasts which also express contractile proteins typically associated with myocytes such as alpha smooth muscle actin (αSMA). The de novo appearance of these interstitial "myofibroblasts" is an essential prerequisite for interstitial fibrosis and has been used clinically as a prognostic indicator in diseases such as membranous nephropathy where renal outcome is highly variable (60). The myofibroblasts produce not only ECM that constitutes the normal interstitial matrix scaffold (such as the fibrillar collagens I and III and fibronectin), but they may also synthesize a variety of proteins not normally present, including glycoproteins, proteoglycans and various matrix proteins more typically found in basement membranes. Transformed mesangial cells appear to play a similar role during glomerulosclerosis.

The origin of these interstitial myofibroblasts is of great interest given their central role in kidney scarring. It appears that they may derive from several different sources (*Fig. 67-13*). Also unknown is whether their origin determines functional diversity. These questions have been difficult to answer due to the lack of specific cell markers to differentiate unique subsets of interstitial myofibroblasts. In normal kidneys, αSMA+ pericytes are associated with arterial and capillary vessels. It is possible that these cells migrate into the interstitium in response to injury. In addition the population of αSMA-negative

Figure 67-12

Macrophage polarization and functional heterogeneity in CKD pathogenesis. Circulating monocytes that enter the kidney in response to inflammatory cues undergo distinctive pathways of differentiation into classically activated M1 macrophages or an alternative M2 phenotype. Activation of M1 inflammatory macrophages by classical immune pathways may lead to the expression of MHC class II antigens and release of pro-inflammatory cytokines. In response to ongoing injury, M1 macrophages propagate inflammation and ultimately the development of fibrosis. Dependant on microenvironmental cues, M2 macrophages may be recruited from the circulation or activated in situ as a result of a M1 to M2 phenotype switch. M2 anti-inflammatory macrophages secrete regenerative trophic factors that promote cell proliferation and reduce apoptosis and stimulate angiogenesis. Macrophages derived from engrafting bone marrow myeloid progenitors may contribute to the repopulation of injured tubular epithelial and glomerular cells by a process of transdifferentiation or cell fusion leading to replacement of damaged cells. Ex vivo modulation of macrophages to a M2 phenotype for transplantation may be used therapeutically to suppress the immune response and promote tissue remodeling leading to structural repair and functional recovery. Reproduced from (52).

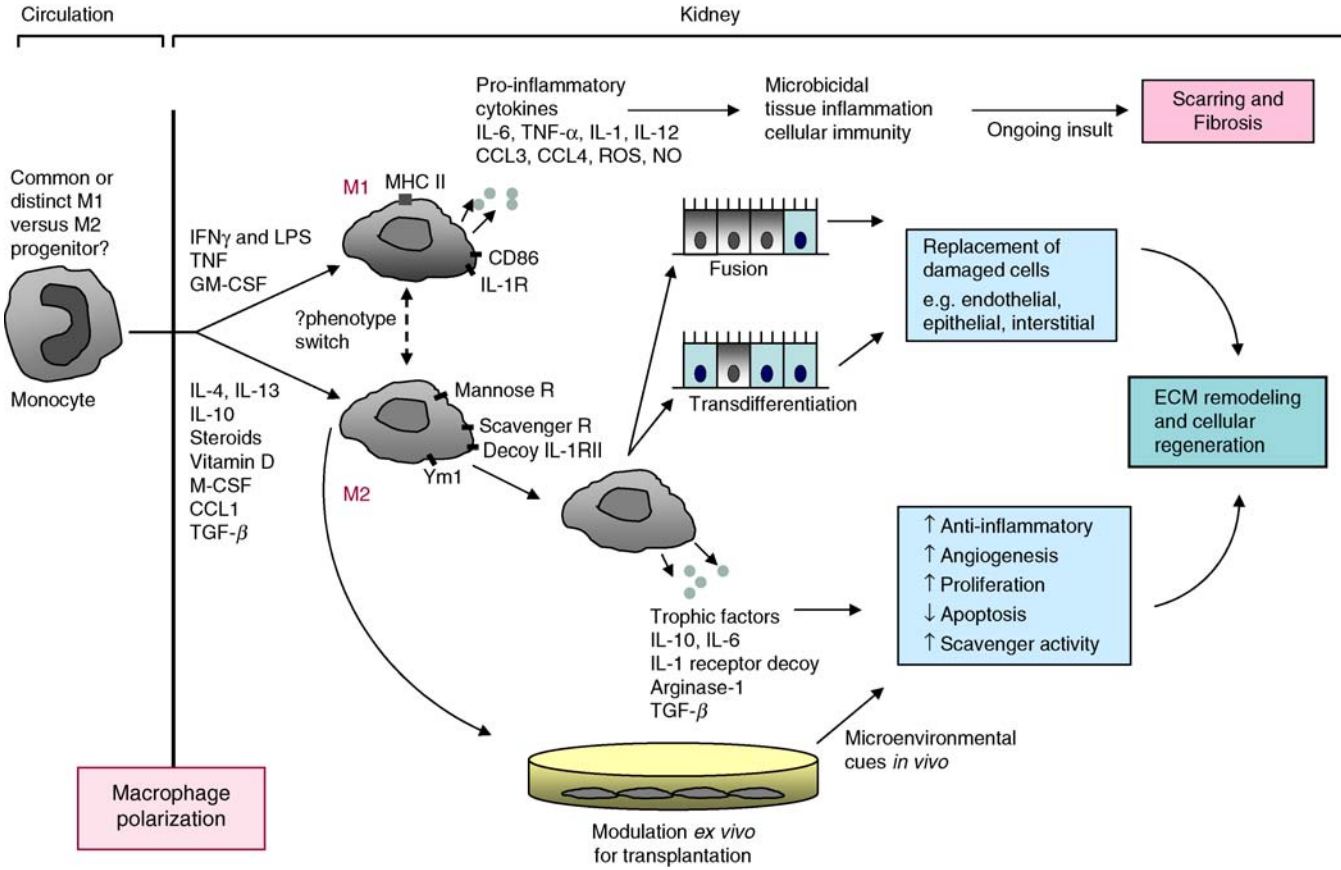


Figure 67-13

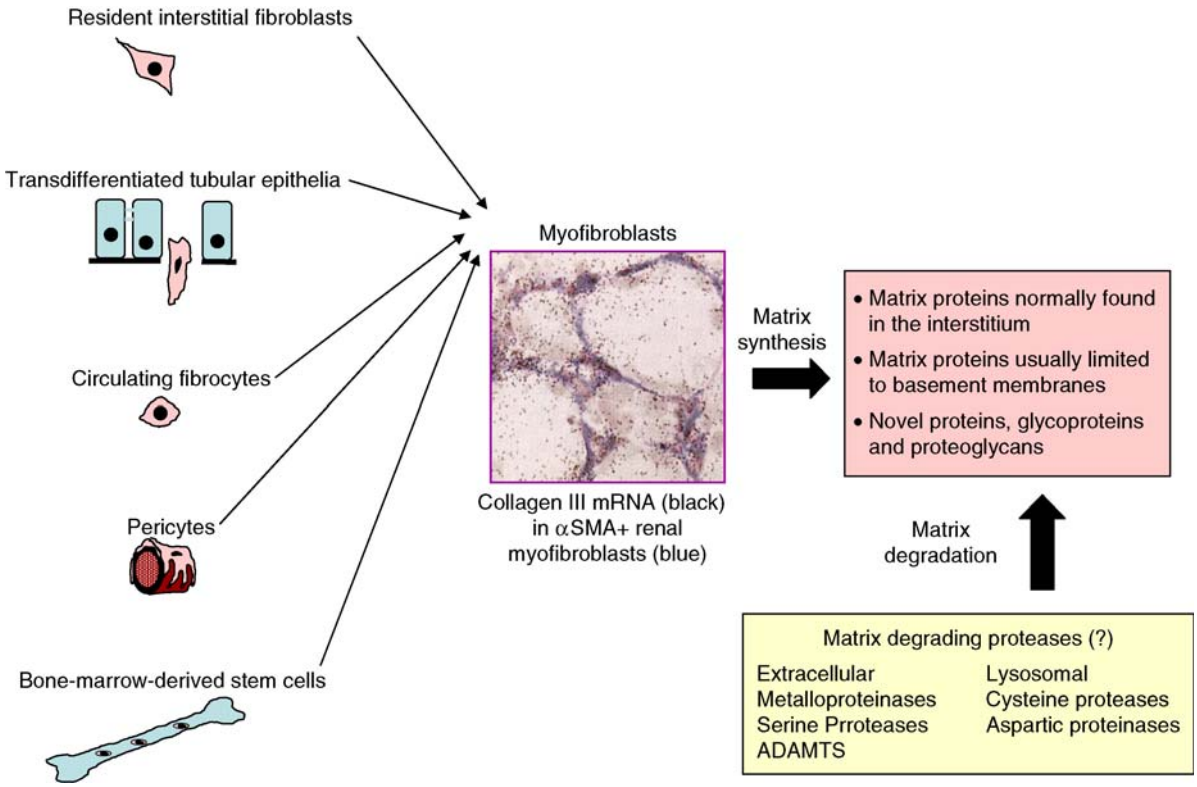
Renal interstitial myofibroblast origins in CKD. Although resident interstitial fibroblasts are considered the primary source of the interstitial myofibroblasts that an important source of scar-forming extracellular matrix (ECM) proteins, four alternative sources have been reported. In addition to increased ECM synthesis, impaired activity of matrix-degrading pathways is also thought to contribute to fibrosis, although the primary protease(s) that perform this function in vivo in the kidney is still unknown. The photomicrograph is from (61). (See color plate 43)



interstitial fibroblasts that reside in the normal interstitium are an alternative source of the population of interstitial myofibroblasts that expand early in the course of chronic kidney disease through processes of activation and proliferation (62). Numerous factors released by damaged kidneys have been shown to function as fibroblasts mitogens in in vitro studies. TGF-β is an especially potent inducer of fibroblasts αSMA expression and matrix protein synthesis.

As renal disease progresses, tubular cells that have undergone a process of transdifferentiation or epithelial-to-mesenchymal transition (EMT) may make their way into the interstitium, where they may be characterized by a myofibroblast-like phenotype and are presumed to contribute to the expanding pool of interstitial matrix proteins (63, 64). The relative contribution of tubular epithelia and resident interstitial fibroblasts and pericytes to the pool of interstitial myofibroblasts is unclear, although it is possible that the latter predominates in early disease and the former in more advanced disease as tubules degenerate. A study in an obstructive uropathy model using of genetically tagged tubular cells provides the most compelling evidence for the EMT process in CKD (65).

A fourth origin of interstitial myofibroblasts is from a blood-borne pool of fibrocytes. It has been established in a study of obstructive uropathy that CCR7+ fibrocytes migrate into the kidney in response the chemokine SLC/CCL21 and contribute to renal fibrosis (66).

Myofibroblasts are presumed to have a finite lifespan. Therapeutic interventions that reduce myofibroblasts numbers by blocking their appearance or hastening their demise should in theory be an effective anti-fibrotic strategy. Blocking the EMT process through the use of hepatocyte growth factor (HGF) or bone morphogenic protein-7 (BMP-7) has been shown to reduce the severity of experimental chronic kidney disease (67, 68).

Tissue-type plasminogen activator (tPA) acting through its receptor low density lipoprotein receptor related protein 1 (LRP1) has been shown in in vitro experiments to block fibroblast apoptosis, while in vivo studies comparing tPA wild-type and knockout mice found that genetic tPA deficiency reduced αSMA^+-cell numbers and fibrosis severity after ureteral obstruction (69, 70). The use of tPA-specific inhibitors may be a therapeutic possibility, although its classical endogenous inhibitor plasminogen activator inhibitor-1 (PAI-1) has several other biological effects that lead to impressive pro-fibrotic effects (71).

Within damaged glomeruli, mesangial cells may also transform into myofibroblast-like cells (72). The transition from a normal to a sclerotic glomerulus is characterized by important changes in the composition of glomerular ECM that have not yet been fully explored; that is, mesangial matrix expansion and segmental/global glomerulosclerosis have distinct molecular compositions. Glomerulosclerosis is characterized by the accumulation of novel ECM proteins not normally present within the mesangium such as fibrillar collagens I and III. An important distinction is the ease of reversal of an expanded mesangial matrix as seen in acute glomerular proliferative disorders, while sclerotic glomerular lesions are more resilient, although the potential for regression has been reported. In addition to transformed mesangial cells, there are a few studies reporting that inflammatory macrophages and even endothelial cells may co-express smooth muscle cell markers during certain pathological states but the role of these cells as important sources of extracellular matrix proteins during chronic kidney disease is unclear (73, 74).

Microvascular Endothelial Cells Due to active transport and other metabolic activities that take place within a relatively hypoxic milieu, renal tubular health is highly dependent upon an adequate oxygen supply delivered via an extensive peritubular capillary network (75, 76). Although this is a low pressure microcirculation, these cells – together with tubular epithelial cells and the tubular basement membranes – can be considered as a tubulointerstitial barrier unit analogous to the glomerular capillary wall. One of the earliest responses to kidney damage is an increase in permeability that leads to interstitial edema composed of fluid and plasma-derived proteins. Exactly how this plasma exudate contributes to the ensuing fibrogenic response in the kidney is not clear. The presence of fibrinogen and its cleavage to fibrin have been implicated in pulmonary fibrosis. Fibrin not only forms an early provisional matrix upon which additional ECM can expand, but it is also a powerful monocyte chemoattractant. Despite many strong associations between fibrin accumulation and pulmonary fibrosis, its fundamental role has recently been questioned by studies in genetically engineered mice which found that experimental pulmonary fibrosis was similar between fibrinogen wild-type and knockout mice (77). The specific role of fibrinogen and other plasma proteins such as oxidatively modified albumin that leak into the interstitial space during chronic kidney disease has not been determined. Another fundamental unanswered question is what mediates changes in the permeability of the interstitial microcirculation. In other inflammatory models, changes in the expression and/or function of endothelial adherens junction proteins (such as VE-cadherin) and triggers such as thromboxane A2 and the Galphai-coupled receptors CXCR2 and Galphai2 are known to be important (78, 79).

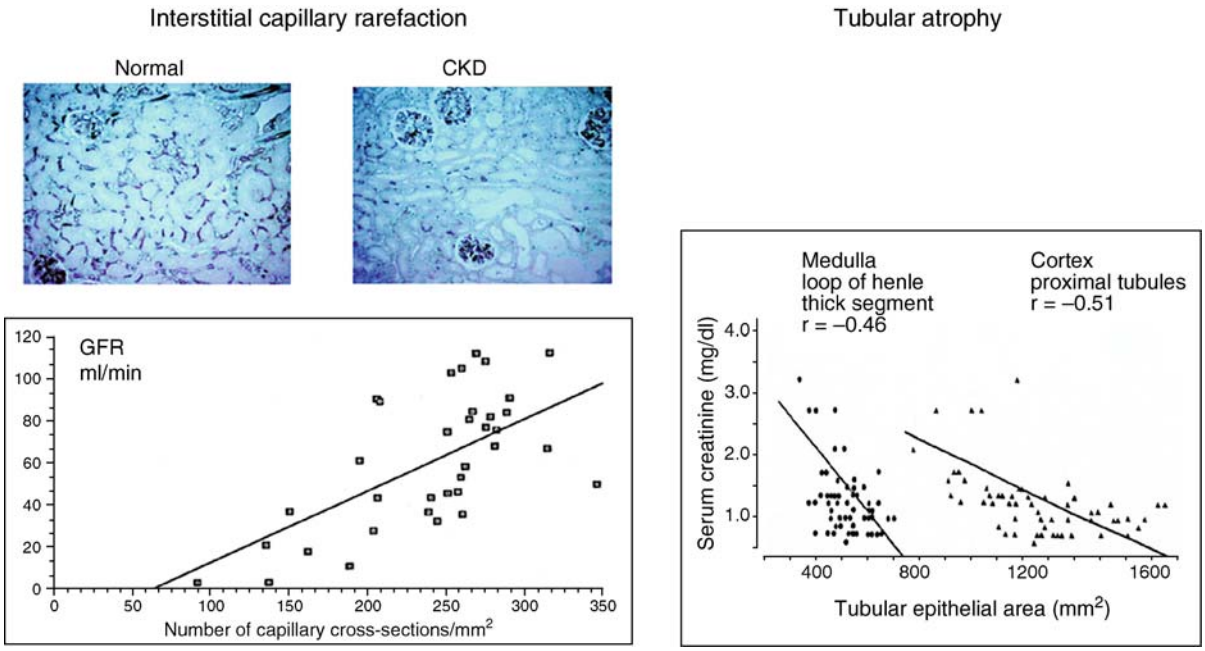
Peritubular capillaries also serve as the conduit for blood-borne inflammatory cells that migrate into the interstitium in response to injury. Locally generated signals may induce endothelial cells to express certain transmembrane proteins that enable them to facilitate this process. In particular, the family of endothelial selectin proteins serve to slow leukocyte flow through capillaries, while specific leukocyte adhesion molecules – such as intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) – in turn form tighter associations between leukocytes and the endothelium, facilitating their transmigration into the interstitium. ICAM-1 and VCAM-1 interacting with their leukocyte counter-receptors (CD11/CD18 and α_4 β_1 leukocyte integrins) also activate intracellular signaling pathways that regulate endothelial cell function.

A perplexing and unique aspect of the renal interstitial microcirculation is its resilience to angiogenesis. Many pathological processes are characterized by excessive angiogenesis, but this is not so in the renal interstitium, where lack of angiogenesis leads to capillary rarefaction in association with renal disease progression as shown when capillary density is mapped using endothelial cell proteins such as the von Willebrand factor, rat endothelial cell antigen RECA-1 or endothelial antigen platelet-endothelial cell adhesion molecule (PECAM) (*Fig. 67-14*) (83). Functional studies suggest that prior to capillary loss vasoconstrictor molecules reduce perfusion leading to tubular ischemia (84).

An inverse correlation between interstitial capillary density and glomerular filtration rate has been reported (80). These findings suggest that therapeutic administration of angiogenic factors to help preserve the interstitial capillary network and tubular oxygenation and to reduce oxidant stress might reduce chronic kidney disease severity. When a long-acting form of the angiogenic factor angiopoietin-1 was administered in an experimental

Figure 67-14

Loss of peritubular capillaries and renal tubules correlates with renal functional decline. Quantitative histological studies of human kidney biopsies demonstrate an inverse correlation between interstitial capillary density, tubular epithelial cell area and renal function. The photomicrographs are kidney sections stained with the endothelial cell antibody JG-12 and demonstrate a striking reduction in the number of peritubular capillaries in the rat remnant kidney model, reproduced from (80). The capillary density graph is reproduced from (81) and tubular epithelial cell graph from (82). (See color plate 44)



model of chronic kidney disease, it bound to the endothelial cell receptor Tie-2, increased interstitial capillary density and reduced the degree of fibrosis (85). Rats with remnant kidneys treated with vascular endothelial growth factor (VEGF) showed improved renal function (80). Placenta-derived cell growth factor (Plgf), an interesting angiogenic factor that is only produced during pathological states including chronic kidney injury (unpublished data) appears to be another potential angiogenic factor worth investigating. As a consequence of tubulointerstitial hypoperfusion, hypoxia and oxidant stress develop and perpetuate renal injury as discussed below in section C.

It has recently been appreciated using histological techniques that important changes in lymphatic vessels are a feature of chronic kidney disease. In normal kidneys, lymphatic vessels are limited to regions around arteries and arterioles. With the recognition that lymphatic but not endothelial capillaries express lymphatic vessel endothelial hyaluronan receptor-1 (LYVE-1) and podoplanin, it has become possible to map the fate of lymphatic capillaries using imaging techniques. In both human and experimental chronic kidney disease, a new network of interstitial lymphatic vessels has been identified (86, 87). The origin and significance of these neocapillaries in CKD pathogenesis awaits exploration.

Renal Epithelial Cells Renal tubules are estimated to account for approximately 80% of the kidney by volume and thus play a central role in chronic kidney disease. Renal tubular atrophy is probably the single most important factor that determines the rate of decline in renal function and final outcome (*Fig. 67-14*) (88). Quantitative evaluation of kidney biopsies from patients with chronic kidney disease demonstrates a strong correlation between glomerular filtration rates and tubular area, both cortical and medullary. The presence of atubular glomeruli is an histological feature of CKD (89). Irreversible degeneration of renal tubules occurs primarily through a process of programmed cell death or apoptosis.

While the tubular epithelia are viable they play multiple roles in the renal response to chronic injury and disease progression. Recent studies have focused on

these cells as active participants in inflammation and fibrosis, but it is also obvious that preservation of normal tubular structure and biological function is key to kidney health and interventions that protect renal tubules should have significant therapeutic benefit for CKD patients.

In addition to their important role as transporters of water and several solutes present within the glomerular ultrafiltrate, renal tubular epithelial cells produce a vast repertoire of molecules that may be modulated by injury and many more that are expressed de novo in response to injury. Renal tubular cells are thought to promote interstitial inflammation via their ability to synthesize chemokines and chemoattractants such as activated complement components. This function has been most extensively investigated in the context of chronic proteinuric kidney diseases (*Fig. 67-10*) (26, 90). Following studies in animal models showing an association between proteinuria and interstitial inflammation, numerous studies have reported that cultured tubular cells exposed to high concentrations of albumin (especially lipidated forms) and other proteins lost by glomerular filtration in glomerular disease states such as transferrin can stimulate expression of chemokines such a monocyte chemoattractant protein-1, interleukin-8 and RANTES. Proximal tubular receptors megalin, cubulin and amnionless are thought to be involved, although the specific signaling pathways and possible role of other receptors has not yet been fully explored (91). It is assumed that these small peptides are able to cross the TBM and find their way into the interstitium, although this has not been definitely shown. Tubular epithelia may also be directly involved in signaling pathways that are activated in response to inflammation by virtue of their ability to express receptors such as toll-like receptor and receptors for members of the interleukin-6 family of receptors, such as gp130 (92, 93). Normally thought to form a watertight barrier that blocks urinary backflow, it is clear that renal injury that disrupts epithelia cell tight junctions and/or glomerulotubular junctions allows urinary products (including those generated by inflamed and diseased glomeruli) to leak into the interstitium and become involved in inflammatory processes. Breaks in Bowman's capsule in association with glomerular crescents is another pathway of communication with the interstitium. Interleukin-1 has been associated with periglomerular inflammation in experimental crescentic interstitial nephritis (94). Increased intratubular pressure due to obstruction may cause early disturbances in tubular cell tight junctions. Leakage of Tamm-Horsfall proteins produced by the thick ascending limb of the loop of Henle into the interstitium has been demonstrated histologically.

As chronic kidney disease transitions from an acute inflammatory to a chronic fibrotic phase, tubular epithelia may take on new roles. They have been shown to produce profibrotic factors such as TGF-β, endothelin-1, angiotensinogen, FGF, CTGF, and PAI-1. They have the capacity to synthesize specific ECM proteins. An important contribution of tubular epithelial cells results from their expression of receptors that may induce EMT upon ligand engagement; these include receptors for transforming growth factor β, angiotensin II, MMP-9, and plasmin. As these transdifferentiated cells find their way into the interstitium through gaps in the TBM they may function as matrix-producing cells that accentuate fibrosis (*Fig. 67-13*).

A recent observation derived from genetic studies of polycystic kidney disease is that normal tubular epithelia cells express a prominent single cilium that is clearly involved in the maintenance of epithelial cell health given the striking phenotypic change that occurs when genetic mutations generate abnormal ciliary-associated proteins (95). The role and fate of tubular cilia in chronic kidney disease is a new area of investigation that is likely to be important.

The resident glomerular epithelial cell, the podocyte, plays a central role in the preservation of normal glomerular capillary wall function. Abnormalities in podocyte function underlie pathologic proteinuria in glomerular disease states (96). There is emerging evidence that proteinuria may in turn modify the function of podocytes in ways that may contribute to glomerulosclerosis (97). Podocytes also produce factors such as vascular endothelial growth factor (VEGF) that appears to be able to travel upstream against glomerular ultrafiltration to reach glomerular endothelial cells (98). This pathway appears critical to preserve the endothelial cell barrier as mice genetically deficient in podocyte VEGF develop chronic kidney disease due to a thrombotic microangiopathic process.

Like tubular epithilia, loss of glomerular podocytes ("podocytopenia") is the common final pathway leading to glomerulosclerosis (99, 100). When podocytes were selectively depleted in a transgenic rat strain in which the human diphtheria toxin receptor was specifically expressed in podocytes, a correlation was found between podocyte number and the number of sclerosed glomeruli (101). However, in contrast to tubular epithelia, glomerular podocytes lack the ability to proliferate except under rare circumstances, making early podocyte loss of considerable concern.

Mechanisms of Renal Fibrosis: Matrix Deposition and Turnover

In normal kidneys, the extracellular interstitial space is barely visible histologically, especially in the renal cortex

where tubules align "back-to-back" with little intervening space. However using antibody-based immunohistochemical staining techniques, small amounts of interstitial collagens and fibronectin can be detected within the normal interstitium. Expansion of interstitial ECM is the fundamental process of kidney fibrogenesis that characterizes progressive kidney disease. An important pathogenetic concept is that the ECM components that constitute the scar participate in a dynamic process. The specific molecular components change with time and those that persist undergo significant biochemical modifications such as forming cross-links between themselves and neighboring proteins. Such alterations make the matricial scar more resistant to protease-based degradation. In addition to forming a scaffold within the interstitium that becomes increasingly dense and rigid over time, this new multi-molecular network has a profound effect on the behavior of adjacent cells and proteins. Hypoxia occurs as a consequence of impaired oxygen diffusion. Inflammatory cells, (myo)fibroblasts, and epithelial cells express cell surface receptors such as integrins that bind to specific ECM proteins and activate intracellular signaling pathways. More recently, other cellular receptors have been identified as matrix-binding, such as the low density lipoprotein receptor-related protein (LRP) and CD36 that bind to thrombospondin and biglycan that interacts with toll-like receptors (102). The term "dynamic reciprocity" has been used to describe this interaction between matrix-synthesizing cells and the modification of the behavior of these same cells in response to their extracellular matrix milieu (103).

Many of the interstitial matrix components that appear de novo in scarring kidneys have unique biological activities that may modulate the fibrogenic response. The profibrotic growth factor TGF-β can be sequestered in an inactive form by binding to the small proteoglycans decorin and biglycan. Alternatively, thrombospondin is known to active TGF-β. Fibroblast growth factor can also be sequestered due to interactions with proteoglycans. PAI-1 binds avidly to vitronectin. Hyaluronan has complex functions that influence inflammatory processes and TGF-β activation (104). PDGF and VEGF bind to secreted protein acidic and rich in cysteine (SPARC).

While this network of ECM develops, a competing enterprise dependent upon the activity of matrix-degrading proteases attempts to remodel and degrade it. Their task becomes more difficult when cross-linking molecular bridges are generated by enzymes such as lysyl oxidase and transglutaminase. Use of transglutaminase inhibitors or genetic transglutaminase 2 deficiency has been shown experimentally to attenuate fibrosis (105, 106). Virtually all of the cells involved in the renal fibrogenic process are involved in the production of these proteases.

There are five primary families of matrix-degrading proteases: the metalloproteinases (MMP) and the serine proteases have been most extensively investigated in chronic kidney disease, but others include lysosomal cysteine proteases and aspartic proteinases and the ADAMTS (a disintegrin and metalloproteinase with thrombospondin motifs) family. The MMPs are a large family with each member having specific preferred matrix substrates. The most abundant kidney MMPs are the gelatinases that effectively degrade basement membrane collagen IV: MMP-2 (inducible) and MMP-9 (constitutive). CKD is associated with collagen IV accumulation in the interstitium. Published research with MMP inhibitors as antifibrotic agents are limited and generally unimpressive, suggesting that endogenous MMP-2 and -9 may not function as interstitial fibrosis inhibitors. In a mouse model of Alport syndrome MMP inhibitors were beneficial if administered before the onset of proteinuria; disease was accelerated if they were started once proteinuria was present (107). This is further supported by the observation that genetic deficiency of endogenous tissue inhibitors of MMPs such as TIMP-1 has no impact on interstitial fibrosis severity despite the fact that TIMP-1 is highly induced by chronic injury (108). In contrast, in the liver TIMP-1 expression has been closely correlated with fibrosis (109).

There are still several studies that need to be performed before the role of the entire MMP family is understood in renal fibrogenesis, although the prospects that MMP activity might be therapeutically manipulated does not appear promising as an approach to CKD. The reason for this may be that MMPs have additional functions that can promote fibrosis (110). The activity of the gelatinases in degrading collagen IV-rich basement membranes has been implicated in glomerular injury and in the tubular EMT process. Several MMPs are involved in regulating chemokine activity during inflammation. Some MMPs serve as ligands for specific cellular receptors (LRP1, integrins) to activate cellular signaling. These alternative activities likely explain why mice genetically engineered to over-express MMP-2 in renal tubules spontaneously develop interstitial fibrosis as they age (111). MMP-7, also known as matrilysin, is expressed by damaged tubular epithelia where it may promote interstitial fibrosis via its ability to cleave E-cadherin and facilitate EMT (112).

Recent studies on the role of the serine protease family in renal fibrogenesis have also led to some surprising findings, including the observation that their roles appear to be organ-specific (113). PAI-1 is expressed by and is

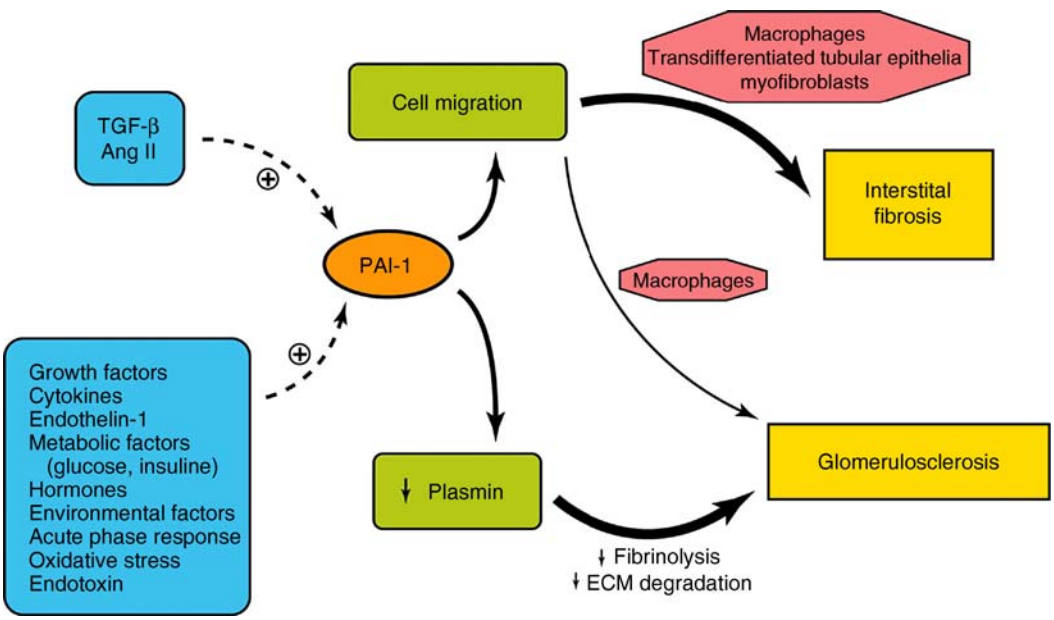
fibrosis-promoting in many solid organs (kidney, liver, lung) but current evidence suggests that in the renal interstitium, this effect is not due to serine protease inhibition (*Fig. 67-15*) (71). Urokinase-type plasminogen activator (uPA) is produced in large quantities by renal tubules but it is secreted across the apical membrane into the urinary space. Chronic injury induced experimentally by ureteral obstruction is associated with a further increase in renal uPA activity. The potential for uPA to mediate anti-fibrotic functions has been ascribed to its ability to degrade certain matrix proteins such as fibronectin, to activate plasminogen and to activate latent hepatocytes growth factor (HGF), an important anti-fibrotic growth factor. The latter action is thought to account for the ability of uPA to reduce pulmonary fibrosis (114). uPA can also serve as a fibroblast mitogen acting through classical (uPAR) and non-classical uPA receptors (LRP1, acetylcholine receptor, for example) (115). However, the observation that uPA deficiency has no effect on fibrosis severity after ureteral obstruction indicates that it plays a non-essential fibrosis-regulating role in the kidney (116). These findings do not negate the possibility that uPA might still be beneficial as a therapeutic agent. It is interesting that uPA has been used in Japan as a treatment for IgA nephropathy (117).

In the tubulointerstitial compartment, plasmin activity has been of interest as a possible anti-fibrotic pathway, especially given its ability to activate certain latent MMPs and to directly degrade matrix proteins, including fibronectin, laminin, tenascin, and perlecan Chronic kidney disease is associated with an increase in renal plasmin activity. However, when the obstructive uropathy model was compared in plasminogen wild-type and knockout mice, interstitial fibrosis was more severe in the wild-type mice (118). This difference was at least in part due to plasmin's ability to activate latent TGF-β and to promote tubular EMT via a process that involved the protease-activated receptor 1 (PAR1) and ERK signaling.

The other classical serine protease, tissue-type plasminogen activator (tPA), is traditionally viewed as an intravascular protease primarily involved in fibrinolysis. However, recent studies indicate that tPA may promote fibrosis in the kidney via at least two distinct mechanisms. tPA can bind to LRP1; when this interaction occurs on fibroblasts, their apoptotic death is inhibited (69). In the extracellular space adjacent to TBMs, tPA activity may

Figure 67-15

Plasminogen activator inhibitor-1 (PAI-1) profibrotic effects in CKD. Renal PAI-1 expression can be induced by a number of factors involved in disease pathogenesis. The ability of PAI-1 to reduce plasmin activity appears to promote thrombotic and necrotizing glomerular lesions, many of which progress to sclerosis. However, within the tubulointerstitium the pro-fibrotic effects of PAI-1 align more closely with its ability to promote cell migration, of monocytes/macrophages, transdifferentiated tubular epithelia and (myo)fibroblasts in particular. The figure is reproduced from (71).



increase MMP-9 dependent-TBM destruction to facilitate EMT and worsen fibrosis (70).

At this juncture it is not at all clear how matrix remodeling occurs normally and in pathological states. However, it is clear that matrix turnover does occur and that even early interstitial fibrosis can be reversed. This has been shown in models of self-limited kidney injury such as acute tubular necrosis and puromycin aminonucleoside nephrosis when mild interstitial fibrosis disappeared with resolution of the primary disease process (44). Recent studies in a model of reversible ureteral obstruction demonstrate that even more advanced fibrosis can partially regress with time (119) (*Fig. 67-16*). Regression of glomerulosclerosis has also been reported (120).

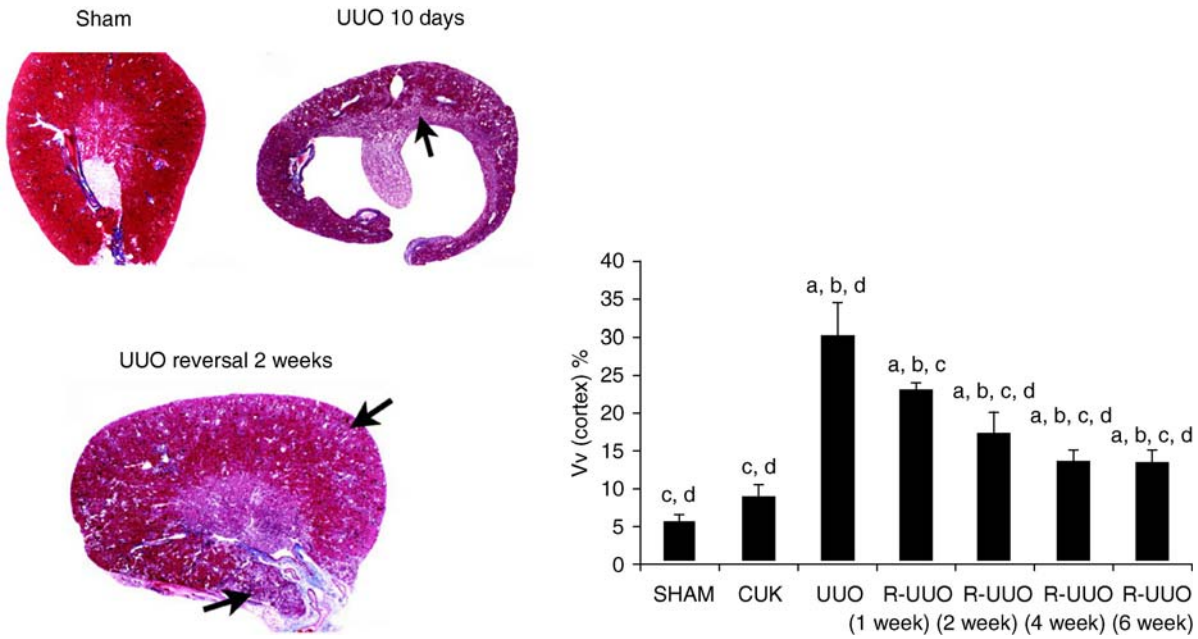
With the recent recognition that the endocytosis receptor Endo180 (also known as uPAR-associated protein) binds to several collagen proteins, it raises the possibility that lysosomal proteases and intracellular degradation pathways may play a significant role in renal fibrogenesis (121). Indeed, we have recently found that renal fibrosis is significantly worse in Endo180 knockout mice (122).

The effects of matrix-degrading proteases may differ in the glomerulus, especially in diseases such as thrombotic microangiopathies where significant fibrin deposition is a factor. In these situations, the serine proteases may play a significant role in reducing glomerulosclerosis. Glomerular PAI-1 expression is also an important harbinger of glomerulosclerosis, though the extent to which its role in glomeruli is dependent on protease inhibition or other biological effects is unclear (*Fig. 67-15*) (71). Certain members of the MMP family, such as MMP-2, have been shown to interact directly with mesangial cells, inducing proliferation and activation pathways (123). Thus, much more needs to be learned about the mechanisms involved in remodeling mesangial matrix in areas of glomerular fibrosis. Megsin is a unique serine protease inhibitor that has been identified in human glomerulopathies associated with mesangial cell proliferation and matrix expansion. Megsin transgenic mice develop glomerular lesions (124). Although it inhibits plasmin, it is not clear if this or other biological actions of megsin underlie mesangial matrix expansion in the transgenic mice. Its role in glomerulosclerosis remains unclear.

An emerging story of interest is that several small peptides derived from ECM proteins have significant effects on angiogenesis. These include the inhibitors arresten, canstatin and tumstatin derived from collagen

Figure 67-16

Renal fibrosis regression. Studies in a mouse model of reversible unilateral ureteral obstruction (UUO) illustrate the potential for fibrosis regression (as shown in the interstitial cortical volume [Vv cortex] graph) and reconstitution of renal tubules (shown in the photomicrographs) after UUO was released (R-UUO). The figures are reproduced from (119). (See color plate 45)



IV (125). Angiostatin, an internal fragment of plasminogen, and thrombospondin also inhibit angiogenesis. These observations suggest that there may be a close interplay between matrix turnover and angiogenesis in the renal interstitium. Pathways that preserve the interstitial microcirculation should help to attenuate fibrosis severity.

Mechanisms of Renal Fibrosis: Oxidant Stress

Reactive oxygen species have long been implicated in the pathogenesis of acute ischemic renal diseases such as acute tubular necrosis. The best clinical translation of this information is the use of the antioxidant N-acetylcysteine to prevent contrast-induce nephropathy (126). Beginning with studies in diabetic nephropathy, the importance of oxidant stress as a participant in kidney disease progression has been increasingly recognized. However the metabolic, cellular and molecular pathways involved are complex and thus the specific pathogenetic mechanisms in CKD are far from clear.

Oxidant stress is usually triggered by hypoxia and characterized by the production of reactive oxygen species (ROS)* due to the presence of an unshared electron pair: oxygen (O_2) → superoxide (O_2-)* → hydrogen peroxide (H_2O_2) → hydroxyl radical ($OH^{\cdot}$)* → water. CKD is characterized as an "oxidant stress" state systemically as well as locally within the kidney (127). ROS may oxidize DNA, proteins or lipids with important functional consequences. It is increasing recognized that ROS may also modulate intracellular signaling responses to potentiate tissue injury (128). Despite its high blood flow, tissue oxygen tension is rather low in the kidney (30 mm Hg in the cortex; 10 mm Hg in the medulla) making it especially vulnerable to hypoxic injury.

Summarized in *Fig. 67-17* are the four primary pathways that can induce oxidant stress: the classical pathway activated by mitochondrial dysfunction; the chlorinated pathway dependent on myeloperoxidase activity typically associated with inflammation; nitrosative stress that occurs when nitric oxide is available to produce reactive nitrogen species such as peroxynitrate (a situation that also depletes nitric oxide, a potentially beneficial product); and, the carbonyl stress that occurs when glucoxidation generates advanced glycosylation end-products (AGE). Iron catalyzes $OH^{\cdot}$ production via the Haber-Weiss reaction. There is experimental evidence that tubular iron accumulation (as a consequence of transferrin filtration during proteinuric states for example) enhances tubular damage and renal dysfunction (127).

Tissues have developed an array of antioxidant defense mechanisms that include catalase, glutathione peroxidase and superoxide dismutase. Thus intrarenal oxidant stress may also occur as a consequence of reduced activity of endogenous antioxidants.

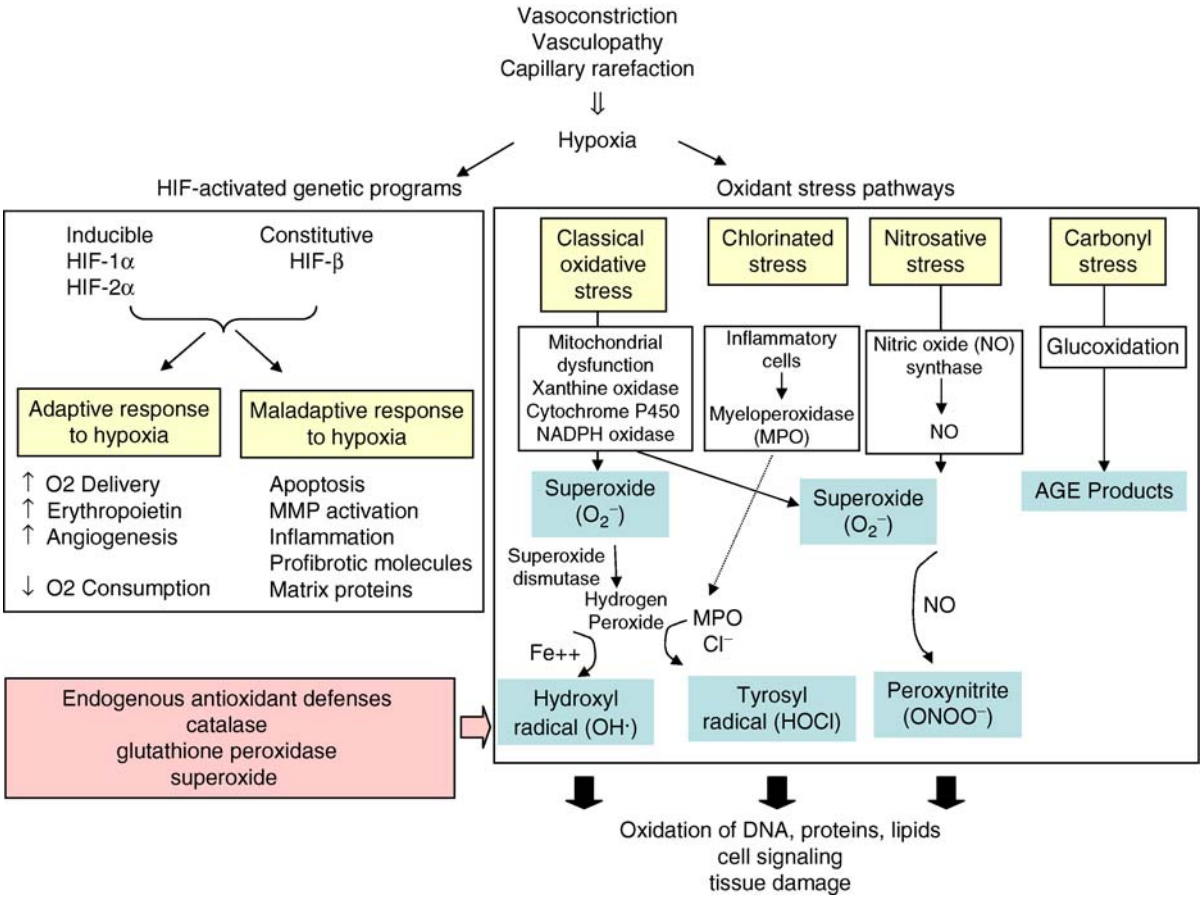
Another important consequence of renal hypoxia that may contribute directly to fibrosis is the activation of the hypoxia inducible factor (HIF) transcription factors (*Fig. 67-17*). HIF-β is constitutively and ubiquitously expressed; HIF-α expression (3 isoforms) is induced by hydroxylation in response to hypoxia. Numerous genes express HIF-responsive elements. Many of them encode proteins that allow cells to survive in a low oxygen environment such as erythropoietin, angiogenic factors, vasoactive molecules and proteins that promote anaerobic energy metabolism. However other HIF-dependent responses can lead to inflammation, EMT and fibrosis (129). The HIF-α isoforms are differentially expressed; in a model of acute renal ischemia HIF-1α was detected in tubules while HIF-2α was associated with erythropoietin-producing interstitial fibroblasts (130). Genetic deletion of renal tubular HIF-1α inhibited interstitial fibrosis (131). More work is needed to determine if these differential expression patterns occur in CKD and activate distinct genetic programs.

Much remains to be learned about the cellular and molecular basis of oxidant stress-induced kidney injury. Protein and lipoprotein modifications by reactive oxygen species is presumed to have significant functional consequences, yet most of the specific molecular targets remain to be identified. One known reaction produces oxidized low density lipoprotein (oxLDL). While hyperlipidemia is common in CKD patients, oxLDL may be generated within damaged kidneys even when serum lipoprotein levels are normal, due to an imbalance in the endogenous kidney pro-oxidant and antioxidant systems. Unlike native LDL that binds to LDL receptors primarily expressed in the liver, oxLDL bind instead to a unique family of scavenger receptors that are expressed by inflammatory and endothelial cells. These interactions play an essential role in atherogenesis and similar events within the kidney contribute to CKD progression. Renal tubular epithelial cells have recently been identified as an important source of scavenger receptors that are activated by oxLDL (132). Scavenger receptors (SR) are currently divided into 7 families (A – G), only some of which bind oxLDL. The later include receptors in class A (SR-AI, SR-AII), class B (CD36), class D (CD68), class E (LOX-1) and class G (SR-PSOX/CXCL16).

The classical macrophage scavenger receptor (SRA) and CD36 are the primarily oxLDL receptors implicated in atherogenesis; both are expressed by macrophages and renal tubular cells. Studies comparing renal outcomes in

Figure 67-17

Functional consequences of renal hypoxia in CKD progression. Schematic summary of the hypoxia-response pathways that are activated in chronically damaged kidneys and thought to perpetuate renal damage. The hypoxia-inducible factors (HIF) are a family of transcription factors that regulation the expression of a large number of genes, many of which are detrimental to the kidney. In addition, four distinct pathways synthesize several reactive oxygen species that contribute to ongoing kidney injury.



wild-type and CD36-deficient mice have identified CD36 as an important profibrotic pathway. Obstructed kidneys of CD36-deficient mice are characterized by lower levels of the pro-inflammatory transcription factor nuclear factor kappa B (NFκB) and lower levels of cytochrome C and hypochlorous acid halides, indicating reduced activity of pro-oxidant pathways and by significantly less interstitial fibrosis compared to wild-type mice (133).

Elucidating the expression and function of other scavenger receptors in chronic kidney disease is incomplete. Lox-1 is normally expressed by endothelial cells but tubular expression has been observed in response to obstruction and diabetes (132, 134). Dyslipidemia is also thought to contribute to the genesis of glomerular inflammation and fibrosis via an activating effect on macrophages and mesangial cells although little is known about the cellular pathways involved (135, 136). There is considerable experimental evidence that inhibition of 3-hydroxy-3-methylglutaryl CoA reductase by statins attenuates CKD but it is not clear if this occurs as a consequence of cholesterol reduction or other effects since these drugs have also been shown to blunt inflammation and/or fibrosis via other mechanisms.

Mechanisms of Fibrosis: Pro-Fibrotic Molecules

Clearly, there are a multitude of molecules that are activated in order to execute a full fibrogenic response (*Fig. 67-3*). A key question is which molecules initiate this cascade of events? At present, most pathways incriminate TGF-β. This growth factor plays a vital role

in wound healing responses and immune surveillance. Due to transplacental transport and secretion into breast milk, TGF-β genetically deficient mice are normal until weaned. Thereafter, they die within a few weeks due to a systemic inflammatory disease and cardiopulmonary failure (137). In the absence or TGF-β, advanced fibrosis may not occur although experience with the mice illustrates the dangers inherent in systemic TGF-β inhibition. Understanding mechanisms of TGF-β activity thus becomes critically important if novel therapeutics are to be developed (138, 139). TGF-β (tissue fibrosis is primarily associated with the TGF-β1 isoform) is produced as a latent molecule that can be activated by different agents, including the proteases (cathepsins, plasmin, furin, MMP), thrombospondin and αvβ6 integrin. Monocytes and macrophages are a major cellular source; some intrinsic renal cells may also produce TGF-β and they all express its receptors. Binding to decorin, biglycan (accumulating in the interstitium) or soluble TGF-β receptors inhibits TGF-β activation. This information has been used successfully as therapeutic interventions in experimental CKD models to inhibit TGF-β activity and reduce fibrosis severity.

The active form of the growth factor requires a dimeric receptor complex: the type II receptor captures the ligand and interacts with receptor I to initiate phosphorylation and intracellular signaling (140). Several intracellular pathways appear to be involved, activated by phosphorylation of serine threonine kinase activity of the TGF-β RI. The Smad 2/3 signaling pathway is typically implicated in profibrotic responses. Mice with genetic Smad3 deficiency develop significantly less fibrosis after ureteral obstruction (141). An important endogenous inhibitor of the Smad 2/3 pathway is Smad7. Interventions that increase renal Smad7 levels reduce fibrosis severity (142). There are additional endogenous pathways that block TGF-β-dependent fibrosis including Smurf, SnoN and Ski. Numerous target genes that promote fibrosis are activated by this pathway, including matrix genes, integrin receptors, tubular cell transdifferentiation pathways and fibroblast activation. Some effects of TGF-β are dose-dependent and cell and tissue specific. These include cell proliferation and apoptosis. In particular, fibroblasts may proliferate while epithelial cells undergo apoptosis – both with negative consequences in the tubulointerstitium of a damaged kidney.

Two TGF-β target genes deserve further mention due to their own intrinsic fibrosis-promoting effects that may amplify the fibrogenic cascade. The first is connective tissue growth factor (CTGF), also known as CCN2, a protein induced by TGF-β that promotes fibrosis via interaction with its receptor LRP1. CTGF has been reported as increased in a variety of human and animal models of chronic kidney disease and implicated in renal fibrosis (143).

The other TGF-β-regulated protein is PAI-1, which is often induced when TGF-β is active. Not detected in normal kidneys, PAI-1 is typically present in glomeruli undergoing sclerosis and within scarring interstitial regions. In addition to TGF-β, numerous other PAI-1 agonists are known (*Fig. 67-15*) (144). Another serine protease inhibitor, protease nexin-1 is often up-regulated together with PAI-1. Expression of protease nexin-1 has also been reported in mice with cryoglobulinemic nephropathy but its functional role has yet to be determined (145). That PAI-1 plays a significant role in CKD has been shown in studies of obstructive nephropathy in genetically engineered mice: PAI-1 deficiency reduces fibrosis while PAI-1 over-expression exacerbates fibrosis (71). In experimental models of glomerulonephritis and diabetic nephropathy, mesangial matrix expansion is blocked by a mutant PAI-1 peptide that functions as an antagonist of endogenous PAI-1 (146).

Many cells can produce PAI-1. Hepatic production occurs as an acute phase response. Adipose tissue is another important source of PAI-1 (147). PAI-1 mRNA is not detected in normal kidneys but in response to injury inflammatory cells, glomerular cells, tubular cells and myofibroblast may produce it (71, 144). Exactly how PAI-1 promotes fibrosis is still under investigation, but recent data suggests that in the tubulointerstitium its ability to facilitate the recruitment of myofibroblasts and macrophages is most important. This is a complex process that involves PAI-1 interactions with vitronectin, the urokinase receptor and some of its co-receptors (integrins and LRP1 in particular). The classical urokinase receptor (uPAR or CD87) is a complex receptor that does not signal alone. Working in collaboration with LRP1, it serves as the only currently known endocytic degradation pathway for PAI-1 which may explain in part why renal fibrosis after ureteral obstruction is more severe in uPAR-deficient mice (113).

Two molecular pathways are of particular interest as potent TGF-β agonists, as they are highly expressed in the kidney during fibrotic reactions and orally active inhibitors are already available for clinical use in humans: the renin-angiotensin system and the endothelin system. In addition to its important role in blood pressure regulation, all components of the renin-angiotensin-aldosterone system (RAAS) are expressed locally within the kidney and are often activated in CKD. Coupled with the local expression of the angiotensin II (ATII) receptor, aldosterone and renin receptors this local system makes an

important contribution to initial as well as ongoing kidney injury (148). ATII receptor signaling is known to induce the expression of several inflammatory and fibrogenic signals, especially TGF-β. There is also evidence that it can directly stimulate matrix protein synthesis. These effects likely explain why beyond their important antihypertensive effects, angiotensin converting enzyme inhibitors (ACE) and angiotensin receptor blockers (ARB) have impressive renoprotective effects. Numerous experimental studies have documented the ability of ACE and/or ARB therapy to reduce TGF-β activity and renal fibrosis severity. These observations are supported in mice with genetically-regulated differences in the activity of the RAAS system. The RAAS also regulates rates of urinary protein excretion which are closely associated with the severity of tubulointerstitial inflammation and fibrosis. Since polymorphisms in ACE-encoding gene are associated with enzyme activity levels (highest with the deletion [D] and lower with the insertion [I] variants), there has been considerable interest in ACE genotyping as a determinant of CKD outcomes. Results have been highly variable, perhaps due to ethnicity differences (148).

In addition to its role in regulating angiotensin II levels, the ACE degrades bradykinin. Some of the renoprotective effects of ACE inhibitors may be attributed to increased bradykinin levels. Mice with impaired bradykinin responses due to a genetic bradykinin B2 receptor deficiency or treatment with a receptor blocker develop severe fibrosis in response to ureteral obstruction (149).

In addition to its vasoconstrictor properties endothelium-1 (ET-1) is known to promote inflammation and fibrosis in damaged kidneys (150). ET-1 transgenic mice are not hypertensive yet they develop progressive renal fibrosis. Tubular ET-1 production in response to proteinuria has been suggested as one mechanistic link between glomerular with progressive tubulointerstitial disease (26). Orally active ET-1 receptor (ETA and ETB) blockers have been reported to reduce renal fibrosis although ETB blockade appears to accelerate renal cystic disease (151).

Platelet-derived growth factor (PDGF) is known to exist in four isoforms (A to D). PDGF is a potent mitogen for mesangial cells, which likely account for its role in proliferative glomerular diseases (152). In chronic tubulointerstitial disease, tubular and interstitial cells produce PDGF-B, -C and –D and express both receptors (PDGFR-α and -β). Genetic ablation of several members of the PDGF family causes embryonic death. Renal interstitial abnormalities were observed in the face of combined PDGF-A and -C or PDGFR-α deficiency. Up-regulated PDGF expression has been reported in several human kidney diseases as well as animal models. Infusing rats with high doses of PDGF-B rapidly induces the appearance of interstitial myofibroblasts. Evidence that PDGF contributes to interstitial fibrosis comes from studies in experimental models using neutralizing antibodies to PDGF-AB or –C or –D or a PDGF-B-specific oligonucleotide aptamer (152). The PDGF receptor kinase blocker imatinib has been protective in several models of CKD but not in renal ischemia/reperfusion injury. PDGF-B is also known to be a potent mesangial cell mitogen that is up-regulated in several proliferative glomerular diseases. Its interaction with mesangial cells also induces the synthesis of several pro-inflammatory and pro-fibrotic proteins.

Additional cytokines, growth factors and hormones have been implicated in fibrogenesis. Basic fibroblast growth factor (FGF-2) expression has been associated with podocyte injury and glomerulosclerosis; and with fibroblast proliferation, EMT and interstitial fibrosis (153, 154). Increased expression acidic of FGF (FGF-1) by inflammatory cells and its receptor FGFR-1 by renal tubules has been reported in human chronic kidney diseases. Interleukin-13 (IL-13) is fibrogenic in the liver and the lung due to its ability to induce TGF-β expression and activation. The soluble decoy receptor IL-13Rα2 can attenuate fibrosis progression in these organs. However, in the kidney IL-13 has been shown to have renoprotective effects in acute models of injury associated with inflammation such as ischemia-reperfusion, transplantation and crescentic glomerulonephritis while infusion of an IL-13-expressing expression vector induced minimal-change-like nephropathy (155–157). Further studies are needed to delineate the role on IL-13 in CKD. Epidermal growth factor (EGF) can induce cell proliferation, migration and collagen synthesis. Interaction with its receptor EGF-R, which also binds transforming growth factor (TGF)-α, has been shown to play a role in the development of renal cysts (158). Mice lacking TGF-α or over-expressing a dominant-negative EGF-R develop less fibrosis in experimental kidney disease models (159, 160). The pro-inflammatory cytokine tumor necrosis factor (TNF)-α is of current interest due to the availability of biological neutralizing agents available for use in humans. Mice with a genetic deficiency of TNF-α receptors (TNFR1 or TNFR2) developed less inflammation and fibrosis after ureteral obstruction while TNF-α blockade with a neutralizing antibody or soluble receptor was reported to reduce glomerulosclerosis and interstitial fibrosis respectively (161–163). It may be that the pro-fibrotic effects of TGF-α occur as a secondary consequence of persistent inflammation. Tubular expression of parathyroid hormone-related protein (PTHrP) has been detected in

both and chronic models of renal injury. Evidence that it promotes renal fibrosis comes from studies in transgenic rats that over-express PTHrP in renal tubules and develop more severe inflammation and fibrosis following renal injury (164).

Deciphering intracellular signaling pathways has identified specific molecular targets that might be accessible to therapeutic agents that are able to penetrate cell membranes. Smad 2/3 inhibition or deficiency reduces the fibrogenic effects of TGF-β. Drug inhibitors of p38 mitogen-activated protein kinases (MAPK), Ras-Raf-Mek-Erk and the Rho kinase ROCK have reduced renal fibrosis in experimental models (165). Protein kinase C inhibitors have reduced interstitial fibrosis in experimental diabetic nephropathy. Recently the Notch-1 pathway has been shown to play a role in proteinuria and glomerulosclerosis (166). Toll-like receptors (TLR) can activate fibroblasts into collagen-producing myofibroblasts suggesting that TLR signaling pathways may contribute to renal fibrosis (167).

Anti-Fibrotic Factors

Several endogenous pathways have been shown to attenuate renal fibrosis severity. Some of these are expressed within normal kidneys and chronic kidney injury is associated with activity down-regulation. Others may not have significant renal expression but systemic administration has been shown to be protective. Hepatocyte growth factor (HGF) activity has impressive anti-fibrotic effects as shown in studies of HGF-deficient mice or by therapeutic HGF administration (67). HGF can be synthesized by a variety of cells. Latent HGF requires proteolytic activation and how this is accomplished in the kidney is still unclear. In the lung but not the kidney uPA appears to be an important activation pathway (114). Endogenous HGF activator inhibitors (HAI-1 and -2) are known to be key regulators of HGF activity, but whether this pathway is important in the kidney is unknown. Relevant to its ability to prevent fibrosis, HGF blocks TGF-β-induced tubular EMT and it has significant anti-inflammatory properties.

Bone morphogenic protein-7 (BMP-7) is produced by normal renal medullary tubules. Kidneys of mice with genetic BMP-7 deficiency fail to develop normally, leading to death in the neonatal period. Recombinant BMP-7 therapy has been shown to attenuate renal fibrosis through activities closely associated with tubular EMT blockade (168). Kidneys also express molecules that modify endogenous BMP-7 activity such the inhibitor uterine sensitization-associated gene-1 (USAG-1) (169). USAG-1 knockout mice developed less fibrosis after ureteral obstruction.

Relaxin is an endogenous hormone of the insulin-growth factor family that is produced in several organs including the kidney. It inhibits TGF-β-induced matrix production and promotes fibronectin degradation (170, 171). Relaxin-deficient mice spontaneously develop renal fibrosis with aging and manifest worse fibrosis after ureteral obstruction (172, 173) while exogenous relaxin therapy had renoprotective effects in several experimental models. Heme oxygenase-1 (HO-1) is an ubiquitous intracellular enzyme that is induced by a wide variety of stimuli (174). HO-1 has important cytoprotective actions that relate in part to its role in heme degradation and to the effects of its reaction products (carbon monoxide, biliverdin, bilirubin). Antioxidant, anti-inflammatory, anti-proliferative, anti-apoptotic and vasoactive properties have been reported that may be relevant to renoprotection in CKD. Interferon gamma (IFNγ) has been associated with anti-fibrotic properties in a variety of organs but there are less data available for CKD. In a remnant kidney model IFNγ therapy was reported to reduce glomerular and interstitial fibrosis Other agents that have been associated with anti-fibrotic effects in experimental models include vitamin D (175), peroxisome proliferator-activated receptor (PPAR)-γ agonists (176) and adiponectin (177).

Fibrosis Regression and Renal Regeneration

Until excessive renal extracellular matrix deposits become highly organized, they may be degraded by specific proteolytic pathways that have not yet been clearly identified. Whether this process of fibrosis regression is associated with an improvement in renal function depends upon the status of adjacent nephrons. If intact nephrons are preserved and/or regenerated, renal function should be restored. Therefore, it is a great importance to determine how renal tubules can be preserved and what goes wrong when they degenerate and atrophy. Although still not fully understood, current evidence suggests that tubular regeneration is a self-renewal process as surviving tubular epithelial cells proliferate and repopulate regions of cell loss. Bone marrow-derived stem cells may contribute via a process of cell fusion, but their primary role may be an indirect one dependent upon the release of soluble survival factors that facilitate tubular epithelial cell regeneration or they may fuse with resident kidney cells (178–180). Most of the available data come from detailed studies of nephron recovery following acute ischemic injury, observations that require confirmation in chronic progressive models of renal injury.

Tubular regeneration is characterized by the reactivation of a set of developmentally programmed genes that

may determine cell fate. In recent years there has been considerable interest in tubular cell transdifferentiation from an epithelial to a mesenchymal cell phenotype as a pathway to matrix-producing interstitial cells. However, it also appears that this might be a reversible process (168). As long as these mesenchymally transformed cells remain confined by intact tubular basement membranes, phenotypic reversal should preserve nephron structure.

Preservation of the endothelial aspect of the tubulointerstitial barrier is also essential if surviving nephrons are to remain functional. In chronic kidney disease, the histological features of tubular atrophy and peritubular capillary rarefaction are tightly correlated but the nature of their co-dependency in survival and revival is unclear.

In summary, great advances have been made in our understanding of the cellular and molecular pathways that lead to nephron destruction and renal functional decline as a consequence of extracellular matrix accumulation. Several candidate targets for new therapeutics have emerged and captured the interest of research and development enterprises. It is clear that the process of renal fibrosis is complex and progresses in a temporally, spatially, and at times an organ-specific manner. By analogy with the lessons learned from cancer biology and therapeutics, a revolutionary new approach to CKD treatment now seems within the realm of possibility but will require the use of regimens that employ several agents that target different critical elements. Since there appears to be a common progression pathway shared by most chronic kidney diseases, such an approach should have broad clinical application. One of the greatest future challenges is the need to distinguish progressors from non-progressors amongst the population of chronic kidney disease patients.

68 Management of Chronic Kidney Disease

René G. VanDeVoorde · Bradley A. Warady

Introduction

Chronic kidney disease (CKD), although uncommon in children, can be a devastating disorder with many long-term consequences. Despite similarities to adult disease, CKD in children has many unique features that are not seen in older patients. Its manifestations can affect multiple body systems (cardiovascular, endocrine, hematopoietic, gastrointestinal, central nervous) during particularly vulnerable times of development in children with the potential for permanent sequelae. It is noteworthy that children with CKD, like adults, may often be asymptomatic in the initial stages of the disease and its complications may go undiagnosed and untreated early in its course. However, as renal function gradually declines, various signs and symptoms (e.g., volume overload, hypertension, fatigability, and failure to grow) become more evident. In most cases, the dysfunction is progressive and shares a common pathway of injury, whether the etiology of the CKD state is developmental, genetic, immunologic, metabolic, traumatic, or infectious in origin. Thus, early recognition and intervention is of significant importance as only then might the progressive loss of kidney function, and the associated morbidity, be prevented or delayed (1).

Historically, the terms chronic renal failure (CRF) and chronic renal insufficiency (CRI) have been used to describe varying degrees of renal dysfunction. In this chapter, we will use the term chronic kidney disease (CKD) as this is now the accepted terminology in the adult and pediatric nephrology communities in North America and around the globe. The use of the term chronic kidney disease allows for both consistency when discussing degrees of injury and also highlights the fact that renal dysfunction occurs along a continuum rather than as discrete steps of declining function. Also, the primary focus of this chapter is on the management of the earlier stages of CKD and does not address the management of patients with end stage renal disease (ESRD).

Estimation of GFR

The glomerular filtration rate (GFR) is the sum of the filtration rates in all functioning nephrons and an estimate of GFR provides a rough measure of the number of functioning nephrons. The normal GFR varies with age, gender, and body size with children generally achieving size-adjusted adult values of GFR by age two (2). Whereas the GFR may be measured by inulin or iohexol clearance (3), the estimation of GFR may be predicted by the measured creatinine clearance in a 24 h urine collection. Unfortunately, the accuracy of a 24 h urine collection is often compromised by incomplete collections (4) and the tubular secretion of creatinine when the GFR is decreased (5). Urine collections preceded by oral cimetidine, which blocks tubular secretion of creatinine, have also proven to be a fairly accurate means of estimating the GFR (6), although this approach is rarely used clinically. As a result, multiple prediction equations have been developed to more simply estimate GFR by using the serum creatinine concentration, with recognition of the fact that the GFR is overestimated when kidney function is decreased because of creatinine secretion. The MDRD equation has been developed for use in adults with CKD, but it has not proven to be applicable to the pediatric population (7). The Schwartz (8) and Counahan-Barratt equations (9) have been the most commonly used GFR estimating equations used in children. The Schwartz equation, which was developed based on creatinine determinations using the Jaffe methodology, estimates GFR by utilizing the subject's height in centimeters, plasma creatinine, and a constant, K, based on the subject's age and gender (see *Table 68-1*). Despite its ease of use, the Schwartz equation is imprecise in most instances, as a result of the current widespread use of enzymatic methods for creatinine measurement (10). A new and more accurate estimating equation has been developed by the investigators of the Chronic Kidney Disease in Children (CKiD) study

© Springer-Verlag Berlin Heidelberg 2009

Table 68-1

Different constant values (K) for the Schwartz formula for the estimation of GFR

$GFR = \frac{K \times Height\ (in\ cm)}{P_{cr}\ (mg/dl)}$	
Table 1- Values of K for different age groups	
Low birth weight infants (<2.5 kg)	0.33
Infants (0–18 months)	0.45
Children 2–13	0.55
Adolescent girls (13–16)	0.55
Adolescent boys (13–16)	0.70

Table 68-2

K/DOQI stages of chronic kidney disease

Stage	Description	GFR (ml/min/1.73 m^2)
1	Kidney damage with normal or increased GFR	≥ 90
2	Kidney damage with mild decrease in GFR	60–89
3	Moderate decrease in GFR	30–59
4	Severe decrease in GFR	15–29
5	Kidney failure	< 15 (or dialysis)

using measured GFR values based on the plasma disappearance of iohexol. The formula, which is applicable to children between the ages 1–16 and with GFRs ranging from 15 to 75 ml/min/1.73m^2, incorporates the patient's height, plasma creatinine (P_{cr}), serum cystatin C level, blood urea nitrogen (BUN), and gender into the following:

$$\text{Estimated GFR} = 39.1 \times [\text{Height}/P_{cr}]^{0.516} \times [1.8/\text{CysC}]^{0.294} \times [30/\text{BUN}]^{0.169} \times [1.099^{\text{male}}] \times [\text{Height}/1.4]^{0.188}$$

A "bedside" version of the equation that can easily be used in clinical practice for patients with CKD uses the similar ratio of height (cm) divided by plasma creatinine (mg/dL) but multiplied by the set constant of 0.413, irrespective of age or gender (10).

Serum cystatin C, a protease inhibitor which is produced by all nucleated cells, has also been closely investigated as a potentially more accurate biomarker of renal function than serum creatinine. Cystatin C is freely filtered at the glomerulus but is reabsorbed and catabolized by the proximal tubule and, therefore, is not a classic marker of glomerular filtration. However, cystatin C has several advantages over creatinine. Its inverse has been shown to correlate with renal function independent of age, gender, height, and body composition in patients over 2 years of age (11) and GFR-estimating formulas using cystatin C have been developed (12, 13). All but one study comparing serum cystatin C to creatinine have shown superiority or equivalence of cystatin C as a marker of GFR in pediatric patients (14). Early criticisms of cystatin C were based upon its variability in measurement; however, with the consistent use of immunonephelometry, serum cystatin C measures have been shown to have lower intrapatient variability than serum creatinine (15). Serum cystatin C has not been endorsed to estimate renal function in CKD, mainly because the studies prior to this were characterized by limited sample size and lack of consistency in terms of the assay method (16). More recently, and as noted before, the CKiD study has incorporated the measure of cystatin C as determined by the turbidimetric assay along with blood urea nitrogen in generating the new GFR estimating equation for children with CKD (10).

Classification of CKD

In 2002, the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (K/DOQI) published their CKD classification scheme that is based on estimated GFR and is applicable to adults and children above 2 years of age (16). CKD is categorized into five different stages, from Stage 1 (mild disease) to Stage 5 (kidney failure) (see *Table 68-2*). Characterization of these different stages has allowed nephrologists and general health care providers, both adult and pediatric, to have a common nomenclature when discussing CKD with respect to the anticipation of co-morbidities and treatment plans. Although this system has been criticized, as it is argued that earlier disease stages may be better defined by the associated abnormalities (e.g., proteinuria, structural anomalies) while more advanced stages would be better characterized by the severity of renal solute clearance (17), the scheme has proven to be clinically useful and has been incorporated into everyday care.

Epidemiology of CKD

Information on the epidemiology of CKD in the pediatric population is somewhat limited, especially for less advanced stages of the disease. As mentioned previously, this is partly because of the asymptomatic nature of CKD early in its course which has resulted in it often

being underdiagnosed and underreported in children. Historical epidemiologic data have also used a variety of criteria to define chronic impairment of kidney function prior to K/DOQI. The term, chronic renal insufficiency (CRI) has traditionally been used to refer to the condition associated with an estimated GFR less than 75 ml/min/1.73 m^2. Other traditionally used terms such as mild (50–80% of normal GFR), moderate (25–50%), and severe (<25%) kidney disease do not directly correlate with the same GFRs as classified by K/DOQI, making direct comparisons of the data difficult.

Perhaps the most comprehensive pediatric epidemiologic data comes from the ItalKid Project, a prospective population-based registry which includes all incident and prevalent cases of CKD (defined as GFR <75 ml/min/1.73 m^2) in children below the age of 20 throughout Italy. This registry has reported an incidence of CKD of 12.1 cases per million of the age-related population and a prevalence of 74.7 cases per million (18). Other sources of epidemiologic data have included national surveys such as in Chile (19) and Sweden (20) which have reported incidence rates from 5.7 to 7.7 cases per million population; however, most of this data has focused on children with severe kidney disease (GFR <30 ml/min/1.73m^2). Reports from major tertiary hospitals in Jordan (21) and Nigeria (22) have reported the incidence of severe CKD to be 10.7 and 3.0 cases per million population, respectively; however these data likely reflect the accessibility to hospital care in these nations. Finally, pediatric data on CKD in North America primarily arises from the registry of the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS). It began as a voluntary transplant registry in 1987 (23) and expanded to include data on patients with CRI (GFR <75 ml/min/1.73 m^2) in 1994. Its data is gathered voluntarily from pediatric nephrologists in Canada, Costa Rica, Mexico, and the United States. While this registry contains a wealth of information on more than 6,000 children with CKD, no incidence or prevalence information is available.

Unlike adults in whom the primary etiologies of CKD are diabetes and hypertension, the greatest percentage of pediatric CKD cases are congenital in origin, with some variability among nations. In the CRI/CKD registry of NAPRTCS, nearly half of the cases have congenital causes of renal disease such as obstructive uropathy (21.1%), renal dysplasia (17.5%), reflux nephropathy (8.4%), and Prune Belly syndrome (2.8%). These disorders make up four of the six most prevalent diagnoses (see *Table 68-3*). Data from Italy has also revealed renal hypoplasia to account for the majority (nearly 58%) of all pediatric CKD cases (18). In contrast, data from the Japanese registry has revealed that 34% of their pediatric CKD cases were secondary to glomerulonephritis, primarily focal segmental glomerulosclerosis and immunoglobulin A (IgA) nephropathy (24). Heritable causes of

Table 68-3

2007 NAPRTCS report, primary diagnosis of CRI

Primary Diagnosis	Number of patients (Total N = 6,794)	Percentage
Obstructive uropathy	1,436	21.1
Aplastic/Hypoplastic/ Dysplastic Kidney	1,187	17.5
Focal segmental glomerulosclerosis	589	8.7
Reflux nephropathy	568	8.4
Polycystic disease	271	4.0
Prune Belly	192	2.8
Renal infarct	157	2.3
Hemolytic Uremic Syndrome	138	2.0
Systemic Lupus Erythematosus nephritis	108	1.6
Familial Nephritis	108	1.6
Membranoproliferative Glomerulonephritis, Types I and II	102	1.5
Cystinosis	100	1.5
Pyelo/interstitial nephritis	95	1.4
Medullary cystic disease	86	1.3
Chronic Glomerulonephritis	81	1.2
Congenital Nephrotic Syndrome	74	1.1
IgA (Berger's) Nephropathy	66	1.0
Idiopathic crescentic glomerulonephritis	46	0.7
Henoch-Schonlein nephritis	42	0.6
Membranous nephropathy	35	0.5
Wilms tumor	31	0.5
Other systemic immunologic disorders	25	0.4
Wegener's granulomatosis	21	0.3
Sickle cell nephropathy	14	0.2
Diabetic glomerulopathy	11	0.2
Oxalosis	7	0.1
Drash syndrome	6	0.1
Other	1,020	15.0
Unknown	178	2.6

CKD such as cystic kidney disease, primary hyperoxaluria, cystinosis, Alport syndrome, and congenital nephrotic syndrome have been reported to represent a greater percentage of the cases of CKD in Jordan (21) and Iran (25) where consanguinity is more common. In less developed nations, acquired etiologies of CKD seem to predominate. This may reflect differences in the ability to detect CKD in many of these nations, where patients often present in the later stages of the disease. It may also reflect the burden of infectious diseases, with subsequent infection-related glomerulonephritis, in these countries. Publications from Nigeria have reported various infections glomerulopathies as the cause of CKD in half of its pediatric patients (22), while Familial Mediterranean Fever and resultant amyloidosis was responsible for 10% of CKD cases in Turkish children (26). Human Immunodeficiency Virus (HIV)-associated nephropathy, which causes ESRD in only a small number of children in the United States (27), is also likely an underreported source of nephropathy in children, as an increasing incidence of pediatric HIV is evident in the underdeveloped regions of South America, Africa, and Asia (28), where pediatric CKD data is poorly collected or non-existent.

Characterization of the pediatric patient population having CKD shows some similarities worldwide with regards to gender. Incidence and prevalence rates are universally greater for boys than girls (18, 22, 23, 25, 29). Sixty-four percent of the patients in the NAPRTCS CRI registry and 67% of patients in the ItalKid registry are male (18, 23). This gender distribution reflects the higher incidence of congenital causes of CKD seen in boys.

Prevention of CKD Progression

Although information about children is limited, there appears to be certain modifiable and non-modifiable risk factors associated with CKD progression. Most available data shows that acquired glomerular diseases tend to progress more rapidly than congenital disorders, evident in a relatively higher proportion of glomerular diseases that are characterized by the more advanced stages of CKD (30). Renal hypoplasia and dysplasia appear to have a pattern of disease progression characterized by an initial period of improving renal function, followed by a prolonged period of stabilized function, and then ultimately a period of declining function (31). This deteriorating phase is often seen during periods of rapid growth, such as puberty, and its later appearance may account for the slower progression seen in congenital renal disorders.

Other non-modifiable factors for CKD progression include race and genetics. An increased racial susceptibility may be present in African Americans as an increased concordance of kidney disease (32) and a faster rate of disease progression have been noted in this population compared to their adult Caucasian counterparts (33). Similarly, the incidence rate of pediatric ESRD is nearly doubled in African American children compared to Caucasians (34) and is significantly higher during late adolescence, although this may reflect, in part, different incidence rates of acquired glomerulopathies such as focal segmental glomerulosclerosis. Certain genetic polymorphisms of the angiotensin-converting enzyme (ACE) gene have been associated with an increased susceptibility to disease progression in IgA nephropathy (35) and congenital uropathies (36, 37) in some, but not in all (38), studies and may also play a role.

There is clear and consistent evidence from adult studies that hypertension is a significant and modifiable mediator of CKD progression (39, 40). Numerous studies have shown that anti-hypertensive therapy slows the rate of ESRD development in adults, with a linear relationship existing between the achieved median blood pressures on therapy and the rates of renal failure progression (41). This has resulted in a target blood pressure range in adults of less than 120/80 mmHg within the guidelines from both the American (42) and European (43) expert panels. Mitsnefes and colleagues reviewed the NAPRTCS database and demonstrated that hypertensive children with CKD had a more rapid decrease in their estimated GFR or progression to renal replacement therapy than normotensive children with CKD (44). Systolic hypertension was found to be a significant, independent predictor of disease progression along with the patient's age, acquired etiology of CKD, and African-American ethnicity. A large prospective study of European children with CKD has, in fact, found that a systolic blood pressure greater than 120 mmHg was associated with a faster decline of GFR (45). However, the optimal blood pressure goal for children with CKD is not known and no published studies in pediatrics have demonstrated a slowing of CKD progression following the prospective introduction of improved blood pressure management. Presently, the recommendation from K/DOQI for children with CKD is a targeted systolic and diastolic blood pressure less than the 90th percentile for age, height, and gender or less than 130/80 mmHg, whichever is lower (46). This mirrors the recommendations of the National High Blood Pressure Education Program (NHBPEP) Working Group on Children and Adolescents (47) for children with concurrent diseases. The Effect of Strict Blood Pressure

Control and ACE Inhibition on Progression of Chronic Renal Failure in Pediatric Patients (ESCAPE) trial, a large-scale prospective study in Europe, is addressing the question of whether even lower mean blood pressure targets, such as the 50th percentile for age, provides added reno-protection in children with CKD (48).

Proteinuria has also been demonstrated to be a significant, modifiable risk factor for CKD progression, especially in adults (49, 50). In an Italian study on the efficacy of ramipril in adults (REIN study), the degree of proteinuria was the only baseline variable which correlated with a decline of kidney function towards ESRD (51). This same group also showed the efficacy of anti-proteinuric therapy with ACE inhibitors as a means of slowing GFR decline, as the reduction of proteinuria by one gram daily resulted in a decreased decline in GFR of 2 ml/min per year (52). Similarly, the European Study Group for Nutritional Treatment of Chronic Renal Failure in Children first showed that proteinuria was a significant risk factor for pediatric CKD progression from Stage 3–4 to ESRD (45). The ItalKid project also demonstrated that the degree of proteinuria predicted disease progression in patients with renal dysplasia (53). Finally, initial evidence from the ESCAPE trial has shown that the degree of residual proteinuria, irrespective of ACE inhibition, is also associated with the rapidity of CKD progression (54).

There is evidence that decreasing blood pressure alone will reduce proteinuria to some degree (39, 55), and therefore any anti-hypertensive agent may prove to be anti-proteinuric. However, while several classes of anti-hypertensive agents are often comparable in their blood pressure-lowering efficacy, there are significant differences in their ability to reduce proteinuria (55, 56). ACE inhibitors and angiotensin II type 1 receptor blockers (ARBs) are most effective in this respect, with both primary anti-hypertensive and anti-proteinuric effects. These agents, in turn, have been found to be most reno-protective. Studies of adults have shown a 30–40% reduction of proteinuria in non-diabetic patients with CKD who receive an ACE inhibitor compared to placebo (56), while ARBs have been associated with similar results in patients with diabetic nephropathy (57). The renal protection afforded by both classes of medication are likely mediated through a combination of reduced proteinuria, lowered intra-glomerular pressure, reduced sympathetic hyperactivity, and anti-fibrotic effects. ACE inhibitors may potentially have greater reno-protective effects because of the accumulation of bradykinin, with its vasodilatory and anti-fibrotic effects, that accompanies their use but is not seen with ARBs. Nevertheless, an equivalent clinical effect was seen in a comparative clinical trial between the two drug classes (58). There is limited data on the role of ACE inhibitor or ARB therapy for renoprotection in children with CKD. Small studies have shown stability of kidney function with ACE inhibitor use in patients with a history of hemolytic uremic syndrome (59) and combined ACE inhibitor and ARB use have been associated with slowing the histopathologic progression in IgA nephropathy (60). However, the ItalKid study did not show a significant change in CKD progression with the use of ACE inhibitors in children with renal dysplasia (61). The aforementioned ESCAPE trial is also evaluating the impact of ramipril therapy on CKD progression in children (48).

Other anti-hypertensive medication classes have been associated with effective reduction in GFR decline in patients with CKD but without effective anti-proteinuric effects, with two exceptions. The beta-blocker metoprolol was shown to have anti-proteinuric effects comparable to ramipril in the African American Study of Kidney Disease and Hypertension trial (55) and the newer beta-blocker carvedilol has also been shown to have improved anti-proteinuric effects compared to other beta-blockers (54). Perhaps direct adrenergic stimulation of the renal sympathetic nervous system is as important in the progression of CKD as the other theorized etiologies that ACE inhibition targets and accounts for these results.

Other methods have been proposed as means by which CKD progression might be slowed, purportedly by targeting other mechanisms, such as oxidative stress and inflammatory pathways. Proposed methods have included treatment of dyslipidemia, early erythropoietin therapy, phosphorus control, and dietary protein restriction. Some of these interventions compliment data collected from the NAPRTCS database which identified low values for serum albumin (<4.0 gm/dl), serum calcium (<9.5 mg/dl) and hematocrit (<33%) and elevated values of serum phosphorus (>5.5 gm/dl) and BUN (>20 mg/dl) as risk factors for progression to ESRD (62). Lipid-lowering therapy is commonly prescribed for adults with CKD for the primary prevention of cardiovascular morbidity and mortality. However, evidence also suggests that statin therapy may slow renal disease progression as well through its anti-inflammatory and oxidative stress reducing properties (63). Additionally, there has been evidence that statins may possess the ability to limit proteinuria in adults (64). However, the utility of statins to slow CKD progression in children has not been proven.

Although erythropoietin therapy has not been shown to influence the progression of CKD in children, adult studies have provided evidence that early therapy of mild to moderate anemia in patients with CKD may slow the progression of kidney disease (65) by reducing oxidative

stress in the renal interstitial and tubular cells and/or by the mobilization of progenitor cells for renal tissue injury repair (66).

Treatment with active vitamin D has been associated with attenuation of CKD progression in animal models (67), but it is not yet clear if the same effect exists in humans. Studies in adult CKD have suggested that dietary phosphorus restriction may help reduce progression of kidney disease (68) and oral paricalcitol has been shown to have an anti-proteinuric effect in adults (69).

Lastly, there is no evidence that a low-protein diet will affect the progression of CKD in children. For decades, it had been hypothesized that dietary protein restriction would diminish renal injury as high protein diets have been associated with increased renal scarring in animal models (70). In adults, the Modification of Diet in Renal Disease (MDRD) trial did not demonstrate that a restricted protein intake could modify the progression of CKD in adults with non-diabetic nephropathies (71). Likewise, Wingen et al. showed no efficacy of a low protein diet on the decline in GFR in children with CKD after 1 year of treatment (72). Not surprisingly, there is also concern that caloric intake and growth may be compromised in pediatric patients on a restricted diet.

Anemia in CKD

Anemia is one of the most common complications of CKD during childhood and its near universal presence in patients with advanced disease has prompted the development of anemia evaluation and treatment guidelines in both Europe and North America (73, 74). The treatment of CKD was revolutionized in 1986 with the introduction of recombinant human erythropoietin (rHuEPO or EPO) therapy (75). Despite the proven benefits of correcting anemia in children with CKD and the availability of consensus recommendations, there remain several unresolved issues about anemia management in pediatric CKD, including target goals of treatment and factors contributing to the frequent presence and persistence of anemia in patients with early stages of CKD.

Definition of Anemia

The 2000 K/DOQI Anemia Management guidelines defined anemia as a hemoglobin value less than 11 gm/dl in pre-pubertal patients with CKD (76). This, in turn, was translated into the threshold goal for therapy. However, the guidelines did not take into account the fact that hemoglobin values in children vary greatly by age and gender. The NHANES III Study (see *Table 68-4*) showed that the fifth percentile for hemoglobin may vary by as much as 2.8 gm/dl from younger to older boys and by 2 gm/dl for girls and boys of a similar age group (77). This wide variation in hemoglobin values was studied in 350 children with CKD by Wong et al. (78). There were significant differences in the prevalence of anemia using the age- and gender-specific reference intervals compared to the uniform level originally recommended by the guidelines committee, as 90 subjects met the age- and gender-variation definition versus only 54 subjects who did so by the K/DOQI criteria ($p<0.001$). More recently, Staples et al. reviewed the NAPRTCS database and found a 25% increase in the prevalence of anemia in pediatric CKD subjects when using the age and gender appropriate norms for hemoglobin compared to the age-independent definition of anemia previously used by K/DOQI (79). The recent revision of the K/DOQI anemia guidelines now states that anemia is present in the pediatric CKD patient "when the observed hemoglobin is less than the fifth percentile of the normal, adjusted for age and sex" (80).

Pathophysiology of Anemia

Multiple factors may contribute to the development of anemia in pediatric patients with CKD (see *Table 68-5*). The principal cause is the diminished production of erythropoietin by the interstitial cells of the renal cortex. As GFR declines, there is a decrease in the fractional reabsorption of sodium by the kidney and a decrease in oxygen utility. This, in turn, leads to an increase in kidney tissue oxygen pressure and a subsequent decrease in

Table 68-4

Hemoglobin levels from NHANES III for boys and girls of all race/ethnic groups according to age

Age (years)	5th percentile hemoglobin level for boys (gm/dL)	5th percentile hemoglobin level for girls (gm/dL)
1–2	10.7	10.8
3–5	11.2	11.1
6–8	11.5	11.5
9–11	12.0	11.9
12–14	12.4	11.7
15–19	13.5	11.5

Table 68-5

Common causes of anemia in chronic kidney disease

Erythropoietin deficiency
Iron deficiency
- Dietary iron deficiency
- Gastrointestinal loss, Phlebotomy, Menses
- Poor absorption of enteral iron
- Iron depletion from ESA use
Chronic inflammation
- Complement activation from dialysis
- Systemic inflammatory diseases (systemic lupus erythematosus, Wegener's granulomatosis,. . .)
- Surgical procedures
Bone marrow suppression
- Inhibitory factors
- Hyperparathyroidism
- Medications (immunosuppressive drugs)
Increased red cell turnover
- Carnitine deficiency
- Primary renal disease (Hemolytic Uremic Syndrome)
Malnutrition
- B12 or Folate deficiency
- Carnitine deficiency
Aluminum toxicity

erythropoietin production (81). Decreased erythropoietin leads to an increase in apoptosis of erythroid progenitor cells (82) and decreased red cell maturation. Children with CKD have been shown to have erythropoietin levels that are inappropriately low for their degree of anemia (83), which was generally thought to occur when the GFR decreases below 35 ml/min/1.73 m^2, with a linear correlation between hematocrit and creatinine clearance noted (83, 84). Most recently, results from the CKiD study showed that hemoglobin levels decreased by 0.1 gm/dL for every 5 ml/min decrease in measured GFR until the GFR fell below 43 ml/min/1.73 m^2 (85). Below that level, the decline in hemoglobin was 0.3 gm/dL for every 5 ml/min drop in GFR. However, the prevalence of anemia in children with Stage 2 CKD has been estimated at 19–30% (78, 79, 85) highlighting the fact that there is not an "absolute threshold" for anemia in CKD.

Iron deficiency is another factor that frequently contributes to the development and/or persistence of the anemia associated with CKD. The etiology of iron deficiency is multi-factorial. Patients with CKD may experience greater than normal blood loss, estimated at 6 ml/m^2 daily from gastrointestinal losses (86) as well as from the repeated phlebotomy necessary for routine serum laboratory tests. Low dietary intake of iron may occur as a result of anorexia related to advanced stages of CKD and there may be poor adherence with oral iron supplementation secondary to gastrointestinal side effects (87).

Recently, hepcidin, a hepatically-activated peptide first discovered because of its anti-bacterial properties (88, 89), has been found to be a key regulator of systemic iron homeostasis in patients with CKD (90). Hepcidin affects the turnover of the iron exporter, ferroportin, on the cell surface of enterocytes and attenuates the uptake of iron by the intestine. Taes et al. have shown that serum hepcidin correlates inversely with creatinine clearance (91) and its serum accumulation may have a direct negative effect on enteral iron absorption (92).

Hepcidin accumulation may also be one of the main mechanisms by which inflammation contributes to the development of the anemia of chronic disease. Inflammatory markers are often increased in patients with CKD, either secondary to uremic impairment of the immune system, decreased clearance of inflammatory factors (93), or directly from systemic diseases such as vasculitides. The cytokine interleukin-6 (IL-6) is a key mediator in the inflammatory-anemia effect as IL-6 has been shown to increase the liver production of hepcidin (94). Hepcidin also affects ferroportin on the cell membrane of macrophages in addition to enterocytes, preventing iron release from the reticulo-endothelial system and limiting iron bioavailability. Thus, hepcidin may be the key mediator in the inflammatory "block" to the utilization of total body iron stores in patients with CKD.

The erythrocyte life span is also shortened in children with CKD (86) and may contribute to the development of anemia. Erythrocyte survival in CKD patients has been shown to increase through the use of rHuEPO (95) although the direct mechanism is not known. Carnitine deficiency may also reduce the strength of the red cell membrane (96) and contribute to decreased red cell survival, an effect primarily noted in hemodialysis patients associated with dialysis-related carnitine removal. In addition to decreased erythropoietin production and red cell survival, bone marrow suppression may also occur in patients with CKD. In vitro assays have shown erythropoiesis to be suppressed with the addition of serum from children with CKD (83). The inhibitory substance in the serum of patients has not yet been identified, but it is thought to be effectively removed by hemodialysis, as rHuEPO doses often decrease after initiation of that dialysis modality (97). Hyperparathyroidism has also been

shown to cause suppression of erythropoiesis (98) and may also contribute to the anemia seen in CKD.

Finally, malnutrition may contribute to the anemia seen in the later stages of renal dysfunction. A low serum albumin level has been associated with the anemia of CKD (99). However, a low serum albumin may merely be a surrogate marker of either CKD severity or inflammation, rather than having a direct contribution to anemia. In addition to deficiencies of iron or carnitine, deficiencies of other water-soluble vitamins, such as B12 and folate, may also contribute to anemia. Routine folate supplementation has been shown to improve the response to rHuEPO even without frank serum folate deficiency (100).

Evaluation of Anemia

All children with CKD, regardless of the disease etiology or stage, should have their serum hemoglobin checked at least annually (80). In younger children, more frequent laboratory monitoring for CKD stage and hemoglobin level is often performed because of expected changes in values during growth, although no specific recommendations for an age-related frequency of laboratory evaluation have been made (80). The serum hemoglobin level rather than the hematocrit should be used as the standard assessment for anemia, as the hematocrit may vary from changes in volume status, body temperature, and blood sugar (101).

Once the diagnosis of anemia is made, the initial evaluation of anemia in patients with CKD should include a complete blood count with red blood cell indices, reticulocyte count, serum ferritin and iron levels, and a total iron binding capacity. Erythropoietin deficiency typically causes a normocytic anemia with an inappropriately decreased reticulocyte count, although a microcytosis may be seen when the anemia is secondary to iron deficiency or chronic disease. Other contributing factors to anemia should be considered if abnormalities of the other cell lines or red cell indices are found (see *Table 68-6*). Decreased white blood cell or platelet counts should elicit inquiry as to other factors possibly contributing to bone marrow depression such as transient viral infections, malignancy, medication side effects, or an auto-immune disorder. A high mean corpuscular volume (MCV) suggests a folate or vitamin B12 deficiency while a low MCV may be seen in thalassemia and other hemoglobinopathies, in addition to iron deficiency and anemia of chronic disease. An elevated reticulocyte count should prompt consideration of either blood loss or hemolysis.

Iron status is evaluated by both the serum ferritin and transferrin saturation levels. While serum ferritin levels reflect total iron body stores, it is also an acute phase reactant and may be elevated in the face of systemic

Table 68-6

Differentiation of types of anemia based on mean corpuscular volume (MCV) and red blood cell distribution width (RDW)

	Low MCV (microcytosis)	Normal MCV	High MCV (macrocytosis)
High RDW	Iron deficiency	Early iron deficiency	Folate deficiency
	Hb S-β thalassemia	Hemoglobinopathy (SS, SC)	Vitamin B12 deficiency
	Hemoglobin H	Myelofibrosis	Hemolytic anemia
	Erythrocyte fragmentation	Sideroblastic anemia	Immune hemolytic anemia
			Cold agglutinin
Normal RDW	Heterozygous thalassemia	Normal	Aplastic anemia
	Chronic disease	Chronic disease	Pre-leukemia
		Chronic renal failure	
		Chronic liver disease	
		Hemoglobinopathy (AS, AC)	
		Transfusion	
		Chemotherapy	
		Hemorrhage	
		Chronic myelocytic leukemia	
		Hereditary spherocytosis	

Reproduced from Management of Renal Anemia in *Pediatric Dialysis* by Warady B, et al., Springer, 2004

inflammation or malnutrition, compromising its ability to serve as a reliable measure of iron status when its value is elevated. The target serum ferritin level in the absence of inflammation is >100 ng/ml and a low serum ferritin level has been shown to be a specific predictor of iron deficiency in pediatric CKD (102). Transferrin saturation is a measure of iron immediately available for hemoglobin synthesis. It is typically expressed as a percentage and is calculated as the serum iron divided by total iron binding capacity multiplied by 100%, with a therapeutic target of greater than 20% in patients with CKD (76). Although it too is a highly specific predictor of iron deficiency in pediatric CKD patients (103), this measure also has limitations as it loses its value for evaluating the availability of iron when the total iron binding capacity is low (< 200 mcg/dL), as may be seen in malnutrition or severe proteinuria (104). The percentage of circulating hypochromic red blood cells and the reticulocyte hemoglobin content have been proposed as additional methods to evaluate functional iron adequacy in adults (105, 106). In contrast, the experience with these laboratory tests is limited in children with CKD (107).

Treatment of Anemia

The use of erythropoietic stimulating agents (ESA) such as rHuEPO, in addition to iron supplementation, are the key elements of anemia management in patients with CKD related anemia. Prior to the availability of rHuEPO, virtually all pediatric ESRD patients required repeated blood transfusions with their incipient risks of iron overload, antigenic exposures, and infectious complications. Now, blood transfusions should be reserved for patients with symptomatic anemia, significant on-going hemolysis, or unresponsiveness to ESA therapy. Many of the symptoms of CKD, some of which were historically attributed to the presence of uremia, were actually secondary to anemia, as correction of the anemia with rHuEPO has regularly been associated with clinical improvement. Studies on the use of rHuEPO in pediatric CKD patients have documented improvements in appetite, exercise tolerance, oxygen consumption, intelligence testing scores, and quality of life (108–111) subsequent to the initiation of therapy. Severe left ventricular hypertrophy has also been associated with low hemoglobin values (112) and treatment of anemia with rHuEPO has produced a significant reduction in left ventricular mass index within a year of the introduction of therapy (113). Possibly most important is the fact that the persistence of anemia 1 month after dialysis initiation has been associated with a significant increase in morbidity (e.g., hospitalizations) and mortality in pediatric patients (114).

As mentioned above, rHuEPO (trade names- Epogen, Procrit, Eprex, NeoRecormon) is a component of the treatment of CKD related anemia and it has been shown, for more than 15 years, that it is efficacious in children with CKD (115, 116). The maintenance dosing of rHuEPO must be individualized and factors known to be associated with an increase in the required per kilogram dosing of rHuEPO include greater renal dysfunction, younger patient age (117), a fall in the remaining endogenous erythropoietin activity, and iron deficiency. Generally, an appropriate starting dose for subcutaneous rHuEPO, the route of therapy for most pre-dialysis CKD patients, is 100 units/kg/week divided into semi-weekly doses. Patients younger than 5 years of age, however, often require a 50–100% increase in these starting dose recommendations (150 units/kg/week per subcutaneous route) as there may be more non-hematopoietic binding sites for rHuEPO in younger children (118). Recently, adult CKD patients were found to maintain adequate hemoglobin levels using less frequent dosing of rHuEPO, every 2–4 weeks (119), but this decreased frequency has not been evaluated in children.

The hemoglobin level, MCV, and iron stores should routinely be monitored subsequent to the initiation of ESA therapy. The K/DOQI guidelines recommend that when ESA therapy is used, hemoglobin and iron status should initially be monitored monthly, while iron studies may be checked quarterly once the patient is receiving a stable ESA dose (80). The hemoglobin value should be evaluated every 2 weeks following a change in ESA dosage to make sure that there is not too rapid an increase in hemoglobin and the development of complications related to the rapid change. Typically, when patients respond to therapy, a mild increase in MCV may be seen as a result of the reticulocytosis. An initial poor response to ESA therapy is often secondary to iron depletion and is reflected by a decrease in transferrin saturation, as plasma iron stores are quickly depleted.

Dose adjustments are often needed with rHuEPO therapy as factors which affect rHuEPO dosing may change.The goal of the treatment is to achieve a monthly increase of hemoglobin by 1–2 gm/dL until reaching target levels. The rHuEPO dose should be increased 25% if the patient is still anemic and their hemoglobin value has not increased by at least 1 gm/dL over the past month. Similarly, the dose should be reduced by 25% if the hemoglobin exceeds target levels or the rate of increase in hemoglobin is greater than 2 gm/dL per month. Generally, the dose of rHuEPO in children should be

reduced and not held when the serum hemoglobin level is excessively high. This approach decreases the risk of "hemoglobin cycling" (120).

Complications from rHuEPO use are most commonly related to changes associated with the rate of rise in the serum hemoglobin. Increases in blood pressure can be the result of a rapid rise in hemoglobin (121) or secondary to a direct effect of rHuEPO on blood vessels (122). Rarely, the development of antibodies against erythropoietin, both endogenous and the recombinant exogenous forms, may occur causing pure red cell aplasia (123).

Darbepoetin-alfa (trade name Aranesp) is an effective alternative to rHuEPO with less frequent administration requirements (124, 125). Darbepoetin-alfa has one amino acid substitution and additional N-glycosylation sites which gives the molecule a longer half-life than rHuEPO. The half-life of darbepoetin-alfa given intravenously to children is approximately 22 h and given subcutaneously is nearly 43 h (126), almost three times longer than that of rHuEPO. In general, therapy with subcutaneous darbepoetin-alfa is initially provided on a weekly basis. However, in patients previously requiring rHuEPO only weekly, darbepoetin-alfa may be given every other week or even over longer intervals. Typical starting doses for an ESA-naïve patient is 0.5 mcg/kg/week; however, patients converting from rHuEPO should be prescribed approximately 0.42 mcg/kg/week darbepoetin-alfa for every 100 units/kg/week of rHuEPO. The side effect profile of darbepoetin-alfa is similar to that of rHuEPO with some reports of increased pain at the injection site with darbapoetin-alfa (124, 127).

As mentioned above, iron supplementation is typically also part of the therapeutic regimen in children with anemia from CKD, not only because of the high prevalence of iron deficiency as a result of poor intake or increased losses, but also because of the increased iron demands associated with the use of ESAs. Oral iron therapy (3–5 mg/kg of oral elemental iron daily) is usually adequate in patients with CKD, although intravenous iron can be provided to children unable or unwilling to take oral supplement or in those who are unable to meet the targets for iron therapy with oral supplement alone (128, 129). Oral absorption of iron is somewhat limited and may be adversely affected by its administration with food or the concomitant use of either calcium-containing binders or H2-receptor antagonists. Other adjunctive therapies for the anemia of CKD such as carnitine (130) or vitamin C (131) have not been shown to be associated with a significant improvement in outcomes and are not currently recommended by K/DOQI.

The target hemoglobin level continues to be somewhat controversial, especially as it applies to the pediatric patient. Currently, there are no pediatric studies which define the ideal target hemoglobin level. However, in 2007, the United States Food and Drug Administration (FDA) issued a warning stating that the use of ESA agents with targeted hemoglobins greater than 12 gm/dL increases the risk of cardiovascular events and death, all based upon the results of studies conducted in adults with CKD (132, 133). K/DOQI recommended target hemoglobin levels for children and adults were subsequently amended to generally fall in the range of between 11 and 12 gm/dL and not to exceed 13 gm/dL (134), while the FDA established a target range of 10–12 gm/dl. The lack of variability for target hemoglobin levels obviously does not take into account the age and gender-related variability of normal hemoglobin values in children (135). Additionally, Staples et al. recently reviewed NAPRTCS data on children with CKD and found that hospitalization rates decreased as hematocrits increased, even with hematocrits in excess of 42% (79).

The proven benefits of treating anemia in CKD are slowly being realized as ESAs are being prescribed more frequently in CKD. According to the 2007 United States Renal Data Systems Report, the percentage of children receiving ESAs prior to dialysis initiation increased from 34.5% over the years 1996–2000 to 39.1% during the span of 2001–2005 (34). During those same time periods, the mean hemoglobin at dialysis initiation had increased from 9.1 to 9.7 gm/dL. There remains some variability in terms of the population of children receiving an ESA as over 45% of children less than 15 years old received ESA therapy prior to dialysis compared to only 30% of those aged 15–19. Additionally, patients with cystic kidney disease were most likely to receive early treatment with an ESA in contrast to those with glomerulonephritides ($>$ 50% vs 37%, respectively). The immediate challenge is to optimize the management of anemia throughout all stages of CKD so that there is universal achievement of the target hemoglobin level.

Mineral and Bone Metabolism

Disorders of calcium and phosphorus homeostasis associated with pediatric CKD inevitably develop with worsening kidney function. The changes in calcium and phosphorus regulation can cause significant alterations in bone re-modeling and somatic growth. There is also increasing evidence that the presence of hyperphosphatemia and hypercalcemia in patients with CKD contribute

to cardiovascular morbidity even during childhood. Thus, early astute management of mineral and bone disorders of CKD during childhood is of utmost importance.

Pathophysiology of Mineral and Bone Disorders

The intricacies of the renal regulation of calcium, phosphorus, and bone metabolism are covered in greater detail in other chapters of this book. However the two basic causes for much of the pathology of the bone and mineral disorders associated with CKD are decreased calcitriol (1,25-dihydroxy vitamin D3) synthesis and decreased phosphate secretion by the kidney. The kidney regulates calcium metabolism through the actions of 1α-hydroxylase, which converts 25-hydroxy (OH) vitamin D3 to its active form, 1,25-dihydroxy vitamin D3 (calcitriol). Calcitriol, in turn, helps regulate intestinal calcium absorption and, thus, has a significant impact on serum calcium levels. The loss of functioning renal mass in CKD leads to suppression of calcitriol synthesis, often very early in the disease before changes in serum calcium, phosphorus, or parathyroid hormone (PTH) can be detected (136). Also, the phosphaturic hormone fibroblastic growth factor (FGF)-23 may also have a role, as it is known to suppress calcitriol synthesis (137) and it too accumulates in CKD (138).

The decrease in intestinal calcium absorption that occurs with CKD leads to decreased serum calcium levels which are quickly mitigated by an increase in PTH synthesis and secretion. In order to maintain normocalcemia, PTH stimulates the resorption of calcium and phosphorus from the bone matrix. PTH also has secondary phosphaturic effects (139) and, in early CKD, elevated PTH levels are often associated with a normal or slightly decreased serum phosphrous level. However, as CKD advances and there is a progressive loss of glomerular filtration, urinary phosphorus excretion decreases and serum phosphorus levels increase. Hyperphosphatemia in children with CKD is not typically seen until Stage 4 or 5 CKD (GFR <30 ml/min/1.73 m^2), although impaired phosphate clearance may first occur when the GFR decreases below 40 ml/min/1.73 m^2 (140).

The combination of deficient calcitriol synthesis and impaired phosphorus excretion results in the changes of bone and mineral metabolism. Hyperphosphatemia potentiates PTH secretion in and of itself (141), while the lack of calcitriol causes decreased suppression of PTH transcription (142). With time, the stimuli of low calcium, elevated phosphorus, and decreased calcitriol levels lead to secondary hyperparathyroidism and subsequent parathyroid gland hyperplasia and possibly even chromosomal changes (143, 144). Elevated PTH levels cause increased activation of the PTH receptor protein on osteoclasts and osteoblasts, increasing their cellular activity. This, in turn, results in high bone turnover which, if persistent, may lead to fibrous changes of the bone, referred to histologically as osteitis fibrosa cystica. Increased skeletal resistance to PTH is also seen in CKD, secondary to either low calcitriol levels or the accumulation of uremic toxins or PTH fragments from a decreasing GFR (145, 146).

More recent work has focused on the pathology of vascular calcifications seen in patients with CKD, since their presence is closely linked with cardiovascular mortality (147). Unlike the calcification of atherosclerotic plaques which are found in the intimal layer, vascular calcifications in CKD are primarily found in the medial layer (148). It is unclear why these calcifications develop in CKD, but the hypotheses have centered around three potential etiologies- the common mesenchymal origin of vascular smooth muscle cells and osteoblasts (149), the increase of mineralization factors seen in uremia (150, 151), and the suppression of inhibitors of calcification (152). Although the pathophysiologic mechanisms causing the calcifications have not been fully elucidated, their presence has been associated with elevated serum phosphorus levels, elevated calcium-phosphorus product, elevated PTH levels, and increased doses of vitamin D and calcium-containing phosphorus binders (153–156). Rising awareness that altered mineral metabolism contributes to the increase in cardiovascular pathology seen in CKD has led to the reclassification of mineral, skeletal, and vascular diseases together under the term CKD mineral and bone disorder (CKD-MBD) (157), encompassing the more systemic nature of the disorder.

Evaluation of Mineral and Bone Disorder

As the bone remodeling of renal osteodystrophy is preventable, patients with CKD should have their serum calcium, phosphorus, CO2, alkaline phosphatase and PTH levels checked regularly. Secondary hyperparathyroidism has been reported in children with Stage 2 CKD (158) and thus annual monitoring is recommended even at this early stage (159). The pediatric K/DOQI bone guidelines have also addressed the frequency of monitoring (see *Table 68-7*) with a recommendation for increased vigilance with more advanced kidney disease and for more frequent monitoring if treatment of renal osteodystrophy has already been initiated. Recommendations from the

Table 68-7

Frequency of measurement of bone and mineral factors and target ranges of serum PTH by stage of CKD

CKD Stage	Frequency of calcium, phosphorus, and CO2	Frequency of PTH and alkaline phosphatase	Target serum PTH (pg/ml)
2	annually	annually	35–70[a]
3	every 6 months	every 6 months	35–70[a]
4	every 3 months	every 3 months	70–110[a]
5	every month	every 3 months	200–300

[a]based on expert opinion

European Pediatric Dialysis Working Group concur with these guidelines for monitoring frequency, except for delaying routine monitoring until Stage 3 CKD and monthly monitoring of all five parameters in Stage 5 CKD (160). Newer recommendations from the Kidney Disease: Improving Global Outcomes (KDIGO) initiative will be forthcoming (157).

Intact serum PTH is routinely monitored as a less-invasive surrogate biomarker for osteodystrophy and may be used to discern between high and low bone turnover states. PTH levels should be checked using a first generation immunometric assay (159), which recognizes an epitope of the intact PTH (1–84) molecule between residues 7 and 34. However, these assays have been found to react with PTH fragments lacking the N-terminus of the molecule (161) and may over-estimate biologically active PTH. Therefore, second generation assays were developed with antibodies binding to the N-terminus and measuring intact PTH more specifically (162), with values often 50–60% of those measured with first generation assays. The difference in the measures of the two assays represents the N-terminus truncated fragments of the molecule. However, studies comparing the two assay types in children have shown similar predictive values in determining the specific bone histology (163, 164). Therefore, because of the limited experience and availability of second generation assays, first generation assays are still used. In mild to moderate CKD (Stages 2 and 3), normal PTH levels are desired as this correlates with normal bone formation rates (165). In more advanced stages of the disease, increased PTH levels are desired (159, 160) because of the increased skeletal resistance to PTH and the increased risk of adynamic bone disease associated with low/normal PTH values (see *Table 68-7*).

Therapeutic target levels of serum phosphorus and calcium are the age-appropriate norms in CKD Stages 2–4 (159) with increased stringency in CKD Stage 5. Target levels for serum calcium in Stage 5 CKD is towards the lower end of the normal range, 8.8–9.5 mg/dL [2.20–2.37 mmol/L] with interventions to lower serum calcium recommended if levels exceed 10.2 mg/dL [2.54 mmol/L] (159).

Serum alkaline phosphatase is a measure of the osteoblastic activity of bone. It is assessed in conjunction with serum PTH as it increases the predictive power of PTH for determining high versus low bone turnover (166). In patients with hepatic disease, total alkaline phosphatase may be elevated and the determination of the skeletal fraction of the enzyme may be determined by separately measuring the heat-stabile and labile fractions. Alkaline phosphatase levels may be useful in monitoring skeletal response to vitamin D therapy with decreasing levels indicating improved histologic bone appearance (167). Other bone markers (osteocalcin, collagen C-terminal telopeptide) have not been studied widely in children with CKD.

Serum levels of 25-OH vitamin D3 provide an estimate of vitamin D body stores, with a value of less than 30 ng/ml indicative of deficiency. Monitoring of 25-OH vitamin D3 is often practiced in pediatric CKD patients once they have elevated PTH levels (159). K/DOQI recommends that the 25-OH vitamin D3 level should be checked annually if it remains in the normal range and more frequently, every 6 months, if patients are vitamin D deficient and receiving replacement therapy. With the recently reported high prevalence of vitamin D deficiency in pediatric CKD patients and the documented efficacy of vitamin D repletion therapy on bone mineralization in earlier stages of CKD (168), more regular monitoring may soon be recommended. Since serum calcitriol levels offer limited information and are expensive to check, they are not currently recommended as part of routine clinical monitoring in patients with CKD.

Routine skeletal radiography has little diagnostic yield in the early stages of CKD, but may be indicated if bone disease is already present. In severe secondary hyperparathyroidism, subperiosteal mineral resorption may be seen, especially in the phalanges of the hand. Therefore, annual hand and wrist X-rays are recommended in Stage 5 CKD (160), when high turnover bone disease is most often present. In contrast, no pathognomonic radiologic findings are present in adynamic bone disease. Other bone density imaging techniques, such as DEXA scans, are not routinely indicated at this time. Finally, the gold standard for the determination of bone histology is bone biopsy. Although it is a safe procedure in the hands of experienced practitioners, the cost and invasive nature of bone

biopsy precludes its inclusion in the care of most pediatric CKD patients; it is generally considered only in patients with pathologic fractures, suspected aluminum toxicity, or with persistent hypercalcemia despite normal PTH levels (159).

Treatment of Mineral and Bone Disorder

The main tenets of treatment of pediatric CKD bone and mineral disorder is the maintenance of normal mineral metabolism and prevention of high turnover bone disease. The close monitoring of serum calcium, phosphorus, and PTH are used to guide therapy and minimize the development of the secondary complications of impaired growth, adynamic bone disease, and extra-skeletal calcification. As hypophosphatemia can contribute to bone disease at earlier stages of CKD, the maintenance of serum phosphorus above the lower limits for age is recommended (159). Total CO_2 is also routinely monitored in CKD because of the effect metabolic acidosis has upon bone remodeling and its potential remediation with bicarbonate supplementation.

The development of high turnover bone disease associated with CKD may be optimally prevented by limiting the development of hyperphosphatemia. Hyperphosphatemia tends not to develop in the earlier stages of CKD, as the loss of the kidney's phosphate excretory ability typically does not occur until the GFR is less than 40 ml/min/1.73 m^2, as noted previously. In these early stages of CKD, elevated serum phosphorus levels and the accompanying elevated PTH value are often the result of an excessive dietary intake and may be ameliorated by dietary restriction (169) with recommended limits of 80% of the Dietary Reference Intake for age (170). However, as CKD progresses and phosphate excretory function decreases, the need for dietary phosphate binders, in addition to avoidance of high phosphate containing foods, becomes more apparent.

Calcium salts (calcium carbonate or acetate) are frequently first-line treatments as phosphate binders. They are inexpensive and are most often well-tolerated with gastrointestinal complaints as their most common side effect. The phosphate binding capacity of calcium salts are, however, limited and large doses are often required. The recommended total (diet and binders) intake of calcium for children with CKD is twice the daily dietary recommended average for age (159), which may easily be exceeded with large calcium-based binder dosages. The use of calcium acetate, which has less elemental calcium and is able to bind more phosphorus per unit of calcium than calcium carbonate, may result in a lower incidence of hypercalcemia than might be seen with the latter agent. Calcium citrate is as effective as acetate and carbonate in its phosphate binding capabilities, but has been shown to enhance aluminum resorption across the gastrointestinal tract and is not usually recommended. In most cases, hypercalcemia in CKD is secondary to renal osteodystrophy therapies and modification of calcium-containing phosphate binders or vitamin D supplementation is therapeutic.

Sevelamer hydrochloride is a metal-free phosphate binder which has been shown to effectively lower serum phosphorus levels (171) and may shortly be approved for adult use in non-dialysis CKD. Sevelamer is resistant to digestive degradation and, therefore, it is not absorbed from the intestinal tract and does not accumulate in tissues. Although not yet approved for use in children, it has been shown to be effective in lowering serum phosphorus levels in children requiring dialysis (172) with a lower risk of hypercalcemia in comparison to calcium-based binders (173). Sevelamer use has also been associated with a decreased progression of vascular calcifications (174) and lower overall mortality rates in adults (175). Although decreased serum bicarbonate levels may be seen with sevelamer hydrochloride use (173), the recently FDA approved agent, sevelamer bicarbonate, does not have that associated side effect when taken by adults; pediatric studies with this agent have not yet been completed. Sevelamer hydrochloride has also been shown to lower total and low-density lipoprotein (LDL) cholesterol levels in children (173), an action that may have secondary benefits on overall cardiovascular risk.

Metal-containing phosphate binders are of limited use in pediatric CKD. Aluminum-containing binders were an early mainstay of therapy but are no longer recommended, except for limited time periods in very rare circumstances (159) because of the risk of aluminum toxicity. Magnesium salts also have limited use in pediatric CKD because of their associated side effects of hypermagnesemia, hyperkalemia, and diarrhea. Lanthanum carbonate is a more potent binder of intestinal phosphate than other current binders. However, tissue accumulation of lanthanum has been shown in rats (176) and increased bone lanthanum levels have been seen in adult subjects 2 years after drug discontinuation (177). The long-term effects of lanthanum carbonate on growing bone and tissues are not known and, hence, its use is not recommended in pediatric CKD.

Vitamin D deficiency is a relatively common finding in patients with CKD (178, 179) and the current K/DOQI guidelines recommend replacement of vitamin D when

25-OH vitamin D3 levels are less than 30 ng/ml (159). Therapeutic Vitamin D is currently available in two forms, ergocalciferol (D2) and cholecalciferol (D3). Ergocalciferol is available as a component of most multivitamins, usually at 400 IU; however, multi-vitamin supplementation is not recommended because of the risk of vitamin A toxicity (180). Ergocalciferol is also available as an 8,000 IU/ml liquid and a 50,000 IU (1.25 mg) capsule. Current recommended upper limits of Vitamin D intake is 2,000 IU daily in patients with normal renal function (181) which has been safely prescribed for older children and adolescents (182). Recommendations for repletion therapy are correlated with the severity of Vitamin D deficiency (see *Table 68-8*). No controlled studies have directly compared the efficacy of ergocalciferol to cholecalciferol in children, although an improved response of serum 25 (OH) D3 levels has been seen with cholecalciferol when compared to ergocalciferol in healthy adults (183, 184). Recently, Menon et al. (168) showed that treatment of the vitamin D deficient pediatric CKD population (Stages 2 through 4) with ergocalciferol significantly decreased serum PTH levels within 3 months of treatment, consistent with findings seen in adults (185, 186).

If secondary hyperparathyroidism persists despite normal serum phosphorus and vitamin D levels, treatment with a vitamin D sterol or vitamin D analog is indicated. Calcitriol and its prohormone, alfacalcidol, are widely used in children and both are effective in suppressing PTH (187, 188) by increasing intestinal calcium absorption and suppressing PTH gene transcription. Alfacalcidol is not available for use in the United States currently, but it has been widely used in Europe. Calcitriol may be given orally or intravenously with initial doses from 5–10 ng/kg/day and may be administered daily or intermittently with equivalent effectiveness in controlling secondary hyperparathyroidism (187). Calcitriol does increase intestinal absorption of phosphorus by nearly 50% and therefore may worsen hyperphosphatemia. Additionally, there is an increased prevalence of hypercalcemia and an associated increase in the calcium-phosphorus product with its use, especially when it is co-administered with a calcium-based phosphate binder. Newer vitamin D analogs, such as paricalcitol and doxercalciferol, minimize the likelihood of hypercalcemia while continuing to suppress PTH transcription (189). In the pediatric dialysis population, intravenous paricalcitol has been shown to effectively lower PTH when compared to placebo (190) and has been shown to decrease the calcium-phosphorus product when compared to calcitriol (191). However, its use was not associated with a decreased prevalence of hypercalcemia. Oral paricalcitol has recently been approved for use in adults with CKD Stages 3–5, although studies on its use in pediatrics have not yet been reported.

Calcimimetics treat hyperparathyroidism by binding to the calcium sensing receptor of the parathyroid gland and, through allosteric modification of the receptor, increase its sensitivity to ionized calcium. Cinacalcet, the only currently available calcimimetic agent, has been shown to effectively lower serum PTH levels in adult ESRD and CKD patients (192, 193). Cinacalcet has not been approved for use in children; however a recent open-label study of its dosing in pediatric ESRD patients showed that it was well-tolerated and effective, with no treatment-related adverse events (194).

When refractory hyperparathyroidism develops despite aggressive pharmacotherapy, total parathyroidectomy with auto-transplantation to the forearm or abdomen may be considered a safe and effective alternative (195) in pediatric patients. This approach to management is usually considered a last option because of the resultant potential difficulties with calcium homeostasis following renal transplantation (159).

Table 68-8

Recommended supplementation for vitamin D deficiency in patients with CKD

Serum 25(OH) D (ng/ml)	Definition	Ergocalciferol (Vitamin D2) dose
<5	Severe Vitamin D deficiency	8,000 IU/day orally (or 50,000 IU per week) × 4 weeks, then 4,000 IU/day (or 50,000 IU twice per month) × 2 months*
5–15	Mild Vitamin D deficiency	4,000 IU/day orally (or 50,000 IU every other week) × 12 weeks*
16–30	Vitamin D insufficiency	2,000 IU/day (or 50,000 IU every 4 weeks)*

*Recommended therapy duration is 3 months then re-measure 25(OH)D3 levels to determine if further treatment needed

Cardiovascular Disease

Adults with CKD have significantly increased rates of cardiovascular morbidity and mortality compared to the

general population (196, 197). Much of this increased risk is secondary to the fact that many of the traditional risk factors for adult cardiovascular disease (hypertension, diabetes mellitus, hyperlipidemia) are also primary etiologies of adult kidney disease. However, this increased cardiovascular risk is not unique to adults with CKD. Estimates of cardiovascular mortality rates in children and young adults who developed end stage renal disease during childhood are 1,000 times greater than comparably aged healthy individuals (198).

The life expectancy of children with ESRD who remain on dialysis is shortened by as much as 40–60 years with 30–50% of all deaths in this population attributed to cardiovascular causes (34, 154, 199, 200). However, the cardiovascular causes of mortality are different in children with CKD than in adults. Adult cardiovascular deaths are frequently from coronary artery disease and congestive heart failure while the leading causes of cardiac death in children with CKD are arrhythmia, valvular disease, and cardiomyopathy (201). Therefore, many questions about cardiovascular risk factors in pediatric CKD exist and firm recommendations still cannot be made on whether primary prevention should focus upon traditional "adult" cardiac risk factors, which appear earlier and are more accelerated in children with kidney disease, or upon uremia-related risk factors, which are unique to the CKD population.

The mechanism by which cardiovascular disease develops in children with CKD is thought to occur by two, potentially concurrent, processes- cardiac remodeling and vascular injury. Remodeling of the left ventricle with resulting hypertrophy occurs from mechanical or hemodynamic overload of the muscle and subsequent sarcomere changes. The development of concentric left ventricular hypertrophy (LVH) is most often secondary to increased resistance from hypertension while eccentric LVH is often secondary to volume overload or anemia. Over time, worsening LVH changes may lead to decreased subendocardial perfusion and an increased risk of arrhythmia generation. Persistent hypoperfusion may lead to myocardial fibrosis and diastolic or systolic dysfunction.

Vascular injury may occur through either atherosclerotic or arteriosclerotic changes, or both. Atherosclerosis involves penetration of the intimal layer of the vasculature with lipid-containing macrophages, the accumulation of smooth muscle cells and collagen to form an atheroma, with subsequent luminal narrowing. Arteriosclerosis involves thickening of both the intimal and medial layer of the arteries and is often characterized by increased wall thickness, luminal enlargement, and loss of vessel elasticity. Calcification of vessels may occur with either atherosclerosis or arteriosclerosis, primarily involving the large to medium-sized vessels such as the aorta and brachial artery, but is also noted to involve the smaller coronary arteries in children with advanced uremia on occasion (155, 156).

Markers of vascular injury are commonly found in pediatric patients with CKD. The prevalence of dyslipidemia in pediatric dialysis patients ranges from 70 to 90% (202) and a study examining the internal iliac artery samples of pediatric patients at the time of renal transplant revealed that >40% of subjects had histopathologic evidence of atherosclerosis with one-third having intimal micro-calcification or atheromatous plaque formation (203). Asymptomatic atherosclerosis, as measured by abnormal carotid intimal medial thickness (IMT) and vessel calcification, has been noted in pediatric CKD patients prior to the initiation of dialysis as well (204). In a study by Litwin et al., arteriopathy correlated with systolic blood pressure and dyslipidemia in pediatric CKD subjects (204).

Endothelial function, as measured by flow-mediated dilation of the brachial artery, has also been shown to be impaired in children with CKD (205). Recently, Muschietes et al. compared carotid IMT values and flow-mediated dilation in pediatric CKD, dialysis, and transplant patients (206). A majority of CKD patients had reduced flow-mediated dilation, which correlated well with increased carotid IMT and was thought to precede the arteriopathic findings. Although not shown in the longitudinal studies of children with CKD, there may be a progression of vascular injury from initial endothelial dysfunction to vascular wall thickness changes to eventual calcification of vessels. Likewise, the risk factors for disease progression may also change depending on the degree of pathology, with blood pressure and dyslipidemia having greater effects during earlier stages of CKD and calcium, phosphorus, and PTH levels in latter stages.

Hypertension is a traditional cardiovascular risk factor which develops early in the course of CKD. In the Chronic Kidney Disease in Children (CKiD) study, the prevalence of systolic and diastolic hypertension at study initiation were 53% and 54%, respectively (207), consistent with an earlier report in which the prevalence of hypertension in pediatric CKD was 50% (44). Risk factors associated with the presence of an elevated blood pressure at the time of study initiation in the CKiD study included a shorter duration of CKD, indicating that hypertension was often present early in the disease process, but either went unrecognized or under-treated. A potential reason that hypertension may be missed in this population is that the early BP changes in CKD are often associated with alterations of the

circadian rhythm of blood pressure regulation. Though not explicitly recommended, K/DOQI guidelines suggest that the use of ambulatory blood pressure monitoring (ABPM) may be a valuable tool in patients with CKD (46) because its use may help detect changes in BP which would likely not be discovered with casual blood pressure checks alone. Recently, Dionne et al. found that ABPM detected abnormalities in nearly 50% of pediatric CKD patients that were otherwise not detected by casual clinic readings (208). Mitsnefes et al. has reported rates of nocturnal hypertension in pediatric CKD patients as high as 24% (209) with attenuated nocturnal dipping in nearly 60% of subjects. Blunted nocturnal dipping has been shown to correlate with decreasing GFR (208, 209). In adults with CKD, Andersen et al. found that ABPM detected masked hypertension in 26–29% of their subjects which was otherwise not detected by office BP readings alone (210). Additionally, ABPM readings have been found to correlate better than casual blood pressures with measures of LVH in children and adults with CKD (209, 211) and, therefore, it may serve as a better means of predicting end organ injury than casual blood pressures in this at risk population.

Hypertension has been clearly linked to LVH in adults with CKD (212); however, the direct link in children is still being investigated. One-third of children with mild to moderate CKD have been reported to have an increased left ventricular mass index (LVMI) (213–215). In a prospective longitudinal study of pediatric patients with CKD Stages 2 to 4, Mitsnefes et al. reported a 32% incidence of LVH development over 2 years (216). In that analysis, increased LVMI, defined by mass divided by height raised to a power of 2.7, was associated with an increased nocturnal systolic blood pressure load as well as increased serum PTH and decreased hemoglobin levels. However, in the larger ESCAPE trial, Matteucci et al. did not find any relationship between casual or ambulatory blood pressure readings and LVM in their cross-sectional analysis (215), questioning the significance that hypertension alone has in cardiac remodeling.

Alterations in left ventricular function are also different in children with CKD compared to adults. Systolic function does not appear to be compromised in children (213, 217) but the earlier-appearing changes of diastolic dysfunction may be found. Studies have shown impaired left ventricular relaxation in children requiring dialysis (213 218). The newer index of diastolic function, tissue Doppler imaging, has also been shown to be impaired in children with CKD and those on chronic dialysis (219). Whereas the clinical significance of diastolic dysfunction in children is still under study, the poor diastolic function in pediatric dialysis patients has been associated with factors such as anemia and hyperphosphatemia (219), and may offer some insight into the complex interactions contributing to cardiac remodeling in CKD patients. Over the past few decades, abnormalities of the left ventricle and arterial circulation have been identified as strong predictors of cardiac risk in the adult CKD population and recent investigations have shown that children with CKD may also have many of these same cardiovascular abnormalities (220).

Evaluation and Treatment of Cardiovascular Disease Risk Factors

Recommendations for monitoring and treatment of cardiovascular risk factors in children with CKD have been primarily derived from adult data and have focused upon the traditional cardiovascular risk factors of hypertension and dyslipidemia. Target blood pressure in children with CKD should be less than the 90th percentile for age, gender, and height or 120/80 mmHg, whichever is lower, as recommended by the Fourth Report on Blood Pressure in Children (47). Routine screening ambulatory blood pressure monitoring is not currently recommended by the K/DOQI guidelines, but many experts endorse its use in high-risk populations (221) and recommendations for a standardized approach have recently been published (222). Currently, echocardiography is recommended for children at the initiation of dialysis to screen for the presence of end-organ damage or valvular disease (46) which may have developed during earlier stages of CKD. However, its routine use to screen for end organ injury in children with persistent hypertension or those at high-risk for cardiovascular morbidity (i.e., patients with CKD) should also be considered (221).

The preferred antihypertensive agents to be used for the treatment of hypertension in CKD are ACE inhibitors or ARBs because of their effects on proteinuria and slowing of CKD progression, as discussed earlier. Their role in the reduction of renal sympathetic activity, and the possible secondary effects on cardiac remodeling are additional rationale for selecting these first-line agents. Recent cross-sectional analysis of CKiD study data showed that uncontrolled hypertension was associated with the absence of ACE inhibitor or ARB use in pediatric patients with CKD (207). Diuretics may also be considered in children with CKD, to address the sodium and fluid overload that may be present in patients who do not have salt-losing nephropathies. Thiazide diuretics may be used in patients with earlier stages of CKD, but they are not effective when the

GFR falls below 30 ml/min/1.73m(2). Loop diuretics may be considered in CKD Stages 4 and 5. Beta-blockers may be used as second-line anti-hypertensive agents as well. Calcium channel blockers are also potent anti-hypertensive medications and may be considered for adjunctive therapy; however, dihydropyridine (DHP) calcium channel blockers, such as nifedipine and amlodipine, increase intraglomerular pressure and proteinuria (223, 224) and may have less beneficial effects in terms of slowing CKD progression when compared to other anti-hypertensive options. Although non-DHP calcium channel blockers, verapamil and diltiazem, have been shown to have effects equivalent to ACE inhbitors in slowing of CKD progression in adult diabetic patients (225), there are no published safety data regarding their use in children with hypertension and they are known to cause prolongation of the PR interval in adults (224). Alpha-adrenergic agents (prazosin, clonidine) and other vasodilators (hydralazine, minoxidil) may also be considered for therapy with their selection and continued usage dependent on efficacy and side effect profile in the individual patient.

The treatment of dyslipidemia in pediatric CKD is not well-studied and, therefore, not addressed in depth in the K/DOQI guidelines. Adolescents with CKD should be evaluated for dyslipidemia with a fasting lipid profile for total cholesterol, LDL, HDL, and triglycerides (226). Treatment recommendations are, however, limited to adolescents with Stage 5 CKD. The National Cholesterol Education Panel initially recommended that the use of lipid-lowering drugs in children be restricted to those over age 10 years with a fasting LDL >190 mg/dl or >160 mg/dl and two other risk factors (227). However, the American Heart Association expert panel released an updated scientific statement addressing high-risk pediatric patients which considered pediatric CKD patients to be in the highest risk group (228). In children with CKD and a fasting LDL >100 mg/dl, therapeutic lifestyle changes, such as reduced dietary saturated fat and cholesterol intake and moderate exercise, are first recommended for the initial 6 months. If target LDL levels (<100 mg/dl) are not reached, initiation of statin therapy is indicated. There is no information on the efficacy of lipid-lowering therapies on cardiovascular morbidity or mortality of pediatric CKD patients. Therefore, the presumed benefit in children is extrapolated from adult studies. However, statin therapy has been proven to be effective in improving endothelial function in children with hypercholesterolemia (229).

Other management strategies for minimizing cardiovascular risk in pediatric CKD address uremia-related risk factors. Anemia should be treated to maintain serum hemoglobin levels in the recommended range to reduce any potential effects on cardiac remodeling. Serum PTH, calcium, and phosphorus should also be closely maintained to K/DOQI recommended levels because of the growing evidence of their contribution to vascular abnormalities. Other potential uremia-related risk factors, such as hyperhomocysteinemia (230), elevated C-reactive protein (231), elevated asymmetric dimethylarginine (232), and low adiponectin levels (233) have not been well-studied in pediatric patients.

Fluid, Electrolyte, and Acid-Base Balance

With the gradual decrease in GFR, the remnant functioning nephrons and tubules compensate by increasing their excretory function in an attempt to maintain solute homeostasis. Such compensation will generally allow for adequate fluid and electrolyte balance until greater than 75% of renal function is lost. However, these adaptive changes are gradual and may not compensate for sudden changes in volume or solute load.

Sodium balance in CKD is generally maintained by a progressive decrease of sodium reabsorption by the proximal and distal tubules (i.e., gradual increase in the fractional excretion of sodium). Children with CKD from obstructive uropathy or renal dysplasia have defective urinary concentrating abilities, from a decreased tubular responsiveness to vasopressin (234). Because of a limited capacity to reduce distal tubular fluid sodium concentration in these patients, sodium excretion often becomes dependent on urine flow (235). Thus, these patients are often polyuric with substantial urinary sodium losses despite advancing renal disease. Fluid balance is normally maintained because of an intact thirst mechanism. Acute problems may arise if fluid intake is not maintained in these patients because of gastrointestinal illness or iatrogenic limitations. On a chronic basis, sodium balance may not be normally maintained because of chronic urinary losses, with the resultant signs of sodium depletion often being subtle, such as impaired somatic growth. In fact, linear growth has been shown to improve in young children with CKD with sodium and water supplementation (236). Supplementation with sodium chloride up to 4–7 mEq/kg/day is often required.

Conversely, children with CKD from primary glomerular diseases or with associated oliguria often require sodium and fluid limitation to minimize the risk for the development of edema and hypertension. While the exact sodium restriction that is needed in this population is not known, limitation to less than 1,500 mg daily as

recommended for hypertensive individuals (237) or 25–70 mg/kg/day (1–3 mmol/kg/day) in younger children seems reasonable, but can be sometimes difficult to achieve practically. In-depth education by a renal dietician about the sodium content of foods and the need to avoid processed foods is highly recommended.

Potassium homeostasis is usually preserved until the GFR is less than 15 ml/min/1.73 m^2. This is because aldosterone-stimulated distal tubular potassium secretion is maintained. Aldosterone also stimulates increased potassium secretion within the colon with as much as 35% of dietary potassium able to be excreted in the stool (238). However, children with renal dysplasia, obstructive uropathy, reflux nephropathy, or interstitial nephritis may have tubular resistance to the aldosterone activity and can develop hyperkalemia with relatively higher creatinine clearances (239). This hyperkalemia may be exacerbated by volume contraction and, in turn, responds to sodium and fluid repletion. Additionally, potassium-sparing diuretics, ACE inhibitors, and ARBs contribute to the hyperkalemic risk in these patients. For patients with persistent hyperkalemia, dietary potassium intake should be limited. As food labels frequently lack potassium content, patient and family education by a renal dietician about potassium-rich foods (chocolate, potatoes, green leafy vegetables, etc...) and alternate food preparation methods, such as soaking vegetables before cooking, should be reviewed. In infants and young children, the use of low-solute formulas or the incorporation of sodium polystyrene sulfonate (Kayexalate) resin with the formula should also be considered (240). In hypertensive children, calcium polystyrene sulfonate may also effectively bind potassium (241) with much less of a sodium load provided to the patient. Lastly, any constipation should be treated to improve the gastrointestinal elimination of potassium.

Unlike sodium and potassium disorders which develop late in the progression of CKD, metabolic acidosis may occur when the GFR declines below 50% of normal. As glomerular filtration decreases, the relative ammonia production of the remaining tubules increases (242) while titratable acid excretion is initially preserved. However, with progressive renal dysfunction, absolute ammonia, phosphate and titratable acid excretion decreases while bicarbonate resorption decreases (243, 244), leading to metabolic acidosis. In infants and children, the endogenous hydrogen ion load is actually increased compared to adults. Chronic acidosis has been associated with increased protein degradation (245) and decreased albumin synthesis (246). Additionally, chronic acidosis causes bone demineralization (247) and may suppress native growth hormone secretion (248). Therefore, a serum bicarbonate value of greater than 22 mEq/L should be maintained in order to maximize growth in children with CKD (249). Oral bicarbonate therapy is the standard treatment for metabolic acidosis as citrate preparations should be avoided because of the aforementioned increase in aluminum absorption seen with their use (250).

Growth Failure and Nutrition

Growth failure or failure to grow is a common and the most visible complication of CKD in children. Patients often fail to achieve final adult heights consistent with their genetic potential or within population norms. The cause of growth failure in these children is most often multi-factorial, based on a combination of nutritional, metabolic, and endocrine abnormalities. Affected children may have secondary physical and psychological complications associated with their poor growth. However, aggressive management of secondary causes of poor growth and the prudent use of recombinant growth hormone (rhGH) can minimize the prevalence of growth failure and its secondary sequelae.

According to the most recent NAPRTCS registry data, the average height of children with CKD is nearly 1.5 standard deviations below the age- and gender-specific norms upon entrance to the registry (23). More than 35% of children with CKD have significant growth failure, defined as a height less than the third percentile or a height standard deviation score (SDS) more negative than −1.88 (23). Although there is some correlation between kidney function and growth impairment, significant growth failure was seen at all levels of kidney function in the NAPRTCS registry, including 19% of subjects with the highest estimated GFR values (50–75 ml/min/1.73 m^2). A more significant correlation was found between growth failure and young age at the time of registry entry. The average height SDS in infants (age 0–1) and young children were −2.33 and −1.65, respectively, while it was only −0.93 for adolescents. Additionally, significant short stature was seen in 58% and 41% of all infants and young children, respectively, while it was present in only 22% of adolescents. This is important as one-third of overall postnatal linear growth is attained in the first 2 years of life, such that any early growth insults may have a profound long-term impact on final height.

Although other factors (acidosis, secondary hyperparathyroidism, and electrolyte imbalance) may contribute to growth failure in all children with CKD, malnutrition has the most marked effect in infants and

young children with CKD (251). Energy intake is the principal determinant of growth at this age (252) and maximizing caloric intake to at least 80% of requirements has been found to effectively improve height velocity in children who developed CKD as infants (252, 253). Inadequate protein intake may also contribute to insufficient growth in infants and experiments in young animals have shown that decreased protein intake during normally rapid periods of growth can adversely affect overall growth (254). Uauy et al. showed that even a modest restriction in protein intake had a negative impact on the growth of infants with CKD (255). It is equally important to note again that dietary protein restriction has no discernable effect on the progression of CKD when studied in children (45).

Outside of infancy and early childhood, perturbations of the growth hormone/insulin-like growth factor (GH/IGF) axis are the predominant influences on growth. In children with CKD, there is increased pituitary release and decreased renal clearance of GH, resulting in increased serum GH levels. However, down regulation of GH receptors by the liver and changes in post-receptor signal transduction results in decreased synthesis of IGF-1. Additionally, increased concentrations of IGF binding proteins, whose concentration is inversely correlated to GFR, lead to decreased levels of the bio-active or "free" IGF, which mediates many of the biological effects of GH such as longitudinal bone growth. Thus, CKD is associated with a state of dysregulation or resistance, and not deficiency, of the GH/IGF/binding protein system which alters somatic growth. Additionally, disturbances in the gonadotropic hormone axis, namely decreased pituitary secretion of lutenizing hormone (256) and reduced free testosterone levels (257), may be seen in adolescents with CKD. This is associated with both a delayed and shortened pubescence and contributes to a suboptimal peak height velocity during this period, estimated at only 50% of that experienced by children without CKD (258). All of this may often result in children with a final adult height that is far below their genetic potential. A retrospective analysis of children who were transplanted before age 15 showed that the median height of subjects was below the third percentile for age at the time of dialysis initiation and did not improve significantly following transplantation. Significant growth failure was present in 77% of adult male subjects and 71% of females (259). More recent clinical trials also support the observation that pre-existing height deficits in children with CKD are still associated with decreased final adult heights (260, 261).

The impact of growth retardation in the CKD population is most evident in a number of studies that have addressed quality of life. In a study of adults with short stature, 60% of patients who had kidney failure as a child reported wanting to be taller and 33% stated that they would sacrifice years of life expectancy to do so (262). A questionnaire given to 240 adults who received a kidney transplant in childhood showed that final height was significantly associated with marital status and level of education, while inversely related to level of employment (263). A survey of young adults on dialysis or with a functioning transplant revealed that 36% were dissatisfied with their final height and this dissatisfaction correlated with patient perceptions of quality of life (264).

The negative effect of growth impairment in children with CKD may extend beyond psychosocial issues to an increased risk of morbidity and mortality. Utilizing data from the U.S. Renal Data System on over 1,000 children on dialysis, Furth et al. showed that children with more severe growth failure, as defined by height velocity, had higher deaph rates than those with a normal growth rate (265). Additionally, growth failure was associated with an increased incidence of hospitalization, primarily for infectious complications. In a second study of 2,300 children in the NAPRTCS registry, Furth et al. demonstrated that children with CKD and a lower height SDS (more negative than −2.5) at the time of dialysis initiation had an increased risk of hospitalization and a two-fold higher risk of death (266). Although the cause of increased mortality in these studies was not clear, the results suggest that short stature is associated with a more complex clinical course of CKD and may be a reflection of other clinical risk factors, such as a poor nutritional status.

The current K/DOQI pediatric nutrition guidelines recommend correction of nutritional deficiencies and metabolic abnormalities prior to the use of growth hormone therapy for growth failure (249). This is especially true in infants and young children, whose growth is primarily dependent on caloric intake. Current experience suggests that the caloric intake of children with CKD should be equal to the recommended daily allowance (RDA) (267) as compromised growth is seen when caloric intake is less than 80% of the RDA, as noted above. A prospective study in children with CKD between 1.5 and 10 years of age showed that more than 50% of patients had less than the recommended energy intake, with the poorest results reported in the older patients (268). In order to achieve the necessary caloric intake, caloric supplementation through added density to formula should be considered in young children with fluid restrictions.

Nasogastric, gastrostomy, and gastrojejunostomy tubes, with daytime intermittent bolus or continuous nightly feeds, may also be used successfully in patients unable to maintain oral caloric needs secondary to anorexia, an approach that has been associated with improved height and weight SDS in young children with CKD (269). Caloric sources should be divided so that 50% of total calories are provided by primary complex carbohydrates and the remaining non-protein calories should be divided in a 2:1 ratio between polyunsaturated and saturated fat.

Protein energy malnutrition may also contribute to the poor growth of children with CKD. However, a study reviewing the nutritional intake of children with CKD by 4 day food records revealed a mean protein intake greater than 150% of the RDA (268), hinting that protein malnutrition is not as prevalent in this population as once thought. In the previously mentioned European study which examined the impact of a modest reduction in dietary protein (0.8–1.1 gm/kg/day) in children with CKD over 3 years, there was no impairment of subject growth, however there was also no benefit in terms of the prevention of disease progression (45). Therefore, it is recommended that children with CKD receive 100% of the age-recommended RDA for protein and that 50% of that protein come from high biologic sources such as milk, eggs, and meats. Protein intake should not be excessive and must be repeatedly evaluated with respect to the CKD stage because of its potential contribution to hyperfiltration and excess metabolite generation (270).

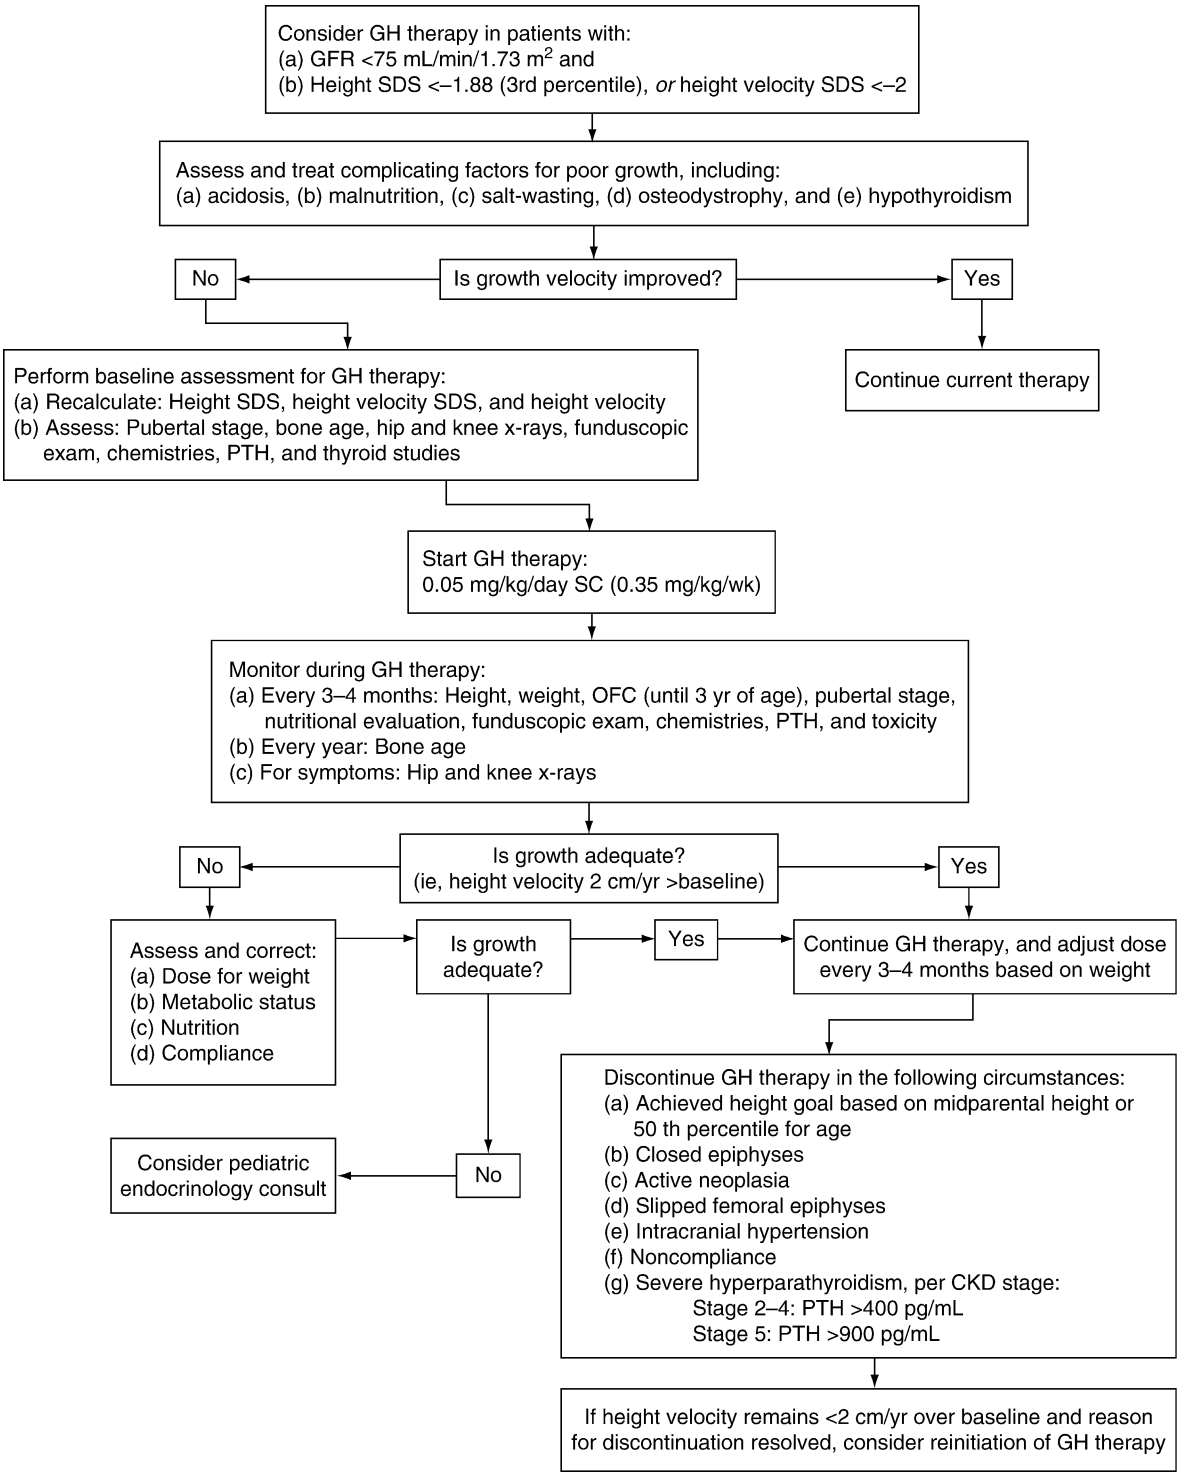
Despite optimization of nutritional management and correction of metabolic abnormalities, normal growth may not be obtained by these measures alone. A review of NAPRTCS data showed that catch-up growth without growth hormone treatment was primarily observed in children with CKD younger than age five (271). Therefore, the use of recombinant human growth hormone (rhGH) likely will be needed in order to achieve height norms in a substantial number of children with CKD and growth retardation. Multiple clinical trials have demonstrated the efficacy of rhGH to improve height velocity and height SDS in children with CKD (272). Recombinant GH has been approved for the treatment of growth failure in children with CKD at an optimal subcutaneous dosage of 0.35 mg/kg/week (28–30 IU/m2/week) administered daily. Children who are Tanner stage I-III and have either a height SDS of −1.88 or worse and/or a height velocity SDS of −2 or worse are candidates for -therapy (249). The safety profile of rhGH use in children with CKD is excellent, as its use has not been associated with a significant increase in adverse effects when compared to children not receiving rhGH (273, 274). Nevertheless, close monitoring of patients for the safety and efficacy of the therapy is routinely indicated. Increased insulin levels have been seen during the first year of rhGH use (275, 276), however irreversible diabetes mellitus has not been observed (274) and a return to baseline insulin levels usually occurs with long-term treatment (275). rhGH use has been associated with increased PTH levels in children with CKD, a problem that seems to be most significant in pubertal age children (277), and at least temporary discontinuation of therapy may be necessary in the setting of severe secondary hyperparathyroidism. The development of intracranial hypertension has also been noted (278) and mandates a stoppage of therapy. An algorithm for the treatment of growth failure, including the monitoring of growth hormone therapy, is provided in *Fig. 68-1*.

Although children who receive rhGH while on dialysis or after kidney transplantation generally experience a beneficial growth response to rhGH therapy, children with CKD have been shown to have the best response (279). A Cochrane review of rhGH studies in pediatric CKD showed a better response in patients with Stage 3 or 4 CKD than in those with Stage 5 disease (273). In recent analyses of longitudinal use of rhGH in French children with kidney disease and of the Pfizer International Growth Database (KIGS), height SDS gain was significantly better in patients with CKD treated conservatively than in children receiving dialysis or in those who had received a kidney transplant (261, 280). Additionally, a better response was associated with younger age at therapy initiation (261) with pre-pubertal children responding better than pubertal children (273). Because of the improved response apparent in younger children and during earlier stages of CKD, rhGH therapy should be initiated early in the course of the disease in order to maximize growth potential (272, 280). Other factors that are associated with the best response to rhGH include the extent of height SDS gain during the 1st year of therapy (280), total duration of therapy (261, 280), renal dysplasia as the primary disease etiology (281), degree of bone age retardation (261), and the lack of pubertal delay (261). Sustained use of rhGH therapy in children with CKD can often lead to an adult height within norms. Results from two European studies have provided evidence that 60–65% of children with CKD on rhGH therapy will have a final adult height SDS greater than −2 (258, 280).

Despite the benefits of rhGH therapy, a substantial number of growth-impaired children with CKD do not receive treatment. The 2007 NAPRTCS Report showed that rhGH utilization in eligible children in the CRI registry was only 11% upon entry into the registry and increased to

Figure 68-1

Algorithm for evaluation and treatment of growth failure in children with CKD.



only 22% after 12 months (23). Even more alarming is the fact that rhGH utilization seems to be decreasing. From 2000 to 2002, rhGH was used by 28.7% of eligible CRI patients at 1 year after registry entry, but decreased to 21.9% from 2003 to 2006 (23). A recent multi-center study examining obstacles to rhGH use in children with CKD revealed that psychosocial reasons (family refusal or non-compliance) was cited in 30% of the patients. However, there was no identifiable reason precluding rhGH use in 25% of the patients, based on a review of the medical records (282). Additionally, this study noted that boys with growth failure were twice more likely to be treated than girls, implying that growth failure may still be viewed more as a cosmetic issue which may be more acceptable in girls.

Cognitive and Psychosocial Development

The impairment of growth evident in pediatric CKD is not limited to somatic growth, as neurocognitive development and psychosocial adjustment have been shown to be affected as well. The etiology of these impairments is not clear. It may be a direct effect of uremia or other accumulated metabolites on the growing brain or it could be secondary to the impact of other sequelae of kidney disease on brain development. Environmental influences, such as lost educational opportunities from parental occupation or school absenteeism, are also likely contributions. The evolution of these issues and their influence on long-term outcome has become better appreciated as the overall care of the pediatric CKD population has improved.

Original reports on the neurological and developmental outcomes of infants and young children with CKD showed devastating results. Rotundo et al. reported on 23 children who developed CKD at less than 1 year of age with a remarkable 87% of the patients having evidence of a progressive encephalopathy and 83% with developmental delay (283). McGraw and Haka-Ikse found that of their subjects diagnosed with CKD at less than 1 month of age, only 20% had a normal developmental quotient and 75% developed a seizure disorder (284). These early and poor neurologic outcomes have been at least partially attributed to aluminum toxicity from the aluminum-containing phosphate binders that were commonly used at that time. Indeed, aluminum-containing binders were used in all of McGraw's subjects and in all but four of Rotundo's subjects had neurological sequelae. Poor nutritional status was also a common manifestation of CKD in these patients and, therefore, probably played a role in the genesis of the poor neurologic outcome. Not surprisingly, all of Rotundo's and 67% of McGraw's study subjects had significant growth impairment. Nearly a decade ago, Warady et al. showed a much improved developmental outcome in patients who initiated dialysis during infancy (<3 months old) with the avoidance of aluminum binders and the regular use of supplemental feedings, in this case provided by the nasogastric route (285). Of 28 infants in this study who were observed for a long-term, nearly 80% had normal developmental scores and only 4% had significant developmental delay. Thus, the prevention of aluminum exposure and the use of aggressive nutrition with dialysis contributed to improved neurologic outcomes in this high-risk population of infants with severe CKD. Other more recent reports have provided similar data (286, 287).

While cognitive function has been shown to be impaired in children with ESRD in a number of studies (288–290), data addressing the cognitive status of patients with less severe CKD are limited. Hulstijn-Dirkmaat et al. compared patients with ESRD to those with CKD and showed improved developmental index scores in those not requiring dialysis (288). Duquette et al. compared children with CKD to control subjects in the areas of intellectual and academic functioning and found that children with CKD had significantly lower scores on intelligence quotient (IQ), reading, and mathematical testing (291). Kidney function was found to correlate with intellectual and academic scores; recent school absences correlated negatively with IQ and math scores, as well. In more specific areas of cognition, Fennell et al. compared 56 children with CKD to age-matched controls and found that children with CKD had deficits in verbal abstraction, visual-motor abilities, and memory (292) with worsening of memory skills 1 year later. More recently, Gipson et al. compared the neurocognitive status of 20 children with CKD Stages 2–5 with age-matched controls (293). They found that the children with CKD demonstrated significantly lower memory abilities, specifically short-term verbal and visual memory, as well as impairment of new learning capacity. In addition, they found that children with CKD had deficits in selective higher order executive functioning of the brain related to attention. In a separate study, Slickers et al. found that in children with CKD, lower IQ scores were associated with greater severity of the disease and onset of the disease at a younger age while decreased memory function was associated with longer duration of disease (294). Recommendations for a battery of tests to help identify children with CKD who possess neurocognitive deficits have been published (295).

At present, there is no identified threshold of renal dysfunction that has been shown to affect neurodevelopment in children with CKD, as many of the previously cited studies included patients on dialysis (291, 293). However, this is currently being investigated in the CKiD study (296). The contribution of other sequelae of CKD to cognitive dysfunction is also being investigated as anemia (297) and hypertension (298) have been associated with lower intelligence and academic scores in non-CKD populations.

Psychological well-being has also primarily been studied in the pediatric ESRD population (299–301) with limited studies in children with less advanced kidney disease. A study comparing children with kidney transplants, CKD, or nephrotic syndrome to healthy controls failed to find differences in the prevalence of behavioral problems between these groups (302). In the few studies that have been performed, social functioning and quality of life were impaired in pediatric CKD patients. Gerson et al. compared the health-related quality of life in pediatric CKD patients to controls and found overall poorer functional health status in children with CKD (303). McKenna et al. studied 20 Canadian children with CKD and found that they had significantly lower quality of life scores in the areas of physical health and school performance when compared to healthy controls (304). In adults, survivors of pediatric ESRD have been shown to have low self-esteem, low rates of living independently, and are less likely to establish intimate relationships (299, 305). Whereas it has been thought that the basis for the lower quality of life scores in children with CKD is often the physical limitations from CKD, poorer scores have also been associated with worsening GFR (306) and anemia (111). Impaired self-esteem and perceptions of others may also have a significant impact, as improved quality of life scores have been associated with height gain (306).

Although initial studies indicate that children with more protracted or more severe CKD are at particular risk for cognitive and psychosocial impairment, all children with CKD should be considered at risk. In turn, early participation of experts in behavioral and developmental pediatrics to assess the cognitive ability and emotional well-being of children with advanced CKD is prudent so that individualized education plans and counseling may take place and educational, emotional, and functional potential may be optimized. Currently, only 15% of school-aged children with CKD in the United States receive special education services (307) which may under-estimate the needs of these patients. Lastly, incorporation of a multi-disciplinary approach, including individuals with psychosocial expertise, into the transition programs of adolescents with CKD as they move to "adult care" may help to maximize the success of patients as they aim to develop social and functional autonomy (308).

Transition to ESRD

Although a goal of early and aggressive treatment of CKD is the abatement of disease progression, ESRD will inevitably develop in most pediatric CKD patients. Therefore, early preparation for the transition to ESRD is warranted to avoid any emergent procedures and potentially unnecessary associated morbidity. K/DOQI guidelines recommend that formal discussions regarding ESRD preparation should begin once patients reach Stage 4 CKD (GFR less than 30 ml/min/1.73 m^2) (16). In practice, the introduction of anticipatory measures to avoid unnecessary morbidity at an even earlier stage is often most effective.

In anticipation of the possible need for long-term dialysis, the limitation of vascular procedures using multiple blood vessels should be emphasized, especially with the growing use of peripherally inserted central catheters (PICC) in pediatrics. Early identification of the non-dominant arm and its protection from proximal intravenous access will help preserve that extremity for future hemodialysis vascular access. Early consultation with a vascular surgeon to address the development of a fistula prior to the need for dialysis is also recommended (309). Subclavian catheters, as opposed to internal jugular catheters, should only be used as a last option for central venous access in pediatric patients (310) as there are high rates of subclavian stenosis found in adults even with short-term subclavian access placement (311). Additionally, femoral access should be avoided except for emergent situations as there is an increased risk for the loss of inferior vena cava patency and a resultant inability to use those vessels for kidney transplant anastamosis (312).

Since congenital abnormalities of the urinary system are present in a significant percentage of children with CKD, surgical procedures (cystoplasty, vesicostomy) involving the lower urinary tract may be necessary prior to transplantation. Abdominal surgical procedures should also be completed well in advance of progression to ESRD not only to allow for proper healing but, in the case of peritoneal dialysis candidates, to minimize any disruption of the peritoneal membrane. These procedures include pre-emptive nephrectomy as well as gastrostomy tube placement, which may be needed for nutritional supplementation and medication administration.

Avoidance of unnecessary blood product exposure should also be prioritized in order to minimize antigen exposure prior to transplantation. Multiple red blood cell transfusions prior to transplant increase the risk of donor specific antibody formation and have been associated with an increased risk of acute rejection episodes post-transplant (313). Therefore, aggressive use of erythropoiesis stimulating agents and iron supplementation to achieve hemoglobin goals, especially prior to any surgical procedures, should be encouraged.

Children with CKD should receive their standard immunizations. However, certain vaccinations merit special consideration in anticipation of renal replacement therapy. Vaccination for measles, mumps, and rubella (MMR) should ideally be given prior to the initiation of dialysis as variable responses have been noted in dialyzed patients (314). The MMR vaccine is contraindicated in immunosuppressed children following kidney transplantation (315) and should be given more than 6 weeks prior to the transplant procedure (316). The varicella-zoster vaccine (VZV) should also be given in advance to sero-negative transplant candidates to minimize post-transplant morbidity risk, as it too is contra-indicated in immunosuppressed individuals. Although it is not contra-indicated in immunosuppressed patients, the hepatitis B vaccine series should be completed 6 weeks prior to transplantation as well, as the antibody response to the vaccine is better when given to children with CKD before initiation of dialysis (317) or receipt of a transplant (318). Children who will require dialysis are at increased risk for pneumococcal infections and should receive the 23-valent polysaccharide pneumococcal vaccine (319); dialysis patients less than age 6 should also receive the heptavalent vaccine (PCV-7) (320). Annual influenza vaccinations should also be given to children with CKD, including those with kidney transplants or requiring dialysis.

Formal discussions regarding planning of renal replacement therapy should be multi-disciplinary, including not just the family and nephrologist but also the surgeons, specially trained nurses, social workers, dieticians, and psychologists. Pre-emptive transplantation should be considered in patients who are without contra-indications to transplant, as this approach allows for an improved quality of life, an easier rehabilitation to normal activities (321), and possibly the prevention of the various morbidities associated with dialysis dependence. While pre-emptive transplant was previously only thought possible for children with living donors, the substantial preference currently provided to children on the deceased donor list in the United States may make it possible for these children to also receive a transplant before dialysis is necessary. For children who will require dialysis prior to transplantation, discussion of the available dialysis options including their advantages and disadvantages should be conducted and the choice of dialysis modality made with respect to both the medical and psychosocial considerations of the patient and family.

69 Handling of Drugs in Children with Abnormal Renal Function

Ihab M. Wahba · Ali J. Olyaei · David Rozansky · William M. Bennett

Introduction

Determining the dosage and frequency of a particular drug in a child with kidney dysfunction can often seem daunting. Many therapies have not been fully tested in children, even in those children with normal kidney function. Despite laws instituted in the past two decades to encourage pharmacological studies in pediatric populations, drug dosing in children is often based on extrapolation from adult data. Yet, children often metabolize drugs differently than adults, depending on the drug category or age group. In addition, renal dysfunction adds a further level of complexity to drug dosing as absorption, distribution, metabolism, and secretion of agents can be altered as kidney function worsens. The extent to which derangements in drug handling alter dosage can depend on the GFR, the child's age or size, the precision of the GFR estimation, or, when in renal failure, the modality of the renal replacement therapy.

The overriding principle of this chapter is that drug dosing in the pediatric population with renal impairment requires consideration of many factors and persistent scrutiny. The chapter reviews general pharmacological principles of drug handling and presents specific tenets for how dialysis alters drug levels. It also offers a step-wise approach for nephrologists and other providers to consider when making decisions about drug dosage and intervals in children with impairment of renal function.

Drug Dosing in Renal Failure: General Principles

In order to provide a safe and effective treatment protocol for children, rational drug selection is required. It is necessary for pediatric health care providers to know the therapeutic benefits, indications, contraindications, adverse effects, drug interactions, and precise mechanism of drug used in pediatric patient. Although children experience adulthood diseases there are very limited clinical trials in the pediatric population. In one study over 90% of neonates in intensive care units (1) and 70% of pediatric patients were receiving a drug which was not approved in the pediatric population (2). Most drug dosing are based on "targeted effects" or "concentration effects." Pharmacotherapy is complicated in pediatric patients with kidney disease as very limited information exist involving drug dosing in this setting. It is very important to emphasize that children are not miniature adults. In fact, children are not "just children." The pharmacokinetic properties of most drugs are different from 24 week gestation to 18-year-old adolescent. Metabolic activities, total body water, gastrointestinal functions and structure, overall renal function, body surface, tissue perfusion, skin thickness and protein binding are continually changing during child development (3, 4) (› *Fig. 69-1*).

Drug actions are further different when compared with adult in patients with normal renal function. The addition of renal dysfunction makes appropriate drug management complex and unpredictable in children. Not only is it vital to understand the disease states, comorbid conditions, pharmacodynamic properties of the selected drug, and potential drug-drug interactions, it is also vital to recognize the pharmacokinetics of these agents in the pediatric population. Pharmacokinetics is defined by the individual patient's ability to absorb, distribute, metabolize, and eliminate the drug from the body. Pharmacodynamics is characterized by how drugs affect the body (› *Fig. 69-2*). The objective of pediatric pharmacotherapy is to provide empathic but effective and rapid drug delivery with safe therapeutic outcomes. To attain this aim, pediatric health care providers must understand basic pharmacokinetics and pharmacodynamics (5).

The pharmacodynamics of drug therapy and desirable outcomes are controlled by the concentration of a specific drug at the site of drug action. To some degree, therapeutic plasma concentration is controlled by drug absorption, distribution, metabolism and excretion. First, the drug must be partially or completely absorbed in order to enter into plasma concentration. Next the drug must be distributed to the primary site of action to exert its critical modulation or pharmacodynamic effects. Lastly, drug

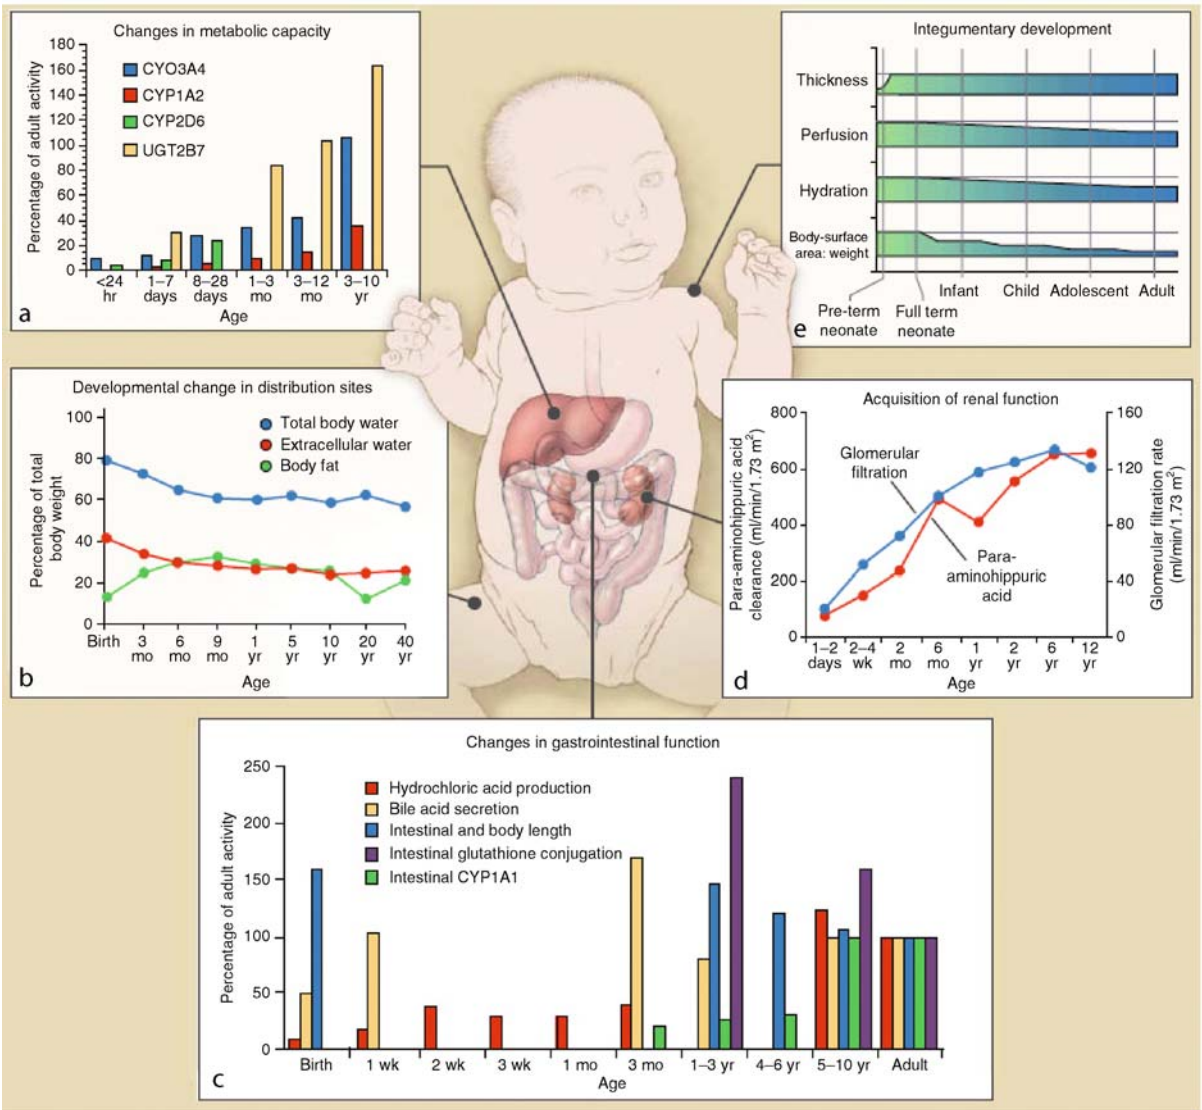
Figure 69-1

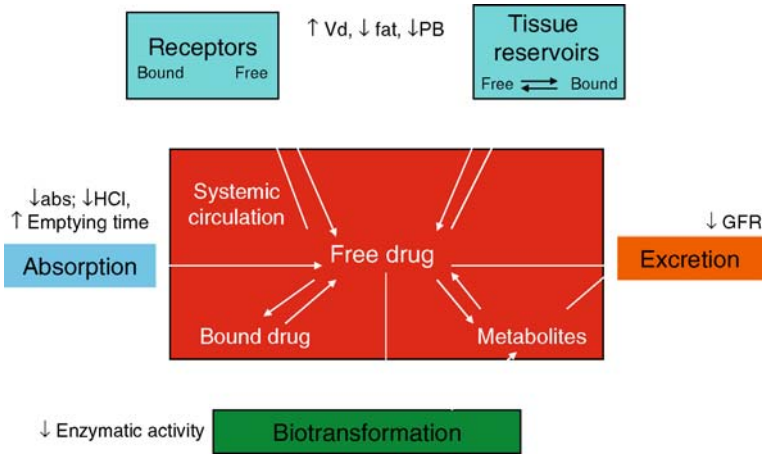
Human development and pharmacokinetic alteration in infant, children and adolescents. Many changes through human development may alter drug disposition. This figure emphasize on age-adjusted need for drug and dosage adjustment during the human development. Panel A shows the metabolic activity of phase I and II enzymatic reactions, Panel B reflect the changes in total body water at different time period, Panel C illustrate the gastrointestinal function and acid production, Panel D demonstrate active tubular secretion by clearance of para-aminohippuirc acid, and Panel E demonstrate age depended changes in skin structure, perfusion and body surface area. (Adapted from Kearns et al. (3)).



must be eliminated from body without causing unwanted adverse reactions. Drugs do not produce a new function, they only modify pathological processes. Pharmacologic agents act by affecting biochemical and physiological processes in the body. Most drugs bind to or interact with a specific receptor but may produce multiple effects because of the location of the receptors in different organs. Familiarity with these drug pharmacodynamic and pharmacokinetic properties helps pediatric health care providers to predict the behavior of a drug in the body. A complete presentation of these basic pharmacological principles is beyond the scope of this chapter. This chapter briefly reviews basic principles of pharmacokinetics in the pediatric population with renal dysfunction.

Figure 69-2

Pharmacokinetic activities; Differences between pediatric and adult patient. Abs: Absorption, HCL: hydrochloric acid, Vd: Volume of distribution, PB: protein binding.



Drugs or their active metabolites are eliminated changed or unchanged through the renal system. Thus, renal dysfunction from both acute kidney injury and chronic kidney disease may influence drug elimination. Assessment of renal function and drug behavior during kidney aids dysfunction ultimately help in appropriate choice of dose of drug and dosage interval (6). Due to the complexity of pharmocotherapy in pediatric patients with renal insufficiency, three important principles should be considered (1) identifying patients with acute kidney injury or chronic kidney disease, (2) accurately estimating level of renal function, and (3) adjusting drug dosages accordingly.

Pharmacokinetics

Pharmacokinetics defines and analyzes the time course of the drug in the body. Pharmacokinetic properties are altered in renal dysfunction. These include bioavailability, volume of distribution (Vd), protein binding, and biotransformation (7).

Drug Absorption

Following oral administration, the drug must be absorbed before reaching its site of action. Absorption is the first stage of pharmacokinetics. Bioavailability is a better pharmacokinetic phrase compared to drug absorption. Bioavailability defines the percent of the drug that reach the systemic circulation. In children with kidney disease, especially CAPD patients, vomiting out medications is a common problem; therefore, drug absorption would be variable and incomplete (8). Bioavailability is primarily determined by the rate and route of administration. For example, drugs administered intravenously are generally 100% bioavailable, because the entire dosage reaches the systemic circulation. When given orally, subcutaneously, or intramuscularly, bioavailability decreases. Uremia also alters drug absorptions or bioavailability. Most drugs require an acidic environment to be absorbed. At birth until age of 2–3 the gastric pH remain high approximately 6–8. For example, both phenytoin and phenobarbital require an acidic atmosphere to be absorbed completely. In addition, uremia may further affect the absorption of most drugs. Uremia-induced vomiting or gastroparesis may slow gastric emptying time leading to reduced drug absorption (9).

Children with kidney dysfunction commonly have bowel wall edema, which may impair drug absorption. Drugs that increase gastric pH, such as phosphate binders and H2-receptor blockers, may impair absorption of concomitantly administered drugs. Most pharmacological agents are absorbed by passive diffusion and changing ionization states may change drug diffusion through the gastrointestinal wall. Concomitant administration of some phosphate binders for the treatment of hyperphosphotemia (aluminum- or calcium-containing) with antibiotics or iron-containing supplements may result in the formation of insoluble complexes that both limit absorption and slow gastrointestinal motility. Parenteral drug

administration might provide a more reliable route of administration, but more painful and should be avoided as much as possible. In addition, because of a low muscle mass and poor blood flow to the muscle, drug bioavailablity is unpredictable following intramuscular administration. Finally, some intramuscular preparations are oil-based formulation and have a prolonged absorption period (6).

Drug Distribution

After reaching the systemic circulation, most drugs are distributed throughout body compartments in several phases. Initially, drugs are distributed to highly perfused organs such as the heart, liver, kidney, and brain. In the second phase, drugs are distributed to other areas with less or slower blood flow such as fat, bone, and skin. The rate of distribution and extent of drug concentration at the site of action determines the onset of drug action. Body composition, total body water, cardiac output, regional blood flow, and protein binding may affect drug distribution through the body (7). Compared to adults, pediatric patients population have significantly higher total body water and a larger volume of distribution (Vd). The volume of distribution is calculated by dividing the total amount of drug in the body by the concentration of the drug in the blood. The volume of distribution does not refer to a specific anatomic compartment. It is a mathematical model which is useful for calculating the appropriate dosage regimen needed to achieve a desired systemic plasma concentration. An inverse correlation exists between the serum concentration and the volume of distribution. For highly hydrophilic drugs such as aminoglycosides, both renal failure and higher total body water in children and neonates results in an increased volume of distribution. This rise in extracellular fluid volume results a lower serum concentration of aminoglycosides. Drug diffusion is also dependent on protein binding and lipid solubility. A highly water-soluble drug has a small volume of distribution and a high plasma concentration. A highly fat-soluble drug possesses a large volume of distribution and has a low plasma concentration. Pharmacologically, only unbound drugs are active and able to bind to specific receptors. The affinity of pharmacologic agents to receptors and degree of protein binding determines the pharmacodynamic properties of any agent. Drugs that are highly protein bound have a very large volume distribution. Any changes to protein binding due to decreased protein synthesis or proteinuria may alter therapeutic plasma concentration and potentially desired outcomes. In addition, drugs with high affinity to protein mostly distribute in the vascular compartment. Children with kidney dysfunction have decreased protein synthesis and increased protein elimination. For drugs such as phenytoin, which is highly protein bound, the free fraction concentration is elevated while total phenytoin plasma levels are subtherapeutic. In this setting only free, unbound phenytoin should be measured to avoid toxicities (10). Finally, in neonates with high bilirubin and kidney disease, most of the sites for drug binding are occupied with endogenous bilirubin or uremic molecules and results in increased plasma concentration of drugs that are highly protein bound. For example, about 97% of mycophenolate in the plasma is bound to albumin while 2–3% is free. Hypoalbuminemia (albumin less than 2.5 gm/dl) causes increased risk of toxicities due to an increased concentration of free mycophenolate in the plasma. Hypoalbuminemia may cause an increased from free fraction of mycophenolate from 3% to 6%. Although small increased in free fractions seems trivial, the amount of free mycophenolate available to exert immunosuppressive or adverse drug reactions is doubled, with possible serious consequences (11, 12).

Drug Metabolism

Most drugs are metabolized to more soluble compounds which are then removed from the circulation (13). In general, most drug metabolites are pharmacologically inactive, however, a number of drugs have active metabolites that are excreted through the kidney. Patients with chronic kidney disease are at a higher risk of drug accumulation and toxicities in this setting. For example, procainamide has an active metabolite; *N*-acetyl procainamide (NAPA). NAPA has pro arrhythmic properties and is excreted by the kidneys (14, 15).

There are two major metabolic pathways. In phase I reactions drugs are metabolized through oxidation, reduction, and hydrolysis. In oxidation reactions, oxygen atoms cause lipophilic pharmacologic agent to become more water soluble. The oxidative reactions typically involve the cytochrome P-450 enzymatic system (16–18). Cytochrome P-450 enzyme systems are subject to significant maturation through childhood development. In general, microsomal enzyme systems are immature in infants and neonates. It has been shown that drug metabolism is slower in the children than adult at this stage of life. However, drug metabolism is higher compared to adults during the toddler age and early stages of puberty. The mechanisms that account for this alteration of drug

metabolism are correlated to age-adjusted hormonal changes (19). Consequently for many drugs that are metabolized through the P-450 enzyme system a high dosage per kilogram body weight is required to achieve the same therapeutic plasma concentration compared to adult patients (20, 21) (*Figs. 69-3* and *69-4*). The second important pathway for drug metabolism is called synthetic or conjugation reactions. Phase II reactions involve the attachment of another chemical group to the drug resulting in greater water solubility and renal elimination. Most drugs undergo one or both of the phase I and II reactions in order to be eliminated from systemic circulation and the body. There is increasing evidence to suggest that there are significant amount of polymorphism exists on expression of both enzymatic systems in children and adolescents. Most patients with kidney disease take several drugs and these enzyme systems can be induced or inhibited by other pharmacotherapuetic agents (22). Drugs that stimulate this enzymatic system are considered inducers and may decrease the therapeutic benefit of other agent. For example, phenytoin may increase the metabolism of prednisone and cyclosporine and result in acute

Figure 69-3

Figs. 3 and 4 Illustrate that a higher dosage of drugs are needed for children than adults adjusted for body weight.

See Fig. 3.

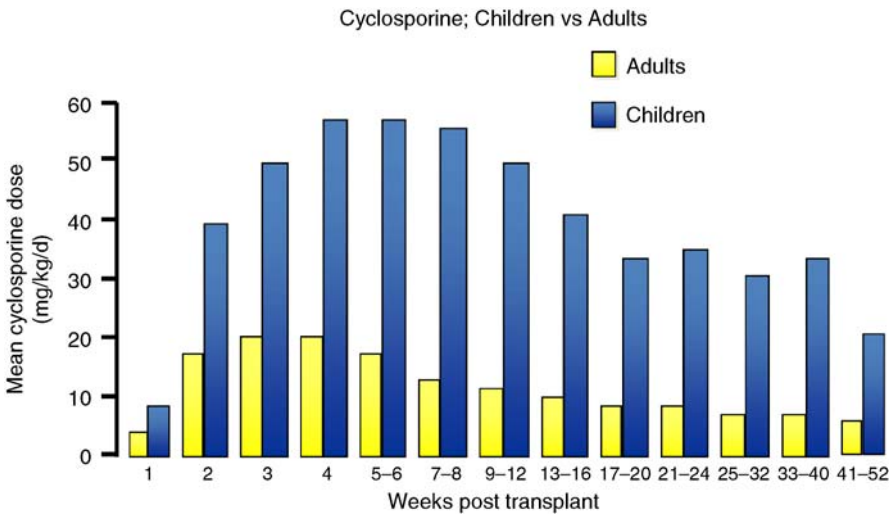

Table 69-1

Commonly used drugs with potential drug interaction in pediatric population with kidney disease. Modified form Lynch et al. (22)

Enzyme	Potent inhibitors	Potent inducers
CYP1A2	Amiodarone, cimetidine, ciprofloxacin, fluvoxamine	Carbamazepine, phenobarbital, rifampin, tobacco
CYP2C9	Amiodarone, fluconazole, fluoxetine, metronidazole, ritonavir, trimethoprim/sulfamethoxazole	Carbamazepine, phenobarbital, phenytoin, rifampin
CYP2C19	Fluvoxamine, isoniazid,ritonavir	Carbamazepine, phenytoin, rifampin
CYP2D6	Amiodarone, cimetidine, diphenhydramine (Benadryl), fluoxetine, paroxetine, quinidine, ritonavir, terbinafine	No significant inducers
CYP3A4 and CYP3A5	Clarithromycin, diltiazem, erythromycin, grapefruit juice, itraconazole, ketoconazole, nefazodone, ritonavir, telithromycin, verapamil	Carbamazepine, Hypericum perforatum, St. John's wort, phenobarbital, phenytoin, rifampin

rejection or allograft loss after kidney transplantation. Other drugs may inhibit the metabolism of another drug and increase the risk of toxicity. Erythromycin may decrease the metabolism of cyclosporine and cause in cyclosporine toxicity and drug induced-allograft injury (11, 23). Commonly used drugs in the pediatric population which can cause drug interactions through their effect on metabolism are listed in *Table 69-1*.

Dialysis and Drug Dosing

There is a paucity of published studies pertaining to drug pharmacokinetics and clearance in children undergoing various dialytic modalities. Therefore, most of the data are extrapolated form the adult literature. In general, drugs that are eliminated primarily via renal excretion are those which are significantly affected by dialysis, whereas drugs that undergo extrarenal elimination are not significantly altered by dialysis (24, 25). Drug removal during hemodialysis is a function of the dialysis dose, (Kt/V), "K" being the dialyzer clearance, "t" the time on dialysis, and "V" the urea volume of distribution which is practically equivalent to total body water (approximately 60% of body weight) (24). Since total body water is smaller in children, some authors suggested that dialytic drug clearance should be higher in children than in adults, if "K" and "t" are the same (24). This may be especially true for continuous renal replacement therapies (CRRT), where the same dialyzers used for adults are also used for children (24). The dialyzability of a drug is dependent on a number of variables that can be related to drug and/or dialytic properties. This section will discuss those variables in detail, and will outline the principles of drug dosing in children receiving various forms of dialytic therapies.

Drug Properties that Affect Dialyzability

The following drug characteristics affect drug dialyzability: molecular weight and size, protein binding, volume of distribution and electrostatic charge (24, 26, 27). In general, drugs with small molecular size or volume (<500 D) are more readily dialyzable than larger molecular-sized drugs (27). However, the molecular weight as a determinant of dialyzability is most relevant when low-flux dialysis membranes are used. In regions of the world where the majority of dialysis membranes used are high-flux such as in the U.S.A. and some European countries (28, 29), molecular size of the drug has become less relevant, since high-flux membranes can still remove drugs with molecular weights of more than 30,000–40,000 D (25). For instance, vancomycin (molecular weight 1,450 D) clearance with low-flux membranes is minimal, whereas a significant amount is cleared by high-flux membranes (30).

Protein binding affects drug clearance during dialysis. Drugs that are highly protein bound (>80%), in general, are poorly dialyzable, whereas unbound drugs and those with low protein binding capacity are more readily dialyzable (31). In patients with renal failure, there is a tendency for an increase in the unbound fraction of some drugs due to changes in the metabolic milieu or a reduction in plasma albumin, rendering them more dialyzable (32–34).

The volume of distribution of drugs also affects dialyzability. Drugs with a low volume of distribution (e.g., hydrophilic drugs, such as β–lactam antibiotics, aminoglycosides and glycopeptides), usually are confined to the intravascular and extracellular spaces, and therefore, are effectively removed by dialysis. Drugs with a large volume of distribution are usually highly tissue bound and

distribute throughout the extravascular and intracellular compartments such as adipose tissue (e.g., lipophylic drugs, such as the macrolides, tetracyclines, fluoroquinolones and linezolid), and are not effectively removed by dialysis even if the extraction across the dialysis membrane is 100% (25). In general, drugs with a volume of distribution less than 0.7 L/kg are well dialyzed, whereas drugs with a volume if distribution greater than 2 L/kg are not. Drugs whose volume of distribution is between 0.7 and 2 L/Kg have variable but low dialyzability (31, 34–36).

The effect of intercompartmental equilibration can also affect drug removal and blood concentration during high-flux intermittent hemodialysis, particularly with respect to drugs with a middle or large molecular weight (4). Although dialysis may rapidly clear a drug from the intravascular compartment thus causing a significant reduction in blood concentration immediately post-dialysis, slow equilibration of intracellular drug concentration with the extracellular fluid may cause a rebound effect with a gradual increase in intravascular drug concentration lasting several hours after dialysis (35). For instance, vancomycin blood concentration falls significantly immediately following high-flux dialysis, but it rebounds to as high as 90% of the predialysis blood concentration several hours post-dialysis (37, 38). This effect should be considered when dosing drugs and interpreting drug concentration in patients undergoing hemodialysis.

Drug molecular charge may affect dialytic clearance (39, 40). Cationic drugs may be retained by anionic protein charges in the blood, and therefore may not cross the dialysis membrane to the dialysate compartment, even if the molecular weight and other drug properties favor its dialyzability. Conversely, the movement of anionic drugs from the blood to the dialysate compartment across the dialysis membrane may become enhanced. For example, the anionic drug clavulinic acid is cleared much more rapidly by high-flux membranes than is simply predicted by its protein binding and volume of distribution characteristics, likely owing to its negative charge (41, 42).

Dialysis Characteristics that Affect Drug Dialyzability

Dialysis-related variables that affect drug dialyzability can be related to the dialysis procedure (blood and dialysate flow rates, ultrafiltration rate, dialysate pH) or the dialysis membrane (dialyzer pore size or flux, dialyzer surface area, membrane charge and membrane binding characteristics) (24, 26). Among those variables, dialyzer flux, surface area, ultrafiltration rate and blood flow rate are probably the most important.

Drug clearance during dialysis occurs via two mechanisms: diffusion and/or convection (43). Diffusion of a drug from the blood to the dialysate compartment occurs because of a favorable concentration gradient. This gradient is facilitated by the countercurrent of blood and dialysate which run in opposite directions during dialysis, thus maximizing the blood-to-dialysate drug concentration gradient. Diffusion of drugs to the dialysate compartment increases as the molecular weight of the drug decreases. It also increases with increased surface area of the dialyzer and increased blood and dialysate flow rates (24–26). Convection is the process of drug removal during ultrafiltration across the dialysis membrane, and is the result of the hydrostatic pressure generated across the dialysis membrane. Convection is important for clearance of drugs with middle or large molecular weights that cannot be removed by diffusion, and increases as the ultrafiltration rate increases. Convection is thus dependent on the surface area of the dialyzer, membrane pore size (flux), and the hydraulic pressure gradient across the membrane, and is independent of concentration gradient (24–26). In summary, drugs with small molecular weights are removed mainly by diffusion, whereas drugs with middle or large molecular weights are removed by convection. For example, gantamicin which has a relatively small molecular weight, is easily removed with low-flux cuprophane membranes (44). By contrast, vancomycin, a drug with a relatively large molecular weight, is only significantly removed by high-flux dialyzers with large pores but not with low-flux cuprophane dialyzers (3).

Membrane electrostatic charge and drug binding to the dialysis membrane may also affect clearance. For instance, positively charged drugs such as gentamicin may bind to negatively charged membranes such as polyacylonitrile, resulting in reduced clearance during dialysis (26, 45, 46). Furthermore, dialysis membranes that are reused may become protein coated over time, which may reduce the dialyzer surface area and therefore, drug clearance (47). These factors must be considered before determining appropriate drug dosing for patients on dialysis.

Drug Removal and Dosing During Intermittent Hemodialysis

A logical approach to drug dosing during intermittent hemodialysis in children has been outlined by Veltri et al. (24). The first step is to evaluate the residual renal function (RRF) of the patient. If the RRF is significant, and if the drug is primarily eliminated renally, dosing

requirement will increase. Unfortunately, most references assume that once patients are on dialysis, then RRF is negligible, and dosing recommendations are solely based on the effect of dialytic clearance. Therefore, therapeutic drug level monitoring may be necessary for drugs that can be accurately measured in plasma to guide dosing, especially for drugs with a narrow therapeutic index.

Drug and membrane characteristics should also be considered before appropriate dosing. If the drug is likely to be significantly removed during dialysis, a supplemental dose should be given following dialysis. Unfortunately, there is a paucity of data published on dosage regimens and supplemental dosing in children, and most data are extrapolated from adult dosing guidelines. It may be appropriate to consider a larger supplemental dose for small pediatric patients when the amount of drug removed may be larger than in an adult (24). Supplemental dosing may be calculated using the following formula (26):

$$\text{Supplemental dose} = (C_{desirable} - C_{obtained}) \times V_d$$

where $C_{desirable}$ is the desirable plasma concentration, $C_{obtained}$ is the obtained plasma concentration, and V_d is the volume of distribution (L/kg). Vancomycin is an example of a drug that can be significantly cleared renally if the RRF is significant and can also be significantly cleared by high-flux dialysis membranes (30, 37, 38). Therefore, therapeutic drug monitoring is necessary to guide dosing to avoid underdosing or toxicity. Drug doses due around the time of the dialysis session are usually given post-dialysis to avoid significant drug removal during dialysis. For some drugs with a narrow therapeutic-toxic window such as aminoglycosides, predialysis dosing may be more appropriate to maintain a high peak and avoid prolonged exposure that may cause toxicity (26). This approach, however, needs further validation in clinical studies before it can be implemented.

Drug Removal and Dosing During Continuous Renal Replacement Therapies

Continuous renal replacement therapy (CRRT) is increasingly being used in children in the critical care setting (27). As in adults, the major indication for CRRT use is acute renal failure in the setting of hemodynamic instability. CRRT modalities include continuous hemofiltration alone (high-rate ultrafiltration + replacement fluid, no dialysate), continuous hemodialysis (no or minimal ultrafiltration + dialysate) or continuous hemodiafiltration (high rate of ultrafiltration + replacement fluid + dialysis). Replacement fluid is added to compensate for the high-rate of ultrafiltration. This can be added predilution (before the dialysis filter) or post-dilution (after the dialysis filter) (40–43).

The major forms of CRRT currently used are continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD) and continuous venovenous hemodiafiltration (CVVHDF), with the latter two modalities accounting for close to 80% of CRRT in the United States (28). Continuous arteriovenous hemofiltration (CAVH), hemodialysis (CAVHD) or hemodiafiltration (CAVHDF) are rarely used nowadays due to complications associated with arterial access. Slow continuous ultrafiltration (SCUF) is the process of slow isolated ultrafiltration without replacement fluid.

Dialysis filters used for CRRT are high-flux synthetic membranes, such as the polysulfone, polyamide, polyacrylonitrile or polymethylmethacrylate membranes (24). Drug removal during continuous hemofiltration occurs mainly via convection, whereas drug removal during continuous hemodialysis occurs mainly via diffusion. During hemodiafiltration, drug removal occurs via both convection and diffusion, and is usually greater than with either modality alone (24, 40). *Table 69-2* lists the clearance mechanisms and key parameters influencing drug removal during the different forms of CRRT and intermittent hemodialysis. It is important to remember that drugs with large volumes of distribution which are not significantly removed by intermittent hemodialysis may be significantly removed during CRRT since the length of therapy is prolonged over 24 h, which allows for greater removal of total body drug stores (24, 25).

Continuous Ultrafiltration and Hemofiltration

Drug removal during hemofiltration occurs via convection. Therefore, middle or large molecular weight drugs can be significantly removed by hemofiltration. Drug removal is proportional to the ultrafiltration rate and the sieving coefficient (S) of the drug and is not dependent on blood flow rate (24, 40, 49). The sieving coefficient is a mathematical term that reflects the extent of solute or drug removal during hemofiltration, and is expressed as the ratio of drug concentration in the ultrafiltrate to drug concentration in plasma (35, 49):

$$S = C_{uf}/C_a \quad (1)$$

where S is the sieving coefficient, C_{uf} the concentration of drug in the ultrafiltrate and C_a the drug concentration in plasma (or in the pre-filter plasma water concentration)

Table 69-2

Comparison of drug clearance with intermittent hemodialysis and different types of continuous renal replacement therapies (Adapted with permission from Joy et al. (48))

Technique	Clearance mechanism		Key parameter influencing drug removal
	Convection	Diffusion	
IHD	+	++++	Blood flow rate
SCUF	+		Ultrafiltration rate
CAVH/CVVH	++++		Ultrafiltration rate
CAVHD/CVVHD	+	++++	Dialysate flow rate
CAVVHDF/CVVHDF	+++	+++	Dialysate flow and ultrafiltration rate

IHD intermittent hemodialysis; *SCUF* slow continuous ultrafiltration; *CAVH* continuous arteriovenous hemofiltration; *CVVH* continuous venovenous hemofiltration; *CAVHD* continuous arteriovenous hemodialysis; *CVVHD* continuous venovenous hemodialysis; *CAVHDF* continuous arteriovenous hemodiafiltration; *CVVHDF* continuous venovenous hemodiafiltration
+ negligible; ++ some; +++ marked; ++++ major

(24–26, 40). A sieving coefficient close to one indicates that the drug freely crosses the dialysis membrane, while a sieving coefficient close to zero indicates no drug removal. Protein binding and drug-membrane interaction are the most important factors determining the sieving coefficient of a drug during hemofiltration (50, 51). Only the unbound fraction of the drug is removed by ultrafiltration (SCUF) or hemofiltration (CAVH or CVVH). The sieving coefficient of many drugs, but not all, therefore equates to the unbound fraction of plasma proteins (f_{up}). *Tables 69-3* and *69-4* list the sieving coefficients and the unbound fraction (f_{up}) of some commonly used drugs. The clearance of a drug ($Cl_{convection}$) during pure ultrafiltration (without dialysis) can then be calculated as (40):

$$Cl_{convection} = Q_f \times S \quad (2)$$

$$\text{Or, } Cl_{convection} = Q_f \times f_{up} \quad (3)$$

where Q_f is the ultrafiltration rate

Calculation of the clearance of a drug solely on the basis of the unbound fraction (3) should be approached with caution, because the unbound moiety may not always equate to the sieving coefficient (25). Vancomycin clearance is such an example. This may be especially true in critically ill patients due to factors such as hypoalbuminemia, alteration of protein binding to certain drugs, or drug binding to dialysis membranes (25, 47, 52). Therefore, frequent monitoring of plasma concentration of certain drugs during CRRT is necessary for dosage adjustment.

It is important to consider the effect of replacement fluid on drug clearance during CRRT (25, 43). If the fluid is administered in the post-dilution mode (post-filter), drug clearance can be calculated from the ultrafiltration rate as shown in (2). When the replacement fluid is added pre-filter, drug clearance is expected to be lower due to a dilution factor (DF) as (25, 53):

$$DF = Q_{bf}/Q_{bf} + Q_{rf} \quad (4)$$

where Q_{bf} is the blood flow rate and is Q_{rf} the replacement flow rate. Combining both (2) and (4), drug clearance in case of pre-dilution can be calculated as:

$$Cl_{convection\ (predilution)} = Q_f \times S \times Q_{bf}/Q_{bf} + Q_{rf} \quad (5)$$

Continuous Hemodialysis and Hemodiafiltration

In continuous hemodialysis, countercurrent dialysis is used during CRRT. There is minimal or no ultrafiltration. Therefore, drug clearance occurs mainly by diffusion, and is therefore dependent on the molecular weight of the drug, protein binding, volume of distribution and charge (24, 40). Drug clearance can be enhanced by increasing dialysate or blood flow rates, although the blood flow rate is usually limited to 50–180 mL/min. Diffusive drug clearance ($Cl_{diffusion}$) can be estimated as (40):

$$Cl_{diffusion} = Q_{dial} \times f_{up}$$

where Q_{dial} is the dialysate flow rate (mL/min)

In continuous hemodiafiltration (CAVHDF or CVVHDF), both a high rate of ultrafiltration that is replaced

Table 69-3

Sieving coefficient (S) and unbound fraction of selected antimicrobial agents (f_{up}). (Adapted with permission from Olyaei et al. (26) and from Pea et al. (25))

Drug	S	Unbound fraction (f_{up})
Amikacin	0.9	0.9
Amphotericin B	0.3	0.1
Ampicillin	0.7	0.8
Ceftazidime	0.9	0.9
Ceftriaxone	0.8	0.1
Cilastin	0.8	0.6
Ciprofloxacin	0.76	0.7
Clindamycin	1	0.4
Doxycycline	0.4	0.2
Erythromycin	0.4	0.3
Gentamicin	0.8	0.9
Imipenum	1	0.8
Meropenem	0.9	0.8
Metronidazole	0.8	0.8
Nafcillin	0.5	0.2
Penicillin	0.7	0.5
Piperacillin	0.8	0.8
Sulfamethoxazole	0.9	0.6
Tobramycin	0.8	0.9
Vancomycin	0.8	0.9

by IV fluids, and countercurrent dialysis are employed. Therefore, drug clearance occurs via both diffusion and convection. Total drug clearance during during hemodiafiltration (Cl_{CVVHDF}) can be calculated as (40):

$$Cl_{CVVHDF} = Cl_{convection} + Cl_{diffusion}$$

Drug clearance during any form of CRRT (Cl_{CRRT}) can be estimated from the following equation, by measuring drug concentration in the ultrafiltrate/dialysate effluent and in multiple plasma samples, and collecting the total volume of the ultrafiltrate/dialysate effluent (40):

$$Cl_{CRRT} = (C_{df} \times V_{df})/AUC_{0-t}$$

where C_{df} is the drug concentration in the ultrafiltrate/dialysate effluent, V_{df} is the volume of the effluent, and AUC $_{0\text{-}t}$ is the AUC during a timed effluent collection.

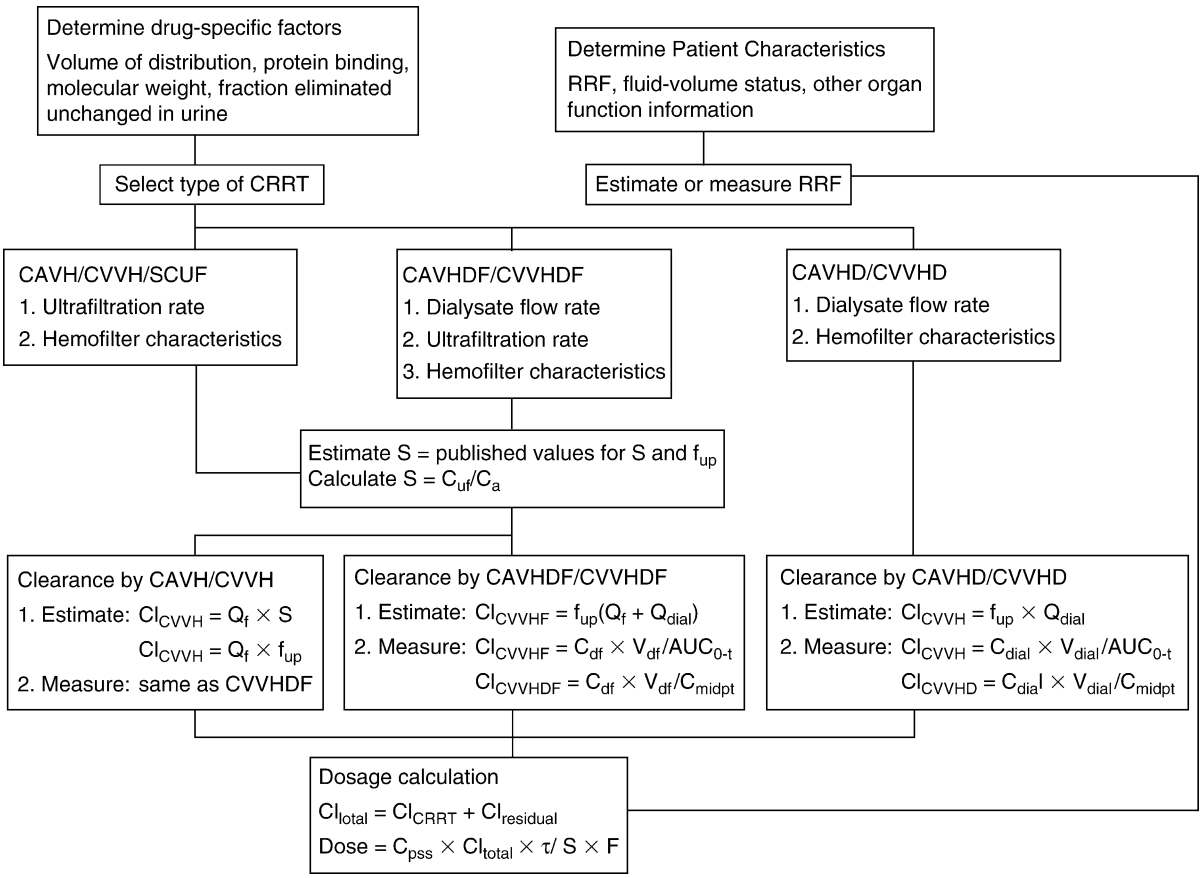
Principles of Drug Dosing During CRRT

Drug clearance during CRRT tends to be greater than during intermittent hemodialysis, therefore dosing usually needs to be greater. Increasing the amount of the drug per dose, the dosing interval or both may be necessary. In deciding on a dosing regimen, several factors must be considered: the severity of the illness, patient fluid-volume status, pathogen susceptibility to antibiotics, RRF, and the pharmacokinetic characteristics of the drug being administered (25). For instance, for time-dependent antimicrobials (e.g., β-lactams), increasing the individual dose without altering dosing frequency may be an appropriate approach to maintain a suitable minimum inhibitory concentrations for bacterial killing. Conversely, for concentration-dependent antimicrobials (e.g., aminoglycosides), it may be more appropriate to increase dosing interval. For life-threatening infections, it may be prudent to consider a high loading dose to ensure maximum efficacy (25). It is also important to consider the effect of RRF, since the renal clearance of some drugs may be significant and may affect the expected dialytic clearance. For instance, the total body clearance of meropenem is significantly increased, while its dialytic clearance is reduced during CRRT when the RRF is significant (54).

An algorithm for individualizing drug dosing during CRRT in adults has been developed by Joy et al. (40), and has also been recommended for use in pediatric patients (24) (*Fig. 69-5*). Although this algorithm provides an excellent framework to calculate drug dosages during CRRT, it has to be used with caution, since the kinetics of several drugs have not been rigorously studied in children,

Figure 69-5

Algorithm for individualization of drug dosing in patients receiving continuous renal replacement therapy (CRRT) (Adapted with permission from Joy et al. (40)). *Abbreviations: AUC $_{0\text{-}t}$* AUC during timed effluent collection; *C_a* prefilter plasma concentration; *CAVH/CVVH* continuous arteriovenous/venovenous hemofiltration; *CAVHD/CVVHD* continuous arteriovenous/venovenous hemodialysis; *CAVHDF/CVVHDF* continuous arteriovenous/venovenous hemodialfiltration; *C_{dial}* concentration in the dialysate; *C_{df}* concentration in the dialysate/ultrafiltrate effluent; *C_{midpt}* plasma concentration at the mid-point of effluent collection; *C_{uf}* concentration in the ultrafiltrate; *Cl* clearance; *Cl_{total}* total clearance; *Cp_{ss}* steady-state plasma concentration; *F* bioavailability; *f_{up}* fraction unbound to plasma protein; *Q_{dial}* dialysate flow rate; *Q_f* ultrafiltrate flow rate; *RRF* residual renal function; *S* salt from the drug; *S* sieving coefficient; dosing interval; *V_{dial}* volume of the dialysate; *V_{df}* volume of the effluent.



and extrapolation from the adult literature is necessary (6). In addition, drug clearance during CRRT can vary widely depending on changes in blood flow, ultrafiltration, and other CRRT parameters and on the patient's condition. This may further limit the accuracy of calculations. We therefore recommend rigorous patient and drug level monitoring when feasible to assess efficacy and avoid toxicity.

Drug Removal by Peritoneal Dialysis

Peritoneal dialysis is less efficient than hemodialysis at removing drugs. Usually, if the drug is not removed by hemodialysis, it will not be cleared by peritoneal dialysis. Drug removal is most effective for small molecular weight drugs with less protein binding and a small volume of distribution (55). The slow dialysate flow during continuous ambulatory peritoneal dialysis (CAPD) limits drug removal. Increasing dialysate flow via rapid exchanges such as during automated peritoneal dialysis (APD)

enhances peritoneal drug clearance. For instance, the removal of vancomycin and phenobarbital has been shown to be significantly enhanced with APD when compared to CAPD (56, 57). Therefore, APD may require different drug dosing regimens than CAPD. In addition, as in hemodialysis, the effect of RRF must be considered before dosing.

Pharmacokinetic studies for drugs administered during peritoneal dialysis in children are lacking, and much of the information has to be extrapolated from the literature in adults (58, 59). Recent observations in children suggest that current dosing guidelines for antimicrobial therapy in children with dialysis-related peritonitis, despite being mostly opinion-based, are effective (59). A recent study showed that vancomycin clearance by the pediatric peritoneal membrane was similar to that observed in adults, but the total body clearance was greater (60). The reasons for this are not clearly understood, and certainly more studies are needed to characterize drug pharmacokinetics in children receiving peritoneal dialysis.

Drug Dosing for Children with Renal Dysfunction: An Approach

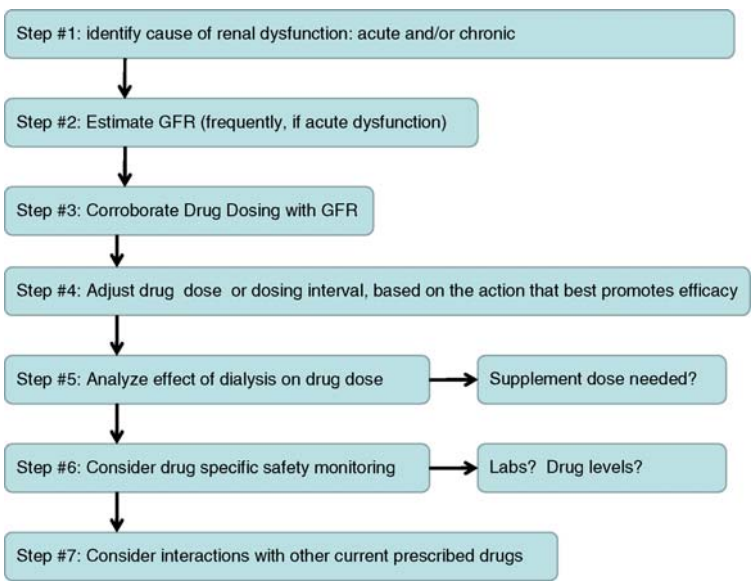
Optimizing the prescription of a drug in a child with some level of renal impairment is benefited by a thorough process of evaluation. We offer a step-wise format to aid in this scrutiny, in which the provider should arrive at answers to the following questions (*Fig. 69-6*). (1) What is the cause of the renal impairment? Is it acute kidney injury or chronic kidney disease? What is the level of residual renal function? (2) What is the estimated GFR in the patient? (3) How does this level of renal impairment affect the patient's current drug prescription(s)? For new drugs, how does renal impairment modify the loading dose of a drug? (4) How does renal impairment alter the maintenance dose, by the dosing interval or by the dosage itself? (5) How does the addition of a dialysis modality influence the drug's elimination? Is there an additional dose required, or more frequent interval dosing? (6) How is the drug action or renal function being monitored to promote safe usage of the drug? (7) What effect does a new drug, if any, have on the action or elimination of other currently prescribed drugs?

When renal impairment is due to acute kidney injury, the potential transient nature of the process means that there may be fluctuations in the GFR. Drugs that contribute to a reduction in renal function should be avoided, including angiotensin converting enzyme inhibitors, angiotensin receptor blockers, and non-steroidal anti-inflammatory agents. During the recovery phase of acute kidney injury, a drug's elimination properties could change drastically, necessitating more frequent monitoring of renal function as well as certain drug levels.

In chronic kidney disease, changes in renal function generally occur less frequently. Residual renal function, though, may be important in delineating a

Figure 69-6

Drug Dosing Strategy in Renal Dysfunction.



drug's dosage and interval, especially in patients undergoing complicated therapeutic regimens. As noted in previous chapters, methods to estimate GFR in children yield results that give a medical provider varying levels of confidence in that value. Radiolabeled tracers, such as DPTA, or studies using iohexol represent better methods of estimating GFR. Although more economical, creatinine clearance, or equations that utilize serum creatinine levels, are less reliable in their accuracy for GFR; in addition, the confidence of the calculated GFR from other biomarkers remains controversial. When feasible or when accuracy is critical (such as in chemotherapeutic regimens to treat malignancies), we recommend that the best available method be used to estimate the child's GFR and that reasonable follow-up monitoring occur. In addition, it should be recalled that renal tubules mature functionally at around 34 weeks gestation and that the GFR using the units ml/min/1.73 m^2 does not achieve comparable adult levels until the child reaches two years of age.

Guidance on changes to the loading or maintenance dose of a drug in the setting of renal impairment is available from multiple sources, including reference books and electronic sources. Loading doses can be affected by the changes that occur in renal failure when drug absorp-

Table 69-5

Recommendations for dosage adjustment in children with renal insufficiency. Modified form Daschner (6)

Drugs	Normal	Dose at GFR (ml/min/1.73 m^2)		
	Dose	50–30	30–10	Less than 10
Antibiotics				
Aminoglycosides				
Amikacin	15 mg/kg/day	40%	20%	10%
Gentamicin	3–5 mg/kg/day	60%	10%	5%

Tramadol	4–8 mg/kg/day	Normal dose	50%	50%

tion and distribution properties are altered, as is the case for digoxin (61). In general, pharmacological agents in which 20% or more of the drug or its metabolites are eliminated through renal mechanisms may require dose adjustments in renal impairment (*Table 69-5*). The maintenance dose can be altered in dose or frequency of delivery. Drugs in which peak values predominate the therapeutic efficacy should have their dosing interval increased. Examples include antivirals like acyclovir (62) or aminoglycosides like gentamicin (63). Drugs in which therapeutic levels need to be maintained should have their doses reduced but the intervals maintained. Examples comprise the cephalosporins and some anticonvulsants like carbamazepine (64).

When a patient is receiving renal replacement therapy, the drug's elimination properties may be altered, as noted previously in this chapter. The extent of that elimination depends on the dialysis modality, but each potential modality may require a supplementation of the drug dose and a change in the interval of the dosing. Aminoglycosides illustrate the dilemma and the variability in dosing approach quite well. With adequate hemodialysis, gentamicin is eliminated effectively and is therefore redosed at the end of dialysis treatment. With peritoneal dialysis, gentamicin is dosed based on the volume of the dialysate prescription. Yet, even with therapeutic drug monitoring, the risk of acquiring vestibular toxicity is higher in peritoneal dialysis than in hemodialysis, likely due to the variability in absorption properties across the

peritoneum. For renal replacement therapy, drug monitoring is essential to determine proper dosing intervals.

Drug interactions can often be subtle and yield deleterious consequences. Children with acute kidney injury typically have co-morbid features that oblige multiple pharmacological agents. Children with chronic kidney disease require a compendium of medications to treat the etiology or offset its sequelae. Individualization of drug dosing is recommended to prevent complications with ongoing monitoring of renal function, blood pressure, and drug levels to assess for any evidence of renal toxicity. Drug monitoring should be directed at more than just known nephrotoxic agents, as careful attention should also be paid to drugs that may indirectly create renal impairment. Drugs that alter P450 enzyme activity are particularly notable as noted in *Table 69-1*. Antifungals like ketoconazole, macrolides like erythromycin, or non-hydropyridines like diltiazem all inhibit P450 enzymes. If these medications are prescribed for kidney transplant patient on a calcineurin inhibitor, renal function can worsen due to the toxic levels of the calcineurin inhibitor.

With the implementation of the electronic medical record, integrated pharmacy systems that recognize drug interactions ideally will reduce the number of mistakes leading to renal toxicity and other untoward outcomes, and there is some evidence to support that conjecture. It is additionally proposed that these systems will aid in individualization of therapy, allowing for safer treatments for children and adults with, or at risk for, renal impairment. Until such improvements are more widely available, vigilance by the medical providers and pharmacists will remain at the forefront for proper drug administration.

70 Endocrine and Growth Disorders in Chronic Kidney Disease

Franz Schaefer

Endocrine Disorders in Chronic Kidney Disease

Pathophysiological Mechanisms

Uremia interferes with metabolism and regulation of hormones by various mechanisms. Disturbed endocrine function may arise either from inappropriate circulating hormone *concentrations* or from altered hormone *action* at the target tissue level. Both conditions may be present in the uremic state.

Increased Plasma Hormone Concentrations

Renal catabolism accounts for one to two thirds of the metabolic clearance rates of various polypeptide hormones (1). Most polypeptide hormones are almost freely filtered in the glomerulus, followed by either intratubular (brush border peptidases) or intracellular (cytosolic or lysosomal) degradation in tubular cells. Moreover, certain hormones are subject to receptor-mediated uptake across the basolateral tubular cell membrane. Hence, any reduction of renal mass will result in a decrease in the metabolic clearance of these hormones (*Fig. 70-1*). If catabolic mechanisms differ for different isoforms or subunits of a hormone, an imbalance of these constituents may arise, altering the relation between biologically active and inactive hormone fragments. In addition to renal clearance, extrarenal hormone elimination may also be reduced in renal failure. For example, degradation of insulin in skeletal muscle tissue is diminished (3), and hepatic catabolism of biologically active PTH is reduced in uremia (4). Finally, *hypersecretion* of various hormones or hormone binding proteins occurs in renal failure, either as an appropriate response to secretory stimuli (e.g., PTH) or without an apparent homeostatic signal (e.g., prolactin).

Decreased Plasma Hormone Concentrations

The reduction in functional renal mass is assumed to be the main cause for decreased levels of hormones produced by the *kidney* (erythropoietin, 1,25-OH_2-Vitamin D_3). In addition, the uremic milieu may suppress the production of these hormones by alterations of the internal milieu. For example, intracellular phosphate accumulation may inhibit 1-hydroxylase even before the reduction of renal mass becomes quantitatively important. Levels of *extrarenal hormones* may be decreased when the hormone-producing gland is the final effector organ of a complex hormonal axis (e.g., testis-testosterone, ovary-estradiol). In these cases, insufficient production of hormones may result either from direct toxic damage to the endocrine gland, from insufficient stimulatory input from the superior part of the hormonal axis, or from hyporesponsiveness of the gland.

Disorders of Hormone Action

Disturbed Activation of Prohormones

Concentrations of certain prohormones are elevated in chronic kidney disease (CKD), e.g., pro-IGF1A, a precursor of insulin-like growth factor 1 (IGF1) which is not detectable in normal serum (5), or proinsulin, which is not converted appropriately to insulin or C-peptide in patients with end-stage renal disease (6). Peripheral conversion of thyroxine (T4) to tissue-active tri-iodothyroxine (T3) is impaired (7). Some prohormones may block hormone action by competitively inhibating receptor binding at the tissue level.

Multimolecular Forms of Variable Bioactivity

Some polypeptide hormones circulate in plasma in multiple isoforms characterized by varying composition of their carbohydrate side chains. In CKD, altered glycosylation

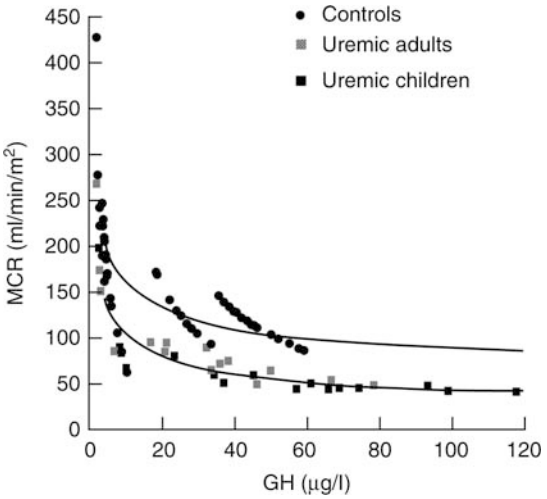
Figure 70-1

Total metabolic clearance rate (MCR) as a function of steady-state plasma GH concentrations in controls and CKD patients. MCR is reduced in children and adults with CKD at any prevailing plasma GH level. (From (2)).



and sialisation (8) may shift the isohormone spectrum towards less bioactive forms (e.g., LH (9)). This may be due to alterations of posttranslational processing or to differences in the renal clearance of individual isoforms.

Hormone Binding to Plasma Proteins

Excessive concentrations of several insulin-like growth factor (IGF)-binding proteins are found in CKD (10, 11). Binding proteins can compete for the hormone with target organ receptors, and this explains in part the reduced somatomedin bioactivity in the presence of normal total serum IGF. Abnormal concentrations of other polypeptide binding proteins may similarly be related to abnormal hormone action in uraemia.

Alterations of Target Tissue Sensitivity

Diminished target organ responsiveness is observed in various endocrine systems in uremia. Mechanisms for altered target tissue sensitivity include reduced cellular receptor activation due to the diminished receptor abundance, the presence of inhibitory substances, the accumulation of molecules inhibiting hormone-receptor interaction (e.g., insulin-like growth factor 1) and structural changes of either the hormone or its receptor (10). Moreover, defects of hormone–receptor complex dependent intracellular signalling may occur. Such postreceptor events seem to play a key role in the pathogenesis of insulin (12) and growth hormone (13) resistance in uraemia.

Gonadotropic Hormone Axis

Clinical Findings

The onset of puberty is usually delayed in adolescents with CKD. At least 50% of adolescents with end-stage renal disease (ESRD) enter puberty later than the normal range (14) and achieve the pubertal milestones beyond the normal age range (15–17). Late puberty is observed both in children on dialysis and after renal transplanation. In the Cooperative Study for Pubertal Development in CKD the onset of puberty was delayed by 2–2.5 years on average (18). The start of genital maturation (Tanner G2) was delayed by 1.8 years in uremic and 2.5 years in transplanted boys. Full genital maturation was achieved with a delay of 2.2 and 3.2 years, respectively. Thus, once started, puberty appears to proceed at a normal rate. However, in individual patients, particularly on long-term dialysis, pubertal maturation may arrest for years. Almost half of the girls treated by dialysis or renal transplantation fail to menstruate before the upper normal age limit of 15 years. Menarche even tends to occur later in transplanted than in dialyzed girls (15).

Unlike the development of secondary sexual characteristics, which is delayed but not permanently halted in CKD, reproductive function may be permanently impaired. In autopsy studies in boys with CKD, germ cell depletion in the testicular tubules has been described (19). These changes do not appear reversible after renal transplantation (20). Persistently reduced sperm counts were observed in 10 of 12 successfully transplanted young adults who had suffered from ESRD during childhood (20). Erectile dysfunction, decreased libido and fertility are primarily organic in nature and are due to uremia as well as to other comorbid conditions, fatigue and psychosocial factors (21). The frequency of conception is decreased in women with CKD and pregnancy is uncommon in adolescents with ESRD. The percentage of surviving infants ranges from 70% to 100% in women with CKD on conservative treatment or after renal transplantation (20) and from 50% to 80% in women on dialysis (22–24). Intrauterine growth retardation is frequent and the risk of delivering prematurely and/or a small-for-date baby is increased (17, 21, 22).

Gonadal Hormones

In adults with CKD plasma concentrations of *testosterone* (T) are usually low or low normal (25), due to reduced synthesis and, perhaps, increased metabolic clearance rate

(26, 27). In prepubertal children with predialytic renal failure, low total and free T and dihydrotestosterone (DHT) plasma concentrations have been reported (28). However, since the adrenal cortex is the major site of androgen production before puberty and specific adrenal androgens are also low in children with CKD (29), low prepubertal plasma androgen levels do not provide evidence for gonadal damage before puberty (30, 31). In pubertal patients, normal or slightly subnormal plasma T concentrations are observed (32–34). In late puberty, however, DHT concentrations are significantly reduced in children with CKD compared with healthy or post-transplant children (own unpublished observation). Impaired conversion of T to DHT due to decreased 5-reductase activity has been suggested (35, 36). Because this metabolite is responsible for many tissue actions of the androgens, reduced conversion of T to DHT may explain the frequently sparse development of secondary sexual characteristics in boys with advanced renal failure.

The testicular response to supraphysiological stimulation by human chorionic gonadotropin (HCG) is impaired in adult men (25) as well as in prepubertal and pubertal boys with CKD. Testicular insufficiency is most prominent in boys on hemodialysis (32). Leydig cell resistance is caused by a cAMP-dependent mechanism (37). A factor with LH-inhibitory activity has been demonstrated in uremic serum (38) (*Fig. 70-2*). The disorder is reversible after renal transplantation (32).

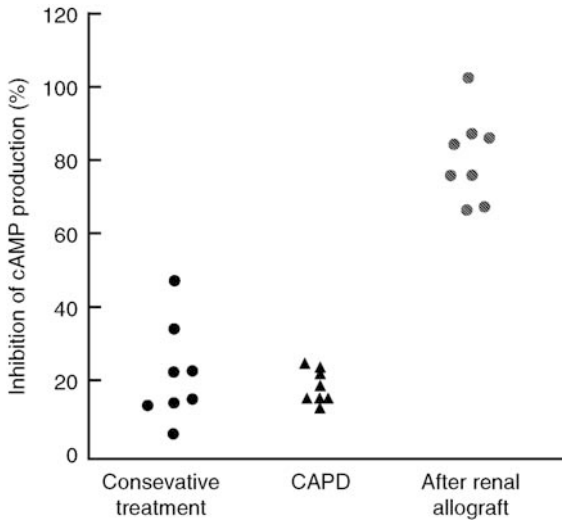
The physiological age-related decrease of sex-hormone binding globulin is conserved in prepubertal children on dialysis (33); however, at a given age sex-hormone binding globulin concentrations are higher and the unbound T fraction is lower than in normal children. The increase of sex-hormone binding globulin may be due to accumulation in end-stage renal failure; a normal fraction of free T has been reported in prepubertal children on conservative treatment (28).

The plasma concentration of *inhibin*, a polypeptide produced by the Sertoli and Granulosa cells, is elevated in peripubertal boys with CKD (39). It is unclear whether elevated plasma inhibin levels in uremia reflect alterations of Sertoli cell function, impaired feedback regulation of the pituitary-gonadal axis or decreased metabolic clearance of the hormone.

Estradiol plasma concentrations in the low normal range are observed in women with CKD (40). In pubertal girls with CKD, estradiol plasma levels were normal or low when related to pubertal stage (41, 42). An inverse correlation between serum creatinine levels and estradiol concentrations was found in patients with predialytic CKD. Longitudinal analysis revealed an insufficient increase in estradiol during puberty in those patients whose renal function deteriorated, whereas following renal transplantation, even after several years of dialysis, estradiol concentrations increased (42).

Figure 70-2

Evidence for circulating LH inhibitor in sera of boys with CKD. HCG-induced cAMP production by cell line expressing human LH/HCG receptor is suppressed in presence of serum of patients on conservative or CAPD treatment (upper panel). (Adapted from (38) with permission.)



Gonadotropins

Plasma luteinizing hormone (LH) levels are high normal or elevated in adult men, women, prepubertal and pubertal boys and girls with CKD (9, 25, 28, 40, 41, 43); follicle-stimulating hormone (FSH) concentrations are also usually elevated both in adults and children with CKD. After transplantation, LH levels usually return to normal, whereas plasma FSH frequently remains elevated.

The combination of elevated gonadotropins with decreased or low-normal gonadal hormone levels has been taken as evidence for a state of compensated hypergonadotropic hypogonadism (28, 44). However, the degree of hypergonadotropism in CKD is usually inadequate for the prevailing degree of hypogonadism, suggesting an additional defect of hypophyseal gonadotropin secretion.

An alteration at the pituitary level is suggested by the blunted increase of plasma LH and FSH following stimulation by a bolus of exogenous GnRH in men, women, boys and girls with CKD (25, 28, 41). These abnormalities appear even more marked when the diminished metabolic

clearance of gonadotropins is taken into account (45). The gonadotropin response to GnRH is normalized after successful transplantation (41).

LH is released from the pituitary in episodic (pulsatile) bursts occurring every 90–120 min. The plasma LH concentration peaks reflect intermittent secretion of hypothalamic GnRH into the hypophyseal-portal blood stream (46). Hence, the analysis of plasma LH pulses gives indirect information about the functional state of the hypothalamic GnRH "pacemaker". A differentiation of the secretion and elimination components underlying the fluctuating plasma LH concentration patterns by means of the deconvolution methodology (47) revealed that the elevation of basal plasma LH concentrations is entirely due to the diminished renal metabolic clearance of the hormone (45) both in humans (48) and in rats (49). Plasma half-life of LH is inversely correlated with GFR (48). In contrast, actual pituitary LH secretion rates are decreased in CKD; pubertal dialysis patients secrete 3 times less immunoreactive LH and 2.5 times less bioactive LH in episodic nocturnal peaks than normal adolescents (48). This abnormality, which has been reproduced in experimental uremia (50), gives strong evidence for a dysregulation of the gonadotropic axis at the hypothalamo-pituitary level. After transplantation, a regular pattern of LH pulses is reestablished (9, 51). As the onset of puberty is heralded by the emergence of a nocturnal pattern of pulsatile LH secretion, the observed disturbance of pulsatile LH secretion suggests that the delayed pubertal development in CKD is caused by a primary hypothalamic defect. Experimental evidence confirms that the subnormal pituitary gonadotropin secretion is caused by diminished release of gonadotropin-releasing hormone (GnRH) into the hypophyseal portal circulation (49, 52). In cultured GnRH producing neurons GnRH release is inhibited upon addition of a high-molecular weight fraction of uremic serum. The inhibitor is a hydrophilic protein suppressing GnRH exocytosis, but not synthesis (53). Moreover, using in vivo intracerebral microdialysis in experimentally uremic rats we observed an increased tone of the neuroinhibitory amino acid GABA in the extracellular fluid of the hypothalamic medial preoptic area, the region where the GnRH neurons reside (54). Hence, central nervous GABA accumulation may be another mechanism of downregulation of the gonadotropic hormone axis in uremia.

Clinical and experimental evidence indicates that the neuroendocrine control of pulsatile LH secretion is altered in CKD. Although overt hypogonadotropism is masked by a simultaneous reduction of metabolic clearance rates, the deficient physiological pulsatile GnRH-LH signal may be the key abnormality underlying the delayed onset of puberty in CKD. The observed disorders of LH secretion and metabolism appear to be reversible after successful renal transplantation.

Besides the quantitative insufficiency of the hypothalamo-pituitary unit, the biological *quality* of the circulating gonadotropins is also altered in uremia. LH bioactivity, measured by the potency of a plasma sample to induce testosterone in a Leydig cell culture, depends on the degree of glycosylation and sialisation of this glycoprotein hormone (55). During normal puberty, the relative bioactivity of LH gradually increases (56). In pubertal (57, 58) and adult patients (51) on dialysis, the ratio of bioactive to immunoreactive plasma LH is reduced, suggesting that the spectrum of circulating LH molecules is shifted towards bioinactive forms (9, 48, 51, 59). This may be attributed to altered glycosylation of plasma proteins in uremia (8). The physiological increase in hormone bioactivity during puberty is absent in dialysis patients (58). The recently characterized inhibitor of LH action circulating in serum of uremic boys may represent an accumulating LH fragment (38). After successful renal transplantation, LH biopotency tends to normalize.

Prolactin

Prolactin is a proteohormone secreted by the pituitary that is involved in the hormonal regulation of lactation. Its function in non-puerperal women, in men and in children is not clear. However, prolactin attenuates gonadotropin release. Plasma prolactin levels are elevated in men (60), and, more markedly, in women and pubertal girls (41, 60) with CKD. Uremic hyperprolactinemia appears to result from both decreased metabolic clearance rate and increased production rate of the hormone (61). Hyperprolactinemia may play a role in the pathogenesis of uremic hypogonadism, since elevated prolactin levels exert a suppressive effect on the GnRH-LH pulse generator (62). The physiological sleep-related nocturnal prolactin surge is absent (63), and the circadian rhythm of secretion is deranged (64). Prolactin secretion in CKD patients is insensitive to stimulation by TRH (65), chlorpromazine, metoclopramide, arginine or insulin-induced hypoglycemia (66). L-dopa and dopamine are not effective in suppressing prolactin secretion (66); however, hyperprolactinemia may be corrected by long-term treatment with dopaminergic agonists (67, 68). Uremic hyperprolactinemia may be related to other complications of CKD such as vitamin D deficiency and renal anemia. Substitution

of 1,25-Vitamin D_3 (69) and erythropoietin (70) leads to a partial normalization of plasma prolactin levels.

Various physiological studies and pharmacological tests reveal a partial disintegration of the gonadotropic hormone axis at the hypothalamo-pituitary level, in addition to alterations of gonadal function. The analysis of hormone secretory patterns has confirmed that the central nervous dysregulation is not restricted to the functional reserve capacity of the reproductive hormone system, but affects physiological spontaneous hormone secretion. The reversibility of the observed changes after successful renal transplantation gives further evidence that regulatory mechanisms, rather than toxic end-organ damage, affect gonadal function in uremia. It remains to be shown to what extent the apparent dysregulation of hormone secretion represents a "physiological" adaptation to an adverse metabolic environment.

Growth Hormone – Insulin-Like Growth Factor Axis

During normal childhood, the somatotrophic hormone axis plays a key role in the regulation of body growth. In addition, growth hormone is part of a complex system of counter-regulatory hormones maintaining the homeostasis of carbohydrate metabolism.

Growth Hormone (GH)

Serum Concentrations and Kinetics

Fasting GH concentrations are variably elevated in uraemic children and adults dependent on the extent of renal failure (71, 72). The kidney is a major site of GH degradation (73). In patients with endstage renal failure, the metabolic clearance rate of GH is reduced by approximately 50% (2, 74) (*Fig. 70-1*). Deconvolution analysis of GH plasma concentration profiles revealed that the increase in plasma GH concentrations is mainly due to an increased plasma half-life of the hormone, whereas the actual pituitary GH secretion rate varied between patients and studies. GH secretion rate was high-normal in prepubertal children with ESRD and increased in adult patients on hemodialysis, possibly as a result of attenuated bioactive IGF-I feedback of the hypothalamo-pituitary unit (75, 76). In pubertal patients with advanced CKD reduced GH secretion rates were observed, indicating an altered sensitivity of the somatotropic hormone axis to the stimulatory effect of sex steroids during this stage of development (77).

The variability of plasma GH levels in CKD may in part be due to associated conditions such as acidosis and malnutrition, which independently affect GH secretion. Metabolic acidosis suppresses GH release both in rodents and humans (78).

Neuroendocrine Control of GH Release

Dysregulation of GH secretion may be related to abnormalities of central neuroendocrine control mechanisms. Evidence for this is provided by several hypothalamo-pituitary function tests. The GH response to intravenous GH-releasing hormone (GHRH) is augmented and prolonged in children (79). Exogenous thyrotrophin-releasing hormone (TRH), which does not affect GH release in healthy subjects, markedly enhances GH secretion in subjects with renal failure (71, 80). Also, CKD patients respond to acute hyperglycaemia by a paradoxical increase of GH secretion (71, 81). Stimulation tests such as arginine infusion and insulin-induced hypoglycaemia lead to a sustained, exaggerated increase of GH (71, 82, 83). However, the altered metabolic clearance rates of GH as well as of the provocative agents in renal failure (84) make a meaningful clinical interpretation of such tests virtually impossible.

GH Receptor Signaling and Tissue Action

Growth failure despite elevated circulating GH concentrations suggests a state of GH resistance in children with CKD. Indeed, GH-induced hepatic IGF-I synthesis is markedly reduced in rats with CKD (13, 85). This GH insensitivity may in part be due to deficient GH receptor expression, although this is controversial. Reduced hepatic GH receptor mRNA and receptor binding has been reported in some but not all studies carried out with animals (13, 85–88). These discrepancies may be related to the effect of reduced nutritional intake. Indeed, controlling for the anorexia of chronic uremia by pair feeding control animals abolished the difference in GH receptor protein expression and binding to liver plasma membranes seen when ad-lib controls and uremic animals are compared (13, 87), although receptor mRNA levels remained subnormal (13). On the other hand, reduced GH receptor protein expression was observed in the growth cartilage of rats with CKD even though nutritional intake was controlled (89). In humans serum levels of GH binding protein, putatively reflecting hepatic GH receptor status, were decreased in some, but normal in other studies (74, 90–93).

Another mechanism accounting for the resistance to GH in uremia is provided by a marked *post-receptor* GH signaling defect recently observed in livers of chronically uremic rats (13). Despite unaltered GH receptor protein levels, phosphorylation of the GH receptor associated

tyrosine kinase janus kinase-2 (JAK2) was diminished by 75% (Fig. 70-3). This resulted in a similar suppression of GH/JAK2-dependent phosphorylation of specific downstream signaling molecules, namely signal transducer and activator of transcription (STAT)-1, -3 and -5. This defect was possibly caused by up-regulation of intracellular JAK2 inhibitors, namely the suppressors of cytokine signaling (SOCS)-2 and -3. Since these regulatory proteins are induced by inflammatory cytokines, it may be postulated that GH resistance in uremia is caused by the commonly associated with this condition.

Insulin-Like Growth Factors

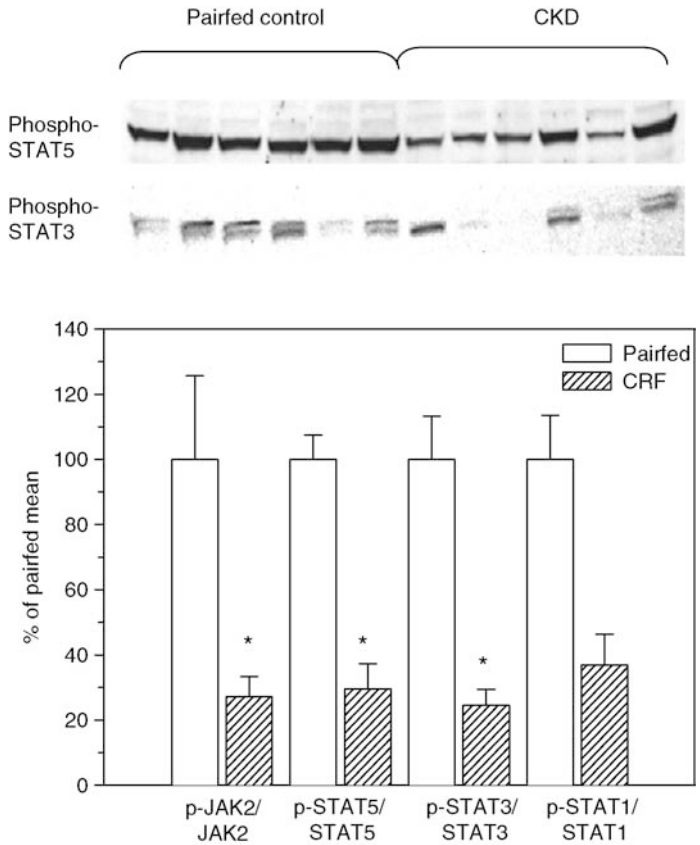
As most metabolic effects of GH are mediated by IGF-I, GH insensitivity in uremia may also be due to IGF resistance. Indeed, several studies in the rat as well as in humans demonstrated marked IGF-I resistance in CKD (94–97).

IGF Serum Concentrations

The effect of GH on longitudinal growth is partially mediated by stimulating the production of somatomedins, the two most important of which are the insulin-like growth factors (IGF) 1 and 2. Serum IGF-I and IGF-II levels in children with CKD are in the normal range, whereas in ESRD mean age-related serum IGF-I levels are slightly decreased and IGF-II levels moderately elevated (98). Hence, total immunoreactive IGF levels in CKD serum are normal. In contrast, IGF *bioactivity* is markedly reduced. Similarly, the level of free IGF-I is reduced by 50% in relation to the degree of renal dysfunction (99). This finding is one of the key abnormalities of the GH/IGF axis in children with CKD.

Figure 70-3

Impaired post-receptor GH signaling in rats with experimental uremia. Upper panel: Deficient nuclear accumulation of tyrosine-phosphorylated STAT5 and STAT3 protein in livers of rats with CKD compared to pair-fed controls. Lower panel: Reduced hepatic phosphorylation of JAK2, STAT-5, -3 and -1 in uremic rats. (Reproduced with permission from (13)).



IGF Plasma Binding and Tissue Action

The discrepancy between low somatomedin activity by bioassay and normal or elevated insulin-like growth factor by radioimmunossay or radioreceptor assay suggests the presence of circulating somatomedin inhibitors in uremia. An early study suggested the presence of a low-molecular weight IGF inhibitor (approximately 1 kDa), whose molecular structure has however not been characterized further (100).

The most likely explanation for the inhibition of somatomedin action in uraemia has emerged from the identification of six insulin-like growth factor-binding proteins (IGFBP-1 to -6) of which IGFBP-3 appears to be the most abundant in humans, constituting more than 95% of total circulating IGFBP. In children with CKD, the serum concentrations of IGFBP-1, -2, -4 and -6 are increased in a manner inversely related to glomerular filtration rate (10, 11, 98, 101–104) (*Fig. 70-4*). Ligand blotting shows that the elevation of radioimmunoassayable IGFBP-3 is due to an increase in low molecular weight forms mainly in the range of 14 and 19 kDa, whereas intact IGFBP3 (38 and 41 kDa) is markedly reduced (105, 106). IGFBP-1, -2 and -6 inhibit somatomedin bioactivity in vitro (107). Somatomedin bioactivity in uraemic serum can be returned to normal by removing unsaturated IGFBP (108). Experimental evidence suggests that the increase of IGFBP-1 and -2 is not only due to reduced renal metabolic clearance but also to increased hepatic synthesis (109). An important question is whether the imbalance between normal total IGF and the excess of unsaturated IGFBPs contributes to growth failure in children with CKD. Serum levels of IGFBP-1, -2 and -4 correlate inversely with standardized height in CKD children (98, 104, 110). While it is tempting to speculate that these IGFBPs could contribute to growth failure in children with CKD it is difficult to prove causality since IGFBP levels and height SDS are all correlated with GFR.

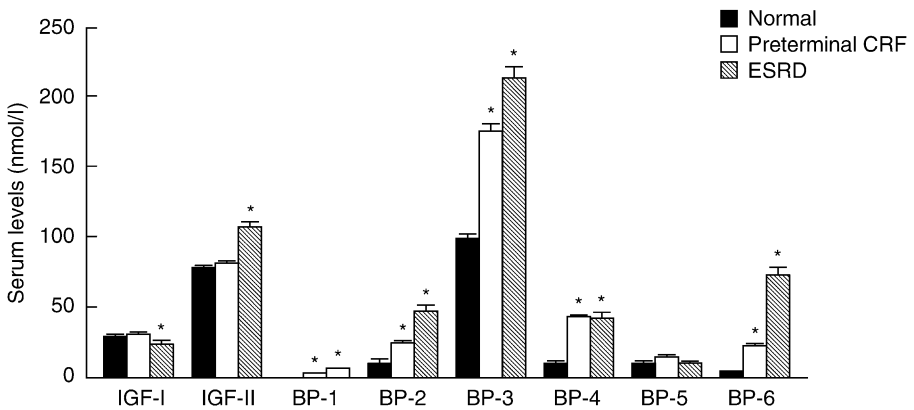
Apart from the increased plasma IGF-I binding capacity, a post-receptor IGF-I signaling defect may also contribute to IGF-1 resistance in CKD. In uremic rats the effect of IGF-I and various IGF-I analogs on protein turnover was suppressed (94). The observation that the inhibitory effect of IGF-I and its analogs were affected to a similar degree indicates that the resistance arises because of a defect at a cellular level and not because of changes in the IGFBP levels. Deficient autophosphorylation of the IGF-I receptor in skeletal muscle of uremic rats has been reported (94), but not confirmed in a later study (111).

GH-IGF-1 Homeostasis in Chronic Renal Failure

The pattern of elevated GH, normal total IGF and markedly elevated IGFBP plasma concentrations in uremia has interesting implications with respect to the estimated IGF production rate. In a functioning homeostatic system, the diminished free IGF-1 levels would be expected to stimulate IGF production in order to restore the steady-state between bound and unbound hormone at a higher level. In uremia, however, total IGF concentrations are normal rather than increased. Kinetic modeling suggests that the metabolic half-life of IGFs is markedly elevated, and the IGF production rate is decreased 10- to 100-fold in

Figure 70-4

Molar concentrations of IGFs and IGF binding protein concentrations in children with CKD and on dialysis in comparison to age-matched healthy children. (From (104) with permission.)



uremia (112). Taken together, the markedly deficient IGF1 synthesis and the modest elevation of plasma GH levels, which is mainly due to impaired metabolic clearance, in the presence of increased IGF binding capacity strongly support the notion of a multilevel homeostatic failure of the GH-IGF-1 system in uremia: Pituitary GH secretion is insufficiently feedback-stimulated by reduced free IGF-1 levels, and marked tissue GH resistance prevents an increase in total IGF-1 levels in the presence of elevated GH.

Glucocorticoids and GH-IGF Hormone Axis

Following renal transplantation, the use of glucocorticoids for immunosuppression interferes with the GH-IGF-1 axis on various levels. Endogenous GH secretion is reduced in pediatric renal allograft recipients, mainly by a reduction of amplitudes of the GH secretory bursts (34, 113). The physiological increase of GH burst amplitudes during puberty is blunted, and the normal correlation between sex steroid plasma levels and GH secretion rate is absent (34). GH release after insulin-induced hypoglycemia is inadequate (113). The insufficiency of spontaneous and stimulated GH secretion in post-transplant patients is most likely explained by a glucocorticoid-induced enhancement of hypothalamic somatostatin release (114). On the target tissue level, glucocorticoids suppress GH receptor and IGF-I gene transcription (115, 116). Nevertheless, basal IGF-I plasma levels in renal transplant recipients are in the normal range (117–119). This discrepancy between clinical and experimental findings suggests that glucocorticoids alter translation, synthesis and/or secretion of IGF-I in such a way that the IGF-I mRNA redundancy no longer reflects IGF-I protein synthesis. Whereas circulating immunoreactive IGF-I concentrations are not consistently reduced, IGF bioactivity is markedly diminished in patients on glucocorticoid treatment (117, 120). This may be due to the induction of IGF inhibitors of 12–20 kD molecular weight and/or to increased serum IGF-BP3 levels (117, 120). Moreover, increased IGFBP-2 concentrations are found in patients with Cushing's syndrome (121). IGFBP-2 may be another functional IGF-1 inhibitor in patients receiving chronic glucocorticoid treatment.

Glucocorticoids also interfere with chondrocyte growth and enchondral bone formation in various ways. They inhibit sulfate incorporation into cartilage matrix as well as mineralization and formation of new bone (122). In cultured epiphyseal chondrocytes, dexamethasone decreases DNA synthesis and cell proliferation, GH receptor expression and paracrine IGF-I secretion (123).

Thyroid Hormone Axis

Clinical Findings

The thyroid hormone axis plays an important role in the regulation of tissue metabolism. Throughout childhood, thyroid hormone is involved in growth and skeletal maturation, stimulating both cartilage proliferation and epiphyseal differentiation.

The prevalence of goiter is increased in patients with ESRD (124, 125). The prevalence of hypothyroidism ranges between 0% and 9.5% (124). Whereas primary hypothyroidism is observed 2.5 times more frequently in dialysis patients than in patients with other chronic non-renal disease, the prevalence of hyperthyroidism is not different (124). In children, the prevalence of hypothyroidism may be higher due to the greater proportion of patients treated for cystinosis and nephrotic syndrome. In cystinotic patients, deposition of cystine crystals in the thyroid can lead to destruction of the gland and frank hypothyroidism (126). Children with severe nephrotic syndrome, particularly with the congenital form (127), may become hypothyroid due to the renal loss of thyroid-hormone binding globulin.

As some manifestations of hypothyroidism, like hypothermia, pallor and dry skin also occur in uremia, the exclusion of the diagnosis of hypothyroidism on clinical grounds may be difficult in a uremic child. Therefore, exploration of the hormonal status of a patient is essential for the recognition of an accompanying thyroid disorder.

Thyroid Hormones

Inorganic iodine is physiologically excreted by the kidney, and plasma inorganic iodine levels increase as kidney function decreases (128).

The plasma levels of total T4 (thyroxine) and T3 (triiodothyronine) are decreased in patients with CKD (129). Significant depression of T4 and T3 levels usually occurs once the glomerular filtration rate falls below 50%. Thyroid hormone *production rates* are normal in patients with CKD (130, 131). Metabolic clearance rates of the hormones may (132) or may not (131) be increased. Due to impaired peripheral deiodination of T4 to T3 (7, 132), there is a more distinct suppression of T3 than of T4 levels. In ESRD, diminished T4 levels are found in a third, and diminished T3 levels in 50% of patients (125, 133–136) including children (137). Concentrations of reverse T3 (rT3), the inactive metabolite of T4 in plasma, are low (138) or normal (136). Production and metabolic

clearance rates of rT3 are normal (130) but extravascular binding of rT3 is increased (131).

The more pronounced decrease of plasma T3 compared to T4 levels in CKD resembles the thyroid hormone pattern observed in other states of chronic nonthyroid diseases ("sick euthyroid" or "low T3" syndrome). However, whereas in the sick euthyroid syndrome rT3 levels are elevated as a result of impaired peripheral conversion of T4 to T3, rT3 levels are in the low normal range in CKD. This constellation has been explained by a redistribution of rT3 into extravascular compartments in uremia (131).

Binding Proteins

Circulating thyroid hormones are bound to thyroid hormone-binding globulin (TBG), albumin and prealbumin. TBG levels usually are normal in hemodialysis (133, 139); they are frequently low in CAPD patients, who lose thyroid-hormone binding proteins via the dialysate (139, 140). Patients with severe nephrotic syndrome may have markedly low TBG plasma levels due to urinary protein loss. Only the unbound (free) T4 (fT4) and T3 (fT3) fractions are biologically active. Plasma fT4 and fT3 as measured by radioimmunoassay are low (141), and dissociation constants for specific T4 and T3 binding are normal (142).

Thyroid-Stimulating Hormone (TSH)

Despite low plasma total and free T4 and T3 levels, TSH concentrations are usually normal in adults (133, 141) and in children with CKD (137). Normal TSH in the face of low fT_3 and fT_4 points to altered regulation of the hypothalamo-pituitary–thyroid axis. Experimental evidence suggests that the sensitivity of the thyrotroph to feedback inhibition is increased in uremia. In addition, thyrotrophin-releasing hormone (TRH) administration causes a blunted, delayed rise of plasma TSH (7, 80, 142) The duration of the TSH response is prolonged due to decreased metabolic clearance and increased half-lives of both thyrotrophin-releasing hormone and TSH (84, 143). While basal iodine uptake is low (133), thyroid responsiveness to stimulation by thyroid-stimulating hormone is normal (144).

The most convincing evidence for a primary hypothalamic defect comes from studies on the temporal organization of TSH release. The physiological nocturnal TSH surge is frequently blunted in children and adults with ESRD (137, 145), and the pattern of pulsatile TSH secretion is altered towards low-amplitude, high-frequency pulses (145).

CKD is associated with a resetting of the central thyrostat towards lower levels of circulating thyroid hormones. The lacking upregulation of spontaneous TSH secretion despite low thyroid hormone levels may either indicate a failure of the thyrotroph to respond to the physiological stimulus of low thyroid hormone concentrations, or be interpreted as a "physiological" downregulation resulting from a reduced *demand* for thyroid hormone in the specific state of metabolism caused by uremia.

Children with nephropathic cystinosis are exceptional in that, even in advanced renal failure, they exibit an exaggerated TSH response to TRH stimulation. This reflects primary hypothyroidism due to destruction of the thyroid gland by deposition of cystine crystals (126). TSH may also be elevated in children with severe nephrotic syndrome (127), reflecting a hypothyroid state due to renal loss of TBG-bound thyroid hormones.

Thyroid Hormone Action

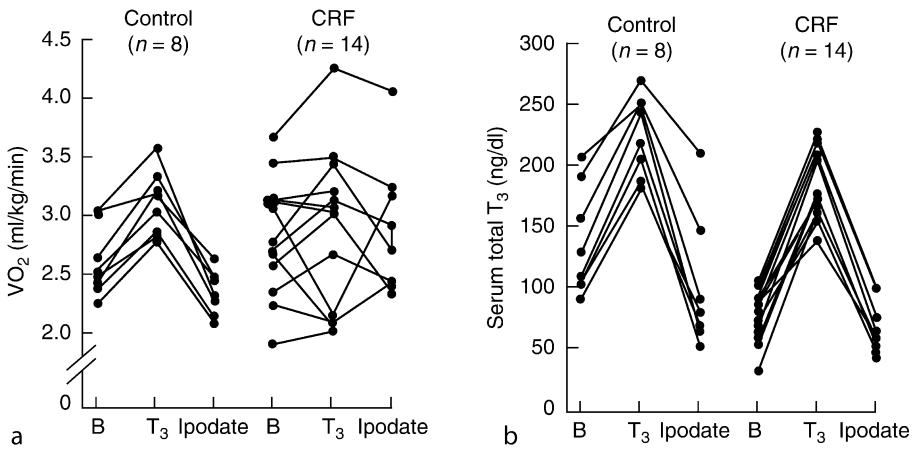
Clinically, patients with CKD usually appear euthyroid. Measurements of basal metabolic rate and rough clinical indices yield normal results (134, 146). Normal TSH concentrations suggest that euthyroidism is also present in pituitary thyrotrophs. In experimental uremia an upregulation of T3 receptor expression, possibly as a compensatory mechanism to low circulating T3, and normal expression of T_3-dependent hepatic proteins have been observed (147, 148). In contrast to apparently efficient endogenous hormone action, CKD patients show a marked resistance against exogenous thyroid hormone administration with regard to thermogenesis. Oxygen uptake is neither stimulated by administration of T3 nor suppressed by its antagonist sodium ipodate (149) (*Fig. 70-5*). In contrast to normal subjects, T3 supplementation in CKD patients results in exaggerated protein degradation and a negative nitrogen balance (138, 150, 151), similar what has been observed in patients with chronic illness or malnutrition (152). Hence, the "low T3 syndrome" of uremia may in part be interpreted as a physiological adaptation to conserve energy in an adverse metabolic environment, and supplementary thyroid hormone treatment might be not only useless but even harmful.

Diagnosis and Clinical Management of Thyroid Disorders in CKD

In a uremic patient hypothyroidism should only be diagnosed if total and free T4 levels are distinctly low, the TBG concentrations normal and basal TSH levels elevated

Figure 70-5

Failure of thyroxin administration to stimulate, and of thyroid suppression to reduce, oxygen consumption (VO_2, panel A) despite adequate changes in plasma T3 levels (panel B) in patients with CKD. (From (149) with permission.)



(>20 μU/mL). A normal plasma TSH is probably a valid indicator of tissue euthyroidism. Treatment with thyroid hormones should be limited to patients with clinical hypothyroidism and elevated plasma TSH. The increased risk for induction of tissue catabolism by thyroid hormone treatment needs to be recognized.

In hemodialysis patients heparin may interfere with the thyroid hormone status. Heparin competes with T4 at intra- and extravascular binding sites, thus increasing total and free T4 serum levels for at least 24 h post-dialysis (153). Therefore, strict standardization of the timing of investigations relative to dialysis is essential. Other substances can cause similar artifacts, e.g., high-dose furosemide (154).

Patients with CKD who undergo repeated radiologic investigations with iodinated contrast agents may be at increased risk of developing iodine-induced hyperthyroidism because of reduced iodine clearance.

Adrenal Hormone Axis

Clinical Findings

Analogous to thyroid disorders, dysfunction of the pituitary-adrenal axis may be difficult to diagnose in patients with CKD. Uremia shares certain clinical signs and symptoms with Cushing's syndrome, such as osteopenia, proximal muscle weakness with atrophy, glucose intolerance, negative nitrogen balance and hypertension (155); therefore, Cushing's syndrome may easily be missed if it occurs concomitantly with renal failure. Similarly, adrenal insufficiency may present with symptoms which are not uncommon in renal failure, e.g., hypotension, weakness, and hyperkalemia. To confirm or reject the diagnoses of Cushing's syndrome or adrenal failure, the clinician has to rely on the evaluation of the patient's hormonal status under basal and stimulated conditions. For a comprehensive interpretation of the endocrine status, the changes of the hypothalamo-pituitary-adrenal axis induced by CKD per se must be kept in mind.

Cortisol

Cortisol is conjugated in the liver to water-soluble metabolites, which are predominantly excreted by the kidney and accumulate in renal failure. While normal morning fasting cortisol levels are found in the majority of adult and pediatric patients with CKD (156–159), 24-h integrated mean total and free cortisol concentrations are consistently elevated (160). Basal hypercortisolism is particularly prevalent in patients on hemodialysis (159). The diurnal rhythm and the pulsatile mode of cortisol secretion is conserved in renal failure; however, the half-life of the endogenous secretory peaks is prolonged (156, 160, 161). In hemodialysis patients, the secretory activity is shifted towards the dialysis hours, whereas a normal pattern is observed on days off dialysis (160).

Stimulation of the zona fasciculata with exogenous ACTH in uremic patients yields a normal cortisol response, irrespective of whether supraphysiological

(159, 162, 163) or low doses of ACTH are used (163). Zona glomerulosa steroids (aldosterone, 18-OH-corticosterone) are stimulated normally in CAPD (163) but not in hemodialysis patients (164). Transient hyporesponsiveness to ACTH is observed in the majority of patients who return to dialysis after transplant failure (165).

Adrenal Androgens

Adrenarche marks an important milestone in endocrine maturation. Adrenarche occurs about 2 years before the initiation of puberty and is independent of it. Low plasma levels of dehydroepiandrosterone (DHEA) and DHEA-sulfate, the marker hormones of the zona reticularis, are observed in adult men as well as in pre- and midpubertal boys on hemodialysis, whereas normal levels are found in patients on conservative treatment (31, 166, 167). Conversely, androstendione, an adrenal androgen produced by the ACTH-dependent zona fasciculata, is elevated in patients on conservative treatment, and normal or elevated in hemodialysis patients (31, 159). A similar elevation of androstendione is observed in girls with CKD (42). In renal allograft recipients, glucocorticoid treatment invariably lowers adrenal androgen production to almost undetectable levels (30, 31, 159).

Adrenocorticotropic Hormone (ACTH)

Basal ACTH levels are normal (159) or elevated (157, 162) in patients with CKD. The functional status of pituitary corticotrophs in uremia is still under discussion. ACTH secretion is not suppressible by standard oral doses of dexamethasone (162, 168). Oral absorption of dexamethasone is, however, reduced in uremia (156), and suppression of ACTH can be achieved at higher doses (156, 160). After intravenous administration of dexamethasone, only incomplete suppression of plasma cortisol levels is observed; however, the metabolic clearance of dexamethasone is possibly increased in uremia (156, 169). The responsiveness of the corticotroph to stimulation by metapirone may (162) or may not (156) be reduced in uremia. The ACTH release after administration of corticotropin-releasing hormone (CRH) occurs early but is blunted (157). In normal subjects acute hypoglycemia elicits a counterregulatory stimulation of the CRH-ACTH-cortisol axis. In patients with CKD this stress reaction is markedly suppressed. The increase of ACTH and cortisol following insulin-induced hypoglycemia is blunted in patients on hemodialysis (156), providing further evidence of a disordered hypothalamo-pituitary regulation of the corticotropic axis in uremia.

Diagnosis and Management of Pituitary-Adrenal Disorders

The most frequent circumstance for a pediatric nephrologist to encounter adrenocortical failure is upon discontinuation of glucocorticoids in patients returning to dialysis after transplant failure. Also, accidental adrenalectomy can occur during nephrectomies particularly in young infants, and adrenal hemorrhage leading to functional disorders is not uncommon in the perinatal period, in children with coagulation disorders and as a side effect of therapeutic anticoagulation. Also, adrenal insufficiency is occasionally seen as a complication of amyloidosis also compromising renal function, as typically seen in patients with severe chronic vasculitis or familial Mediterranean fever. Demonstration of low cortisol levels and insufficient cortisol response to ACTH is required to confirm the diagnosis. In transplant recipients adrenal responsiveness is suppressed by steroid treatment (165). This poses the risk of acute adrenal insufficiency during severe stress, e.g., surgical procedures or after abrupt steroid withdrawal.

The diagnosis of Cushing's syndrome in a patient with CKD requires elevated plasma cortisol levels, measured by a radioimmunoassay in extracted serum. While a single measurement of cortisol may be misleading, loss of diurnal rhythm (24 h cortisol profile) is a characteristic of Cushing's syndrome not seen in uremia-related adrenal dysfunction. Failure of high-dose dexamethasone to suppress ACTH and cortisol levels is confirmatory evidence.

Hormones Involved in Carbohydrate Metabolism

Glucose intolerance is a common feature of CKD. The introduction of the euglycemic and hyperglycemic clamp techniques has been important in understanding insulin and glucose metabolism in patients with CKD (170). In the euglycemic insulin clamp technique, a given level of insulinemia is maintained and blood glucose is kept constant by infusing glucose at a continuously adjusted rate. Thus, the infusion rate equals tissue glucose uptake and metabolism. This allows to quantitate tissue sensitivity to insulin. In the hyperglycemic clamp technique, blood glucose levels are acutely raised by a priming infusion of

glucose, and then maintained constant at about twice the fasting level by a variable glucose infusion. Under these steady-state conditions, the glucose infusion rate is a measure of glucose uptake and metabolism by all cells of the body. The early plasma insulin response is an index of the ß cell responsiveness to the hyperglycemic stimulus, whereas the late insulin response is a measure of peripheral tissue sensitivity to insulin.

Insulin Secretion

Fasting serum insulin levels are usually normal or slightly elevated in patients with CKD. In contrast, serum levels of proinsulin and C-peptide are elevated. This discrepancy is explained by differences in the relative contribution of the kidney to the metabolic clearance rates of these peptides (171). Nevertheless, insulin half-life is increased two- to threefold in CKD. Taking this into account, a relative insulin hyposecretion is present under fasting conditions in CKD patients (172).

In hyperglycemic clamp studies the early insulin response, an indicator of the pancreatic ß-cell sensitivity to glucose, is variable: decreased (173), delayed (174), normal (175) or even increased (176, 177) responses have been reported. A decreased initial insulin release in response to high glucose concentrations is found in isolated pancreatic islets of uremic rats (178). The late insulin response is unvariably increased in uremic patients, indicating tissue resistance to insulin, and improves by dialysis (179).

Insulin is physiologically secreted in frequent, low-amplitude oscillations which are superimposed on slow, high-amplitude secretory pulsations (q. 75 min). In contrast to other states of insulin resistance, a characteristic slowing of both rhythms, and hyperrhythmicity and exaggerated width and amplitude of the low-frequency insulin pulses in response to meals was observed in patients with CKD, pointing to a specific abnormality in the neuroendocrine regulation of insulin secretion (172).

The variable ß-cell response may explain why only some patients develop overt glucose intolerance despite constant peripheral insulin resistance. Glucose intolerance becomes manifest only when the ß-cell insulin response to glucose is so impaired that it can no longer increase and overcome peripheral insulin resistance (81).

Some evidence suggests a role for parathyroid hormone (PTH) in the deranged ß-cell function of CKD. In children with CKD and severe secondary hyperparathyroidism, glucose intolerance resolves after parathyroidectomy by an improvement of the pancreatic insulin secretory capacity, whereas insulin insensitivity persists (180, 181). High PTH levels, with or without uremia, impair insulin secretion by a cAMP-independent mechanism (182). Chronic hyperparathyroidism might enhance calcium entry into the pancreatic islets, resulting in an accumulation of calcium that impairs insulin release. This hypothesis is supported by the prevention of glucose intolerance and the normalization of islet insulin secretion in uremic rats treated with the Ca-channel blocker verapamil (183).

Tissue Resistance to Insulin

Insulin resistance is a major independent risk factor for vascular disease both in healthy subjects (184) and in patients with CKD, in whom it has been found correlated with coronary artery calcifications (185).

Euglycemic insulin clamp studies in adults (186) and children (187) with CKD unanimously show marked decreases in tissue sensitivity to insulin, glucose uptake and metabolic clearance of insulin.

After 10 weeks of dialysis treatment all indices are markedly improved. The two major sites of carbohydrate metabolism are the liver and the muscle tissue. Impaired insulin action may be characterized by diminished splanchnic glucose extraction, increased hepatic gluconeogenesis, decreased peripheral glucose uptake or a combination of these. Most studies in uremic patients report normal basal and insulin- or glucose-suppressed hepatic glucose output (12, 186, 188). However, these observations may be valid only for supraphysiological insulin concentrations. When endogenous insulin secretion is blocked by somatostatin and insulin infused in physiological doses, suppression of hepatic gluconeogenesis is incomplete in uremic patients (189). Moreover, isotope studies suggest reduced glucose oxidation to CO_2 and increased glucose recycling (188). In contrast to these subtle changes of hepatic glucose turnover, glucose metabolism in the peripheral tissue is markedly impaired (186, 190, 191). Hence, the major site of resistance to insulin-mediated glucose uptake in uremia is the peripheral tissue, mainly skeletal muscle.

Studies in adipocytes, monocytes, hepatocytes or human muscle tissue showed a normal or even elevated expression and binding characteristics of the insulin receptor, normal insulin receptor kinase activity and normal receptor-mediated transmembranous hexose transport (12, 192–196). Insulin membrane receptors are expressed in abundance, and maximal hormone action occurs when only 10% of receptors are occupied. Consequently, insulin resistance at the receptor level can be

overcome by high insulin concentrations while a post-receptor defect cannot. Glucose uptake evaluated by the euglycemic clamp technique remains severely reduced in uremic patients even at the highest dose of insulin (12) (*Fig. 70-6*). This observation is direct evidence of a post-receptor defect.

Etiology and Mechanisms of Insulin Resistance

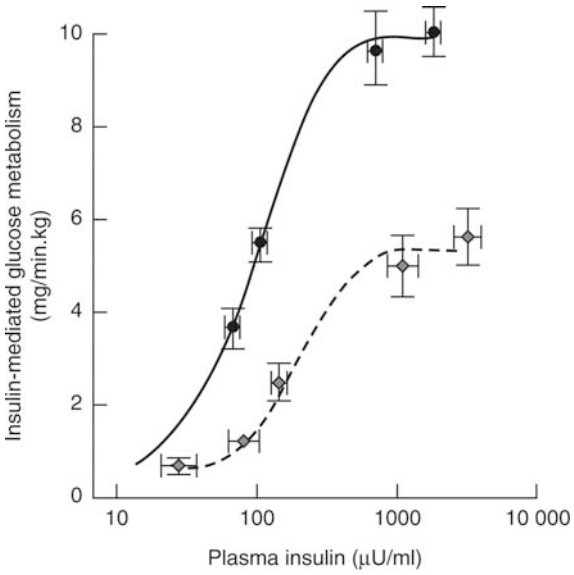
Glucose intolerance in patients with CKD is improved by dialysis (179, 197). This observation suggests the presence of dialyzable factors in uremic serum which compromise the biological actions of insulin. Several peptides possibly interfering with glucose metabolism have been isolated in uremic sera (198–200). Furthermore, 1,25-OH_2D_3 deficiency may play a role in the pathogenesis of insulin resistance in uremia (201). Also, insulin resistance improves in adolescents on dialysis after correction of anemia and amelioration of iron overload by recombinant erythropoietin therapy (202).

Recent research has linked CKD-associated insulin resistance to persistent inflammatory processes. Cytokine levels (e.g., IL-6, tumor necrosis factor, IL-1ß, and resistin) are increased in CKD (203). Inflammation is independently associated with insulin resistance in CKD patients. Inflammatory cytokines stimulate the synthesis of Suppressors of Cytokine Signaling (SOCS), a family of intracellular proteins regulating the sensitivity of cells to cytokines during acute inflammation. Since SOCS proteins also inhibit insulin signaling (204), they represent a potential molecular mechanism linking elevated cytokines with insulin resistance in CKD. Raj et al. recently demonstrated an association of the inflammatory response during hemodialysis with elevated SOCS-3 levels and insulin resistance (205).

While uremia and its sequelae entail specific mechanisms of insulin resistance, the growing global epidemic of obesity is also begining to take its toll in the CKD population. In a recent clinical study of adult patients with mild to moderate CKD, the body mass index (and alternatively percentage body fat) remained the only independent predictor of insulin resistance after controlling for age, race, sex, GFR and adiponectin levels and the prevalence of an abnormal HOMA index did not differ significantly between CKD patients (98%) and BMI-matched control subjects (94%) (206).

Figure 70-6

Dose–response relationship between the plasma insulin concentration and insulin-mediated glucose metabolism in patients with CKD (dashed line) and controls (solid line). Diminished maximal insulin-mediated glucose metabolism suggests insulin resistance by postreceptor defect. (From (12) with permission.)



Glucagon

Glucagon plasma levels are markedly increased in uremia. The biologically active 3.5 kD glucagon moiety is increased threefold. This increase is entirely due to decreased metabolic clearance; secretion is normal (207). Glucagon exerts its hyperglycemic action primarily by stimulating hepatic gluconeogenesis. Patients with CKD exhibit reduced endogenous glucose output after a glucagon challenge (189). Diminished glucagon binding with unchanged binding affinity by hepatic membranes was demonstrated in chronically uremic rats (208). Normal basal, but diminished stimulated adenylate cyclase activity was found. These results may be explained by receptor downregulation in response to chronic glucagon excess, since healthy rats treated with exogenous glucagon exhibit similar changes.

Carbohydrate Metabolism during Peritoneal Dialysis

Chronic peritoneal dialysis is characterized by continuous glucose absorption from the peritoneal fluid, which

amounts to 2–3 g/kg/day in children on an average PD regimen. In view of the known glucose intolerance of uremia, this has raised some concern. Basal glucose and insulin levels are normal or increased in CAPD patients (174, 209, 210). A transient increase of plasma glucose and insulin levels occurs during a CAPD cycle, which is correlated with the glucose content of the PD fluid (209). The area under the curve following an oral glucose load is increased in uremic patients on CAPD compared to non-dialysed and hemodialysed patients (193). Conflicting results have been reported with respect to the effect of CAPD on glucose tolerance and glucoregulatory hormones (192, 210). Peripheral insulin sensitivity improves after initiation of CAPD (211); the improvement is significantly better with peritoneal dialysis than with hemodialysis treatment (197). Insulin binding affinity and receptor numbers decreased on adipocytes of CAPD patients within the first 3 months of CAPD treatment, but no change in insulin sensitivity was observed as assessed by the effect of insulin on glucose uptake and lipogenesis (192).

The available information indicates that glucose intolerance is not exaggerated in patients on CAPD. Insulin resistance tends to improve after initiation of peritoneal dialysis, even more so than in newly hemodialyzed patients. This may be explained by removal of circulating inhibitors of insulin action. The partial substitution of dialysate glucose by icodextrin, an oligosaccharide mixture resorbed slowly and degraded to maltose, leads to a decrease of plasma insulin levels (212).

Adipokines

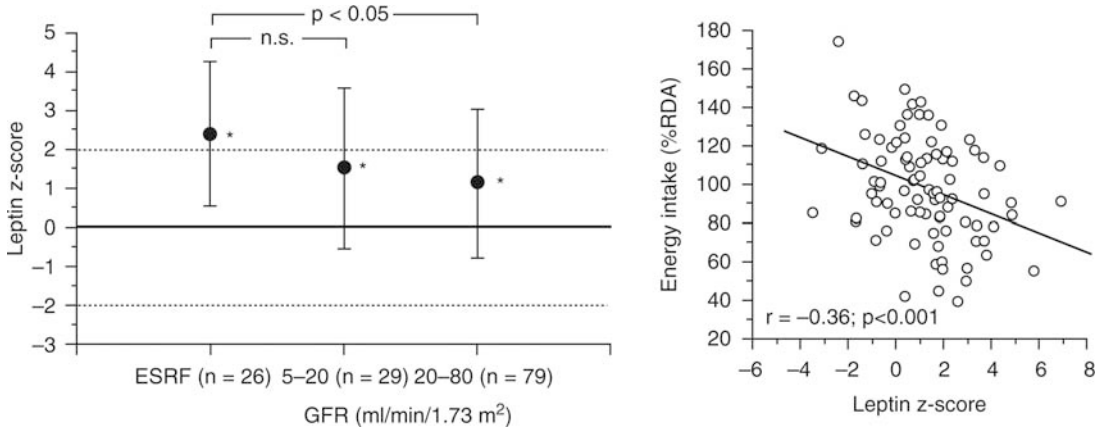
An increasing body of evidence suggests that the adipose tissue has complex pleiotropic functions far beyond the mere storage of energy. Fat tissue secretes various "adipokines", i.e., pluripotent signaling peptides with cytokine and endocrine properties affecting energy homeostasis, tissue metabolism, inflammatory processes and vascular functions (213).

Since the plasma concentrations of most adipokines are markedly elevated in CKD due to impaired renal metabolic clearance, this novel class of signaling molecules has recently been implicated in the pathogenesis of uremic anorexia, catabolism, inflammation, insulin resistance and cardiovascular morbidity (214).

Leptin was initially described as a modulator of feeding behavior, and thus of fat mass, in rodents, but has multiple additional functions. Plasma levels closely correlate with body fat mass, but are independently elevated in adults and children with reduced renal function (215, 216). Moreover, Daschner et al. found an inverse linear correlation of leptin levels normalized for body fat mass with spontaneous energy intake in children and adolescents with CKD, suggesting that leptin accumulation may contribute to uremic anorexia (*Fig. 70-7*) (216). Indeed, leptin signaling in the central nervous system is an important cause of anorexia in uremic mice (217). Experimental uremic cachexia can be ameliorated by blockade of leptin signaling through the hypothalamic melanocortin-4 receptor (218).

Figure 70-7

GFR-dependent elevation and inverse relationship with energy intake of serum leptin levels normalized for age, gender and BMI in 134 pediatric CKD patients. (From (216) with permission.)



Moreover, leptin levels are associated with those of inflammatory biomarkers in CKD (219, 220), suggesting that it may play a role in the malnutrition-inflammation-atherosclerosis (MIA) syndrome associated with uremia. Experimental findings in rodents suggest that circulating bioactive leptin is increased during acute inflammation (221). CRP may directly interact with leptin to attenuate its biological function (222). Furthermore, while leptin is capable of initiating the recruitment and activation of immunocompetent cells, leptin production may in turn be regulated by TNF (223). Notably, serum leptin levels predict epoetin requirements in CKD, even after adjustment for inflammation (224). While these data support the notion that leptin is an important mediator of uremic anorexia, catabolism and inflammation, the association of low leptin levels with poor outcome in dialysis patients (225) is likely explained by the fact that severe uremic wasting leads to a low fat mass with consequent leptin depletion.

Adiponectin is an endocrine peptide secreted exclusively by adipocytes (226). Adiponectin improves insulin sensitivity in the liver (227) and periphery (228), ameliorates endothelial dysfunction and counteracts pro-inflammatory signaling (229). The disruption of the specific adiponectin receptors Adipo-R1 and -R2 increases tissue inflammation and oxidative stress. In contrast to other adipokines, increasing adipose tissue mass is associated with low circulating levels of adiponectin (230). Circulating adiponectin is generally low in populations at enhanced risk of CVD (231, 232). Plasma adiponectin levels are generally markedly elevated in CKD patients (233, 234), and both adiponectin receptors are upregulated on circulating mononuclear cells in CKD patients. CKD patients with relatively lower adiponectin levels have an increased risk of cardiovascular events (234). Surprisingly however, large studies have associated high, rather than low, adiponectin levels with mortality in CKD (235). Hence, the role of upregulated adiponectin signaling in CKD is still unclear. It may be an adaptive, protective mechanism which is most activated in patients with the greatest vascular, metabolic and inflammatory stress (236).

Resistin, a peptide predominantly secreted by immunocompetent cells, is involved in obesity-induced insulin resistance (237). Increased circulating resistin levels in end-stage renal disease patients are not associated with fat mass, but rather correlate closely with GFR and inflammatory biomarkers (238, 239). Resistin is not a significant predictor of insulin resistance when correcting for GFR (238, 239).

Visfatin is a ubiquitous intracellular enzyme with insulin-mimetic effects which is selectively upregulated in the adipose tissue (240). Visfatin plasma levels correlate with endothelial damage in CKD 5 patients (241) and with insulin resistance and proteinuria in type-2 diabetes (242). The mechanistic link between the circulating levels of this cytosolic protein and albuminuria is unclear. In vitro overexpression of visfatin in human vascular smooth muscle cells lengthens cell lifespan and increases their resistance to oxidative stress (243); hence, increased visfatin expression may be a physiological cell response to elevated oxidative, or other, stress.

Growth and Developmental Disorders in Chronic Kidney Disease

Impact of Developmental Stage on Growth in CKD

The regulatory mechanisms of statural growth during childhood differ at the successive stages of development. During the first 1–2 years of life, growth is mainly driven by nutritional factors, particularly the intake of energy and protein. In later childhood, growth appears to depend mainly on the somatotropic hormone axis, with nutrition exerting a more permissive influence. In puberty, the growth process is dominated by the gonadotropic hormone axis, which stimulates and finally terminates body growth by direct action on the growth cartilage and by modulation of the somatotropic hormone axis. In view of these differences in growth regulation, the description of growth in renal disorders deserves separation for the periods of infancy, midchildhood, and puberty.

The first 2 years of life are the most dynamic period of growth. Some 30% of total postnatal statural growth normally is achieved during this period. Any disturbance of growth in infancy has a greater impact on growth potential than at later stages of development. Spontaneous growth in children with congenital CKD is characterized by a rapidly increasing height deficit during the first 2 years of life, followed by a rather percentile parallel growth pattern in the midchildhood years. In the late prepubertal period, height velocity again decreases disproportionately, resulting in a further deviation from the normal percentiles. A late pubertal growth spurt of diminished amplitude eventually results in an irreversible loss of growth potential, leading to a stunted adult height.

Infancy

Untreated CKD during early infancy is usually associated with severe growth retardation (244–247). The mean loss

in relative height in untreated patients is as high as 0.6 SD per month during the first year of life. A detailed analysis of the early infantile growth pattern observed in children with congenital CKD by means of the Infancy-Childhood-Puberty model revealed that the "Infancy" growth phase, starting in intrauterine life and vanishing during the second year of life, is affected in 50% of the patients (248). Height SDS was already reduced at birth, decreased further during the first 3 postnatal months, behaved normally between the 3rd and 9th month, and again decreased between the 10th and 12th month of life. The intrauterine period, the first 3 postnatal months and the period preceding the first birthday each contributed by about one-third to the overall reduction in height SDS observed in congenital CKD. The observed intrauterine growth retardation raises the question whether the prenatal accumulation of certain circulating substances not cleared by the placenta in children with severe renal hypoplasia may compromise fetal growth. Conversely, intrauterine malnutrition could be the primary cause not only of fetal growth retardation but also, if present in the early stages of pregnancy, of abnormal renal morphogenesis. With regard to early postnatal life, anorexia, water and electrolyte imbalances due to uremia, recurrent vomiting and catabolic responses to infections, metabolic acidosis and secondary hyperparathyroidism are the main factors compromising growth during this period. If appropriate management is instituted early enough, severe stunting can usually be prevented. Consequent forced enteral feeding using nasogastric tubes, gastrostomies and even fundoplication as required appears essential to prevent or reverse malnutrition (249, 250). Under optimal conditions it is possible to keep infants with CKD within 1–2 SD below the mean height for age (250, 251).

After a transient stabilization of growth rates, a variable further loss in relative height is commonly seen between 9 and 18 months of age. According to the Infancy-Childhood-Puberty model, this period reflects the transition from the "Infancy" to the "Childhood" growth phase. An irregular onset or maintenance of the Childhood growth component was observed in 60% of the patients and resulted in a further decrease in mean standardized height by 0.7 SDS (248). The reasons for this secondary deterioration of growth in infancy, which may occur despite adequate nutritional and medical supplementation, are poorly understood.

Midchildhood

After the period of rapid infantile growth, height velocity slows down to an almost constant increment per year. During this period endocrine mechanisms regulate growth.

In midchildhood, patients with hypoplastic renal diseases usually grow along the percentiles attained around the end of infancy (252). Patients who develop CKD after the 2nd year of life exhibit a loss of relative height early in the course of disease and follow the growth percentile after stabilization of the disease process. The degree of renal dysfunction is the principal determinant of the variability in growth during this period. Spontaneous midchildhood growth tends to be subnormal when glomerular filtration rate (GFR) is below 25 mL/min/1.73 m^2 (245, 252–254) (*Fig. 70-8*). Mid-childhood growth rates are consistently correlated with GFR, although only 10 – 15% of the variability in growth are actually accounted for by this parameter (252). The degree of anemia, metabolic acidosis and malnutrition contribute only marginally to annual growth rates.

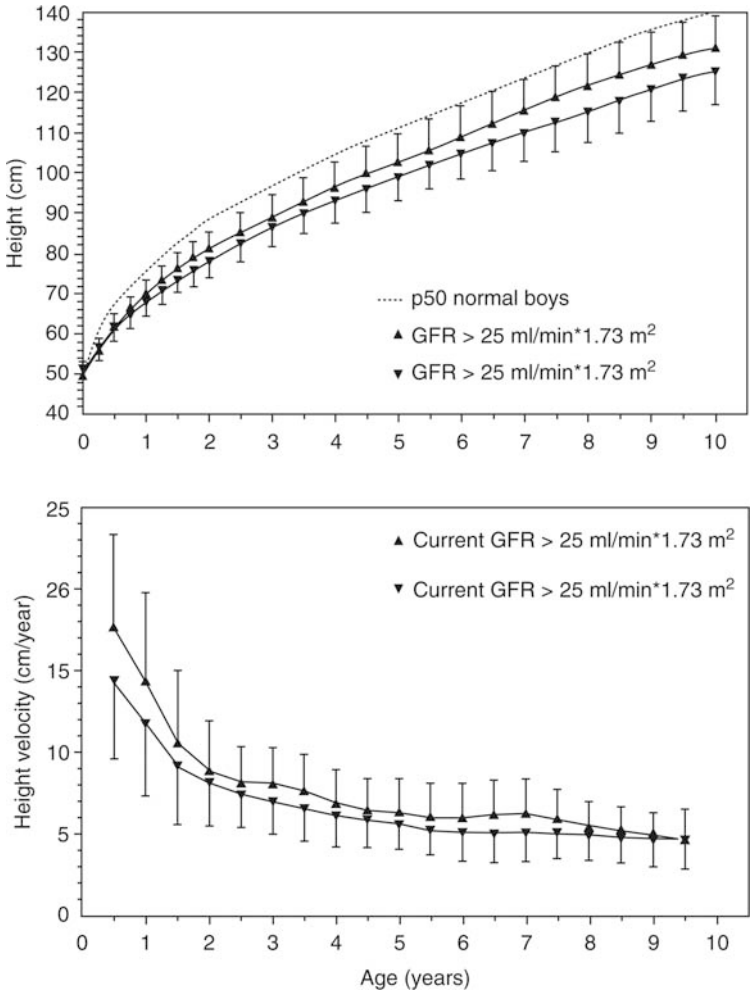
The more or less percentile-parallel growth of uremic children in mid-childhood has been interpreted as a "normal" growth pattern that could be expected after a loss of growth potential in early infancy. Such readjustment of the growth channel is seen in children with cardiac diseases after surgery or in children with adrenal insufficiency overtreated in infancy (255). However, the observation that complete catch-up growth, although not common, does occur in children in whom renal function is normalized by successful renal transplantation and glucocorticoid treatment can be minimized or withdrawn (256) suggests that catch-up growth is continuously suppressed in the uremic milieu. The percentile-parallel growth pattern during this period may therefore reflect a net balance between the growth-suppressive effect of uremia and the organism's inherent tendency for catch-up growth.

Puberty

The height gain achieved during the pubertal growth spurt is usually reduced (18, 118, 257, 258). In a longitudinal analysis of the growth curves of 29 adolescents with various degrees of CKD, the growth spurt started with an average delay of 2.5 years (18). The degree of the delay was correlated with the duration of uremia. Although a distinct acceleration of growth during puberty occurred, the total pubertal height gain was reduced in both sexes to approximately 50% of normal late-maturing children. This reduction was due to a marked suppression of the late prespurt height velocity, a subnormal peak height velocity, and a shortening of the pubertal growth period by 1 year in boys and 1.5 years in girls. Notably, the prolonged prepubertal growth phase, resulting from the delayed onset of the pubertal growth spurt, permitted the patients to grow up to an almost normal immediate prespurt height (−1 SDS in boys, +0.1 SDS in girls).

Figure 70-8

GFR-dependent growth pattern in children with chronic renal failure due to hypo-/dysplastic renal disorders. Approximately 100 children per age interval were evaluated. Upper panel: Mean ± SD of height in children with average GFR less or greater than 25 mL/min/1.73 m^2. Lower panel: Annual height velocity in children with current GFR greater or <25 mL/min/1.73 m^2 in the year of observation. (Adapted from (252) with permission.)



Subsequently, relative height was gradually lost during the pubertal growth spurt, ending up in an average relative height of −2.9 SDS in boys and −2.3 SDS in girls. This pattern of pubertal growth was confirmed in a control group of ESRD patients followed in the late 1990s who were not treated with recombinant GH (259).

In prepubertal children with long-standing renal failure, bone maturation is invariably retarded (260–263). In dialysis patients, skeletal maturation is increasingly retarded before the start of puberty and then accelerates dramatically. This observation and the fact that uremic boys respond to exogenous application of testosterone esters by an exaggerated increase in skeletal maturation (263) suggests that the sensitivity of the growth plate to sex steroids is at least conserved. Because proliferation, i.e., growth, cannot keep pace with differentiation, i.e., bone maturation, growth potential may irreversibly be lost during puberty in uremia.

In contrast, in many transplant patients an apparent standstill of bone maturation is observed even when the patient is growing and puberty is progressing. This phenomenon is thought to be related to direct interference of corticosteroids with the differentiation of the growth plate. Despite the delayed bone age, late growth is usually not observed (18, 264, 265). In fact, the successive stages of the pubertal growth spurt seem to occur at increasingly earlier bone ages than would be assumed in a normal population (18).

Final Height

Adult heights below the normal range are attained by 30% to 50% of children with CKD, although a trend of improving final heights has been noted during the past decade (264, 266–277). The mean final height in CKD patients stage 3–5 ranged between −0.6 and −3.5 SD in different studies. Consistent predictors of a low final height are young age at onset of ESRD, long duration of uremia, the presence of congenital nephropathies and male gender, whereas the use of recombinant growth hormone (rhGH) has been observed to improve adult height. It appears that the use of rhGH and the trend towards early transplantation are the major factors contributing to the gradual improvement of final height observed in developed countries.

Body Proportions

Conflicting information exists with respect to segmental growth in CKD. Graaff et al. investigated body proportions in 37 children with CKD. Body segments were related to height and expressed as "shape" values (278). All children had normal shape values, indicating unaltered body proportions. In contrast, a detailed and standardized prospective assessment of body morphology in 190 boys with CKD noted age-related disproportionate growth patterns in children with a long-term history of CKD and renal replacement therapy (279). Disproportionate growth failure was most obvious in early childhood. Sitting height was mostly preserved, whereas growth of the legs and arms was most severely affected.

Impact of Underlying Renal Disease on Statural Growth

Hypo-/Dysplastic Nephropathies

Congenital renal hypoplasia or dysplasia, with or without urinary tract obstruction, is the most common cause of ESRD during the first 5 years of life. Renal dysplasia is characterized by tubular dysfunction with electrolyte losses and polyuria, and a gradual decline of GFR. The time to ESRD is highly variable and depends on the degree of hypoplasia, tubular dysfunction and the incidence of infections. Growth failure usually develops during the first year of life. Thereafter, growth rates remain more or less stable, and are usually sufficient to keep the patient's height parallel to the centiles. In the care of these patients, it is important to compensate for tubular electrolyte losses and acidosis. Pharmacological renoprotective therapy with renin-angiotensin system antagonists may have a positive long-term impact on statural growth by stabilizing residual renal function.

Glomerulopathies

Progressive glomerular injury may appear as acute or chronic glomerulonephritis, or as nephrotic disease. Growth rates decline in patients with progressive glomerulonephritis as glomerular function deteriorates. Growth velocity is affected even in mild renal insufficiency (253). In patients with nephrotic syndrome, proteinuria per se impairs growth, both in congenital nephrosis and resistant nephrotic syndrome that appears later in childhood (280, 281). The dose and duration of glucocorticoid treatment in nephrotic syndrome and the evolution of renal function are predominant factors affecting growth. Prolonged high-dose corticosteroid administration suppresses growth rates (281–284). Although partial catch-up growth occurs after steroid withdrawal, final height is correlated with the cumulative glucocorticoid dose (281). Congenital nephrotic syndrome usually is associated with severe stunting during the first months of life while GFR still is in the normal range but massive edema and proteinuria are present. Growth failure in these infants may be secondary to edema, recurrent infections, protein-calorie malnutrition and endocrine alterations due to urinary loss of protein-bound and small peptide hormones. Bilateral nephrectomy, replacing proteinuria, edema and cachexia by ESRD, may be required to improve growth and nutritional status (285). In less severe cases of congenital nephrotic syndrome unilateral nephrectomy and medical treatment with prostaglandin synthesis inhibitors and RAS antagonists may reduce proteinuria sufficiently to permit satisfactory growth and weight gain (286, 287).

Tubular and Interstitial Nephropathies

Primary *tubular dysfunctions and interstitial disorders* may lead to severe growth impairment even in the absence of chronic renal insufficiency. Patients with either proximal or distal renal tubular acidosis may present with growth failure during the first years of life (288, 289). Growth impairment may be due to tissue catabolism, volume depletion, electrolyte disorders and/or to malnutrition. Catch-up growth is observed after correction of *acidosis* with alkaline therapy in distal RTA (288, 290).

Growth retardation occurs in about 50% of patients with nephrogenic *diabetes insipidus*; hypernatremia, volume contraction and malnutrition interfere with growth. Maintaining water balance and treatment with indomethacin are associated with catch-up growth (291). Bartter's syndrome and related disorders with chronic *potassium depletion* usually are characterized by a failure to thrive (292). Experimental potassium deficiency leads to growth failure characterized by both reduced endogenous GH secretion and complete resistance to exogenous GH (293, 294). In patients with hyperprostaglandin E syndrome, indomethacin medication leads to partial catch-up growth (295). In view of the various isolated tubular deficiencies that can cause growth impairment, it is conceivable that complex disorders of proximal and distal tubular function, such as idiopathic *Fanconi syndrome* (296, 297) or hereditary *fructose intolerance* develop severe growth failure. In these cases, only partial catch-up growth is possible even with rigorous electrolyte supplementation (288, 290, 292, 295).

Systemic metabolic disorders resulting in complex tubular dysfunction, progressive loss of renal function, and involvement of other vital organs usually lead to severe growth failure (298, 299). In children with *nephropathic cystinosis*, growth failure occurs already in infancy when glomerular function is typically not yet compromised, mainly due to water and electrolyte imbalances. In addition, dysfunction of the growth plate and multiple endocrine insufficiency (affecting the hypothalamus, pituitary, and thyroid) develops due to generalized cystine crystal deposition, adding further local and endocrine pathomechanisms of growth failure. Early initiation of treatment with the cystine depleting agent cysteamine results in improved growth and slows the progression of renal failure (300–302). As an additional option, rhGH effectively stimulates growth in cystinosis patients independently of renal function and cysteamine treatment (303). In patients with *primary hyperoxaluria* supplementary treatment with citrate and pyridoxine can delay the progression of nephrocalcinosis and renal failure, thereby contributing to maintained longitudinal growth (299). In patients with systemic oxalosis combined liver and kidney transplantation is a curative option; however real catch-up growth after combined transplantation is rarely observed even in prepubertal oxalosis patients (304).

In patients with chronic or recurrent interstitial disease, a minor degree of growth retardation may develop. Persistent or recurrent *urinary tract infections* may cause growth impairment by tubular dysfunction, by the catabolic effect of chronic disease, and/or progressive renal insufficiency. Growth rates may increase after medical and/or surgical intervention (305–307). In patients with vesico-ureteral reflux, moderate growth retardation has been demonstrated in case of bilateral disease and significant renal scarring (308). Whereas previous reports noted a growth spurt after successful anti-reflux surgery (306, 307), multiple regression analysis of 54 patients with obstructive urinary tract malformations suggested a positive relationship between the increase in relative height and the duration of antibiotic treatment, but no independent effect of surgical intervention (309).

Etiology of Growth Failure in CKD

The pathogenesis of impaired growth in CKD is complex. Although a particular cause can occasionally be found, a combination of pathophysiological mechanisms factors is usually responsible for growth impairment. Furthermore, the patient's age, the type, duration and severity of renal disease, the treatment modality, and the patient's social environment all play important roles.

Malnutrition and Inflammation

Protein-energy malnutrition frequently occurs in children suffering from CKD. Infants and young children are particularly prone to malnutrition because of their low nutritional stores and the high energy demands required allow high growth rates in this age group.

Malnutrition is a critical issue in children as it is in adults with CKD due to its close association with patient mortality (310, 311). Recently, malnutrition has been causally linked to inflammation and atherosclerosis as a distinct syndrome (MIA syndrome) peculiar to dialysis patients (312–314). It is thought to be caused by the combined effects of cytokine induction during dialysis, decreased clearance of inflammatory cytokines, oxidative and carbonyl stress, nutrient loss through dialysis, anorexia and low nutrient intake, uremic toxicity, volume overload and other dialysis-related factors. The MIA syndrome is considered the common cause of the high prevalence of early cardiovascular disease, excessive mortality, erythropoietin hyporesponsiveness, frequent hospitalizations and poor quality of life in dialysis patients. It is tempting to speculate that growth failure is a pediatric manifestation of the MIA syndrome. In support of this notion, adverse clinical outcomes including a two- to threefold elevated risk of death are associated with growth failure in children on dialysis (310, 315). Preliminary experimental and clinical evidence suggests an association

of both growth failure and malnutrition with elevated inflammatory cytokine levels.

Anorexia is one of the cardinal features of CKD, and universally observed in infants. Adequate energy intake is a primary prerequisite for tissue anabolism and growth. Energy malnutrition is particularly prevalent in uremic infants during the first year of life, when the metabolic rate in relation to body mass is high. Height SDS is correlated with body cell mass and serum transferrin or albumin in infants, emphasizing the importance of malnutrition for growth failure in this age group (244, 316, 317). Energy intake is inversely related to the degree of renal failure (318), and is correlated with growth rates if it is less than 80% of recommended dietary allowances (RDA) (319). However, further augmentation of energy intake above 100% RDA typically results in obesity rather than in a further stimulation of growth (319, 320). In later childhood, spontaneous food intake is usually low when related to the patient's age, but normal when adjusted for body mass (321, 322). Thus, it is difficult to differentiate whether low energy intake is the cause or the consequence of impaired growth.

In contrast to deficient calorie intake, spontaneous protein intake usually meets or even exceeds the RDA (321, 322). Dietary protein intake is not independently correlated with longitudinal growth in children with CKD. In a prospective study limiting protein intake to the safe levels of the WHO (e.g., 0.8–1.1 g/kg/day) but ensuring adequate calorie intake in a large cohort of children with CKD stage 2–4, no impairment of height or weight gain was seen during 3 years of observation (323).

Ample evidence suggests that the protein wasting observed in children with CKD is due to increased protein catabolism and/or impaired protein synthesis, independent of dietary intake. In experimental renal failure, the conversion of dietary to body protein at any given level of dietary intake is less efficient in uremic compared with pair-fed control animals (324). Resistance to the anabolic effects of insulin and IGF-1 and increased protein breakdown by activation of proteolytic ubiquitin-proteasome pathways may contribute to poor growth. The latter mechanism is caused to a large degree by metabolic acidosis (325).

Metabolic Acidosis

Metabolic acidosis usually develops when GFR is decreased by more than 50% due to the kidney's reduced ability to excrete ammonia. The severity of the acidosis is aggravated by nutritional protein and acid load, catabolism and altered electrolyte balance. Metabolic acidosis is associated with increased glucocorticoid production and increased protein degradation by activating branched chain ketoacid catabolism and the ubiquitin-proteasome pathway (326–328). In young children with CKD, the degree of protein wasting is tightly correlated with serum bicarbonate levels (329). Moreover, metabolic acidosis has profound suppressive effects on the somatotropic hormone axis by downregulating GH secretion (78), GH receptor and IGF-1 gene expression (330) and serum IGF-I levels (331). Hence, metabolic acidosis per se causes tissue catabolism and a state of GH-IGF1 insufficiency.

Disturbances of Water and Electrolyte Metabolism

Many congenital renal diseases that slowly progress towards renal insufficiency lead to a loss of electrolytes and a reduced ability of the kidney to concentrate urine. In particular, sodium chloride is lost in patients with obstructive uropathies and renal hypoplasia, and potassium is lost in patients with proximal tubular damage, most markedly in cystinosis. Polyuria, an expression of the reduced ability of the kidney to concentrate the urine, is seen in patients with Fanconi's syndrome and in nephronophthisis, but also in hypoplastic kidney disease.

It is not possible to independently assess the extent to which disturbances in water and electrolyte metabolism contribute to growth retardation in individual patients with CKD. The probability of these factors being significant has, however, been shown by analogous clinical and animal studies. In rats, sodium deficiency decreases protein synthesis and growth, which is only partially reversible by sodium repletion (332, 333). Part of the effects usually attributed to sodium deficiency are actually caused by concomitant depletion of chloride, which per se, if removed selectively from a sodium-replete diet, causes growth retardation and diminished muscle protein synthesis (334). The same applies to patients with a reduced chloride diet or with familial chloride diarrhea (335). Growth failure also occurs in children with diabetes insipidus, indicating that polyuria per se may contribute to growth retardation in CKD (336).

Anemia

Children with CKD develop increasing anemia as a result of erythropoietin deficiency. It is not certain if or to what extent chronic anemia leads to growth impairment.

Children with untreated chronic anemia of non-renal origin, e.g., thalassemia major, show retardation of growth and development. When treated with high-frequency transfusion regimens to keep hematocrits close to the normal range, growth rates may improve in these patients (337). Theoretically, anemia may interfere with growth via various mechanisms such as poor appetite, intercurrent infections, cardiac complications and poor oxygenation of the cartilage cells in the growth plate. The introduction of recombinant EPO for the treatment of renal anemia has offered the opportunity to study whether changes in growth are induced by the compensation of renal anemia. Correction of anemia in children with CKD leads to improved exercise capacity and decreased heart rate and resting oxygen consumption (338, 339). Although short-term stimulatory effects of erythropoietin-treatment on longitudinal growth have been reported anecdotally, no persistent catch-up growth could be demonstrated in several multicenter clinical trials.

Renal Osteodystrophy

Although gross skeletal deformities can contribute to the retardation of a child's growth, the appearance of renal osteodystrophy is not inevitably paralleled by alterations in epiphyseal growth of the long bones. Significant osteodystrophic changes are often detected radiologically in patients with relatively good growth rates. In such cases, osteopathy is unmasked by rapid growth. Growth is impaired only when severe secondary hyperparathyroidism results in destruction of the metaphyseal bone architecture.

Whereas treatment with vitamin D and $1,25(OH)_2D_3$ improves growth in uremic rats (340), an equivalent therapeutic success has not been achieved in children with CKD. Neither vitamin D_3 nor $1,25(OH)_2D_3$ treatment consistently affect growth in dialyzed children (341). This therapeutic failure contrasts with the remarkable growth improvement observed in patients treated for vitamin D deficient rickets, in whom a similar disorder of renal vitamin D metabolism without renal failure is present. Intermittent high-dose $1,25(OH)_2D_3$ administration, probably by inducing a low bone turnover state, can even impair growth in dialyzed children (342).

The extent to which secondary hyperparathyroidism contributes to growth impairment is unclear. Parathyroid hormone (PTH) is an anabolic hormone and an intrinsic growth factor, stimulating mitosis in osteoprogenitor cells and growth plate chondrocytes and upregulates the vitamin D receptor (343, 344). Intermittent PTH administration stimulates the skeletal growth of normal and uremic rats (345). Whereas two clinical studies reported weak positive associations between intact PTH levels and longitudinal growth in children with pre-dialytic CKD and on dialysis (342, 346), growth rates were neither correlated with complete 1,84-PTH nor with non-1,84-PTH fragments in recent studies using both whole- and intact PTH assays (347, 348). While there is no clear effect of mild to moderate hyperparathyroidism on growth, excessive PTH levels can lead to the destruction of growth plate architecture (349), epiphyseal displacement (350) and metaphyseal fractures (351).

Hormonal Factors

The multiple alterations of endocrine systems associated with CKD have been described above. Of particular relevance for statural growth is the complex state of GH and IGF-I resistance, which results in an impaired promotion of endochondral and appositional growth by IGF-1.

Treatment of Growth Failure in Chronic Kidney Disease

General Measures

Adequate *nutritional intake* is the most important prerequisite for early infantile growth. Growth rates in this period are correlated with energy intake (319). Consequently, forced feeding via nasogastric tube, gastrostomy or even fundoplication is an essential component in the management of infantile CKD (249, 250, 352). In later childhood, adequate nutrition is a permissive factor for growth; however, catch-up growth cannot be obtained by dietary manipulations alone. *Energy intake* should be targeted to achieve 80% to 100% of the Dietary Reference Intake (DRI) of healthy children. The caloric intake prescription should be related to height age rather than chronological age in patients whose height is below the third percentile. Increasing caloric intake in CKD patients above 100% of DRI is not useful since it usually leads to obesity rather than to additional catch-up growth. *Protein intake* should be 100% of RDA. In patients on peritoneal dialysis, a slightly higher intake (+0.2 to 0.4 g/kg/day) is recommended to compensate for dialytic protein losses. Higher protein intake should be avoided since anabolizing or growth promoting effects are not achieved by high-protein diets, which may even be detrimental in CKD by aggravating metabolic acidosis and augmenting the nitrogen and phosphorus load.

Supplementation of water and electrolytes is vital in patients presenting with polyuria and/ or salt losing nephropathies (251, 353, 354). Sodium losses are also common and require continuous replacement in anuric infants on peritoneal dialysis, who may lose up to 5 mmol/kg/day via the ultrafiltrate.

Metabolic acidosis should be vigorously treated by oral alkaline supplementation, aiming at serum bicarbonate levels of at least 22 mmol/L. *Water and electrolyte losses* must be consequently compensated (251, 353, 354). Prevention of renal osteodystrophy by *vitamin D* treatment is a further precondition for optimal growth rates. However, apart from the period of infancy, none of the above therapeutic procedures has been demonstrated to induce catch-up growth in short children with CKD.

Dialysis

Conventional dialysis does not improve growth in uremic children. Several large studies found mean annual losses of 0.2–0.8 SD standardized height (355–358).

More recently however, emerging clinical evidence indicates that catch-up growth can be induced in growth retarded children switched to intensified hemodialysis protocols with either short daily or extended thrice weekly sessions. (359, 360).

As with standard hemodialysis, catch-up growth is not commonly observed in children on *peritoneal dialysis*. Whereas early experience suggested continued significant losses of standardized height on CAPD/CCPD (247, 361–363), more recent studies suggest percentile-parallel growth patterns or slight losses of less than 0.5 SD per year (364, 365). Residual renal function is a more important predictor of growth on PD than dialytic clearance (365). In addition, a high peritoneal transporter state, a known morbidity and mortality risk factor in adults, predicted poor growth (−0.5 SD per year) in a prospective study of 51 children followed for 18 months (364). It is currently believed that apart from causing increased dialytic protein losses, the high transporter status may be an indicator of microinflammation, a putative cause of GH resistance in uremia.

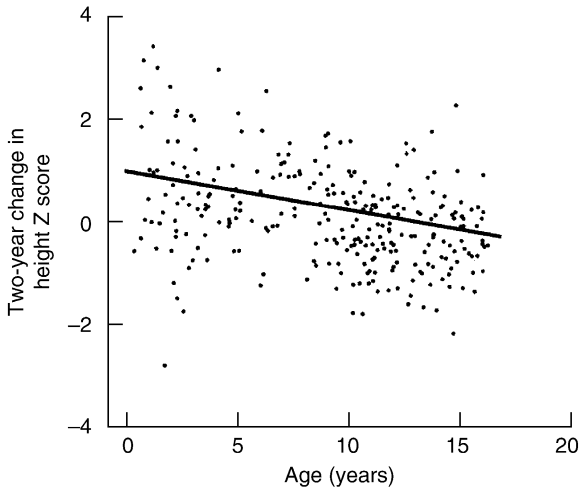
Transplantation

Only successful kidney transplantation is able to restore the conditions for normal growth compromised by the uremic state. However growth rates after transplantation vary widely, from further deterioration of standardized height to complete catch-up growth (118, 257, 276, 366–373). In an analysis of the North American Pediatric Renal Transplant Cooperative Study, the mean effect of transplantation before puberty on adult height was 0 SDS (269), confirming that the relative height achieved at time of transplantation is the most important predictor of final height (276, 372). Whereas pubertal patients tend to lose relative height following transplantation (374), a potential for post-transplant catch-up growth exists in patients younger than 6 years (277, 371, 373, 375) (*Fig. 70-9*). Infant allograft recipients typically exhibit excellent spontaneous growth rates, with a relative height gain of 1.5 SD within 2–7 years (366, 373, 377). Apart from the inverse relationship with age, the degree of growth retardapion positively predicts post-transplant growth rate (276, 277, 371, 373, 378). Furthermore, post-transplant growth critically depends on graft function (269, 273, 276, 277, 371, 373, 378). A marked deceleration in post-transplant growth is observed when GFR is below 60 mL/min/1.73 m^2, and in the French experience catch-up growth only occurred in children with a GFR above this value (379).

The daily and cumulative dose of glucocorticoids seem to be inversely related to the post-transplant growth rate (18, 380, 381). The hope that the prednisolone derivative deflazacort would interfere less with catch-up growth at equivalent immunosuppressive biopotency has not been substantiated (382, 383). Alternate-day corticosteroid

Figure 70-9

Change in standardized height during the first 2 years after transplantation. Improvement in mean height Z score is limited to children at pre-school age. (From (376) with permission.)



administration has been demonstrated in a controlled, randomized trial to improve growth growth by 0.25–0.5 SD of height per year (368, 384). The most impressive catch-up growth has been observed in patients in whom steroids could be completely withdrawn (256, 367, 385–388). The risk of early rejection and loss of renal function by steroid withdrawal, historically rated as 40–50% (367, 389, 390), has diminished considerably with the advent of more powerful and selective immunosuppressive agents. A cumulative height increment by 1.5 SD was observed within 3 years in children less than 5 years of age receiving tacrolimus monotherapy, and catch-up growth even occurred in pubertal patients (386). Glucocorticoids had to be reinstituted in 10% of patients. In a retrospective case control study glucocorticoids were weaned off in 20 selected patients on cyclosporine A and mycophenolate mofetil without acute allograft rejections and with stable graft function for at least 1 year (388). Standardized height increased in prepubertal patients off steroids by 1.5 SD, contrasting to no change in children on continued steroid medication (*Fig. 70-10*) (388) Even complete steroid avoidance seems to be possible in selected patients; in a study of 107 patients receiving induction therapy with IL-2R antibodies and maintenance tacrolimus combined with either steroids or mycophenolate mofetil, infants gained 1.5 SD (vs. −0.4 SD on steroids) and children aged 5–15 years 0.7 SD (vs. +0.2 SD) (391). Preliminary results from prospective controlled trials appear to confirm that steroids may be safely withdrawn or even entirely avoided with beneficial effects on growth and multiple metabolic features; however, subclinical rejection might still develop more commonly after steroid withdrawal and the risk of late acute or chronic rejection needs to be addressed in future long-term trials. Furthermore, it is currently unclear whether steroid withdrawal or avoidance will permit complete catch-up growth in severely growth retarded children; in clinical practice this is not seen consistently. Notably, incomplete catch-up growth is observed following transient local application of glucocorticoids to the tibial growth plate in rabbits, suggesting the induction of a permanent growth deficit (392).

An interesting observation is that living-related allografts appear to permit better long-term statural growth than grafts from deceased donors. In a restrospective analysis of children with similar standardized height at time of transplantation, recipients of living donor grafts developed superior catch up growth within 5 years of follow-up compared to recipients of deceased organs (393).

Treatment of Renal Growth Failure with Recombinant Growth Hormone

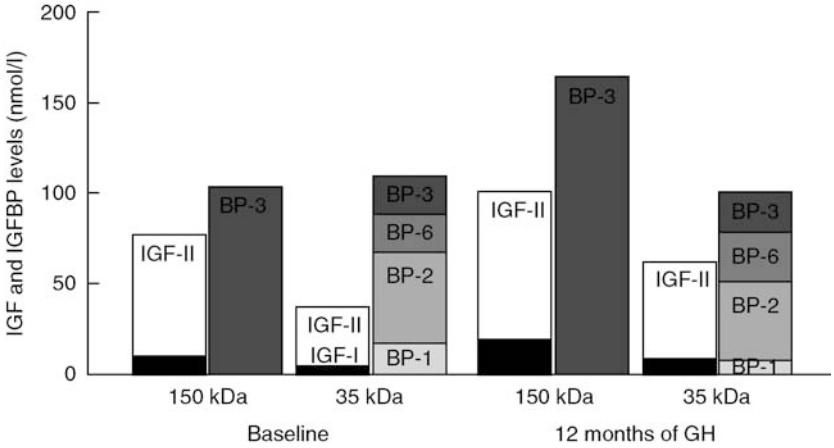
The GH resistance observed in uremia and during glucocorticoid treatment and the experimental proof that GH resistance can be overcome by supraphysiological doses of exogenous GH (394) have provided a rationale for treating children with CKD and after renal transplantation with recombinant human growth hormone (rhGH). Administration of rhGH increases the production of IGF-1 to a greater extent than that of IGF-binding proteins, thereby raising the availability of free IGF-1 at the tissue level (93) (*Fig. 70-11*).

rhGH Use in Prepubertal Children

In prepubertal children with CKD, numerous studies including two double-blind placebo-controlled trials rhGH demonstrated that rhGH induces a nearly twofold increase in height velocity during the first treatment year, with a diminishing but still significant effect on growth rate during the second year (396–403). Although the maximal height increment occurs in the first 3 treatment years, standardized height continues to increase slightly during extended treatment. After 5–6 years of rhGH administration, mean height SDS had increased from −2.6 at baseline to −0.7 in a North American study (402),

Figure 70-11

Balance between IGFBPs and IGFs in serum of CKD children before (baseline) and after 12 months of rhGH treatment. rhGH increases IGF/IGFBP ratio in the 35 kD complex. (Adapted from (395) with permission.)



from −3.4 to −1.9 in German children (401) and from −3 to −0.5 in Dutch patients (403). The remarkable prepubertal growth acceleration was not associated with a disproportionate advancement of bone age, resulting in a remarkable increase in predicted adult height at the end of the prepubertal phase (401).

There is limited data on the efficacy of rhGH therapy in *infants* with CKD. A placebo-controlled study in CKD patients younger than 2.5 years of age showed a mean increase in standardized height of 2 SD in the rhGH group versus −0.2 SD in controls (404). Along with similar findings in a previous uncontrolled study, these results provide support to the concept of early rhGH initiation in infants and young children with CKD if adequate energy intake fails to restore normal growth (405).

Prepubertal children on dialysis respond less well to rhGH than children with CKD on conservative treatment (401, 406). In the German multicenter study, 13 prepubertal dialysis patients gained only 0.8 SDS in height on average during the first two treatment years, as compared to an increment of 1.3 SDS in 41 CKD patients (401) (*Fig. 70-12*). These results were confirmed in a large cohort of French children on hemodialysis who exhibited only 0.5 SDS height gain during the first treatment year, with continued small annual increments for up to 5 years (407). The growth response to rhGH is similar in children on peritoneal and hemodialysis (408). In prepubertal children with nephropathic cystinosis, GH increased height by 0.8 SDS during the first year, and by 1.7 SDS within 5 treatment years (409). In prepubertal renal allograft patients, in whom alternate-day glucocorticoid administration does not induce catch-up growth and complete steroid withdrawal is not considered an option for safety reasons, a therapeutic trial with GH may be considered. Several studies have demonstrated a growth promoting effect of GH in prepubertal children with renal allografts over average treatment periods of 1–3 years (119, 410–415). Treatment efficacy was slightly inferior to that observed in CKD patients on conservative treatment, with mean cumulative height gains of 1–1.5 SD during the first 3 years.

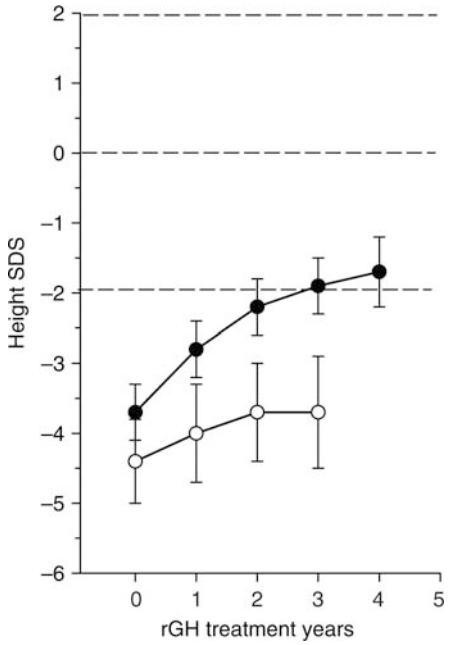
rhGH Use in Puberty

A systematic analysis of rhGH treatment efficacy in pubertal children is difficult due to methodological problems (416). These include delayed puberty with a lack of appropriate growth reference data, potential effects of rhGH on the onset and duration of the pubertal growth spurt, and frequent changes in treatment modalities with variable relative efficacy of rhGH. In addition, rhGH is usually discontinued at time of transplantation but is sometimes reinstituted if the growth rate remains low, introducing large variability in the duration of rhGH treatment during puberty. Hence, only controlled long-term observations, ideally recording total pubertal height gain in treated and untreated pataents, with comparable distributions of treatment modalities, permit a meaningful analysis of rhGH efficacy in puberty.

Haffner et al. followed 38 children with CKD in whom rhGH was initiated at prepubertal age until they reached

Figure 70-12

Superior efficacy of rhGH treatment in children with pre-endstage CKD (closed circles, n = 19) compared to children on dialysis (open circles, n = 6). (Adapted from (401) with permission.)



adult height (259) (*Figs. 70-13*, *70-14*). Since rhGH was stopped at time of transplantation, the patients received GH during 50% of the pubertal observation time. Fifty children, matched for age and degree of CKD, who did not receive rhGH due to still normal height, served as controls. The children receiving rhGH showed sustained catch-up growth, whereas the control children developed progressive growth failure (*Fig. 70-13*). Dissection of the prepubertal and the pubertal growth phases disclosed that the additional height gain relative to the control group was almost entirely limited to the prepubertal period, whereas pubertal height gain was insignificantly greater in the rhGH treated patients than in the controls (*Fig. 70-14*). The apparent inefficacy of rhGH in puberty may be explained in part by the incomplete continuation of treatment, as suggested by a positive correlation of the fractional duration of rhGH therapy with total pubertal height gain. In fact, Hokken-Koelega et al. demonstrated that allograft recipients may respond very well to rhGH even in late puberty (399), with an almost threefold greater 2-year height gain compared to untreated historical controls (417).

An advanced onset of puberty was not observed in the German study nor in the Dutch cohort (403), although a subtle acceleration of bone maturation and a

Figure 70-13

Favourable effect of long-term rhGH treatment on final adult height in children with CKD. Synchronized mean growth curves during GH treatment for 38 children (32 boys and 6 girls) with CKD, as compared with 50 control children with CKD not treated with GH. Normal values are indicated by the 3rd, 50th, and 97th percentiles. The circles indicate the time of the first observation (the start of GH treatment in the treated children) and the end of the pubertal growth spurt. (From (259) with permission.)

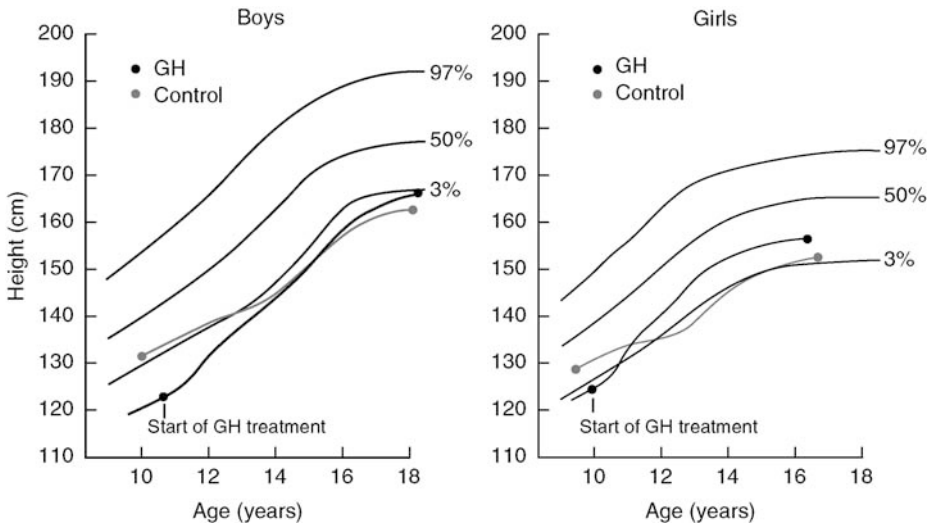


Figure 70-14

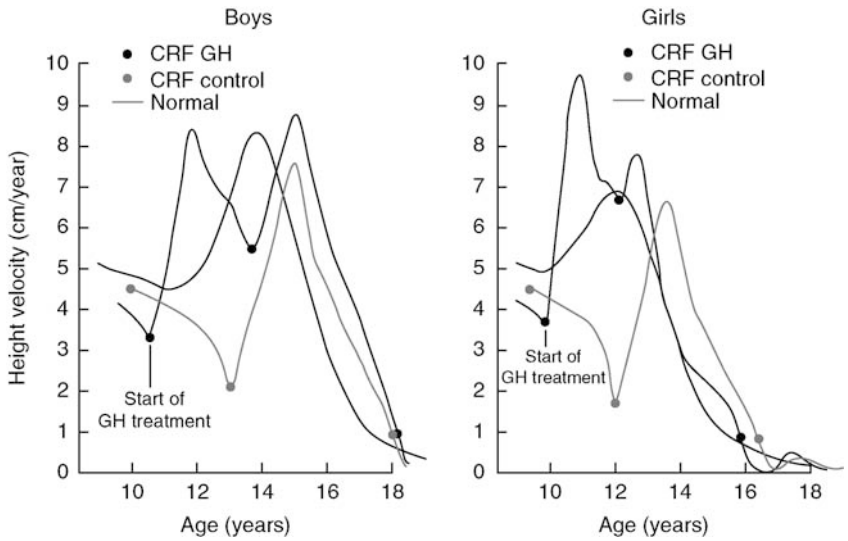
Synchronized mean height velocity curves during GH treatment for the same children as shown in *Fig. 70-13*. The circles indicate the time of the first observation (the start of GH treatment in the treated children), the time of minimal prespurt height velocity, and the end of the pubertal growth spurt. (From (259) with permission.)



slight shortening of the pubertal growth spurt was noted by Haffner et al. (259).

Adult Height Following rhGH Treatment

Final height outcome data are beginning to emerge which will permit to assess the ultimate treatment efficacy of rhGH therapy. In the German multicenter study, the mean adult height of 38 children who received rhGH for a mean of 5.3 years was −1.6 SDS, with two-thirds of patients ending up at a height above the 3rd percentile (259). The patients ultimately gained 1.4 SD when compared to their standardized height at baseline. Conversely, mean height SDS decreased in the untreated control group from −1.5 to −2.1 SDS at attainment of adult height (*Fig. 70-14*). Figures in the same range were reported from several other trials (*Table 70-1*). Of course, the variability of final height outcomes is large. The cumulative height gain appears to be positively associated with the initial target-height deficit and the duration of rhGH therapy, and negatively with the percentage of the observation period spent on dialysis (259, 403). The relative height gain attained during rhGH treatment appears to be maintained until final height in patients undergoing renal transplantation; neither spontaneous catch-up nor catch-down growth are common (420, 423).

Potential Adverse Effects of GH Treatment

The safety of long-term rhGH treatment in CKD has been monitored in numerous randomized clinical studies and registries. Both in the large cohort of the NAPRTCS registry and in a recent Cochrane meta-analysis of randomized clinical trials, adverse event rates in children with CKD patients on conservative treatment, on dialysis, and after renal transplantation, the use of rhGH was not associated with increased incidences of malignancy, slipped capital femoral epiphysis, avascular necrosis, glucose intolerance, pancreatitis, progressive deterioration of renal function, acute allograft rejection or fluid retention (424, 425).

Concern was raised initially that prolonged GH treatment might provoke *diabetes mellitus*, because patients with CKD already show impaired glucose tolerance due to peripheral insulin resistance. Insulin secretion increases persistently during rhGH treatment due to a direct inulin agogic effect of growth hormone. This increase is most pronounced in transplanted patients on concomitant glucocorticoid therapy. However, oral glucose tolerance did not change during up to 5 years of rhGH therapy in CKD patients on conservative treatment, dialysis, and after renal transplantation (426). The long-term consequences of increased insulin secretion are uncertain. Theoretically it may contribute to atherosclerosis or eventually induce diabetes mellitus by exhaustion of pancreatic ß cells.

Table 70-1

Synopsis of studies reporting adult height data after rhGH treatment of growth failure due to CKDMean values are given for age, time period and SDS values unless indicated otherwise

Study	Number of patients studied	CKD treatment modalities	Age at start of rhGH (years)	Pubertal status at start of rhGH	Duration of follow-up (years)	Duration of rhGH (years)	Initial height SDS	Final height SDS	Change in height SDS

Mean values are given for age, time period and SDS values unless indicated otherwise
n.i. = no information given. *median. **percent patient years spent in each treatment category

Although not a single case of irreversible diabetes mellitus has been observed in children with CKD treated with rh GH through 1998 (427, 428), initial reports of an increased incidence of type-2 diabetes mellitus in non-renal children undergoing GH therapy mandate continued surveillance (429).

An aggravation of secondary *hyperparathyroidism* has been reported anecdotally (430, 431). This effect does not appear to be due to stimulation by GH, but rather result from slight decreases of ionized calcium as a consequence of GH-stimulated bone apposition or an increase in serum phosphate concentration secondary to improved appetite. Furthermore, pre-existing renal osteodystrophy may be unmasked by an increased growth rate and may become radiographically apparent (432).

Concern has also been raised that rhGH may cause glomerular hyperfiltration and accelerated *renal failure progression*. However, long-term observations over up to 8 qears showed no evidence of an accelerated GFR loss in CKD patients prior to or after transplantation other renal disorders and in renal allograft recipients (259, 401, 403, 409).

Since growth hormone is an immunomodulatory hormone (433), allograft rejection might be triggered by rhGH administration in post-transplant patients. Several controlled trials have ruled out a major impact of rhGH on the overall risk of rejection, with the possible exception of high-risk patients who experienced more than one acute rejection episode prior rhGH therapy (413, 415, 434, 435).

Extensive surveys in thousands of patients failed to disclose any significant relationship between rhGH treatment and the occurrence of malignancies (436–438). A review of adverse events in 583 patients with CKD and ESRD treated with GH revealed one solid tumor and one B-cell lymphoma among patients undergoing PD and one lymphoma in a transplant recipient (439). However, reports on renal cell carcinoma in two children 9 and 11 years post-transplant who had received rhGH, premalignant

tubuloepithelial changes in a pediatric renal allograft (414), and a borderline increase in the risk of post-transplant lymphoproliferative disorder associated with pre-transplant rhGH use among 41 cases reported to the NAPRTCS database (440) raise the suspicion that tumor risk may be selectively increased by rhGH in children receiving maintenance posttransplant immunosuppression.

GH induces an IGF-1 mediated increase in distal tubular sodium reabsorption and upregulates the renin-angiotensin system (441, 442). As a consequence, a transient, usually mild retention of sodium and water occurs during the first few days of treatment.

Benign intracranial hypertension has been reported as a rare adverse effect of GH treated patients with various underlying diseases. In CKD, the risk of developing this complication appears to be increased up to 10-fold compared to children receiving rhGH due to other underlying disorders (443, 444). A survey of 1,670 children with CKD treated with rhGH reported intracranial hypertension in 15 subjects (0.9%) within a mean treatment period of 13 weeks (445). Symptoms generally abated upon rhGH discontinuation, but two patients had persistent blindness and in at least 4 patients the symptoms recurred after reinitiation of GH therapy. While this uncontrolled survey suggested a particular risk of CKD patients to develop intracranial hypertension while on rhGH, a prospective, controlled cohort study of patients in the NAPRTCS database noted intracranial hypertension in only 3 out of 1,376 rhGH-treated CKD patients (incidence 1 per 3,000 patient years), 2 of whom were not receiving rhGH at the time when the condition developed (425). Intracranial hypertension was not seen in any of 957 rhGH-treated, but in 7 of 3,983 untreated children on dialysis or post-transplantation. These data suggest that the incidence of the condition may be generally increased in CKD, but whether rhGH further increases the risk is questionable. Nonetheless a baseline fundoscopy should be performed in children initiating rhGH. Since hypertension and fluid overload may be predisposing factors, the state of hydration should be well controlled at start of treatment. Headache, vomiting and other clinical signs of increased intracranial hypertension mandate careful clinical investigation including fundoscopy.

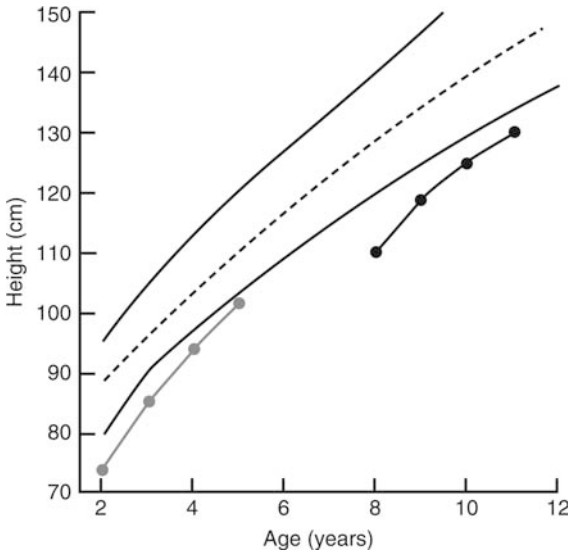
Strategies to Optimize Growth by rhGH Treatment

The response to rhGH is positively influenced by the residual GFR, target height, the initial target height deficit and the duration of GH treatment, and negatively by the age at start of treatment (416). A curvilinear dose-response relationship appears to exist. Although a dosage of 4 IU/m^2/day was more efficient than 2 IU/m^2/day in a double-blind trial (446), no further improvement of the growth response was observed with 8 IU/m^2/day, at least in a pubertal cohort (417). Daily dosing is more efficacious than three applications per week (447). Discontinuation of rhGH treatment will result in loss of height SDS in 75% of children with CKD on conservative treatment (448), whereas catch-down growth seems to be uncommon when rhGH is discontinued due to renal transplantation (420, 422).

Since the absolute growth response to rhGH (in cm height gain per year) is independent of age but the reference range increases with age (401), rhGH treatment should be started as early as possible in the course of renal disease (*Fig. 70-15*). A fixed daily dose of 4 IU/m^2

Figure 70-15

Age-dependent relative efficacy of GH treatment exemplified by individual growth curves predicted for two patients aged 2 and 8 years, started on GH at a basal height SDS of −3.5 and a height velocity of SDS −2.0. The reference lines indicate the 3rd, 50th and 97th percentile of a normal population. Growth is accelerated over baseline height velocity in both patients by 4.5 cm in the first, 1.9 cm in the second, and 1.0 cm in the third treatment year (empirical means observed in patients on conservative treatment followed for 3 years). The young child reaches the 3rd percentile within 3 years, whereas the older child does not. (From (401) with permission.)



(or 0.05 mg/kg) should be used. Treatment should not be stopped if the annual gain of height SDS diminishes after the third treatment year to avoid the risk of catch-down growth. It should also be continued when the patient becomes dialysis-dependent. If rhGH is initiated in a small child already on dialysis, transplantation should not be postponed for the sake of approved rhGH treatment, since the efficacy of rhGH in dialysis patients is limited and short-lasting. Treatment should be stopped at time of renal transplantation to observe the spontaneous evolution of growth. If no or insufficient catch-up growth occurs within 12 months, glucocorticoid withdrawal is the first option. If unsuccessful, rhGH reinstitution should be considered. Treatment decisions should be made without delay to save growth potential. The question of rhGH continuation through puberty is still controversial. The evaluation of treatment efficacy is difficult due to the dynamic changes of growth rate as part of the pubertal growth spurt, which occurs independently of concomitant rhGH treatment. Controlled prospective study results are not available. Hence, the decision to continue or restart rhGH in puberty must be made on an individual basis, taking into account the degree of growth retardation, the residual growth potential and the expected therapeutic compliance of the adolescent.

It remains uncertain whether a low growth rate (e.g., height velocity below the 10th–25th percentile over several years) should also be a treatment criterion in a child with a relative height still in the normal range. Such "preventive" therapy might prove to be more effective in increasing adult height than initiation of treatment when short stature is already established. This treatment strategy appears justified if a growth arrest is noted which is not explained by non-endocrine circumstances. It is also an issue of current consideration whether in patients with imminent or early puberty skeletal maturation should be delayed by pharmacological intervention by GnRH analogues or aromatase inhibitors to prolong the prepubertal growth phase for GH treatment.

71 Chronic Kidney Disease Mineral and Bone Disorder

Katherine Wesseling-Perry · Isidro B. Salusky

The kidney plays a major role in bone and mineral homeostasis by regulating calcium, phosphorus, parathyroid hormone (PTH), fibroblast growth factor-23 (FGF-23) and calcitriol (1,25 dihydroxyvitamin D_3, $1,25(OH)_2D_3$) metabolism. Disordered regulation of mineral metabolism occurs early in the course of chronic kidney disease (CKD) and results in alterations in bone modeling, remodeling, and growth. These alterations have been a focus of CKD management in children for decades. However, a growing awareness that cardiovascular calcifications accompany CKD, that cardiovascular disease is the leading cause of mortality in both adults and children with kidney disease, and that therapies designed to treat the skeletal consequences of CKD affect the progression of vascular pathology, has led to a reclassification of the mineral, skeletal, and vascular complications associated with progressive kidney disease. Together, these alterations are termed "CKD Mineral and Bone Disorder" ("CKD-MBD") (1).

The CKD-MBD is defined as a systemic disorder of mineral and bone metabolism due to CKD that is manifested by either one or a combination of the following: (1) abnormalities of calcium, phosphorus, PTH, or vitamin D metabolism, (2) abnormalities in bone histology, linear growth, or strength, or (3) vascular or other soft tissue calcification. "Renal osteodystrophy" is the specific term used to describe the bone pathology that occurs as a complication of CKD and is therefore one aspect of the CKD-MBD. Traditionally, such lesions have been defined according to alterations in bone turnover, ranging from high bone turnover (secondary hyperparathyroidism, osteitis fibrosa) to lesions of low bone turnover (adynamic bone disease and osteomalacia). However, alterations in skeletal mineralization and volume are also common in patients in CKD (1) and may contribute to such outcomes as fractures, skeletal deformities, and poor growth which persist despite normalization of bone turnover (2). Bone histomorphometry continues to be the gold standard for the assessment of three essential aspects of bone histology: turnover, mineralization, and volume (1). This chapter summarizes the major aspects of the pathogenesis, clinical manifestations, histologic features, and therapeutic interventions currently used in the management of CKD-MBD. The clinical and histologic features of bone diseases after successful kidney transplantation are also described.

Pathogenesis of CKD-MBD

Abnormalities of Calcium, Phosphorus, PTH, Vitamin D, and FGF-23 Metabolism

Calcium and Phosphorus

1,25 dihydroxyvitamin D_3 is the most active form of vitamin D and regulates calcium balance and serum calcium levels by increasing intestinal calcium absorption. The kidney generates the majority of circulating $1,25(OH)_2D_3$, converting 25(OH) vitamin D to $1,25(OH)_2D_3$ by means of the enzyme 1α-hydroxylase. As renal failure progresses, calcitriol levels and intestinal calcium absorption decline. However, at the same time, rising PTH levels increase 1α-hydroxylase activity and also release calcium and phosphorus from bone, thus maintaining serum calcium levels until late in the course of CKD (*Fig. 71-1a*) (3).

Likewise, serum phosphorus levels are usually maintained in the normal range throughout mild to moderate CKD (*Fig. 71-1a*). Elevated serum PTH and FGF-23 levels increase single nephron phosphate excretion, thus maintaining overall phosphate balance until GFR declines to 25–30% of normal (4, 5). In late (stage 4) CKD, hyperphosphatemia ensues and contributes to secondary hyperparathyroidism (3).

FGF-23

A recently described phosphaturic hormone, FGF-23, was first identified in patients with tumor-induced osteomalacia, autosomal dominant hypophosphatemic rickets, and X-linked hypophosphatemic rickets. In these

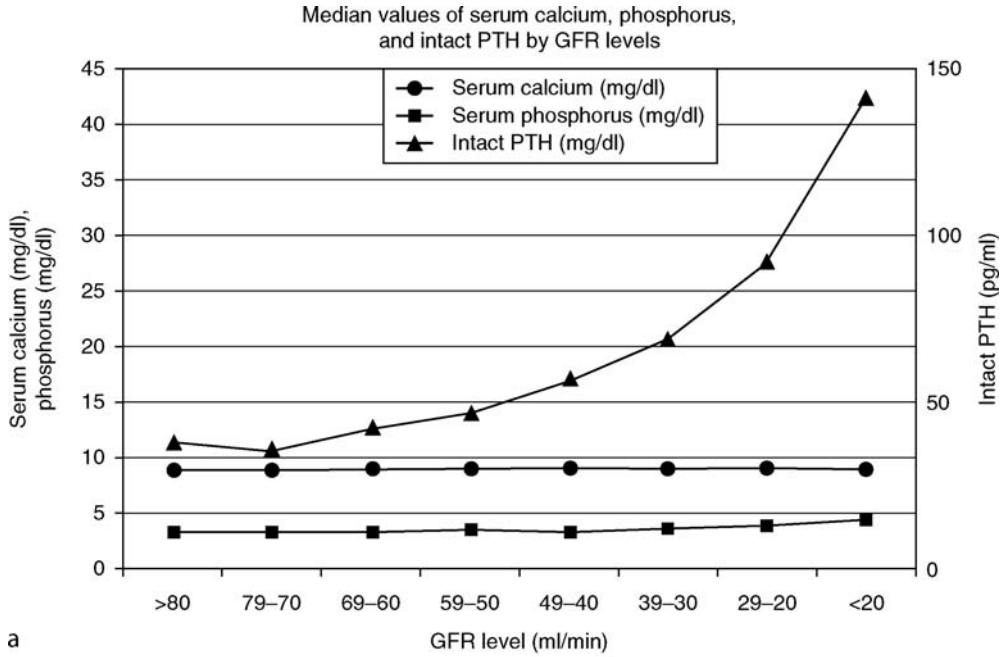
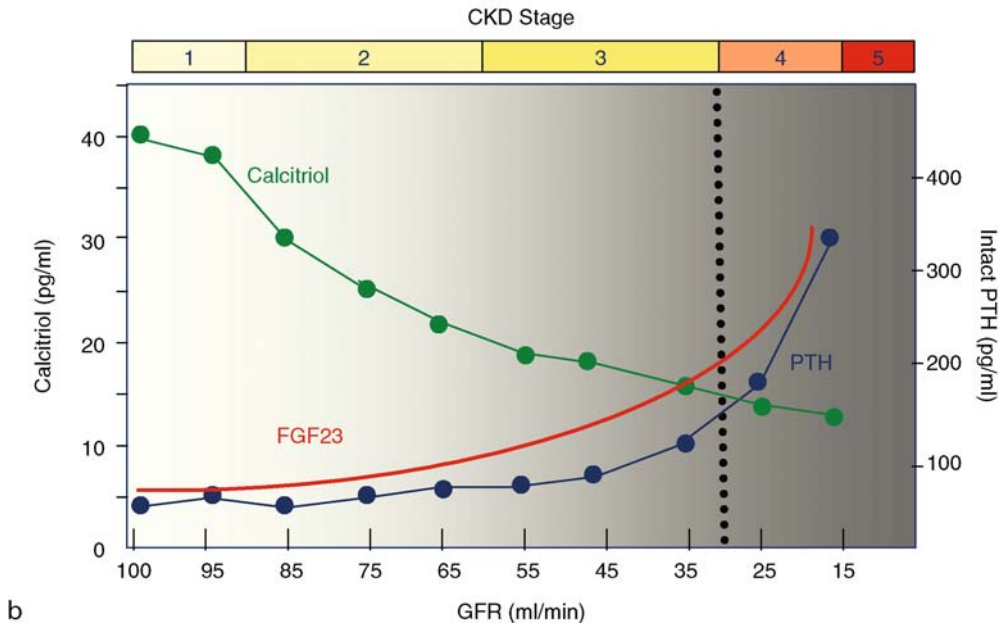
Median levels of calcium, phosphorus, PTH, FGF-23 and PTH per stage of CKD. (a) Median serum levels of calcium and phosphorus stay constant until late in the course of CKD; PTH levels rise before any changes are seen in calcium and phosphorus. (Reprint by permission from Levin A et al., *Kidney International* 2007. vol 71 pp31–38). (b) Rising serum FGF-23 and decreasing levels of 1,25 dihydroxyvitamin D occur prior to a rise in serum PTH. (See color plate 46)





conditions, elevated circulating levels of FGF-23 result in renal phosphate wasting and suppression of $1,25(OH)_2D_3$ production. The protein is made in bone (6, 7) and the presence of a cofactor, Klotho, is essential for its action in many tissues (8). FGF-23 levels may be regulated by phosphorus intake (9, 10) and serum values increase as CKD progresses, becoming markedly elevated in individuals with end-stage kidney disease (*Fig. 71-1b*) (11).

In animals with normal renal function, FGF-23 suppresses 1α-hydroxylase activity (12) and, in patients with CKD, $1,25(OH)_2D_3$ levels are inversely related to levels of circulating FGF-23, suggesting that the hormone may play a significant role in mineral metabolism – in declining active vitamin D levels in CKD, specifically (13). FGF-23 levels have been implicated in parathyroid gland regulation; higher levels of FGF-23 have been shown to suppress PTH release (14, 15). FGF-23 has also been shown to act directly on PTH secretion in vitro, through a mechanism independent of its actions on vitamin D metabolism (14, 15).

Vitamin D

In patients with CKD, serum $1,25(OH)_2 D_3$ levels decline early in the course of kidney dysfunction, before any changes in serum calcium or phosphorus concentrations occur and prior to any rise in serum PTH levels (*Fig. 71-1b*) (3, 16). $1,25(OH)_2D_3$ levels decline as 1α-hydroxylase activity decreases and low levels have been implicated as the initial event of the altered mineral and bone metabolism associated with CKD (3, 16). In late stages of CKD, phosphate retention and increased serum phosphorus levels directly suppress 1α-hydroxylase activity (9). However, while these factors contribute to declining 1α-hydroxylase activity, current evidence demonstrates that rising FGF-23 levels may be of even greater importance (13).

Low circulating levels of $1,25(OH)_2D_3$ have consequences for many tissues. Aside from its effect on intestinal calcium absorption, $1,25(OH)_2D_3$ plays a direct role in the suppression of PTH gene transcription. Animal studies also indicate that $1,25(OH)_2D_3$ is essential for normal skeletal physiology – particularly in growing animals – and that this effect may not be mediated by the vitamin D receptor (VDR). Mice who lack the VDR (i.e., mice unable to respond to the actions of $1,25(OH)_2D_3$ through its classical receptor) are phenotypically similar to those lacking the 1α-hydroxylase gene itself (i.e., mice unable to generate $1,25(OH)_2D_3$); both sets of mice are hypocalcemic with markedly elevated serum PTH levels, parathyroid gland hyperplasia, and rickets (17). However, a diet replete in calcium, phosphorus, and lactate is sufficient to normalize the serum calcium, phosphorus, and PTH levels, and to prevent the development of rickets in VDR deficient animals (18). By contrast, this "rescue diet" is unable to completely reverse growth plate abnormalities in 1α-hydroxylase deficient mice, suggesting that $1,25(OH)_2D_3$, acting through a receptor other than the classical VDR, may be essential for proper growth plate development (19). $1,25(OH)_2D_3$ has also been shown to regulate the renin-angiotensin system; 1α-hydroxylase deficient mice demonstrate cardiac hypertrophy and dysfunction which are reversed with angiotensin converting enzyme blockade (20, 21). Thus, $1,25(OH)_2D_3$ may be essential for cardiac health, a finding that may explain observational data suggesting that active vitamin D sterol therapy improves survival in patients treated with maintenance dialysis (22, 23).

Native 25(OH) vitamin D (25(OH)D) deficiency is prevalent in patients with CKD; low levels of this form of the hormone also contribute to altered mineral metabolism. Vitamin D is either made in the skin or ingested from the diet (24, 25). UVB (290–315 nm) photons penetrate the skin and are absorbed by 7-dehydrocholesterol to form previtamin D_3 which then spontaneously converts to vitamin D_3. Vitamin D_3 is extruded from the skin cell into the extracellular space where it binds vitamin D-binding protein (26). While the vitamin D created in the skin is exclusively of the D_3 form, dietary sources of vitamin D as well as food supplements may contain either vitamin D_2 (created through the UV irradiation of ergosterol in yeast) or D_3 (from animal sources – particularly fish). Vitamin D (both D_2 and D_3) undergoes hydroxylation by the liver, forming 25(OH)D (27). Subsequently, 25(OH)D is taken up by the renal tubular cells by a megalin dependent process and undergoes a second hydroxylation, facilitated by renal 1α-hydroxylase, to $1,25(OH)_2D_3$, a more potent stimulator of gut calcium absorption (28, 29). Although conversion of 25(OH)D–$1,25(OH)_2D_3$ is, in the general population, a substrate-independent process, it becomes a substrate dependent process in patients with CKD (30). Furthermore, although the actions of 25(OH)D have been underemphasized in CKD, extrarenal 1α-hydroxylase activity may significantly contribute to $1,25(OH)_2D_3$ production, even in anephric patients (31–33). Thus low levels of the precursor, 25(OH)D may exacerbate $1,25(OH)_2D_3$ deficiency in the context of CKD.

Since levels of 25(OH)D below 32 ng/ml are associated with increased PTH levels, reduced bone mineral density (BMD) (34), and increased rates of hip fractures (35) in the general population, such levels are therefore considered to represent insufficient vitamin D storage. Levels between 15 and 30 ng/ml are defined as vitamin D "insufficiency", levels between 5 and 15 ng/ml are characterized as vitamin D "deficiency" and levels less than 5 ng/ml as "severe deficiency" (36). Interestingly, 25(OH)D levels in the vast majority of the general population meet the definition of D insufficiency and a large percentage – as many as 57% in one series of medical inpatients (37) – have serum levels less than 15 ng/ml,

thus qualifying as vitamin D deficient. A high prevalence of vitamin D deficiency is also present in the pediatric population; 24% of adolescents with normal kidney function in Boston display 25(OH)D levels less than 15 ng/ml (38). The prevalence is higher in individuals with darker skin pigmentation; 52% of Hispanic and black adolescents from the same cohort demonstrating evidence of D deficiency (38).

Several studies have also documented a high prevalence of 25(OH)D deficiency in patients with CKD; this prevalence increases as renal function declines (39, 40) and the vast majority of patients treated with maintenance dialysis have insufficient vitamin D storage (41,42). Patients with CKD are at increased risk of vitamin D deficiency for several reasons: 1) many are chronically ill with little outdoor (sunlight) exposure. 2) CKD dietary restrictions, particularly of dairy products, curtail the intake of vitamin D rich food and lead to decreased dietary calcium intake (43), resulting in greater conversion of 25(OH)D–$1,25(OH)_2D$, thus necessitating higher vitamin D intake and/or production (44); and 3) patients with CKD display decreased skin synthesis of vitamin D_3 in response to sunlight compared with individuals with normal kidney function (45). Decreased skin synthesis of D is particularly prominent in individuals with darker skin due to higher skin melanin content (46). Proteinuric diseases further exacerbate D deficiency in the CKD population, as 25(OH)D, in combination with vitamin D binding protein, is lost in the urine (47, 48).

Apart from its conversion to $1,25(OH)_2D_3$, 25(OH)D may have its own effect on tissues. Indeed, supplementation with ergocalciferol has been shown to decrease serum PTH levels in patients with CKD (49, 50). Recent evidence demonstrates that 1α-hydroxylase is present in the parathyroid glands; thus, 25(OH)D is converted inside the gland to $1,25(OH)_2D_3$, suppressing PTH (51). Furthermore, 25(OH)D administration suppresses PTH synthesis even when parathyroid gland 1α-hydroxylase is inhibited, indicating that 25(OH)D may contribute to PTH suppression, independent of its conversion to $1,25(OH)_2D_3$ (51).

Parathyroid Hormone (PTH)

Due to alterations in calcium, phosphorus, FGF-23, and $1,25(OH)_2D_3$ metabolism, PTH levels increase as CKD progresses (*Fig. 71-1a*). Calcium is the primary stimulus for PTH release, however, changes in serum calcium are not common until late in the course of CKD while serum PTH levels begin to rise before any changes in serum calcium are evident. Altered $1,25(OH)_2D_3$ metabolism is a primary factor in the development of secondary hyperparathyroidism early in the course of CKD (52–54). $1,25(OH)_2D_3$ has been shown to suppress PTH gene transcription, both *in vitro* (bovine parathyroid cell culture) and *in vivo* (intact rats). In conjunction with the vitamin D receptor (VDR), $1,25(OH)_2D_3$ binds negative vitamin D response elements in the parathyroid gland which inhibit pre-proPTH gene transcription (55, 56). In a positive feedback loop, $1,25(OH)_2D_3$ itself increases VDR gene expression in the parathyroid gland, further suppressing PTH gene transcription. $1,25(OH)_2D_3$ also increases the expression of the calcium sensing receptor (CaSR), the expression of which is reduced in hyperplastic parathyroid tissues obtained from patients with renal secondary hyperparathyroidism (57). Vitamin D deficiency in animals is associated with decreased expression of CaSR mRNA in parathyroid tissue, while $1,25(OH)_2D_3$ therapy increases CaSR mRNA levels in a dose dependent manner (58). Thus, in CKD, reduced circulating $1,25(OH)_2D_3$ contributes to secondary hyperparathyroidism and parathyroid gland hyperplasia in a number of ways: through decreased intestinal calcium absorption, decreased binding to the VDR, reduced CaSR expression, and decreased VDR expression.

Phosphorus retention and hyperphosphatemia have also been recognized for many years as important factors in the pathogenesis of secondary hyperparathyroidism. The development of secondary hyperparathyroidism is prevented in experimental animals with chronic kidney disease when dietary phosphorus intake is lowered in proportion to the glomerular filtration rate (GFR) (59). Dietary phosphate restriction can also reduce previously elevated serum PTH levels in patients with moderate renal failure (9, 60). Phosphorus retention and hyperphosphatemia indirectly promote the secretion of PTH in several ways. Hyperphosphatemia lowers blood ionized calcium levels as free calcium ions complex with excess inorganic phosphate. The ensuing hypocalcemia stimulates PTH release. Phosphorus also impairs renal 1α-hydroxylase activity, which diminishes the conversion of 25(OH)D to $1,25(OH)_2D_3$ (9). Finally, phosphorus can directly enhance PTH synthesis by the parathyroid cell by interrupting the normal calcium sensing receptor (CaSR) signal cascade. High serum phosphorous levels decrease cytosolic phospholipase A2 (normally increased by CaSR activation), leading to a decrease in arachidonic acid production with a subsequent increase in PTH secretion (61). Hypophosphatemia also decreases PTH mRNA transcript stability *in vitro* (62), suggesting that phosphorous itself affects serum PTH levels,

probably by increasing the stability of the PTH mRNA transcript.

Alterations in parathyroid gland CaSR expression also occur in secondary hyperparathyroidism and may, in turn, contribute to parathyroid gland hyperplasia. The CaSR is a seven transmembrane G protein-coupled receptor with a large extracellular N-terminus, which binds acidic amino acids and divalent cations (63). Low extracellular calcium levels result in decreased calcium binding to the receptor, a conformational relaxation of the receptor and a resultant increase in PTH secretion (64), while activation of the receptor by high levels of serum calcium decrease PTH secretion (65, 66). The expression of the CaSR is reduced by 30–70% as judged by immunohistochemical methods in hyperplastic parathyroid tissue obtained from human subjects with renal failure (57, 67). Decreased expression and activity of CaSR has been linked to decreased responsiveness in PTH secretion due to altered calcium levels (68). This decreased expression of the CaSR results in an insensitivity to serum calcium levels with subsequent uncontrolled secretion of PTH. Increased stimulation of the CaSR by calcimimetics has been shown to decrease PTH cell proliferation, implicating the CaSR as a regulator of cell proliferation, as well as PTH secretion (69).

The link between the CaSR and vitamin D in cell cycling in the parathyroid gland is incompletely understood. However, there is some evidence that vitamin D may work to decrease parathyroid hyperplasia by activating the CaSR. CaSR gene transcription has been shown to be regulated by vitamin D through two distinct vitamin D response elements in the gene's promoter region (70), suggesting that alterations in vitamin D metabolism in renal failure could account for changes in calcium sensing by the parathyroid glands and that vitamin D may act upstream of the CaSR in preventing parathyroid cell hyperplasia (17).

The temporal relationship between the duration and/or the severity of renal failure and the decrease in parathyroid CaSR expression has yet to be determined. In vivo studies of parathyroid gland function in patients with end-stage renal disease indicate that calcium sensing by the parathyroid glands is altered in advanced, but not in mild to moderate, secondary hyperparathyroidism (71,72). However early *in vivo* findings have yet to be confirmed by *in vitro* assessment of either calcium-regulated PTH release or CaSR expression. It remains uncertain, therefore, whether alterations in CaSR expression fully account for disturbances in PTH secretion in mild to moderate chronic renal failure.

Recent evidence suggests that FGF-23 may also regulate PTH secretion. *In vitro* experiments indicate that increased FGF-23 levels suppress PTH release. This effect appears to be independent of the action of FGF-23 on vitamin D metabolism (14, 15).

Pathogenesis of Renal Bone Disease

Abnormalities in Bone Turnover, Mineralization, Volume, Linear Growth, or Strength

Evaluation of skeletal histology by bone histomorphometry provides both a method for understanding the pathophysiology of renal bone disease and a guide to its proper management. The routine assessment of bone histology is not performed in the clinical setting; however, current recommendations from the National Kidney Foundation (KDOQI Guidelines) suggest that a bone biopsy should be considered in all patients with CKD who have fractures with minimal trauma (pathological fractures), suspected aluminum bone disease, or persistent hypercalcemia despite serum PTH levels between 400–600 pg/ml (1, 73). After double tetracycline labeling, bone tissue is obtained from the iliac crest on an outpatient basis with minimal morbidity (74, 75). As recently recommended by the *Kidney Disease Improving Global Outcomes* (KDIGO) workgroup, three areas of bone histology are examined: bone turnover, mineralization and volume, all of which may be altered in patients with chronic kidney disease (1).

Bone Turnover

Traditionally, renal osteodystrophy has been classified primarily by alterations in bone turnover. The primary lesion of renal osteodystrophy in children is one of high bone turnover, also termed "secondary hyperparathyroidism". Since PTH activates the PTH/PTHrP receptor on osteocytes and osteoblasts, increasing cellular activity of both osteoblasts and osteoclasts (76, 77), excessive levels of circulating PTH result in increased bone turnover (78). Serum PTH levels are inversely correlated with GFR, and the majority of patients with GFR less than 50 ml/min have increased serum PTH levels and high turnover bone disease (79–81). These findings are nearly universal in untreated children at the initiation of dialysis (2). Secondary hyperparathyroid bone disease is marked by

an increased numbers of osteoblasts and osteoclasts. Excess osteoclastic activity leads to increased resorption of mineral and matrix along both the trabecular surface and within the haversian canals of cortical bone. Osteitis fibrosa cystica, the advanced lesion of secondary hyperparathyroidism, is also associated with peritrabecular fibrosis (*Figs. 71-2a, b*) (82).

A state of low-turnover bone disease (adynamic renal osteodystrophy) also occurs in children treated with maintenance dialysis, although it has not been demonstrated in children with earlier stages of CKD (80). Adynamic renal osteodystrophy is associated with disorders such as age-related or postmenopausal osteoporosis (in adults), steroid-induced osteoporosis, hypoparathyroidism (idiopathic or surgically induced), and diabetes mellitus. Reversible causes of adynamic renal osteodystrophy include aluminum toxicity, subtotal parathyroidectomy, prolonged treatment with calcium-containing phosphate-binding medications, use of high dialysate calcium concentration, and aggressive vitamin D therapy (83). The prevalence of adynamic lesions of bone is less than 20% in children and adolescents with end-stage renal disease who are treated with daily doses of calcitriol, although adynamic bone is present in as many as 33% of pediatric patients treated with high dose intermittent calcitriol therapy and calcium-based binders for the control of secondary hyperparathyroidism (84). Due to a direct suppressive effect of bone agents on bone turnover, adynamic bone often develops in these patients despite markedly elevated serum PTH levels (84).

On bone histomorphometric analysis, adynamic bone is characterized by normal osteoid volume, an absence of fibrosis, and a reduced bone formation rate, as indicated by a reduced or absent double tetracycline label (*Figs. 71-3a, b*) (84, 85). A paucity of osteoblasts and osteoclasts are present (78). Adynamic bone is associated with low PTH levels, low alkaline phosphatase levels, high serum calcium levels, and a propensity for increased vascular calcification (86, 87). In addition to the increased risk for fractures that is observed in adults with adyamic bone, dialyzed children with low bone turnover display an increased severity of growth retardation (88, 89).

The presence of CKD markedly attenuates the effect of PTH on bone (90, 91). Indeed, serum levels of PTH that are three–five times the normal range are associated with normal bone turnover in patients treated with maintenance dialysis, while similar PTH values in patients with mild to moderate kidney disease are associated with high turnover osteodystrophy (80, 92, 93). Although the precise mechanisms are poorly understood, uremia has been associated with this "skeletal resistance" to the actions of PTH. Uremic animals and humans display decreased PTH/PTH-related protein receptor mRNA expression in bone and growth plate (94, 95). Hyperphosphatemia and alterations in vitamin D metabolism, among other factors, have been implicated in these changes and calcitriol administration has been shown to partially restore the calcemic response to PTH in both experimental animals and in patients with moderate CKD (96).

Mineralization

Although renal osteodystrophy has traditionally been defined by lesions in bone turnover, alterations in skeletal mineralization are also prevalent in children with CKD (93). Increases in unmineralized bone (osteoid) in conjunction with delayed rates of mineral deposition are

Figure 71-2

Bone histology, Osteitis Fibrosa. (a) Under light microscopy, an increase in cellular activity, osteoid accumulation, erosion, and fibrosis are visible. (b) An increase in double tetracycline labeling signifies an increase in bone formation. (See color plate 47)

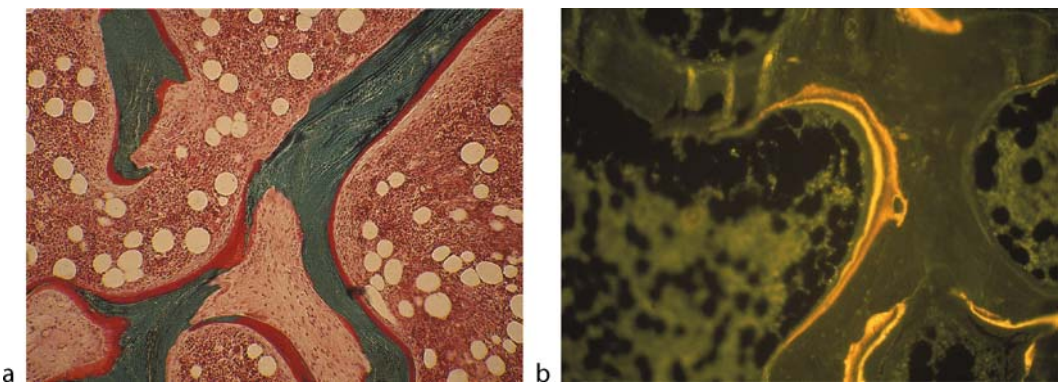


Figure 71-3

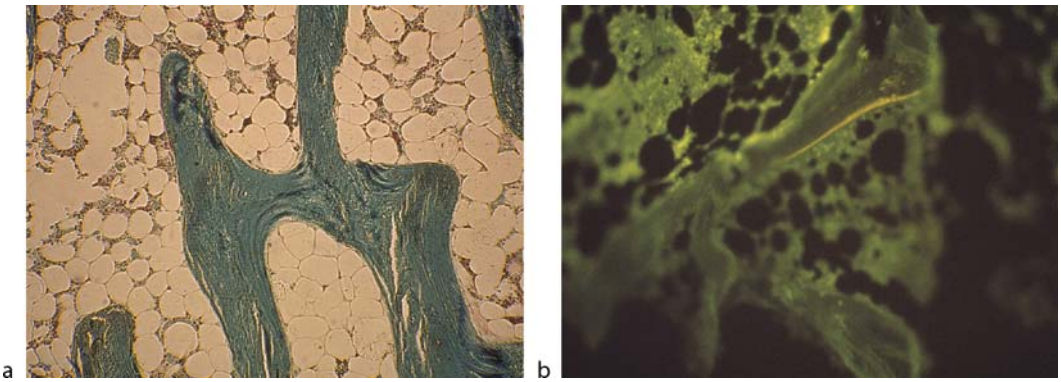
Bone histology, Adynamic Bone. (a) Under light microscopy, decreased cellular activity with minimal osteoid accumulation. (b) Very little double tetracycline labeling signifies a decrease in bone formation.



common (82, 93). Defective mineralization that is associated with high turnover bone disease is termed "mixed lesion"; when associated with low to normal bone turnover, it is referred to as "osteomalacia" (1). In children with CKD, osteomalacia may result from inadequate dietary intake of calcium, phosphorus, or vitamin D, particularly during periods of rapid growth, when the skeletal demand for these nutrients is high. During previous decades, aluminum toxicity from the use of aluminum based phosphate binders resulted in low bone turnover and poor skeletal mineralization in many patients.

The skeletal histology of the "mixed lesion of renal osteodystrophy" has features of both osteitis fibrosa and osteomalacia (97). Patients with this lesion often display high serum PTH and alkaline phosphatase levels. Mixed lesions are seen with high-turnover bone disease in patients who are developing aluminum toxicity or in patients with low-turnover aluminum-related bone disease during Desferoxamine (DFO) therapy (98). In these cases, mixed lesion represents a transitional stage between high-turnover and low-turnover bone disease.

Although the mechanisms of skeletal mineralization are incompletely understood, other factors, including 25(OH)D deficiency and altered FGF-23 metabolism, have been implicated in the pathogenesis of osteoid accumulation in the CKD population. In the general population, nutritional 25(OH)D deficiency results in osteomalacia and a similar phenotype may occur in children with CKD. FGF-23 may also play a role; both overexpression (99–101) and ablation of FGF-23 (102, 103) in mice result are associated with abnormal mineralization of osteoid, although by different mechanisms. The phosphaturic effect of increased FGF-23 may cause rickets and osteomalacia through an insufficiency of mineral substrate. The mechanisms leading to impaired mineralization in FGF-23-null animals, which have severe hyperphosphatemia and normal or elevated serum calcium levels, remain uncertain; however, osteomalacia in these animals suggests that FGF-23 may play a direct role in skeletal mineral deposition. While the ramifications of defective mineralization remain to be established, increased fracture rates, bone deformities, and growth retardation are prevalent in patients with CKD despite adequate control of bone turnover. These complications may be due, in part, to alterations in bone mineralization.

Bone Volume

Since PTH is an anabolic steroid at the level of trabecular bone, high levels of serum PTH are typically associated with increases in bone volume, trabecular volume, and trabecular width (75, 93, 104, 105). Thus, children with CKD typically have normal or high bone volume as assessed by bone histomorphometry. Those treated with corticosteroids, however, may display loss of bone volume, termed "osteoporosis". The impact of osteoporosis in childhood may not always be immediately apparent; however, sub-optimal peak bone mass accretion in adolescence is associated with an increased risk of osteoporosis, hip fractures, and mortality in adulthood (106).

Clinical Manifestations

Renal osteodystrophy in children presents with nonspecific signs and symptoms and often goes unnoticed.

Clinically, patients may refrain from physical activity, making early diagnosis difficult, and radiographic changes may not reflect the severity of bone disease. Careful and detailed physical examination must be performed in the evaluation of these patients, since renal osteodystrophy contributes to long-term morbidity (including short stature, deformities, and chronic disability) in the majority of adults who developed renal failure as children (2).

Growth

Growth retardation is the hallmark of CKD in children. Protein and calorie malnutrition, metabolic acidosis, end-organ growth hormone resistance, and renal bone disease are the factors most commonly implicated in growth failure (107). Despite correction of acidosis and anemia, normalization of serum calcium and phosphorus levels, and vitamin D sterol therapy replacement, the majority of children with CKD continue to grow poorly. Growth failure worsens as renal function declines; the average height of children with even mild CKD (GFR 50–70 ml/min/1.73 m^2) is 1 standard deviation (SDS) below the average for healthy children. Moderate CKD (GFR 25–49 ml/min/1.73 m^2) is associated with a height SDS of -1.5, and, at the time of initiation of dialysis, the mean height SDS is -1.8. Boys, younger patients, and those with prior renal transplants are at greatest risk for growth failure (108).

Acidosis has been linked to delayed linear growth in patients with renal tubular acidosis and normal renal function, and correction of metabolic acidosis often leads to acceleration in growth velocity (109). Acidotic rats have been found to have decreased growth hormone (GH) secretion, serum insulin-like growth factor 1 (IGF-1), and hepatic IGF-1 mRNA expression. Moreover, metabolic acidosis has been shown to inhibit the effects of GH in rats with normal and decreased renal function (110–112). Growth plate mRNA levels of GH receptor, IGF-1 receptor, and IGF-1 expression are downregulated, while IGF-binding proteins are upregulated in the face of acidosis (113). In adults treated with maintenance dialysis, correction of acidosis has been shown to decrease the progression of secondary hyperparathyroidism and improve skeletal mineralization (114).

Calcitriol deficiency has also been thought to contribute to growth retardation and bone disease in children with CKD. Secondary hyperparathyroidism remains prevalent in children with advanced renal disease, and osteitis fibrosa continues to be the most common skeletal lesion of renal osteodystrophy in those undergoing regular dialysis despite regular treatment with daily doses of oral calcitriol (75, 115). Secondary hyperparathyroidism contributes to growth retardation, although optimal target values for PTH in children in all stages of CKD remain controversial. In children with moderate CKD, some data indicate that normal growth velocity is achieved when PTH levels are maintained within the normal range (116) while others have demonstrated a linear correlation between growth and PTH levels in the same patient population – those with the highest PTH values maintaining the highest rates of growth (117). Treatment of secondary hyperparathyroidism with large, intermittent doses of calcitriol and calcium-based phosphate binders has been shown to significantly reduce bone formation and suppress osteoblastic activity in both adults and children (96, 118). During such therapy, adynamic bone may develop and linear bone growth decrease, despite serum PTH levels in the KDOQI recommended range (73, 89). By contrast, normal rates of bone formation are achieved and adynamic bone avoided when serum PTH levels are maintained between 300–500 pg/ml during intermittent vitamin D sterol therapy (105).

The mechanisms responsible by which calcitriol inhibits epiphyseal growth plate cartilage remain poorly understood; however, it is well-known that calcitriol exerts dose-dependent inhibitory effects on cell proliferation of chondrocytes and osteoblasts *in vitro*. In addition, vitamin D sterols increase expressions of a number of IGF binding proteins (IGFBPs), IGFBP-2, -3, -4, -5, which sequester IGF-1 and may exert IGF-1-independent antiproliferative effects through their own receptors (119–123).

GH resistance also contributes to impaired linear growth in renal failure. In CKD, poor growth develops despite normal or increased serum GH levels (124, 125). While the underlying molecular mechanisms for this GH resistance are incompletely understood, uremia has been associated with diminished hepatic GH receptor and IGF-1 mRNA expression, defects in post-receptor GH-mediated signal transduction (126, 127), reductions in serum GH-binding protein levels (128), along with increased synthesis and reduced clearance of IGF binding proteins (128–130). Improved growth velocity during recombinant human GH (rhGH) therapy has been ascribed to increased bioavailability of IGF-1 to target tissues. Children who are treated with maintenance dialysis respond less well to rhGH therapy than children with less severe CKD, but the mechanisms for the differences in response to GH therapy remain to be determined.

Bone Pain

In the early course of renal osteodystrophy, bone pain is nonspecific and difficult to distinguish from common

aches and pains, and a great variability in clinical presentation occurs among patients. Pain often localizes to the lower back and to weight-bearing joints, including hips, knees, and ankles. Symptoms worsen with pressure and changes in posture. Limping requires prompt and thorough evaluation in a previously ambulatory child with secondary hyperparathyroidism due to the increased prevalence of fracture and slipped epiphysis in this population (66).

Slipped Epiphyses

Slipped epiphyses are one of the most severe and physically incapacitating manifestations of bone disease in children with CKD. In preschool children, the upper and lower femoral epiphyses are often affected, while the upper femur and the radial/ulnar epiphyses are involved in older children. The distal radius and metacarpal and metatarsal heads may also be affected (66). In one report, slipped epiphyses were found in as many as 10 of 33 children with newly diagnosed CKD and in 1 of 82 of those who are undergoing dialysis therapy (66). The clinical presentation may include limping, waddling gait, limitation of the range of motion, and inability to ambulate. Severe osteitis fibrosa with marked endosteal fibrosis is present on bone biopsy. A dense fibrous tissue develops between the growth plate cartilage and the adjacent metaphysis, where the plane of slippage may occur (131). The diagnosis is usually established by roentgenograms. Total joint replacement is often required when the proximal femur is involved.

Skeletal Deformities

Bone deformities are also common in uremic children due to altered skeletal remodeling and, due to their increased growth velocity, are most evident in children younger than 10 years. The pattern of bone deformities varies with the child's age. Patients younger than 4 years have skeletal abnormalities similar to those due to vitamin D-deficient rickets, including rachitic rosary, metaphyseal widening (leading to wrist and ankle enlargement), craniotabes, and frontal bossing. Slipped epiphyses, genu valgum (*Fig. 71-4*), femoral and wrist deformities (*Fig. 71-5*) are most common in preadolescent children with long-standing CKD (2, 131). Avascular necrosis of the femoral head and pathologic fractures of the extremities and chest wall due to osteoporosis and bone deformities may occur with minimal trauma. In addition, vertebral crush fractures contribute to significant morbidity in this population. Patients may also present with ulnar deviation, pes varus, pseudo-clubbing, and dental abnormalities. The initial management of skeletal deformities requires the normalization of serum calcium, phosphorus, and PTH levels. Surgical correction is often also

Figure 71-4
X-rays of genu valgum.

Figure 71-5
X-rays of skeletal erosions in the hand.

necessary but should be performed only after correction of biochemical abnormalities (73).

Muscle Weakness

Myopathy in children with CKD may be progressive and the diagnosis is clinical; no specific tests are available. Electromyographic studies are non-specific and serum levels of creatine phosphokinase, aldolase, and transaminases are usually within normal limits. Initially, patients may complain of nonspecific aches and pains; subsequently they report limited ability to perform activities of daily living. These symptoms may go undiagnosed by the clinician, as patients may self-restrict physical activity, limiting their quality of life and social development. Similar to the proximal muscle weakness seen in patients with nutritional vitamin D deficiency, children with CKD may develop a characteristic waddling gait (132, 133). The mechanism behind this proximal myopathy is not well understood, although secondary hyperparathyroidism, phosphate depletion, aluminum bone disease, and disorders of vitamin D metabolism may contribute (134). Progressive and debilitating myopathy that develops in association with severe bone pain is a common manifestation of aluminum-related bone disease. No specific treatment is available, although an improvement in muscle strength in both proximal and distal muscles has been shown after treatment with vitamin D (135). Subtotal parathyroidectomy also results in clinical improvement.

Extraskeletal Calcification

Visceral, tumoral or periarticular, and vascular calcifications may develop in patient with CKD. Autopsy data from 120 children who had undergone dialysis or renal transplantation identified soft tissue calcifications in 60%, and the most commonly affected sites were blood vessels, lung, kidney, myocardium, coronary arteries, central nervous system, and gastric mucosa (136). Calcification was associated with multiple factors such as treatment with vitamin D, peak calcium-phosphorus product, age at onset of CKD, and male gender. Deposition of calcium and phosphorus in the conjunctiva leads to inflammation (termed the "red-eye syndrome") in 10% of dialyzed patients. Calcifications in the cornea are demonstrated by slit-lamp examination and may result in band keratopathy. Pulmonary calcifications may progress despite optimal dialysis therapy and may lead to restrictive lung disease. Parathyroidectomy and renal transplantation are often the best therapeutic options (137). Calcific periarthritis is characterized by episodes of acute inflammation in and around small joints, with periarticular warmth and erythema. Radiographic findings demonstrate small effusions within the joint and calcifications in adjacent periarticular tissues.

The mortality rate in adults and children with CKD is markedly higher than that of the general population, and cardiovascular disease is the leading cause of death in both children and adults treated with maintenance dialysis (138, 139). The etiology of cardiovascular disease in CKD is multifactorial and includes traditional risk factors, such as hyperlipidemia, hypertension, and inflammation, as well as alterations in mineral metabolism specific to CKD. Furthermore, a link exists between alterations in mineral metabolism, bone disease, and cardiovascular disease (1). Cardiovascular changes associated with increased mortality have their origins in CKD prior to dialysis and these alterations begin in childhood (*Figs. 71-6* and *71-7*) (136, 138, 140). In contrast to the calcifications of atherosclerotic plaques that develop with age in the vascular intima of individuals with normal kidney function, vascular calcification in the uremic milieu develops primarily in the tunica media. This form of calcification does not contribute to plaque instability or rupture, but is associated with decreased distensibility of blood vessels, causing a rigid "lead pipe" pathology which is associated with increased risk of congestive heart failure (1). Electron beam computed tomography (EBCT) is used in the assessment of vascular calcifications in the adult population, and measurements in young adults who were treated with maintenance dialysis as children demonstrated that a significant proportion of this population has evidence of vascular calcification (138, 139). Carotid ultrasound measurement of intimal-medial thickness (IMT) has been validated for the assessment of cardiovascular pathology in children – increased thickness being associated with worsening disease (140, 141). Recent concurrent EBCT and IMT evaluation of pediatric patients treated with maintenance dialysis demonstrated a positive correlation between serum PTH levels and calcification score by EBCT as well as between PTH levels, increased IMT and decreased vascular distensibility, suggesting that both EBCT and IMT are useful in the evaluation of cardiac disease in young patients with CKD (142).

The pathophysiology of cardiovascular changes remains to be fully elucidated but factors such as altered mineral metabolism, hypertension, hyperlipidemia, oxidative stress, and uremic toxins play a role. Hypercalcemia, hyperphosphatemia, elevated levels of the calcium x phosphorus product, and high doses of vitamin D sterols

(136, 138) have all been implicated. However, 40% of adult patients with stage 3 CKD, without these risk factors, show evidence of calcification (143), suggesting that factors in the uremic milieu itself, apart from high levels of calcium and phosphorus, contribute to cardiovascular disease. Indeed, vascular tissues in the uremic milieu express osteoblast differentiation factors (144). Osteoblasts and vascular smooth muscle cells have a common mesenchymal origin; Core binding factor-1 (Cbfa1) is thought to trigger mesenchymal cell to osteoblast transformation. Mice that are deficient in Cbfa1 fail to mineralize bone (145), and arteries obtained from patients undergoing renal transplantation show increased levels of this protein (144). Upregulation of the sodium-dependent phosphate transporter PIT-1 likely also contributes to increased calcification (146), and upregulation of

pro-mineralization factors such as osteopontin, bone sialoprotein, osteonectin, alkaline phosphatase, type I collagen, and bone morphogenic protein-2 (BMP-2) is potentiated by the uremic milieu (147–150). By contrast, expression of calcification inhibitors, such as fetuin A, matrix gla protein, and klotho is suppressed (151–154). Levels of circulating FGF-23 may also contribute, as values are inversely correlated with peripheral vascular calcification in adult dialysis patients (155). Klotho, the cofactor necessary for the actions of FGF-23, has also been implicated in vascular calcification. Animals lacking the Klotho gene display elevated levels of calcium, phosphorus, and vitamin D, along with vascular calcification and premature aging. CKD is associated with low circulating levels of Klotho (154), which has been implicated in regulating sodium/phosphate cotransport in the aorta (156).

As the pathophysiology of cardiovascular disease in CKD is multifactorial, treatment strategies are also multifaceted and vary according to stage of CKD. Therapies that are effective in early CKD may not be effective in later stages – lipid lower agents decrease mortality in adults with CKD (157) and in those with stable renal allografts (158) but have not been shown to benefit patients treated with dialysis(159). By contrast, normalization of mineral metabolism, by avoiding hypercalcemia and hyperphosphatemia, limiting calcium intake, and avoiding adynamic bone is effective at slowing the progression of cardiovascular calcification in patients treated with maintenance dialysis (73, 138, 160, 161). Thus, at different stages of CKD, the relative importance of individual risk factors and the value of different biomarkers may vary.

Diagnostic Evaluations

Biochemical Determinations

Calcium

Serum calcium levels are typically maintained within the normal range until late (stages 4 and 5) CKD, when serum calcium levels drop. Hypocalcemia often resolves during treatment with calcium-containing phosphate binders, vitamin D, and with initiation of dialysis. Typical dialysis solutions containing 2.5 mEq/L calcium concentrations are generally adequate to maintain serum calcium within acceptable limits.

Recurrent or persistent hypercalcemia in patients with CKD is uncommon yet may occur with severe secondary hyperparathyroidism, aluminum-related bone disease, adynamic bone, prolonged use of high dose vitamin D sterols, large amounts of calcium-containing phosphate-binding agents, and prolonged immobilization (85, 162, 163). Malignancy and extrarenal production of calcitriol in disorders such as sarcoidosis or tuberculosis result in hypercalcemia, but these conditions are uncommon in the pediatric age group. Patients with adynamic bone lesion without evidence of aluminum toxicity are prone to develop hypercalcemic episodes, which are related to the skeleton's inability to incorporate an acute calcium load (164).

Phosphorus

Serum phosphorus levels are often maintained within normal limits in early CKD. However, when the GFR falls below 30 ml/min/1.73 m^2 (stage 4 CKD), hyperphosphatemia ensues (4). In order to prevent the development and progression of secondary hyperparathyroidism and vascular calcification, measures should be initiated to maintain serum phosphorus levels within age-appropriate levels and calcium phosphorus product lower than 55 mg^2/dl. Normal values for phosphorus are higher in infants and decline to adult values by late adolescence. During the first 3 months of life, values range from 4.8 to 7.4 mg/dl (mean: 6.2 mg/dl), levels decrease to 4.5–5.8 mg/dl (mean: 5.0 mg/dl) at age 1–2 years, and 3.5–5.5 mg/dl (mean: 4.4 mg/dl) during childhood (*Fig. 71-8*) (138).

Alkaline Phosphatase

Serum total alkaline phosphatase is a biochemical marker of osteoblastic activity. Values generally correspond to the histologic severity of osteitis fibrosa, and serial measurements may be helpful in the follow-up of children with renal osteodystrophy. During intermittent calcitriol therapy, serum alkaline phosphatase levels have been found to be good predictors of adynamic renal osteodystrophy (89). Indeed, serum alkaline phosphatase levels often decrease below baseline in patients with bone biopsy-proven secondary hyperparathyroidism, and such changes correspond to marked reductions in bone formation documented by bone biopsy. In addition, changes in Z-scores for height during intermittent calcitriol therapy correlate with serum alkaline phosphatase levels, although a similar relationship is not observed during daily calcitriol therapy (89). Bone-specific alkaline phosphatase activity may be useful in predicting the histologic lesion of renal osteodystrophy, but whether these values are superior

13.20	2.3–4.5	8.8–10.2	1.12–1.30	40–180

to total alkaline phosphatase levels remains to be demonstrated.

Parathyroid Hormone

Accurate measurements of the concentration of PTH in serum or plasma are essential for the proper assessment of renal osteodystrophy (92, 93, 165–167). Indeed, determinations of PTH levels are used as surrogates for bone turnover, although bone histology, remains the most reliable method by which to establish the diagnosis of renal osteodystrophy (75, 97, 168). Serum PTH levels are usually normal in early CKD and rise in patients with moderate and severe CKD (9, 60). Increasing skeletal resistance to the actions of PTH necessitate that serum PTH levels be maintained at higher ranges in more severe renal failure (*Figs. 71-9* and *71-10*).

Because PTH and its fragments are cleared by the kidneys, active and inactive fragments of the molecule accumulate as renal failure progresses. In the 1980s, PTH assays were developed that detected PTH epitopes in the midregion and carboxy-terminal ends of the molecule. These assays therefore detected both full-length (active) PTH as well as many of the inactive fragments retained in renal failure (166), thus yielding spuriously high assessments of the amount of active PTH in circulation. Andress et al. later demonstrated that an assay detecting the amino terminal region of the molecule better avoided inactive fragments and was a better predictor osteitis fibrosa than the inactive carboxy terminal/midregion PTH fragments (169). Subsequently, the first clinically useful two-site immunometric PTH assay (PTH-IMA) was developed using antibodies direct both against amino- and carboxyl-terminal epitopes. These assays were predicted to measure full length PTH (also called "PTH(1–84)") exclusively (170).

During the past 25 years, this first-generation PTH-IMA (1st PTH-IMA) has proven to be a reasonable predictor of the different subtypes of renal osteodystrophy. It has also performed well in assessing the therapeutic response to active vitamin D sterols in patients with renal failure (92, 93, 165). Subsequent observations, however, have highlighted important shortcomings of this and other PTH-IMAs (171, 172). In particular, a series of studies by D'Amour and colleagues (171–173) demonstrated that 1st PTH-IMAs detect not only the intact hormone, but also additional PTH fragments truncated at the amino-terminus (173). 1st PTH-IMAs thus overestimate the true concentration of PTH(1–84) in serum or plasma both in patients with ESRD and in those with normal renal function. By contrast, more recently developed second-generation PTH-IMAs (2nd PTH-IMAs) using detection antibodies raised against the first four amino-terminal amino acids of human PTH recognizes only PTH(1–84) (and possibly PTH fragments that are truncated at the carboxyl-terminus) but not amino-terminally truncated fragments, such as PTH(7–84) (64, 174). Consistent with this assessment, human PTH(1–34) but not human PTH(2–34) or other amino-terminally truncated fragments of human PTH(1–34) cross-reacted with the detection antibody (64, 174).

In addition to interfering with current PTH assays, current *in vitro* and *in vivo* experimental data also indicate that one or more amino-terminally truncated PTH fragments (PTH(7–84) and other fragments) may antagonize the calcemic actions of PTH(1–84) and diminish bone cell activity. These actions may be mediated through a receptor distinct from the type I PTH/PTHrP receptor (174, 175). These fragments may modulate bone metabolism and may contribute to the skeletal PTH resistance that occurs in patients with renal failure (174, 175). It is therefore possible that an independent assessment of PTH (1–84) and amino-truncated PTH fragments may have better value for diagnosis of the different subtypes of renal osteodystrophy than each parameter alone. Indeed, it has been suggested that estimates of the ratio between PTH(1–84) and amino-truncated PTH(1–84) fragments

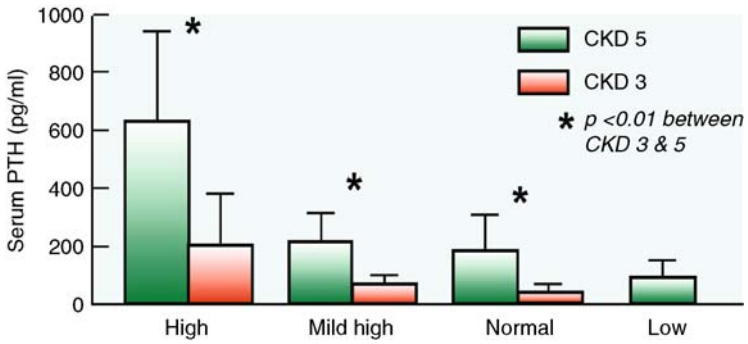
Figure 71-9

Target PTH levels according to stage of CKD (Reprinted with permission from the KDOQI guidelines).

Stage of CKD	GFR (ml/min/1.73m^2)	1st PTH-IMA Target Range (pg/ml)
3	30–59	35–70
4	15–29	70–110
5	Less than 15	200–300

Figure 71-10

PTH levels corresponding to high, normal and low turnover bone histology in two different stages of CKD.



more accurately predicts bone remodeling and turnover in patients with ESRD (176). However, others have failed to confirm such findings (104, 177).

Although 2nd PTH-IMAs are more specific for the concentrations of the full-length, active molecule, current data demonstrate that measurements of PTH using either 1st or 2nd PTH-IMAs are highly correlated and provide similar accuracy for predicting bone turnover in pediatric patients undergoing maintenance peritoneal dialysis (*Fig. 71-11*) (104, 177). Therefore, current recommendations for indications of therapy with active vitamin D sterols should be based on the relationship between indices of bone formation and PTH levels determined by 1st generation immunometric assays.

Aluminum

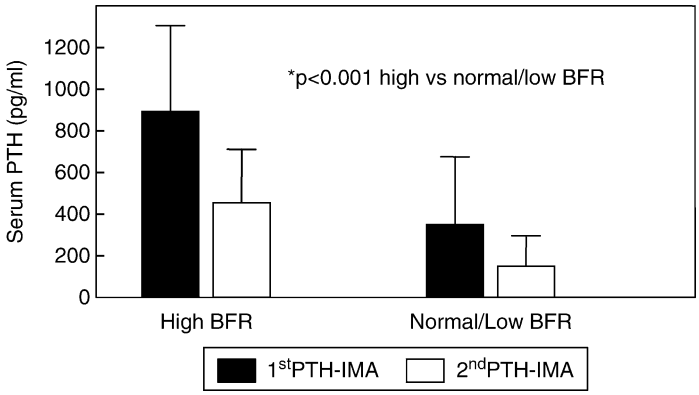
Aluminum toxicity occurs in dialysis patients or CKD patients with GFR less than 30 ml/min/1.73 m^2 because aluminum that is absorbed from the gut, from the dialysate, or from parenteral infusions is inadequately excreted by the diseased kidney. Accumulation occurs in various tissues, including bone, liver, brain, and parathyroid glands, and can produce toxicity such as dialysis encephalopathy, osteomalacia, and microcytic anemia. The gold standard for the diagnosis of aluminum bone disease is a bone biopsy demonstrating increased aluminum staining of the bone surface (greater than 15–25%) with histologic evidence of adynamic bone or osteomalacia. The presence of aluminum deposits in the bone and liver do not correlate with plasma levels (178); however, plasma aluminum levels are useful in monitoring patients who are undergoing chronic dialysis therapy and receiving aluminum-containing phosphate-binding agents for prolonged periods. DFO should be administered to symptomatic patients with aluminum levels between 60 and 200 μg/L or a positive DFO test. The DFO infusion test is performed by infusing 5 mg/kg of DFO during the last hour of the dialysis session. Serum aluminum is measured before DFO infusion and 2 days later, before the next dialysis session. In order to prevent DFO-induced neurotoxicity, DFO should not be administered if serum aluminum concentrations are greater than 200 μg/L (104, 169).

Radiography

Radiographic features of secondary hyperparathyroidism resemble those of nutritional rickets. Subperiosteal resorption may occur at the distal ends of the clavicles, ischial and pubic surfaces, sacroiliac joints, junction of

Figure 71-11

PTH levels by different assays according to bone histology (high vs normal/low bone formation rate-BFR) in patients treated with maintenance dialysis.



the metaphysis and diaphysis of long bone, and in the phalanges (179, 180). A diffuse ground-glass appearance, generalized mottling, focal radiolucencies, and sclerotic areas may be evident in the skull. Metaphyseal changes, called growth zone lesions or rickets-like lesions, are best demonstrated in hand radiographs. Although subperiosteal erosions are a hallmark of secondary hyperparathyroidism, these lesions can also be seen in patients with aluminum-related bone disease, which may represent unhealed lesions from a previous state of secondary hyperparathyroidism (181). To enhance the sensitivity of hand radiographs, the use of fine-grain films and magnification by hand lens has been recommended (180).

The radiographic features of osteomalacia are less evident, particularly in older children and adolescents. In young children, widening of the epiphyseal growth plate and other deformities of the growth plate cartilage are evident, whereas pseudofractures and looser zones, which appear as straight, wide radiolucent bands within the cortex, may be the only findings in older children and adults. The radiographic density of bone on conventional skeletal radiographs is reduced in many patients with renal osteodystrophy, but osteosclerotic changes or localized increases in bone density are a prominent finding in children with chronic renal failure.

Bone Scintigraphy

Bone scans using the technetium-99-labeled diphosphonate are helpful in estimating the severity of bone disease and differentiating between high-turnover lesions of osteitis fibrosa and low-turnover lesions of osteomalacia (182). Uptake is usually diffuse and symmetric in patients with severe secondary hyperparathyroidism, whereas patients with osteomalacia exhibit a less intense uptake (182). Calcifications may also be demonstrated in various organs, including the lungs and heart, using the bone scan.

Bone Biopsy

Iliac crest bone biopsy provides the most valuable diagnostic information of the skeletal lesions of renal osteodystrophy. The procedure is safe and well tolerated in children and is done in an outpatient setting (75). Bone biopsy provides information about the histologic appearance and dynamics of bone formation and mineralization. Although not routinely performed in the clinical setting, a bone biopsy should be considered in all patients with CKD who have fractures with minimal trauma (pathological fractures), suspected aluminum bone disease, or persistent hypercalcemia despite serum PTH levels between 400–600 pg/ml (73).

For bone labeling, a 2 day course of tetracycline is administered at 15 mg/kg/day (divided in twice or thrice daily doses). Fourteen days later, the 2 day course is repeated. For children younger than 8 years, tetracycline dosage is usually kept below 10 mg/kg/day to avoid toxicity. Histochemical staining procedures demonstrate the deposition of abnormal components within bone such as iron, aluminum, and oxalate (75, 134).

Treatment of CKD-MBD

In order to minimize complications on the growing skeleton and to prevent extraskeletal calcifications, particular

attention must be made to the alterations of bone and mineral metabolism in children with CKD.

Dietary Manipulation

Evaluation of dietary intake and growth must be performed at regular intervals to maximize the growth potential of children with CKD. Nutritional requirements are based on the recommended dietary allowances for energy and protein. Nutritional supplements, which may be given orally or through a nasogastric or gastrostomy tube, are necessary when recommended dietary allowances for energy and protein are not achieved by food intake alone or when there is impaired linear growth and/or weight gain, particularly during the first few years of life. The dietary reference intake (DRI) for phosphorus for the different age groups is based on the report from the Food and Nutrition Board (183). The average phosphorus intake of children in the United States is higher than the DRI and is approximately 1,500–2,000 mg/day, of which 60–70% is absorbed. Phosphorus is present in nearly all foods and with highest concentration in meat and dairy products. Dietary phosphorus intake is frequently restricted to 600–1,200 mg/day when serum phosphorus levels exceed age appropriate levels (73). Similar restrictions are recommended for patients with serum PTH levels that are higher than the target range according to the stage of CKD. In dialysis patients, phosphorus removal by peritoneal dialysis (240–440 mg/day) or hemodialysis (600 mg during a 4 h session) is inadequate to maintain target phosphorus levels (184); therefore, dietary phosphorus restriction is usually required. More frequent hemodialysis, however, such as nocturnal hemodialysis, which is performed 6–7 nights per week for 8–10 h during sleep at home, has been shown to remove twice as much phosphate per week than conventional hemodialysis (185). As a result, patients undergoing nocturnal hemodialysis do not require phosphate binders, are able to ingest higher dietary phosphate and protein intake, and may even require the addition of phosphorus to the dialysate (185–187).

Dietary phosphorus restriction is recommended in the majority of patients with more advanced CKD; however, protein requirements for growth and the unpalatable taste of low phosphorous diets make long-term compliance with such restrictions difficult. Accordingly, the use of phosphate-binding agents is integral to the treatment of these children. Since calcitriol enhances intestinal phosphorus absorption, vitamin D sterol therapy may complicate the management of hyperphosphatemia and higher dosages of phosphate binding agents are often required (188).

Serum phosphorus levels should be measured at least every 3 months after starting the phosphorus-restricted diet to prevent hypophosphatemia, particularly in those who are also given large doses of phosphate-binding agents. Infants are particularly at risk for hypophosphatemia due to the use of low phosphorus-containing formulas, aggressive use of phosphate binders, increased peritoneal dialysis phosphate removal (due to a higher peritoneal surface area to body area ratio than in older children) (189). Patients with severe and persistent hypophosphatemia have been reported to develop bone disease such as osteomalacia and rickets, proximal myopathy, rhabdomyolysis, and congestive heart failure (189, 190).

In order to attain peak bone mass and reduce risks of osteoporosis and fractures later in life, the DRI of calcium intake and regular exercise are strongly recommended throughout childhood and adolescence, even in patients with CKD. The main source of calcium is milk and dairy products, although various foods such orange juice and cereals are fortified with calcium. Calcium supplementation is recommended when the DRI is not met by dietary intake. To limit the development of cardiovascular calcifications, however, calcium intake from both diet and calcium containing phosphate binders should be limited to no more 2,500 mg/day in children with CKD stages 3 through 5 (73).

Phosphate-Binding Agents

Phosphate-binding agents are recommended in patients with persistent hyperphosphatemia despite dietary phosphorus restriction. These agents form poorly soluble complexes with phosphorus in the intestinal tract, thereby decreasing phosphorus absorption. Calcium-containing phosphate binders are widely used as the initial agent for the management of hyperphosphatemia. They also provide an additional source of calcium. Several calcium-containing salts, including calcium carbonate, calcium acetate, and calcium citrate, are commercially available. Since citrate increases intestinal absorption of aluminum, calcium citrate should not be administered to patients with CKD who are also receiving aluminum-containing phosphate binders (191).

Calcium carbonate is the most widely prescribed calcium salt, and its effectiveness in reducing serum phosphorus levels has been reported in adult and pediatric patients (85, 192). Calcium carbonate therapy has also been shown to decrease serum intact PTH levels in adult

patients with secondary hyperparathyroidism (193–195). The dose of calcium-based phosphate binders varies widely among children and should be adjusted to maintain normal calcium levels and age-appropriate serum phosphorus levels. Hypercalcemia is a major complication associated with the long-term use of high doses of calcium-based phosphate-binding agents, particularly in patients treated with vitamin D or those with adynamic bone lesions (196, 197). Hypercalcemia usually resolves with lowering doses of vitamin D and calcium-based binders. Furthermore, bedtime administration of vitamin D may decrease intestinal calcium absorption and limit hypercalcemia.

The use of calcium-containing binders has been linked to the development of vascular calcifications in adult and pediatric patients treated with maintenance dialysis (138) as well as in adults with stage 4 CKD (198). Furthermore, there is substantial evidence that abnormalities in mineral metabolism, hypercalcemia, hyperphosphatemia, and elevated calcium-phosphorus ion product are associated with the development of soft tissue and vascular calcifications (136, 138, 140). Although it is difficult to differentiate between the effects of calcium intake and vitamin D sterols on the development of hypercalcemia, intake of calcium-containing phosphate binders may play a role in the development of accelerated cardiovascular disease that occurs in patients treated with dialysis (136, 138).

Alternative phosphate binders have therefore been developed to limit the risks of hypercalcemia and vascular calcification associated with the use of calcium salts. When used with active vitamin D sterols, sevelamer hydrochloride (Renagel^{R}), a calcium- and aluminum-free hydrogel of cross-linked poly(allylamine-hydrochloride), effectively lowers serum phosphorus, PTH, and bone formation rate without inducing hypercalcemia in pediatric patients with ESRD (105, 199–203). Furthermore, treatment with sevelamer hydrochloride, when compared to calcium-containing binders, halts the progression of vascular calcification and reduces mortality in adult patients with CKD stages 4 and 5 (160, 161). Serum total cholesterol and low-density lipoprotein cholesterol levels also decrease, whereas high-density lipoprotein increase, during sevelamer treatment (202). These effects may offer additional benefits in reducing cardiovascular complications in patients with ESRD. Sevelamer carbonate (Renvela^{R}) has recently been introduced and is also an effective phosphate-binder. The carbonate in its composition may decrease the incidence of mild acidosis that sometimes accompanies the use of sevelamer hydrochloride (204).

Additional phosphate binders include magnesium, iron, and lanthanum compounds. Magnesium carbonate reduces serum phosphorus levels, but predisposes dialysis patients to developing hypermagnesemia and diarrhea. Iron compounds, such as stabilized polynuclear iron hydroxide and ferric polymaltose complex, are also effective in short-term studies in adults with CKD (205). Lanthanum carbonate, another new agent, also is an effective phosphate binder that does not induce changes in serum calcium levels (206); its role on the process of vascular calcification has not been defined. Lanthanum is a heavy metal that accumulates in liver and bone in rats with renal failure (207). In dialysis patients, lanthanum has been shown to persist in bone as long as 2 years after discontinuation of the drug (208). Due to the accumulation of lanthanum in tissues, this medication is not recommended for routine use in children.

Aluminum-containing gels are also effective phosphate binding agents. Due to their toxicities (encephalopathy and bone disease), the lowest possible dose should be used for a limited period (4–6 weeks), and plasma aluminum levels should be followed closely. Since citrate enhances aluminum absorption by altering tight junctions in the intestinal epithelium, simultaneous use of citrate (found in such medications as calcium citrate, Alka-Seltzer, Shohl's solution, and sodium citrate (Bicitra/Polycitra), as well as in citrus fruits) with aluminum should be avoided (191). Current guidelines for maximum safe dosages of aluminum hydroxide are: 30 mg/kg/day for children and 2,000–3,000 mg/day for adults (209, 210). Despite the recommended dosages, aluminum accumulation still occurs, as seen by a rise in plasma aluminum level after deforoxamine (DFO) infusion and by histologic evidence of aluminum deposits in the bone (211).

Vitamin D Therapy

Despite control of serum phosphorus levels, secondary hyperparathyroidism is present in the majority of pediatric patients treated with maintenance dialysis; vitamin D sterols are therefore used to control serum PTH levels. Vitamin D therapy inhibits PTH release by two mechanisms: directly, by inhibiting pre-pro-PTH gene transcription, and indirectly, by increasing intestinal calcium absorption and increasing serum calcium levels. In patients with CKD stages 2–4 whose PTH levels are greater than the recommended target range, 25(OH) vitamin D levels should be measured and, if less than 30 ng/ml, should repleted with cholecalciferol or ergocalciferol (73).

Active vitamin D sterol therapy is indicated when PTH levels are above the target range despite repletion of 25 (OH)vitamin D stores (73). It is important to ensure that serum phosphorus levels are within the normal range for age before starting vitamin D sterol therapy. Calcitriol or alfacalcidol are started at a daily dose of 0.25–0.5 μg, and the dose is gradually titrated in 0.25–0.5 μg increments to achieve 1st PTH-IMA levels within the normal range for stage of CKD. In patients with CKD stage 5 or those requiring regular dialysis, vitamin D therapy is recommended when 1st PTH-IMA levels exceed 300 pg/ml and serum phosphorus concentrations are at age-appropriate levels (73). Similar to patients with moderate CKD, daily calcitriol or alfacalcidol therapy may be initiated at a dose of 0.25–0.5 μg, with gradual dosage increases of 0.25–0.5 μg in order to achieve 1st PTH-IMA levels between 200 and 300 pg/ml. Paricalcitol and doxercalciferol therapy is typically initiated at 2.5–5 μg and titrated upwards in 2.5 μg increments. Serum levels of calcium, phosphorus, and 1st PTH-IMA should be monitored at regular intervals after start of therapy (73). In all dialyzed children, PTH levels below 200 pg/ml, have been associated with an increased risk for adynamic bone and subsequent growth retardation (88).

Intermittent (thrice weekly) doses of vitamin D sterols may be considered when serum PTH levels are greater than 500 or 600 pg/ml. Intravenous vitamin D sterols given in a thrice weekly dosing regimen are also effective at reducing serum PTH levels in children treated with maintenance dialysis; starting doses depend on serum PTH levels and, for calcitriol, are typically between 0.5 and 1.5 mcg/kg. Paricalcitol is also effective at starting doses of 0.04–0.08 μg/kg (212, 213). Vitamin D should be titrated to maintain serum calcium levels less than 10.2 mg/dl, serum phosphorus levels within the age-appropriate range, and PTH levels between 300–400 pg/ml, since PTH levels in this range have been associated with normal rates of bone formation during intermittent vitamin D sterol therapy (105).

Hypercalcemia and hyperphosphatemia are undesired consequences of active vitamin D therapy. Hypercalcemia is a particular problem when active D sterols are administered in conjunction with calcium-based phosphate binders and have been associated with the progression of vascular calcification in the CKD population (160, 161), calling into question the safety of this form of therapy. Thus, newer active vitamin D sterols, with lower calcemic activity, have been developed. In the United States, 19-nor-1,25-$(OH)_2D_2$ (paricalcitol) and $1\alpha(OH)D_2$ (doxercalciferol) have been introduced, while 22-oxa-1,25 $(OH)_2D_3$ (maxacalcitol) is used in Japan. These newer sterols offer the potential for reduced episodes of hypercalcemia (214, 215), though their superiority over calcitriol has not been consistently demonstrated in controlled trials in humans (105). When active vitamin D sterols are used with sevelamer, the skeletal and biochemical features of secondary hyperparathyroidism are markedly improved without inducing changes in serum calcium levels. Thus, the use of calcium-free phosphate binders may enhance the margin of safety during therapy with active vitamin D sterols.

Despite its calcemic properties, current evidence suggests that active vitamin D sterol therapy may in fact confer a survival benefit to patients treated with maintenance dialysis. Cross sectional data from several large dialysis databases suggest that the administration of active vitamin D sterols confers a survival benefit over no therapy with active vitamin D regardless of serum calcium, phosphorus and PTH levels (22, 216, 217). Furthermore, it appears that there may be differences in survival benefits of some newer active vitamin D sterols (paricalcitol and doxercalciferol) over calcitriol in patients treated with maintenance dialysis (23, 217). Although prospective trials remain to be performed and the mechanism involved remain to be elucidated, these results are intriguing. The systemic effects of vitamin D on the immune and cardiovascular systems may contribute to these survival benefits.

A role for vitamin D has long been implicated in organ systems other than the bone/mineral axis; indeed, a growing body of evidence suggests health benefits for both active vitamin D sterols and native vitamin D in the general population. In addition to the parathyroid gland and bone, arterial smooth muscle cells, pancreatic islet cells, macrophages, T and B cells, hepatocytes, lung alveolar cells, dermal keratinocytes, and renal parenchymal cells have been shown to respond to vitamin D (218). Many of the effects on these organ systems appear to be due to the immune-regulatory role of vitamin D. Evidence from as far back as the nineteenth Century has implicated 25(OH)D in immune regulation. Sanitoriums located at high elevations, and thus with increased UV light to facilitate dermal vitamin D production, were central to the treatment of infectious diseases, including tuberculosis (26). Recent investigations suggest that 25(OH)D has a direct effect on macrophage function that cannot be reproduced by active $1,25(OH)_2D$ administration. Indeed, macrophages have their own 1α hydroxylase and require sufficient ambient levels of 25 (OH)D substrate in order to internal $1,25(OH)_2D$ (219). Striking evidence of macrophage 1α hydroxylase activity is found in granulomatous conditions such as tuberculosis,

sarcoidosis, and inflammatory bowel disease, in which $1,25(OH)_2D$ levels may be markedly elevated (220). Serum from patients who are vitamin D deficient induce a lower bactericidal response than serum from vitamin D replete individuals, suggesting decreased macrophage function under conditions of vitamin D deficiency (219).

Not only may the immune system require sufficient vitamin D in order to fight foreign antigens but suboptimal vitamin D levels may lead to dysregulation of the immune system and autoimmunity. Indeed, type I diabetes, an autoimmune disorder, has been associated with vitamin D deficiency (221) and a reduced incidence in type I diabetes associated with vitamin D repletion in pregnant women (222). Moreover, immune-surveillance of tumor activity may be a vitamin D dependent process. Calcitriol has demonstrated regulatory active of over 200 genes and is thus thought to be responsible for maintaining cellular health and providing antitumor activity (26, 223) in many cell types, including skin, prostate, breast, colon, lung, brain, and placenta that express 1α hydroxylase suggesting that therapy with 25(OH)D itself may be required to generate sufficient internal calcitriol levels for proper immune surveillance and control of cell proliferation.

Aside from immune regulation, active vitamin D therapy has been associated with protective effects on both the kidney and the heart. Administration of active vitamin D sterols results in less proteinuria, decreased fibrosis, and a decrease in podocyte hypertrophy in sub-totally nephrectomized rats (224). Moreover, paricalcitol treatment of CKD patients decreases proteinuria (225). Studies in rats have also demonstrated a beneficial effect of active vitamin D sterols on cardiac hypertrophy (20). Furthermore, the constituative left ventricular hypertrophy found in VDR knockout animals are successfully treated with captopril (226). These effects may be mediated by suppression of the renin-angiotensin system (RAS); indeed *in vitro* studies have demonstrated that calcitriol, paricalcitol, and doxercalciferol all suppress the RAS to a similar degree (227).

The systemic benefits of 25(OH)D in patients with CKD are less well established, but current intriguing observations suggest a role for the native vitamin in improving survival in patients treated with maintenance dialysis (216). Recent studies have demonstrated that supplementation with ergocalciferol in patients with all stages of CKD increased both 25(OH)D levels and $1,25(OH)_2D$ levels and suppress PTH levels (41, 49, 228). Furthermore, dialysis patients require lower doses of epogen and active vitamin D sterols during ergocalciferol supplementation (41). However, the long term effect of this form of therapy in patients with CKD remains to be carefully evaluated as well as the effects of combined therapy with active vitamin D sterol administration, on target organs remain to be more completely defined.

Calcimimetic Agents

Cinacalcet, an allosteric activator of the calcium sensing receptor, is now available for the treatment of hyperparathyroidism. This small organic molecule reduces serum PTH levels and has also been shown to decrease the calcium-phosphorous ion product in adult patients treated with maintenance dialysis (69, 229). Experiments in uremic rats have demonstrated that calcimimetics are able to halt the progression of parathyroid cell hyperplasia (69); the antiproliferative effect of this agent shows promise for use of the molecule as a "medical parathyroidectomy". Studies in animals also suggest that the use of calcimimetic agents may play a role in reversing the process of vascular calcification (230); however such effects need to be further evaluated in humans. Due to the presence of the calcium sensing receptor on the growth plate, these agents are not approved and should be used with caution in growing children.

Growth Hormone Therapy

Recombinant growth hormone (rhGH) should be considered in children with growth failure that does not respond to optimization of nutrition, correction of acidosis, and control of renal osteodystrophy. Serum phosphorus and PTH levels should be well controlled prior to the initiation of rhGH in children with CKD. Serum phosphorus levels should be less than 1.5 times the upper limit for age and 1st PTH-IMA levels less than 1.5 times the upper target values for the CKD stage prior to rhGH therapy (73). Growth hormone therapy will increase serum PTH levels during the initial months of therapy; therefore, serum PTH levels should be monitored monthly. GH therapy should be temporarily discontinued if PTH levels exceed three times the upper target value for the CKD stage (73).

Parathyroidectomy

Parathyroid gland hyperplasia, which is characterized by serum PTH elevations and osteitis fibrosa on

bone biopsy, is a result of poorly controlled secondary hyperparathyroidism. Calcitriol resistance may develop in the presence of an enlarged nodular hyperplastic parathyroid gland because of the decrease in the number of VDRs and the presence of monoclonal proliferation in nodular areas (231, 232). When vitamin D therapy fails to correct the signs of secondary hyperparathyroidism, parathyroidectomy must be considered. Urgent indications for parathyroidectomy include persistent or recurrent hypercalcemia (particularly when associated with intractable pruritus not responding to intensive dialysis), progressive extraskeletal calcifications, bone pain, multiple and recurrent fractures, and the appearance of calciphylaxis (136). However, prior to parathyroidectomy, care must be taken to ensure that these symptoms are attributable to secondary hyperparathyroidism and high turnover renal osteodystrophy, since all may also be associated with adynamic bone disease (233). Before the 1980s, the development of hypercalcemia in patients receiving little or no vitamin D suggested the presence of aluminum-related bone disease. Currently, hypercalcemia is more commonly due to the development of adynamic bone disease from the administration of high doses of vitamin D and calcium containing compounds (75, 88, 89).

Hypocalcemia may develop after parathyroidectomy in patients with severe secondary hyperparathyroidism. This condition, called "hungry bone syndrome", is caused by a high rate of skeletal calcium uptake, which may continue for some time after serum PTH levels are lowered by parathyroidectomy. Serum calcium decreases 24–36 h after surgery; daily doses of calcitriol at 0.5–1.0 g/day for 2–6 days before surgery can be administered to prevent hypocalcemic episodes. Other forms of active vitamin D sterols are also effective and may be used. Calcium gluconate infusion should be started immediately after parathyroidectomy to provide 100–150 mg of elemental calcium per hour during the 1st 4–6 h. The infusion rate should be adjusted thereafter according to serum calcium measurements. Daily doses of calcitriol or other active vitamin D sterols should be continued in the post-operative period and may be increased to several micrograms per day in order to maintain serum calcium levels. Intravenous administration of these compounds is generally preferred in the immediate post-operative period due to its higher bioavailability better tolerability. Hypophosphatemia may also develop post-operatively, but supplemental phosphorus may aggravate hypocalcemia and should be avoided unless serum levels of phosphorus are below 2.0 mg/dl.

Bone Disease After Successful Kidney Transplantation

Successful kidney transplantation corrects many of the metabolic abnormalities associated with the development of renal osteodystrophy. Despite a well-functioning graft, however, osteopenia, growth failure, spontaneous fractures, and avascular necrosis remain prevalent in adult and pediatric kidney recipients (234–239). Significant bone loss has been shown to occur as early as 3–6 months after kidney transplantation (238, 239). Several factors are implicated in the development of bone disease after transplantation, including persistent alterations in mineral metabolism, prolonged immobilization, and the use of immunosuppressive agents required to maintain graft function.

In both adult and pediatric kidney recipients, bone histologic changes associated with secondary hyperparathyroidism have been shown to resolve within 6 months after kidney transplantation (239). However, some patients have persistently elevated rates of bone turnover, while others develop adynamic lesions, despite moderately elevated serum PTH levels (240). Bone biopsy data from pediatric kidney recipients indicate that 67% of patients with stable graft function have features of normal bone formation, while 10% have adynamic bone lesion, and 23% have bone lesions characteristic of secondary hyperparathyroidism (241). Bone resorption is typically increased (242), leading to a net loss of bone mass over time. Serum PTH levels are unable to discriminate between adynamic, normal, and increased bone turnover in the pediatric transplant population (241). The use of maintenance corticosteroids have been implicated in these alterations; steroids decrease intestinal calcium absorption, enhance urinary calcium excretion, inhibit osteoblastic activity, decrease bone formation, and increase osteoclastic activity and bone resorption (243–246). Likewise, cyclosporine has been reported to increase both bone formation and bone resorption and reduce cancellous bone volume in the rat (247, 248). By contrast, azathioprine has been shown to have minimal impact on skeletal remodeling (249). The role of other immunosuppressive agents, such as mycophenolate mofetil, as potential modifiers of bone formation and bone resorption has not been evaluated.

While bone turnover may return to normal, defective skeletal mineralization is present in the majority of pediatric transplant recipients (241). Osteoid volume is increased while mineral apposition rate is markedly

reduced (241). Although the factors responsible for the persistent increase in osteoid formation remain to be fully explained, corticosteroid use may contribute, as may persistent imbalances in PTH, vitamin D, and FGF-23 metabolism (250).

After successful kidney transplantation with standard immunosuppressive regimens (daily corticosteroids, calcineurin inhibitor, and anti-metabolite), growth may be accelerated by an improvement in kidney function, but catch-up growth may not be observed even in children who undergo transplantation very early in life (108). Moreover, height deceleration occurs in approximately 75% of patients who undergo transplantation before the age of 15 years (251). The etiology of persistent growth retardation is not completely understood, but immunosuppressive agents, persistent secondary hyperparathyroidism, altered vitamin D and FGF-23 metabolism, and the persistence of defective skeletal mineralization may all contribute. Children receiving steroid-free immunosuppressive regimens, those treated with alternate day steroids and those with better height SDS at the time of transplant attain the greatest final adult height (108, 251–253). Recombinant human growth hormone has been used in children with significant height deficit after kidney transplantation. A substantial increase in linear growth occurs within the 1st year of rhGH therapy, but the magnitude of growth response may decline thereafter (254).

Cardiovascular disease continues to be prevalent after renal transplantation. In the post-transplant period, the presence of hypertension is strongly linked to increased IMT and poor vessel distensibility in children (255). EBCT data also indicate that vascular calcifications, present in young adults on dialysis, do not regress post-transplantation and may contribute to the burden of cardiovascular disease in this population (256).

72 Peritoneal Dialysis

Enrico Verrina

Introduction

Peritoneal dialysis (PD) represents a well-established dialysis modality for pediatric patients with end-stage renal disease (ESRD). Chronic peritoneal dialysis (CPD) currently is the dialysis treatment modality most commonly prescribed for children and adolescents throughout much of the world, and the preference for CPD over hemodialysis is most pronounced among infants and young children 0–5 years of age (1–3). PD has evolved substantially during the past three decades (4).

Since the subject of PD is extremely wide, and textbooks have been published on its use in adult (5) as well as in pediatric patients (6, 7), an effort has been made in this chapter to summarize accurately current knowledge specific to this field. However, readers are encouraged to consult references cited throughout the chapter for more details on specific topics. In addition, issues such as anemia, growth, and osteodystrophy, which are pertinent to all pediatric patients, are addressed by other chapters of this book.

Brief History of the Development of Pediatric Peritoneal Dialysis

Experience with PD in children has been reported for the first time in 1948 (8), when the worldwide reported clinical experience with PD was less than 100 patients; the technique consisted of a *continuous peritoneal lavage* with large volumes of warmed dialysate. At that time, widespread use of PD was still hindered by its practical requirements: keeping sterile water in 40-L drums and preparing and sterilizing dialysate. During the 1950s, the development of disposable nylon catheters and commercially prepared dialysis solutions made PD a practical short-term treatment for ARF, known as *acute intermittent PD (IPD)*. Successful adaptation of the technique for use in infants and children with ARF was first reported in 1961 (9). However, early acute IPD techniques required reinsertion of the catheter for each treatment, making prolonged use in small patients impractical and hazardous because of frequent infections. This all changed in the 1960s, when Henry Tenckhoff developed a "permanent," indwelling peritoneal catheter (10). The "Tenckhoff catheter," combined with a close loop reverse osmosis automated delivery system ("cycler") for purifying dialysate, that freed patients from their dependence on the huge drums of water and could be used at home (11), made *chronic IPD* an accessible form of renal replacement therapy (RRT) for pediatric ESRD patients. A new era in the history of PD started with the introduction of a "novel portable/wearable equilibrium dialysis technique," called *continuous ambulatory PD* (CAPD) (12). The glass bottle were replaced by plastic bags containing 2 L of dialysate which were folded and fixed on the abdomen until the next exchange; the dwell time was extended to 4–8 h and four exchanges of the dialysate volume per day usually proved to be adequate (13). In children CAPD was first applied in Toronto, Canada in 1978 (14), and pediatric nephrologists were quick to recognize the potential advantages that CAPD offered to their young patients. Importantly, CAPD made possible the routine treatment of very young infants with ESRD, thereby extending the option of RRT to an entire patient population previously considered too young to be suitable for chronic treatment.

At the beginning of the 1980s, there was a rediscovery of IPD techniques, which were now performed with the help of new automatic machines to assist the delivery and drainage of dialysate. *Automated PD* (APD) is a broad term that is used to refer to all forms of PD employing a cycler. The various forms of APD include *intermittent PD* (IPD), *continuous cycling PD* (CCPD), *nightly intermittent PD* (NIPD) and *tidal PD* (TPD). The evolution of these modalities has been closely linked with the development of new ad hoc cyclers, incorporating microchips and computer technology, and with recent advances in prescription and monitoring of PD treatment. The benefits of the APD technique results from the fact that it can deliver different dialysis regimens, thus meeting various dialysis needs and increasing treatment efficacy; moreover, it provides children and parents with more daytime freedom (15, 16).

CAPD has the undoubted advantage of ease of use and limited cost of equipment, while there can be limitations to the use of APD in many developing countries owing

© Springer-Verlag Berlin Heidelberg 2009

to cost constraints and technical problems (reliability of electricity supply, for instance). However, a recent report from Mexico showed how the organizational effort to provide the desired PD treatment to a large pediatric patient population can be successfully performed (17).

The Peritoneal Dialysis System

PD System Components

The PD system has three major components: peritoneal microcirculation, peritoneal membrane (PM), and dialysis fluid (18).

Peritoneal microcirculation: Peritoneal capillary blood flow has been reported to vary between 50 and 100 ml/min; however, the effective amount of this flow that is involved in peritoneal exchanges is unknown, and is subject of controversy. The peritoneum has an active lymphatic system, which is comprised of specialized structures located on the undersurface of the diaphragm (the lacunae).

Peritoneal membrane: PM lines the inner surface of the abdominal and pelvic walls (parietal peritoneum), covers the intraperitoneal organs, forms the visceral mesentery and omentum, and connects loops of bowel (visceral peritoneum) (19). PM represents the barrier that solutes and water have to cross, and is composed of:

1. Capillary wall; peritoneal capillaries are mainly of the continuous type, with less than 2% of fenestrated capillaries (20); endothelial cells are linked to each other by tight junctions and surrounded by a basement membrane; healthy endothelium plays a central role in the control of vascular permeability (21).
2. Interstitium, which is made of extracellular matrix, containing a limited number of cells (fibroblasts, mononuclear cells) and some lymphatic vessels; hyaluronan, a major component of the extracellular matrix, was reported to be an important determinant of the resistance to fluid and solute transport (22).
3. A layer of mesothelial cells, which have a system of tight and gap junctions, microvillous projections at the free surface and several organelles in their cytoplasm; mesothelial cells were reported to participate in glucose transport and regulation of water and solute fluxes through tight junction modulation, but their actual role as rate-limiting barrier is still debated (23, 24).

Dialysis fluid compartment: This compartment includes the composition of the solution and the modalities of delivery. Dialysis fluid is infused in the peritoneal cavity in an amount that is scaled on patient's body size and clinical conditions; standard dialysis solutions contain an osmotic agent to produce the osmotic gradient required to obtain ultrafiltration (UF), a buffer to correct patient's metabolic acidosis, calcium, magnesium and electrolytes.

Driving Forces of Solute and Water Exchange

The driving forces of solute and water exchange across the peritoneal membrane, between the dialysis solution and the capillary blood and surrounding tissues (24) are represented by diffusive transport, ultrafiltration and convective mass transfer.

Diffusive transport: Diffusion consists in a solute exchange between two solutions (blood and dialysis fluid) separated by a semipermeable membrane (peritoneal membrane). Main factors affecting the rate of solute diffusion are represented by:

1. Concentration gradient between blood and dialysate; since blood flow through the peritoneal membrane is relatively stable, concentration gradient is best maintained by changing the dialysate in the abdomen as often as is feasible.
2. Molecular weight (MW); since diffusion is a size-selective process, small molecules (urea, creatinine) diffuse more rapidly than larger molecules (vitamin B_{12}, "middle molecules").
3. Effective surface area and permeability of peritoneal membrane. Indeed, it is the functional and not the anatomic peritoneal surface area that is important in peritoneal exchange. The vascular surface area available for dialytic exchange can be determined using the so-called three-pore permeability model (25). According to this model, the peritoneum is characterized as a heteroporous three-pore membrane with few ($\sim$ 1–2%) water-exclusive ultra-small pores (aquaporins) (radius 2–4 Å), a small percentage ($\sim$ 5%) of large pores (radius 200–300 Å) and a majority ($\sim$ 90–95%) of small pores (radius 40–60 Å). Small hydrophilic solute transport occurs primarily by diffusion across the small pores (although convection also plays a certain role), while the movement of proteins and other macromolecules occurs across the large pores and is driven by hydrostatic forces. Fluid transport can occur across all the three pathways and is determined by crystalloid and colloid osmotic pressures. Total membrane pore area that is engaged in exchanges can be influenced by fill volume, patient posture, and PD fluid composition (26, 27). The impact of dialysate volume is felt to rest on the principle of

geometry of diffusion (28), which simply states that the larger the dialysate volume, the longer the transperitoneal concentration gradient will persist to drive diffusion. The permeability of the tissue between the capillary lumen and the peritoneal space can be altered by disease: it increases during acute peritonitis, while can be progressively impaired by peritoneal fibrosis. The concentration gradient and hence diffusive transport are also impacted by the presence of residual peritoneal volume from previous exchanges. Small solutes in the residual fluid will likely have equilibrated with serum; this will lead to a time "zero" solute concentration that is much greater than zero, despite the fact that the instilled dialysate concentration of a solute was zero. This will impact fluid flux and solute transport. Residual volume can be substantial and of clinical relevance in children (29).

Ultrafiltration (UF): UF consists in the bulk movement of water along with permeable solutes across the peritoneal membrane; in PD the driving force for UF is primarily represented by the osmotic pressure of dialysis fluid that is exerted by glucose or other osmotic agents; the effects of hydrostatic pressure gradient are usually of minor importance in PD unless exceedingly high levels of intraperitoneal pressure (IPP) are reached (30). Other factors that can affect UF are membrane surface area and hydraulic permeability. The flux of water (J_F) across the membrane can be expressed by the following equation (31):

$$J_F = K_f\left([P_c + s_f] - [p_c + P_f]\right)$$

where: K_f = peritoneal membrane permeability coefficient; P_c = hydraulic pressure in the capillary; s_f = osmotic pressure of the peritoneal fluid; p_c = oncotic pressure in the capillary; P_f = hydraulic pressure of the fluid under flux.

Net UF results from the balance between osmotic UF and peritoneal fluid absorption, which can play a role in some patients in whom net UF is reduced, as well as in the absorption of a significant amount of macromolecules. Lymphatic absorption was estimated to account for 20% of fluid absorption (32), which is believed to move primarily into interstices in the peritoneal cavity and to be driven by intraperitoneal hydraulic pressure (33). The limited data on lymphatic absorption in children are conflicting (32, 34).

Fluid absorption rate can be determined when a PD exchange is modeled using the three-pore model. In one pediatric study, the absorption rate increased with body size in absolute terms but decreased when normalized to body size. The decrease was slight when scaled to body surface area (BSA), but marked when scaled to body weight (BW) (35).

Convective mass transfer: As water moves from capillaries to peritoneal cavity on a pressure gradient, the dissolved molecules are dragged along (solvent drag). The convective transport of a solute depends on the amount of UF and on membrane permeability, that can be expressed by the sieving coefficient and calculated by dividing the concentration of solute in ultrafiltrate by its concentration in plasma water (in the absence of a concentration gradient). During PD exchanges, the contribution of convection to solute removal is limited for small molecules, but significant for large molecules, such as proteins.

Relationship Between Peritoneal Surface Area and Dialysate Fill Volume

Whereas peritoneal membrane surface area per unit (Kg) of BW is twice as large in infants than in adults, the relationship between BSA (m^2) and peritoneal membrane surface area is constant and age-independent (36). Scaling IPV by BSA maintains the ratio of dwell volume to peritoneal surface area constant across patient age groups, thus avoiding the false perception of peritoneal hyperpermeability in infants and small children while performing peritoneal function tests (36), and has become a standard in pediatric PD prescription (37, 38). BSA can be calculated from weight and height by use of the Gehan and George formula (39):

$$\text{BSA}\ (m^2) = 0.0235 \times (\text{height},\ \text{cm})^{0.42246} \times (\text{weight},\ \text{kg})^{0.51456}.$$

Both IPV and patient posture are factors that can dynamically affect the recruitment of effective peritoneal membrane area available for dialytic exchange, which corresponds to the unrestricted pore area over diffusion distance ($A_0/\Delta X$) as determined using the three-pore model (25, 26). The peritoneal vascular surface area is maximized as IPV is raised from 800 to 1,400 ml/m^2 BSA (26). An excessive IPV may cause patients discomfort, as well as a series of complications, such as pain, dyspnea, hydrothorax, hernia, and loss of UF due to an increased lymphatic drainage. Measurement of the hydrostatic intraperitoneal pressure (IPP) can help to determine fill volume tolerance of the individual patient (30). Maximum tolerable IPV was defined as the volume causing an IPP of 18 cm H_2O in the supine position; at and above this limit, abdominal pain and/or a decrease in respiratory

vital capacity may occur (40, 41). While IPP is influenced by factors such as gender and ponderosity, and gradually adapts to a given IPV, the level of IPP in general is a reproducible patient-characteristic parameter (42).

Methods to Assess Peritoneal Membrane Transport Characteristics and Function

Peritoneal solute and fluid transport may vary considerably from patient to patient and in the same patient during different phases of CPD treatment, as a consequence of the recurrence and/or severity of peritonitis episodes, or of the exposure of PM to CPD solutions and materials. Therefore, PM transport characteristics should be assessed at the beginning of CPD and then monitored every 6–12 months, and in case of recurrent or particularly severe peritonitis episodes, or of any other clinical event that may have altered transport capacity, thus requiring a re-evaluation of patient's PD prescription (38, 43).

The application of PM function tests to the pediatric patient population has long been hampered by a lack of standardization of dialysis mechanics during the test (44). Scaling the exchange volume by BSA maintains the relationship between dialysate volume and PM surface area across populations, and makes comparison of peritoneal transport properties between patients of different body sizes possible (36, 45). An exchange volume of 1,100 ml/m^2 BSA approximates the standard 2,000 ml/1.73 m^2 volume applied to adult patients.

Mass transfer area coefficient (MTAC): This parameter is an expression of the diffusive permeability of the peritoneal membrane, and describes the maximal clearance theoretically achievable at a constantly maximal gradient for diffusion (i.e., when dialysate solute concentration is zero), and is independent of dialysate osmotic agent concentration. Calculation of MTAC requires rigorously performed PD exchanges and solutions of complex equations. In pediatric patients, Warady et al., by using a standardized exchange volume of 1,100 ml/m^2 BSA, found non-linear decrements of the MTAC with age for creatinine, glucose and potassium, indicative of a greater transport capacity in children younger than 3 years, as a consequence of higher peritoneal permeability, or larger effective surface area of the peritoneal membrane (29). In a study based on the three-pore model, MTAC values for children, when scaled for BSA, were similar to those of adults (46).

Peritoneal equilibration test (PET): PET is the most commonly employed means of characterizing PM transport capacity in adult as well as in pediatric patients (29, 47–49). This test measures the rate at which solutes, usually creatinine (Cr), urea and glucose, come to equilibration between the blood and the dialysate. In order to reach a satisfactory level of reproducibility of results, standardized PET procedure in children should include the use of a 2.5% dextrose PD solution with a dwell volume of 1,100 ml/m^2 BSA (29). A 4.25% dextrose solution can be used to obtain a more accurate assessment of UF and of sodium sieving (50). Dialysate to plasma (D/P) ratio of Cr, and dialysate glucose concentration to initial dialysate glucose concentration at time 0 (D/D_0) are calculated at 2 and 4 h of the test; a serum sample is obtained at time 2 h. Dialysate Cr concentration must be corrected for the interference of the high glucose levels in the dialysate by the formula:

$$\text{Corrected Cr (mg/dl)} = \text{measured Cr (mg/dl)} - \text{correction factor} \times \text{dialysate glucose (mg/dl)}$$

The correction factor should be determined in the laboratory of each dialysis center, by dividing measured Cr of a fresh PD solution by glucose concentration. In addition, measured plasma solute concentrations must be divided by 0.9 to account for their presence in plasma water only and not in whole plasma.

Urea and Cr D/P ratios, and glucose D/D_0 ratio can be compared to the reference kinetic data developed from the results of a large pediatric study in which the same standard pediatric PET was adopted (29), in order to characterize patients as having a high, high average, low average or low PM solute transport capacity (*Figs. 72-1* and *72-2*). High transport for Cr (and/or urea) implies its fast removal from blood, while high transport for glucose denotes its fast elimination from dialysate, thus dissipating the osmotic gradient required for UF. High transporter status may be associated with poor treatment outcome, and has been identified as a significant risk factor for inadequate weight control, poor statural growth (51), and low-turnover bone disease (52).

Recently, Warady and Jennings reported that the PET results obtained at 2 and 4 h, based on either creatinine or glucose transport in 20 PD pediatric patients, provided identical characterization of peritoneal membrane transport capacity for the same solute (53). Therefore, the Authors proposed the use in children of a simplified, 2-h PET procedure, the so-called short PET, as already described in adults by Twardowski in the original PET publication (47). However, further study with a larger patient cohort is required to confirm the accuracy of the short PET in the characterization of membrane transport capacity in this setting (54).

Figure 72-1

Peritoneal equilibration test results for creatinine. Colored areas represent high, high-average, low-average, and low transport rates. The four categories transport are bordered by the maximal, mean + 1 standard deviation (SD), mean, mean −1 SD, and minimal values for the population. D/P, dialysate:plasma ratio (from (29) with permission).

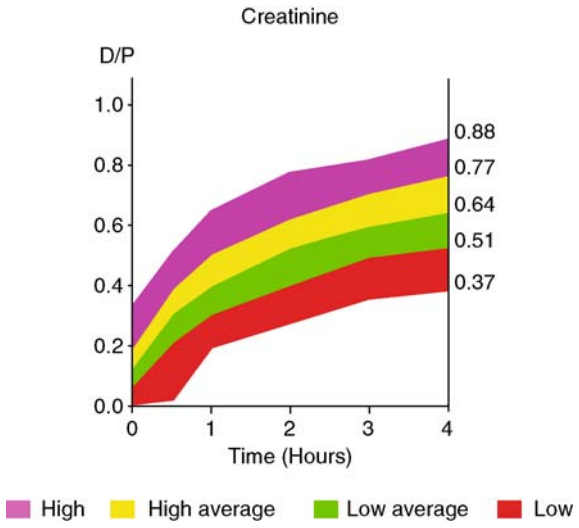

Figure 72-2

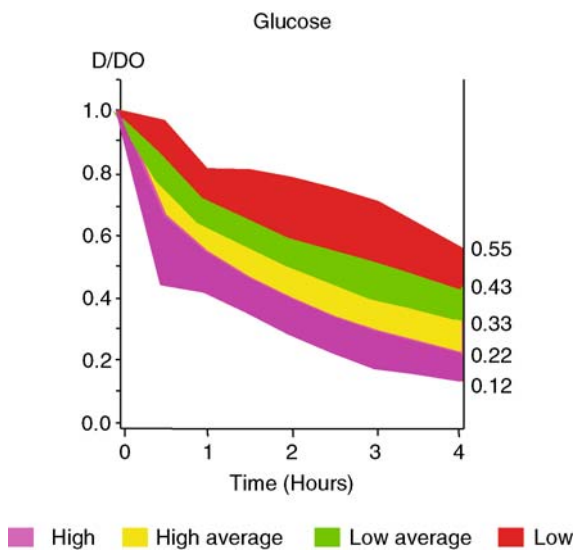
Peritoneal equilibration test results for glucose. Colored areas represent high, high-average, low-average, and low transport rates. The four categories transport are bordered by the maximal, mean + 1 standard deviation (SD), mean, mean −1 SD, and minimal values for the population. D/D_0, dialysate glucose: initial dialysate glucose concentration ratio (from (29) with permission).



Standard permeability analysis (SPA): In this test, poly-disperse dextran-70 is added to the PD solution employed to perform a PET in order to obtain the simultaneous measurement of transcapillary ultrafiltration (UF), markers clearance rate, and intraperitoneal volume (IPV). SPA conducted with a test IPV of 1,200 ml/m^2 and a 1.36 or 3.86% glucose PD solution gave comparable results in adult and pediatric patients (46, 55).

Personal dialysis capacity (PDC) test: In this test, which is based on the three-pore model of solute and fluid transport across the peritoneum, the following three parameters are calculated: (1) the effective peritoneal surface area, or unrestricted pore area over diffusion distance ($A_0/\Delta X$), corresponding to the diffusion capacity for solutes; (2) absorption, i.e., the final rate of fluid reabsorption from the abdominal cavity, and (3) the large pore volume flow, that represents the rate of protein-rich fluid passing through the large pores from blood to dialysate (25). PDC protocol includes five exchanges to be performed in 24 h using different dwell times and two glucose solutions for patients on CAPD; a simplified protocol for patients on APD is also available (35). PDC test has been successfully employed in children to model individual peritoneal membrane function (35). In one pediatric study, D/P or D/D_0 ratios derived from PET analysis were used to estimate $A_0/\Delta X$ by using a specific computer program (26).

Peritoneal Dialysis Equipment

Peritoneal Catheters for CPD

A reliable peritoneal catheter is the cornerstone of successful CPD. Careful attention should be paid to:

- A planned approach to PD initiation
- The choice of catheter type
- Technical details of placement procedure, that should be performed by a competent and experienced surgeon or nephrologist (56)
- Optimal postoperative care of the catheter and exit-site by a dedicated nurse team also involved in the training of patient's caretakers (57).

There are multiple types of PD catheters presently available, with a variety of configurations. In general, most long-term PD catheters are constructed of soft material, such as silicon rubber or polyurethrane. The catheters can be thought of as having two separate regions: the intraperitoneal portion and the extraperitoneal portion. The intraperitoneal portion contains holes or slots to

allow passage of peritoneal fluid. The optimal position of the catheter tip is the most dependent portion of the pelvis, a few degrees lateral to the midline. The shape of the intraperitoneal portion is straight or curled, the latter configuration often associated with less patient pain with dialysate inflow and a decreased predisposition to occlusion and omental wrapping of the catheter. The most common catheters have been the straight and curled Tenckhoff catheters. The extraperitoneal portion of these catheters has one or two Dacron cuffs to prevent fluid leaks and bacterial migration and to fix the catheter's position. The first or single cuff is positioned between the posterior and anterior fascia of the rectus sheath; the second cuff should be located within the subcutaneous tunnel, 1.5–2.0 cm from the catheter exit site. The shape of the extraperitoneal portion of the catheter may be straight or have a preformed angle (e.g., swan neck or pail handle) to help create a downward-directed exit site and facilitate drainage (58).

In children, a midline incision through the skin, with a paramedian fascial incision is more effective than a strictly midline approach (56). Infants and young children with vesicostomies, ureterostomies, colonostomies, or other sources of contamination require placement of the catheter exit site as far from the stoma as possible to prevent contamination and infection. Placement of the exit site on the chest wall has successfully limited the number of infections in such high-risk situations in two small series of pediatric patients (59, 60).

Laparoscopic catheter placement has been successfully employed in children (61, 62). This procedure allows careful inspection of the abdominal cavity, and the performance of adhesiolysis and inguinal hernia repair, in addition to guiding catheter placement; it can also be employed to rescue blocked catheters.

The use of intravenous antibiotic prophylaxis at the time of catheter placement has been shown to significantly reduce the risk for peritonitis within the first 4 weeks, but not the risk for exit site and tunnel infection (63, 64). The routine use of mupirocin as part of exit site care has been shown to reduce *Staphylococcus aureus* related exit site infection and peritonitis (58); however, concern regarding the emergence of mupirocin resistant organisms has arisen (65). Since mupirocin is not effective against *Pseudomonas*, which is frequently involved as causative organism in peritonitis and exit site infection among PD children (66, 67), topical application of gentamicin cream to exit site daily has been recently recommended in adult patients (68).

The primary reason for catheter revision is catheter malfunction (69), often caused by omental wrapping of the catheter. Although there are no prospective studies to support routine omentectomy, the majority of pediatric surgeons recommend that a partial omentectomy be performed in conjunction with the initial catherer placement (56, 70). Catheter occlusion by fibrin may also occur but can usually be successfully relieved by the instillation of fibrinolytic agents into the catheter (71, 72).

Catherer tip migration in the peritoneal cavity may occur as a result of too much torque placed on the catheter at the time of surgical placement, since the "memory" of the synthetic materials used to manufacture the catheter makes the catheter itself to assume again its original curvature. Occasionally, tip migration may be due to constipation or excessive bladder distension.

Dialysate leakage more often occurs in the immediate post-operative period, is usually external in nature, and is evident at the catheter exit or incision site. Early leakage may be related to poor catheter implantation technique, and can occur when initial exchange volumes are too large, when the catheter is frequently manipulated (as in too aggressive exit site care), or when traction is placed to it. Therefore, catheter implantation should be timed to allow 2–6 weeks for healing prior to dialysis initiation; if dialysis is required early, small volume exchange in the supine or recumbent position can be performed with frequent check of leakages. During this time, catheter immobilization (without the use of surgical sutures) and weekly exit site dressing changes conducted by trained dialysis personnel using aseptic technique have been recommended (57, 58). Late leakage (>30 days from catheter implantation) usually occurs into the abdominal wall, and can cause genital edema; exploration of the incision site or evaluation for an anatomical defect, resulting in the need for catheter revision, are often required.

Data from the 2007 NAPRTCS report have shown that the time to the initial episode of peritonitis is longer and peritonitis annualized rate is lower in association with catheters characterized by two cuffs, a swan neck tunnel and a downward oriented exit site (69). In the experience of the International Pediatric Peritonitis Registry (IPPR), the use of Tenckhoff catheters with a straight ending was associated with an increased rate of post-peritonitis technique failure (66).

Connection Technology

Over the years, a number of dialysate transfer sets and associated devices have been developed with the aim of reducing the risk of bacterial contamination during either

the catheter-to-transfer set or the transfer set-to-dialysate bag connections, and has contributed to simplify PD connecting maneuvers, thus shortening patient and partner training (73).

Catheter-to-transfer set connector: To prevent cracking or accidental disconnection of old plastic plug-in connectors, industry developed a Luer-lock catheter adapter made of titanium, which was chosen for its light weight and resistance to electrolyte-containing PD solutions, or of more durable plastics.

Transfer set-to-container connection: The original spike-and-port connecting system has been replaced in many systems with a Luer-lock system, resulting in easier insertion and a low chance of accidental dislodgement.

Transfer set: Starting from 1980, the standard straight Oreopoulos System was replaced by the Y set to free the patient from the need to remain attached to the empty bag between exchanges, and to allow a flush-before-fill phase after the connection, thus significantly reducing the incidence of peritonitis episodes due to touch contamination. A further evolution of the Y set was represented by the double bag system, where the Y set is attached to the PD solution bag and to an empty bag, which are connected to an adapter tubing during the exchange and discarded after each use. With this system, the patient has only to wear a small adapter tubing, that is closed with a disinfectant containing cap.

Peritoneal Dialysis Solutions

The composition of standard, commercially available PD solutions has been designed to achieve a satisfactory removal of fluid and waste products, and to maintain acid-base and calcium balance, and electrolyte homeostasis. Clinical concerns about the harmful effects of prolonged exposure of the peritoneal membrane to standard PD solutions with high glucose and lactate concentration, low pH, high osmolarity, and high level of glucose degradation products (GDPs) has led to the development of more biocompatible, second generation PD solutions. In fact, the results of a series of experimental studies support the hypothesis that peritoneal membrane hypervascularization and fibrosis observed during long-term PD are correlated to acute and chronic toxicity of conventional PD fluids. In addition, progressive decline of residual renal function, that is considered a major determinant of PD treatment outcome, can be exacerbated by the metabolic and cardiovascular burden related to glucose load, GDPs accumulation, and oxidative stress (74, 75).

Osmotic Agents

Glucose: Glucose is still the most widely employed osmotic agent in the clinical setting. It removes fluid from the extracellular volume by a mechanism known as crystalloid osmosis, which is exerted through the system of ultrasmall pores (the aquaporins), and can be effectively enhanced by increasing glucose concentration in the PD fluid. Rapid glucose absorption rate from the peritoneal fluid dissipates the osmotic gradient and makes it unsuitable to obtain adequate UF during long dwells and in patients with high peritoneal transport. Glucose absorption may worsen the anorexia, hyperglycemia, dyslipidemia, and insulin resistance as well as the increased oxidative stress that are often associated with the uremic syndrome. Moreover, long-term exposure to the elevated glucose concentration of PD fluids contributes to structural changes of the peritoneal membrane, such as submesothelial thickening and fibrosis and vascular proliferation, which are associated to functional impairment, represented mainly by UF failure. The main mechanisms by which glucose-based PD fluids induce these deleterious effects on peritoneum are represented by (76–79):

- Hyperosmolar stress
- Highly reactive glucose degradation products (GDPs), that impair mesothelial cell functions and modulate cytokine generation
- Glycation of structural proteins and formation of Amadori adducts and advanced glycosylation endproducts (AGE)
- Effects on peritoneal cell metabolism via the polyol pathway, protein kinase activation and gene induction.

Reduced GDPs formation has been obtained by the separation of glucose from the other constituents in a double chamber bag system, which allows glucose sterilization at a lower pH than is possible in single chamber bags (78, 80). In pediatric patients, significant reduction of plasma AGE levels has been reported by administration of low-GDP PD solutions (81).

In summary, glucose is effective in UF induction along short dwells, but the lowest glucose concentration of PD solution should be used while still being compatible with patient's clinical needs (82).

Icodextrin: Icodextrin consists of a family of glucose polymers with an average MW of 16,200 Da and exerts its colloid osmotic effect through the small pore system. A 7.5% icodextrin solution is able to obtain a sustained UF during a prolonged dwell, and when compared to a 3.86% glucose solution, it yields similar volumes after

8 and 14 h (83). Studies in pediatric patients showed the same UF profile than in adults and an increase in solute removal, with rare and mild side effects mainly manifesting by a mild to moderate skin rash, which usually resolves without any sequelae after icodextrin discontinuation (84–86). However, a positive correlation between age and net UF was reported in a small group of patients, with negative UF in infants characterized as high transporters on PET (87). Rusthoven et al. (88) found that with a 3.86% glucose solution the increase in IPP was positively correlated with transcapillary UF and inversely correlated with patient BSA, while by using an icodextrin solution, IPP hardly increased and no correlation was found with fluid kinetics or patient BSA. Since colloid osmotic effect exerted by icodextrin does not induce sodium sieving, sodium removal is usually higher than that obtained with glucose-based solution (89). In pediatric patients icodextrin absorption, which occurs via convective pathways, such as peritoneal lymphatics, was reported to be 45% over 14 h (86). Icodextrin is metabolized by amylase to maltose and a number of oligosaccharides, whose serum levels usually reach a steady-state within 2 weeks from the start of treatment, and go back to zero 1–2 weeks after its discontinuation (84). Sterile peritonitis was reported in some patients treated with icodextrin, and was caused by peptidoglycan contamination of dialysate by thermophilic, acidophilic bacteria (90). In vitro and ex vivo studies have shown that icodextrin solution is more biocompatible with the peritoneal membrane than glucose-based solutions, possibly due to its iso-osmolar property, lack of glucose, and lower GDP content (91). However, icodextrin may restrain the normal process of mesothelial cell repopulation and induce connective tissue formation (92). In adult patients, the use of icodextrin PD solutions to increase fluid removal was associated with less functional deterioration of the PM as the use of solutions with high glucose concentrations could be avoided (93).

Icodextrin is currently licensed for use in not more than one dwell per day out of concern for the potential side effects of its low molecular weight metabolites.

In practice, icodextrin solution is indicated for:

- Long night-time dwell in CAPD
- Long daytime dwell in CCPD
- Patients with type I UF failure
- Patients with transient UF failure associated with peritonitis.

Amino acids (AA): In children on CAPD the use of AA solution in a long dwell gave controversial results on patient's nutritional status and was associated with increases of blood urea nitrogen and worsening of acidosis (94). On the other hand, combined intraperitoneal infusion of AA and glucose during a nocturnal APD session in children was reported to promote utilization of AA for protein synthesis and to improve anthropometric parameters (95, 96). A 1.1% AA solution is as osmotically efficient as a 1.36% glucose solution; in adult patients an increase in UF and solute removal was observed, since AA tend to induce peritoneal vasodilatation and hence recruitment of microvascular surface area to a greater extent than glucose (97).

Buffer

Lactate: Lactate has long been the standard buffer traditionally applied in PD solutions. Lactate is absorbed from dialysis fluid along its concentration gradient, and is metabolized to bicarbonate in the liver. Use of acidic (pH 5.5–6.5) lactate-buffered PD solutions is associated with a series of clinical, metabolic and biocompatibility drawbacks (98): bicarbonate back diffuses in dialysate; some patients experience pain during inflow; lactate may induce local release of growth factors that stimulate fibrogenic processes and neoangiogenesis, thus contributing to peritoneal fibrosis and to the impairment of peritoneal membrane transport function.

Bicarbonate: Bicarbonate, the physiological buffer of the body, has been made available in PD solutions by the use of multi-compartment bag systems, which allow bicarbonate and calcium to be separated during sterilization and storage. Neutral pH (7.0–7.6) PD solutions contain 34 mmol/l of bicarbonate, or 25 mmol/l of bicarbonate plus 15 mmol/l of lactate. Both in adult and pediatric patients, the results of experimental and clinical studies showed that the use of these bicarbonate buffered PD solutions is associated with better biocompatibility, more effective correction of acidosis, and lower incidence of infusion pain than that of conventional lactate buffered solutions (99–101). Schmitt et al. (102) found that peritoneal mass transfer kinetics were similar with bicarbonate and lactate for water and most solutes, except for slightly lower phosphate and creatinine transport rates at 1-h dwell time with bicarbonate solution. These more physiological PD fluids have been shown to prevent hyperperfusion, and to reduce the loss of proteins into dialysate; their use was associated with lower intraperitoneal pressure reflecting enhanced fill volume tolerance, but also with a reduction of the unrestricted area over diffusion distance and of the vascular exchange area (101). APD solution with a neutral pH combined with a reduced

lactate concentration, partially replaced by bicarbonate, significantly increased UF in a group of adult PD patients, conceivably by causing less peritoneal vasodilation than conventional acidic lactate-based PD solutions (103), while no difference in net UF has been reported in children (100–102).

Sodium

Since most of the commercially available PD solutions have sodium concentration (132–134 mmol/l) that is slightly lower than plasma sodium concentration, diffusion of sodium is usually less important than its convective transport, which can be accomplished by transcapillary UF, colloid osmosis induced backfiltration and absorption into the lymphatic system. Sodium sieving associated with the transcellular water transport through ultrasmall pores can contribute to a reduction in the dialysate concentration of sodium during the initial phase of the dwell. By this mechanism, more water than sodium may be removed during the shorts dwell of APD. In patients on APD, PD solutions with lower sodium concentration than in CAPD patients may be employed, especially when a large amount of high glucose solutions is prescribed. In infants, higher sodium concentration PD solutions (137–138 mmol/l), or oral sodium supplementation, may be required in case of increased sodium loss in the dialysate and in the residual urine volume associated with congenital uropathies.

Calcium

Since calcium transfer across the PM is driven by both diffusion and convection, its peritoneal flux depends on serum ultrafiltrable calcium concentration, PD solution concentration, dwell duration, and UF rate. PD solutions contain: (1) 1.75 mmol/l of calcium; in these solution ionized calcium level is higher than that normally present in blood; therefore, diffusion of calcium from dialysate to blood would lead to a positive calcium balance, (2) 1.25 mmol/l; these solutions are frequently employed with the goal of reducing the risk of hypercalcemia, especially in children receiving calcium carbonate or calcium acetate as phosphate binders, and treated with vitamin D analogues (82). Hypercalcemia and/or a high calcium $\times$ phosphate product should be avoided for the potential risk of inducing vascular and soft tissue calcification. Use of non-calcium containing phosphate binders is indicated in these cases.

Peritoneal Dialysis for End-Stage Renal Disease

Indications for End-Stage Renal Disease Therapy

The indication for initiating dialysis therapy in children with ESRD depends on a combination of biochemical, clinical, and psychosocial assessments that should be individualized for each child. When possible, dialysis should be initiated early enough to prevent the development of malnutrition and/or any significant uremic symptomatology. Although there is no definite level of blood urea nitrogen or serum creatinine concentration that mandates dialysis initiation, this should be considered when the residual glomerular filtration rate (GFR) (104) has declined to a value between 9 and 14 ml/min/1.73 m^2 BSA, and should be recommended when GFR is 8 ml/min/1.73 m^2 or less (49). Decreased school performance and restricted daily activities are also important factors in children (105).

Selection of Peritoneal Dialysis or Hemodialysis for Children with End-Stage Renal Disease

Because CPD proceeds over prolonged periods (i.e., 24 h/day for CAPD and CCPD; 8–12 h for NIPD), body fluid composition and volume change slowly, resulting in a near steady state. Thus, the disequilibrium syndrome does not occur in children receiving CPD, which can be safely performed in children who have cardiovascular instability. Almost all children receiving CPD may be encouraged to eat an appropriate diet, relatively high in protein, and with reasonable allowances for fluid and sodium. The relative simplicity and safety of CPD, also in its automated form, allow performance at home, thereby returning the child with ESRD to regular school attendance and other normal childhood activities; this is particularly advantageous for children living far from a pediatric dialysis center. CPD avoids the many difficulties associated with the maintenance of a vascular access, especially in very small patients, and eliminates the need for regular dialysis needle punctures.

There have been no randomized comparative studies of CPD and HD outcome in children. Pediatric dialysis programs that once focused almost entirely on CPD have recognized that the availability of a chronic hemodialysis designed for pediatric patients is of equal importance to the provision of optimum care for children with

ESRD (106). While the preference for CPD is most pronounced among younger patients, older children are almost equally distributed between CPD and hemodialysis (2), and are more likely to receive maintenance hemodialysis than CPD if treated in nonpediatric units (107).

Patients and families must be given the opportunity to actively participate in the selection of the chronic dialysis modality that is best suited to their individual needs and lifestyle (49, 105). Action points of patient/family selection for home CPD treatment should include:

- Early patient/family referral to dialysis staff.
- Evaluation of patient's clinical needs and patient and family life-style.
- Structured, unbiased information on dialysis modalities.
- Evaluation of physical and psychological ability of the caregiver(s) to perform dialysis tasks.
- Assessment of patient's home environment.

Table 72-1

Absolute and relative contraindications to the use of chronic peritoneal dialysis (CPD) in pediatric patients

Absolute contraindications
• Omphalocele
• Gastroschisis
• Bladder extrophy
• Diaphragmatic hernia
• Obliterated peritoneal cavity
• Peritoneal membrane failure
Relative contraindications
• Inadequate living situation for home dialysis
• Lack of appropriate caregiver
• Impending/recent major abdominal surgery
• Imminent living-related donor transplantation (within 6 months of dialysis initiation)

Patient Selection

CPD can be attempted in any child whose peritoneal cavity is intact and will admit a sufficient volume of dialysate. Experience has shown that CPD can be used successfully in children even with the following conditions: polycystic kidney disease (usually after unilateral or bilateral nephrectomy), vesicostomy, cutaneous ureterostomy, colostomy, prune belly syndrome, bilateral Wilms' tumor, recent abdominal surgery (if no draining wounds are present), ventriculoperitoneal shunt, spina bifida, and concurrent immunosuppressive therapy. However, absolute and relative contraindications to the use of CPD in children still exist, and are listed in *Table 72-1* (49).

CPD is the clear treatment of choice for infants (2, 108–111). It is now widely recognized that CPD can be an effective maintenance RRT in babies who develop ESRD as early as the first few days or weeks of life (112, 113). The short cycles, high dialysate flow rates, and high intraperitoneal volumes that can be delivered during APD make this modality appropriate to manage the high fluid intake of the infant diet. The development of cycling machines with smaller tubing dead space and recirculation of dialysate, that allow drainage at low flow rate without alarming, has further facilitated the PD procedure in infants. In a recent report (114), peritonitis rate in PD patients under 2 years of age was comparable to that in older children. Despite these favorable results, mortality rate among infants on CPD is as much as four times that of children beyond infancy, with most deaths occurring in the first year of life (111, 115). In infants, a survival rate of 85% at 1 year, 74% at 2 years and 68% at 3 years was reported, as compared with 95, 90, and 86% at the same time intervals in children starting dialysis after infancy (108, 116). The presence of non-renal disease, particularly pulmonary disease/hypoplasia, and oliguria or anuria, is a major risk factor for patients receiving CPD during the first 2 years of life (117, 118). Similarly, neurodevelopmental outcome is better nowadays than in the past (119), but it may be conditioned by extrarenal disorders such as neonatal hypoxia or certain syndromes and chromosomal abnormalities (111). Poor nutritional status and growth are frequently observed in infant phase, and should be managed intensively by supplemental feeding and growth hormone therapy (110, 120, 121). The hospitalization rate for infants on CPD may be higher than that for older children (122), and is mainly due to inpatient treatment of peritonitis, catheter revision, hernia repairs and re-evaluation of therapy (123).

Preparation of the Patient and Family

A treating facility that provides CPD to children should be able to provide the necessary multidisciplinary services required by the child and family. The team consists of CPD nurse specialists, nephrologists, urologists, general surgeons, renal dietitians, renal social workers, child psychologists, child psychiatrists, child development specialists, child life therapists, speech pathologists, school teachers, and chaplains, all of whom are pediatric specialists.

Table 72-2

Patient and family preparation for home chronic peritoneal dialysis (CPD)

Patient and family preparation for home CPD should:
→ Start well before dialysis initiation
→ Involve a specialized, multidisciplinary team
→ Make use of appropriate written information and other teaching aids
→ Encourage contacts with similar-aged children on home dialysis
→ Include a home visit to ensure safe delivery of home dialysis, and a liaison with the nursery/school/college, and the family doctor
→ Include a nutritional assessment and the evaluation of any clinical conditions that could be susceptible of surgical correction before, or at the moment of peritoneal catheter placement

Preparation of the patient and family for CPD and their education to perform home dialysis should be accomplished through a structured comprehensive program, involving the whole multidisciplinary team of the dialysis facility (*Table 72-2*). Training for home PD procedures should involve two family members and may be completed in the home environment (105, 106). Once PD treatment has started, regular telephone contact and support for the family should be planned, in order to avoid exhaustion and burnout. Moreover, acquired knowledge and skills of performing home PD should be assessed at regular intervals according to a formal home update program (105).

According to the recommendations of the NKF K/DOQI Guidelines for peritoneal dialysis adequacy in pediatric patients (49), each home CPD training unit should establish quality improvement programs with the goal of monitoring clinical outcomes and implementing programs that result in improvements in patient care. Since any pediatric center takes care of a relatively small number of patients, single-center clinical outcomes should be compared with the results reported by large pediatric databases.

Children require a great investment of time and resources from the CPD team, and the effort that is involved is often several orders of magnitude greater than that required to care for the typical adult CPD patient (106).

Peritoneal Dialysis Prescription

Optimal PD prescription for each individual child should be tailored on his/her age, body size, residual renal function (RRF), nutritional intake, and peritoneal membrane transport capacity. In addition, PD schedule should be compatible to the psychological and social needs of the patient and family. The importance of evaluating PM transport status by means of validated functional tests and selecting PD solution according to its biocompatibility and potential UF capacity has been already underlined. Two other technical parameters that should be primarily considered in the prescriptive process are represented by exchange fill volume and dwell time (38, 49, 124).

Fill volume prescription: As previously described, scaling IPV by patient BSA has become a standard in pediatric PD. Both IPV and patient posture dynamically affect the recruitment of effective peritoneal membrane area available for dialytic exchange, which corresponds to the unrestricted pore area over diffusion distance ($A_0/\Delta X$) as determined using the three-pore model (25, 26). Maximization of peritoneal vascular surface area has been obtained by raising IPV from 800 to 1,400 ml/m^2 BSA (26). On the other hand, excessive IPV may cause patients discomfort, abdominal pain, dyspnea, hydrothorax, hernia, gastroesophageal reflux, and loss of UF due to increased lymphatic drainage. Hydrostatic IPP is a reproducible, patient-characteristic parameter, and its measurement helps to evaluate fill volume tolerance in the individual patient (30). Fill volume leading to an IPP of 18 cm H_2O in the supine position is considered the maximum tolerable IPV, above which abdominal pain and a decrease in respiratory vital capacity may occur. An IPV of 1,400 ml/m^2 BSA seems to be optimal to ensure optimal recruitment of vascular pore area in children; however, this should be considered as a maximal limit, the safety of which has not been validated in children. In clinical practice, in order to obtain as high recruitment of vascular pore area as possible, fill volume can be increased in steps, remaining under the limit of 1,400 ml/m^2 BSA for a night exchange while the patient is lying down, and monitoring patient's clinical tolerance and IPP (37).

Dwell time prescription: Dwell duration should always be adjusted on individual patient's transport status and on required small and middle-sized molecule removal and UF. (38, 49, 124). Short dwells are more efficient for small solute clearance and UF, which can be further enhanced by increasing dialysate glucose concentration. High transport patients would benefit from short exchanges, but dissipation of osmotic gradient due to fast glucose absorption should be taken into account. Removal of solute of relatively higher molecular weight, such as creatinine and phosphate, is favored by prolonged exchanges, but these can be associated with impaired UF or even with dialysate reabsorption while using glucose solutions. Icodextrin solution is more appropriate for long dwells (82, 85).

A potentially useful way to individualize dwell duration in pediatric patients on automated PD (APD) according to peritoneal transport capacity is the calculation of the so-called APEX time. While performing a PET, APEX time corresponds to the point at which D/P urea and D/D_0 glucose equilibration curves cross, and should represent the optimal length of APD cycles (125). Similarly, phosphate clearance, which is usually insufficient to obtain a satisfactory control of hyperphosphatemia, thus requiring strict dietary restriction and phosphate binder administration, can be improved by optimizing exchange duration through the calculation of the so-called phosphate purification dwell time (PPT) (125).

PD Treatment Modalities

CPD can be performed manually (CAPD), or by means of a cycler (APD). APD regimens can be continuous, with dialysis solution present in the peritoneal cavity evenly throughout 24 h, or intermittent, with empty abdomen for part of the day, usually during daytime. Continuous regimens allow complete equilibration of small solute as well as a certain removal of middle molecules. However, the presence of a large volume of dialysate in the abdomen during the day can be associated with patient discomfort, the occurrence of abdominal hernias (especially in infants and young children), and problems of body image (especially in adolescents). Moreover, continuous absorption of glucose from the dialysate compromises appetite and aggravates uremic dyslipidemia.

CAPD: This continuous PD modality has the advantage of ease of use and limited cost of the equipment. The guidelines of the European Committee on adequacy of the pediatric PD prescription (38) suggest to employ an initial fill volume of 600–800 ml/m^2 during the day and 800–1,000 ml/m^2 overnight; then, dwell volume can be gradually increased according to patient tolerance and IPP measurements. An icodextrin-based solution can be used for the prolonged night-time dwell. In order to further increase the delivered dialysis dose, there is no other means than increasing the number of exchanges. CAPD is usually effective in patients with RRF, but its decline should be closely monitored. Patients with a low-average or high-average peritoneal transport status at the PET can be maintained on CAPD with close monitoring of dialysis adequacy indexes.

APD: During the past 15 years, APD has progressively expanded as the PD modality of choice for children and has largely replaced CAPD, at least in those countries where it is not limited by cost constraints (2, 17, 69). The preference for APD has mostly been a lifestyle choice, since the night-time APD course enables children to attend school full-time and reduces the impact of dialysis treatment on the way of life of the patients and their families (16). The wide range of APD schedules help in tailoring dialysis prescription to patient's age, body size, clinical conditions, growth-related metabolic needs, residual renal function and PM transport status. In addition, performing the night-time exchanges in the lying position allows the use of large fill volumes, thus increasing the recruitment of functional peritoneal surface area (26).

The selection of an individualized APD prescription can be facilitated by kinetic modeling. Mathematical modeling software programs, that have a specific individual peritoneal function test as data entry, have been developed to calculate kinetic parameters, to simulate the results of APD regimens, and to rapidly find the best personalized dialysis schedule (126). Two of these software programs have been validated in children (35, 127, 128), and their accuracy in predicting solute removal is good. The accuracy of these programs in UF prediction was less good, owing to the inability of kinetic modeling to account for changes in residual dialysate volumes, the marked day-to-day variability of UF, the large variability of daily fluid intake, and the confounding effects of residual diuresis in non-anuric patients (129, 130). Therefore, computer-assisted kinetic models represent useful tools to help selecting the optimal dose of dialysis for a given patient, but the evaluation of the actually delivered dialysis dose by direct measurement of solute clearances and UF rate is always needed.

Nightly intermittent PD (NIPD): NIPD consists of a number of short nocturnal cycles, without a daytime dialysate dwell, and is primarily indicated in patients characterized by a high-transport peritoneal membrane, which allows rapid solute equilibration. The main advantages of a dry abdomen during the day include normal

IPP, and the reduction of glucose absorption, of AA and protein loss, and of membrane exposure to glucose. On the other side, the absence of a daytime dwell is a limitation for solute clearance (especially for middle-size molecules), and makes NIPD not suitable for patients with low and low-average peritoneal transport. Even in NIPD a small daytime fill volume is often prescribed in order to allow the flush of the catheter and of the lines at the start of the night PD session, thus reducing the risk of peritoneal contamination. NIPD is frequently adopted as the first APD regimen in patients with a significant RRF. As clearance and UF requirements increase, mainly as a consequence of the decline of residual renal function, NIPD efficiency can be improved by: enhancing dwell volume according to patient's tolerance (37); extending total treatment time; increasing the number of exchanges, up to a point beyond which clearance solute and water removal may decrease as the non-dialytic time, corresponding to the fill and drain phases, becomes more important than the benefit of further increasing total dialysate volume.

Continuous cycling PD (CCPD): In this continuous form of PD, a fresh exchange of dialysis solution, ranging in volume from 50 to 100% of the fill volume applied at night, is left in the abdomen at the end of the night APD session. Daytime exchange dialysate can be drained at bedtime when the cycler is reconnected, so that patient involvement is reduced to one session for preparation of the equipment and connection to cycler, and one short disconnection in the morning. Prolonged daytime dwell significantly contributes to dialytic clearances since removal of middle-sized uremic toxins, which is poorly influenced by short cycles of APD, is increased (131). Daytime solute clearances are also influenced by convective transport associated with net UF, which in turn depends on the type of osmotic agent, fill volume related IPP, and membrane transport status. Colloid osmotic effect exerted by icodextrin solution is able to obtain net UF during a long daytime exchange in the majority of patients (82, 84, 86, 87).

A continuous PD regimen is particularly indicated in patients with high-average peritoneal transport, and should be considered when the contribution of RRF to solute removal and UF has become negligible. If a further increase of solute clearance and UF is desired, more than one diurnal exchange can be performed, optimizing the length of each dwell according to patient's peritoneal transport and the type of employed osmotic agent *(continuous optimal peritoneal dialysis, COPD)* (38, 131). With this schedule, an exchange is usually performed at mid-day or after school, using the cycler in a disconnectable manner.

Tidal PD (TPD): In this modality, an initial infusion of PD solution into the peritoneal cavity is followed by only partial dialysate drainage, thus leaving always an intra-abdominal reserve volume. Tidal drain volume is replaced with fresh dialysis fluid to restore the initial IPV with each cycle, while the entire dialysate volume is drained at the end of the PD session (sometimes also once in the middle of the session). The expected amount of ultrafiltrate during each cycle must be estimated and added to the drain volume to prevent overfilling of the peritoneal cavity. With tidal PD, enhanced clearances are expected as a result of the continuous contact between dialysate and peritoneal membrane, which maintains a sustained diffusion of solutes. The efficiency of the dialysis modality can be further increased by reducing inflow and outflow dead times, especially if high dialysate flow rates are employed. Tidal PD is also adopted to avoid repeated cycler alarms of low flow rate in case of catheter malfunction, and to reduce pain occurring during the drainage phase. Major determinants of TPD efficiency are total volume of delivered PD fluid and individual peritoneal transport status. Patients with high transport status can reach adequate solute clearances with intermittent nightly TPD, while high average transport patients would better benefit from a continuous regimen of TPD with one or more daytime dwells. Studies on pediatric patients showed that TPD efficiency was equal or higher than that of standard APD, even requiring larger total dialysate volumes (132, 133). Optimization of TPD efficiency can be attained by adapting tidal volume to the drainage profile of each patient, thus reducing the fill and drain dead times (134). In fact, peritoneal catheter drainage profile is not linear, since a high flow rate is maintained until a critical intraperitoneal volume is reached. After this point, also called breakpoint, the flow rate drops and during the final, slow-flow portion of the drainage phase peritoneal cavity is almost empty and solute clearance greatly reduced (135). Since the critical intraperitoneal volume is an individual characteristic, tailoring tidal volume to the drainage profile of each patient reduces idle time and improves the overall efficiency of the system.

Peritoneal Dialysis Adequacy

The correlation between the delivered dialysis dose and the adequacy of dialysis treatment was first analyzed in hemodialysis patients by studies mainly based on urea kinetics evaluation. The resultant concept of "adequate" dialysis was originally created to define a minimum hemodialysis dose, below which a clinically unacceptable

rate of negative outcome might occur (patient hospitalization, morbidity, mortality). During the 1990s, the influence of small solute clearance on the outcome of patients on PD was a major focus of interest. Observational studies in adult CAPD patients suggested that better patient survival and lower morbidity was associated with higher clearances of small molecules, as urea and creatinine (136, 137). As a consequence, small solute clearance was considered the key criterion of PD adequacy in clinical practice guidelines such as those of the Kidney Disease Outcomes Quality Initiative (K/DOQI) (138). Subsequently, a re-analysis of the data from the original Canusa study, as well as the results of prospective randomized interventional trials (139–141) were unable to demonstrate any clear survival advantage with increases in peritoneal small solute clearances and showed that RRF is a much stronger predictor of patient survival than peritoneal clearance. Possible, speculative explanations for failure of increased PD dose to improve outcomes are: higher IPP associated with larger exchange volume; failure to increase clearance of middle molecules; increased exposure to glucose-based dialysate (142). Moreover, some recommendations proved difficult to be fully applicable in clinical practice, especially among pediatric patients.

Indeed, in children, even more than in adult patients, adequacy of PD treatment cannot be solely defined by targets of solute and fluid removal. Clinical assessment of treatment should take into consideration a series of clinical, metabolic and psycho-social aspects, such as:

- Hydration status
- Nutritional status
- Dietary intake of energy, proteins, salts and trace elements
- Electrolyte and acid-base balance
- Calcium phosphate homeostasis
- Control of anemia
- Blood pressure control
- Growth and mental development
- Level of psycho-social rehabilitation

In clinical practice, delivered dialysis dose can be adjusted and monitored following the guidelines by an ad hoc European committee on adequacy of the pediatric PD prescription (38) and the 2006 update of the NKF-K/DOQI clinical practice recommendations for pediatric peritoneal dialysis adequacy (49).

The following issues will be specifically, even briefly, addressed: small solute clearance; clearance of middle-sized molecules; fluid balance and UF; clinical correlates of PD adequacy.

Small Solute Clearance

In the absence of definitive outcome data in pediatrics to indicate that any measure of dialysis adequacy is predictive of well-being, morbidity, or mortality, 2006 K/DOQI guidelines (49) stated that by clinical judgment the "delivered" small solute clearance in children should meet or exceed adult standards.

A minimal "delivered" dose of small solute clearance should be at a Kt/V_{urea} of at least 1.8 per week. Data from pediatric and adult studies found serum albumin level to be a predictor of patient survival, and a Kt/V_{urea} of 1.8 or greater in adult PD patients has been associated with better serum albumin values (49, 143).

The above reported target should be intended as total (peritoneal plus renal) clearance, or peritoneal clearance alone in patients without RRF (defined as urine Kt/V_{urea} <0.1 per week). For practical reasons peritoneal and renal clearance can be added to determine total clearance, even if they have a different impact on patient's outcome. The term "delivered" refers to the actual dose the patient is receiving based on direct measurement, not to an estimated value obtained by using a kinetic modeling program. Solute clearance should be measured within the first month after starting PD, and at least once every 6 months thereafter, when the patient is clinically stable, and at least 1 month after resolution of a peritonitis episode. More frequent measurements should be conducted when dialysis clearance may have been compromised (e.g., after peritonitis), there is a progressive loss of RRF, or there is clinical evidence of inadequate dialysis. However, if a patient is not doing well and has no other identifiable cause other than kidney failure, a trial of increased dialysis is indicated (49).

Historically, both Kt/V_{urea} and creatinine clearance (CrCl) have been employed to evaluate PD clearance. A discrepancy between urea and creatinine PD adequacy parameters was often reported (144–147), especially in patients on APD and in children (38). Indeed, urea clearance is mostly related to dialysate volume and number of exchanges, while CrCl is predominantly affected by the duration of the dwell time, and by the presence of residual renal function. The 2006 K/DOQI recommendations suggested the determination of dialysis and urine Kt/V_{urea} alone for follow-up, based upon the simplicity of its calculation, and because studies on adult PD patients have not provided evidence of a benefit in terms of patient outcome when expressing clearance in any manner other than Kt/V_{urea} (49, 144, 147).

Kt/V_{urea} is normalized for urea distribution volume (V), which is assumed to equal total body water (TBW).

Therefore, accurate estimation of TBW is a critical component of dialysis dose measurement. Since gold-standard isotope dilution technique to determine TBW are laborious, costly and not widely available, anthropometric prediction equations based on height and weight are commonly used to estimate TBW. Equations derived from healthy children (148) systematically overestimates TBW in pediatric patients receiving PD, and recently a new set of anthropometric TBW prediction equations have been developed in this patient population, and validated by comparison with the determination of TBW by means of heavy water (H_2O^{18} or D_2O) dilution technique (149). These formulae are based on a new anthropometric parameter called "*height times weight*," that correlates linearly with TBW when both values are log-transformed, and are as follows:

$$\text{Boys}: \quad \text{TBW} = 0.10 \times (\text{HtWt})^{0.68} - 0.37 \times \text{weight}$$

$$\text{Girls}: \quad \text{TBW} = 0.14 \times (\text{HtWt})^{0.65} - 0.35 \times \text{weight}.$$

An alternative measure of PD dose, other than Kt/V urea and CrCl, is represented by the solute removal index (SRI), which normalizes removal by the solute content of the body at the beginning of treatment, so that the ratio between net urea removal and pre-dialysis urea body pool is calculated. By SRI different dialytic treatments, or the results of the same treatment in patients differing in body size, can be compared (150).

In conclusion, numerical targets of small solute clearance, as defined by currently available guidelines, should be interpreted cautiously and in the context of patient clinical assessment.

Clearance of Middle-Sized Molecules

Failure to achieve an adequate clearance of the so-called middle-sized molecules (from 300 to 5,000 Da MW) is one of the possible explanations for the lacking effect of increased dialysis dose on patient survival (142). Small solute and middle-sized molecule clearances respond differently to changes in PD prescription; while the former is mainly determined by the frequency and volume of dialysate dwell, the latter depends more on the duration of contact of the peritoneum with dialysate (151, 152). Removal of middle-sized molecules and low-molecular weight proteins, such as β_2-microglobulin and leptin, mainly depends on RRF (153, 154). Moreover, an increase of the restriction coefficient for macromolecules was reported in relation to time on chronic PD, which is associated with an increased size selectivity and a reduced peritoneal permeability for higher molecular weight solutes (46). Hence, particular attention should be paid to middle molecule clearance especially in children on NIPD, and as RRF is declining. In these cases a continuous PD regimen (CCPD or CAPD) should be adopted even if small solute clearance is above target without the longer dwell (49). Increased β_2-microglobulin and leptin clearance have been reported in patients receiving a long dwell with icodextrin solution (155).

Fluid Balance and UF

PD prescription should be continuously adjusted in order to achieve and maintain fluid balance and normal blood pressure. PD has been considered an optimal approach to reach this therapeutic result thanks to its continuous nature, which avoids fluctuations of volume and offers better homeostatic stability than intermittent therapies. Nevertheless, PD population surveys show a high prevalence of hypertension and cardiovascular mortality, and UF proved a significant predictor of survival in anuric adult patients (156, 157). Data from the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) (158) showed that 57% of nearly 4,000 patients on dialysis had blood pressure values higher than age-, sex-, and height-specific 95th percentile. Left ventricular hypertrophy was documented by echocardiography in 68% of 38 long-term pediatric patients on PD therapy (159). Hypertension and cardiac impairment were most frequently found in the younger and nephrectomized PD patients (160). Even if the cause of hypertension is multifactorial, volume overload is likely to play an important etiologic role in a relevant percentage of patients on PD therapy (49).

Routine evaluation of volume status, daily UF volume and daily residual diuresis volume is therefore essential in the process of attaining adequate PD, and can be performed according to the recommendations for PD adequacy in pediatric patients (38, 49). In the absence of validated, readily applicable indicators of volume status, the assessment of patient "target weight" mainly relies on clinical judgement. In clinical practice, the desirable target weight of a PD patient could be reasonably approximated to that weight at which the patient is edema free and normotensive with minimal need for antihypertensive medications. Since fluctuations in patient weight secondary to growth and to changes in nutritional status may

occur, re-evaluation of target weight at regular intervals is mandatory.

Recommended interventions to maintain patient fluid balance include:

- Dietary counseling on sodium and fluid restriction; this recommendation should take into account renal and/or dialysis-related sodium losses, since sodium depletion may result in hypotension and impaired growth
- Use of loop diuretics in children with RRF
- Evaluation of PM transport characteristics; these affect net fluid removal at a given dwell time by determining the osmotic gradient time curve; a modification of the standard PET utilizing 4.25% dextrose solution can be employed to better evaluate the UF kinetics (129, 130)
- Tailoring of dwell time and PD solution tonicity; these parameters are interrelated and should be considered jointly; for instance, low dialysate dextrose concentration and prolonged dwell time will inevitably lead to inadequate fluid removal in high transport patients (130); an increase of dextrose tonicity is associated with enhanced UF, but the osmotic gradient dissipates over time; therefore, dextrose solutions are indicated for short dwells, while for the night-time dwell in CAPD and the daytime dwell in APD, icodextrin solution may be more appropriate; icodextrin is also effective in maintaining adequate UF rate during peritonitis episodes (161); the observation that icodextrin may behave differently in young children, in whom UF may not be as successful as in older patient, requires further confirmation (87)
- Correction of peritoneal catheter malfunction leading to incomplete dialysate drainage, especially after prolonged dwells on CAPD and CCPD.

In practice, PD prescription strategies to improve UF rate could be summarized as follows:

- During short dwells on the cycler: increase number of cycles and/or overall treatment time and/or glucose concentration (even if any effort should be done to employ the lowest possible dextrose concentration required to achieve the desired UF rate
- During prolonged dwells: utilize icodextrin solution; replace single long exchange with two or more exchanges.

Clinical Correlates of PD Adequacy

Large-scale, prospective outcome studies on pediatric PD patients are lacking owing to the small number of patients per center, and the relatively short period of time on dialysis prior to renal transplantation. Nevertheless, some pediatric studies have effectively addressed the issue of the correlation between PD dose and selected clinical aspects.

Growth is a potentially valuable outcome measure specific to pediatrics. Multivariate analysis of the data of a multicenter study (162) showed a weak positive correlation of height standard deviation score (SDS) with dialytic creatinine clearance, and a negative correlation with peritoneal transport status (i.e., children with high transport on PET had a lower change in height SDS). Accelerated height velocity was reported in 62% of the patients who met or exceeded DOQI target clearances (163). Chadha et al. (164) presented data showing that growth correlates with renal solute clearance, but not with peritoneal clearance. Similar to adult studies, these data may suggest that peritoneal and residual renal small solute clearances are not equivalent.

Nutrition is an issue of particular interest in pediatric PD, since it can significantly affect growth and development of children. Dietary protein intake is inconsistently correlated with delivered Kt/V urea (165–167). However, the relationship between Kt/V urea and the normalized protein equivalent of nitrogen appearance (nPNA) has often been criticized as merely being the result of mathematical coupling (168). Finally, a higher Kt/V was associated with a lower serum albumin level in children, suggesting that enhancing PD dose may reach a point of no further benefit (i.e., a Kt/V value of more than 2.75), owing to an increased loss of albumin in the dialysate (169).

A study in 18 children on PD showed that increasing weekly Kt/V and CrCl was positively correlated with cardiac function and inversely with left ventricular mass (170).

Preservation of Residual Renal Function

Prospective randomized trials of dialysis adequacy and observational studies in adult patients have confirmed that RRF is a much stronger predictor of patient survival than peritoneal clearance (139, 140, 141). In pediatrics, no data from large-scale trials on the correlation between RRF and patient outcome are currently available. However, the already cited single-center observational study on PD pediatric patients by Chadha et al. reported that

growth velocity was higher in a group of children with RRF than in a group of children without RRF even if the same mean total solute clearance was achieved in the two groups (164).

The rate of RRF decline in pediatric patients on PD was reported to be slower than in patients on HD (171, 172). PD prescription should be aimed to preserve RRF as long as possible, by gradually increasing the dialysis dose in steps, accurately targeting UF rate to maintain patient's dry body weight, and using the lowest possible dialysate glucose concentration required to achieve the desired UF volume (49, 172). Prevention of RRF loss also involves avoidance of nephrotoxic insults (medications, radiocontrast agents, urinary tract obstruction and infection); in particular, aminoglycoside antibiotics should be employed in the treatment of PD related peritonitis taking into account their nephrotoxicity, as well as ototoxicity and vestibular toxicity.

Data on adult PD patients support the role of angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) in slowing RRF decline (173, 174), but no experience on the use of these agents is yet available in children with ESRD. ACE inhibitors and/or ARBs can be prescribed to PD patients who require antihypertensive therapy, but close monitoring for the occurrence of hyperkalemia is recommended (175).

In summary, interventions that may contribute to the preservation of RRF should be adopted whenever possible (49). At the same time, RRF should be routinely measured by means of 24-h urine collection and PD prescription should be adjusted to its decline in a timely fashion, in order to anticipate the occurrence of signs and/or symptoms of inadequate treatment.

PD Adequacy Monitoring: Practical Schedule

The assessment of PD delivered dose is fundamentally based on the direct measurement of dialytic and renal clearances, through a 24-h collection of dialysate and urine (49). All dialysate discharged during 24 h should be accurately collected (including daytime exchange, if present), total volume precisely measured, and a sample obtained after mixing effluent thoroughly. The same attention should be paid to perform complete 24-h urine collection, although this may be difficult to do accurately in children, requiring good cooperation by caregivers. Urine collection requires a preservative, such as thymol, to be added to the collection or refrigeration to inhibit the growth of bacteria that can degrade urea; dialysate does not require refrigeration or preservative.

Weekly peritoneal Kt/V urea can be calculated with the following formula (176):

$$(24\ \text{h D/P urea} \times 24\ \text{h dialysate volume} \times 7)/\text{V}$$

where D/P represents the dialysate to plasma concentration ratio.

In patients with RRF, renal Kt/V corresponds to:

$$(\text{ml/min urea clearance} \times 1440\ \text{min/day} \times 7)/(1,000\ \text{ml} \times \text{V}).$$

CrCl calculation is normalized to BSA, that can be calculated from weight and height by use of the Gehan and George formula (39).

The following formula can be employed to calculate dialytic CrCl per week (176):

$$(24\ \text{h D/P Cr} \times 24\ \text{h dialysate volume} \times 7 \times 1.73\ \text{m}^2)/\text{BSA}\ (\text{m}^2)$$

Residual renal clearance is better expressed as the average of CrCl and urea clearance, each of which can be calculated by the standard formula (and normalized to patient's BSA):

$$\text{solute clearance (ml/min)} = (24\ \text{h urine volume in ml} \times \text{urine solute concentration})/(1,440\ \text{min/day} \times \text{serum solute concentration}).$$

PD dose assessment should be coupled with an evaluation of nutritional status, which will be discussed in the following paragraph.

A practical schedule of routine outcome evaluations in pediatric patients on chronic PD can be organized as indicated in *Table 72-3*.

Methods of Monitoring Patient Adherence

Non-adherence is an important obstacle to achieving an adequate dialysis dose, and a significant cause of morbidity, patient hospitalization and technique failure (177, 178). Several methods to assess patient adherence to PD prescription have been proposed, based on comparison of measured versus predicted creatinine excretion (177); home visits to check dialysis solution supply inventories (179); patient self-report confidential questionnaires (180); or the comparison of self-reports of compliance with the rate of predicted versus measured Kt/V urea and CrCl (181). However, none of these methods provides a complete assessment of non-adherence in patients on home PD.

Table 72-3

Timetable of routine clinical and biochemical evaluation in pediatric patients on stable chronic PD (UF = ultrafiltration; CrCl = creatinine clearance)

Parameters to be evaluated	Frequency
• Clinical and physical examination	Every month
• Height	
• Weight	
• Head circumference (in infants)	
• Blood pressure	
• Blood urea and creatinine	
• Serum electrolytes	
• Acid-base status	
• Hemoglobin/hematocrit	
• Serum albumin	
• Daily urine volume and UF	
• Serum ferritin	Every 3 months
• Serum iron	
• Total iron binding capacity	
• Alkaline phosphatase	
• Parathyroid hormone	
• Kt/V urea and CrCl from 24-h dialysate and urine collection	
• Neurodevelopment assessment	Every 3 months
• Ambulatory blood pressure monitoring	Every 12 months
• Echocardiography	
• Hand and wrist X-ray for bone age	

Thanks to the introduction of microchips and computer technology, modern APD cyclers can store the patient's prescription, medical history and treatment events on an electronic device. This system provides information on the home dialysis PD treatment and an objective means to monitor patient adherence. Comparison of the prescribed versus the actually delivered therapy shows any change the patient and/or caregiver may have done in the prescribed dialysis schedule on his/her initiative. More frequent changes include skipping treatment cycles; shortening overall treatment time; manually changing treatment parameters; bypassing therapy phases or cycles; or, reducing fill volume by performing manual drains.

The preliminary results reported on the use of telemedicine in a pediatric PD program (178), show that this type of tele-communication allows to identify and successfully address clinical and psychosocial problems, and increase patient and family satisfaction with home PD treatment. Whether the so-called "teledialysis" is able to significantly reduce the need for patient hospitalization or the incidence of technique failure in a population of children on home APD has still to be evaluated in large-scale studies.

Nutritional Management of Children Receiving Continuous Peritoneal Dialysis

The achievement of normal growth is uncommon among children treated with CPD, despite access to an essentially unlimited diet. Compared with normal healthy children, pediatric patients receiving CPD have significantly lower energy intake, as well as diminished height, weight, triceps skinfold thickness, and mid-arm muscle circumference (182–184). Hypoalbuminemia, hypertriglyceridemia and hypercholesterolemia are commonly seen (185).

Children on CPD commonly suffer from protein and calorie malnutrition with loss of muscle mass and protein stores, and this condition is associated with increased morbidity and mortality (184). The term malnutrition would infer that dietary replacement would be curative, which is not always the case in ESRD patients, which usually have a loss of lean body mass combined with normal or even increased fat mass, high resting energy expenditure and inadequate response to nutrient supplementation (183, 184, 186, 187).

Assessment of nutritional status: In pediatric patients on PD, an accurate assessment of the nutritional status is essential to provide the most appropriate diet as well as the most effective dialysis prescription. However, although many indices have been proposed for this assessment, no single or easy measure of inadequate nutritional status does exist, and no gold standard has been yet defined (183, 184). Anthropometric measures that are routinely obtained in clinical practice are height (Ht), weight Wt), and head circumference (in younger children), and are plotted on percentile charts to evaluate weight changes and height velocity. Another way to express the relative weight and height is the body mass index (BMI, Ht/Wt^2), that should be calculated according to height age (183). Extreme values of BMI have been associated with increased morbidity and mortality, but it may not reflect body composition precisely, since is not able to distinguish between fat mass and fat-free mass (FMM) (183, 188). Direct measurements of tricipital skinfold thickness and arm circumference are used to calculate mid arm muscle circumference (MAMC), arm muscle area (AMA) and arm fat area (AFA) by means of appro-

priate formulae (189). These parameters can be compared with the corresponding age- and gender-specific reference values and then expressed as standard deviation score (SDS). In pediatric patients, anthropometric variables standardization by chronological age is questionable, and correction for height age has been suggested (190). Patient's nutrient intake should be estimated by means of retrospective dietary recall or, even better, by prospective food record. The latter is usually performed over 3 days and requires the cooperation of parents, who should receive detailed instructions by a pediatric renal dietician. Frequency of dietary reviews should be every month in PD children under 2 years of age, and every 3–4 months in older patients. Their accuracy and the role of the pediatric renal dietician, who should work with the patient and family, are crucial to the successful management of nutrition in pediatric patients on chronic dialysis (183, 184, 191).

In steady state patients, protein intake can also be estimated by calculating the protein catabolic rate (PCR), which is also called protein nitrogen appearance (PNA), by means of the modified Borah equations, as suggested by the KDOQI guidelines (191), or the formula proposed by Mendley and Majkowski (192).

Among biochemical parameters, serum albumin is the most frequently used nutritional index, and has been identified as a surrogate marker for nutritional status as well as for morbidity and mortality in ESRF patients. Low serum albumin is associated with an increased risk of death in ESRF children, and is more common in patients on PD, who suffer from protein malnutrition more frequently than their peers treated with hemodialysis (143, 193). The rate of protein and AA loss with dialysate varies with peritoneal transport status, and is inversely correlated with body weight and BSA, so that it may impair nutritional status and even normal growth especially in infants (183, 194, 195).

Metabolic status of patients on chronic dialysis can be evaluated by calculating the nitrogen balance, which represents the difference between nitrogen intake and nitrogen losses. Since direct measurement of nitrogen losses in urine, stools and dialysate is quite complicated, a mathematical model for its estimation in pediatric patients treated with PD has been developed (196).

Body composition of children on PD has been evaluated by means of a series of methods (DEXA; isotope dilution techniques; total body nitrogen; densitometry), all of which are difficult to use on a regular basis in clinical practice. Bioelectrical impedance analysis (BIA), that is non-invasive and quite easy to perform at the bedside, has been widely employed to assess patient's dry weight. The interpretation of the results obtained by using the parameters that are measured by BIA (resistance and reactance) and the indices directly derived from them (phase angle; distance; BIA vector) to estimate body composition is still debated. Reference values of the whole-body BIA vector have been determined in healthy children by a multicenter, cross-sectional study (197), but more data on pediatric patients on dialysis are required. Specific equations to predict free fat mass (FFM) and TBW from BIA data have been provided (198); however, their use in the clinical setting should take into account a certain degree of unpredictable variability of some parameters. In a group of children on APD, Edefonti et al. (199) found that the BIA indices (reactance, phase angle and distance) were able to detect alterations in body composition earlier than anthropometry. The comparison of the values measured by BIA with previous data relating to the same patient, taking into account patient's height increase and fluid status, allows to identifying changes in body composition with a satisfactory level of accuracy.

Since none of the above mentioned methods can stand alone to define the nutritional status of children on PD, the use of a combination of them is reasonably advisable in the everyday practice. Edefonti et al. (200) recently proposed the so-called ABN score, that is based on nine anthropometry and BIA parameters: height, weight, BMI, MAMC, AMA, AFA, reactance, phase angle, and distance. These indices are expressed as SDS and elaborated by means of a dedicated software program to calculate an ABN score that may vary from 3 to 15. Distribution percentiles were calculated in healthy children, and an ABN score of 10.33 was established as the limit of normality (third percentile). A multicenter study on PD pediatric patients (200) showed that 48.8% of them had an ABN score lower than 10.33 as well as significantly lower levels of serum albumin, hemoglobin and creatinine. Therefore, the ABN score seems a valuable tool for monitoring nutritional status in children on chronic PD, even if further studies on a larger patient population are required to validate it.

The NKF-K/DOQI clinical practice guidelines for nutrition in children with chronic renal failure (191) recommend to including in the minimal nutritional assessment of dialysis patients an estimate of nutrient intake by dietary interview, diary or PNA calculation, serum albumin and a complete anthropometric and growth evaluation.

Nutritional requirements of children on PD: Current guidelines from the NKF-KDOQI program suggest the need to provide an energy intake of at least 100% of the recommended daily allowance (RDA) for children of the same gender and chronologic age (191). The cal-

ories derived from the absorption of glucose contained in the PD solutions should be taken into account while calculating daily total energy intake, since it can increase calorie intake by as much as 7–12 kcal/kg/day (201, 202). Dietary protein intake in PD pediatric patients should provide 100% of RDA plus an allowance for the loss of proteins and AA in the peritoneal effluent. Protein losses of 100–300 mg/kg/day have been reported in children on PD (195). Without an energy source nitrogen will not be effectively incorporated into protein (201, 202). In a study on 31 children on dialysis, growth velocity was negatively correlated with daily protein intake, while it positively correlated with total energy intake (203).

Dietary energy and protein prescription should be adjusted on the individual child's response by routine assessment of nutritional status. Moreover, energy and protein intake should be increased in the case of enhanced metabolic needs associated with acute illness or conditions of stress (184).

Poor appetite as well as early satiety, nausea or vomiting are quite common in children with ESRD and may contribute to an inadequate spontaneous oral intake, thus requiring nutritional interventions. The K/DOQI guidelines recommend that supplemental nutritional support be considered when a child does not have a normal height velocity or is failing to consume the RDA for energy and/or protein (191). Oral nutrient supplementation is obtained by using modular carbohydrate, fat and protein components which can be added to infant formulas, or provided in liquid or bar form to the older children. In patients who fail to meet their nutritional requirements by the oral route alone, enteral nasogastric or gastrostomy tube feeding should be considered. Nasogastric tubes are easy to insert, but must be periodically replaced and may cause vomiting. Gastrostomy tubes or buttons are usually well tolerated, but are also associated with emesis as well as with an increased risk of exit-site infection, leakage and peritonitis in patients on PD (120, 121, 204). Feeding dysfunction were reported in infants with severe chronic renal failure after long-term use of nasogastric tube (205), but oral feeding is successfully resumed in the majority of children after renal transplantation (206, 207).

Intraperitoneal AA supplementation has given controversial results in children on CAPD (94, 208, 209). APD with a combined intraperitoneal infusion of AA and glucose has been proposed as a means of providing an extra amount of readily available nitrogen and calories thanks to an adequate non protein calorie/nitrogen ratio. The use of this APD regimen in eight children for a period of 6 months (95) was associated with an improvement of anthropometric measures (MAMC, AMA, AFA), and of the weight for height percentile. No modification of nitrogen waste products was observed, while nitrogen balance significantly increased from 47 $\pm$ 33 mg/kg/day at baseline to 126 $\pm$ 74 mg/kg/day at 6 months. These data support the hypothesis that AA, when infused simultaneously with glucose, can be more efficiently utilized for protein synthesis, rather than catabolized for energy production. The main advantages of administering supplemental AA by the peritoneal route are the good compliance, without modification of the normal dialysis procedure, and that the supplementary nitrogen by AA carries no additional phosphorus. However, further studies are needed to confirm the potential of intraperitoneal AA infusion to improve the nutritional status of children on chronic PD.

The potential need for sodium, potassium, and phosphorus supplementation requires special attention. Young infants may have significant sodium loss in dialysate, as well as from their native kidneys as a result of underlying obstructive uropathy. Hypophosphatemia is especially common in association with the use of low phosphorus infant formulas (210), even if in any other condition there is the need to restrict phosphate dietary intake and to administer phosphate binders. Iron supplementation is usually needed, together with advice to increase dietary iron (183). Low dietary intake of zinc and copper is also reported (211), and their monitoring and, if necessary, supplementation is recommended by the K/DOQI guidelines (191).

Little prospective evidence is available to support supplementing water-soluble vitamins above the RDA or the dietary intakes for age (191, 212, 213). In adult PD patients, blood concentrations of such water soluble vitamins as vitamin C, vitamin B_6 and folic acid have been reported to be low, as a consequence of inadequate intake, peritoneal loss and increased needs. According to K/DOQI guidelines (191), supplements of these vitamins should be considered if dietary intake alone does not meet the RDA, if blood vitamin levels are below normal values, or if there is clinical evidence of deficiency (212, 213). If folic acid is given to lower plasma homocystein levels, which is considered an independent risk factor for cardiovascular disease, administered doses largely overcome daily requirement and dialysate loss of folate (214). Supplements of the fat-soluble vitamin A should be avoided, because elevated levels of vitamin A have been reported in children and can lead to hypercalcemia, anemia and hyperlipidemia (215).

Peritonitis

Despite a series of improvements in connection technology and procedure, peritonitis remains the single most common complications that occurrs in CPD children, and the most important cause of morbidity, patient hospitalization and technique failure (2, 216). Peritonitis annualized rate varies in different part of the world, from 0.68 in North America (69) to 0.58 in Italy (217), and to the exceptional rate of 0.31 found in Japanese children (218). The same registry data show an inverse relationship between patient's age and peritonitis rate; in North America the youngest patients (0–1 years) have an annualized rate of 0.86, while the adolescents have a rate of 0.61 (69).

Reductions in observed peritonitis rate have been reported in association with use of a two-cuff catheter with a swan neck tunnel and a downward oriented exit site; intravenous antibiotic prophylaxis at the time of catheter placement; the flush-before fill technique; and a well structured, prolonged PD training (58, 63, 64, 69, 219–221). The questions whether local prophylaxis, by antibiotic placement in the nares and/or at the exit-site, should be provided to all patients or only to those patients/parents who are determined to be carriers by screening, and whether the preferred agent should be mupirocin or gentamicin requires further studies (58, 68, 222, 223). Prompt diagnosis of exit-site/tunnel infections, based on objective criteria, and effective antibiotic therapy, chosen according to the susceptibilities of the cultured organism, are also important elements of peritonitis prevention measures (219). Finally, time to first peritonitis episode was reported to be shorter in CAPD versus APD children (69).

Recent data from the International Pediatric Peritonitis Registry (IPPR), an initiative designed to prospectively evaluate the clinical application of the pediatric treatment guidelines (66, 67, 219, 224), showed that 44% of 501 reported peritonitis episodes were caused by Gram-positive and 24% by Gram-negative bacteria, while 2% were fungal peritonitis and in 30% of the episodes the culture remained negative. Staphylococci were the most frequently isolated organisms, with *S. epidermidis*/other coagulase negative staphylococcal organisms accounting for 24% and *S. aureus* for 22%. In comparison with previous pediatric peritonitis surveys (108, 225), there have been an overall shift from Gram-positive to Gram-negative causative organisms, that largely reflects a decreased absolute frequency of Gram-positive peritonitis, secondary to improved connection technology and decreased touch contamination, as well as to the implementation of *S. aureus* prophylaxis programs (58, 219). However, the proportion of Gram-negative organisms varied widely between regions (66). The likelihood of acquiring Gram-negative peritonitis was inversely related to patient age and its clinical presentation is more severe (224). *Pseudomonas* was the most frequent organism simultaneously isolated from the peritoneal cavity and exit-site, and 70% of peritonitis episodes caused by this organism developed in association with patient's previous exposure to antibiotics (67). The high rate of culture negative peritonitis, that should not account for more than 20% of peritonitis episodes (219, 226), could be the result of incubation of insufficient effluents volumes, long transport times, or extreme ambient temperature; therefore, the diagnostic work-up of peritonitis should be performed according to a standardized protocol (219).

In the year 2000, a set of 15 pediatric-specific peritonitis treatment guidelines that incorporated the specific risk factors and unique clinical aspects of children were developed by an international committee of physician and nurses under the auspices of the International Society of Peritoneal Dialysis (219). These treatment recommendations were largely opinion based as a result of the limited evidence on the topic that exists in the pediatric nephrology and infectious disease literature. They were also influenced by the concern that had arisen regarding the potential development of vancomycin-resistant organisms and of ototoxicity, vestibular toxicity, and nephrotoxicity of aminoglycosides, with the possible loss of residual renal function. Empiric intraperitoneal antibiotic therapy consisted of a first-generation cephalosporin combined with ceftazidime for children without risk factors for severe infections, while for children with certain risk factors, a combined administration of a glycopeptide and ceftazidime was recommended. Recommendation for treatment of Gram-positive, Gram-negative, and fungal peritonitis, and indications for catheter removal and replacement were also given.

Based on the first available data collected by the IPPR on the results of the application of the guidelines into clinical care (66, 67, 224), the following issues should be considered while developing the upcoming set of new ISPD peritonitis treatment guidelines for children:

- Local variability of causative organisms and, even more, of antibiotic sensitivities; the choice of antibiotic for empiric therapy should take into account patient- and center-specific history of organisms and their sensitivities;
- Only 80% of Gram-negative organisms were sensitive to ceftazidime as compared with 88% aminoglycoside sensitivity; therefore, empiric antibiotic therapy rec-

ommendation should include the initial use of aminoglycosides with subsequent, prompt modification of antibiotic management based on culture and susceptibility results (monitoring of blood aminoglycoside concentration should be considered for therapy exceeding the first 72 h);
- Identification of initial treatment response as an independent predictor of final outcome strengthened the importance of adequate empiric therapy;
- The observed increased risk of *Pseudomonas* peritonitis associated with topical mupirocin, and frequent exit-site care raises doubts about the current concept of topical prophylaxis;
- Special consideration should be given to the management of culture negative peritonitis.

Relapsing peritonitis is defined as the recurrence of peritonitis with the same organism as in the preceding episode, according to antibiotic susceptibilities within four weeks of completion of antibiotic treatment (216, 219). The most common organisms involved are slime-forming coagulase-negative staphylococci, which can survive antibiotic treatment in fibrinous adhesions and biofilm matrix on the catheter surface, *S. aureus*, and *Pseudomonas aeruginosa*, which may cause subclinical microabscesses in the tunnel region or in intra-abdominal adhesions. Catheter decontamination by local instillation of fibrinolytic agents and high-dose antibiotics can be attempted in case of relapsing peritonitis with coagulase-negative staphylococci. Early catheter removal should be considered as part of relapsing peritonitis management when the origin of the re-infection can be localized to the catheter tunnel and in case of *Pseudomonas* infections.

Finally, sclerosing encapsulating peritonitis is a rare but extremely serious clinical entity characterized by the presence of continuous, intermittent, or recurrent bowel obstruction associated with gross thickening of the peritoneum (227). Although primarily diagnosed in adult patients, it may also occur in children, typically those who have been on CPD for more than 5 years (228, 229). The presence of peritoneal calcifications on abdominal computed tomography scan in association with ultrafiltration failure is highly suggestive of the diagnosis, and may be an indication to discontinue CPD.

Peritoneal Catheter Exit Site Infection

Peritoneal catheter exit site infection (ESI) represents an important risk factor for peritonitis, and frequently requires catheter removal and replacement, especially after its recurrence (219, 230).

Since the subjective evaluation of an exit site status may differ widely, the diagnosis of an ESI should be based on objective criteria by using an objective scoring system of such infectious symptoms as swelling, crust, redness, pain on pressure, and secretion (219, 225). It should be remembered that a positive culture is not required for the diagnosis of ESI, and a positive culture in a non-inflamed exit site indicates colonization, not infection. Accordingly, *Staphylococcus epidermidis* is frequently cultured, but is rarely causative of ESI. On the contrary, *Staphylococcus aureus* is the most frequent involved organism, followed by *Pseudomonas*, enterococci, *E. coli*, and *Klebsiella*. ESI due to *Pseudomonas* species has become a frequent predisposing factor for peritonitis, especially in patients with previous antibiotic exposure (67).

Antibiotic treatment of ESI should be based on the susceptibilities of the cultured organism, and close monitoring of clinical response should be applied, especially for ESI that are treated with an empiric therapy in the absence of a positive culture or Gram stain results (57, 219).

Nonocclusive sterile dressing should be changed daily (or twice daily) as long as discharge from the sinus tract is evident. Exuberant granulomatous tissue can be removed by cauterization with silver nitrate.

Duration of antibiotic treatment should be of 2–4 weeks and for at least 7 days following complete clinical resolution of the ESI (219). After this period of treatment, refractory exit site and/or subcutaneous tunnel infection, and/or the development of a peritonitis episode secondary to the same organism are indications to peritoneal catheter removal. Catheter replacement during the same surgical procedure is possible unless infection is severe with purulent discharge, and/or a tunnel infection is present.

Mechanical Complications of Peritoneal Dialysis

Pain: After the catheter insertion wound has healed, PD should be a painless procedure. Apart from peritonitis, the presence of pain on inflow can be due to dialysate that is not at body temperature, local reaction to the low pH of commercial dialysate, local irritation from rapid dialysate inflow when straight catheters are used, omental or adhesion trapping of the catheter tip, and excessive distension of the abdomen. Rectal or suprapubic pain is usually due to migration or faulty placement of the catheter tip too deep in the pelvis between the bladder and the rectum.

Peritoneal pain may be referred to the shoulder, and in this case it may be due to air under the diaphragm. Outflow pain can be seen early in the course of dialysis when the peritoneal cavity is drained too completely (catheter irritation in the dry abdomen). Abdominal pain may also be due to processes not directly related to PD procedure, such as peptic ulcer disease, pancreatitis, or diffuse peritoneal calcification.

Investigation of painful dialysis should include abdominal radiographs that provide a three-dimensional picture of catheter location. Constipation is a frequent contributing factor to both poor catheter drainage and painful dialysis. Prescription of bicarbonate or bicarbonate/lactate-buffered PD solutions results in the resolution of pain that is secondary to the low dialysate pH (99). Tidal PD may be successful in reducing infusion pain, or pain related to peritoneal calcifications (231).

Hemoperitoneum: The incidence of hemoperitoneum in children is likely lower than in adult PD patients, but is difficult to ascertain accurately (231). Italian registry data reported an incidence of 1.3% in 363 children of less than 15 years of age at dialysis initiation (232).

Hemoperitoneum can be observed in female PD patients in the reproductive age group. It can be mild and can occur either 2–3 days before the onset of menses, or as a mid-cycle bleeding. A more severe bleeding can be associated with the rupture of ovarian corpus luteum cysts.

Causes of hemoperitoneum that are not associated with the female reproductive apparatus are several and include (231): post.catheter insertion; coagulopathy or anticoagulant therapy; intra-abdominal malignancies; physical activity; pancreatitis; cholecystitis; gastric ulcer; rupture of liver or renal cysts; retroperitoenal bleeding; cytomegalovirus infection; slerosing peritonitis; post-radiation, following laparoscopic cholecystectomy, and post-colonoscopy. In children, trauma to the abdomen or the catheter is a relatively common cause of bleeding.

Abdominal hernias: The incidence of hernias is higher in pediatric than in adult PD patients, and is inversely proportional to age (114, 233, 234). Hernias can be incisional, umbilical, or inguinal. Incisional hernias occur more commonly when the catheter is placed through the midline instead of the paramedian approach through the rectus muscle. Inguinal hernias are more common in boys, become clinically evident at a younger age than in girls, and are frequently bilateral. A patent processus vaginalis can be found in up to 80–90% of newborns, and its incidence progressively falls with increasing patient age. With instillation of PD fluid in the abdomen, a patent processus vaginalis may progress to frank hernia quite early in the course of PD treatment (233). Laparoscopic inspection of the abdominal cavity at the time of catheter insertion allows to detect the presence of patent processus vaginalis and/or of inguinal hernias, and to conduct prophylactic herniorraphys, if needed (61, 62).

Since IPP for a given intraperitoneal fill volume presents marked interindividual variations, the optimum dwell volume to maximize dialysis clearances while reducing the risk of hernia cannot be easily defined, and should be personalized according to each individual patient characteristics (41, 235). Hernias left untreated tend to increase in size as PD treatment continues, and almost all hernias must eventually be repaired surgically. Before and for 1–2 weeks after repair, dwell volume should be reduced by up to 50%, and patient should receive APD (without or with small daytime dwell) if possible.

Hydrothorax: The incidence of hydrothorax is reported to be 2.8–3% in children on PD (236–238). Pleural effusion is usually unilateral (more commonly on the right), and can develop within hours to days of initiating PD, or may be delayed up to several months. It may be responsible for a gradual onset of inadequate UF, or it can dramatically present with dyspnea in the absence of volume overload. In many patients, fluid effusion occurs through a small, often congenital, diaphragmatic defect, while in others no communication can be demonstrated, and the etiology is postulated to be via sub-diaphragmatic lymphatics (231).

Management of hydrothorax is to stop PD temporarily, or to reduce dwell volumes, changing the patient to an NIPD regimen. Since recurrent hydrothorax may result in PD discontinuation and transfer to hemodialysis, surgical repair of diaphragmatic defects has been successfully performed in pediatric patients (237). Suggested treatments also include pleurodesis with tetracycline (239), talcum powder, or autologous blood.

Treatment Outcome

Long-Term Preservation of Peritoneal Membrane Function

The stability of the peritoneum as a dialyzing membrane is of particular interest because of the potential for the long-term need for CPD, especially for children going back to dialysis after renal transplant failure. In pediatrics, limited data are available on the long-term viability of the PM in terms of UF capacity and solute transport. Infection would seem to be a likely contributor to decreased long-term membrane function, but data are conflicting.

In a retrospective study in children, peritonitis caused by *Pseudomonas aeruginosa* or alpha streptococcal organisms was an independent predictor of membrane failure, defined as the severe loss of UF capacity (240). When two groups of children were assessed by means of solute D/P ratios derived during the performance of a PET conducted without standardized study mechanics, a decrease of the D/P creatinine ratio over time was observed in those with a history of peritonitis, while the D/D_0 glucose ratio was unchanged over time in both groups (241). The peritonitis history of the cohort of children studied to develop the pediatric PET curves was reanalyzed and revealed higher MTAC for glucose and creatinine in those who had previous episodes of peritonitis (29, 242). Similarly, in a pediatric prospective evaluation of the PM as assessed by PET testing over a mean of 20 months between studies, there were no changes in MTAC for glucose or creatinine over time. However, in the children with a history of peritonitis, the MTAC values increased (243). The role of the duration of CPD treatment was studied in a group of children who did not experienced peritonitis; no remarkable change was found for D/P creatinine or D/D_0 glucose during the first 24 months of CPD but thereafter, D/P creatinine increased gradually and D/D_0 decreased gradually (244). Finally, in one of the few studies evaluating peritoneal biopsy material from children, a reduced density of mesothelial microvilli presumably related to the duration of CPD treatment and the presence of peritonitis was documented, as was fibrosis of the PM. However, the latter did not correlate with the frequency of peritonitis or the duration of CPD therapy (245).

Standard PD solutions with low pH and containing high concentrations of lactate and glucose have been demonstrated to negatively affect the peritoneal membrane integrity, mesothelial cell viability, residential peritoneal cells and also to inhibit phagocytic functions. An increasing body of experimental evidence supports the idea that the peritoneal hypervascularization and fibrosis observed in long-term PD are causally related to the acute and chronic toxicity of conventional PD solutions (74–76, 78–80, 82, 98). The potential of dialysis regimens based on more biocompatible low-GDP, pH-neutral PD solutions to slow down peritoneal damage associated with long-term CPD treatment should be evaluated in extended clinical trials.

Health-Related Quality of Life of Children on Peritoneal Dialysis

Health-related quality of life (QOL) refers to the measure of a patient's functioning well-being, and general health perception in each of three domains: physical, psychological, and social (246). In turn, a patient's QOL is an important indicator of the effectiveness of the medical therapy he or she receives (247). Children on chronic dialysis have specific challenges such as physical changes related to illness and to dialytic access, chronic dependence on medical equipment to sustain life, maintaining a restricted dietary and fluid regimen, time away from school and peers, and the knowledge that they will live their whole lives with the recurrent cycle of dialysis and transplantation (248, 249). The ability to attend school every day may be one of the most beneficial features of CPD for children. Data from the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) 2007 Report showed that among school-age patients maintained on CPD, 78% were attending school full-time and 9% part-time, compared to 53 and 28% of children on hemodialysis (69). Very few restrictions to physical activities are necessary. This philosophy also facilitates the ability of these children to participate in summer camping experiences that are commonly coordinated by dialysis team personal (250). Nevertheless, data suggesting a decline in the QOL over time for adult patients on CPD mandate the performance of formal investigations of QOL in pediatric patients to better evaluate this critical aspect of patient care (247–249). So far, the results of the studies describing health-related QOL in children with ESRD are often conflicting, reporting either significantly lower QOL scores than in healthy controls (251, 252), or scores similar to that of the general population despite lower physical functioning (253). No difference was noted between hemodialysis and PD patients (251). A potential limitation of those studies was that the instruments used were not ESRD specific and cannot yield detailed information for the specific factors that impact on QOL in children with ESRD. Recently, an ESRD-specific health-related QOL instrument has been proposed (254); initial data support the feasibility, reliability, and validity of the PedsQL 3.0 ESRD Module, but additional validation testing is still in course to further establish the psychometric properties of this instrument.

Patient and Technique Survival

Technique failure: Data on termination of CPD therapy are available from national registries' reports. A NAPRTCS study in 2003 (255) showed that 194 (20%) of the 997 incident PD patients transitioned to hemodialysis over the 6-year study period. Excessive infections largely represented the main reason for CPD failure (43%), followed by inadequate UF or solute clearance, patient/family choice, and dialysis access failure. Similar data have been reported by the Italian Registry in a study on a smaller group of patients (n = 295) that had started their first course of CPD from 1989 to 2000; among 44 (15%) patients who were switched to hemodialysis, peritonitis and/or catheter exit-site infection accounted for up to 66% of technique failures (2). In both reports, patients showed a slow and steady increase in CPD termination over time as they transitioned to hemodialysis. In the Italian study (2), actuarial technique survival of CPD patients resulted significantly higher than that of 160 patients on hemodialysis; PM transport failure was reported in 6 out of 44 cases of CPD abandonment (13.6%), and was registered after a mean of 46 months of CPD (range 7–102 months). A higher percentage of transfer to hemodialysis due to UF failure and/or underdialysis (27% of total transitions) was reported by the Japanese Registry (256). This figure might be explained by the fact that in Japan, where cadaveric transplantation is rare, the percentage of children maintained on CPD for longer than 5 years was 24.8% compared with 5.9% in North America (227) and 7.1% in Italy (2). In a single center study, Gulati et al. found the likehood of technique failure to be increased in PD patients with hypoalbuminemia 1 month after dialysis initiation (257).

Patient mortality: Dialysis in children carries a significantly higher mortality rate than that for the age-matched healthy population, and also than that for children who have received a renal transplant (258–260). An overall mortality rate between 5.8 (2) and 8.5% (108) was noted for the pediatric CPD population. An assessment related to age of NAPRTCS data (4) revealed a mortality rate of 14.9% for patients younger than 5 years at dialysis initiation, which was significantly greater then the mortality rate of 5.7 and 4.5% for patients in the 6–12 and older than 13 years age groups. The mortality rate of patients 0–1 years and 2–5 years was 18.9 and 8.3% with 1- and 3-year post-initiation mortality rates of 15.3 and 32.5% for the youngest patients, and 5.8 and 13.7% for the 2- to 5-year age group. Data from the Italian pediatric dialysis registry showed that actuarial patient survival was significantly lower in the group of children of less than 5 years at the start of CPD than in the group of 5- to 15-year-old patients (2). These reports, as well as the data collected from children in Japan (261), confirm the high-risk status of the infant and young child with ESRD. At the same time, the outcome of dialysis initiated in the neonatal period (<1 month of age) is comparable to that of dialysis in children <2 years of age (113).

The results of several studies confirmed the importance of non-renal co-morbidities, such as multi-system involvement from inherited disorders, prematurity, pulmonary hypoplasia, severe development delay, congenital cardiac disease, inherited metabolic disorders, malignancy, or chronic renal disease following overwhelming infection with multi-organ damage, as significant risk factors for increased mortality in infants and young children as well as in older CPD pediatric patients (2, 115, 117, 118).

Differences in the rate of mortality with the type of dialysis were reported by McDonald et al. (259), that found an overall mortality rate of 4.8 (95% confidence interval, 4.2–5.6) per 100 patient-years among children receiving hemodialysis, and of 5.9 (95% confidence interval, 4.9–7.2) per 100 patient-years among those receiving PD. On the other hand, the survival rates of two groups of age-matched patients (5–15 years of age at the start of dialysis) treated in Italy either with CPD (n = 193) or with hemodialysis (n = 160) were not significantly different (2). Similarly, Wong et al. (143) did not find any difference in adjusted relative risk of death for 1,723 pediatric patients (<18 years at dialysis initiation) treated with HD versus PD.

Peritoneal membrane function was reported to be an independent predictor of patient survival, with patients with high transporter status and, therefore, decreased UF capacity demonstrating worse outcomes (260, 262, 263).

The primary reported causes of death for pediatric PD patients of all ages are cardiovascular disease and infection. Cardiovascular disease is increasingly recognized as a major cause of morbidity, and a life-limiting problem in young patients with chronic kidney disease, giving a 1,000-times higher risk of cardiovascular death than in healthy age-adjusted population (264, 265). Indeed, long-term dialysis may be associated with an increasing incidence of cardiovascular diseases, as a result of prolonged exposure to cardiovascular risk factors, such as hypertension, dyslipidemia, the presence of a pro-inflammatory state and endothelial dysfunction, and vascular calcification due to calcium phosphorus metabolism disturbances (266). Pediatric PD registries reported cardiovascular disease as the cause of patient's death in 20.9% (108), 43% (260), and 58,8% (2) of cases.

Infection is the second leading cause of death for PD pediatric patients, accounting for 17.6% (2) to 27.9% (108) of cases, and is the primary cause of death for patients 0–5 years of age (108). Warady et al. (224) reported 5 (0.9%) lethal outcomes in the follow-up of 548 episodes of peritonitis that were recorded in 392 patients by the International Pediatric Peritonitis Registry; three patients died from uncontrolled hypervolemia and one from venous access complications when switched to hemodialysis, while in one case the cause of death remained unclear. Broad categories for cause of death are currently reported by dialysis registries and multicenter studies, while a better characterization of these diagnoses would be necessary in order to attempt preventive measures.

73 Hemodialysis

Lesley Rees

Chronic dialysis, including both hemodialysis and peritoneal dialysis, is now technically feasible in children of all ages, including infants (1). In countries with active pediatric transplant programs, however, it is not used as the first choice of chronic renal replacement therapy, as most pediatric nephrologists would aim for pre-emptive transplants for their patients. There are exceptions to this, including the neonate, in whom a period of dialysis may be necessary until adequate size for transplant is reached, the child needing urgent treatment because of presentation in end-stage kidney disease, and children needing native nephrectomies, or other corrective surgery pre-transplant. This means that at any time, around 20% of the pediatric end-stage kidney disease population is being dialyzed (2, 3). Only a minority of children are able to escape a period of dialysis altogether, either while waiting for their first transplant or because of subsequent graft failure (4).

The choice of dialysis modality varies from country to country. In Europe, peritoneal dialysis is the commonest modality choice, with a ratio of 2:1 peritoneal dialysis to hemodialysis (2, 5), whereas in the US this ratio is reversed (3). Of course, many children will need to switch modality, usually from peritoneal to hemodialysis because of peritoneal membrane failure. Total numbers of children on hemodialysis throughout the world are small, for example being only 70 in the UK (6) and around 900 in the US at any time (3). Despite these international differences in choice of dialysis modality, there are some general rules, including the avoidance of chronic hemodialysis in the infant due to difficulties with vascular access, and the use of hemodialysis when there is technique failure, intrabdominal pathology or social difficulties that preclude peritoneal dialysis. Because of this bias towards the use of hemodialysis in preference to peritoneal dialysis in the more complicated patient, it might be expected that outcome would be inferior in hemodialysis patients, but there is no evidence to suggest a difference either in morbidity (7) or transplant outcome (8). There is good evidence, however, that the longer the duration of dialysis, the greater the risk of cardiovascular disease and premature death, regardless of the dialysis modality (9).

There is no prescribed GFR at which children should start dialysis. The optimum time varies between individual patients and requires assessment not only of renal function, fluid status and biochemical abnormalities but also of wellbeing, both physical and psychosocial. Some children can be managed extremely successfully with diet and medications, and continue to remain well with good growth for prolonged periods with very poor renal function. This is particularly true for young children with structural renal abnormalities, in whom renal function can remain stable for many years, and who often continue to produce large volumes of urine. However, uremic symptoms frequently begin when the GFR falls below 15 ml/min/1.73m^2. In the US, registry data (USRDS) shows that the mean GFR of 4,808 children who were initiated on dialysis was 8.2 + /−4.1 ml/min/1.73m^2; 49.6%, had an estimated GFR greater than 10 ml/min/1.73m^2 and 7.3% an estimated GFR less than 5 ml/min/1.73m^2 (10).

What is clear is that the care of children on hemodialysis requires input from a large multidisciplinary team including pediatric nephrologists, renal nurses and dieticians, transplant surgeons, urologists, interventional radiologists, anesthetists, pharmacists, play specialists, schools teachers, psychologists and social workers, all of whom need the special skills necessary to treat such children. Availability of hospital school teachers and liaison with local schools is particularly important for children on hemodialysis, who spend so much of their time at the hospital. Many children with CKD have associated comorbidities, which can include congenital abnormalities in other organ systems. This amount of expertise can only be provided by bringing patients together in specialist pediatric nephrology centers generally sited in major cities. This inevitably means that some families have to travel long distances to obtain the best possible care for their child, placing particular stresses on the family with a child on hemodialysis.

Principles of Hemodialysis

In the normal kidney, water is removed from the blood by ultrafiltration (UF) and solutes by convection. Solutes of

molecular weight below 40,000 daltons are able to pass freely across the glomerular basement membrane allowing the passage of low molecular weight molecules and retention of larger molecules such as plasma proteins. The purpose of hemodialysis is to mimic the role of the kidney, removing waste products and prescribed quantities of solutes and fluids that have accumulated between dialysis sessions. The semi-permeable membrane in the dialyzer allows the passage of water and small molecular weight molecules and inhibits the movement of larger molecules. Solute transfer (clearance) occurs by diffusion and convection and water is removed by ultrafiltration.

Diffusion

Diffusion is the movement of a solute down a concentration gradient. The rate of diffusion of a solute is inversely proportional to its molecular weight and directly proportional to the temperature of the solution, in this case the dialysate. It is also affected by the electrical charge of the solute. The hemodialysis membrane itself will also affect rate of diffusion; its permeability is a reflection of its thickness and the number of pores in it and their density, and diffusion across it will also be affected by its surface area. The transmembrane concentration gradient is maintained and maximized by high flow rates of blood and dialysate in opposite directions (countercurrent). As well as being the main mechanism for the removal of solutes, diffusion is also responsible for the replenishment of bicarbonate. As they are buffered in plasma, hydrogen ions are in low concentration so are not readily removed by dialysis. Fluid can stagnate on either side of the dialysis membrane, and this is referred to as 'unstirred' fluid, which can decrease diffusion. This can be minimized by maintaining high flow rates, and by dialyzer design. Clearly the dialysate only comes into contact with the intravascular compartment, so, although rapid equilibrium can take place with circulating solutes, predominantly intracellular solutes such as phosphate take time to move into the blood and clearance is less effective. Furthermore, protein bound solutes will not be removed.

Ultrafiltration (UF)

Ultrafiltration is the process whereby water is moved across the membrane by convective flow down an osmotic gradient or a pressure gradient, which is created by generating a transmembrane pressure (TMP) within the dialysate compartment by the dialysis effluent pump. Large molecular weight molecules are removed better by convection than diffusion. The net rate of ultrafiltration is affected by the surface area, structure and thickness of the dialyzer, blood flow rate and the transmembrane hydrostatic pressure and osmotic pressure.

Convection

Convection (solute drag) is the passive movement of solute 'dragged' by water moving down an osmotic or pressure gradient. It is independent of the concentration gradient but dependent on the ultraflitration rate and the sieving properties (coefficient) of the dialyzer, i.e., if the molecular weight of the molecule is such that it is not held back and sieving does not occur, it is swept across the membrane by the ultrafiltrated water.

Mass Transfer

Removal of toxins depends on their distribution in the body compartments: those in the intravascular space will be rapidly removed, but those that are predominantly intracellular will need time to move into the intravascular space as concentration gradients change. Molecular size will also affect removal: *Table 73-1* shows the definitions of uremic retention solutes by molecular weight, and their method of removal during dialysis. Uremic

Table 73-1

Definitions of uremic retention solutes by molecular weight (MW), and their method of removal during dialysis

Solute	Molecular weight	Example (MW)	Method of removal
Small solutes	<500	Urea (60), creatinine (113)	Diffusion
Middle molecules	300–5000	Vitamin B12 (1355)	Diffusion/convection
Low Molecular Weight proteins	5000–50000	β2-microglobulin (11800)	Diffusion/convection
Large proteins	>50000	Albumin (60000)	Convection

retention solutes such as urea and creatinine are rapidly removed. Large numbers of biochemically active, potentially toxic 'middle molecules' have been identified. Many are peptides that affect many organs and may contribute to the symptoms and morbidity of uremia, such as poor appetite, anemia, inflammation and cardiovascular disease. Well over 100 have been identified. The best known is ß 2-microglobulin, which causes dialysis related amyloid. Recently interest has focused on the dinucleotide polyphosphates, structural variants of angiotensin II, interleukin-18, p-cresylsulfate and the guanidines. Large pore dialyzers and hemodiafiltration may improve their removal by increasing convection. Some protein bound middle molecules may also be toxic, one example being leptin, and are particularly difficult to remove by any dialysis technique (11).

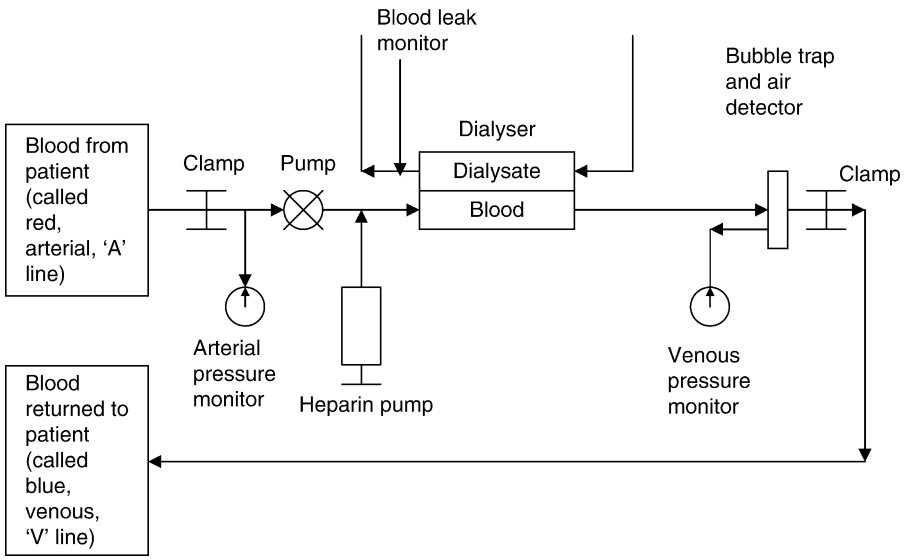
The HD Machine, the HD Circuit, Dialysate, Water and Dialyzers

The Hemodialysis Machine and Blood and Dialysate Circuits (Fig 73-1)

There are two circuits, the blood circuit and the dialysate circuit, that run in opposite directions, separated by the semi-permeable membrane of the dialyzer. The blood circuit includes lines through which blood is pumped from the patient to the dialyzer, and then back to the patient. Conventionally, the lines taking blood from the patient are called arterial, 'red' lines, and those returning blood to the patient are the venous, 'blue' lines. Pressures in the blood lines are monitored in the 'arterial' segment between the blood pump and the dialyzer, and in the 'venous' segment at the venous bubble trap and air detector, so that vascular access problems are indicated by arterial or venous pressure alarms. Low arterial pressure alarms indicate that there is an insufficient blood flow reaching the blood pump. This is commonly referred to as 'sucking' and is usually a result of poor access position in the vessel. Arterial pressure between 150 and 200 mmHg limits trauma to the vascular endothelium. A low venous pressure alarm also indicates poor blood flow. A high venous pressure alarm indicates that there is an occlusion to the flow of returning blood. It is due either to poor access position, fistula stenosis or the presence of clot formation. If an alarm is activated, the blood pump is stopped and the lines are clamped. Precise occlusion of tubing by the pump is vital in order to prevent backflow, foaming and hemolysis. There is a separate system for delivery of anticoagulant to the blood circuit before the dialyzer. Sample ports in either side of the circuit allow blood samples to be obtained whilst the child is on the machine (Fig 73-1).

The dialysate circuit is separated from the blood circuit by the semi-permeable membrane of the dialyzer.

Figure 73-1
The blood and dialysate circuits.



Dialysate is run in the opposite direction to the blood to maintain the concentration gradient between the blood and the dialysate. There is a blood leak detector (to detect rupture of the dialyzer fibers with leakage of blood into the dialysate) just distal to the dialyzer. The machine is able to further purify the water supply using reverse osmosis, and to prepare the dialysate by mixing the water with prescribed quantities of electrolytes and bicarbonate.

There are certain specific features that are necessary in a pediatric hemodialysis machine: it must be capable of low blood flow speeds, and be able to use lines of varying blood volumes and to measure and remove very small amounts of fluid so that it can be used even in infants. A volumetric fluid removal system allows accurate fluid removal. It does this by measuring the inflow and outflow volumes from the dialyzer so that ultrafiltrate volume is measured directly, allowing the automatic calculation and application of a pressure across the dialysis membrane, the transmembrane pressure (TMP) and prescribed fluid removal throughout the dialysis session. New machines have systems for continuous on-line monitoring of the hematocrit and therefore blood volume, oxygen saturation, blood pressure and pulse and for Kt/V urea.

Dialysate

Dialysate is prepared during the dialysis session. Sodium, potassium, magnesium, calcium, chloride, dextrose and bicarbonate are added to the purified water by the machine and their concentrations can be varied within certain prescribed limits. They are mixed and proportionated by the dialysis machine. Standard settings are 138–140 mmol/l for sodium, 2 mmol/l for potassium, 1.25–1.75 mmol/l for calcium, 0.5–1 mmol/l for magnesium and glucose 1g/l. The dialysis machine monitors the electrical conductivity of the dialysis solution to ensure the correct proportion of water to concentrate is occurring before it is delivered to the hemodialyzer. Bicarbonate is used as a buffer. The bicarbonate preparation has a separate acidic component to prevent precipitation of calcium and magnesium carbonate and is added by a second proportionating pump. Inevitably with time there will be deposition of calcium and magnesium salts, so the dialysate system needs daily decalcification. The dialysate is warmed before delivery to the dialyzer. Temperature selection is between 34.5 and 37.5 °C. Lower temperatures are associated with less hypotensive events, but diffusion is increased at higher temperatures. Typical dialysate flow is 500 mls/min (range 300–800 ml/min).

Water

Although water from the mains supply is satisfactory for human consumption, it is not suitable for dialysis. At each session the patient's blood is directly exposed to 120 liters of water and all its potentially hazardous contaminants, including particles, dissolved substances such as ions, trace elements, organic substances, nitrogen compounds, microorganisms and their toxins. Therefore filters of progressively smaller sizes to remove particulate matter, activated carbon for chlorine and chloramines and water softeners to remove calcium and magnesium must be in the water circuit before the water reaches the dialyzer. Finally, a reverse osmosis unit purifies softened filtered water before it is of a quality suitable for dialysate production by removing residual particulates, dissolved inorganic and organic substances, microorganisms and toxins.

There are detailed standards for the design of the water delivery circuit and its management, and for all aspects of water purity (12, 13). Water quality is defined as 'pure' or 'ultrapure' (*Table 73-2*). 'Pure' water is adequate for conventional dialysis, but ultrapure water is preferable, and is essential for high flux dialyzers, when back filtration can occur, and in high flow hemofiltration, when large volumes of replacement fluids are used (see below). Even very low levels of endotoxin in the water can cause cytokine mediated inflammation which, in turn, may contribute to the increased risk for cardiovascular disease seen in patients on dialysis (14). Water quality standards need to be maintained and regularly checked to ensure bacterial contamination and mineral content are within acceptable limits. Microbiological contamination of the delivered water should comply with published recommendations and acceptable levels of all other recognized contaminants have also been defined (12, 13).

Table 73-2

European Pharmacopoeia definitions for the upper limit of water quality (12)

	Bacterial growth (cfu/mL)	Endotoxin (EU/mL)	Cytokine induction
Mains water	200	5	+
Regular water	100	0.25	+
Ultra-pure	0.01	0.03	–
Sterile	10^{-6}	0.03	–

The Hemodialyzer

The hemodialyzer is composed of two compartments, one for blood and one for dialysate, which are separated by the semi-permeable membrane. A capillary (hollow fiber) configuration achieves the maximal membrane surface area over which blood and dialysate make contact in a relatively low fill volume with low compliance.

The membrane can be composed of modified cellulose or a synthetic material. Unmodified cellulose membranes are the least biocompatible, and may cause activation of complement and leucocytes and a severe allergic reaction within minutes of starting dialysis. Sterilizing solutions (e.g., ethylene oxide) may also cause allergic reactions.

Each type of dialyzer has an ultrafiltration coefficient (KUf), which describes its ability to remove water. For example, a KUf of 2.0 means that 2 ml/hr of UF will occur for each mmHg of TMP at a blood flow rate of 200 ml/min. KUf depends on the surface area of the dialyzer as well as its membrane characteristics. Dialyzers with KUfs of less than 10 are referred to a low-flux and those with a rate of 15–60 ml/hr/mmHg are called high flux. Synthetic membranes tend to be high-flux.

Solute transport properties of dialysate membranes are expressed as the mass transfer-area coefficient (KoA). Dialyzers of usual efficiency (for removal of small solutes) have a KoA of 300–500; high-efficiency dialyzers may have a KoA of more than 700. Clearance values, generally achieved at blood flow of 200 ml/min, for creatinine, urea, vitamin B_{12} and phosphate are given for all dialyzers in the manufacturer's specification sheet. Clearance of a solute is inversely proportional to the molecular size; most dialyzers allow the passage of solutes of up to 5–10,000 Daltons.

Dialyzers may be sterilized with irradiation, heat or ethylene oxide. The latter is particularly likely to cause reactions. Priming the circuit with 1–2 L of saline to expel air and prepare the capillaries for use will also help flush out remaining ethylene oxide and other soluble compounds in the circuit, which may be toxic or cause allergic reactions at the commencement of dialysis.

Factors Affecting the Dialysis Prescription

Types of Dialysis

Conventional hemodialysis uses a low flux (small pore size) membrane and solute removal is primarily by diffusion. High efficiency hemodialysis refers to a more rapid removal of urea, K^+ and other small solutes. This is achieved by using a low flux membrane with a high efficiency (KoA) for removal of small solutes. It is also achieved by using a larger surface area membrane and a high blood flow. Because conventional dialysis is principally diffusive based, even when using high flux dialyzers it is limited in clearing middle-sized molecules (MW 200–20,000), which are better removed by convection.

High flux hemodialysis utilizes high flux (large pore size) membranes. It is more efficient in removing solutes that are substantially larger than urea (middle and large molecules such as vitamin B_{12} and ß-2 microglobulin respectively), but may not be more efficient than conventional hemodialysis in removing small solutes. Better clearance of ß-2-microglobulin may reduce the risk of amyloidosis. A more effective form of dialysis is to superimpose convection upon standard diffusive blood purification using hemodiafiltration. It is possible to use a high flux hemofilter to ultrafilter up to 30% of the blood volume passing through it. The desired volume of replacement fluid is then infused into the blood circuit. Ultrapure dialysate is necessary. Care must be taken that excess fluid removal does not occur, so a volumetrically controlled machine is essential. High flux dialyzers should be considered in larger children who are likely to be on hemodialysis for more than a few years and those showing evidence of amyloidosis. For other children the balance of evidence favors low flux synthetic and modified cellulose over unmodified cellulose membranes (15).

Online hemodiafiltration machines are available which generate ultrapure dialysis fluid. High flux membranes (Kuf $\geq$ 50ml/h/mmHg, solute permeability KoA urea >600, ß-2 microglobulin >60 ml/min) are necessary. The surface area of the membrane needs to be large and blood flows high, which restricts use in small children as the UF volume is limited by the blood flow rate. In this technique, up to 20 L of 'extra' fluid, over and above the patients' interdialytic fluid gain is removed through the dialyzer and an equal volume of physiological 'replacement' fluid is returned to the blood either before (predilutional) or after (post-dilutional) the dialyzer. If the replacement fluid is given before the dialyzer the UF can be even as high as the blood flow rate. If it is given after the dialyzer the volume that can be removed is less, because of hemoconcentration and the risk of clotting in the dialyzer.

Size of the Extracorporeal Circuit

The lines and the hemodialyzer are selected on the basis that the child can tolerate 8% −10% of their total blood

Table 73-3

Examples of the volumes of lines available for dialysis according to the size of the patient

Patient size	Venous (mls)	Arterial (mls)	Total (mls)
Mini-neonatal (<6 kg)	21	8	29
Neonatal (6–12 kg)	22	18	40
Pediatric	42	30	72
Adult	70	62	132

volume (TBV, 80 ml/kg estimated dry weight) in the extracorporeal circuit. For example, a child weighing 10kg has a TBV of 800mls (10 × 80 ml), therefore the extracorporeal circuit can be 64–80 mls. The total volume of the lines and hemodialyzer therefore must not exceed 64–80 mls. There are lines that are made in a variety of sizes by different companies. Some examples are shown in *Table 73-3*.

Lines are primed with saline. However, in the very young, even the smallest circuit may exceed the safe extracorporeal volume. In this situation, the circuit must be primed with blood. The blood is not washed back into the child at the completion of dialysis to prevent hemoconcentration. Obviously this is not ideal because the repeated prescription of blood increases the risks of infection and HLA sensitization, with its consequent difficulties for transplantation. This is one of the reasons for opting for peritoneal dialysis in infants.

The dialyzer is selected on the basis of its surface area and the priming volume. Roughly, the surface area should be equal to but not exceed that of the child's. At present, hemodialyzer surface areas range from 0.25 m^2 up to 1.7 m^2 and above. The greater the surface area, the greater the clearance of water and solutes.

Frequency of Sessions

It is conventional to dialyze for 4 hours 3 times a week. Middle molecules diffuse slowly into dialysis fluid, so treatment times that are less than this have a proportionately greater deleterious effect on their clearance than other molecules. This may have implications for the long-term health of dialysis patients. There is increasing evidence that, even in children, more intensified dialysis is beneficial. This can vary from long intermittent hemodialysis ranging from 6 to 8 hours 3–7 times per week, or short frequent hemodialysis for 2–3 hours 5–7 times per week, and can be carried out in center or at home. Intensified dialysis has been reported from several pediatric centers, but, for resource reasons, is usually reserved for those on conventional dialysis who would benefit from longer hours because of chronic fluid overload or hyperphosphatemia, because of poor growth, or for infants, whose predominantly liquid diet requires removal of relatively large fluid volumes. However, some children and families are not prepared to commit to the increased time spent on the dialysis machine. Home hemodialysis is possible for children who have adequate housing and a family member who is prepared to take on the responsibility. Reports demonstrate better phosphate and BP control, with many patients being able to come off all their medications, improved appetite and growth, and, despite increased time spent dialyzing, improved quality of life (16–20).

Blood Pump Speeds

The speed at which the blood is pumped out of the child and around the circuit is calculated as the equivalent of their extracorporeal volume total i.e., up to body wt (kg) × 8 ml/min. Thus, the 10kg child, with an extracorporeal circuit of 64–80 mls can have blood speeds of up to 80 ml/minute. The blood pump flow rate is a very important determinant of solute clearance, allowing maximum diffusion and convection.

Estimation of Dry Weight and Fluid Removal

The aim is to end the hemodialysis session with the child at their target weight, which is the weight below which the child will become symptomatically hypotensive. However, estimation of dry weight can be difficult and needs to be reassessed at least monthly, and more often in very small children, in particular infants, to allow for growth. It can only be determined by careful but persistent fluid removal to achieve a normal BP after dialysis. The child who is always hypertensive is likely to be above their dry weight; antihypertensives can usually be discarded when this is achieved. However, attainment of dry weight with conventional three times a week dialysis can be difficult in the child who has high interdialytic weight gains requiring large UF volumes. Much better results have been obtained with daily dialysis, with most children no longer needing antihypertensives at all (16–18).

The amount of fluid to be removed is calculated by the weight gain since the previous session (assuming dry

weight had been achieved then), the volume of saline required for the 'washback', and any drinks to be consumed during the session. The hemodialysis machine will adjust the TMP accordingly, depending on the time (in hours), and the venous pressure (which is affected by the blood speed, and peripheral resistance), to give an hourly UF rate.

The greater the TMP that is set, the greater the amount of fluid that will be removed from the child, and the more likely it is that the child will feel unwell. High UF rates whilst diffusion is occurring are not well tolerated. To counteract this, isolated UF can be performed, in which the flow of dialysate is halted, therefore dialysis and hence diffusion ceases so that the osmolality of the intravascular space is maintained. This allows more fluid to be removed more quickly from the child and is useful when there are large volumes requiring ultrafiltration. As dialysis does not occur during isolated UF, the length of time on the dialysis machine will increase.

The amount each child will tolerate losing per hour varies but 10 ml/kg/hr is a safe starting point. Up to 600 ml/hr can be removed in children weighing > 40 kg who are consistently volume overloaded. No more than 5% of body weight should be removed in one session, or 0.2 ml/kg/min.

Fluid loss (UF) can only be achieved if the fluid is in the vascular space. As the vascular space empties, refilling must occur from the other compartments, to allow ultrafiltration to continue. The child will show signs of hypovolemia if ultrafiltration (from hemodialysis or isolated UF) continues unchecked. If hypovolemia occurs, the UF rate should be decreased and the child given a drink or bolus of saline to correct hypotension, if necessary. Many patients collapse having had no prior warning of feeling unwell, therefore close monitoring of blood pressure and other observations (including peripheral temperatures) is important during isolated UF. However, chronic hemodialysis children are often able to recognize the early warning signs and can prevent such episodes.

Another way to prevent intravascular volume depletion due to slow refilling from the extravascular space is to vary the concentration of the dialysate sodium throughout the course of the session. The machine can be programmed to deliver a sodium concentration higher than that of the plasma at the beginning of the session so that sodium diffuses into the plasma and balances the change in osmolality caused by diffusive urea removal. The sodium concentration in the dialysate is then progressively reduced. This is important as leaving the patient with a high plasma sodium will stimulate thirst between sessions. Although this technique, which is has been called sodium ramping, profiling or modeling, helps intradialytic hypotension, the danger is that there is inadequate sodium removal, hence contributing to chronic fluid overload and hypertension.

Newer machines are able to monitor circulating blood volume by determining changes in hematocrit. It has been shown that a decrease in blood volume of >8% in the first 90 minutes or >4% thereafter is likely to lead to hypovolemia (21).

The Electrolyte Concentrations in the Dialysate and Blood Biochemistry

Sodium – the dialysate sodium must be within 10mmols of the child's plasma sodium to avoid disequilibrium. The sodium dialysate concentrate level can be altered on the machine within preset parameters. If it is set below that of plasma, then more sodium and therefore water will be removed, although this may cause intradialytic hypotension. Sodium modeling can improve these symptoms but may results in more salt and water retention (see above).

Potassium – the standard dialysate potassium is 1–2 mmol/l. Adjustment may be needed for children with low plasma potassium levels or in those requiring a long dialysis session, when a dialysate potassium of 3–3.5 mmol/l can be used; if the child has a very high potassium, a zero-potassium dialysate can be used for a short period of time, before reverting to the standard potassium dialysate. There is a danger of severe hypokalemia if a zero-potassium is used for too long. The use of serum potassium monitoring equipment (ionometer) facilitates the management of hyperkalemia.

Bicarbonate – the dialysate level can be adjusted on the machine, within preset limits. The level is usually around 35 mmol/l.

Calcium – the standard dialysate level is 1.75 mmol/l. This does, however, result in an influx of calcium into the patient and a rise in serum calcium post dialysis. Dialysates containing calcium concentrations from 1.25 mmol/l (which is equivalent to the blood in the normal child) are available, and can be used in situations of hypercalcemia in order to remove calcium from the patient.

Phosphate – clearly there is no need for phosphate in dialysate. After an initial fall in plasma levels during the first 1–2 hours, movement from the intracellular compartment is slow, so very little is removed thereafter and levels are back to 80% of pre-treatment values by 12 hours post dialysis so that dietary phosphate restriction and phosphate binders are almost always necessary. Long

dialysis sessions or frequent short sessions result in the best phosphate clearance.

Urea – care needs to be taken if serum urea levels are over 40 mmol/l because a rapid reduction in serum levels can result in disequilibrium syndrome (see complications). Mannitol can be infused (1G/kg) during hemodialysis, through the bubble trap to counteract this. The best way to avoid disequilibrium is to keep the dialysis session short, at less than 2 hours.

Creatinine – will fall rapidly during the session as there is none in the dialysate, but it will rebound and rise rapidly following the end of dialysis.

Administration of Blood Products

Albumin – a low serum albumin will result in edema and difficulty in removing excess fluid. If the child is oligoanuric 20% albumin should only be given when on dialysis, as the resultant fluid shifts can cause pulmonary edema. It must be given in small boluses through the arterial infusion port at the beginning of the session, to allow time for movement of fluid from the extravascular into the intravascular compartment.

Blood – blood should only be required to prime the lines if the volume of the dialyzer and lines exceeds the safe extracorporeal circuit volume i.e., in infants. This blood prime is not washed back into the child at the end of the session. If blood is required for the treatment of anemia, the calculation for number of mls of blood required = weight (kg) × 3 × number of grams that the Hb is to be raised. The blood is infused in small boluses at the beginning of dialysis, through the arterial infusion port, so that potassium will be dialyzed out.

Resulting fluid shifts with blood or albumin may lead to the need for ultrafiltration towards the end of the session.

Anticoagulation

Heparin is the standard anti-coagulant used during hemodialysis. It can be infused slowly and continuously throughout the session to prevent the blood clotting in the circuit. It is given at a rate of 5–50 units/kg/hour through the arterial side of the circuit. Some units use low molecular weight heparin, given as a bolus of 1mg/kg at the beginning of the session.

The circuit needs to be constantly monitored for the formation of clots. If suspected, a bolus of 50–100 ml of saline flushed through the circuit with the arterial lines clamped may reveal clot formation. Clots may form when there is slow blood flow because of access problems, a raised hematocrit, a long period of ultrafiltration as the hematocrit is raised as fluid is removed, and inadequate heparinization. If a circuit clots off completely, the blood in the lines is lost. This will not have a detrimental effect on the child, providing the extracorporeal rules have been observed. However, UF will need to be increased to remove the extra saline. The heparin dose may be increased and/or a bolus of heparin given. The venous side of the blood circuit can be changed during the session to prevent total clotting. If clotting problems persist, long-term aspirin and/or dipyridamole or warfarin or treatment may need to be considered.

The heparin infusion needs to be stopped 30 minutes prior to the end of dialysis if a fistula is being used, to prevent bleeding after the needles have been removed. The heparin dose will need to be adjusted in the patient with abnormal clotting or low platelets. Heparin free dialysis can be used, for example if dialysis is taking place just before surgery. In this situation the circuit can be primed with heparinised saline (3000–5000 u/l) as this will bind to the dialyzer. The dialyzer must then be flushed before connecting to the patient. The dialyzer must be checked regularly for signs of clotting. High blood flows will help prevent clotting. Heparin may induce thrombocytopenia in some patients, which resolves on stopping it.

Complications of HD

Intradialytic Hypotension

The commonest complication of hemodialysis during the treatment is hypotension. Hypotension occurs because of the movement of fluid from the extracellular to the intracellular space due to a decrease in serum osmolality, impaired sympathetic activity, vasodilation in response to warm dialysate, and splanchnic pooling of blood while eating during dialysis. Hypotension may also be due to excessive UF requirements because of a high interdialytic salt and water intake or to the use of anti-hypertensive agents, although it is usual to omit the dose of antihypertensive medication on the morning before dialysis.

The treatment is the prescription of normal saline 5 ml/kg and cessation of UF. It is important to reassess the dry weight in case this has been underestimated, and also the daily salt intake and fluid allowance, which may be too high so that too much fluid needs to be removed. Another cause is the use of a dialysate sodium lower then plasma, as this leads to hyponatremia in blood returning

to the patient and, therefore, the movement of water into cells from the intravascular compartment. Sodium modeling (use of decreasing dialysate sodium concentration during a session, see above) to optimize vascular refilling; UF separate from dialysis; and on-line blood volume monitoring may help patients with recurrent hypotension. Symptoms such as nausea, vomiting, itching, pains and cramps are also common, frequently occurring during hypotensive episodes.

Disequilibrium

A less common complication is disequilibrium, which is due to the plasma urea falling more rapidly than brain cell urea with the resultant movement of water into brain cells by osmosis. It is particularly likely to occur if the plasma urea is high at the start of dialysis, especially when the patient is initiating a course of hemodialysis. Disequilibrium can present with headache, nausea, dizziness and progress to disorientation, seizures and coma. Symptoms resolve spontaneously but if severe can be treated with intravenous mannitol using 1 gm per 10% of body weight. Disequilibrium should be avoided by assuring that the fall of urea during treatment is not too rapid or too great. In some units, mannitol is infused during the beginning of the treatment or evenly throughout it to prevent a rapid change in serum osmolality.

Hemolysis

Hemolysis may occur due to overheating, contamination or hypotonicity of dialysate, kinking of the lines or a malfunctioning pump. Dialysis should be stopped and the potassium should be checked immediately. Hemolysis may continue for some hours. It presents with pains and nausea and a dark appearance to the venous blood.

Air Embolism

Air may enter the circuit and this is particularly likely to happen before the blood pump as there the blood is under negative pressure. Air embolism, however, is rare, as air detectors will clamp the return lines. One ml/kg may be fatal. Air embolism presents with fitting or coma in the upright patient, and chest symptoms if recumbent. Treatment is to clamp the lines, stop the pump, put the patient head down in the left lateral position, give 100% oxygen (to enhance nitrogen diffusion out of air bubbles) and resuscitation as necessary. Air may need to be aspirated from the ventricle.

Anaphylaxis

An anaphylactic reaction to the dialyzer can occur at any time, but is more common after first use ('First use syndrome'). It occurs soon after the start of dialysis and disappears with dialyzer reuse and predialysis rinsing. It causes hypotension (or sometimes hypertension), angioedema, pulmonary symptoms, chest and abdominal pain, vomiting, fever, urticaria, and pruritus and results from activation of plasma complement or kinin systems by the dialysis membrane, or the release of noxious materials which may have contaminated the dialyzer during manufacture or the sterilization process (e.g., with ethylene oxide). Dialysis must be stopped and blood should not be returned to the patient. Normal saline for hypotension, epinephrine subcutaneously or intramuscularly (1:1000 concentration) and/or hydrocortisone may be necessary. Symptoms may be milder, for example presenting with just urticaria, which can be treated with an antihistamine or hydrocortisone. Severe reactions necessitate a change of dialyzer.

Amyloidosis

Dialysis-related amyloidosis is unusual in childhood but can occur in those who have been dialyzed for a long time; symptoms are typically first reported 7–10 years after commencing hemodialysis, although tissue accumulation of dialysis-related amyloid can be demonstrated much earlier. It is a disabling, progressive condition caused by the polymerization within tendons, synovium, and other tissues of beta-2-microglobulin, a large (molecular weight (MW) 11,600) molecule, which is released into the circulation as a result of normal cell turnover but is not excreted in renal failure and is not removed by cellulose membranes. Exposure to bioincompatible membranes may increase beta-2-microglobulin generation.

Vascular Access

Good vascular access is crucial to the success of dialysis, and is more important than any other factor. The best form of access is an arterio-venous (a-v) fistula, otherwise

a line that is tunnelled subcutaneously is used, or, rarely, shunts or grafts (22). The life of a fistula is superior to a tunnelled line; over two thirds are still functioning after 4 years, whereas reports of the survival of tunnelled lines vary from 30–85% at one year (23). Vascular access problems are indicated by the arterial and venous pressure alarms. Low arterial pressure alarms indicate that there is an insufficient blood flow reaching the blood pump. This is commonly referred to as 'sucking' and is usually a result of poor access position in the vessel. A low venous pressure alarm also indicates poor blood flow. A high venous pressure alarm indicates that there is an occlusion to the flow of returning blood. It is due either to poor access position, fistula stenosis or the presence of clot formation. Tissue Plasminogen Activator, TPA, can be safely used to dissolve suspected clots in the lumen of central lines (24, 25). A solution of 1mg/ml is instilled in the dead space of the catheter and left for at least one hour, preferably overnight or between dialysis sessions. A randomized, controlled trial has shown that TPA is significantly more effective than heparin in preventing clot formation in central hemodialysis lines (26). TPA should be completely aspirated before the line is next used for dialysis. This is important, not only because of its anticoagulant properties, but also because of its phosphate content, so that a spuriously high phosphate level can be obtained if it is not thoroughly removed before blood sampling (27).

Access Recirculation

Adequacy of dialysis may be compromised if the dialyzed blood that returns from the venous line to the circulation is directly taken back into the arterial line to the blood circuit to be redialyzed. This is called recirculation. It can occur if the distance between the site of blood withdrawal and return is small, if there is abnormal blood flow through a fistula, if the needles are wrongly placed or during single needle/lumen dialysis. Recirculation can be measured and expressed as a percentage, which should be less than 10%. If the result is higher than this, then the fistula needs to be assessed with venography for the presence of a venous stenosis.

The procedure for assessment of recirculation is simple. Arterial (A) and venous (V) samples are taken from the access lines 30 minutes after the start of dialysis (without UF). The pump speed is then halved and then switched off. The arterial line is clamped above the port and a sample taken from it (S). Alternatively, this sample can be obtained from the other arm or other site of the patient. The dialysis is restarted, and the urea in the arterial (A), venous (V) and systemic (S) circulations is measured.

$$\text{recirculation } (\%) = \frac{S - A}{S - V} \times 100$$

Arterio-Venous (a-v) Fistule

Children on short-term dialysis (e.g., awaiting a living-related transplant) may elect to be dialyzed via a tunnelled line. An arterio-venous (a-v) fistula is the preferred method of vascular access in children on chronic hemodialysis because of the decreased risk of infection (in comparison to a line); line infection is the most important cause of vessel stenosis (28). Preservation of vessels is particularly important in children, who have a lifetime of renal replacement therapy ahead of them. An a-v fistula can be used in children who are able to co-operate with needling; education and play therapy may enable this even in small children and those with needle phobia. A fistula is created by surgically anastomosing an artery to a vein, so that the higher pressure within the vein causes it to expand to allow large enough needles to be inserted to enable the high blood flows required for dialysis. It may be created at the wrist (radio cephalic or radio basilic), the elbow (brachio-cephalic) or by basilic vein transposition to create a brachio-basilic fistula (29). It is preferable to start distally at the wrist to preserve more proximal vessels for future use. Clearly the larger the vessels the greater the chance of success, but some groups are able to operate on even very young children using microsurgery (30).

The success of a fistula depends on adequate run off distal to the anastomosis. Any distal vessel stenosis will result in high venous pressures and oedema of the arm. For this reason, the child who has had previous central lines will need upper limb venography to establish patency of the arm and central vessels (31). A thrombosed subclavian vein will preclude a fistula being created in that arm as venous return may be obstructed, although balloon dilatation or stenting of the stenosis may be possible. Ultrasound examination of the proximal vessels can be misleading and should not be relied upon because collaterals may be mistaken for patent upper limb vessels, and the veins cannot be easily seen under the clavicle. It is preferable to select the non-dominant arm for the fistula if at all possible.

A fistula should be created at least 6 weeks before it is needed as it takes some time to mature. Prior to surgery, the child must be well hydrated, or left at slightly above dry weight if already on dialysis and antihypertensives

adjusted to decrease the chances of clot formation due to low circulating blood volume or BP. Post operatively the fistula needs to be checked regularly for the presence of a thrill, which, if lost, needs to be assessed urgently as clots can be removed by catheter, surgery or locally instilled TPA but only if this is undertaken as soon as possible (32). Clot removal after 48 hours is rarely successful in restoring flow. It is usual to increase the child's target weight for the next week or so after the surgery. Prophylactic antiplatelet doses of aspirin (1–5 mg/kg/day) may reduce the risk of clotting.

When the fistula is 'mature' for use, needles should be placed proximal to the fistula. It may be necessary to start with a single needle, but it is usual to use two needles, with the arterial needle distal to the venous one, which should be as far away as possible. The arterial needle can point in either direction, but the venous needle should be towards the heart. The needle sites should be changed as repeated needling in the same place will cause weakness of the vessel wall and aneurysm formation. The use of anesthetic creams have reduced the physical and psychological trauma associated with fistula use in children.

Fistula Stenosis and Other Complications

Arterial and venous pressure alarms suggest the presence of stenosis, which can occur in the arterial or venous side or in the fistula itself. Sites of stenosis occur where there is turbulent blood flow, which causes intimal hyperplasia of the vessel wall. The commonest place for stenosis is within a few centimeters of the fistula, just distal to the anastomosis. Low blood flow and arterial pressure with 'sucking' suggests stenosis at the inflow to the fistula. High venous pressure suggests stenosis distal to the fistula. Slow blood flow through the fistula predisposes to thrombosis.

In the first instance, much can be determined by clinical examination of the fistula. A palpable thrill is present if the blood flow through the fistula is >450 ml/min. In the case of a stenosis, the thrill is distal to the pressure drop. With a basilic vein fistula stenosis, the thrill will be further up the arm towards the heart. Another common site of stenosis is where the cephalic vein goes through the clavipectoral fascia. The vein may then be pulsatile all the way up the arm.

Doppler ultrasound studies can be used to examine flow, and can be followed by tests of recirculation which if >10–15% suggests venous stenosis. Arteriography is necessary to examine the arterial flow into the fistula and a fistulogram, also using Xray contrast, is used to demonstrate the blood flow into and out of the fistula. It is usual practice to anticipate the formation of stenosis by screening with Doppler US every 6 months. The risk of clotting has been found to increase when flows are <650 ml/min, but the finding of a downward trend in blood flow is important. If a stenosis is >50% of vessel diameter it needs angioplasty, stenting or surgical repair (33). A stenosis at the clavipectoral junction is much harder to dilate than a basilic vein stenosis.

Other complications include ischemia of the hand or 'steal syndrome', and pseudoaneurysm, due to communication of the fistula with an enclosed area of surrounding tissue. The latter may lead to prolonged bleeding and needs to be repaired. Infection of the fistula can also occur. It is also possible for the fistula to become too large with unsightly forearm veins and flows that are too high, predisposing to heart failure.

Grafts and Shunts

These are less commonly used in children, and shunts are really a last resort. An artificial conduit can be inserted between an artery and vein subcutaneously (graft) where it can be needled, or may be brought out externally (shunt) where the loop can be disconnected to attach to dialysis lines. Grafts and shunts are, like a-v fistule, also liable to stenosis (particularly at the anastomosis site) and to clotting. Stenosis can be suspected by the presence of a thrill, which would not normally be present. Although 1, 3 and 5 year survival are similar to a-v fistule, at 90%, 50–60% and 40% respectively, the need for surgical intervention is higher in grafts (34). They also have an increased risk over fistule of infection, which can be difficult to eradicate. Shunts carry the further risk of disconnection and blood loss.

Tunnelled Lines

Tunnelled lines are used in children who are too young for an a-v fistula, or in children who are not expected to be on dialysis long; e.g., when a parent is being prepared as a donor. They can be inserted so that the tip is in the right atrium using US guidance (35). The success rate is superior to non-tunnelled lines but inferior to an a-v fistula (34). The internal jugular veins are the first choice. The presence of a line, particularly if it becomes infected, can lead to vessel stenosis, so the subclavian vein should not be used if possible as a subclavian vein stenosis would preclude the use of that arm for future fistula formation.

Table 73-4

Catheter size and siting according to the weight of the child

Size of child	Catheter size	Siting
Neonate	5Fr (single lumen)	Femoral vein
3–6 kg	7Fr	Internal or external jugular or femoral vein (preferably not subclavian)
6–15 kg	8Fr	
>15 kg	9Fr	
>30 kg	≥ 10Fr	

The bigger the gauge of the access the faster the blood flow that can be obtained. The majority of vascular access is either 7–8 FG or 11FG in differing lengths (12 or 18 cm or 12 to 19 cm for smaller or bigger gauges respectively) and is chosen according to the size of the child and their vessels. Some examples are shown in *Table 73-4*.

Most lines are dual lumen, allowing a continuous flow of blood around the circuit. However, hemodialysis can also be achieved using single lumen access. In very small children single lumen access may be more appropriate as the lumen of the catheter will be larger and therefore the flow that can be obtained through it is relatively greater, as flow is proportional to the fourth power of the radius. In order to obtain two directional blood flows with a single lumen line, the dialysis circuit has to be modified. This can be achieved by the double-pump method, using two blood pumps which pump alternately, or by using a single pump which pumps intermittently, using gravity to let blood flow back in to the child. Disadvantages of the single lumen catheter are that an expansion chamber is necessary in the circuit to allow for the pressure changes and this increases the volume of the blood circuit; also the superior blood flow rates are compromised by a greater degree of recirculation.

Infection in Vascular Catheters

Infection in vascular catheters may be at the exit site, in the subcutaneous tunnel or in the catheter. The development of biofilm within the catheter makes bacterial eradication particularly difficult. Line sepsis may present as a rigor soon after starting dialysis, fever with raised CRP or septicemic collapse. The factors increasing the risk of catheter infection include: exit site and/or tunnel infection or contamination of the hub, failure of aseptic technique, frequent need to access the catheter during dialysis and long duration of use, use of non-tunnelled rather than tunnelled lines, immunosuppression, hypoalbuminemia, diabetes and nasal and cutaneous colonization with Staphylococcus aureus. Post dialysis heparin or alteplase into the line decreases infection risk by decreasing clot formation, which predisposes to infection (26).

Treatment of Catheter Related Infection (*Fig 73-2*) (36)

Figure 73-2 demonstrates the steps in the management of exit site, tunnel and catheter infections. Exit site infection presents with erythema and tenderness within 2 cm of the exit site, and discharge from the exit site itself. Great care should be taken to immobilize the catheter as far as possible as movement within the exit site encourages infection. There are different types of dressings but there is no evidence to suggest superiority of any particular type. It is important to check for carriage of Staph aureus so the exit should be swabbed every month, along with 3 monthly nasal swabs. Staph aureus carriage can be treated with topical exit site and nasal mupirocin for 5 days every month. If there are clinical signs of infection then swabs should be taken, daily cleaning instituted and oral antibiotics commenced. If there is no response after 4 weeks, removal of the catheter with replacement after 24–48 hours is warranted.

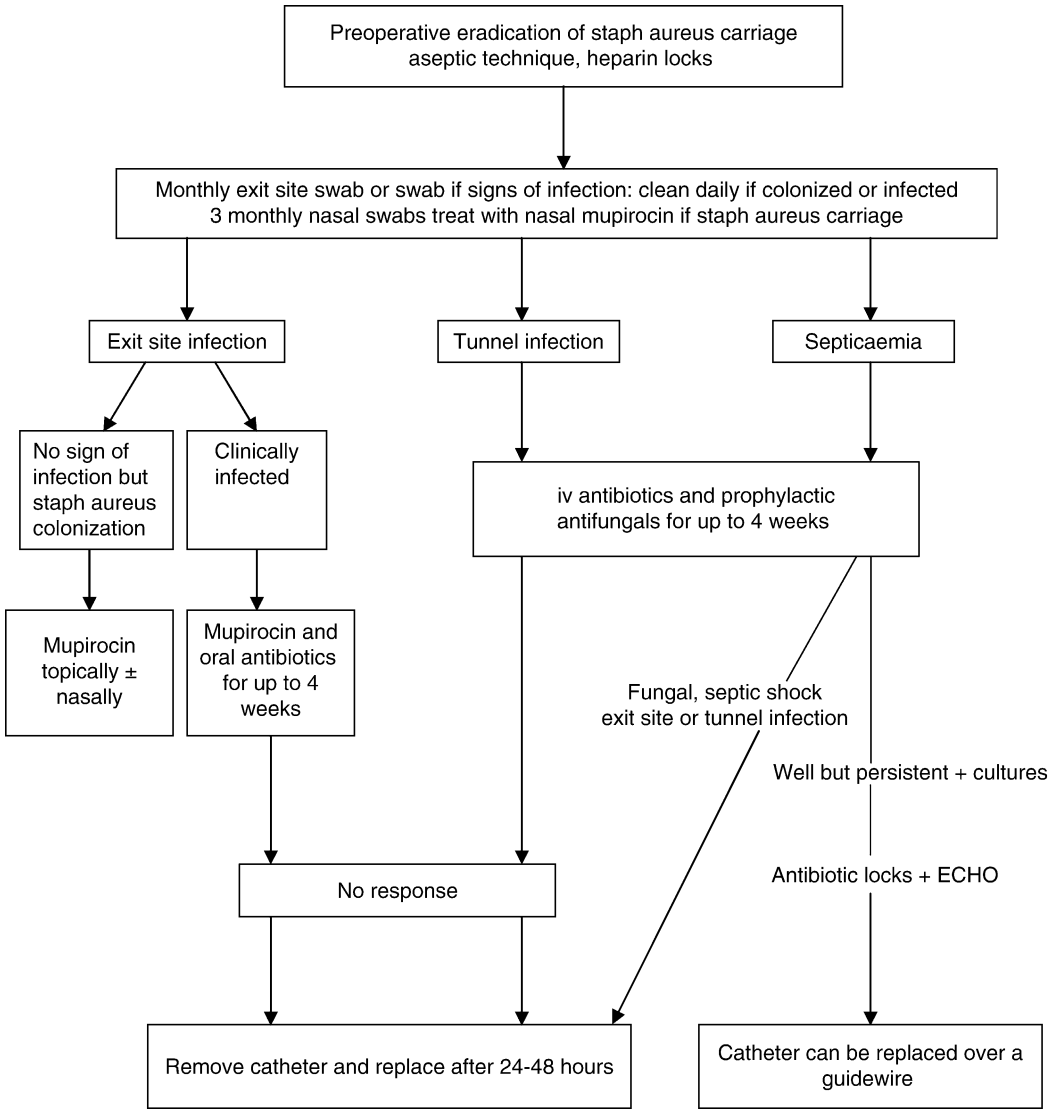
Exit site infection can spread down the subcutaneous tunnel of the catheter, when in addition there will be tenderness, erythema and induration along the subcutaneous tract >2cm from the exit site. A tunnel infection is much more difficult to eradicate, and may track into the blood stream, resulting in septicemia. Intravenous antibiotic therapy is warranted, along with antifungal prophylaxis, and if there is no response after 4 weeks, the catheter should be removed and replaced after 24–48 hours.

The catheter itself may become colonized, so that there is repeated growth of the same organism on blood drawn through the line, but without signs of sepsis. Antibiotic locks may be helpful in eradication of line colonization (37). Antibiotic locks use an antibiotic to which the organism is sensitive and are instilled into each lumen after dialysis. The antibiotic is then removed at the start of the next dialysis session. With ongoing positive growths but no systemic symptoms, it has been shown to be safe and effective to replace the line over a guidewire, as long as antibiotics have been started and there is no tunnel or exit site infection (38). This is preferable as it means that the access point in the vessel is not lost.

The presence of septicemia, bacteremia or fungemia with at least one positive culture of the same organism from the catheter and a peripheral vein, clinical signs of

Figure 73-2

Prevention and treatment of hemodialysis catheter related infection.



infection (fever, hypotension), no other cause of infection and a raised C-reactive protein indicate catheter infection. Antibiotics need to be started immediately, but in the presence of septic shock, the catheter should be removed.

Septicemia treatment is usually started with Vancomycin in units with a significant incidence of MRSA. If there is severe systemic illness, two antibiotics are used. An example could be to initially use both intravenous vancomycin and ciprofloxacin until the gram stain/culture are available, when the treatment can be modified accordingly. However, antibiotic policy will depend on local resistance patterns, which are changing, with the emergence of more resistant organisms being seen (39). It is wise to use antifungal prophylaxis when broad-spectrum antibiotics are used. Antibiotic therapy (intravenous) would usually be continued for 2 weeks, but may need to be longer if there is fungal infection. If there is persistent fever, endocarditis is a possibility so an echocardiogram should be performed.

If there is septicemia the catheter should be removed, particularly if the infection is occurring in a non-tunnelled line or one that is no longer being used or if there is septic shock. If the septicemia is caused by a fungus or if the same organism as is infecting the exit

site or tunnel, if there is persistence of fever after 48 hours of therapy or ongoing positive blood cultures, then the chances of clearing the infection are low and again this is an indication to remove the line.

Dialysis Adequacy

The concept of dialysis adequacy was introduced in order to define the dialysis prescription (blood flow rate, dialyzer clearance, treatment time) required to minimize patient morbidity and mortality. Obviously such correlations can only be made in adults, as large numbers of patients with significant complications are required for statistical analysis. However, attempts have been made to correlate adequacy with features such as hospitalization rates in children (40).

The clearance of urea has been selected as the basis for all the calculations of dialysis adequacy, although of course urea represents small molecule clearance and not clearance of other larger molecules that move more slowly across the dialysis membrane. Dialysis adequacy is defined as the minimum amount of urea clearance and nutritional intake that prevents adverse outcomes. The figures that have been calculated for dialysis adequacy represent a minimum acceptable level; determination and calculation of what is optimal, i.e., the dose above which no further improvement in outcome occurs, is less easy to achieve. Some hemodialysis machines provide on-line calculation of urea clearance.

Urea is evenly distributed throughout the body fluid compartments. During dialysis, urea is removed from the extracellular space. However, movement from the intracellular space into the intravascular compartment occurs more slowly so that there is a difference in levels between the two compartments that persists for an hour or so after dialysis. If this difference is not taken into account in calculations, then the amount of urea removed is overestimated and the dialysis dose appears greater than it is. Thus calculations of adequacy may be either 'single pool' or 'double pool'. As well as urea clearance, nutritional status is also assessed as part of the adequacy measurement. The interdialytic accumulation of urea reflects protein catabolism so that, in a steady state, the protein catabolic rate is equivalent to the amount of protein ingested and can be taken, therefore, as an indication of nutritional status. When calculations of dialysis adequacy use both urea clearance and patient nutritional status (i.e., urea generation rate), this is called urea kinetic modeling (UKM).

The amount of urea that is removed during a hemodialysis session is affected by the urea clearance coefficient of the dialyzer, the pre and post treatment blood urea, the treatment time, the total body water, the UF, residual renal function and the interdialytic urea generation rate. Therefore these factors are fed into the UKM equation to obtain the measure of dialysis adequacy. UKM requires samples over two sessions, and is less commonly used because of its complexity

A more common assessment of dialysis adequacy is Kt/V, where K is the urea clearance of dialyzer, t the treatment time and V is the volume of distribution (0.6 × body weight in kg). It can be predicted from the pre and post dialysis urea, weight loss and duration of dialysis. For the single pool Kt/V the blood urea can be obtained straight after the end of the dialysis session. Although urea rises rapidly post dialysis, it is impractical to wait to take the post dialysis blood urea sample until after urea rebound is complete, which takes approximately one hour; mathematical calculations can be used to allow for this (double pool Kt/V). Methods of standardization of post-dialysis sampling that aim to reduce variability in the timing of blood sampling are called the slow-flow and stop-flow methods. The stop dialysate flow, when dialysate flow is stopped but the blood pump is kept running for five minutes, is the most commonly used, but gives higher results. There are several different formula available for the calculation. Most would use the Daugirdas II formula:

$$\mathrm{Kt/V} = -\ln(\mathrm{C_1/C_0} - 0.008^{*}\mathrm{t}) + (4 - 3.5^{*}\mathrm{C_1/C_0})^{*}\mathrm{UF/W}$$

Where C_0 and C_1 = pre and post dialysis blood urea (mg/dl) respectively, t = time (hrs), UF = ultrafiltration volume (Kg), W = post dialysis weight

The simplest way to assess dialysis adequacy is the urea reduction ratio (URR), which is calculated as follows:

$$\frac{\text{Pre dialysis urea} - \text{post dialysis urea}}{\text{pre dialysis urea}} \times 100\%$$

URR underestimates the dose of dialysis as it does not take into account convective losses. Recirculation, on the other hand, will give a falsely high Kt/V as the urea result will be underestimated. Residual renal function is an extremely important contributor to urea clearance and should be included in all calculations of dialysis adequacy. However, 24 hour urine collections may be extremely difficult to obtain in children on dialysis with poor urine output.

Measures of adequacy in children have not been defined, but consensus standards propose that they should be equal to or better than adult recommendations

of > 1.2 for Kt/V and > 65% for URR (23). One study in children demonstrated an improvement in the risk for hospitalization up to a Kt/V of that level, but above 1.4, no further improvement occurred (40). However, the improvement in all aspects of patient well-being with daily or frequent short hemodialysis suggests that a higher Kt/V is likely to be better (16–20).

The normalized protein catabolic rate (nPCR) is a reflection of protein intake, and is more sensitive and specific than albumin as a marker of nutritional status because many processes unrelated to nutrition can affect albumin concentrations. nPCR may be useful for monthly nutrition status in adolescent patients receiving maintenance HD: adolescents with nPCR less than 1 g/kg/d may be at increased risk for subsequent weight loss (41).

Of equal, or perhaps even more importance in the assessment of dialysis adequacy is the well being of the patient, which can be objectively assessed in children by height and weight gain. Control of BP, anemia, acidosis and bone disease are also part of the overall assessment of dialysis adequacy.

Blood-Borne Viruses

Hemodialysis unit patients and staff are at risk from blood-borne viruses, particularly hepatitis B, hepatitis C and HIV. Transmission may result from percutaneous exposure to blood or other fluids, via droplets or through contaminated equipment. Universal precautions should be followed as for all patients, and the entire dialysis circuit should be decontaminated after each use by heat or chemical disinfection. External surfaces should be wiped over between patients using a chlorine based disinfectant.

All staff and patients should be immunized and/or show immunity to hepatitis B. It is preferable to administer the vaccine before dialysis is necessary for the best chance of a good response. The vaccine can be given at any age at intervals of 0, 1 and 6 months. An accelerated course can be used so that the third dose is given 2 months after the first dose (i.e., doses at 0, 1 and 3 months and a booster dose at 12 months). The anterolateral thigh (intramuscular) is the preferred site in infants and young children. The deltoid muscle is the preferred site in older children. It should not be injected into the buttock as vaccine efficacy is reduced.

If the antibody level is <10 iu/L 2–3 months after the last vaccine, the course of vaccine is repeated and hepatitis B surface antigen (HBsAg) is measured 3 monthly until there is a satisfactory antibody response (>10 iu/L 2–3 months after last vaccine). If antibody levels are >10 iu/L, then it can be assumed that immunity is sufficient and antibody levels can be measured annually, with booster doses as necessary. The usual dose of hepatitis B vaccine is doubled for patients on dialysis. If a patient is exposed to hepatitis B or has been to an endemic area, such as the Middle and Far East, and has antibody titers < 100 iu/L in the last year, then hepatitis B immunoglobulin and vaccine should be given by intramuscular injection, and the patient should be screened weekly for HbsAg for 3 months. Patients who are or who might become HbsAg positive should be dialyzed in a separate room with their own machine.

Although screening for hepatitis C or HIV is not universally recommended at present, many units do so. Hepatitis C can be spread nosocomially, so a separate room is recommended for the patient who is hepatitis C positive, but a dedicated machine is not necessary. HIV is less infectious but the same criteria apply. Testing for hepatitis C antibody every 3 monthly and for HIV annually is a reasonable compromise (42).

Nutrition in Hemodialysis

Nutrition is fully covered in chapters 12 and 68, but there are some nutritional issues that are specific to hemodialysis. Malnutrition is common in children on hemodialysis, and is associated with increased mortality (43). Both UK (44) and US (45) guidelines advise an increase in the recommended protein intake for age in children on hemodialysis, varying from around 20% in very small children to up to 50% in older ones. This increase is not as large as that recommended for children on peritoneal dialysis. It is to allow for losses of amino acids into the dialysate, which depend on their plasma concentrations and molecular weights.

It may be difficult to achieve an adequate intake of protein without dietary supplementation, which can be administered either orally or enterally. Studies of the effect of dietary supplementation on nutritional status and growth have given variable results (46), so because of this, some centers have explored the use of intradialytic parenteral nutrition (IDPN). There are only four studies of IDPN during hemodialysis in children, and these involve very small numbers so it is difficult to draw conclusions about its effectiveness (44, 46).

There may be specific deficiencies occurring in patients on hemodialysis, one of which is carnitine. Carnitine has a MW of 162 daltons and is water-soluble and unbound. It may therefore be cleared by dialysis, and deficiency in dialysis patients has been reported to be

common. The biologically active L-carnitine plays an important role in fatty acid metabolism and energy production in cardiac and skeletal muscles, and carnitine deficiency has been associated with poor response to erythropoietin, intradialytic hypotension, cardiomyopathy and muscle weakness. However, studies of the benefits of carnitine supplementation have been inconsistent (47).

CKD-MBD

Abnormal mineral metabolism and altered bone structure and composition is almost universal in children on dialysis (48) and bone related problems which adversely affect quality of life, including bone and joint pain and fractures, are the most common complaint in young adult survivors of pediatric renal failure programs (9). It is not only morbidity but also mortality that are affected by abnormal mineral metabolism: the association with extra skeletal, and in particular vascular calcification, is strongly suggestive of a causative link, although the pathological mechanisms are yet to be unraveled. In order to reflect the complex issues surrounding these areas it has been suggested that CKD-mineral and bone disorder (CKD-MBD) should be used as an encompassing definition (49).

Current management of CKD-MBD hinges on the concept of an optimum range for plasma parathyroid hormone (PTH) levels, which is a range that maintains normal bone turnover without increasing the risk for ectopic calcification. The risks of extra skeletal calcification are thought to be increased with both low and high bone turnover because both types result in high plasma calcium and phosphate: low bone turnover because of the inability of bone to buffer changes in plasma calcium and phosphate, and high turnover because high PTH levels mobilize calcium and phosphate from bone, increase tubular reabsorption of calcium, and promote gut absorption of calcium and phosphate by hydroxylation of 25, OHD3. PTH itself is thought to be an independent risk factor for myocardial fibrosis, arteriolar thickening, and hypertension (50). There are detailed guidelines from the US (KDOQI) (51) and Europe (52) on PTH management, and all aspects of calcium, phosphate and vitamin D control in order to achieve these aims. European recommendations for children on dialysis are that the plasma PTH should be kept at 2 to 3 times the upper limit of normal and KDOQI sets higher levels of 3 to 5 times the upper limit of normal. However, there is limited evidence for these recommendations (50), and review of the evidence that is available suggests that high PTH levels are associated with abnormalities of vascular structure and function and vascular calcification, and indeed these vascular abnormalities are less common in children on dialysis with PTH levels $< 2\times$ the upper limit of normal (53). What is known is that hyperphosphatemia and a high calcium $\times$ phosphate product are toxic to the vasculature and should be prevented. It is also known that both too much and too little intake of calcium is bad, and that high PTH levels, and plasma levels of vitamin D that are either too low or too high, are associated with increased cardiovascular morbidity (54). This is discussed further in the chapter on renal bone disease.

Drug Prescribing in Patients on Hemodialysis

Great care needs to be taken when prescribing for children with renal failure. Drug handling in hemodialysis is made more complicated by reduced bioavailability due to abnormal gastrointestinal motility, nausea, vomiting and anorexia. The drug volume of distribution may be altered by the presence of volume overload (edema and ascites) and reduced if there is volume depletion or muscle wasting. Protein binding is altered by acidosis, malnutrition and inflammation. This can result in high levels of the free drug despite normal blood levels (e.g., phenytoin).

Many drugs will be cleared by hemodialysis. This depends on the molecular weight of the drug and the degree of protein binding. Drugs with a large volume of distribution are generally lipid soluble and not confined to the circulation; they are not well cleared by hemodialysis. It is logical to administer drugs known to be cleared by hemodialysis immediately at the end of the dialysis session.

There is a tendency within units to administer drugs intravenously during the hemodialysis process. This is particularly helpful with iron therapy, which is often poorly tolerated orally. However, there is no evidence that other drugs such as erythropoietin or activated vitamin D are more effective when administered intravenously, although this route does overcome concordance issues.

Hemodialysis for Acute Renal Failure

Hemodialysis is less commonly used as treatment for acute kidney injury in the intensive care unit as it is better managed by continuous veno-venous hemofiltration-dialysis, which does not cause major fluid shifts and

disturbances to BP and cardiac output. Situations in which hemodialysis may be useful are when there is a need to rapidly remove large volumes of fluid, particularly if there is pulmonary edema, or an urgent need for the fastest possible clearance of toxic metabolites, such as with inborn errors of metabolism, drug poisoning or tumor lysis syndrome.

Emergency hemodialysis in ARF is usually started with a temporary percutaneous dual lumen non-tunnelled catheter. The principles of management are not different from chronic hemodialysis. A short session may be the best starting point, followed by daily sessions. Dry weight assessment may be particularly difficult in the child presenting acutely, and awareness of potential reactions to the procedure are necessary as these are unpredictable in the new patient. A more complete description of treatments for acute kidney injury is given in Chapter 67.

Long-Term Outcome

Despite all the improvements that have taken place over the years, such as more biocompatible and high flux dialysis membranes and UF controlled machines, and better understanding of the management of nutrition, anemia and CKD-MBD, mortality in adults is showing no signs of improvement. Amyloidosis, malnutrition, LVH and accelerated atherosclerosis remain common. Although mortality in children on dialysis remains low, it is still around 30 times greater than that of the age-matched normal population (55), and in young adults on dialysis is equivalent to that of an 85 year old (56). Most of this excess mortality is due to CVD. Age at the start of dialysis also affects outcome: dialysis before 1 year of age increases the mortality risk by 2.7, and between 1 and 5 years by 1.8. However, more importantly co-morbidity, which affects a significant proportion of patients, increases mortality risk 7.5 times (4, 57). Lifespan is reduced by 40–60 years in children on dialysis, with about 50% of deaths due to CVD (58). The challenge to pediatric nephrologists is to improve the long-term outcome for these children. Much can be gained by careful attention to fluid overload and LVH, to metabolic abnormalities, particularly CKD-MBD and prevention of anemia, but further research is needed into the benefits of more frequent dialysis, types of dialysis and the prevention of CVD. Most importantly of all, bypassing dialysis altogether by pre-emptive renal transplantation is currently the best option for our patients.

74 Transplantation Immunobiology

Elizabeth Ingulli · Stephen I. Alexander · David M. Briscoe

Introduction

Allograft rejection is an inflammatory reaction that occurs rapidly after transplantation and is associated with a characteristic cellular and humoral attack on the graft. However, allograft rejection can also occur more chronically, as a result of an insidious immunological process involving delayed type hypersensitivity mechanisms. Both the early acute, and the later chronic rejection processes are mediated by the recipient's immunological response to donor antigen, which is initiated and coordinated by T cells. All forms of rejection also require the activation of other cell types including B cells and macrophages as well as the induced expression of molecules that enable the trafficking of destructive effector cells into an allograft. New discoveries in the field of immunology have provided many insights into mechanisms that function in the alloimmune response and in the development of rejection. Several of these discoveries have been translated into the clinic, and have resulted in new therapeutics that have the potential to promote long term graft survival. In this chapter, we will review the cellular and molecular basis for the alloimmune response, and we will discuss mechanisms and concepts that have resulted in new targeted therapeutic strategies.

Allorecognition

When a tissue or organ, such as skin, is transplanted from one animal into another, there are two possible outcomes. One possible outcome is that the skin will engraft and will function over time as normal skin. The other outcome is that the skin will not engraft and will be rejected. The immunological basis for these outcomes and the observation that allogeneic tissues are "rejected" has served as a basis for our understanding of concepts about immunity itself, and how our immune system is capable of recognizing foreign tissues as self or non-self. Approximately 50 years ago, a major breakthrough led to the identification of Histocompatibility Antigens (1). Cells or organs transplanted between identical strains of mice or between identical human twins were not rejected. However, cells or organs transplanted between different strains of mice or between unrelated humans are almost always rejected. By inbreeding of mice, it was further discovered that several gene products could determine the rejection of skin between parents and offspring; and the molecular basis for these observations led to the identification of specific "rejection genes" encoded by the major histocompatibility complex (MHC) (1, 2). It is now understood that interactions between a recipient T cell and individual MHC molecule(s) is the basis for allorecognition. In addition, it has been determined that peptides derived from allogeneic tissues or proteins, which are expressed in association with the MHC molecule, mediate T cell activation responses. Furthermore, it is known that peptide interactions with a T cell receptor complex (TCR) results in a signaling cascade that is key to the elicitation of an effective T cell activation response. However, the TCR signal alone is not sufficient to elicit the full activation of T cells. Full activation requires interactions with additional molecules called costimulatory molecules (commonly called signal 2). Once activated, T cells initiate and coordinate a variety of pro-inflammatory events called "effector mechanisms," all of which result in inflammation within an allograft. These include the activation of monocyte/macrophages, cytotoxic $CD8^+$ T cells and alloantibody-producing B cells. Activated T cells also co-ordinate delayed-type hypersensitivity (DTH) responses in part through the activation of vascular endothelial cells, and the induction of a variety of chemoattractants, that serve to facilitate local inflammation (3–7). We will describe these concepts in more detail below.

Major Histocompatibility Complex

The major histocompatibility complex (MHC) is a cluster of genes located on chromosome 6 in humans, which encode the family of human leukocyte antigens (HLA). MHC molecules are divided into two main subgroups: class I (HLA-A, -B, -C) and class II (HLA-DR, -DP, -DQ) molecules. Proteolyzed peptide fragments of proteins derived from allogeneic cells (called allopeptides) bind within the groove of MHC molecules on the surface of

© Springer-Verlag Berlin Heidelberg 2009

antigen presenting cells (APCs). Once expressed, interaction with the T cell receptor complex of proteins expressed on the surface of recipient T cells results in the antigen-dependent signal. $CD8^+$ T cells recognize peptide/MHC class I complexes, which are constitutively expressed on the surface of virtually all nucleated cells. MHC class I molecules consist of a heavy chain non-covalently associated with a β_2-microglobulin (β_2 m) light chain (8). β_2 m is encoded by a non-polymorphic gene separate from the MHC complex. The peptides that associate with MHC class I molecules are eight to eleven amino acids in length and are derived from the cell cytosol. Some studies have suggested that longer allopeptides can also bind within the groove of the MHC class I molecule and mediate the activation of $CD8^+$ T cells (9).

In contrast, $CD4^+$ T cells selectively recognize allopeptides in the context of MHC class II molecules. MHC class II molecules are constitutively expressed by a relatively small number of cell types including B lymphocytes, monocyte/macrophages, and dendritic cells, but they can be induced in expression on many cell types including vascular endothelial cells. MHC class II molecules are divided into three subgroups: -DR, -DP, and -DQ which are structurally and functionally distinct and are composed of non-covalently associated α and β chains. The length of the peptide bound within the grove of MHC class II molecules is typically twelve to nineteen amino acids in length and is longer than those that associate with MHC class I molecules. Further, while MHC class I peptides are endogenous, MHC class II peptides are classically derived from exogenously supplied alloantigens. Once expressed, MHC class II molecules present peptide antigen to $CD4^+$ T lymphocytes, and elicit signals through the T cell receptor/CD3 complex. These signals ultimately result in proliferation and cytokine production that serve to initiate and coordinate the effector immune response.

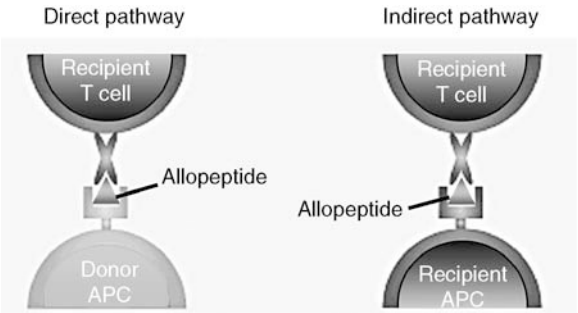
Minor histocompatibility antigens are non-MHC proteins that are also capable of eliciting an immune response and allograft rejection (1). Any non-MHC gene that encodes epitopes capable of binding to both MHC class I and class II molecules and inducing $CD8^+$ and $CD4^+$ T cell response(s) respectively, can be considered a minor histocompatibility gene (10). In principle, polymorphisms among common proteins expressed in the donor can be processed and presented by self-MHC. When presented by self-MHC molecule(s) on self-APCs, peptides derived from these polymorphic proteins can mediate an effective immune response and can promote alloimmunity. Furthermore, in the context of alloimmunity, some minor histocompatibility antigens have been found to be more immunodominant than others (11). For instance, a well characterized minor MHC antigen is the male-specific Y chromosome antigen, also known as the H-Y antigen. When this antigen is processed by MHC molecules in a female, it can induce an anti-Y response against a male donor graft (12–14). $CD8^+$ T cells (15, 16) and $CD4^+$ T cells (17) specific for minor antigens have been isolated from humans and rodents, and have have been shown to play an important role in the rejection of solid organ transplants. Responses to minor antigens have also been shown to be associated with the development of chronic rejection, graft-versus-host disease after bone marrow transplantation and corneal allograft rejection (13, 14, 18, 19).

Pathways of Allorecognition

The recognition of allopeptide by recipient T cells is central to the initiation of the rejection process. Several studies have determined that there are distinct pathways of allorecognition, called the "direct," the "indirect" and the "semi-direct" allorecognition pathways (*Fig. 74-1*). Activation of T cells through the "direct" pathway is unique to the transplantation immunological response. It involves the recognition of intact allo-MHC molecules on the surface of donor cells, including donor-derived APCs and endothelial cells. In contrast, activation of T cells via the "indirect" pathway occurs in an analogous

Figure 74-1

Direct and indirect pathways of allorecognition. In the direct pathway, recipient T cells recognize donor allopeptide presented by donor MHC molecules on donor cells. In the indirect pathway, recipient T cells recognize donor allopeptide presented by self-MHC molecules on self-APCs. The direct pathway is unique to transplantation, where as the indirect pathways is analogous to delayed-type hypersensitivity mechanisms, where foreign proteins are processed by self-APCs.



manner as self-restricted recognition of nominal antigens in delayed type hypersensitivity. In this latter indirect allorecognition pathway, processed allopeptides are presented to T cells by self-MHC molecules on the surface of self-APCs (*Fig. 74-1*). The mechanisms and interactions between these pathways and the relative contribution of either pathway to acute versus chronic rejection is an area of intense research. However, as we will discuss below, it is likely that direct pathway activation is functional in the development of acute rejection, and indirect allorecognition is functional in the development of chronic rejection (20, 21). Finally, T cells can also be activated by a third pathway called the "semidirect" pathway, in which intact allo-MHC molecules can be transferred to recipient APCs where they function to stimulate a recipient T cell activation response (22).

Direct Pathway of Allorecognition and Allograft Rejection

T cells characteristically respond vigorously in vitro in the mixed lymphocyte culture resulting in marked proliferation and overproduction of cytokines. Furthermore, the intensity of the recipient MHC disparate alloresponse to donor cells is thought to reflect the propensity of a recipient to mediate acute rejection (23, 24). The cellular basis for this intense allo-MHC response is associated with allorecognition via the direct pathway. All humans have a high precursor frequency of circulating T cells that are primed to respond through the direct pathway of allorecognition. The direct pathway precursor frequency of T cells is estimated to be between 1–10% of all circulating cells in peripheral blood (25). Circulating T cells survive a process of selection in the thymus that ensures that their T cell antigen receptor has a low but significant affinity for self-peptide/self-MHC molecules. At the same time, selection ensures that circulating T cells maintain a high affinity for foreign peptides in association with *self*-MHC molecules (26, 27). The relatively weak interaction between self-MHC and the TCR is required for the survival of naive T cells during development (28) and in the periphery (29).

Several models have evolved to explain the structural basis for allorecognition and they suggest that direct allorecognition does not conform to classical rules of self-MHC restriction. In the direct pathway, recipient T cells respond to allo-MHC molecules on donor antigen presenting cells. One proposed model suggests that direct pathway alloactivation of T cells can be an allopeptide-independent process (30), while another model suggests that direct alloactivation is peptide-dependent (31). For instance, when donor MHC is structurally different from recipient MHC, alloreactive T cells may directly recognize polymorphic residues with in the allo-MHC molecule itself, independent of allopeptide (32–36). Alternatively, effective allorecognition may require typical presentation of peptide to the TCR, especially in circumstances where donor MHC is structurally similar to recipient MHC (37–39). This latter model suggests that the greater the similarily between allogeneic (donor) MHC molecule(s) and self-MHC molecule(s), the greater the likelihood that the direct T cell allogeneic response will be dependent on allopeptide (40). It is important to note that the crystalline structure of MHC molecules and their analysis of function favor a role for peptide binding in the effective alloactivation of T cells (41–43). Therefore, peptide-dependent activation of recipient T cells through the direct pathway may occur via individual MHC molecule (s) that are similar in structure to self-MHC, while simultaneously, activation of T cells may occur by dissimilar MHC molecule(s) though peptide-independent mechanisms. Collectively, these mechanisms and pathways will result in a profound polyclonal T cell activation response, involving many T cell subsets. It is thus not surprising that we observe such a marked proliferative and activation response in the mixed lymphocyte reaction.

Acute allograft rejection is likely coordinated by T cells activated through the direct pathway (44–46). This possibility is based on the observation that there is a high precursor frequency of T cells in the circulation that are primed to respond through this pathway. Another reason may relate to the observation that the transplanted graft contains a significant number of donor-derived passenger APCs or passenger leukocytes that have a high density of allo-MHC molecules on their cell surface(s). These donor derived APCs also provide the necessary costimulatory signals for the full activation of recipient T cells (see below). In contrast, at later times post transplantation (>1 year), allo-activation via the direct pathway is minimal. This relative hyporesponsiveness, compared to pretransplantation responses, is most notable in the mixed lymphocyte reaction where there is a decreased proliferation/cytokine production of recipient T cells to donor cells. This is called "donor specific hyporesponsiveness" (21). Nevertheless, as will be outlined below, T cells are still activated by donor-specific allogeneic proteins at these later times, only the response is mediated through the indirect pathway of allorecognition (20, 21, 47–49).

Direct allorecognition requires the migration of allo-MHC bearing, and graft-derived cells into secondary lymphoid tissue (50, 51). Early studies showed that the

removal of donor-derived passenger APCs from the graft prior to transplantation resulted in prolonged graft survival (51–54). In contrast, the injection of donor dendritic cells into the recipient could induce acute rejection (55, 56). Dendritic cells are the most potent professional APC (57) and they have been implicated to be the "passenger leukocyte" (58) that functions in the initiation of the direct pathway of allorecognition, and thus in acute rejection. Immature dendritic cells are abundant within peripheral tissues where they are ideally positioned to capture antigens. Upon receiving inflammatory or "danger" signals, APCs undergo a maturation process, reverse transmigrate out of the graft into the afferent lymphatics, and eventually migrate to the paracortex of lymph nodes where T cells primarily reside (59–67). Some "danger" or inflammatory signals that result in APC maturation and migration are unique to transplantation and include characteristic ischemia-reperfusion injury. Ischemia-reperfusion induces the generation of reactive oxygen species (ROS) (68), which can result in the activation of chaperoning proteins, some of which are ligands for toll-like receptors (TLRs) (69–71). Following the stimulation of TLRs, immature TLR-expressing dendritic cells are activated, and respond by migrating from the graft into secondary lymphoid tissues (72–75). Oxidative injury also facilitates signaling through TLR-associated adaptor molecules such as MyD88 and TRIF, which have been shown to induce donor-derived dendritic cell migration into lymph nodes as well as the development of acute rejection (76–78). Knockout of intragraft TLR(s) reduces the degree of ischemia-reperfusion injury. In addition, ischemia-reperfusion injury as well as ROS may be directly toxic to intragraft cells and can result in cellular apoptosis and/or necrosis (79). These processes serve as additional stimuli for dendritic cell maturation and migration into lymph nodes (80, 81). Therefore, ischemia-reperfusion and the generation of ROS and its associated activation of inflammatory events within the allograft (82, 83) can be a factor in the early and rapid activation of the immune system and/or the subsequent activation of T cells throughout the direct pathway.

It is important to note that direct pathway alloactivation of cytotoxic $CD8^+$ T cells may serve as specific initiators of the acute rejection process (3, 84). If donor APCs are removed from allografts (and thus, $CD4^+$ T cell activation is negligible), $CD8^+$ T cells have been shown to mediate acute rejection by direct interactions with the graft (84). Under these circumstances, $CD8^+$ T cells recognize donor MHC class 1 expressed on graft vascular endothelial cells and mediate endothelial cell destruction leading to allograft rejection (3, 84, 85).

Over time however, donor APCs are depleted from the graft and thus activation of T cells via the direct pathway becomes less dominant, and persistent T cell activation is predominantly mediated by recipient dendritic cells, and/or self-MHC restricted alloactivation (20, 21, 49, 55, 86, 87). Furthermore, even in the absence of direct pathway alloactivation, T cells have the potential to mediate acute rejection, presumably as a result of alloactivation through the indirect pathway (88). In general, however, activation through the indirect pathway is thought to be of pathophysiological importance in the development of chronic rejection (89).

Indirect Pathway of Allorecognition

The indirect pathway of allorecognition describes a mechanism whereby T cells recognize processed alloantigens, presented as allopeptides on self APCs (*Fig. 74-1*). This self-restricted mechanism for the activation of T cells is not unique to the transplantation setting, and is the major physiological mechanism for the processing of foreign antigens and the presentation of foreign peptide antigens to T cells. This mechanism of T cell activation is characteristic, for instance, in delayed type hypersensitivity following exposure to bacterial antigens. However, the finding that the indirect pathway allorecognition is functional for T cell activation in the alloimmune response is most important, as this pathway is now proposed to be associated with the development of chronic rejection (90). The alloactivation of T cells via the indirect pathway is a result of processing of donor alloantigens by recipient APCs, and the subsequent presentation of allopeptide to recipient $CD4^+$ T cells in lymphoid organs (91). This process occurs through three mutually exclusive mechanisms. First, donor cell membranes and/or alloantigens may be shed from the graft into the circulation and phagocytosed by recipient dendritic cells that reside within secondary lymphoid tissue. Second, donor cells that migrate to secondary lymphoid tissues may be phagocytosed by recipient dendritic cells, and third, recipient APCs that migrate into the graft may phagocytose intragraft alloantigens (perhaps from apoptotic or necrotic intragraft cells) and then reverse transmigrate out of the graft into the secondary lymphoid tissue, where they serve to activate recipient T cells in a self-restricted manner. Any intragraft protein antigen of donor origin that differs from that expressed in the recipient is potentially a significant alloantigen capable of inducing an indirect anti-graft T cell response. Therefore, the indirect pathway of alloactivation has every potential to be a potent

mechanism to induce anti-graft T cell responses. Furthermore, it is likely that dominant alloantigen(s) driving the indirect response will change from time to time, such that the associated indirect T cell response will also change over time, a process called epitope shifting (92). Thus, the indirect alloresponse can result in ongoing, insidious and chronic T cell alloactivation.

In contrast to the direct pathway discussed above, the precursor frequency of T cells activated via the indirect pathway is very low (less than 1/million T cells), and the magnitude of the T cell response following indirect alloactivation is small (93). However, epitope shifting is a means whereby the indirect pathway elicits polyclonal and persistent activation responses (92, 94, 95).

Persistent alloactivation of T cells though the indirect pathway has been found to be associated with the development of chronic rejection following renal transplantation (95, 96). Furthermore, when donor specific hyporesponsiveness occurs through the direct pathways, T cells activated through the indirect pathway can be dominant, and can be associated with rejection, for instance following human cardiac transplantation (94). Neverthless, although T cells activated via the indirect pathway have the potential to elicit acute rejection, it is generally believed that activation through the indirect pathway results in the development of chronic rejection. Therefore, one might conclude that in the future the inhibition of T cell activation through the indirect pathway will be a means to prevent of chronic allograft rejection.

It is important to note that activation through the indirect pathway (95) and not the direct pathway (97) is also dependent on the degree of immunoregulation. As will be discussed below, self-restricted T cell activation can result in an expansion of low numbers of immunoregulatory T cells which serve to inhibit effector T cell activation responses. These immunoregulatory $CD4^+$ T cells, which are typically identified by high levels of expression of CD25 and FOXP3, inhibit indirect T cell activation. Therefore, indirect alloactivation (and thus chronic rejection) can only occur in those patients with limited numbers of CD25 and FOXP3 immunoregulatory cells (94, 95). Indeed, it has been reported that patients without indirect T cell responses have high numbers of immunregulatory cells in sufficient numbers to suppress the response. Also, patients with active indirect T cell responses and chronic rejection were found to have coincident low numbers of immunoregulatory T cells (95). Thus, one might conclude that one limiting factor for the expansion of T cells with indirect specificity (and thus chronic rejection) is the presence of immunoregulatory cells.

Other studies have suggested that costimulation is necessary for the activation of indirectly activated graft-specific T cells, and it has been demonstrated that some accessory costimulatory molecules inhibit the expansion of immunoregulatory T cells (98). These observations imply that costimulatory blockade might hinder the expansion of T cells activated through the indirect pathway (99).

There may be interplay among T cells activated through the direct and indirect pathways. For instance, directly primed $CD8^+$ T cells can target the graft and elicit an anti-graft destructive response. This response serves to stimulate recipient monocytes to process allontigens, which subsequently results in, and stimulates, an indirect response (3, 12, 84). Also, it is possible that both $CD4^+$ and $CD8^+$ indirect responses occur in the context of transplantation. Dendritic cells have the unique ability to process and produce not only peptide/MHC class II complexes from exogenous antigens, but also peptide/MHC class I complexes (100–103). It is therefore conceivable that both kinds of peptide/MHC complexes derived from donor antigens could be presented to recipient $CD4^+$ and $CD8^+$ T cells. Both indirectly primed $CD4^+$ and $CD8^+$ T cells can elicit rejection, and in some circumstances each specific response may be dominant to mediate ongoing rejection (12, 92, 95).

Semi-direct Pathway of Allorecognition

Intact allo-MHC molecules can be transferred to recipient dendritic cells and are capable of stimulating allo-T cell responses (22). The acquisition of MHC and/or other molecules can occur by direct cell-to-cell contact and/or via the stripping or "nibbling" of molecules from one cell membrane to another (104, 105). For instance, this can occur when recipient dendritic cells transmigrate across allo-MHC expressing graft endothelium (22, 105). Exosomes (nanovesicles < 100 nm) are intriguing in this process, as they are generated by reverse budding of the plasma membrane, and are capable of being secreted into the surrounding mileu and/or transferred between cells. Transfer of allo-MHC via exosomes has been shown to occur both in vitro and in vivo (106–108), but exosome transfer alone may not be sufficient to mediate the activation of naïve T cells (107). The transfer of allo-MHC molecules and processing by self-APCs is a notable mechanism for the stimulation of an indirect response. Thus, the semi-direct pathway may also be a mechanism that links the direct pathway to the indirect pathway of allorecognition (109).

Co-Stimulation/Co-Inhibition of T Cell Activation

The engagement of the T cell receptor with the MHC/allopeptide complex on APCs alone is not sufficient to elicit an effective T cell activation response (110, 111). Full T cell activation requires additional signals, commonly called "costimulatory signals," which are provided to T cells by one or more accessory molecules typically expressed on professional antigen presenting cells (111–115). When T cells receive an alloantigen-dependent signal as well as a costimulatory signal, several intracellular pathways are activated that synergize to result in proliferative, cell survival and migratory responses. Furthermore, the combined signals result in an overproduction of cytokines including proinflammatory IL-2 and IFNγ, and a marked proliferative response result in clonal expansion of the T cell. Inhibition of costimulation, while coincident antigen-presentation is permitted has been shown in cell culture as well as in several models of inflammatory diseases to result in T cell deletion, unresponsiveness (anergy), immune suppression or regulation and/or immune deviation. Together, the effect of costimulatory blockade is to dampen the immune reaction.

In addition, it is increasingly becoming appreciated that co-inhibitory signals are simultaneously transmitted to the T cell through other accessory molecules. Thus, the outcome and the resultant T cell activation response is dependent on the combined effects of both "positive" as well as "negative" accessory signaling. Furthermore, overexpression of co-inhibitory or "negative" signals suppresses activation and are thought to function to maintain a balance that regulates the effective immune response. This balance is somewhat complex as the temporal expression of costimulatory and co-inhibitory signals change over time. In general, costimulation occurs early and co-inhibition occurs late and serves as a physiological means to dampen the outcome of any antigen-dependent interaction. Dysfunction in this balance whereby immunoregulation fails to occur efficiently has been found to result in chronic inflammatory disease states as well as some forms of autoimmunity (116, 117). Alternatively, overexpression of co-inhibitory molecules have been found to augment immunoregulation and are thought be a major mechanism underlying allogeneic fetal tolerance (118). Pharmacological manipulations to block co-stimulation or to augment co-inhibitory signals can be used to change the outcome of alloimmune T cell activation. These types of manipulations have generated significant interest within the transplant community with the recent introduction of costimulatory blockers as therapeutics. We will next review several co-stimulatory and co-inhibitory signaling pathways that have been well characterized in the literature (summarized in *Table 74-1*).

CD28/CTLA-4/B7-1/B7-2 Pathway

Co-stimulation mediated by CD28 is one of the most important and intensely studied of all costimulatory signals. CD28 is a glycoprotein receptor that is constitutively expressed on resting T cells, but its expression is increased following activation. Signaling through T cell CD28 has been demonstrated to be critical in the primary activation and clonal expansion of naïve T cells. In the absence of TCR engagement, ligation of CD28 has no known immunological effect. However, CD28-inducible signals lower the threshold for TCR-inducible signaling so that together

Table 74-1
Costimulatory signaling pathways

Costimulatory receptor	Expression	Ligand	Function
CD28	Naive and activated T cells	CD80/CD86	Required for naïve T cell activation, IL-2 production and IL-2R expression
CD154 (CD40L)	Activated T cells	CD40	Promotes T-B cell interactions to induce B cell activation, antibody production and isotype switching Activation of APC
ICOS	Activated T cells	ICOS-L	Promotes effector function
CD134 (OX40)	Activated T cells	OX40L	Promotes effector function; negative regulator of FOXP3 regulatory cells
CTLA4	Activated T cells	CD80/CD86	Downregulates T cell activation responses
PD1	Activated T cells	PD-L1	Negatively regulates T cell activation and effector function

the signals synergize and promote several T cell activation responses. The biological basis for costimulation was in part defined by the CD28 pathway, whereby CD28 ligation was found to lower the threshold requirement for antigen-dependent and TCR-mediated signaling as well as IL-2 production (110, 119). Indeed, the intracellular signaling cascade mediated by both TCR/CD28-mediated events has profound synergistic effects upon T cell clonal expansion (120), cytokine production, mRNA stability (121–123) and cell cycle progression (124, 125). CD28 signaling also promotes T cell survival through enhanced expression of the anti-apoptotic protein, for instance, Bcl-XL (126). The enhanced proliferation and survival of T cells following CD28-mediated activation also influences immune deviation, including T helper type 1 and T helper type 2 cell differentiation, and thus, the effector immune response (discussed below) (127, 128). In addition, co-ligation of CD28 has biological responses on cytotoxic T lymphocyte (CTL) responses (129) and on $CD4^+$ T cell-dependent B cell effects that facilitate germinal center formation and antibody production (130, 131). Finally, CD28 signaling influences the expression of other costimulatory molecules, including CD154 (CD40L), ICOS, and OX40 (132, 133) (*Table 74-1*), thereby providing for amplification of proinflammatory loops, all of which serve to sustain the response. Together, these biological effects of CD28 are profound and have major implications for the development of transplant rejection as well as the production of alloantibody following transplantation.

The major ligands for CD28, called B7-1 (or CD80) and B7-2 (or CD86), are glycoprotein members of the immunoglobulin family. They are expressed on professional antigen-presenting cells (APC's), including B cells, monocytes, and dendritic cells. B7 molecules are induced in expression on APCs, following activation and/or following differentiation, and each molecule has a distinct patterns of expression. In general, B7-2 is expressed at early times following activation of an APC, whereas B7-1 appears at later times. The higher the level of expression of B7-1 and B7-2 on APCs, the more potent they become in their ability to activate T cells. For instance, immature dendritic cells have low levels of these costimulatory molecules and this correlates with their limited ability to promote alloactivation. In contrast, both B7-1 and B7-2 increase in expression in the course of dendritic cell maturation. Mature dendritic cells have very high levels of expression, which correlates with their characteristic potent APC function (134).

The effect of B7 family molecules on T cell activation is complex, as these molecules also bind an important inhibitory receptor called cytotoxic T lymphocyte-associated antigen 4 (CTLA4), a homologue of CD28. CTLA4 is not expressed on resting T cells but is upregulated after activation and is induced in expression following activation of CD28 signaling. CTLA4 binds to B7-1 and B7-2 with greater affinity than CD28, and thus, once expressed it is likely to function (135). In general, as CTLA-4 expression increases on a T cell, interactions between CD28 and B7 decrease, and thus it functions indirectly to suppress CD28-mediated costimulation. Signaling through CTLA4 also directly antagonizes costimulation via CD28 by inhibiting IL-2 production, IL-2R expression and cell cycle progression (136–138). CTLA4 also promotes expression of idoleamine 2,3 dioxygenase (IDO) in dendritic cells, which stimulates the degradation of tryptophan, thus limiting T cell proliferation (139). Studies using mice deficient in CTLA-4 have confirmed a major immunoregulatory function for this molecule (140). In CTLA-4 knockout mice, T cell proliferation is unrestrained and massive lymphoproliferation from unchecked costimulation occurs and results in autoimmune disease and early death (140, 141). Regulatory T cells have been shown to contain large intracellular stores of CTLA-4 which is thought to influence their suppressive properties (142). These data support the notion that CTLA-4 plays a critical role in the maintenance of self-tolerance, and that agents that interfere with CTLA-4 signaling may augment T cell activation and prevent tolerance induction (143). In contrast, agents that inhibit CD28-mediated activation will limit the T cell activation response to antigens, including alloantigens. Collectively, these observations imply that augmenting CTLA-4 signals while inhibiting CD28-induced responses augment regulatory immune function(s).

As a final note, we wish to point out that physiologically it is most important to keep an immune response "in check," and to suppress constant ongoing activation within the body. CTLA4 may be a prototype molecule in this regard to maintain immune regulation. Without these "checks" it would be difficult to maintain physiological immune regulation over time. It is thus of great interest that there can be an interplay between co-stimulatory and co-inhibitory receptor-ligand interactions. As discussed above, B7 family molecules, which provide for activation via interactions with CD28, also bind CTLA4 to provide for negative costimulatory signals. CTLA-4-mediated inhibition of T cell activation is enhanced at late times allowing for regulation to occur. Recently, it was found that human B7-1 can additionally interact with Programmed Death-1 ligand-1 (PD-L1), another negative co-inhibitory molecule (144). B7-1 binds to PD-L1 with

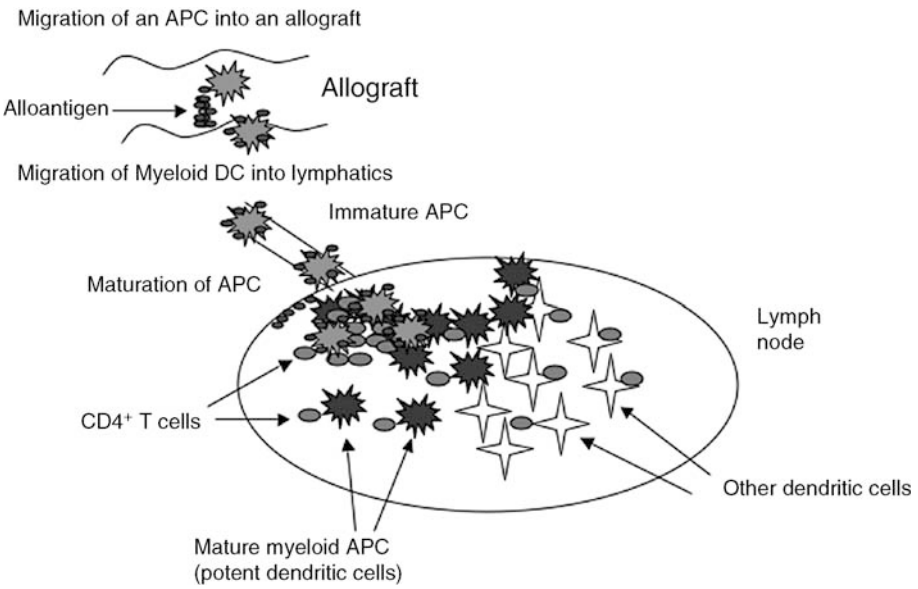
a greater affinity than it binds to CD28, but with less affinity than it binds to CTLA-4 or the interaction between PD-L1 and its co-inhibitory ligand PD-1 (145, 146). Thus, it is important always to consider costimulation and coinhibition as complementary interactions that serve to maintain an immune regulatory balance (147).

CD154/CD40 Pathway

CD40, and its ligand CD154 (also called CD40L, gp39, TRAP, T-BAM) are also important and well characterized costimulatory signaling molecules (148). CD40 is a 50-kDa integral membrane glycoprotein member of the TNF receptor family that has a wide distribution of expression on different cell types including T cells, B cells, monocyte/macrophages, dendritic cells, vascular endothelial cells (EC) and epithelial cells (149–151). The expression of CD40 is highly regulated by cytokines, and the intracellular signaling pathways resulting from the ligation of CD40 have been well characterized (148). CD40 ligand, or CD154 (also called CD40L, gp39, TRAP-1, TBAM) is 39 kDa type 2 membrane glycoprotein that is predominantly expressed on activated T cells and platelets (148, 152, 153). It is also expressed on other cell types within the immune system including B cells, dendritic cells, natural killer cells and endothelial cells. Interactions between CD154 and CD40 promote T cell and B cell activation, as well as the maturation of myeloid-derived APCs into mature dendritic cells (*Fig. 74-2*) (62, 154–156). CD154 is expressed on T cells after TCR signaling and is enhanced following CD28 dependent costimulation. CD154/CD40 interactions were initially shown to be important for T helper-dependent B cell responses, promoting B cell proliferation and isotype switching as well as germinal cell formation (149, 157–160). CD40 signals have also been shown to enhance T cell responses (161, 162). The potent physiological function of CD154/CD40 interactions in immunity were clearly defined when it was found that humans with genetic mutations of CD154,

Figure 74-2

Maturation of myeloid-derived antigen presenting cells. Recipient monocytes are recruited into allografts following transplantation, where they may differentiate into resident macrophages or into dendritic cells. Exposure to, and phagocytosis of, allogeneic necrotic tissue serves to initiate the maturation process. Immature dendritic cells reverse transmigrate out of the allograft into the lymphatics. Ongoing stimulation of these cells by cytokines, growth factors and cell surface molecules further stimulates their differentiation into mature dendritic cells. When they enter lymph nodes, they encounter naïve T cells, and they present allopeptide and stimulate the indirect allogeneic response. Although not illustrated in this figure, donor APCs present within an allograft immediately after transplantation, can reverse transmigrate into the lymphatics using identical mechanisms; when they enter the lymph node, they encounter recipient T cells and stimulate them via the direct pathway of allorecognition.



rendering the protein incapable of binding to CD40, are immundeficient. This human immunodeficiency disease is called the Hyper IgM syndrome (HIM) (163–167), because the dominant effect of this mutation/deficiency was found to be high serum levels of IgM and reduced levels of IgG, IgA, and IgE. The immmunological defect was subsequently identified to be related to an inability of B cells to switch from IgM production to IgG production. Furthermore, patients with CD154 deficiency and the HIM syndrome were also found to have defects in T cell function, and fail to mount appropriate cell-mediated and delayed type hypersensitivity responses (163–167). Thus, the in vivo dysregulation of CD154/CD40 interactions result in an immune deficiency with abnormalities in both cellular and humoral responses (151, 168, 169). Additional studies using CD154- as well as CD40-deficient mice confirmed a major role for CD40 in immunity as well as in several immune inflammatory diseases (170–172). Collectively, these observations have defined CD154 and CD40 as critical molecules in immune responses; and suggest that limiting these interactions alone (in humans) will have biological properties that regulate antibody production as well as effector responses all of which are associated with the rejection process.

Another important aspect of CD154/CD40-dependent costimulation relates to its interplay with the CD28/B7 pathway. Ligation of CD40 on APCs has been found to result in the expression of B7 family molecules. Furthermore, the functional costimulatory effect of CD40 signaling has been found to be associated in part with B7 expression, and with B7-CD28-induced signaling, discussed above. Also, the absence of CD40-induced signaling results in reduced CD28-dependent costimulation, suggesting that these molecules interact for costimulatory responses. In addition, there is an interplay between CD40 ligation and other proinflammatory molecules including, for instance, the overexpression of cytokines, such as IL-12. As discussed above, CD40 signaling has also been found to promote the antigen presenting function of APCs, and to promote dendritic cell maturation and survival (154–156). Other signals such as those mediated by Toll-like receptors (TLRs) have been found to synergize with CD40 to facilitate the maturation of dendritic cells, as well as their function as APCs (173–178). Blocking CD40-induced activation of dendritic cells can thus have pluripotent effects on immunity, resulting in the inhibition of T cell and B cell activation, inhibition of cytotoxic T lymphocyte development (162), reduced autoimmunity (179–184) and the augmentation of peripheral tolerance (185–188). Inhibition of CD40/CD154 signaling has also been shown to be associated with the expansion of immunoregulatory T cells, as well as populations of anergic $CD4^+$ T cells with potent immunosuppressive functions (189).

The functions of CD40 indicate that it is an important costimulatory molecule and that it functions in both humoral and cellular immunity either directly or indirectly via its ability to regulate the several accessory molecules and inflammatory mediators. Therefore it is not surprising that inhibition of CD154 alone has been shown to inhibit both acute and chronic rejection in animal models (190–196); and further, it is not surprising that the biological effect of CD154 blockade is most profound in combination with CD28/B7 blockade (190, 192). Unfortunately, initial studies using CD154 antagonists following human transplantation were unsuccessful as they were found to have significant side-effects (197, 198). However, newer CD40 antagonists are currently under development, and it is possible that they may be useful therapeutically in the future.

ICOS/ICOSL Pathway

As its name suggests, the costimulatory molecule ICOS (inducible T cell costimulator) is expressed selectively on activated and memory subsets of T cells but is not expressed on unactivated/naïve T cells (199–205). ICOS has structural and functional similarities to CD28, but it does not bind to B7 family molecules. Rather, it interacts with its own ligand, ICOS-L, also called B7H, GL50, B7RP-1, and B7-H2 (202, 206–208). The inducible expression of ICOS shortly after T cell activation suggests that it may be particularly important in providing ongoing costimulatory signals to activated T cells. Furthermore, during the course of an immune response, ICOS levels have been found to remain high on subsets of T cells (132, 209, 210).

ICOS-L is typically expressed in peripheral tissues, especially on endothelial cells where it is induced by inflammatory mediators (202, 206, 207). In this manner, ICOS-L may be functional in association with inflammation, and in association with several diseases including allograft rejection (206). The expression of ICOS-L in peripheral tissues is thought to be important for local reactivation responses, as ICOS-mediated costimulation may occur at the local site (206).

Although ICOS-L does not bind to CD28 or CTLA-4, there are similarities in the functions of ICOS and CD28. There also appears to be an interplay between the expression of ICOS and costimulation by CD28, especially since ICOS itself is induced in expression following CD28-dependent costimulation (205). Thus, some of

the functions previously ascribed to CD28, may in part be due to ICOS. For instance, while naïve T cells require CD28 signaling for the initiation of proliferation and cytokine production, it has been suggested that optimal activation of recently-activated T cells is less dependent of CD28, but is dependent on ICOS-ICOS-L interactions. Thus, different than that observed for CD28, ICOS selectively functions at later times in the immune response, and has little effect(s) on the initial stages of T cell activation. In activated T cells, ICOS-mediated signaling appears to induce cytokine production, especially T helper type 2 cytokines (209, 210). ICOS costimulation has also been found to be important for humoral immunity (211, 212). Furthermore, blockade of ICOS can inhibit IL-10 production as well as the development of regulatory T cells (213). Thus, there are several properties of ICOS that make it distinct from CD28.

In the experimental transplant setting, ICOS deficiency or blockade of ICOS can prolong cardiac allograft survival (214) especially when administered later in the course of the immune response (215). Although ICOS blockade does not effect memory T cell expansion, it has been shown to reduce the recruitment of T cells into allografts (216) and inhibits the effector function of memory T cells (217). Inhibition of ICOS-ICOS-L interactions in combination with blockade of CD154/CD40 has been found to prevent the development of chronic allograft vasculopathy (214). In summary, whereas CD28/B7 interactions are functional at early times post transplantation in the initiation of the alloimmune response, ICOS–ICOS-L interactions function to sustain alloimmune inflammation and memory responses.

OX40/OX40L Pathway

Similar to ICOS-ICOS-L, the OX40 (CD134)/OX40L (CD134L) costimulatory pathway does not function in the initiation of alloimmunity, but rather functions in the effector arm of the response. OX40 is expressed on activated T cells after several rounds of division, as well as on cells with potent effector function (218, 219). OX40L, a member of the TNF superfamily, is expressed on activated B cells, dendritic cells and on endothelial cells (220–222). OX40 has been found to possess potent costimulatory properties to promote T cell proliferation and effector cell generation (223–225). Costimulation through OX40 has a profound effect on the generation of memory T cells, and some studies suggest that it is of critical importance in the expansion of populations of memory T cells (226). Stimulation of OX40 can also promote the development of effector function from previously anergic (autoreactive) T cells (227). OX40 costimulates allogenic $CD4^+$ and $CD8^+$ T cell responses and can function in skin allograft survival (219). Stimulation of OX40 on memory T cells promotes their reactivation (228), and enables them to develop effector function and an anti-graft response (229).

Of importance, OX40 is also expressed on regulatory populations of $CD4^+$ T cells expressing FOXP3 (98, 230). Costimulation via OX40 has been shown to inhibit the generation of FOXP3-expressing cells from activated effectors and inhibits their suppressor function (98, 231). Thus, OX40 can act directly on T effector cells to support their expansion and survival or it can function indirectly to enhance the immune response by inhibiting T regulatory cells as well as immunoregulatory mechanisms.

PD-1/PD-L1/PD-L2 Pathway

PD-1 (programmed death 1) accessory molecule and its ligands PD-L1 (B7-H1) and PD-L2 (B7-DC) are members of the CD28/B7 family and have been shown to transmit inhibitory signals to T cells and play a role in peripheral tolerance induction (205). PD-1 is induced on activated T cells and B cells as well as on activated APCs. Its ligand, PD-L1 is expressed on several cell types but is up-regulated in expression on activated T cell and B cells. It is also induced in expression on other cells including, dendritic cells and endothelial cells, where its expression is thought to be important in the regulation of immune responses at peripheral sites (232). In contrast, the expression of PD-L2 is restricted to antigen presenting cells and is induced upon activation by inflammatory mediators (233–235).

Antigen-dependent activation of T cells and co-ligation of PD-1 results in decreased T cell proliferation, cytokine production (i.e., IL-2) and failure to progress through cell cycle (233–235). In addition, PD-1 ligation inhibits B cell activation responses (236). Murine knockouts of PD-1 have been found to have accelerated autoimmunity similar to that observed with CTLA-4 deficiency but to a lesser degree (237). In rodent studies, lack of PD-1 leads to increased numbers of B cells and a lupus-like syndrome with uncontrolled T cell and B cell activation, the development of arthritis and glomerulonephritis (238) and an autoimmune myocarditis (239). Collectively, these observations indicate that PD-1 is critical for the maintenance of peripheral tolerance.

In transplantation models, blockade of this pathway has been found to result in accelerated graft rejection and graft-versus-host disease (240–243). In circumstances

where costimulatory signal blockade has been used to inhibit rejection, augmenting PD-1 signaling can prolong survival, prevent the development of allograft vasculopathy, as well as modulate T cell and B cell dependent alloimmunity and augment peripheral tolerance (244–246). In other studies, blockade of the PD-1/PD-L1 pathway resulted in accelerated rejection of fully MHC-mismatched cardiac allografts (240), and knockout of the pathway within donor allografts was found to result in accelerated allograft loss and chronic rejection (247). In general, it is thought that the novelty of this co-inhibitory pathway relates to the possibility that manipulating its overexpression at peripheral sites will serve to augment peripheral tolerance and could be beneficial in to inhibit inflammation within allografts.

T Cell Activation Responses/Immune Deviation

Upon activation, $CD4^+$ T helper cells produce multiple cytokines and utilize cytokine-responses to elicit distinct effector functions and an inflammatory response (7, 248, 249). $CD4^+$ T helper type 1 cells (also called Th1 cells) predominantly produce IL-2 and IFNγ, whereas T helper type 2 $CD4^+$ cells (also called Th2 cells) produce IL-4, IL-5, IL-10, IL-13, but do not produce IL-2 and IFNγ. In general, T cell activation responses can be considered to be Th1-like or Th2-like depending on the cytokines produced. Furthermore, the nature of the response, Th1- or Th2-, can change over time in the course of a cell-mediated immune inflammatory reaction. The profile of cytokine production (Th1 and/or Th2), and thus the immune response is of importance in the outcome of any inflammatory reaction including allograft rejection. Th1-responses are associated with classical delayed-type hypersensitivity and cell-mediated immune inflammation. In contrast, Th2-like responses are generally thought to be associated with immune regulation and perhaps tolerance induction following transplantation (249–252). Th2 responses are also important in immunoglobulin switching and in eosinophilic inflammation. Thus, it is proposed that when an immune response deviates from a proinflammatory Th1-type response towards a Th2-type response, in general, it will be associated with immune regulation and the suppression of acute inflammatory responses, including allograft rejection.

$CD4^+$ T helper type 1 responses are typically elicited according to the strength of the antigen-induced signal and positive costimulation (253). In addition, the phenotype of the antigen presenting cell has a major effect on the T helper response (254, 255). Mature dendritic cells express high levels of MHC and high levels of positive costimulatory molecules, and thus are most potent to induce Th1 responses and pro-inflammatory cytokines (154, 255, 256). In contrast, immature dendritic cells or semi-professional antigen presenting cells (such as endothelial cells) with low levels of MHC, and/or low levels of costimulatory molecules are less potent to induce Th1 responses, and facilitate higher levels of Th2 responses (187, 255, 257). Furthermore, professional APCs such as dendritic cells that produce high levels of IL-12 tend to stimulate Th1 responses, whereas subsets of dendritic cells that fail to produce IL-12 and perhaps produce other immunregulatory cytokines can facilitate Th2 responses (254, 256). Although, further research is needed in this area, it is important to note that an APC can facilitate proinflammatory Th1-, or immunoregulatory Th2-type immune responses. Furthermore, the concept that it is possible to pharmacologically manipulate a dendritic cell such that it selectively stimulates a Th1- or a Th2- type immune response has significant therapeutic implications (255, 258, 259).

As discussed above, some costimulatory pathways such as, for instance, CD28/B7 and OX40/OX40L can facilitate the deviation of an immune response towards a Th1 profile (224, 225, 260). Nevertheless, interactions with costimulatory molecules for immune deviation are complex. For instance, while CD28 signals drive Th1 responses, OX40 costimulation promotes Th1 and Th2 responses. Furthermore, B7, which augments Th1 responses via CD28-dependent costimulation also binds to CTLA4 and PD-L1, which may serve to suppress IL-2 production and deviate the response towards Th2. Also, it is important to note that the state of activation of a T cell at the time of costimulation is also a determinant of whether costimulation can result in T helper type 1 cytokine production (261). Costimulation via pathways such as ICOS/ICOSL and OX40/OX40L (214, 262) may be critical to sustain Th1-effector responses, and their absence may, by default, result in Th2 cytokine expression.

The activation of $CD4^+$ T cells and the resultant Th1- or Th2 –type immune response has a profound effect on the outcome of many acute and chronic inflammatory diseases including allograft rejection (263). Acute allograft rejection is predominantly associated with Th1-type immune responses. However, acute rejection can occur in the absence of the classical Th1 cytokines IL-2 (264, 265) and IFNγ (266). Although the dominant Th1 cytokine, IL-2, classically drives T cell proliferation and expansion, it also promotes activation induced cell death (AICD). Thus, in its absence AICD is less pronounced, and memory cell

survival is higher, such that immune regulation may be more difficult to achieve (265–268). Another interpretation is that immunoregulation is dependent on alloreactive T cell clonal size and thus, when IL-2 deficiency hinders apoptosis/AICD of effectors, it will change the ratio of effector memory cells to regulatory cells resulting in an associated deficiency in immune regulation (263, 267, 268). In contrast, Th2 responses have been found to inhibit cell-mediated immune reactions and delayed type hypersensitivity and promote immune regulation. Several studies in transplant models have demonstrated that immune deviation to Th2-type responses is associated with long term graft survival following treatment with costimulatory blockade (269, 270). Therefore, it is proposed that Th2 cells may have a functional role as immunoregulatory cells in association with the development of tolerance.

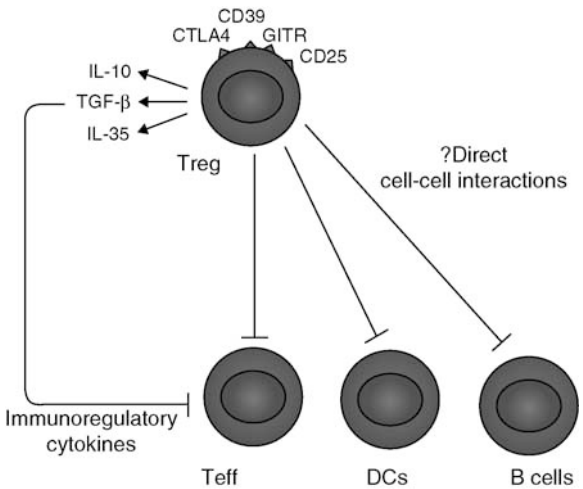
As discussed above, at baseline there is a high precursor frequency of alloreactive T cells primed to respond via the direct pathway, which typically results in a Th1 proinflammatory cytokine profile (251, 271). In contrast, at baseline, there is a relatively low precursor frequency of alloreactive T cells primed to respond via the indirect pathway of allorecognition. In order to sustain indirect pathway alloactivation over time, new naive T cells may be activated towards a Th1 and/or a Th2 response at different times post transplantation. Clonal size, the degree of costimulation and immune regulation may all be factors which determine the dominant T helper response, that in turn is important for long term graft survival. The principle that therapeutics might be used to deviate an immune response over time towards a Th2 profile has been thought to be clinically relevant to promote long term graft survival (263, 269). Nevertheless, it is important to appreciate that most of these studies relate to associations, and thus, it is still controversial whether a Th2 immune deviation alone is sufficient to mediate long term survival and transplant tolerance (127, 272, 273).

Immunoregulation/Regulatory T Cells

It has been well documented for many years that there are naturally occurring circulating T cells that promote immune regulation, prevent autoimmunity and can inhibit acute graft rejection. Furthermore, these cells can be transferred with lymphocytes from one animal to another. Initial studies, attempting to identify the nature of these regulatory cells demonstrated that they were $CD8^+$ T cells (274). More recently however, studies defined a subset of $CD4^+$ T cells expressing CD25 (the IL-2 receptor) and FOXP3 as the potent regulatory lymphocyte cell subtype (275–277) (*Fig. 74-3*). It is now known that naturally occurring regulatory T cells expressing CD25 and FOXP3 represent approximatly 5% of all circulating peripheral $CD4^+$ T cells; and isolation of these cells have confirmed that they exhibit potent regulatory activity against several types of T cell responses in vitro. $CD4^+$ $CD25^+$ $FOXP3^+$ T cells prevent autoimmunity in mice, and their depletion can induce the de novo onset of several immune inflammatory diseases (142, 276, 278, 279). FOXP3 was confirmed as a critical molecule for immune regulation in vivo, when it was identified that mutations in FOXP3 result in an autoimmune disease in humans called the IPEX syndrome (Immunodysregulation, polyendocrinopathy, enteropathy, X-linked) (280). Mutations in the FOXP3 gene in the IPEX syndrome result in defective

Figure 74-3

Immunoregulation by $CD4^+$ $CD25^+$ T cells. $CD4^+$ $CD25^+$ T cells expressing FOXP3 have been found to possess immunoregulatory function (Tregs). It is now established that these cells can regulate the activity and/or the function of effector T cells (Teff), dendritic cells (DC) as well as B cells. The mechanism(s) underlying their immunoregulatory function is an ongoing area of research. Several studies indicate that they may function via direct cell-cell contact, and others suggest that they function via the production of immunoregulatory cytokines. It is possible that different subsets of Tregs mediate immunoregulation via different mechanisms. Treg subsets can be identified by the expression of select cell surface molecules (CTLA4, GITR and CD39).



development of $CD4^+$ $CD25^+$ regulatory T cells and their deficiency leads to severe autoimmune phenomena including autoimmune enteropathy, dermatitis, thyroiditis, and type 1 diabetes, frequently resulting in death within the first 2 years of life (281). In rodent models, the transfer of FOXP3 into $CD4^+$ T cells in vivo, induces regulatory behavior and enables T cells to protect against autoimmune disease in a dominant fashion (282). During development, $CD25^+$ $FOXP3^+$ cells are selected in the thymus and a high proportion of the cells co-express other regulatory molecules including GITR and CTLA-4 (283, 284). FOXP3, is a transcription factor that induces both CTLA-4 expression as well as regulatory activity (282, 285, 286). Thus, FOXP3 controls the generation of regulatory T cells as well as their function. $FOXP3^+$ expressing regulatory T cells can be induced from non-regulatory cells by immunoregulatory cytokines such as TGFβ (287). In addition, following antigen-dependent activation, a subset peripheral $CD4^+$ T cells can be induced to express regulatory markers and subsequently develop functional regulatory activity (286, 288, 289). Indeed, it is established that TGFβ induces the differentiation of naïve $CD4^+$ $CD25^-FOXP3^-$ T cells into $FOXP3^+$ regulatory T cells, typically under conditions of low costimulation and CTLA-4-mediated negative costimulation/signaling. In vivo it has also been found that TGFβ signaling and B7 costimulation are required for expansion and peripheral conversion of $CD4^+$ T cells into regulatory subsets.

$CD25^+$ $FOXP3^+$ regulatory T cells appear to utilize a number of mechanisms to limit immune activation and to induce tolerance. These include the production of cytokines including TGFβ, IL-10 and IL-35 (290). They also have been found to expand following the stimulation of cell surface molecules including CTLA-4, ICOS, PD-1 and CD39 (291–293). Their regulatory function is exerted through T cells, B cells and dendritic cells. Much of their function is thought to involve direct cell-cell contact, although the expression of TGFβ and IL-10 may also be central to their regulatory function (*Fig. 74-3*).

Finally, it is important to note that although $FOXP3^+$ expression appears to dominate as a marker and factor enabling regulatory function, other regulatory cells appear to exist some of which are called Tr1, Tr3, Th3, Qa-1 restricted $CD8^+$ regulatory T cells. It is likely that new therapies in transplantation will focus on the selective expansion of $CD4^+$ $CD25^+$ $FOXP3^+$ T cells, as they are most potent in immune regulation. For instance, if it is possible to sustain their expansion in vivo in the long term with novel drugs or immunosuppressants, then it is hoped that this will translate into the clinic and promote long term graft survival.

Allograft Rejection

Effector Mechanisms

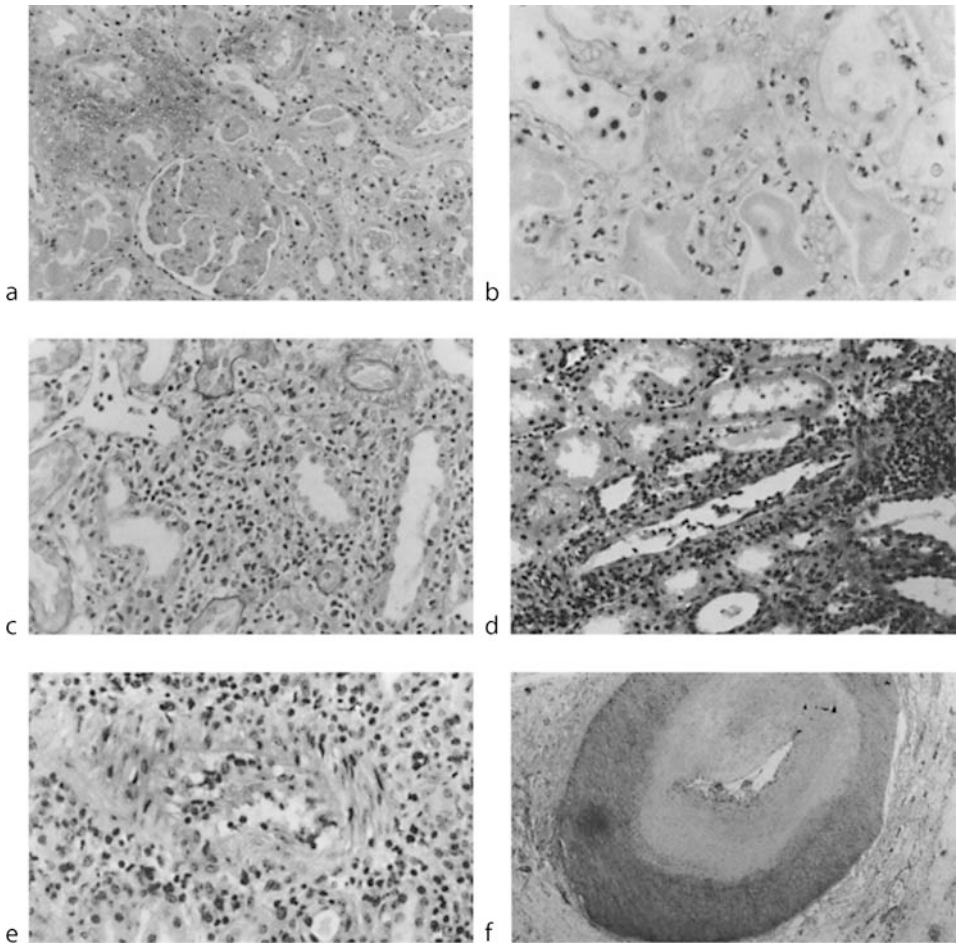
By definition, the development of allograft rejection involves a marked inflammatory reaction, characterized by the recruitment of leukocytes and an intense cellular and humoral attack on the graft (7) (*Fig. 74-4*). As discussed above, the rejection process is mediated by the recipient's immunological response to donor antigen, initiated and coordinated by $CD4^+$ T cells but also involves other cell types including $CD8^+$ T cells, B cells and macrophages (3, 115, 251, 271). The rejection response additionally involves other complex issues including the expansion of effector cells (294, 295), clonal size (267, 268, 296), the mode of allorecognition ("direct" or "indirect" pathways) (49, 271, 297, 298), the degree of immunoregulation (252, 299, 300), and adaptive responses that can occur within the graft (301–303). Nevertheless, activated effector cells and/or memory T cells must be recruited into an allograft in order to mediate graft destruction (3, 4, 84, 304–308). Indeed, several factors within allografts have the capacity to facilitate the rejection process; and the graft itself has the capacity to be dominant to determine the phenotype of rejection (acute or chronic), even in states where immunological tolerance is achieved (304).

$CD4^+$ T cells elicit and coordinate these responses using effector mechanisms (*Fig. 74-5*). They also provide "help" that coordinates the activation of cytotoxic $CD8^+$ T cells as well as alloantibody-producing B cells and mediate the expression of proinflammatory molecules by intragraft cells, such as endothelial cells. Infiltrating mononuclear cells produce a variety of cytokines and chemoattractants which are delivered into the graft. Macrophages also produce fibrogenic growth factors, such as TGF-β, that along with matrix proteins contribute to progressive scarring of the vessels and interstitium. Recently, it has been found that alloantibody development and targeting of graft vessels is of major importance in the destruction of allografts. The binding of alloantibody to cytokine-activated endothelial cells is associated with complement (C4d) deposition, which may result in local vasculitis and endothelial cell death (309). Studies indicate that the production of alloantibody following transplantation is an immunologic risk factor for the development of chronic rejection.

Activated graft vascular endothelial cells function in rejection by facilitating the recruitment as well as the activation of recipient leukocytes, including $CD4^+$ and $CD8^+$ T cells and monocyte/macrophages (3, 12, 84, 306, 308).

Figure 74-4

Pathology of transplant rejection. (Courtesy of Robert Colvin, M.D., Massachusetts General Hospital, Boston, Massachusetts and of Alan Krensky M.D. and Carol Clayberger, Ph.D., Stanford University Medical, Stanford, California).

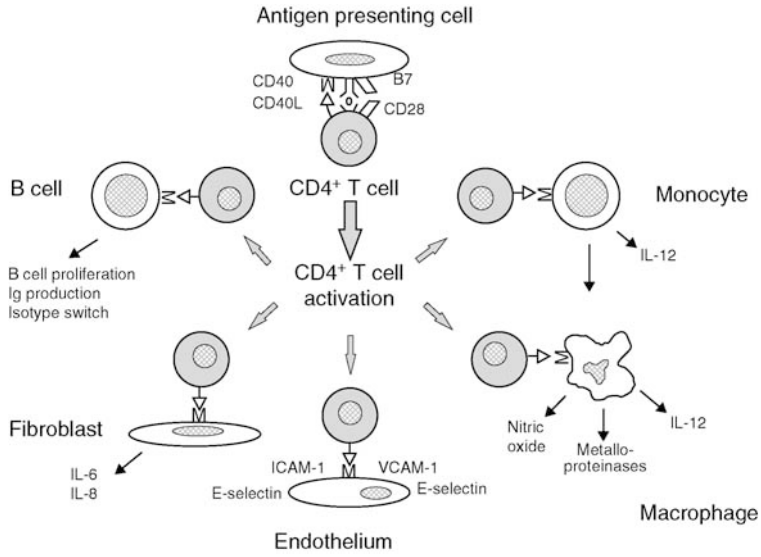


An extensive body of literature has established that endothelial cell activation is a characteristic feature of the rejection process. Ischemia/reperfusion injury, early inflammatory infiltrates and rejection result in endothelial cell expression of several adhesion molecules including E-selectin, ICAM-1 and VCAM-1, as well as chemokines, including the T cell chemoattractants IP-10 and RANTES and the monocyte chemoattractant MCP-1, all of which serve to augment leukocyte recruitment and activation (*Fig. 74-6*). In the course of rejection, it has been reported that endothelial cell activation responses are dynamic, some molecules such as E-selectin are induced at early times and precede rejection. Others such as VCAM-1, IP-10 and Mig are expressed in association with rejection itself (306, 310–312) (*Fig. 74-7*). In addition, activated graft endothelial cells have been found to persistently express HLA-DR, and its expression correlates with the development of rejection (306, 313) (*Fig. 74-8*).

Chemokine-chemokine receptor interactions function in the recruitment of leukocyte subsets, but also

Figure 74-5

Effector CD4$^+$ T cell responses. CD4$^+$ T cell recognition of alloantigen is the primary event that initiates alloimmunity. However, activated T cells mediate graft rejection through a variety of effector mechanisms. These include their ability to provide "help" which promotes the activation of alloantibody-producing B cells as well as other cell types including monocytes and macrophages and vascular endothelial cells. Together, all of these effector response serve to elicit a delayed-type hypersensitivity reaction and rejection.



have direct effects in immunity by facilitating APC function and T-cell activation responses (314–318). Chemokines and chemokine receptors are expressed in allografts; and blockade of one or many of these interactions inhibits the rejection process. Furthermore, chemokines have effects on angiogenesis and vascular repair, which may be of major importance in early destructive events as well as in the development of chronic rejection. For instance, the T cell chemoattractant chemokine IP-10 serves to facilitate recruitment and allograft injury (319), but its anti-angiogenic effects may also serve to sustain injury via the inhibition of vascular repair (320).

Nevertheless, these effector mechanisms account for only some of the well-characterized pathologic and clinical patterns of rejection (321, 322). The rejection process is more complex involving additional growth factors, such as vascular endothelial growth factor (VEGF), angiogenesis, the deposition of extracellular matrix, endothelial to mesenchymal transition and fibrogenesis, all of which are associated with vascular and interstitial disease (*Fig. 74-4*) (5, 90, 323–327). Collectively, these immunologic and nonimmunologic factors contribute to the destruction of allografts, which has been simply called "rejection."

Types of Rejection

Allograft rejection has been traditionally defined according to the timing of the anti-graft inflammatory response as: (1) hyperacute rejection that occurs within minutes to hours following transplantation, (2) acute rejection that occurs over a period of days at any time after transplantation, and (3), chronic rejection that typically occurs insidiously over several years following transplantation.

Hyperacute Rejection

Hyperacute rejection is characterized by rapid thrombotic occlusion of the graft vasculature that begins within minutes after recipient blood vessels are anastomosed to donor graft vessels (328). Hyperacute rejection is mediated by pre-existing antibodies that bind to graft vascular endothelial cells and activate complement. Pre-existing antibodies to blood antigens (ABO) most commonly cause hyperacute rejection, but it can also occur due to prior sensitization to HLA antigens and/or other polymorphic antigens expressed on the allograft endothelium. Following the binding of antibody to vascular

Figure 74-6

Leukocyte recruitment into allografts. Endothelial cells of donor origin play a critical role in the recruitment as well as in the activation of recipient T cells and monocytes/macrophages in vascularized organ allografts. Following transplantation and ischemia-reperfusion injury, endothelial cells express adhesion molecules and chemoattractant chemokines that function to augment leukocyte recruitment. The adhesion molecules E-selectin intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1 are well established to be associated with rejection. Chemokines are produced locally by endothelial cells within the allograft, but also are produced by infiltrating monocytes. When infiltrating monocytes secrete chemokines, they feed back to further amplify the inflammatory reaction. Finally, infiltrating T cells produces many cytokines, which can feedback to activate endothelial cells and promote adhesion molecule expression. Cytokines, such as IFNγ can induce the expression of HLA-DR on endothelial cells (see *Fig. 74-8*). Endothelial cell expression of HLA molecules can facilitate local T cell activation.

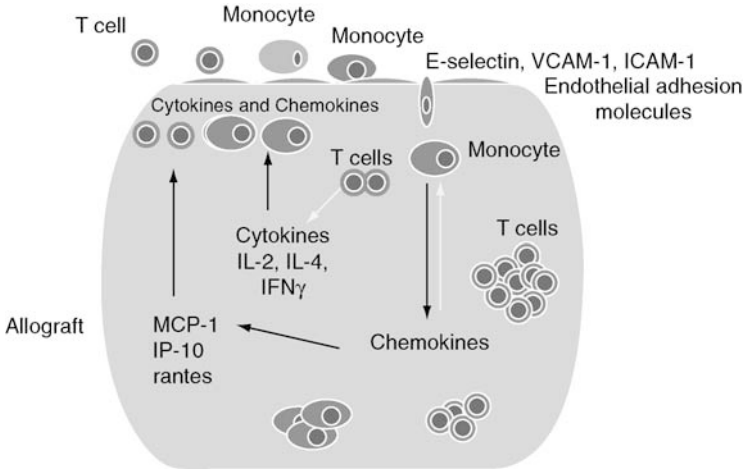


Figure 74-7

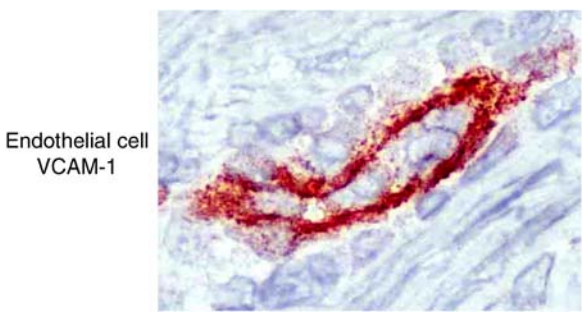
VCAM-1 expression. Illustrated is the immunohistochemical localization of the adhesion molecule VCAM-1 within a rejecting human cardiac allograft. Note that VCAM-1 is expressed on endothelial cells of this microvessel (rose brown color staining) and co-localizes with leukocytic infiltrates within the vessel. It is possible that VCAM-1 expression on these endothelial cells may function to promote local mononuclear cell infiltration. (See color plate 48)



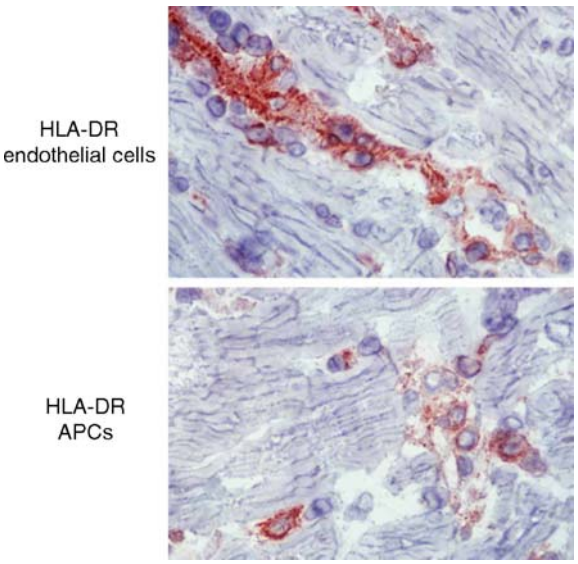
endothelial cells, they are stimulated to secrete high molecular weight forms of von Willebrand factor that mediate platelet adhesion and aggregation. Complement activation also leads to endothelial cell injury, and the exposure of subendothelial basement membrane proteins activates platelets, promotes mononuclear and polymorphonuclear cell recruitment and ultimately mediates destruction of the graft. These processes contribute to thrombosis and vascular occlusion, and the organ suffers irreversible ischemic damage. Although the cause of sensitization (pregnancy, transfusion, previous transplants) is not always apparent, routine crossmatching has virtually eliminated this fulminant type of rejection.

Acute Rejection

Acute rejection is characterized by necrosis of parenchymal cells and is usually accompanied by lymphocyte and macrophage infiltrates (329, 330). Several different

Figure 74-8

HLA-DR expression. Immunohistochemical localization of HLA-DR within a rejecting human cardiac allograft. Note that HLA-DR is expressed on vascular endothelial cells (*upper panel*) as well as on mononuclear cells (APCs) within the graft (*lower panel*). Also, it is noteworthy, that recipient infiltrates appear to encounter donor HLA-DR (and probably allopeptide) in the course of their recruitment into an allograft. (See color plate 49)



mechanisms may be involved in the development of acute cellular rejection including $CD4^+$ T helper cell activation responses (discussed above), cytotoxic T cell-mediated targeting of the graft, activated endothelial cells, chemokine production, monocyte/macrophage-mediated events as well as natural killer (NK) cell-mediated lysis of graft cells. Several lines of evidence suggest that recognition of alloantigen by $CD4^+$ T cells is critical for the initiation and coordination of all of these events. Furthermore, effector responses mediated by $CD4^+$ T cells, discussed above, are characteristic of acute rejection. Inhibition of $CD4^+$ T cell activation using immunosuppressive agents (discussed in Chapter X), and the targeting of T cells with lytic antibodies have been found to markedly inhibit the development of acute rejection.

Importantly, the lysis of graft cells by alloreactive $CD8^+$ cytotoxic T lymphocytes is a critical mechanism in the development of acute cellular rejection. Most vascular and parenchymal cells express MHC class I molecules and $CD8^+$ T cells can directly target the graft to elicit destruction (3, 84). In addition, endothelial cells, as well as other cells within allografts express MHC class II molecules (*Fig. 74-8*), which can be recognized by circulating $CD4^+$ T cells. This antigen-presenting function of endothelial cells may result in reactivation responses within the graft, further amplifying the inflammatory and rejection process (4, 306, 308, 331). There is also considerable evidence that B cells participate in the acute rejection process and produce alloantibody, which also targets the graft vascular endothelium. The binding of alloantibody results in direct lysis of cells, or can result in complement deposition (including C4d), which can be identified in allograft biopsies (332). The identification of C4d deposition is a poor prognostic biomarker.

The production of alloantibody can result in a form of rejection called acute humoral rejection that is characterized by necrosis of cells within graft vessels (309). It is often mediated by IgG alloantibodies directed against endothelial cell alloantigens, especially MHC class I and II molecules. Following the binding of alloantibody to endothelial cells and complement deposition, lymphocytes are recruited into the site. Together, these events result in profound proinflammatory amplication loops leading to activation responses and cytokine production that serve to further accelerate cell death. Thus, the histologic pattern of acute humoral rejection is one of vasculitis and is different than the thrombotic occlusion seen in hyperacute rejection or focal/multifocal inflammation and interstitial disease found in association with acute cellular rejection.

Chronic Rejection

Chronic allograft rejection is a process that occurs in all solid organ transplants, including kidney, heart, lung, pancreas and to a lesser extent liver allografts, and is the most common cause of late allograft failure. It is a poorly understood process and is mechanistically and functionally associated with both alloantigen-dependent and alloantigen-independent processes (90, 115, 251, 333). Histologically, chronic rejection is associated with variable degrees of interstitial mononuclear cellular infiltrates, the deposition of extracellular matrix and the development of fibrosis. It is characteristically associated with the progressive narrowing of vessels following heart and kidney transplantation (commonly called chronic allograft vasculopathy), bronchioles following lung transplantation (commonly called bronchiolitis obliterans) or bile ducts following liver transplantation (chronic cholangitis) (90, 334, 335). While alloantigen has generally been thought to be critical for the initiation of chronic rejection,

improvements in the treatment of acute rejection have failed to impact the development of this process (336, 337). Thus, it is currently proposed that chronic rejection either results from a fundamentally distinct alloantigen-dependent process (e.g., indirect allorecognition, discussed above) and/or is a multi-factorial process.

Despite extensive research, the precise mechanisms involved in the development of chronic rejection remain unclear. It proposed that chronic rejection results from persistent insults to the graft, from the initial ischemia-reperfusion injury and early acute rejection (even low levels of acute rejection, called "silent" acute rejection), the chronic use of nephrotoxic medications (e.g., calcineurin inhibitors) and the chronic insidious inflammatory response associated with delayed type hypersensitivity mechanisms. It has been proposed that persistent ongoing injury to allografts and chronic inflammation will inevitably result in vascular obliteration and parenchymal interstitial fibrosis (*Fig. 74-4*). Consistent with this possibility, it has been observed that there is an association between the incidence of acute rejection and the development of chronic rejection (336); and further, there are correlations between the degree of injury at any time post transplantation and the development of chronic rejection (338).

Pretransplant sensitization and the development of alloantibody post transplantation is also predictive of a high risk for the development of chronic rejection (309). In addition, alloantigen-independent processes including organ injury secondary to brain death in the donor, viral infections, hypertension, hyperlipidemia, cellular senescence and toxicity of immunosuppressive medications are associated with the progression of chronic rejection (339). All of these factors alone may not be sufficient to mediate chronic rejection but each may serve as a component of "chronic persistent injury" to sustain graft destruction (338).

Histopathologically, chronic rejection is also distinct from acute rejection. Extracellular matrix proteins are destroyed by inflammatory proteases, and debris is phagocytosed by macrophages and granulocytes. Fibroblasts undergo morphological changes and produce scar formation by elaborating collagen, fibronectin, and proteoglycans that are organized into new extracellular matrix (326, 327). These highly regulated events probably evolve to maintain the structural integrity of damaged organs, but in this circumstance result in progressive graft dysfunction and eventually graft loss. Cytokines produced by macrophages and lymphocytes, including platelet derived growth factor (PDGF), basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF) induce smooth muscle proliferation and angiogenic responses and facilitate the narrowing blood vessels (90, 323, 340). Cytokines such as TGFβ, which is expressed in allografts undergoing chronic rejection, mediate endothelial to mesenchymal transition and fibrosis (326, 341). Thus, the injury itself, the response to injury as well as the repair process all contribute to the loss of graft function.

Transplantation Tolerance

Following transplantation, clinical tolerance implies that immune unresponsiveness to an allograft is achieved such that it is not rejected by the recipient in the absence of immunosuppression. Tolerance also implies that the recipient will mount a normal immune response to other antigens, including infectious pathogens, and that alloresponses to a third-party is maintained. Our understanding of the immunology of tolerance is based on a long history of basic research and clinical observations.

Historical Observations

The understanding of how an individual discriminates between self and non-self laid the foundation for transplantation immunology. Owen first identified immune responsiveness and "tolerance" as we know it today, when he noted that freemartin cattle, who share a common placenta, become hematologic chimeras and do not recognize each other's blood cells as foreign (342). This observation led to the concept of "neonatal tolerance" and suggested that tolerance is an active process. Burnet and Medawar hypothesized that there was a critical period in neonatal development when the fetal immune system learns to discriminate self from nonself (343, 344). In seminal experiments, Medawar demonstrated that neonatal tolerance could be developed actively in mice. He injected fully allogeneic donor cells into a mouse fetus, and found that the mice subsequently developed tolerance to these donor cells after birth, in as much as they accepted donor strain skin grafts. Furthermore, these same mice rejected skin allografts from a third party mouse strain. This response, which is unique to transplantation, was termed immunological tolerance, and has been studied ever since as a major mechanism by which the immune system learns to recognize self. Brent and Medawar also demonstrated that there is a window of opportunity for the development of neonatal tolerance and that this window varies from animal to animal. Furthermore,

it was found that tolerance was not tissue-specific in as much as injections of leukocytes or other cell types were capable of conferring tolerance to later skin grafts. Altogether, these observations demonstrated that the immune response could be manipulated to lose reactivity to a transplanted organ; and laid the foundation for modern transplantation immunobiology as we know it today.

Many factors promoting immune evasion and neonatal tolerance have been explored in recent years and several theories have been proposed to explain the process. These include clonal deletion, apoptosis, immune regulation, immune deviation and anergy. We will next consider how some of these specific mechanisms are involved in tolerance induction.

Clonal Deletion

This model suggests that all of the T cells capable of recognizing a particular antigen are deleted from the T-cell repertoire. For example, mice expressing a certain HLA class II molecule (e.g., I-E) delete all T cells expressing a particular T-cell receptor variable region (V β 17) (345). This type of tolerance is induced while thymocytes are maturing in the thymus. When whole tissue (e.g., glomeruli, pancreatic islets, or spleen cells) or cells such as dendritic cells, or antigens (e.g., alloantigens or allopeptides) are injected directly into the thymus, they have been found to result in transplant tolerance. These thymic or "central" mechanisms are thought to induce clonal deletion of recipient T cells capable of recognizing the injected cells (346, 347).

Apoptosis and Immune Regulation

Although T-cell deletion during ontogeny leads to immune tolerance, T cells that have exited the thymus into the peripheri can also be deleted. This process is called "peripheral tolerance." In the peripheri, mature T cells can undergo apoptosis by two distinct pathways: activation-induced cell death (AICD) and passive cell death. A1CD occurs in repetitively stimulated T cells and acts to limit the extent of the immune response. AICD is largely mediated through Fas and other members of the TNF receptor superfamily and appears to require IL-2. Once activated, T cells upregulate the expression of Fas and Fas ligand, and when cell-cell contact occurs, the interaction of Fas and Fas ligand results in apoptosis (348). The intracellular events leading to apoptosis/death are mediated though cell signaling pathways (called death pathways) that result in the activation of caspase enzymes which result in DNA breakdown (267). Passive cell death occurs when activated T cells are deprived of growth factors. This pathway results in cell death due to the inhibition of cell survival signaling and the downregulation of anti-apoptotic factors such as Bcl-2 leading to mitochondrial damage and cell death. Both AICD and passive cell death appear to be required for tolerance induction following transplantation (296). In addition, the phagocytosis of apoptotic cells by macrophages often leads to the production of IL-10 and TGF-β (349), which contribute to the development of peripheral tolerance (350).

It is also well established that that there are subsets of cells in the immune system, called regulatory cells, that have the potential to suppress active immune responses (discussed above). This observation was initially discovered as a result of studies in which it was noted that T cells from a tolerant animal can be transferred to another animal to subsequently render the animal tolerant (300). This observation, called "infectious tolerance" led Gershon and Kondo to hypothesize that there were cells (which they thought were $CD8^+$ suppressor T cells) actively involved in the dampening of the immune response (274). Moreover, it now appears that long-term maintenance of peripheral tolerance depends on self-perpetuating immunoregulatory mechanisms that actively inhibit alloreactive T cells. $CD4^+$ regulatory T cells, first identified in 1990 (275, 351), are now recognized to be the critical effectors of peripheral tolerance and the control of autoimmunity (142, 279, 352, 353). As discussed above, these $CD4^+$ T regulatory cells are defined by the expression of CD25 and FOXP3, and they express a range of other regulatory molecules including CTLA4, GITR as well as other receptors such as CD39. FOXP3 is a transcription factor that induces regulatory activity and protects against autoimmune disease. The mechanisms by which peripheral $CD4^+$ regulatory T cells exert their effects remain controversial, but in part involve the inhibition of IL-2 production by the responding T cells (354, 355). Suppression of T-cell proliferation by regulatory T cells may also involve the secretion of anti-inflammatory cytokines such as IL-10 (356) and TGF-β and IL-35 (357), and/or may require direct cell-cell contact (*Fig. 74-3*).

Finally, another mechanism leading to immune regulation and peripheral tolerance is immune deviation. Strategies that result in the deviation of an immune response from a Th1- to a Th2-type also skews the inflammat with immune suppression. Although not necessarily

causal, Th2 immune responses in general are associated with a lesser immune regulation.

Anergy

Anergy is another important peripheral mechanism by which renders mature T cells to be tolerant. The interaction between the T-cell receptor and specific antigen in the context of self-MHC activates the T cell only if a costimulatory signal is also provided (see above and (358, 359)). If a T cell does not receive the costimulatory signal, it will not be activated, proliferate, or differentiate into an effector cell. These cells become anergic; that is, for a prolonged period of time, they will not respond to the appropriate antigenic stimulus even in the presence of an effective costimulatory signal. Clinically, anergy appears to be inducible with soluble antigens, through either donor-specific transfusions (360) or soluble HLA molecules that may be released, for example, following liver transplantation (361).

Clinical Tolerance and Chimerism

Clinical tolerance has been observed rarely in patients following liver and kidney transplants. One study suggested that tolerance can be achieved in 5–10% of patients receiving bone marrow transplantation followed by organ transplantation from the same donor, particularly the liver (362). Tolerance following renal transplantation is extremely rare and while observed, frequently appears to be associated with an insidious form of chronic rejection. Also, it has been associated with an immunosuppressed state in patients with concurrent malignancy (363). Several research groups including Starzl (364, 365), Wood (299, 366), Sachs (367) and Sykes (368) have suggested that donor specific transfusions can serve to facilitate a form of immunological tolerance. These groups pioneered the concept that administration of donor alloantigen in the peri-transplantation period can govern the extent to which post transplant hyporesponsiveness (or tolerance) is achieved. Along with others, these groups have clearly demonstrated that one of the main mechanisms by which a donor specific transfusion can induce allogeneic hyporesponsiveness involves the establishment of mixed chimerism.

Mixed chimerism is defined as a state in which donor and host populations of hematopoetic cells co-exist in the recipient (368). Starzl and Sykes have proposed that the presence of donor cells in a transplant recipient may augment immunological tolerance and is a favorable outcome following transplantation (364, 368). Thus, chimerism may be initiated by "passenger leukocytes" which are inevitably transplanted along with a solid organ allograft. These passenger donor cells, which include stem cells and antigen presenting cells (APCs), migrate from the transplanted organ into the recipient (364, 365, 369).

The mechanism by which mixed chimerism might result in allogeneic hyporesponsiveness involves central (or deletional) tolerance (368, 370). This occurs when donor-derived APCs take up residence within the recipient thymus and mediate deletion of recipient donor-reactive T cells. The degree of chimerism post transplantation could be dependent upon the number of passenger donor leukocytes that are transferred into the recipient from the graft; and this can be different among kidney, heart and liver allograft recipients (364, 369). Liver allografts provide significant numbers of donor cells suggesting that chimerism could be most likely in these recipients. However, even following liver transplantation, chimerism is short-lived and in the absence of persistence should not lead to immunological hyporesponsiveness or tolerance (365, 371, 372). This observation led investigators to initiate studies involving the adoptive transfer of donor cells into the recipient at the time of transplant (or/and following transplantation) to promote and enable the persistence of chimerism. If chimerism is a mechanism underlying tolerance, then these studies could identify if chimerism actually causes immunological hyporesponsiveness as opposed to being simply associated with long-term allograft survival.

One possible clinical approach is to induce hematological mixed chimerism pre-transplantation. Initially this strategy was used in patients with malignancy receiving identical renal transplants (373, 374). In a recent study, this strategy has also been used in the setting of HLA mismatched kidney transplantation (374). Five patients with end-stage renal disease received combined bone marrow and kidney transplants from HLA single-haplotype mismatched living related donors. Transient chimerism developed in four of the five recipients and it was possible to discontinue all immunosuppressive therapy at different times following transplantation. In some of these patients, renal function has remained stable for up to 5 years post transplantation. These trials are the only successful studies that have achieved long term tolerance in patients receiving HLA mismatched kidney transplants. There are however other reports of the development of mixed chimerism and tolerance following HLA-mismatched liver transplantation (375).

Tolerance and Immunosuppressive Agents

Importantly there is also evidence that immunosuppressive medications have major effects on the induction of tolerance. Calcineurin inhibitors reduce regulatory T cell numbers and function (376). Similarly anti-CD25 antibodies cause a temporary depletion of regulatory T cells (377). However, the mTOR inhibitor drug rapamycin, which is efficient to inhibit effector T cell survival, allows for the selective expansion and survival of regulatory T cells. In part this effect relates to the ability of regulatory cells to utilize novel anti-apoptotic mechanisms (378, 379).

Clinical Tolerance and Costimulatory Blockade

In the early 1990s a soluble fusion protein was developed consisting of the extracellular binding domain of CTLA4 fused with the Fc domain of human IgG1, i.e., abatacept (CTLA4Ig) (380). Abatacept binds to both CD80 and CD86 blocking CD28 engagement and signaling (381). The expectation was that graft-specific tolerance would be induced in the clinical transplant setting when CD28-dependent costimulation was inhibited, as was demonstrated in rodents transplant models. However, graft-specific tolerance failed to occur following its use in nonhuman primates (382). Abatacept has been very effective as an immunosuppresant and is currently approved by the U.S. Food and Drug Administration for the treatment of moderate to severe rheumatoid arthritis (383). The failure of abatacept in the transplant setting was thought to be secondary to a fast off-rate of binding to CD86. A second generation agent, LEA29Y or belatacept, was genetically engineered to bind with a higher affinity to CD80 and CD86 compared to abatacept (384). In nonhuman primate renal transplant studies, belatacept is better at preventing acute rejection episodes than abatacept and may offer an alternative to the current maintenance immunosuppressive regimens available (385). Belatacept is currently in phase III human clinical trials to determine if costimulatory blockade can replace calcineurin inhibitors in immunosuppression protocols (383). Preliminary data suggests it may also provide an advantage in reducing the development of chronic rejection.

Targeting other costimulatory pathways such as the CD154/CD40 pathway are also very appealing because of their potent ability to block T cell activation as well as alloantibody production. Initial studies in nonhuman primates demonstrated long-term kidney allograft survival using anti-CD154 (195). However, studies using anti-CD154 (hu5C8) treatment in humans resulted in thromboembolic complications not observed in small animal models (198). This has been attributed to the expression of CD154 on human but not mouse platelets. Nevertheless, newer agents are again being developed that do not have this effect.

Collectively, new costimulatory blockers and tolerance induction studies represent the "tip of the iceberg" in terms of efforts to promote clinical tolerance in humans. Over the next few years, it is likely, that several additional agents will become part of clinical immunosuppressive regimens, and it is hopeful that they will represent a major leap forward to enhance efforts to promote long term graft survival in humans.

75 Pediatric Kidney Transplantation

William E. Harmon

Introduction

Pediatric kidney transplantation is an extraordinary treatment for End Stage Renal Disease (ESRD) which requires the active and collaborative participation of a team of medical and surgical specialists, including pediatric nephrologists, transplant surgeons, transplant coordinators, dialysis personnel, nutritionists, social workers, psychologists, activity therapists, tutors, pharmacists, infectious disease specialists, and many other consultants. Successful treatment, therefore, requires substantial resources at specialized centers. Nonetheless, since ESRD is relatively rare in children, even the busiest of these centers performs no more than several dozen transplant procedures annually. Thus, the most accurate and reliable information about transplantation requires registries that accumulate information from many centers; and research requires multi-center collaborative study groups. Several voluntary and mandatory registries, therefore, now exist in the field. This chapter is based principally on two of those registries, whose databases are freely available on the World Wide Web: The Organ Procurement and Transplant Network (www.optn.org) and the Scientific Registry of Transplant Recipients (www.ustransplant.org) contain the database of every organ donation and transplant event occurring the in United States since 1986 and appropriate scientific analyses of that data. The North American Pediatric Renal Trials and Collaborative Studies (www.naprtcs.org) has collected information on almost 17,000 children with ESRD treated in 147 North American centers since 1987, including 9,854 index transplant procedures. Based on the size of these databases and the extensive analysis available from them, the information they have produced does provide an appropriate and accurate perspective about the field of pediatric kidney transplantation.

Role of Kidney Transplantation in Treatment of ESRD in Children

Renal transplantation is widely recognized as the treatment of choice for children with end stage renal disease (1–3). The life expectancy benefit of renal transplantation over chronic dialysis for these children may be as much as 25–30 years (4); and a recent report has demonstrated that transplanted children have a survival benefit when compared to those on the waiting list that is even more pronounced than what is found in adults (5). A functioning renal transplant enables children to develop almost normally, grow reasonably well and improve their school performance levels (6–9). Both peritoneal dialysis, delivered as CAPD or CCPD, and hemodialysis lead to a deceleration of growth. Data from the dialysis component of the NAPRTCS registry (10) show that dialyzed childrens' overall height deficit of −1.8 S.D. became more negative reaching a value of −2.16 S.D. at 24 months. Additionally children do not tolerate being "dependent" on the treatment and maintenance dialysis induces loss of self-esteem and emotional maladjustment (11). Cognitive achievement testing may diminish with prolonged time on dialysis (8). In contrast, the mobility and freedom from dietary restrictions afforded by a functioning renal transplant enable children to live nearly normal lives. Although renal transplantation has not lived up to the promise of normal growth for all children, dramatic short-term improvements in height can be seen in many and final adult height is improving after transplantation (7, 12–14). Most importantly, successful transplantation permits the child to attend school and to develop normally; school function testing improves dramatically following transplantation (6, 15). And, importantly, young children now have the best long-term outcomes of all ages of transplant recipients, verifying the utility of transplantation in this age group (16). For all of these reasons, successful renal transplantation remains the primary goal of programs that care for children with ESRD.

There has been a substantial change in long-term renal allograft outcome for children during the past decade (17–19). Previously, young children were thought to have poor short- and long-term graft survival related to several factors, most prominently a proposed heightened immune response, especially in infants (20, 21). Conversely, however, adolescents were subsequently noted to have a higher rate of late acute rejections (22) and infants may have a lower rate of acute rejection than older

© Springer-Verlag Berlin Heidelberg 2009

children (23). An important analysis of the UNOS data demonstrated that short-term pediatric renal transplant survival rates became comparable to those in adults about 10 years ago (22). The most recent comprehensive registry reviews have clearly demonstrated a dramatic reversal in outcomes. Improvements in surgical technique (24–28), donor selection (29), immunosuppression practices (30–34), and the enhanced experience of specialized pediatric transplant teams (35), as well as the development of multi-center research consortia have all led to marked improvements in patient and kidney graft survival for infants and young children (17, 18, 36). Indeed, several analyses have identified these very young recipients as now having the best long-term survivals of all age groups (17, 22, 37, 38). In fact, young recipients of adult-sized kidneys who have immediate graft function have been reported as having the longest projected graft half-lives, exceeding even those of adult recipients of 2-haplotype matched living donor transplants (39).

Currently, pediatric recipients under age 11 who receive living donor kidney transplants have 3-year graft survival rates that are as good or better than older age groups (93% for those aged 0–5 years, and 92% for those aged 6–10 years) (38). The results of young recipients of deceased donor kidney transplants are similar to those seen in adults, with recipients aged 1–5 years and those aged 6–10 years having 3-year graft survival rates of 82% (38). Unfortunately, this excellent outcome is not seen in adolescents whose 3-year graft survivals for both living donor (85%) and deceased donor (76%) grafts are worse than all other age groups. As shown in *Fig. 75-1*, 5-year graft survival rates for both living and deceased donor kidney transplants for children less than 11 years of age are better than all other age groups of children and adults (38).

Incidence and Frequency of Pediatric Kidney Transplantation

By the end of 2008, there were about 75,000 individuals registered on the UNOS kidney transplant waiting list. Of these, about 1,800 were children, representing 2.4%. In 2008 16.514 kidney transplants were performed in the United States, of which 773 were children; thus pediatric patients comprise about 4.6% of all transplant recipients in the United States. Pediatric recipients received 293 or 5% of all living donor kidney transplants and 480 or 4.5% of all deceased donor transplants. Although the number of pediatric transplants performed each year has not varied by more then 10%, the donor origin has undergone substantial changes (*Fig. 75-2*).

The Scientific Registry of Transplant Recipients (SRTR) data show that living kidney donation has expanded substantially during the last decade and the number of living donors exceeded the number of deceased donors in the United States for the first time in 2001 (40). Living donation has accounted for 35–42% of all annual kidney transplants in the United States in the past decade. In 1987, only 40% of all transplants performed in children were from living donors; by 1991, the figure had risen to 53%, and until recently living donors accounted for over 60% of all pediatric renal transplants (*Fig. 75-2*) (36, 38). This recent shift of donation to a majority of deceased donors is likely related to a change in the Organ Procurement and Transplant Network (OPTN)

Figure 75-1

Five-year graft survival by age at the time of kidney transplantation. (Adapted from (38)).

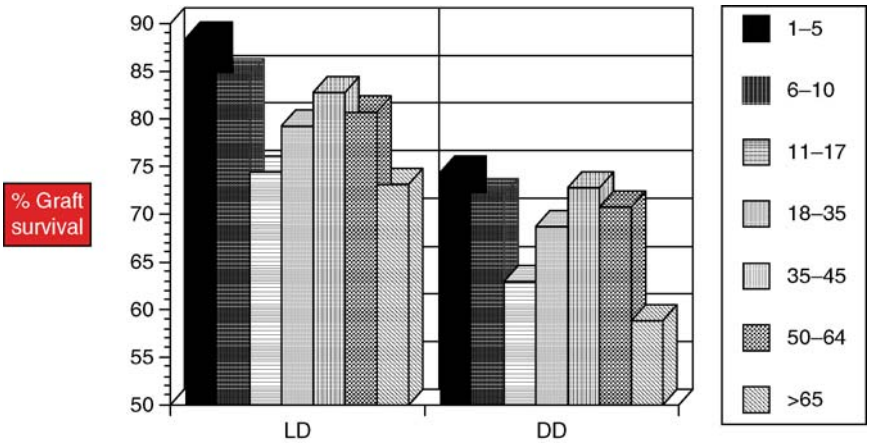

Figure 75-2

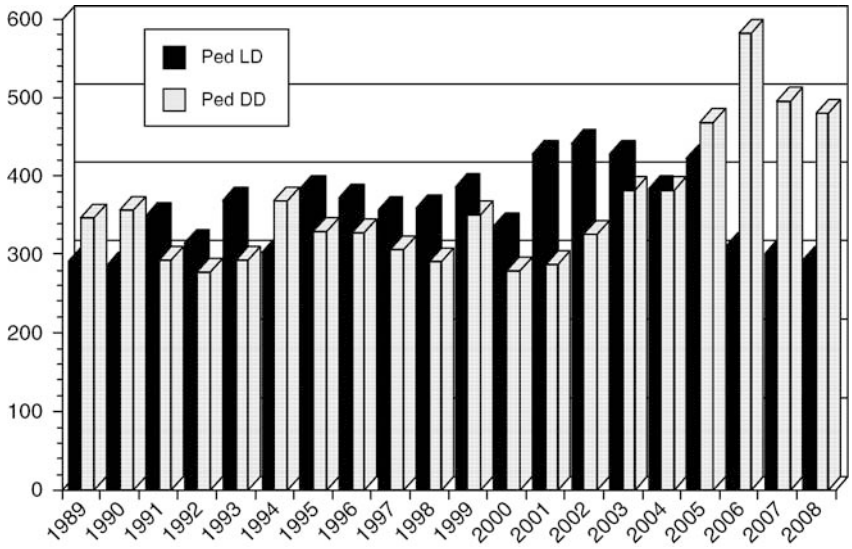
Pediatric living (LD) and deceased (DD) donor kidney transplants by year of transplantation.



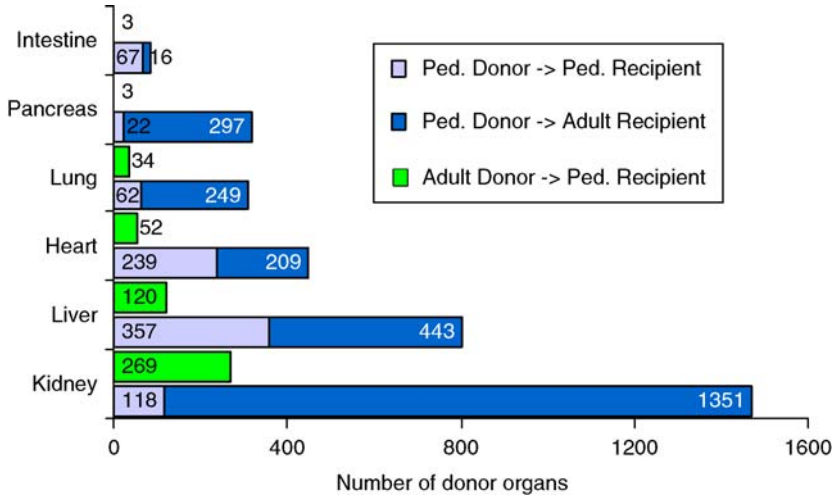
allocation system designed to provide reduced waiting time for children by giving them substantial preference on the waiting list (41).

Parents comprise 80% of living donors for pediatric kidney transplants. Mothers comprise the majority of parent donors; fathers account for 44%. Since there are more boys than girls who receive kidney transplants, it should not be surprising that fathers donate to sons 63% of the time and mothers to sons 59%. A recent analysis of 23,064 1-haplotype matched living related donor transplants in the SRTR database showed that mother-to-child transplants had the worst outcome of all possible groupings (HR = 2.61, $P < 0.0001$), which argued against any advantage of fetal-maternal microchimerism (42). One possible exception is that infants less than 1 year of age seem to have fewer rejections if the mother is the donor (22, 43). Due to the fact that children most often have siblings who are too young to be living donors (less than 18 years), the NAPRTCS registry has recorded only 382 transplants between siblings. Of these, 182 grafts were from donors less than 21 years of age. A review of the NAPRTCS registry identified only 15 living donors under 18 years of age, of which 13 were transplants between siblings and one was from an emancipated-minor parent to child. The majority of these young donors were 2-haplotype matches to the recipients. It is quite clear that most programs seem reluctant to use young donors (44, 45). However, a review of UNOS data revealed that out of approximately 40,000 living donors in the US between 1987 and 2000, 60 were from donors less than 18 years of age (46). Twenty-four of the recipients were children and 36 were adults; only 7 of the transplants were between identical twins. Subsequent to that report, the international transplant community recommended that minors not be used for living organ donation (47). In recent years there has been a substantial interest in living-unrelated donation in adult transplant literature since the outcome of these grafts has been shown to be equivalent to most living related donors and better than that of deceased donor kidneys (48). NAPRTCS has identified 232 instances of living-unrelated donation between 1987 and 2007. In a preliminary analysis of the first 38 living- unrelated recipients, 23 (61%) were male, 30 (79%) were Caucasian, eight were less than 6 years old, and 20 were older than 12 years (49). This was the primary transplant for 29 of the 38 recipients. Of the 38 donors, 22 were non-biologic parents, and a family friend was the donor in 10 of the cases.

About 70% of deceased donor kidneys transplanted into children are recovered from adult donors (*Fig. 75-3*) (17). In the 1980s there was a tendency to preferentially place kidneys recovered from infants into young recipients, with disastrous consequences for patient and graft survival (50). As a result of widespread dissemination of these data (51, 52), there has been a marked change in that practice. From 1987 through 1990, the percentage of deceased donors younger than 10 years ranged from 32 to 41%. From 1991 through 1994, these percentages

Figure 75-3

Numbers of pediatric and adult organ donors and recipients. In general, the number of pediatric organ donors exceeds the number of recipients for all organs transplanted (17).



ranged from 12 to 22%. Prior to 1991, children less then 2 years of age comprised 3.2% of deceased donors. In 1991, no pediatric recipient received a kidney from a deceased donor less than 2 years of age; and in 1995 and 1996, there were no such kidneys utilized in children (53). Between 1991 and 2000, less than 1% of deceased donors for children were <2 years of age (36) and between 1991 and 2007, there have been only 28 such donors (0.8%). This change in allocation of kidneys from young donors corresponded to improvement in graft survival (50). Some specialized pediatric programs have reported good results with young donors (54, 55), but many programs reserve grafts from very young donors for en bloc or single kidney transplantation into older recipients (56–58). It is also important to note that the majority of organs recovered from pediatric deceased donors are transplanted into adults (*Fig. 75-3*) (17).

Demographics of Pediatric Kidney Transplantation

Age, Gender and Race at Transplantation

Kidney transplantation prior to 6 months of age or below a recipient weight of 6 kg is exceptional. From 1987 to 2007, NAPRTCS has recorded 94 transplants performed in children younger than 12 months (59). Of these, seven transplants were performed in children between 3 and 5 months, 22 were performed in children between 6 and 8 months, and 63 were performed in children between 9 and 11 months of age. Seventeen infants have been reported to NAPRTCS since 2000 and UNOS has recorded 26. As is true for older infants, the majority of kidney transplants in infants <1 year of age have come from living donors. In general, the number of kidney transplants performed in infants <1 year seems to be declining, whereas the number in children 1–5 years has increased slightly. Since infants and adolescents have different risk factors for both patient and graft survival, children have been grouped into multiple age categories. NAPRTCS uses 0–1, 2–5, 6–12, 13–17 and 18–21 years of age for analyses. In 1987, 25% of all pediatric transplants were performed in children 0–5 years of age (20), whereas in 1995 the figure was 17% (53) and it currently is 18% (59). It had been suggested that children 0–5 years were at higher risk for graft failure (21, 60) and that was thought to account for poor outcomes in young kidney transplant recipients years ago. It is important to note that excellent results had been reported in very young patients in some individual centers even then (37, 61). The concept of a heightened immune response in young recipients was called into question (62–64). Thus, the unique problems associated with transplantation in young recipients may have been related to correctable conditions, such as infections, technical issues and differences in pharmacokinetics (22, 23, 65–67) rather than their immune response. Recent reports of outstanding

long-term graft survival rates for these young children demonstrate that their specific problems have been overcome successfully and now it is clear that children <10 years of age have the best living- and deceased-donor kidney transplant survival of all age groups of both children and adults (16, 17, 59) (*Fig. 75-1*).

As shown in *Table 75-1*, there is a strong relationship among age at transplant, gender, race and categories of etiology of ESRD. The most common causes of ESRD in infants and young children are renal dysplasia/hypoplasia/aplasia and obstructive uropathy, which are substantially more common in males than females. Thus, almost 2/3 of children less than 10 years of age who receive kidney transplants are males. At older ages, ESRD secondary to reflux nephropathy or to acquired disorders such as focal segmental glomerulosclerosis (FSGS) and lupus nephritis become more common and gender differences tend to disappear. Racial distribution of ESRD leading to transplant is similar to the general population in younger children. However African-Americans make up a disproportionately large percentage of adolescent and young-adult recipients of kidney transplants, and this proportion may be artificially low. Unfortunately, even in a pediatric setting, there are substantial differences in waitlist activation between black and white children (68). In a study of 3,284 children at the time of their first dialysis treatment, blacks were less likely to be waitlisted at any given time. The authors concluded that racial disparities in access to pediatric kidney transplant existed. Sadly, there are even disparities in outcomes after transplant, with blacks having worse outcome, even after controlling for confounding factors (69).

Etiology of ESRD

ESRD in children is generally due to congenital or inherited diseases. In reviewing 9,854 transplants, the most common congenital diagnoses are obstructive uropathy and aplastic/hypoplastic/dysplastic kidneys, each representing about 16% of the patients (36, 59) (*Table 75-2*). Among glomerular disorders, focal segmental glomerulosclerosis (FSGS) is the most common (11.7%), averaging about 60 transplants per year. The primary diagnosis also varies with the race of the recipient. Overall in the NAPRTCS registry, Caucasian children account for 60% of all recipients; however, Caucasian children only account for less than 50% of the children transplanted for FSGS. The data regarding the role of FSGS in leading to ESRD can be better appreciated by observations from the NAPRTCS dialysis registry, in which the two most common diagnoses are FSGS (14.4%) and aplastic/hypoplastic/dysplastic kidneys (14%). Of 933 children with FSGS on dialysis, Caucasian children account for only 34%, with African-American and Hispanic children accounting for 62% of the patients. FSGS accounts for ESRD in 12% of

Table 75-1

Age, gender, race and etiology of ESRD at time of kidney transplantation. All figures are percents (Adapted from (88))

	Age at Transplantation				
	0–1 years	2–5 years	6–12 years	13–17 years	≥18 years

Caucasian children receiving dialysis. In contrast 24% of African-American children on dialysis and 30% of those >12 years old have FSGS. The information about etiology of ESRD becomes critical in predicting graft survival as well as strategies for immunosuppression and preparation for transplantation because of recurrence of the original disease, as discussed below.

Indications for Pediatric Kidney Transplantation

End Stage Renal Disease (ESRD), which is also known as Stage 5 Chronic Kidney Disease (CKD), is the most severe form of chronic loss of kidney function, and, in general, is defined as the need for chronic dialysis or kidney transplant to sustain life. In this context, it is important to recognize that both dialysis and kidney transplantation are treatments for ESRD, but neither can be considered a cure. Currently in the United States, dialysis is rarely indicated in adults until the GFR has fallen below 15 ml/min/1.73 M^2 or the serum creatinine has exceeded 8 mg/dl. Thus, it is appropriate to consider the indications for both chronic dialysis and kidney transplantation to be the same, specifically the attainment of ESRD.

Not all patients who have ESRD can be considered candidates for kidney transplantation, however. The procedure may be too risky for some because of their co-morbidities and others may have some contraindications, such as chronic infections that would be exacerbated by immunosuppression. The general evaluation of potential recipients and the indications for transplantation have been reviewed several times (70–72). For those for whom transplantation is indicated, there is a survival advantage of kidney transplantation over dialysis, thus it appropriately should be considered a "life saving" procedure. This survival advantage has recently been shown to be true for children (5).

Virtually all children who develop ESRD are considered to be candidates for a renal transplant since they rarely have serious co-morbidities or contraindications. Thus, a significant number of children receive a pre-emptive kidney transplant without ever having been on dialysis (73). In a review of 8,990 primary kidney transplants in children transplanted from 1987 through 2006, NAPRTCS noted that 25% of the patients had never received maintenance dialysis prior to transplantation (59). Although dialysis is not necessary before kidney transplantation in children, that fact should not be confused with the indication for pre-emptive kidney transplantation. There is no benefit reported benefit to performing kidney transplantation before a patient reaches ESRD (74). In the past, growth failure was considered a unique pediatric indication for kidney transplantation; but the success of recombinant human growth hormone in overcoming this complication of CKD in children (9, 75) has eliminated growth failure as a valid indication for early kidney transplantation. A very disturbing result from an analysis of UNOS data demonstrated that African-Americans in the US are less likely to

be waitlisted for transplantation at any time after their first dialysis treatment than Caucasians (68).

Thus, the indication for pediatric kidney transplantation is permanent loss of renal function, resulting in ESRD, and the lack of any defined contraindication.

Absolute Contraindications for Pediatric Kidney Transplantation

There are few absolute contraindications to transplantation. One possible contraindication is an active malignancy, especially if has already metastasized, which has a very low likelihood of long-term survival. A recent analysis of the NAPRTCS dialysis registry revealed information on 70 children with Wilms' tumor or Drash Syndrome. Thirteen of these children did not receive a kidney transplant because of uncontrolled or metastatic disease and all 13 died (76). The registry also showed that for 86 children with the same diagnoses but without metastases who did receive a kidney transplant, none had graft loss due to recurrence and none had different outcome from transplant than other recipients. One child, however, who had only 6 months of dialysis prior to transplantation did die of Wilms' tumor within 6 months of transplantation. Thus, children with already existing metastatic disease are not considered transplant candidates and most centers will wait for 12 months after nephrectomy for Wilms' tumor prior to transplantation to assure that the disease is actually cured. Also, children with devastating neurological dysfunction may not be suitable transplant candidates, but the wishes of the parents, as well as the potential for long-term rehabilitation, must be considered in these circumstances. Since the transplant procedure and the life-long need for immunosuppression have several potential risks, there are serious ethical concerns about whether these patients will be able to balance those risks by understanding any of the potential benefits.

The concern of further immunosuppressing an already compromised host previously contraindicated transplantation of HIV+ children. Many children who developed HIV nephropathy succumbed to the systemic ravages of the virus, either before or very shortly after reaching ESRD status (77). However, marked advances of treatment of HIV+ patients, especially with protease inhibitors and other anti-retroviral therapies, makes consideration of kidney transplantation more likely (78, 79). Ironically, initial results from a few centers suggests that HIV+ patients with reasonable CD4 cell counts may have more problems with rejection rather than infection post transplantation.

Potential for recurrence of the original renal disease is of major concern but generally has not precluded at least an initial transplant for most children. Focal segmental glomerulosclerosis and atypical Hemolytic Uremic Syndrome have substantial potential for recurrence in kidney transplants, but our ability to correctly identify recipients in whom recurrence will occur is not yet accurate (see below). Oxalosis, which once was considered an absolute contraindication due to a high incidence of recurrence in the transplanted kidney, as well as extension in other organs, can be treated successfully with combined liver and kidney transplantation (80, 81), although the complication rate remains high (61, 82, 83).

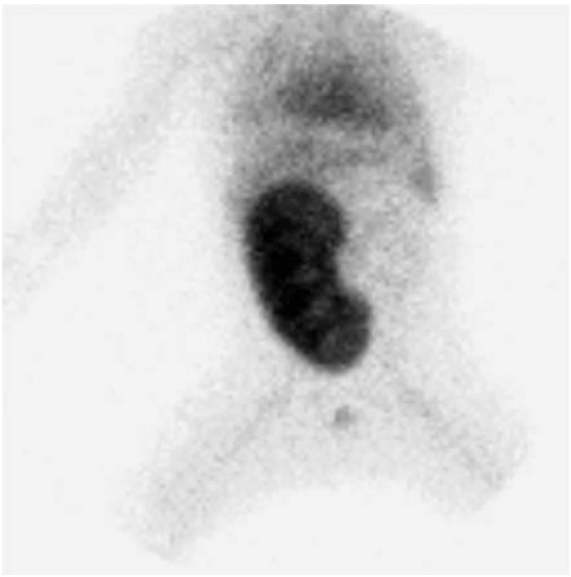
Correctable or Temporary Contraindications for Pediatric Kidney Transplantation

Pediatric kidney transplantation is generally considered an elective procedure. Because of the ready availability of dialysis treatments for children at pediatric transplant centers, even young infants can be maintained for sufficient time so that any correctable problems can be attended to before the transplant. In this setting, kidney transplants can be performed under the best possible conditions, rather than as emergencies. Importantly, donors for pediatric transplant candidates are readily available in the United States, so that they can expect to receive the transplant soon after they have been prepared for it. About half of the transplants are from living donors, who should be available when needed, and the waiting time for pediatric candidates on the deceased donor list in the United States and many other countries is much shorter than adults because of pediatric preference rules.

Most grafts for infants come from adult donors (59). All living donors are currently older than 18 years and the majority of deceased donors for children are adults (*Fig. 75-3*) (17). There is a substantial survival advantage of using adult donors for these infants (39). Thus, one of the major issues for these children is to grow big enough to accept an adult-size kidney. There is no consensus on the appropriate size, but most programs use a weight between 6.5 and 10 kg or a length of at least 65 cm as an appropriate size to meet that standard; while other programs may suggest a minimum age rather than size. *Figure 75-4* shows a Mag-3 renal scan of a small infant who has received an adult kidney transplant. Note that the graft appears to be larger than the recipient's liver and that it slightly passes the midline. Thus, most programs will maintain infants with ESRD on chronic dialysis and provide aggressive nutritional programs and growth

Figure 75-4

Mag-3 nuclear scan of adult kidney transplanted into a 9-month-old infant weighing 7 kg at post-operative day #1. Note the uptake of the tracer in the liver in the right upper quadrant of the abdomen and in the heart in the chest. There is a small amount of tracer in the bladder.



hormone to have them attain an appropriate size. This likely explains the low number of infants who receive kidney transplants prior to their first birthday.

Children with acquired or autoimmune disease often have had extended and rigorous treatments prior to the development of ESRD. It is prudent to withdraw these treatments if there is no hope of reversing or treating ESRD and allowing the child to recover nutritional and metabolic stability. For example, children with FSGS often have received extensive treatment with corticosteroids and other immunosuppressive agents and may also have had extensive protein wasting. For these children, recovery of reasonable nutritional status prior to transplantation is reasonable and this may require months of rehabilitation while receiving treatment with chronic dialysis. Some programs prefer to allow certain diseases, such as lupus nephritis, to "burn out" by maintaining the patient on dialysis for several months after they have reached ESRD rather than progressing to kidney transplantation immediately.

Other children require corrective surgery or native nephrectomy prior to kidney transplantation. For example, children with Finnish-type congenital nephritic syndrome often require native nephrectomy, despite normal renal function, to prevent protein malnutrition, sepsis and vascular thrombosis, followed by months of chronic dialysis to make them suitable for kidney transplantation (84, 85). Similarly, children with serious urologic malformations of the bladder or urinary tract may require extensive reconstructive surgery prior to transplantation to assure that the recipient will have a competent, low-pressure, functional or catheterizable internal reservoir prior to receiving a kidney transplant.

Pre-emptive Pediatric Kidney Transplantation

Since pre-emptive transplantation is an important modality for children, NAPRTCS conducted a special study to determine the frequency and outcome of this approach (73) and has updated it in the annual reports (36, 59). From 1987 through 1992, 26% of the patients were registered as having had pre-emptive transplantation. The study compared data of those recipients who had been on maintenance dialysis versus patients who had no previous dialysis. Of 2,213 primary grafts during that time period, 1,150 (52%) were from a living donor, whereas for the pre-emptive group 70% were recipients of a living donor kidney. More recently, of 8,613 primary transplants, 2,116 (24.6%) were pre-emptive, indicating that the practice has changed very little in the past 2 decades. Pre-emptive transplantation was more common in living donor (34%) than in deceased donor (13%) and in males (28%) than females (20%). The rate varies little among age groups with 19, 24, 28, 23 and 21% for the 0–1, 2–5, 6–12, 13–17 and 18–20 age groups respectively. It varies more across races with Caucasians, African-Americans, Hispanics and "other" races having rates of 31, 14, 16 and 18% respectively. As noted above, African-Americans are also less likely to be waitlisted than Causcasians following initiation of dialysis (68). A proposed objection against pre-emptive transplants has been that without the rigors of prior dialysis adherence with immunosuppression might be poor. To determine whether this hypothesis was correct, graft survival was compared between the two groups, and was determined not to be different at 1 or 4 years (73). When causes for graft loss were analyzed, the pre-emptive group did not have a higher incidence due to nonadherence. NAPRTCS also surveyed the motive for pre-emptive transplantation and determined that the primary reasons were parents' desire to avoid dialysis (34%) and the nephrologists' recommendation (18%). Desire for improved growth

was considered a contributory factor in 50% of the patients (73). A more recent analysis has even shown a survival benefit of early transplantation (5), but not before ESRD has been reached (74). The overall beneficial effects of pre-emptive renal transplantation have been well-documented (5, 73, 86, 87).

Preparation for Pediatric Kidney Transplantation

The typical components of preparation of the child with ESRD for kidney transplantation are shown in *Table 75-3*.

Donor Selection

The selection of the appropriate donor is an integral part of the transplantation procedure and may be a limiting factor in the long-term outcome of kidney transplantation for any individual child. The use of living donors has generally been much more common in pediatric kidney transplantation than in adults (17, 36, 38, 52, 53, 59, 88). In general, the choice of a living donor is a good one since, on average, graft survival can be twice as long when a living donor is used compared to a deceased donor (17, 59, 88). There are limitations to the use of living donors however, such as donor suitability, blood group incompatibility and age; and, thus, not every child may have a suitable living donor. Moreover, there is concern about using living donors when there is a substantial risk of early graft failure or recurrent disease (89, 90). When deceased donors are used for children, careful attention should be paid to utilizing low-risk donors since the mortality risk for children after kidney transplantation is low and children are expected to require the grafts for long periods of time (3, 29, 41, 91, 92).

Living Kidney Donation

The first successful kidney transplants utilized living donors and the use of living donors has been a mainstay of pediatric kidney transplantation since that time. Importantly, as the donor shortage has become more acute, considerations about donor safety have also become apparent (93). Recently, the transplant community has examined this issue and has reached consensus at national and international conferences on the appropriateness of the use of living donors, their evaluation process and the appropriate follow-up and care of those donors (47, 94).

Table 75-3
Standard preparation of pediatric renal transplant candidates

History and physical examination
Laboratory tests
Hematology (CBC, platelets, differential)
Coagulation (PT, PTT, TT)
Chemistry (serum electrolytes, BUN, creatinine, liver function, lipid profile, Ca, PO_4, PTH)
Urine volume, culture, and urinalysis

[a]For selected recipients
[b]Recommended vaccines are age-dependent

Those conferences reiterated the important principle that the donor should never be put at physical, emotional or psychological risk for the benefit of the recipient. Included in this principle was the agreement that children less than 18 years of age should not be considered as living donors, although that has not been universally observed (46, 95). The living donor pool has been increased by the use of genetically unrelated donors, which initially

included spouses, but has expanded to include other genetically unrelated family members, friends or even anonymous non-directed ("good Samaritan") donors. Importantly, the outcomes of these unrelated donors appear to be comparable to 1-haplotype matched related donors (96–103). There have even been proposals that non-directed living donors be compensated for the donation, leading to a commercial system to expand the donor pool (104, 105). Although commercial systems using paid donors have existed in many parts of the world, most countries have declared such practices illegal and the broad transplant community has condemned them (106, 107). The use of non-directed living donors have also played an important role in expanding the donor pool through the practice of donor exchange. These programs have allowed living donors to donate to an unrelated recipient in exchange for that recipient's incompatible donor to donate to the former's family member (108–110). These programs have included simple 2-recipient exchanges, multiple domino-style exchanges and exchanges with the deceased donor waiting list (111–118).

Matching

In general, all living donors are evaluated for ABO blood type, HLA histocompatibility typing and some type of cross-matching with potential transplant recipients. Parents predominate as living kidney donors for children, accounting for about 80%. Unrelated donors, siblings and occasional non-directed donors make up the balance (59). Thus, there are few 2-haplotype donors for pediatric kidney transplantation, with most donors being 1-haplotype HLA matched, or less. Although there may be some disadvantage to the lack of any HLA-B matching (59), overall the lack of histocomatibility matching for pediatric recipients, especially infants, does not seem to compromise long-term outcomes (22, 39).

Donor Evaluation

As noted above, donors are carefully evaluated in order to assure that they are not being paid, coereced or that they might be injured in any way as the result of the donation procedure. The components of an appropriate donor evaluation have been published (119, 120) and can be found on organizational websites (http://www.a-s-t.org/index2.cfm?Section=public_policy&Sub1Section=key_position_statements&content=med_eval_living_kidney_donors.cfm). Much of the evaluation is performed to assure donor safety, but also it is designed to assure that the donor does not transmit infectious or other diseases to the recipient and that the donor organ will provide sufficient function for the recipient.

Contraindications to Living Kidney Donation

In general, donor candidates are excluded if they are too young (<18 years of age), too old (as individuals age, they lose GFR and the potential for cancer, cardiovascular and other diseases increases) or have medical problems that may be exacerbated by the donation surgery or living with only one kidney (47). Conditions such as hypertension, diabetes and a history of metastatic cancer typically exclude donors. Also, chronic infections such as HIV, or hepatitis B or C are exclusionary because of the likelihood of transmission. Although CMV, HPV and EBV may also be transmitted, these are typically not exclusionary, since they can be treated in the recipient.

Laparoscopic Donor Nephrectomy

The use of a laparoscopic technique to remove the living donor kidney has become very popular recently, because it tends to shorten the hospitalization and rehabilitation time for the donors. The procedure does require substantially longer time in the operating room and the rate of delayed graft function is slightly higher. Although most programs indicate that the procedure is safe, a review of 10,000 living organ donations identified three deaths or serious complications; all three followed laparoscopic procedures (121). Single center reports show good outcomes for pediatric recipients when the donor has a laparoscopic nephrectomy (122–124); while other studies suggest more complications in the pediatric recipients (125, 126).

Deceased Donor

The majority of kidney transplants currently come from deceased donors. While living donors were more common for children in the past, recent changes in allocation policy in the United States have led to a predominance of deceased donor transplants for children there in the past 3 years (*Fig. 75-2*) (5, 38, 41). The consequences of this change in donor selection will not be known for years; but, on average, the long-term outcomes of living donor

kidney transplants in children are superior to those obtained from deceased donors (Fig. 75-1) (38, 41, 59, 88), indicating that the short term benefit of having rapid access to the deceased donor list may be counterbalanced by shortened graft survival.

Matching and Sensitization

The influence of matching on transplant outcome used to be substantial, but it has diminished significantly since the introduction of improved immunosuppression (127–130). Pediatric deceased donor kidney transplant outcomes are influenced very little by donor histocompatibility matching (41, 59, 88). ABO blood type compatibility and cross matching are still necessary, however. In general, transplant candidates who have pre-existing antibodies or who develop antibodies after transplantation are at higher risk of early rejection and should have enhanced immunosuppression protocols (131–135).

Donor Evaluation

Deceased donors are typically evaluated to assure that the graft will provide sufficient function for the recipient and that the donor does not transmit infectious or metastatic cancer diseases to the recipient. In the past, the standard for determining the donor eligibility rested on the determination of brain death. However in efforts to expand the donor supply, recent advances have been made in recovering organs from donors whose death has been determined on the basis of cardiac death, so-called donation after cardiac death (DCD). Although there is a substantially higher incidence of delayed graft function when such donors are used, the short term outcomes of kidney transplants from DCD donors is equivalent to that from brain-dead donors (100, 110, 136, 137).

Allocation of Deceased Donor organs

Most countries with national organ allocation systems have provided some sort of preference for pediatric deceased-donor transplant candidates. In the United States, a recent change of the Organ Procurement and Transplant Network allocation system gives children <18 years of age at the time of listing, preference over most other candidates, resulting in much shorter waiting times than adult candidates (41).

Donor-Defined Outcome Risks

Very young donor age was previously identified as a risk for decreased graft survival (29, 138). Since that time, specific techniques for successfully using young donor kidneys have been developed in some centers (55). Similarly, the use of elderly or extended criteria donors (ECD) has continuously been associated with poor outcomes (101, 110, 139, 140). Children rarely receive organs from elderly deceased donors or from extended criteria donors (88).

Desentitization Procedures for Sensitized Recipients

As noted above, the presence of pre-formed anti-HLA and anti-donor antibodies often precludes the use of a specific donor. Similarly, ABO blood type incompatibility will also prevent the use of specific donors for transplant candidates. Programs designed to "swap" donors may permit successful transplantation in these situations, but the chance of finding compatible donor pairs is low. Another approach would be to attempt to remove anti-donor antibodies or isohemagglutinins by desensitizing procedures. Such procedures utilizing plasmapheresis, intravenous immunoglobulins (IVIG), immunosuppression and rituximab have been described (132, 141–146). Long term outcomes of desensitized recipients is generally less successful than unsensitized recipients, however.

Growth and Nutrition

Chronic kidney disease often leads to malnutrition in children, due to anorexia, protein losses, dietary restrictions and the debilitating effects of medications used to treat autoimmune disorders. Thus, it is not unusual for the child to be malnourished when reaching ESRD. In this setting, it is reasonable to begin chronic dialysis and to provide appropriate techniques to improve nutritional status prior to transplantation (84, 85, 147–152).

Immunizations

Once children receive a kidney transplant, they will require life-long immunosuppression, which may diminish their response to subsequent killed-vaccines and prevent the use of live-virus vaccines. Thus, pediatric programs generally attempt to adequately immunize children prior

to the transplant (153–157). Varicella vaccine may be provided after transplantation, when immunosuppression levels have been reduced to low levels (158), but the response is attenuated and concern about vaccine-related disease is present.

Urologic Preparation for Pediatric Kidney Transplantation

Children with the diagnoses described in *Table 75-4* require a thorough urologic evaluation prior to transplantation and they frequently require pre-transplant reconstructive urological surgery. In a NAPRTCS report, 1,878 of 7,651 (25%) pediatric transplant recipients were identified as having lower urinary tract abnormalities (36). For all such patients, a history of voiding pattern prior to development of renal failure is most helpful. Preliminary investigations consist of measurement of urinary flow rate and ultrasound estimation of the post micturition urine volume. Urinary flow rate should be at least 15 ml per second (159), and the residual volume should be less than 30 ml. Further investigations would consist of urethrocystoscopy in patients suspected of a urethral stricture, and a voiding cystometrogram is essential for complete assessment of bladder function (160). This provides information about bladder capacity, pressure rise, and the efficiency of voiding. Still more information can be obtained by combining the urodynamic studies with radioisotope imaging. Routine voiding cystourethrogram is not indicated in older patients with no symptoms related to the urinary tract (161).

A bladder with a very small capacity may not be adequate for a functioning transplant. Occasionally a small capacity bladder may be seen in patients with prolonged oligoanuria. However if the bladder is distensible and the bladder wall compliant, such a bladder may be used safely for kidney transplantation. Other criteria for a useable bladder are an end-filling pressure less than 30 cm of H_2O, and a good flow rate. In patients with a poor flow rate, if urethral and bladder outlet obstruction are ruled out, the problem may be due to detrusor malfunction (159). When a bladder fails to empty completely, infection and obstruction are potential complications that may shorten graft survival. Intermittent, clean, self-catheterization, which is widely used in urologic practice, can be safely used post-transplantation in patients where the primary abnormality is inefficient and uncoordinated detrusor function. Most pediatric patients have a urinary bladder that will adapt to the new kidney. Although the bladder may not appear to have the capacity, especially in patients on long-term dialysis prior to transplantation, it will most often distend with usage (80). However in patients with a truly low capacity or high pressure, bladder augmentation may be necessary prior to transplantation (162–164). The goal of modern reconstructive pediatric urology is to have a competent low-pressure urinary reservoir which can be emptied by voiding or at least by intermittent catheterization. Augmentation cystoplasty consists of adding bowel or gastric wall to the bladder, whereas substitution cystoplasty is performed when most of the bladder is excised and replaced with bowel. Gastric remnants have been popular for augmentation, however they do tend to cause excessive loss of acid in the urine, leading to discomfort and metabolic alkalosis. Early attempts to reconstruct bladders with bioengineered material are ongoing. There are promising reports of "bio-engineered" bladder material, although these have not yet been tried in transplant recipients (165, 166). Urologic reconstruction, including augmentation cystoplasty, typically occurs prior to transplantation (164, 167–174); although some programs have reported successful reconstruction after transplantation also (175). In those patients in whom augmentation has been performed, long-term antibiotic therapy and intermittent catheterization may have to be carried out to prevent urine stasis and infection. In general, the incidence of urinary tract infection and other complications is higher in these recipients, their course is generally no worse than pediatric recipients without urologic abnormalities.

If native kidneys in children with ESRD are causing hypertension, chronic infections or excess losses of protein, urine or other substances, there should be serious consideration for nephrectomy prior to or at the time of transplantation (176). About 25% of children have native nephrectomies prior to index transplants (88).

The Transplant Procedure

Technical Issues in Transplantation

The operative technique differs based on the weight of the child. For small children, less than 15 kg, the transplant is frequently done through a midline incision and the larger vessels are utilized for anastomosis with the donor kidney (80). After reflection of the cecum and the right colon, the anterior wall of the aorta and the inferior vena cava are exposed and dissected (177). The aorta is mobilized from above the inferior mesenteric artery to the external iliac artery on the right side. After ligating and dividing the lumbar branches, the iliac arteries and the inferior mesenteric are encircled. Next the inferior vena cava is mobilized from the left renal vein to the iliac veins. After ligating the lumber veins the iliac veins are encircled. The donor renal vein is anastomosed to the recipient vena cava in an end-to-side technique (178). The donor renal artery is then anastomosed to the recipient aorta in an end-to-side fashion. Careful attention needs to be paid to the recipient hemodynamic response upon clamping and unclamping of the major vessels, and it is desirable to maintain a central venous pressure of 15–18 cm H_2O prior to unclamping (80, 177). The filling of the transplanted kidney may be slow due to the fact that a large adult kidney will take up a significant portion of the normal pediatric blood volume. Hemodynamic studies suggest that the cardiac output of infants must double in order to perfuse the adult donor kidney adequately (179). Thus volume replacement is critical (*Fig. 75-4*). The ureteral anastomosis is done by implanting the donor's ureter into the recipient's bladder using either a Ledbetter-Politano procedure or a modification of it to assure non-refluxing anastomosis. Many surgeons now prefer a non-refluxing extravesical rather than transvesical approach for ureteroneocystostomy because it is faster, a separate cystotomy is not required and less ureteral length is necessary, thus assuring a distal ureteral blood supply (180–182).

The transplantation technique utilized in children with a body weight greater than 15 kg is similar to that employed in adults. Unlike the transperitoneal approach necessary in younger children, this transplant is extraperitoneal, with the renal vein anastomosed to the common iliac or the external iliac vein (177). The arterial anastomosis can be to either the common iliac or internal iliac artery. The ureterovesicular anastomosis is done utilizing the techniques described above.

Evaluation of Graft Dysfunction

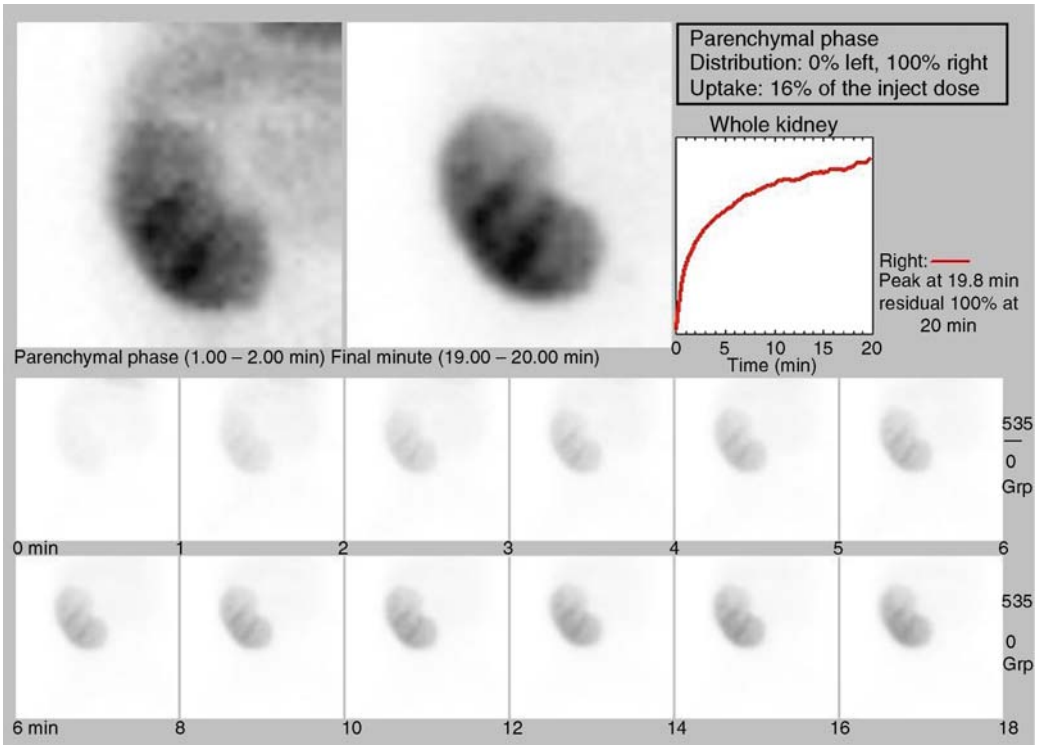
At the completion of the vascular anastomosis and release of the vascular clamps immediate function of the transplanted kidney is demonstrated by the production of urine. Various causes however, may prevent initial function, and evaluation of immediate non-function and the differential diagnosis of this condition is a critical component of the transplant physician's role.

Delayed Graft Function (DGF)

A well-function kidney graft should lead to normal renal function within 2–3 days. The lack of attainment of normal renal function, as demonstrated by a fall of the serum creatinine to normal levels, is termed delayed graft function (DGF). There is no consensus concerning the definition of DGF (183). In some settings, DGF is used only to distinguish recipients who require dialysis after transplantation, but that is a very stringent definition. Acute tubular necrosis (ATN) represents the most frequent cause of immediate graft non-function. Data from the NAPRTCS 1996 Annual Report showed that ATN was observed in 5% of living donor and 19% of deceased donor transplants (53). Since the NAPRTCS definition for ATN is stringent, requiring the use of dialysis in the first post-transplant week, these figures probably under-represent the actual incidence of ATN. The risk of early ATN in living donor kidneys is related to factors such as prior transplants and more than five pre-transplant blood transfusions. Similarly the risk factors of ATN in deceased donor kidneys include prolonged cold ischemia, absence of prophylactic antibody therapy and the use of more than five pre-transplant blood transfusions. The diagnosis is confirmed in most cases by the use of radionucleide scan (*Fig. 75-5*). If recovery of graft function is delayed, however, a transplant biopsy may be necessary since other diagnostic tests cannot distinguish between ATN and rejection (184, 185). Importantly, early acute rejection can mimic ATN or coexist with it (186). The presence of ATN does not auger well for the transplant, particularly for recipients of deceased donor grafts since graft failure and death are more common among patients with ATN (82, 187). The NAPRTCS data shows that 71% of deceased donor grafts without ATN were functioning at 4 years compared to only 51% of those with ATN (188). DGF is an independent risk factor for graft loss and death (189–191). Importantly, although the incidence of DGF is

Figure 75-5

^{99M}Tc-MAG3 radionuclide renal scan of a decease donor renal transplant in a 2-year old boy performed on the first post-op day. The warm ischemia time was prolonged due to a renal artery stenosis in the graft. The recipient was oliguric for 2 days but recovered function subsequently. Note the good perfusion followed by little excretion and "wash out" of the tracer from the graft.



increased when a DCD donor is used, the detrimental affect of DGF on long-term outcomes in this setting does not appear to be as severe as when it occurs after living donation or after transplantation from brain-dead deceased donors (183).

Graft Thrombosis

Graft thrombosis is an almost unique complication of pediatric transplantation. Although usually a major cause of immediate graft non-function, it can be seen later on in the course, and has been recorded to occur as late as 15 days post-transplant following initial engraftment and function. Graft thrombosis has been the third most common cause of graft failure in pediatric renal transplantation (36) and may rise to second if acute rejection rates continue to fall (*Table 75-5*) (59, 192). The critical nature of this complication can be appreciated from the fact that it accounts for 10% of graft failure in index transplantation and 12% in repeat transplants in the NAPRTCS registry. A dreaded event, this condition is irreversible in most cases and necessitates removal of the graft. Graft thrombosis should be suspected in cases where there has been immediate function followed by the development of oligoanuria. The diagnosis is established by a radionucleide scan using diethylenetriamine pentaacetic acid (DTPA) or MAG3 (193), which reveals a photopenic defect with no uptake by the transplant kidney (*Fig. 75-6*).

Since the outcome of graft thrombosis is uniformly dismal, numerous studies have been conducted in an attempt to understand and anticipate this complication. The etiology of graft thrombosis is multifactorial, but it is more commonly seen in young recipients (92). In a special study of 2,060 living donor and 2,334 deceased donor kidneys (194), NAPRTCS has shown that a history of prior transplantation increases the risk, whereas increasing recipient age has a protective effect for living donor kidneys. The prophylactic use of antilymphocyte antibody

Table 75-5

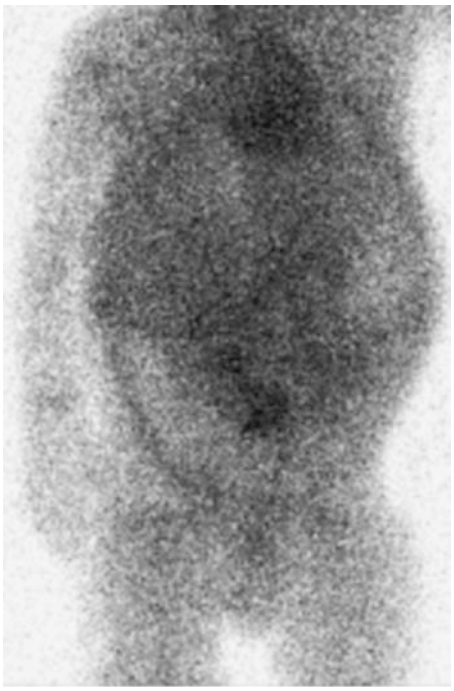
Causes of graft failure for pediatric kidney transplants. The table lists the causes of 2,556 graft losses. The number in each column represents the percent of all graft losses due to that cause (Adapted from (59))

	Index graft failure	Subsequent graft failure	All graft failures
Death with functioning graft	9.4	7.5	9.2
Primary non-function	2.6	0.7	2.3
Vascular thrombosis	10.3	12.5	10.5
Other technical	1.2	1.3	1.3
Hyperacute rejection	0.6	1.4	0.7
Accelerated acute rejection	1.5	2.6	1.6
Acute rejection	12.9	13.1	12.9
Chronic rejection	34.5	36.4	34.7
Recurrent disease	6.4	9.5	6.8
Renal artery stenosis	0.7		0.6
Infection	2.0	1.3	1.8
CNI toxicity	0.5		0.4
De novo disease	0.3	0.7	0.4
Medication discontinuation	4.6	2.6	4.4
Malignancy	1.3	0.7	1.3
Other/unknown	11.3	9.8	11.1
Total	100	100	100

also decreases the risk and this may be particularly true for the monoclonal interleukin-2 receptor antagoinists (IL2r) antibodies (195). For deceased source kidneys, a cold ischemia time longer than 24 h increases the risk of thrombosis. The use of antibody induction therapy, the use of donors greater than 5 years of age, and increasing recipient age were factors that decreased the risk of thrombosis. A heightened thrombotic state has also been implicated (151, 193, 196). One study showed that centers that performed fewer infant transplants had higher rates of graft thrombosis (35) and another suggested that pre-transplant use of peritoneal dialysis increased the risk of thrombosis (197, 198). Some centers routinely administer anticoagulants to pediatric recipients at high risk of graft thrombosis, but no clinical studies of their effectiveness

Figure 75-6

^{99M}Tc-MAG3 radionuclide renal scan in a 1-year old boy who received a living donor renal transplant 10 days previously. The recipient's IVC had been clotted and the renal vein had thrombosed 1 day post-op but had been re-anastosed to the portal vein. The graft never functioned. Note the photopenic area in the right lower quadrant that represents unperfused tissue.



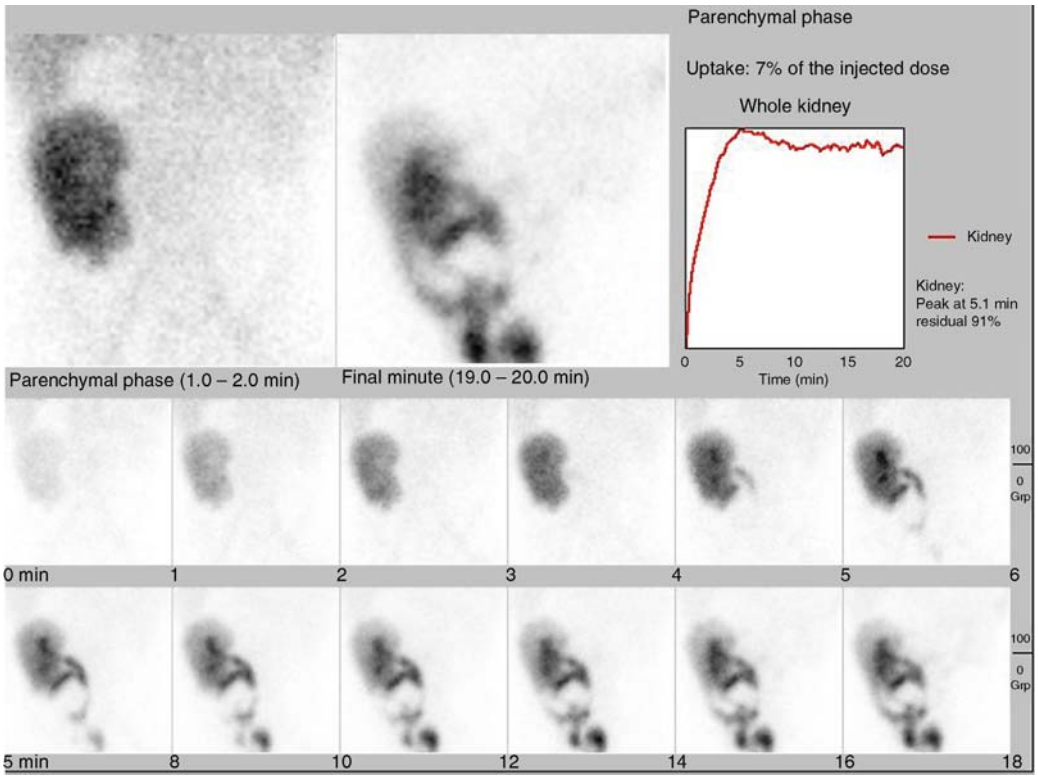
have been performed and its use is not without complications (199). This incidence of graft thrombosis had not changed over almost 15 years (36); however a preliminary report suggests that a new approach to induction therapy by using IL-2 receptor antagonists may be leading to a decrease (195).

Obstruction, Urinary Leak, Urologic Complications

An uncommon but correctable cause of immediate graft dysfunction is obstruction of the urinary flow, which presents as decreasing urine output and the development of hydronephrosis. An ultrasound or radionuclide scan with a furosemide washout enables the clinician to establish this diagnosis. Obstruction can be due to kinking of the ureter, to edema or blockage of the implantation site of the ureter or to development of a lymphocele. A more

Figure 75-7

^{99M}Tc-MAG3 radionuclide renal scan in an 8-year old girl who received a deceased donor renal transplant, performed 12 hours post-op. Note the good perfusion of the graft and the rapid concentration and excretion from the kidney. Tracer, however, rapidly accumulates in the right lower quadrant, outside of the bladder. Investigation demonstrated a traumatic bladder rupture.



ominous cause of immediate non-function is the rare case of urinary leak due to disintegration of the distal ureter or rupture of the bladder. This condition is extremely painful due to the extravasation of urine into the pelvis or peritoneal cavity and is established by radionucleide scan (*Fig. 75-7*). The appearance of the tracer in the peritoneal cavity or in the scrotal, vulvar, or inguinal area clinches the diagnosis and immediate surgical correction is necessary.

Immunosuppression Strategies

Two-thirds of pediatric kidney transplant recipients receive antibody-based induction therapy following kidney transplantation, with the majority of those receiving IL2r antibodies (59). In addition, most children receive "triple" maintenance immunosuppression with tacrolimus, mycophenolate mofetil and steroids (3, 59). Several recent multi-center research efforts have been directed to attempt to decrease the number of types of chronic immunosuppression, with corticosteroids and calcineurin inhibitors being the most common medications targeted for removal (200). Several single center (200, 201) and multi-center trials (202, 203) have reported success in avoiding or withdrawing corticosteroids, although some of these have had substantial side effects (202, 204, 205). There have also been reports of avoidance of calcineurin inhibitors in children designed to prevent nephrotoxicity. At least one of these trials resulted in excellent long-term graft function, but had a high rate of early acute rejections (206). A subsequent trial with enhanced antibody induction may have better short-term results (207).

Allograft Rejection

In the absence of tolerance the renal allograft is destined for loss by some form of rejection. Rejections are classified as hyperacute (occurring immediately upon grafting),

accelerated acute (occurring within the first week after transplantation), acute (generally occurring within the first year of transplantation), late acute (occurring after the first year), and chronic, for which the time sequence is difficult to establish since it may occur as early as three months, but generally occurs years later in the course of the transplant.

Hyperacute Rejection

Hyperacute rejection is the result of specific recurrent anti-donor antibodies against HLA, ABO or other antigens (208). Irreversible rapid destruction of the graft occurs. Histologically there is glomerular thrombosis, fibrinoid necrosis, and polymorphonuclear leukocyte infiltration. In the early years of transplantation, when the HLA matching techniques were not well developed, hyperacute rejection was more common. In most centers, it occurs very rarely. The latest data from the NAPRTCS shows the incidence of hyperacute rejection to be less than 0.7% of causes of graft failure (18 cases) over the last 20 years. The only response is surgical removal of the allograft.

Acute Rejection

A remarkable decrease in the incidence of acute rejection has occurred over the past 20 years (*Table 75-6*). In an earlier study of two cohorts of pediatric renal transplant recipient (1,469 in 1987–1989; 1,189 in 1997–1999), the rejection ratios dropped from 1.6 to 0.7/patient (209). Sixty percent of the latter group was rejection-free compared to 29% of the former and 1-year graft survival was 94% compared to 80%. Previously, over half of the patients experienced a rejection in the first post-transplant weeks. Now, fewer that 20% are expected to have an acute rejection in the first post-transplant year. Risk factors for acute rejection in living donor recipients used to include lack of induction therapy, DR mismatches, black race and age (59). With decreasing rates of acute rejections, the strongest risk factor is transplant year (there is an approximate 10% reduction with each increasing transplant year) and the only remaining statistically significant risk factors are older age (recipients younger than 2 years are less likely to have acute rejections) and the presence of DGF. Risk factors for deceased donor transplants were similar to those of living donor grafts and have undergone similar changes with dramatically lower rates in recent transplants. Currently, only year of transplant and black race are correlated with acute rejections.

In an earlier study the NAPRTCS noted that when reviewed by age groupings, rejection ratios, time to first rejection and the mean number of rejection episodes were not different; however for the initial rejection episode, recipients less than 6 years of age had significantly increased irreversible rejections leading to graft loss (210). There were conflicting data about whether infants and small children have a "heightened" immune response and an increased incidence of acute rejection episodes. Indirect evidence had suggested a more vigorous immune response especially in infants (21). Also, data from the UNOS registry demonstrated a higher rate of acute rejections in young children after both living and deceased donor transplantation, although adolescents were noted to have a higher rate of late acute rejections (22). On the other hand, data from surveillance transplant biopsies suggest equivalent rejection responses in all groups (63). But, data from one large pediatric transplant program demonstrated that infants had a lower rate of acute rejection than older children (23). A recent SRTR report demonstrated that infants and young children now have the best outcomes of all age groups (38). Thus, either the proposed heightened immune response has been overcome by improved immunosuppression or the cause previously poor outcome was related to other factors. The current acute rejection ratios by recipient age are shown in *Table 75-7*.

Table 75-6
Twelve month probability of first acute rejection episode by transplant year (Adapted from (59))

Transplant year	Living %	Donor s.e.	Deceased %	Donor s.e.
1987–1990	54.2	1.7	69.1	1.5
1991–1994	44.8	1.5	60.6	1.6
1995–1998	33.4	1.4	40.8	1.7
1999–2002	22.6	1.3	26.8	1.9
2003–2005	13.2	1.9	15.8	2.3

Diagnosis of Acute Rejection

Rejection is suspected when there is decreasing urinary outflow and a rising serum creatinine. In the past, classical signs of acute rejection included fever and graft tenderness. Under calcineurin inhibitors and prophylactic antibody therapy however, these signs are rarely seen; thus

Table 75-7

Acute rejection ratios for pediatric kidney transplants by recipient age for years 1996–2007 (Adapted from NAPRTCS 2008 Annual Report www.naprtcs.org)

	Living donor			Deceased donor		
	# of Tx	# of ARE	Rejection ratio	# of Tx	# of ARE	Rejection ratio
Total	3,043	1,374	0.45	2,440	1,530	0.63
Recipient age						
0–1 years	231	42	0.18	57	21	0.37
2–5 years	473	181	0.38	302	149	0.49
6–12 years	949	435	0.46	762	484	0.64
>12 years	1,390	716	0.52	1,319	876	0.66

early evidence of graft dysfunction even without other signs, should initiate concern. The differential diagnosis consists of ureteral obstruction, renal vascular compromise from stenosis, urinary leak and an infectious process. When rejection is suspected, a urinalysis and urine culture should be performed to assess the possibility of infection. The urinalysis is also helpful if it suggests intra-graft inflammation or immune response as evidenced by proteinuria and the presence of leukocytes and other cells in the sediment. Blood or urinary cytokine analysis may also be useful for diagnosing rejection (211, 212) and examination of the sediment may be useful in detecting other reasons for graft dysfunction. An ultrasound is performed to rule out anatomical obstruction. Obstruction can be the result of peri-renal fluid collection, a large lymphocele, hematoma, or rarely, an abscess. The ultrasound can also provide information about intragraft blood flow and pressure (184). A radionuclide renal scan, using a tracer such as MAG 3, is a very helpful tool in establishing some diagnoses (*Figs. 75-5–75-7*) (213). Rejection is suggested by rapid uptake of the tracer by the kidney but a delayed excretion. Radionucleide scans cannot distinguish among various causes of intragraft dysfunction, such as rejection, calcineurin inhibitor toxicity and ATN. Thus, a definitive diagnosis of rejection requires a transplant biopsy.

Renal Transplant Biopsy

The renal transplant biopsy procedure is very easy and safe when conscious sedation and ultrasound guidance are utilized. Recent data evaluating pediatric renal transplant biopsies, including some in intraperitoneal kidneys and many performed during the first week post-transplantation, have demonstrated a very low risk (185, 214). Special care is required for intraperitoneal biopsies. A good biopsy core should include glomeruli, tubules, interstitial tissue and vessels. This is facilitated if a dissecting microscope is used at the time of the procedure to identify glomeruli and tubules in the specimen. In acute rejection glomerular changes are restricted to an increased prominence of the mesangial stalk. However it is the presence of tubular changes that is of significance in early acute rejection, and tubulitis is considered the hallmark. Semiquantitative analysis and grading of acute rejection biopsy findings is done by the Banff criteria (215, 216). Grade I is focal interstitial lymphocytic infiltrate with mild tubulitis and normal vessels. In Grade II there is extensive interstitial infiltrate with tubulitis and vacuolation in arterial vessels, whereas Grade III shows extensive interstitial infiltration with tubulitis and lymphocytic infiltration of arterial walls with occasional fibrinoid change.

Treatment of Acute Rejection

Standard treatment of an episode of acute rejection is intravenous methylprednisolone in a single daily dose of 10–25 mg/kg (maximum dose: 0.5 – 1 Gm), for three consecutive days. Most Grade I and II rejections will respond to steroid therapy. Steroid resistant rejection episodes are treated with T-cell antibody, typically the polyclonal antithymocyte globulin, Thymoglobulin. Thymoglobulin is given in a dose of 1.5–2 mg/Kg/dose for a total of 10–14 days. It may be advisable to monitor CD3+ lymphocytes during treatment and restrict the frequency of dosing only to days when the count is greater than 20 cells/mm^3 (217). All antibodies have several side effects. Of concern are the first dose symptoms due to cytokine. This is clinically observed as fever with chills,

and rarely, as pulmonary edema. Precaution against the potential anaphylactic reaction related to polyclonal antibodies consists of using intravenous methylprednisone with the infusion of the antibody and administration of an antihistamine, such as diphenhydramine (Benadryl) and acetaminophen prior to antibody administration.

Reversibility of Acute Rejection

NAPRTCS data from the most recent era (2001–2007) observe that, among living donor kidney transplants, 53% of rejection episodes are completely reversed, 43% are partially reversed and 4% end in graft failure. Similar figures for deceased donor kidney transplants are 47%, 47%, and 6%, respectively (59). When stratified by age, young transplant recipients more frequently have irreversible rejection episodes although they also have higher rates of complete reversibility in those that are not lost. Despite decreasing rejection frequency, reversibility rates of acute rejection for pediatric recipients have not improved over the past 2 decades (53, 59) Molecular or genomic characterization of rejection biopsies may be helpful in describing different types of acute rejection, but there are no clear guidelines about its use at the present time (211, 212, 218–221).

Rescue Therapy

In those patients where neither steroids nor antibody therapy have successfully reversed a rejection episode conversion to an alternative calcineurin inhibitor or to other immunosuppressants might be warranted. There have been no controlled studies to document reversal of rejection with conversion to tacrolimus; however anecdotal reports do suggest that in some cases conversion does help to stabilize graft function (222–224). There have also been preliminary reports of the use of Rituximab for the treatment of B-cell mediated rejection (225).

Chronic Allograft Nephropathy (CAN)

The gradation from acute to chronic rejection is gradual; however many biopsies may show features of both, and some characteristic vascular changes of chronic rejection may be seen as early as 10 days post-transplant (226). The clinical picture is that of gradually declining renal function together with varying degrees of proteinuria and hypertension (227). The clinical condition may be referred to as transplant glomerulopathy, chronic rejection, chronic allograft dysfunction (CAD), chronic allograft nephropathy (CAN) or interstitial fibrosis and tubular atrophy (IFTA) (228). The succession of names reflects lack of clarity of the etiology, clinical course or treatment of this disorder. Nonetheless, this process, which will be referred to as CAN in this chapter, is the leading cause of graft loss following kidney transplantation in children (*Table 75-5*).

An ongoing controversy exists as to whether the changes seen in chronic rejection are immune mediated, secondary responses to infection, ischemic in nature, or non-immunological injury due to hyperfiltration (229–232). Data in children have shown clearly that acute rejection is a predictor of chronic rejection (19). In a study of 1,699 living donor and 1,795 deceased donor recipients NAPRTCS noted acute rejection was a relative risk factor for chronic rejection (RR = 3.1), and multiple acute rejections increased the RR to 4.3. Late acute rejections are also clinical correlates of chronic rejection (233). Even if acute rejection is the most critical element in the genesis of chronic rejection, other immune mechanisms may mediate its progression, such as antibodies directed against the donor, MICA, endothelial cells and B lymphoblasts (135, 234). Gene expression profiles in graft biopsies of patients with established CAN demonstrate upregulation of profibrotic and growth factors (235).

Symptomatic therapy is currently the only available method of dealing with CAN. Hypertension should be controlled and the proteinuria may occasionally respond to ACE inhibitors; however, renal function will generally continue to decline. In children, CAN produces an additional burden since decreased renal function will result in deceleration of growth (236, 237). It is in this context that prevention of chronic rejection by early aggressive therapy in patients who have had an episode of acute rejection may be rewarding. Since currently available immunosuppressive medications have been unsuccessful in preventing or slowing the progression of chronic rejection, the use of immunosuppressives other than those currently approved may be reasonable, such as the use of mTOR inhibitors or co-stimulation blockade rather than nephrotoxic calcineurin inhibitors (206, 238–242). Although some programs have concluded that these techniques might be beneficial after CAN is established (243), there may be a point at which substitution of non-nephrotoxic agents is not helpful (244). The presence of heavy proteinuria in recipients with CAN may also predict lack of benefit of changing chronic immunosuppression (245).

Recurrent Disease After Pediatric Kidney Transplantation

Some diseases will recur in a transplanted kidney, and the recurrent disease may lead to loss of the graft, as it had done to the native kidneys previously. Recurrence of the original disease is the cause of 6.8% of all graft losses (*Table 75-5*); and it is the cause of up to 9.5% of graft losses in subsequent transplants (59). Thus, recurrence is one of the top four causes of all graft losses. The 5-year living donor graft survival for children with FSGS is 71% and for children with glomerulonephritis it is 77%; in contrast to all other causes of ESRD in which 5-year graft survival is greater than 83%. In the deceased donor group, 5-year graft survival rates for children with FSGS, glomerulonephritis and congenital nephrotic syndrome are below 64%; HUS and familial nephritis have rates of 66%; and all other causes have a rate of 70%. Several publications have reviewed the course of recurrent disease in pediatric kidney transplantation (89, 246, 247). In some cases, recurrence of some features of the disease without affecting graft survival up to recurrence of the full disease with substantial reduction in graft survival. Unfortunately, there has been very little change in frequency of recurrent disease in pediatric grafts, despite substantial changes in immunosuppression during the past 2 decades (248).

FSGS

Focal segmental glomerulosclerosis is the most common cause of steroid resistant nephrotic syndrome leading to ESRD and is the most common acquired cause of ESRD in children. Reports of recurrence of FSGS vary from 15 to 50% and about 50% of the recurrences lead to graft loss (246–248). FSGS is a pathologic diagnosis and represents the appearance of a large number of diseases that might be due to immunologic, genetic or other causes. The genetic diseases do not seem to recur in a graft. Risk factors for recurrence include early onset of nephrotic syndrome, rapid progression to ESRD (<3 years), resistance to treatment, white or Asian race, recurrence in a previous transplant, and possible presence of a circulating "glomerular permeability factor" (248, 249). Recurrence can occur immediately after transplantation and result in massive proteinuria, acute tubular necrosis and even graft failure related to small vessel thrombosis (249). Typical FSGS lesions on pathologic examination, other than foot process fusion, may not appear early in the course of recurrence, but may follow early thereafter. In general, children with active nephrotic syndrome are not candidates for pre-emptive transplant because of the heavy proteinuria and consequent risk of graft thrombosis and delayed diagnosis of recurrence (246). Many programs will perform native nephrectomy and will maintain the children on chronic dialysis for some period of time, certainly to improve nutritional status and to normalize the serum albumin. There is no benefit to living donor transplantation in children with recurrent FSGS: although graft loss due to rejection is lower in recipients of living donor transplants, graft loss due to recurrence is higher, leading to equivalent graft survivals in living and deceased donor transplants (249, 250). Whether this result is due to a higher frequency of recurrence in living donor recipients, a more aggressive course in those recipients, or simply a higher rate of rejection in the deceased donor recipients is not known. Plasmapheresis is often used prophylactically prior to transplantation or immediately after it to attempt to prevent or treat recurrence of FSGS (251–254) and some programs report complete remission in up to 60% treated in that manner. Although no specific immunosuppression protocol has demonstrated clear efficacy in treating or preventing recurrent FSGS, there is some evidence that high dose cyclosporine may be effective in doing so (253, 254). Whether the high dose is needed to counteract the effect of high serum levels of low-density lipoprotein which binds free cyclosporine, or whether the beneficial effects are due to direct action on podocytes is not clear (89, 255). Rituximab has also been used to treat recurrent FSGS in children, with mixed results (256–259).

HUS

Hemolytic uremic syndrome in children is most commonly caused by enteropathic bacteria and the disease typically does not cause ESRD or recurrence in a kidney transplant (260). On the other hand, children with atypical or "non-Shiga toxin-associated" HUS have a much higher incidence of progression to ESRD and recurrence of the disease after transplantation (90, 261, 262). The recurrence is very infrequent after diarrhea-associated HUS, but up to 80% in atypical HUS (89). Although calcineurin inhibitors have been associated with de novo HUS in a few kidney transplants, their use in recurrent disease seems to have no effect (89). In patients with factors H, I or B mutations, the recurrence rate appears to be high and transplantation may be deferred. Some have proposed plasmapheresis with fresh frozen plasma in this setting (90) and combined kidney–liver transplantation has been proposed for some children with factor H mutations (90).

Membranoproliferative Glomerulonephritis, Types 1 and 2

Both forms of MPGN can recur in transplants, with variable frequency from 30–60% (89). Type 2 seems to be more severe, and neither form seems to be treatable after recurrence (263).

Oxalosis, MMA and Metaboloic Diseases

Primary oxalosis recurs almost immediately and universally after kidney transplantation and was once considered a contraindication to kidney transplantation. However, treatment with intensive pre- and post-transplant plasmapheresis to lower the body burden of oxalate and the use of combined kidney–liver transplantation has led to substantially better outcomes (81, 83, 264–266). If liver transplantation is being considered, however, careful consideration must be paid to determining whether the child has a variant that might be responsive to lifelong treatment with pyridoxine rather than liver transplantation (89). Methylmalonic acidaemia may be partially ameliorated by kidney transplantation, but full treatment may require liver transplantation in select recipients (89). Certain inherited diseases like insulin-dependent diabetes mellitus and sickle cell disease may recur in a kidney transplant, but this almost universally happens during adulthood, many years after the primary transplant in a child.

Other Autoimmune Diseases

IgA nephropathy, Henoch-Schonlein purpura, lupus nephritis and ANCA-associated vasculitis may recur following kidney transplantation in children, but these recurrence may be minimally apparent and less frequently lead to graft loss (89).

Cystinosis

ESRD is typically the earliest organ failure in children with cystinosis and often accounted for the bulk of deaths from this disorder. However, the use of kidney transplantation and cystine-depleting therapy with cysteamine has extended their life expectancy to the fifth decade (152, 267–269). Although cystine may accumulate in the interstitium of renal grafts, it does not cause graft failure. However, the unremitting accumulation of cystine results in substantial non-renal morbidity and mortality (268, 270).

Graft Survival

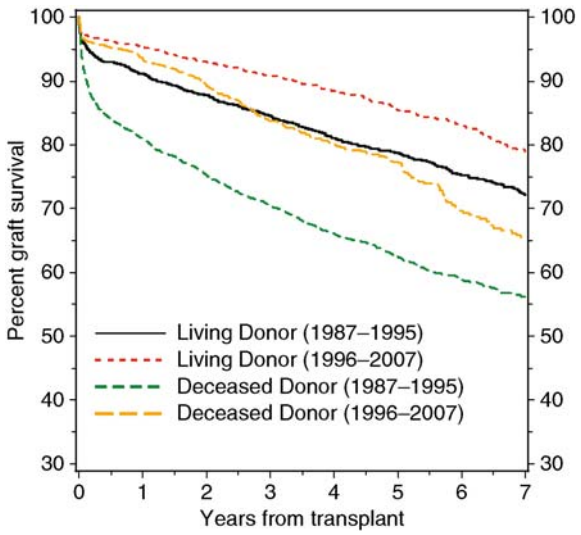
Pediatric renal centers reporting graft survival show varying results. Due to the fact that the number of patients at any one center is small, such data cannot represent the pediatric transplant population at large. Furthermore, multiple factors affect graft survival, such as donor and recipient age, histocompatability matching, recipient race, and so forth. Thus, there cannot be accurate descriptions of graft survival rates without classification of the important variables. In order to obtain a proper population mix representing gender, age, and racial diversity, multi-center registry results such as SRTR and NAPRTCS annual reports have been used (38, 59).

NAPRTCS has recorded a total of 2,556 graft failures occurred between 1987 and 2007, representing about 25% of all transplants in that time frame. Of the failures, about 9% were deaths with a functioning graft, 84% were returned to dialysis, and 7% were re-transplanted at the time of failure. *Table 75-5* provides the distribution of causes of graft failure. With increased length of follow-up, chronic rejection continues to increase in importance; it is now the most common cause of graft failure. Overall, 48% of graft failures are caused by rejection with chronic rejection accounting for 35% and acute rejection accounting for 13%. Recurrence of original disease as a cause of graft failure was observed 174 times, accounting for 7% of graft failures. The specific diseases include: focal segmental glomerulosclerosis accounted for 44% of these graft losses, membranoproliferative glomerulonephritis Type II 9%, hemolytic uremic syndrome 9%, oxalosis 5%, chronic glomerulonephritis 4%, others 28%. Vascular thrombosis remains a major cause of failure, and 361 graft failures (14.1%) were attributed to primary non-function, vascular thrombosis, or miscellaneous technical causes. These data show that such problems occur in about 4% of all pediatric transplants (35, 92, 194, 196–198, 271). Considering just transplants that have been performed since January 1, 2000, chronic rejection is the leading cause of graft loss (41.3%), followed by vascular thromobosis (8%), recurrent disease (7.9%), acute rejection (6.3%) and medication discontinuation (6.3%) (59).

Overall 5-year graft survival curves by donor source are shown In *Fig. 75-8*. Expected graft survival for index transplants performed in the last decade at 1, 3, 5 and 7 years for living donor kidneys is 95, 91, 85 and 79% respectively, and for deceased donor kidneys it is 93, 84, 77 and 65%. There has been a continuous improvement in short and mid-term graft survival rates, mostly due to marked improvements in early graft survival rates. This may be related to the decreased frequency of acute rejection rates and the decreased incidence of acute rejection as

Figure 75-8

Percent graft survival by transplant era and donor source. The graft survival has improved during the most recent era compared to previously. Living donor transplants have better 5-year graft survival than deceased donor transplants from both eras. (Adapted from 2008 NAPRTCS Annual Report (www.naprtcs.org)).



a cause of graft loss. It is notable, however, that as shown in *Fig. 75-8*, the slope of the graft survival curves have not changed significantly over the past 2 decades. These important trends in improved graft survival in pediatric living and deceased donor renal transplant outcome have been reported frequently over the past decade (16, 52, 59) and the most recent data are shown in *Figs. 75-1* and *75-8*.

Table 75-8 shows relative hazards for graft failure for selected transplant characteristics for both living and deceased kidneys. Relative risks of graft failure are derived using Cox proportional hazards regression models. For recipients of living donor grafts, the most influential prognostic variables of index graft survival are race (African American vs. non-African American; RH = 1.95, $p < 0.001$), prior transplant (RH = 1.35, $p = 0.006$), lack of induction antibody treatment (RH = 1.15, $p = 0.035$) and lack of HLA-B matches (RH = 1.40, $p = 0.008$). A linear trend in improvement of graft survival with more recent year of transplantation has also been observed ((RH = 0.95 per year, $p < 0.001$) (59). For deceased donor recipients, the important prognostic factors include: African-American race (RH = 1.56, $p < 0.001$), prior transplant (RH = 1.43, $p < 0.001$), age older than 2 years (RH = 0.59, $p < 0.001$) and male

Table 75-8

Relative hazard (RH) of individual prognostic factors for graft loss in the presence of other factors in multivariate proportional hazards models (Adapted from (59))

	Living Donor		Deceased Donor	
	RH	p-value	RH	p-value
Recipient age (>2 years vs. 0–1 year)	1.13	NS	0.59	<0.001
Prior transplant	1.35	0.006	1.43	<0.001
No induction antibody treatment	1.15	0.035	1.09	NS
>5 lifetime transfusions	1.31	0.003	1.28	<0.001
No HLA-B matches	1.40	0.008	1.16	0.014
No HLA-Dr matches	0.87	NS	1.14	0.024
African-American race	1.95	<0.001	1.56	<0.001
Prior dialysis[a]	1.16	0.052	1.23	0.040
Cold storage time >24 h	–	–	1.14	0.034
Transplant year (per year)	0.95	<0.001	0.94	<0.001
No native nephrectomy	0.87	0.051	0.96	NS
Male gender	0.87	0.036	0.85	0.005

NS not significant; *HLA* human leukocyte antigen

[a]Reported as ever having dialysis

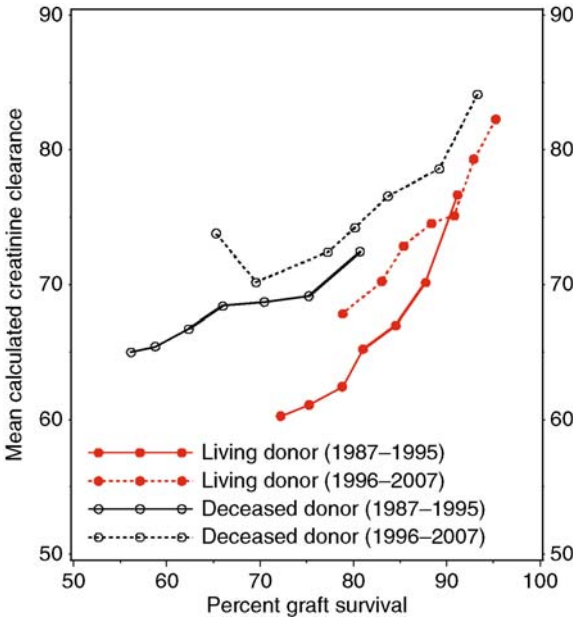
gender (RH = 0.85, p = 0.005. The same linear trend of improved graft survival rates in later transplant years is also seen (RH = 0.94 per year, p < 0.001). A history of prior dialysis may be a slight relative risk (RH = 1.23, p = 0.04. Lack of HLA-B and –DR matches also seem to be relative risks to graft survival in deceased donor transplants, as is prolonged cold-storage time. For both living and deceased donor transplants, a history of more than five lifetime blood transfusions seems to be associated with worse graft survival rates, but the significance of this finding in the modern era is not clear. Also, the interpretation of the use of induction antibody treatment is hampered by selection factors that motivate its usage; the size and direction of these biases cannot be quantified and the evaluation of this factor cannot be considered definitive. Importantly, the improvement in graft survival rates in very young recipients is strongest in the living donor recipients and the overall improvement in this age group may be related to the high percent of living donors used for them.

Another measure of long-term graft function is the calculation of graft half-life. An analysis of 8,922 pediatric and 78,418 adult renal transplants demonstrated superior long-term graft function in young pediatric recipients (22). Infants (age 0–2 years) had the worst 1-year graft survival rates (71%) compared to children (3–12 years) (83%), adolescents (13–21 years) (85%) and adults (86%). However, for all grafts that survived at least 1 year, infants had the longest projected half-life (18 years), compared to children (11 years), adolescents (7 years) and adults (11 years). A similar analysis of UNOS data showed that young recipients who received adult donor kidneys and had immediate graft function had projected half-lives >25 years, better even than HLA-indentical adult donor–recipient pairs (39).

While assessment of graft survival is a reasonable measure of transplant outcome, it does not include an accurate portrayal of the course of chronic allograft nephropathy. The usual course of a kidney transplant includes an inexorable and continuous decline in renal function over many years. Thus, many kidney transplant recipients suffer from the consequences of CKD for many years as graft function deteriorates. This decline is shown in *Fig. 75-9*. As noted above, the various causes for decrease in kidney function include immunologic, such as immune response or rejection, as well as recurrent disease; and non-immunologic, such as nephrotoxic medications, infection, perfusion injury, and so forth. Studies designed to identify the causes and ameliorate any etiologic causes are clearly indicated.

Figure 75-9

Graft survival (%) and calculated GFR (ml/min/1.73M^2) values for children with functioning grafts plotted at each annual follow-up visit for living and deceased donor recipients in two different eras. Continued decreases in graft function and survival are seen through at least the first 5 post-transplant years. (Adapted from NAPRTCS 2008 Annual Report (www.naprtcs.org).



The primary disease causing ESRD can have an effect on graft survival. Children with oxalosis used to have very bad outcomes, to the extent that the diagnosis was considered a contra-indication to transplantation. However, improvements in outcome related to combined liver–kidney transplantation have been encouraging (61, 81–83, 264–266) after the use of intensive hemodialysis prior to and immediately after transplantation, as well as performing the procedure before complications of the disease have caused multiple organ damage in the recipient. There have been reports of using the recipient liver in a "domino" procedure as the graft for another patient with liver failure due to other causes. Unfortunately, all of the complications of oxalosis quickly occur in those recipients (272). Similarly, infants with congenital nephrotic syndrome often had very poor outcomes (82, 152), but strategies designed to reduce the risk of thrombosis and improve nutrition pre-transplantation have led to marked improvements (84, 85, 151, 273). Focal Segmental Glomerulosclerosis (FSGS) can be a devastating disease that may recur very quickly following

renal transplantation, sometimes as early as the first post-transplant day (152, 274–277). Although recurrence is no more frequent in living donor transplants, the graft survival advantage of living donor transplantation is lost for children with FSGS (250). Little is known about the pathophysiology of the disorder or the cause for recurrence (278, 279). There are several proposed approaches to preventing or treating recurrence, mostly involving enhanced immunosuppression with plasmapheresis (89, 277, 280–285). Lupus nephritis surprisingly does not recur following renal transplantation to any great extent. Patients with lupus have similar outcomes compared to other patients (286, 287), except for a slight increase in mortality (287), an increase in incidence of recurrent rejections and a slight tendency to graft failure in those patients receiving deceased donor grafts following peritoneal dialysis(286). Children with sickle cell disease and ESRD can receive kidney transplants successfully (288), as can those with Down Syndrome (289, 290). Hemolytic uremic syndrome has been variably described as likely to recur or not (152, 291). After distinguish the etiologic factors, epidemic shiga toxin-associated hemolytic syndrome is unlikely to recur following renal transplantation (260, 262), whereas atypical or familial HUS may recur with devastating and irreversible consequences (262).

Growth After Pediatric Kidney Transplantation

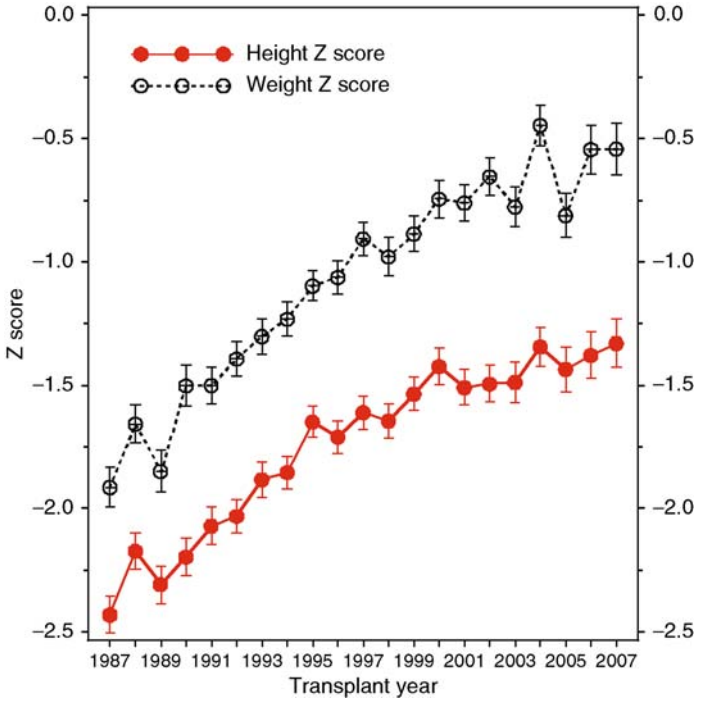
A major distinguishing feature of pediatric from adult recipients is the need for children to grow. The growth failure commonly observed in children at the time of transplantation is multi-factorial; however the most important cause is the reduced response to endogenous growth hormone (75), related to several mechanisms. Growth failure often begins insidiously early in the course of CKD. In a NAPRTCS analysis of 1,768 children with CKD (glomerular filtration rate <75/ml/min/m^2), over one third had a height deficit of more than 2 SDS. It has been amply demonstrated that chronic renal insufficiency beginning in infancy leads to permanent reduction in growth potential (292). Growth retardation continues in children on a dialysis regimen, whether the mode of dialysis is peritoneal or hemodialysis. For several years it has been suggested that a functioning transplant would enable the child to achieve catch-up growth (13). Unfortunately, long term data from registry studies has shown a more disappointing outcome.

NAPRTCS data shows that the mean height deficit at the time of transplantation is – 1.88. Males (−1.92) and younger recipients have greater height deficits at the time of transplantation (36). Younger children can show catch-up growth (7, 9, 13) with complete inversion of Z-score up to 0.60 at 2 years for those <5 years of age at transplant. Older children may grow at a normal rate, but rarely show catch-up growth. The Z-score for 19-year olds is −1.5. Final adult height for children with ESRD is improving, but all of the improvements seem to be related to the gains achieved during treatment for CKD rather than after transplantation (9). On a positive note, however, there has been an improvement in the height deficit at the time of transplantation: In 1987, children receiving their initial kidney transplant were an average of 2.4 standard deviations below average, whereas in the 2003 cohort, the deficit was only 1.5 standard deviations below average (*Fig. 75-10*) (59). As a result, the final adult height of children transplanted more recently is much better than those transplanted years ago. The Z-score for children transplanted in 1987–1991 who have reached their terminal height was −1.93 as compared to −1.08 for those in the 1997–2001 cohort.

These studies on long-term growth post-transplantation are disappointing; however they do focus on mechanisms that prevent growth despite a milieu with normal renal function. Individual center studies have adopted a variety of techniques, such as discontinuation of prednisone (293, 294), alternate-day steroid therapy (295–297), steroid avoidance (12) or the use of recombinant human growth hormone (298). It has been known for several years that steroids used for immunosuppressive therapy will inhibit growth (299). It has also been demonstrated that steroids affect growth hormone secretion (236, 300–302). Measurements of pulsatile and pharmacologically stimulated hormone release reveal that steroids play an inhibitory role (299, 303). Conversion of children to alternate-day steroid therapy has shown improvement in growth (296, 297); however the best catch-up growth is seen in patients completely withdrawn from steroids (12, 223, 304). Numerous uncontrolled studies have shown that steroids can be withdrawn from children post-transplantation (12, 223, 305); however, until recently, acute rejection tended to occur shortly afterwards in many of these patients (306), with marked detrimental long-term effects. More recent studies, using different approaches to long-term immunosuppression, have shown much better success with the avoidance or withdrawal of steroids, but the effects of these approaches on long-term growth rates is not yet known (200, 201, 203, 207). An alternative method of attaining catch-up growth post-transplantation would be the use of growth hormone. Recombinant human growth hormone (rhGH) is not approved for use in children post-transplantation;

Figure 75-10

Standardized height and weight, displayed as Z-scores, at the time of initial kidney transplant over time. There has been a substantial improvement in height and weight over the past 2 decades. (Adapted from NAPRTCS 2008 Annual Report (www.naprtcs.org).



however numerous uncontrolled studies have shown its ability to accelerate growth in this setting (307). Several complications of the use of rhGH post transplantation have been suggested (307–310) but a controlled trial demonstrated that it could be used safely and effectively (311). Although one report suggested that the pre-transplant use of rhGH may be associated with subsequent PTLD, its use post-transplantation had no such association.

Long-Term Outcomes of Pediatric Kidney Transplantation

Complications of Pediatric Kidney Transplantation

There are multiple complications of the transplant surgery and of chronic immunosuppression. These complications tend to diminish the success of kidney transplantation. Specific information about these complications are provided in the chapter, Complications of Renal Transplantation. The complications include multiple types of infections, cardiovascular complications, including hypertension and vascular problems, metabolic abnormalities such as hyperglycemia and dyslipidemias, obesity, growth deficiency, and complications of orthopedic, gastrointestinal, neurologic, pulmonary and hematologic systems.

Adherence to Chronic Immunosuppression Treatment

Non-adherence is often cited as a cause of long term graft loss in pediatric renal transplant recipients, especially adolescents (312). A major reason for non-adherence is thought to be the alteration in appearance that accompanies immunosuppressive medications, including the cushingoid facies and growth retardation related to long-term daily corticosteroid administration and the hirsuitism and gingival hypertrophy associated with cyclosporine. However, the true incidence of non-adherence is unknown. Non- adherence rates of 22% (313), 43% (314) and as high as 64% in adolescents (315) have been reported. Some factors, such as young age, adolescence, poor socio-economic status, and family stress have been

associated with increased levels of non- adherence (313, 315–317). Importantly, however, health care workers are not able to identify a significant proportion of non-adherent patients (318). Treatments such as educational programs (314) and family-based therapy (319) have been proposed, but these types of programs have not been universally successful in changing motivation (312). An alternative proposal for improving non-adherence would be to change the type or frequency of immunosuppressive medications so that the recipients do not have to adhere to rigid schedules; but these proposals are currently only hypotheses (201, 320).

Rehabilitation, School Function, Psychosocial Consequences

Organ transplantation typically results in dramatic improvement of all aspects of physical, emotional and social functioning. Importantly, cognitive skills improve after successful renal transplantation (6), suggesting stabilitzation of neurophysicolgic functioning. Health related quality of life measures are generally good, especially in older children and adolescents, although all ages reports some problems with usual activities (321). Interestingly, the perceived emotional status of the children was actually better than controls, especially during and after adolescence (321).

Long-term survival is generally excellent (322) and measures of quality of life have demonstrated excellent rehabilitation in long-term survivors (323, 324). Over 90% have rated health as good or excellent and most did not feel that health interfered with normal functioning. Most of them were full-time students or were employed. The majority was below normal height and up to a third was dissatisfied with their body appearance. In one report, only a small minority of long term survivors were married (325), but in another, 50% were married and half of those had children (324).

Mortality

Infection is generally the major cause of death, particularly in the first post-transplant years (36). Other major causes include cancer/malignancy, cardiopulmonary causes and dialysis-related complications. The best patient survival results are found in older pediatric recipients and in recipients of living donor transplants (59, 82). Risk factors for excess mortality include young recipient age, graft dysfunction (ATN) at day 30 following transplant and certain underlying renal diseases (oxalosis, congenital nephrotic syndrome, Drash Syndrome) (82). Mortality after 10 years post transplant seems to be related primarily to cardiovascular causes (59, 322), which may be linked to the hyperlipidemia and hypertension associated with chronic immunosuppression. The mortality rate of children, except for the very youngest, is very low and is much better than what is found in adults. Current 1- and 5-year patient survival rates for pediatric living donor kidney transplants are 98% and 96% and for pediatric deceased donor transplants they are 97% and 93%. Although the survival rates for deceased donor grafts are statistically worse than for living donor, they have also improved more dramatically, with 5-year survival rates rising from 91 to 96% over the past 2 decades (59). Young infants tend to have slightly worse survival than older children, but they have also shown marked improvement over the years. During the 1987–1995 era, the 3-year patient survival rates were 90 and 79% for infant living and deceased donor kidney transplant recipients respectively; and, for the most recent era those rates have improved to 95 and 93% (59).

76 Immunosuppression in Pediatric Renal Transplantation

Jodi M. Smith · Thomas L. Nemeth · Ruth A. McDonald

Introduction

The major advance allowing prolonged graft survival has been the use of immunosuppressive drugs that down-regulate the immune response. The immunosuppression that is used varies among centers and evolves with the development of new medications and therapeutics.

A variety of factors influence the choice of immunosuppressive therapies. With the dramatic improvements in short-term graft survival in the past decade, the transplant community has started to focus on improving long-term graft survival. Current research is attempting to find the best combination that will optimize graft survival while limiting the side effects. As such, many centers now consider patient specific factors in choosing which medication regimen the transplant recipient will receive.

Induction Therapy

The goal of induction therapy is to prevent T-cell activation. This can be achieved either through depletion of the T-cell pool with monoclonal or polyclonal antibodies or by specifically inhibiting the action of the cytokine, interleukin–2 (IL-2). Retrospective data from the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) consistently had shown a beneficial effect of prophylactic anti-T-cell antibody in pediatric renal transplant graft survival (1). However, these were retrospective studies and were subject to confounding variables such as center effect and that several different types of T-cell antibodies were used. To date, there have been no controlled trials in pediatric renal transplant recipients that have verified the benefit of using induction antibody (2). In fact, a large controlled trial of OKT3 induction versus induction with intravenous cyclosporine in pediatric kidney transplantation showed no benefit to antibody induction (3).

The choice of induction therapy is center and patient dependent. Considerations in choosing the appropriate agent include the efficacy in that patient population and the side effect profile. For instance, a center may use an IL-2 receptor antagonist for induction in the unsensitized recipient but use T-cell depleting antibody therapy in a highly sensitized patient or a patient who has had a previous failed transplant. Trends in induction therapy have changed over time with a shift away from the polyclonal and monoclonal antibody preparations towards the IL-2 receptor antagonists.

Polyclonal Lymphocyte Depleting Antibodies

Antithymocyte globulins have been used as induction therapy in kidney transplantation with the goal of decreasing the incidence of acute rejection, delaying the introduction of nephrotoxic calcineurin inhibitors, and avoiding or minimizing the use of corticosteroids (4). The primary immunosuppressive effect is mediated through the depletion of circulating T-lymphocytes through complement mediated lysis as well as initiating blockage of T-cell proliferation (5). There are two polyclonal lymphocyte depleting antibodies currently available. Anti-thymocyte globulin [equine] (Atgam®) is a polyclonal horse-derived antilymphocyte globulin. Due to the sclerosing nature of the preparation, Atgam® is given intravenously through a central catheter for up to 15 days. The recommended dose is 15 mg/kg and calcineurin inhibitors are generally withheld during the administration of the antibody. Thymoglobulin® is a rabbit derived antithymocyte globulin. Thymoglobulin® is provided through a peripheral vein at a dose of 1.5–2.0 mg/kg/dose. A recent report suggests daily monitoring of CD3 + subsets to guide therapy with the daily dose is given only when the CD3 + count exceeds 20 cells/mm^3 (6). Pre-medication with acetaminophen, corticosteroids, and diphenhydramine can decrease the incidence of administration side effects which include fever, chills, arthralgia, and dyspnea. As with other depleting antibody preparations, calcineurin inhibitors are frequently withheld during the course of treatment with Thymoglobulin®.

© Springer-Verlag Berlin Heidelberg 2009

Comparison of efficacy of removal of circulating T-cells suggested that Thymoglobulin® may have some benefit over Atgam® (7). A randomized, double blinded trial compared Thymoglobulin® to Atgam® for induction immunosuppression in adult renal transplant recipients found a lower incidence of rejection in the Thymoglobulin® group (4% vs. 25%, p = 0.014) (8). Although prolonged lymphocyte suppression was observed in the Thymoglobulin® group, there was no increase in infection or malignancy at 1 year post-induction (9). A multicenter study comparing Thymoglobulin® induction versus no induction showed similar rates of patient and graft survival but did show a significantly lower rate of biopsy-confirmed acute rejections with the Thymoglobulin induction group (p = 0.001) (4). This group also showed higher rates of adverse events, specifically cytomegalovirus infections and bone marrow suppression. Although there have been no controlled comparisons of the polyclonal agents on clinical outcomes in pediatric renal transplant recipients, Thymoglobulin® has been studied in small groups of this population and was found to be effective (10). In a historical comparison of Atgam® and Thymoglobulin® in pediatric kidney transplant recipients at a single center, the incidence of acute rejection was noted to be lower in the Thymoglobulin®-treated recipients (11), but this result may also be due to the fact that it was provided to the more recent cohort and the outcomes of kidney transplantation have generally improved with time (2).

Monoclonal Lymphocyte Depleting Antibodies

OKT3

Muronab-CD3 (Orthoclone, OKT3) is a monoclonal antibody that binds to the lymphocyte-CD3 complex resulting in rapid cell lysis. OKT3 is effective at reversing acute rejection but often, subsequent treatments are limited due to the production of anti-OKT3 antibodies (12). It is administered as a bolus injection into a peripheral vein daily for 10–14 days at a dose of 5 mg for older children and 2.5 mg for children weighing <30 kg. Calcineurin inhibitors are withheld during the use of OKT3. Especially problematic with OKT3 is the associated cytokine-mediated response caused by an increased amount of T-cell derived cytokines such as tumor necrosis factor, IL-2, and gamma-interferon released with cell lysis. This usually occurs approximately 30–60 min after starting therapy. Side effects include fever, chills, hypotension, nausea, diarrhea, and potentially life-threatening anaphylaxis. Pre-medication with acetaminophen, corticosteroids, and diphenhydramine can help temper side effects. Pulmonary edema is another serious complication that can occur with OKT3 therapy and careful monitoring of the patient's fluid status is necessary to minimize this possibility. Neurologic complications from mild headaches to aseptic meningitis, infection, and increased risk of malignancy are all possible complications of OKT3 therapy (13, 14). A humanized anti-CD3 antibody with a low affinity for Fc receptors may be associated with fewer and less severe adverse reactions (15). Currently, there are a number of humanized anti-CD3 agents that are in various stages of pre-clinical development and in phase I clinical trials. These newer agents include HuM291, HuOKT3-gamma1, Aglycosyl gamma 1 CD3mAB, and Anti-CD3 Immunotoxin.

Although retrospective analysis of pediatric kidney transplantation continued to show a clear benefit to the use of prophylactic induction antibody (3), a recent prospective randomized trial of OKT3 induction showed no clear advantage (3). Currently, very few pediatric transplant recipients receive OKT3 for induction therapy (16).

Alemtuzumab (Campath-1H)

Alemtuzumab (Campath-1H) is a humanized anti-CD52 antibody. CD52 is the most prevalent cell surface antigen on lymphocytes but its function is currently unknown (17). After administration, alemtuzumab quickly depletes T and B lymphocytes, monocytes, and natural killer cells with its effects lasting for months (18). It is currently undergoing clinical trials as a lymphocyte depleting agent in both pediatric and adult renal transplantation to eliminate the use of steroids and minimize other immunosuppressants, specifically calcineurin inhibitors (17). There is no recommended dose for pediatric renal transplant recipients but 0.3 mg/kg/dose has been the most common dose used in earlier intestinal, multivisceral and recent pediatric studies (19). The number of doses ranged from 1 to 4 doses during the first week with 2 doses being the most common. Due to infusion related reactions, premedications with methylprednisolone, acetaminophen and diphenhydramine are recommended with doses of antiemetic as needed for nausea and vomiting. Profound lymphopenia is alemtuzumab's major limitation with potential side effects including infections, autoimmune complications, and malignancies (19).

There have been multiple uncontrolled pilot trials of Alemtuzumab in adult renal transplant recipients.

In 1999, Calne et al. reported the use of 2 doses of Campath combined with low-dose cyclosporine monotherapy in 31 consecutive renal transplant recipients (20, 21). Cyclosporine was begun 48 h post transplantation and doses were adjusted to maintain levels of 75–125 ng/ml. Of the 31, 1 died of heart failure with a functioning graft and 1 had recurrent IgA nephropathy. Twenty-nine grafts were functioning at the time of the report and 6 of these had rejection episodes (19%). All rejections responded to intravenous steroids, 3 of the patients had prednisone and azathioprine added, the rest remained on cyclosporine monotherapy. One patient had systemic CMV and one had reactivation of abdominal tuberculosis. In 2003, Knechtle et al. reported on 29 primary renal transplant recipients who received Campath induction therapy (23 LD, 6 DD) (22). Sirolimus was started on day 1 and adjusted to a level of 8–12 ng/ml. All patients were alive at the time of the report and 28 had functioning grafts. One patient lost the graft due to rejection at 2 months post transplantation. There were no systemic infections and no malignancies. Eight patients had rejection episodes (28%) and 5 of these were acute humoral rejection with C4d-positive staining. Biopsies of long-term survivors showed no evidence of chronic allograft nephropathy. Twenty-two patients remained on sirolimus monotherapy. In 2003, Kirk et al. reported results of 7 living donor kidney recipients who received perioperative Campath and no subsequent immunosuppression (23). All 7 patients had early acute rejection episodes (between days 14 and 28) which were successfully treated. All eventually weaned to sirolimus monotherapy, except one patient who had oral prednisone reinstituted for recurrent FSGS. There were no serious infections in the patients and all 7 had normal renal function at the time of the report.

There have been other uncontrolled studies of Campath in kidney and pancreas transplantation in adults and it generally has been well tolerated without an increase in serious infections. In one small series of 3 high-risk pediatric kidney transplant recipients, Campath was well tolerated, but acute rejection was reported (17). Campath induction has been used more extensively in pediatric small bowel transplantation. In a review of intestinal transplantation at the University of Miami, Tzakis et al. reviewed 54 children receiving grafts between 1994 and 2000 (24). Although there were multiple protocols and this was not a clinical trial, they concluded that the introduction of Campath was associated with improved patient and graft survival and was not associated with an increased rate of opportunistic infections. The Cooperative Clinical Trials in Pediatric Transplantation (CCTPT) program of NIAID has sponsored a multicenter pilot trial of Campath induction in pediatric renal transplant recipients with initial maintenance immunosuppresson of tacrolimus and MMF. Patients free of clinical and subclinical rejection at 2 months, have a substitution of sirolimus for tacrolimus.

Monoclonal Non-Depleting Antibodies to Interleukin-2 Receptor

There are two high-affinity antibodies that act on the inducible alpha-chain of the interleukin-2 receptor (IL-2r) on the surface of the activated lymphocyte, basilizimab (Simulect®) and daclizumab (Zenapax®). The precise mechanism of the antibodies is not known, but is presumed to be saturation of the IL-2 receptor and subsequent competitive antagonism of IL-2-dependent proliferation Basiliximab is a chimeric human/mouse monoclonal antibody to the alpha chain of the IL-2 receptor. Generally, the dosing regime includes 2 doses administered within 2 h of transplant and on post-operative day 4. The dosing recommendation is 10 mg in patients who weigh less than 35 kg and 20 mg in all other patients. Pharmacokinetic studies demonstrate that the clearance is reduced by approximately half in children (age 1–11 years) and did not seem to be altered by weight or body surface area (25). Saturation of IL-2 receptors was studied in 14 children with the mean duration of saturation being 42 ± 16 days.

Daclizumab (Zenapax®) is a humanized monoclonal antibody to the alpha chain of the IL-2 receptor. The dosing regimen is typically 5 doses of 1 mg/kg every 2 weeks. It is thought that 5 doses provides IL-2 receptor blockade for up to 3 months. A comprehensive safety and efficacy review of 67 pediatric patients showed that the 1 mg/kg dosing in all age groups provided adequate levels to successfully saturate and block the IL-2 receptor (26). It also showed that a reduced dose in older children would most likely translate into reduced efficacy. Overall, both are well tolerated with a side effect profile that is similar to placebo. Severe acute hypersensitivity reactions have been observed in patients with both the initial and re-exposure dose. This acute reaction may include hypotension, tachycardia, cardiac failure, bronchospasm, pulmonary edema, respiratory failure, and rash. Analysis of NAPRTCS pediatric transplant recipients demonstrated that use of IL-2 receptor antagonists was associated with a decreased risk of thrombosis (27).

Both antibodies have been studied extensively in children and have been shown to be safe and effective (28–33). A novel 6-month dosing schedule of daclizumab

has been reported as part of a steroid-avoidance pilot study and appears to be well tolerated (29). This steroid-avoidance protocol is currently undergoing a controlled trial against conventional immunosuppression, under the auspices of the Cooperative Clinical Trials in Pediatric Transplantation (CCTPT) program of NIAID, in order to define the risks and benefits of this approach. The NAPRTCS 2008 annual report shows that IL-2 receptor antibody is the most common induction therapy used (34).

Co-Stimulation Blockade

T cells require two distinct signals for full activation (35). The first signal, called allorecognition, is provided by the engagement of the T cell antigen receptor (TCR) with the major histocompatibility plus peptide complex on antigen presenting cells (APCs). The second "costimulatory" signal is provided by engagement of one or more T cell surface receptors with their specific ligands on APCs (36–38). The best characterized and perhaps most important costimulatory signal is that provided by interaction of CD28 on T cells with either B7–1 or B7–2 surface ligands on APCs (35). Cytotoxic T lymphocyte-associated antigen 4 (CTLA4), expressed on the cell surface only after initial T cell activation, also binds B7–1 and B7–2 resulting in an inhibitory signal which terminates the T cell response (39, 40).

Recent evidence suggests that CTLA4 negative signaling pathway may be required for induction of acquired tolerance in vivo (41, 42). Binding of CD28 to B7–1 or B7–2 is blocked by CTLA4Ig, a recombinant fusion protein that contains the extracellular domain of CTLA-4 fused to an IgG heavy chain tail. The administration of CD28-B7 blockade prevents acute allograft rejection and induces donor-specific tolerance in several animal models (43–47). In addition, CD28-B7 blockade prevents development (48, 49) and interrupts progression (50, 51) of chronic allograft rejection in transplant models.

CTLA4Ig is currently undergoing human phase I–II testing in autoimmune diseases. A phase I trial with CTLA4Ig in patients with psoriasis vulgaris has been recently reported (52–54). Other trials in rheumatoid arthritis and multiple sclerosis are underway.

A high affinity variant of CTLA4-Ig, called LEA29Y (belatacept), has been developed. In trials, belatacept is typically administered intravenously once a month, a strategy that potentially could improve adherence in the high risk adolescent transplant population. A calcineurin inhibitor sparing trial using belatacept in adult kidney transplant recipients reported encouraging preliminary results (55). In this study, 218 patients who received induction with basiliximab, MMF, and corticosteroids were randomized into three groups; one group received intensive belatacept, another received less intensive belatacept and the control group received cyclosporine as primary immunosuppression. At 6 months, the incidence of rejection was 6–8% in all groups but at 12-months GFR was significantly higher (62–66 ml/min/1.73 m^2) and the incidence of chronic allograft nephropathy was significantly lower (20–29%) in the belatacept groups than in the cyclosporine group (53 ml/min/1.73m^2 and 44%, respectively). Of concern, was the incidence of three cases of post-transplant lymphoproliferative disorder (PTLD) in the belatacept group, two of which were related to primary EBV infection. Although two of the episodes occurred after the subjects had been changed from belatacept to other immunosuppressive agents, the concern about its use in children who are at higher risk of PTLD should be balanced against its potential benefit.

Maintenance Immunosuppression

Steroids

Steroids have broad anti-inflammatory effects on cell-mediated immunity but leave humoral immunity relatively intact (56). The preparations commonly used are prednisolone, its 11-keto metabolite prednisone, and methylprednisone. Although the half-lives of these preparations are very short they can be administered once daily because their effect on inhibition of lymphocyte production persists for 24 h (57). The dosage is usually high initially; up to 10 mg/kg as induction, starting maintenance at 2 mg/kg/day, with a gradual reduction to approximately 0.12–0.16 mg/kg/day within a 6–12 month period.

Unfortunately steroids have multiple adverse effects including growth retardation in children. Other side effects include increased cushingoid habitus, susceptibility to infection, impaired wound healing, aseptic necrosis of bone, cataracts, glucose intolerance, hypertension, hyperlipidemia, gastic ulcer disease, obesity, and acne (58). In addition, the negative impact steroids has on appearance may play a role in poor adherence, especially in the body image conscious adolescent.

Because of the multiple side effects of maintenance steroid therapy, attempts have been made to withdraw steroids altogether, reported both in adult and pediatric kidney transplantation (59). The use of alternate-day

steroid therapy, which appears to reduce the growth inhibiting effect without unduly increasing rejection episodes, seems reasonable (60, 61). A CCTPT multi-center double-blind, randomized controlled trial of corticosteroid withdrawal in pediatric kidney transplantation enrolled 274 subjects before it was halted due to a high incidence of PTLD using maintenance immunosuppression of calcineurin inhibitor and sirolimus (62). However, those children who had corticosteroids successfully withdrawn did not have higher rates of late rejection and their long-term graft survival was equivalent to the control group who were receiving chronic low-dose daily corticosteroids as part of their maintenance therapy.

An uncontrolled pilot trial of prolonged IL-2r antibody administration to permit steroid avoidance has shown very promising results with low acute rejection rates and low incidence of complications (63). This has prompted a multicenter randomized controlled trial through the CCTPT consortium comparing this combination to conventional triple immunosuppression, in order to define the risks and benefits of this approach. Although the benefits of using steroid free protocols in pediatric patients shows great promise, further study is needed to determine the impact on long term graft function.

Calcineurin Inhibitors

Cyclosporine

Cyclosporine A (Sandimmune®) changed the face of transplantation by providing a more potent alternative to azathioprine and corticosteroids, significantly improving 1 year graft survival after its introduction in 1978 (64). It is a cyclic peptide of fungal origin that inhibits T cell response by inhibiting calcineurin. It binds to cellular proteins called cyclophilins and this complex inhibits the movement of transcription factors into the nucleus, blocking IL-2 production. This cascade of events ultimately results in inhibition of T cell proliferation and differentiation (56). For induction cyclosporine can be started intraoperatively as a continuous 24 h infusion in a dose of 165 mg/m^2 daily for children under 6 years of age, and 4.5 mg/kg daily in children over 6 years. Conversion to oral CSA should be done by 48 h. The recommended starting oral dose of CSA is 500 mg/m^2/day divided every 8 h in children aged 6 years and under and 12–15 mg/kg/day divided every 12 h in children older than 6 years for patients on combination therapy with steroids and/or purine synthesis inhibitors. CSA doses are higher than those prescribed in adults because the drug appears to have a more rapid metabolism in children (65). The maintenance dosage decreases over time with average CSA doses at 1 year varying from 4.36 to 8.4 mg/kg in the NAPRTCS database (66) with higher maintenance doses being associated with lower chronic graft rejection (65). A calcium channel blocker is typically given with cyclosporine to reduce nephrotoxicity (67).

The major side effects of CSA are nephrotoxicity, hepatotoxicity, hypertension, susceptibility to infection, neurotoxicity including tremor and convulsions, hyperlipidemia and increased risk of malignancy. The impact of CSA on renal tubular handling of electrolytes can lead to hyperkalemia (68), hyperuricemia (69) and hypomagnesemia (70). A major concern, especially in children, is the hirsutism, facial dysmorphism (71) and gingival hyperplasia (72) which may have an impact on adherence especially in the image conscious adolescent. The use of the microemulsion form of CSA, (Neoral®) has essentially replaced Sanimmune. Studies comparing Sandimmune and Neoral® have found the new formulation to result in both improved and more consistent CSA absorption, with fewer dose adjustments being required (73). Generic forms of CSA are available. Comparison studies with Neoral® demonstrate equivalent bioavailabilities with similar safety and tolerability profiles in adults (74, 75).

The importance of following CSA levels closely cannot be over-emphasized. There are several techniques available to measure CSA levels but high pressure liquid chromatography (HPLC) and fluorescence polarization immunoassay (FPIA). Appropriate drug levels range from 100 to 200 ng/ml HPLC or 200 to 450 ng/ml TDX whole blood trough level after 3 months with higher levels in the immediate post-operative period (76). Matas et al studied the impact of early CSA levels on the incidence of rejection and found that CSA levels less than 100 ng/ml in the first 6 months were associated with a significantly higher incidence of rejection (77).

Unfortunately, there is considerable intra-patient and inter-patient variability in both the area under the curve measurements and the peak and trough blood concentrations for CSA. AUC_{0-4} monitoring is a very accurate way of measuring the total body exposure to CSA, however, there limitations include numerous blood draws and mathematical calculations (78). The single point that had the best correlation to AUC_{0-4} is the CSA level measured 2 h after administration (C_2) ($r^2 = 0.85$), compared with C_3 ($r^2 = 0.70$) or C_0 ($r^2 = 0.12$) (79). To date, abbreviated AUC calculations remain controversial but many transplant centers advocate following C_2 when monitoring cyclosporine therapy in children (80–82). A C_2 target of 1700 ng/ml by HPLC appears to be the

appropriate levels immediately post-transplant to minimize rejection and side effects (83).

Calcineurin inhibitors require close monitoring not only because of the narrow therapeutic window but also due to numerous drug and food interactions (84–86). The majority of these interactions deal with chemicals that inhibit or induce the cytochrome P450 system 3A4 (CYP3A4). Agents such as rifampin, nafcillin, phenobarbital, phenytoin, and carbamazepine are examples of CYP3A4 inducers causing decreased CSA and tacrolimus levels. In contrast, macrolides, azole-antifungals, and some calcium channel blockers, including diltiazem and verapamil, are examples of CYP3A4 inhibitors causing increased levels. The one drug-food interaction that is critical to inform patients about is that grapefruit and grapefruit juice cannot be given with CSA. Not only does grapefruit contain substrates that inhibit CPY3A4 causing increased levels but it is also a P-glycoprotein inducer, a membrane transporter that also affects intestinal absorption and tissue distribution of CSA, tacrolimus, and possibly sirolimus (87).

The most recent data from the NAPRTCS registry shows that less that 15% of renal transplant recipients are currently receiving cyclosporine as initial immunosuppression (34). Cyclosporine has been used in combination with all other immunosuppressants except tacrolimus. However, because of the potential of increased risk of PTLD, the use of the combination of a calcineurin inhibitor, rapamycin and corticosteroids should probably be avoided, especially in high risk children (88).

Tacrolimus

Tacrolimus (Prograf®, FK506) a calcineurin inhibitor derived from the fungus *Streptomyces tsukubaenis* was introduced as an immunosuppressant for kidney transplantation in the mid 1990s (89–91). Although it is a macrolide like cyclosporine, it differs in its chemical structure and cytosolic binding site. Tacrolimus interacts with the FK binding protein and inhibits T-cell derived lymphokines including interleukin-2, -3, and -4, gamma interferon, as well as inhibiting the clonal expansion of helper and cytotoxic T cells (56). There is no established dosage regimen for tacrolimus in the pediatric renal transplant population. The trend has been away from intravenous use in the early period and rather starting with oral or naso-gastric tacrolimus at 0.1–0.15 mg/kg/dose (92). Because of the similar mechanism of action, virtually all of the side effects of CSA therapy are also seen with tacrolimus (90), except for the hypertrichosis and dysmorphic features (66). Neurological side effects are common and may be seen more frequently than with cyclosporine (93, 94). A concern for the use of tacrolimus in pediatric renal transplantation was the development of post transplant diabetes mellitus (PTDM) possibly related to a diminished insulin secretion in association with the insulin resistance related to steroid use (95). The incidence PTLD was much higher with the use of tacrolimus than with other immunosuppresants during early experience (91, 96). However, a more recent retrospective analysis showed that the use of tacrolimus was not a risk factor for development of PTLD, likely due to the lower doses more recently utilized (97).

Blood monitoring is necessary as with CSA and recommended target whole blood trough levels, measured by an enzyme linked immunosorbent assay (ELISA), range between 5 and 20 ng/L. Blood levels can also be measured by HPLC and the resulting levels are about 10% lower than with the more commonly used ELISA methods. The goal tacrolimus level is center dependent and often depends on whether it is used in conjunction with other immunosuppressive agents. Because of concern with dose-related complications, especially the incidence of PTLD, tacrolimus levels are more commonly maintained at the lower level of recommendations, with some recipients even lower after the first post-transplant year. Diarrhea, which is common particularly in infants, may lead to increased tacrolimus levels (98). In addition, there are genetic differences in metabolism, illustrated by the need for black patients to have higher doses than in whites partially due to the fact that the CYP3A*51 allele is expressed in 90% of black patients but only 5% of white patients (99). Other factors that can effect the bioavailability and clearance includes co-administration with food, medications (such as corticosteroids and antibiotics), hypoalbuminemia, anemia, hepatic dysfunction and length of time post-transplant (100). The role of using AUC monitoring is not as well established as it is for patients receiving cyclosporine. At least one report in pediatric renal transplant recipients showed that trough levels correlated well with calculating a patient's AUC from two levels collected at 2 and 4 h ($r = 0.85$) (101). However, 85% of the patients had at least once occasion where discrepancy between the AUC and the trough lead to incorrect dosing adjustments and of all of the dosing adjustment decisions, 33% were incorrect.

Recent data from the NAPRTCS shows that more than 65% of children are being maintained on tacrolimus at 31 days post-transplantation (34). Tacrolimus has been used in combination with all other immunosuppressants except cyclosporine. However, as noted about with

cyclosporine, the combination of a calcineurin inhibitor, rapamycin and corticosteroids should be used with caution in children at high risk for developing PTLD (88). There have been several centers reporting the use of tacrolimus as a rescue agent in the setting of both acute and chronic rejection (102–104).

Choice of Calcineurin Inhibitor

Calcineurin inhibitors have been mainstays of immunosuppression for pediatric transplantation for the past decade and likely account for the continuing improvement in graft survival rates (76, 105, 106). The choice between the two calcineurin inhibitors has often been based on a center preference and on availability in different countries.

In a retrospective analysis of NAPRTCS data of the two drugs given with MMF and steroids, there was no difference in early rejection rate (29%), risk of rejection, or risk of graft loss (66). At 2 years, graft survival was not different (tacrolimus 91%, cyclosporine 95%). Tacrolimus-treated patients were less likely to require anti-hypertensives and had higher GFR at 2 years. An open-label randomized trial of the two drugs with steroids and azathioprine in pediatric renal transplant recipients was recently completed (107). Tacrolimus-treated patients had a lower rate of acute rejection (37%) than cyclosporine-treated patients (59%), although both rates in that study were higher than current standards and not all episodes were biopsy-proven (16). One-year graft survival rates were similar although the GFR was higher in the tacrolimus group. Hypomagnesemia, diarrhea, and PTDM were higher in the tacrolimus group and hypertrichosis and gingival hyperplasia were higher in the cyclosporine group. In a randomized trial comparing tacrolimus to cyclosporine in 196 pediatric patients, the tacrolimus group had a significantly lower incidence of acute rejection and corticosteroid-resistant rejection than the cyclosporine group (108). First year data did not show a difference in patient or graft survival but the tacrolimus group did show a significantly higher GFR that was sustained through the 4 years of follow-up. Further data demonstrated that at the 4 year follow-up, patient survival was similar but graft survival was significantly in favor of tacrolimus ($p = 0.025$). There was no difference in the incidence of PTLD between the two groups. Early concern about the higher risk of PTLD associated with tacrolimus use (91, 97) seems no longer to be true, probably related to lower levels of tacrolimus used in current practice (109).

As noted above, the majority of pediatric kidney, liver and intestine transplant recipients are currently receiving tacrolimus because of its efficacy and lack of cosmetic side-effects, which is particularly important for adolescent transplant recipients. One unfortunate consequence of chronic calcineurin inhibitor use is nephrotoxicity and chronic renal insufficiency (CRI). One recent review demonstrated an incidence of CRI of 11.8% and an incidence of ESRD of 4.3% 10 years after pediatric heart transplantation (110).

Antiproliferative Agents

Azathioprine

Azathioprine (AZA) was the first immunosuppressive agent approved for organ transplantation use. For several decades, virtually all organ transplant recipients received azathioprine, but other agents have supplanted its use during the past decade (2). Azathioprine (Imuran®), a pro-drug of the chemotherapeutic agent 6-mercaptopurine, acts by directly inhibiting the growth and differentiation of immune cells. After metabolism in the liver, derivatives of the pro-drug inhibit purine synthesis, preventing gene replication, and cell division. In addition to blocking cell-mediated immunity, it inhibits primary antibody synthesis and decreases circulating monocytes and granulocytes (56). The usual dose is 1–2 mg/kg/day with close follow-up, reducing the dose in the setting of myelosuppression. The major side effect of AZA is myelosuppression with leukopenia, thrombocytopenia, and megaloblastic anemia. Other side effects include susceptibility to viral infection, hepatotoxicity, pancreatitis, alopecia, and neoplasia, most notably skin cancer (111). Azathioprine has been used in combination with all other immunosuppressants except MMF.

In 1989 and 1990, 80% of pediatric patients in the NAPRTCS registry were receiving azathioprine, but as more familiarity is established with MMF the use of azathioprine has diminished substantially and is currently in less that 5% of pediatric kidney transplant patients in the United States (34).

Mycophenolic Acid

Mycophenolate mofetil (Cell-Cept®) has recently gained acceptance as a first line agent as a replacement for AZA as part of the standard triple therapy. It is an anti-metabolite agent that interrupts purine metabolism in B and T lymphocytes. In vivo, it is rapidly metabolized to mycophenolic acid which blocks conversion of inosine IMP to

guanosine IMP in the purine biosynthetic pathway. The net result is a decrease in the number of functional B and T lymphocytes and inhibition of the response of human lymphocytes to antigen challenge (56). The current recommended dose for pediatric patients is 1200 mg/m^2/day divided twice a day, adjusting the dose in the setting of myelosuppression. It is currently available in intravenous, capsule, and liquid form. MMF is relatively well tolerated with hematologic and gastric side effects being the main concerns. Practitioners should follow blood counts looking for neutropenia as well as thrombocytopenia. If hematological problems are noted, decreasing the dose is recommended until values normalize. Granulocyte colony stimulating factor (GCSF) may be required to deal with neutropenia. Current data concludes that reducing and more importantly, holding doses of MMF will lead to impaired graft survival (112). A major difficulty in widespread use of the drug in children has been the gastrointestinal disturbance especially in young children (113). Both nausea and vomiting are common, but in some patients the drug has to be withdrawn due to intolerable diarrhea. If the patient has difficulty tolerating MMF, the dose can be split into 3–4 smaller doses throughout the day. Switching the patient to the liquid form can also help with gastric complaints. Frank esophagitis and gastritis with occasional gastrointestinal hemorrhage occur in approximately 5% of patients (114). The goal of the enteric coated mycophenolic acid (EC-MPA) (Myfortic®) is to decrease gastric side effects while at the same time decreasing the amount of time needed to reach mycophenolate therapeutic exposure. In a 12-month study of 423 de novo renal transplant patients comparing MMF to enteric coated mycophenolate, both groups had similar side effect profiles (115). When looking specifically at gastro-intestinal intolerance, 9.4% of patients in the enteric coated group had dose reductions or temporary interruptions while the MMF group had 13.8% of patient reduce or stop the medication; but the difference between the two groups was not significant. A small cross over study was performed in 10 pediatric renal transplant patients to evaluate the impact of converting stable patients from MMF to enteric coated MPA (112). A gastrointestinal symptom rating scale was used looking at 5 criteria; reflux, abdominal pain, constipation, indigestion, and diarrhea. Scores dropped significantly 4 weeks after switching and 9 out of 10 patients reported to still have positive effects from the switch 6 months after the conversion. In a smaller case report, 8 pediatric patients, all patients were switched to the EC-MPA with all of the patients reporting no gastrointestinal disorders. They also noted an increase in MPA levels from a mean level of 0.8 ± 0.3 μg/ml to a mean of 3.2 ± 1.7 μg/ml (target range of 2–4 μg/ml) (116). One limitation of EC-MPA is that it cannot be crushed or made into a suspension forcing practitioners to only use this in patients who can swallow pills whole.

MMF does not have any nephrotoxicity but should not be used in combination with azathioprine for fear of increased risked of neutropenia and infection. MMF is not metabolized by any of the cytochrome P-450 isoenzymes. Some evidence indicates that patients who receive MMF in combination with tacrolimus have higher drug levels of MMF (117). As such, patients on tacrolimus are usually on lower doses of MMF at 600 mg/m^2/day.

In the adult transplant population, MMF has been shown to decrease the incidence of acute rejection episodes by as much as 50% (118, 119). A study in pediatric renal transplant recipients comparing those who received AZA versus MMF along with the standard CSA and prednisone therapy found no significant differences in the incidence of acute rejection episodes, patient, or graft survival (120). The Pediatric MMF study group has reported that MMF in combination with CSA and prednisone provides effective immunosuppression for up to 3 years with excellent graft survival rates of 98% with a low rate of acute rejection (121). Another difference between MMF and AZA is cost; MMF is six to seven times more expensive than AZA. Seikaly argues that a decrease in the number of acute rejection episodes and a potential reduction of CSA dose with subsequent reduction in CSA toxicity under the more potent MMF therapy would help balance its cost (122). Further study of MMF is warranted to assess long-term outcome with respect to incidence of PTLD and other viral infections.

There has been considerable debate regarding the utility of measuring mycophenolic acid levels (MPA). Evidence to support the use of MPA monitoring comes from the association of systemic MPA concentrations with both efficacy in preventing rejection (123–126) and adverse reactions (123, 125, 127). A multicenter study conducted in France showed significantly fewer treatment failures and acute rejection episodes in the monitoring arm with no significant difference in side effects (128). Within this study, the MPA exposure and MMF dosing were higher in the monitoring arm based on three levels measured over the first 3 h post-dose. However, results from the FDCC (Fixed Dose vs. Concentration Controlled) study being performed within 69 international centers have shown no benefit in the monitoring group, but there was no increase in dose (129). The OPTCEPT trial being performed in 65 centers in the United States also did not show any benefit within the monitoring group compared

to the fixed dose group (130). However, there was no difference in trough levels between groups As with CSA, AUC monitoring of MPA levels appears more sensitive than trough levels. However, finding a limited sampling strategy has been challenging due to the second peak level caused by intrahepatic circulation of MPA (131).

Sirolimus

Sirolimus (Rapamune®, rapamycin) is an immunosuppressive agent approved by the FDA for use in solid organ transplantation in 2000. It is a natural fermentation product of *Streptomyces hygroscopicus*, discovered on Easter Islant (Rapa Nui) in 1969. It was first investigated for anti-fungal properties and its immunosuppressant properties were first discovered in 1988. Sirolimus is classified as a TOR inhibitor. TOR is a cytosolic enzyme that regulates differentiation and proliferation of lymphocytes. TOR is activated as a result of the cascade of reactions in lymphocytes by the proliferation of cytokines. It initiates production of messenger RNA that trigger cell-cycle progression from G_1 to S phase. The TOR inhibitors bind to the immunophilin FKBP12 and inhibit the actions of TOR (132–136). The TOR inhibitors may be particularly important in long term immunosuppression because they stimulate T-cell apoptosis. They also inhibit mesenchymal proliferation, which may prove to be important in graft vascular disease (137, 138). Also, since the mechanism of action of rapamycin is different from other currently available immunosuppressive agents, it can be used in combination with all of them. A similar compound that may be an analogue, SDZ-RAD is currently undergoing clinical trials but the pediatric component of that study was halted due to concern about potential complications in immature subjects. Sirolimus is available as an oral preparation, either as a solid or liquid. Sirolimus was shown to have a prolonged half-life in adults that allowed a single daily dose in adults (139–141). However, pharmacokinetic studies in children have demonstrated a much shorter half life, as short as 12 h (142, 143). Thus, children may require twice-per-day schedules in order to maintain therapeutic levels. Retrospective analysis of early trials of sirolimus have suggested a relationship between blood levels and risk of rejection (144). Current suggestions for therapeutic levels remain speculative and range between 25 ng/ml in the early post-transplant period without calcineurin inhibitors (142, 145) and 5–10 ng/ml later in the course of transplantation.

Sirolimus has its own unique side effect profile which can limit its use including poor wound healing, gastrointestinal and oral ulcerations, hyperlipidemia, skin rash, myelosuppression, thrombocytopenia, anemia, and its association with proteinuria (140, 146–148). Studies have shown intolerance leading to dropout rates as high as 42–46% (149, 150). Some side effects can be minimized with dose reduction and delayed wound healing may require suspension of the drug until the wound heals completely. Sirolimus associated proteinuria requires that the drug be discontinued entirely. A side effect that is gaining more attention is the occurrence of interstitial pneumonitis in patients receiving sirolimus. Reports have linked that this correlation appears to be dose related and resolves with withdrawal of sirolimus within 14–28 days (151, 152). One center reported good outcomes in switching some patients to low-dose sirolimus with only one out of six patients relapsing after 5 months (152). Although lower dosing of sirolimus seems to be an option, discontinuation of sirolimus continues to be the safest treatment option. Another complication is the association of sirolimus therapy with prolonged delayed graft function (DGF) in comparison to patients who did not receive sirolimus (153). Within the experimental model, sirolimus has been shown to prolong acute renal failure in animals that had acute ischemic tubular injury, leading to the potential delay in recovering from acute tubular necrosis (ATN) (154). In the setting of acute tubular damage, a balance between proximal tubular cell death and the ability of sublethally injured tubular cells to enter the cell cycle and proliferate occurs (155, 156). Sirolimus is shown to inhibit growth factor induced proliferation of proximal tubular cells and to promote apoptosis by interfering with the survival effects of the same growth factors (154). Therefore, the delay of recovery of DGF from ATN may result from a direct effect of sirolimus by inhibiting normal cell growth (157). Sirolimus is associated with impaired spermatogenesis and may be associated with reduced male fertility (158).

Sirolimus has been found to be effective in combination with calcineurin inhibitors (139–141, 159, 160), in a calcineurin-inhibitor sparing protocol (145), and in a steroid free protocol (161). In renal transplantation, calcineurin inhibitor nephrotoxicity is a key risk factor for reduced long-term allograph survival (162). In no population group is this more important than in children due to the potentially lifetime consequences of immunosuppression. In phase I and II trials in adults, sirolimus was well tolerated and exhibited no apparent nephrotoxic properties or deleterious effects on blood pressure. Because sirolimus has little to no nephrotoxic effects, its use is an attractive alternative to the calcineurin inhibitors.

When used in combination, there appears to be a synergistic effect of the sirolimus-CSA combination allowing for a decreased CSA dose with subsequent reduction in CSA side effects (110). Data directly comparing sirolimus *versus* CSA used in combination with steroids and AZA show no significant difference in the incidence of acute rejection, graft survival, or patient survival at 1 year post-transplant (147). However, an open label phase II study in adult recipients of primary renal allografts receiving CSA and corticosterioids demonstrated that all treatment groups to which sirolimus was added had a lower rate of acute rejection (7–11%) when compared to placebo (32%), during the first 6 months following transplantation (163). In a cohort of 66 pediatric renal transplant patients where sirolimus was added to calcineurin inhibitors plus corticosteroids, acute rejection occurred in 10.6% of patients and graft survival was 98% at 6 months (164). In an attempt to reverse the nephrotoxic effect of calcineurin inhibitors, a retrospective analysis of 17 pediatric patients who underwent calcineurin inhibitor withdrawal and converted to sirolimus and MMF showed a decrease in creatinine clearance at 6 months and 1 year after conversion. Using sirolimus as rescue therapy for chronic graft injury needs to be applied with caution in pediatric patients, especially patients who have advanced graft dysfunction. There seems to be a point where graft injury is severe enough that withdrawing calcineurin inhibitors results in no significant clinical improvement (148). In the adult literature, Wu et al showed no benefit for patients with serum creatinine greater than 4 mg/dL (165) supporting the idea that rescue of patients early in the process of chronic graft injury is likely more beneficial than later. Current research is being undertaken to determine when is the optimal time of switching patients from calcineurin inihibitors to help improve and preserve renal function. One such study was done on 30 pediatric renal transplant patients who were converted from tacrolimus to sirolimus at 3 months post transplant (166). Incidence of acute rejection after conversion was low at 10% but as a group, the average renal function did not improve during follow-up.

The drug interaction with CSA and sirolimus is greatly related to administering both drugs at the same time. The drug interaction may be due to competitive interactions of both drugs as substrates for P-glycoprotein and for the cytochrome P450 isoenzymes (167). This can result in sirolimus trough levels that are 67–85% higher than when given alone (168). The initial recommendations were that sirolimus should not be given within 4 h of CSA. Some institutions give sirolimus at the same time as CSA knowing of the increased levels but start with a lower dose and follow levels. Unlike the CSA/sirolimus combination, sirolimus and tacrolimus pharmacokinetic profiles and adverse effects were not altered with simultaneous administration. Because of this, sirolimus and tacrolimus can be administered at the same time (169). Pharmacokinetics of sirolimus differs substantially in children and adults. In general, the half-life is much shorter in children. The half-life of sirolimus ranges from 4.7 to 6.1 h with tacrolimus and 8.2–11.9 h in children who received cyclosporine. This requires pediatric patients to be dosed twice a day compared to once a day in adults (170). One of the largest pediatric studies using basiliximab showed the combination of a calcineurin inhibitor, sirolimus and steroids did decrease the rejection rate over historical data but also did increase the rate of PTLD (171). Thus, it is highly likely that the combination resulted in over-immunosuppresion in high-risk pediatric patients and should not be used.

Immunosuppression Combinations

Most pediatric renal transplant recipients are currently treated with triple immunosuppression. When the number of drugs was limited, the number of possible combinations was small. However, there are at least 20 possible combinations of the 6 currently available drugs and when the induction antibodies are added, there are over 60 possible reported protocols (172). No "best" protocol for children has been established, although most clinical trials are currently directed at eliminating either steroids or calcineurin inhibitors, or both.

There are many possible targets for immunosuppression strategies for children (173). One promising new protocol of steroid avoidance has been recently reported (29). This approach consists of 6 months of anti-IL2r antibody, tacrolimus, and MMF. Short-term patient and graft survival rates have been excellent and growth rates have been very good. Major complications have included bone-marrow suppression and nephrotoxicity. A randomized, controlled trial of steroid withdrawal was successful in preventing acute and delayed rejections (62) but the initial immunosuppression of IL-2r antibody induction, followed by initial immunosuppression of corticosteroids, sirolimus and a calcineurin inhibitor was too robust, leading to an unacceptably high rate of PTLD in young children (174). Other protocols currently under investigation include calcineurin inhibitor avoidance or withdrawal (175) or co-stimulation blockade (55) with the eventual goal of avoiding both corticosteroids and calcineurin inhibitors (176). One other approach is to

use robust induction therapy with Campath, followed by eventual monotherapy with tacrolimus (177, 178). Clearly, there is no single defined approach to immunosuppression for children, but the eventual goal is to permit long-term graft acceptance with the fewest possible chronic medications.

Treatment of Rejection

There have been no controlled trials of treatment of acute organ transplant rejection in children. In general, the initial treatment of a rejection episode is with pulse intravenous corticosteroids, typically lasting 3 consecutive days with a dose of 10–30 mg/kg for each dose. This regimen may be followed by a slow taper of oral prednisone, but some centers do not routinely use the oral taper. High dose oral prednisone for rejection has been reported in children with equivalent results to intravenous therapy in terms of the rate of rejection reversal (179). Severe, recurrent or steroid resistant rejection episodes are most often treated with lymphocyte-depleting antibodies, including OKT3, Atgam or Thymoglobulin, although Campath is also being studied for this indication (180, 181). To date, there are no studies of IL-2 receptor antagonists for use in rejection (182).

Antibody-mediated rejection may be treated with plasmapheresis, infusion of IVIG, or Rituximab in addition to these other treatments, but the efficacy of these approaches is unknown (183–186). Another novel and unproven approach is the use of photopheresis (187, 188).

Re-evaluation of maintenance immunosuppression is indicated following a rejection episode. One may consider switching to an alternative calcineurin inhibitor and/or from MMF/azathioprine to sirolimus to take advantage of the synergism between sirolimus and the calcineurin inhibitors. In addition, assessment of the patient's adherence to the medication regimen is always important.

Conclusion

Advances in immunosuppressive therapy over the past decade have led to dramatic improvements in graft survival. Children currently have excellent outcomes however, long term success has been limited by the complications of lifetime immunosuppression. The current medications used to prevent graft loss are toxic and have significant complications. With the development of new agents, the focus of the transplant community is to establish regimens which maintain excellent graft survival rates but with fewer toxicities including infection, nephrotoxicity, malignancy, and cosmetic effects. In addition, the need to continue to use these medications on a continuing daily basis requires adherence that few recipients, especially adolescents, can accomplish. The future of immunosuppression for children depends on our ability to develop non-toxic long-term medications that are safe, effective and simple to administer. However, the ultimate goal of transplant immunosuppressive therapy is the induction of tolerance. As we learn more about immune function from basic and clinical research, tolerance to allografts seems an ever more reachable goal.

77 Complications of Renal Transplantation

Vikas R. Dharnidharka · Carlos E. Araya

Introduction

The two preceding chapters have provided a description of the process of pediatric kidney transplantation. There has been tremendous successes achieved in this field over the past few decades. Patient and graft survival have improved markedly with each successive decade from the 1960s to 1990s (1). Early acute rejection rates continue to fall (2, 3).

Yet this most recent decade has seen a leveling-off in terms of improvements in graft and patient survival (3, 4). While acute rejection rates have fallen, the community has seen the emergence of newer infection complications such as post-transplant lymphoproliferative disease (PTLD) and BK virus allograft nephropathy (BKVAN) (5–7). The infection-hospitalization cumulative incidence is much higher at 47% in children in the first 3 years post-kidney transplant than while on dialysis or in comparison to adults post-kidney transplant (8). The total cumulative infection incidence in children did not drop in recent years (9), as it has in adults. With longer patient survival, systemic complications of transplantation such as accelerated cardiovascular disease have become more prominent (10, 11). As the medical community has developed more potent immunosuppression drugs and regimens, transplant recipients have paid a price in terms of more infectious and non-infectious complications (*Table 77-1*), especially long-term complications. In this chapter we discuss the various intermediate and long-term complications associated with pediatric kidney transplantation. Early complications such as delayed graft function and vascular thrombosis as well as chronic allograft nephropathy are discussed in Chapter 83.

Special Considerations in Pediatric Transplantation

In general, organ transplant recipients of any age are at greater risk for infections due to the non-specific nature of the currently used immunosuppressive agents (5). Organ transplant recipients are also at greater risk of disease related and medication-induced systemic complications, due to the severe nature of the underlying disease (kidney failure) and the need for multiple long-term medications. In addition, *pediatric* recipients of organ transplants have some unique and additional features that add to their risk for complications. By virtue of their younger age, these recipients are exposed to disease complications and medication toxicities for a longer period of time. The risk for some infections, especially viral infections, is higher if the child had not been exposed to that organism while still immunocompetent. Thus, a primary infection in a host who is immunosuppressed tends to be more severe. The kidney allograft often acts as the source for the primary infection, since most children receive an adult donor kidney, which harbors latent viruses. Children may not have had the opportunity to receive all vaccinations prior to transplant, thereby preventing development of immunity to certain organisms. Finally, certain complications, such as growth failure, are unique to children.

Bacterial Infections

Urinary Tract Infection

Urinary tract infection (UTI) is the most common bacterial infection in kidney transplant recipients, both in adults (12, 13) and children >5 years (14). The percent of renal transplant recipients who will experience a UTI ranges from 20–65% in the first year post-transplant (12, 15) and 40–80% by 3 years post-transplant (16–20). UTI is not only a cause for morbidity but is also associated with higher rates of graft loss and patient death (16, 21). In a recent analysis of United States Renal Data System (USRDS) data, early UTI (within 6 months of transplant) elevated the risk for graft loss in children, while late UTI did not (22). The urogenital tract is the most common entry point for the development of sepsis (23). Risk factors for UTI in children include bladder

Table 77-1
Typical non-infectious complications

Type	Complication
Cardiovascular	Hypertension
	Left ventricular hypertrophy
	Coronary artery disease
	Renal artery stenosis
Metabolic	Dyslipidemia
	Obesity
	Diabetes mellitus
Musculoskeletal	Growth failure
	Osteopenia
Gastrointestinal	Esophagitis
	Gastritis
	Vomiting/diarrhea
Hematological	Leucopenia
	Neutropenia
	Anemia
Neurological	Tremors
	Headache/stroke
	Peripheral neuropathy
Miscellaneous	Hair/skin: alopecia, hirsuitisim, skin cancers
	Hyperuricemia

abnormalities, the need for chronic or prolonged bladder catheterizations and placement of a ureteral stent (17, 24). In adults, diabetes mellitus and cardiovascular disease are comorbid factors that also associate with a higher incidence (16). UTI risk is highest in the first few months post-transplant but some risk remains at later time points. The organisms implicated are usually the same as in immunocompetent individuals, such as *E. Coli* and *Klebsiella*. A higher percentage of UTIs in transplant recipients are due to unusual organisms such as *Pseudomonas* (25). Clinical symptoms include fever, dysuria, graft tenderness and cloudy urine. In some patients, due to immunosuppression, symptoms may be masked. A rise in serum creatinine often occurs and can mimic acute rejection. UTIs can also precipitate an acute rejection. The diagnosis of UTI is usually confirmed by urine culture, though patients on trimethoprim-sulfa prophylaxis for pneumocystis may not demonstrate positive cultures. In that case, radionuclide scanning or clinical judgment may be necessary. Treatment is with anti-microbial agents. Initially, the anti-microbial prescribed should cover the common Gram negative organisms. Once the organism is known, the most specific and cost-effective anti-microbial can be prescribed. Treatment route and total duration vary somewhat by severity of infection, recipient age and other risk factors present. Shorter oral courses such as used in immunocompetent people can be used for milder cystitis episodes in older children. In more severe acute pyelonephritis in a younger child who was recently transplanted, intravenous antimicrobial therapy for 10–14 days is preferred. Not all centers prescribe routine prophylaxis for UTI. Trimethoprim-sulfa, if given daily, may serve as both UTI and pneumocystis prophylaxis.

Other bacterial infections, such as wound infections, line sepsis and pneumonia are seen with significant frequency in kidney transplant recipients. Wound infections and line sepsis are commonly due to Gram positive staphylococcus and streptococcus. Pneumonia can be due to multiple etiologies (bacterial, viral or fungal); bacterial pneumonia comprises approximately 44% (26). In adult transplant recipients, cellulitis and bacterial abscesses are frequent problems, largely due to co-morbid diabetes mellitus. In general, children are less likely to develop cellulitis and abscesses and are more likely to develop viral infections than adults. The detection and treatment of these infections generally is not different from standard investigation and treatment in immunocompetent hosts, though duration of therapy may be longer.

Bartonella henselae infection (also known as cat-scratch disease) has been reported in pediatric organ transplant recipients, including kidney transplants (27). This infection typically presents as fever and lymphadenopathy, thus becoming a differential diagnosis for PTLD. However, unlike PTLD, this infection is curable with anti-microbial therapy.

In third world countries, *Mycobacterium tuberculosis* infection occurs more commonly than in the West. The incidence is <2% in Western countries but ranges from 5 to 15% in Asian and African countries (28, 29). Use of cyclosporine, co-existing diabetes mellitus, and chronic liver disease increase the risk for post-transplant tuberculosis (30). This infection presents with myriad symptoms, including weight loss, cough, fever and lymphadenopathy, and thus should be part of the differential diagnosis for PTLD. However, pulmonary involvement is more common than lympadenopathy in the post-transplant setting. Early diagnosis is best achieved by staining for acid-fast bacilli or PCR DNA amplification from sputum, bronchoalveolar lavage or gastric aspirate. Four drug therapy with isoniazid, pyrazinamide, ethambutol and either streptomycin or ofloxacin is preferred because of drug resistant strains (29). Rifampicin can also be used but

the dosages and frequency of tacrolimus/cyclosporine/steroids have to be markedly increased to account for enhanced liver metabolism of those drugs.

Cytomegalovirus Infections

Cytomegalovirus (CMV) is a DNA virus of the herpes virus family. When considering all organ transplants as a group, this virus may be the single most important pathogen. In pediatric kidney transplantation, the incidence of CMV infection has been highly variable, ranging from 6 to 40% (31–34). The variation is partly due to differing definitions (e.g., viremia versus disease) and partly due to different detection methods (33, 35). A very recent retrospective study using pp65 antigenemia reported a viremia rate of 21% and disease rate (viremia plus organ involvement) of 9.7% (33). CMV is especially important because of its dual effects: it causes significant morbidity by direct infection, yet its immunomodulatory effects can predispose to other infectious complications (*Table 77-2*). CMV infection post-transplant can be as a primary infection, a reactivation infection or a superinfection. Of these, primary infection in the immunocompromised host is the most likely to lead to disease and often occurs when a seronegative pediatric recipient receives a kidney transplant from a seropositive donor (33, 34). Both CMV viremia and disease usually occur within the first few months post-transplant, though routine anti-viral prophylaxis has led to later appearance, with more CMV cases appearing after prophylaxis ends (35). Viremia may be silent or can manifest as CMV syndrome, characterized by fever, myalgias, malaise, leukopenia and thrombocytopenia, or CMV disease, in which there is clinical evidence of active infection. The transplanted kidney is at higher risk for CMV infection than are the native organs, but pulmonary, liver and gastrointestinal tract involvement are common, regardless of the organ transplanted.

In addition to causing direct infection, CMV has significant indirect effects including an increase in the overall state of immunosuppression leading to a greater risk for opportunistic infections. CMV infection also increases the risk of EBV-associated post-transplant lymphoproliferative disorder (36). In addition, CMV and acute rejection are interrelated. The study by Kranz et al. showed that antecedent CMV infection is a risk factor for acute rejection, while rejection is known to release tumor necrosis factor, triggering the process that ultimately leads to CMV replication (33).

Prevention of CMV infection can be accomplished with either (1) universal prophylaxis: the administration of anti-CMV therapy to all patients except seronegative recipients of an organ from a seronegative donor; or (2) preemptive treatment: the administration of anti-CMV therapy to patients at first sign of CMV infection. There is some controversy as to the optimal strategy, as both methods have advantages and disadvantages. In one recent study of pediatric liver transplant recipients, pre-emptive therapy was superior (37). Most guidelines recommend universal prophylaxis for high risk patients (e.g., seronegative recipients of an organ from a seropositive donor), with preemptive therapy reserved for patients at low or intermediate risk. Although several agents are available for prophylaxis, ganciclovir or valganciclovir have largely supplanted either oral acyclovir or CMV immune globulin (CMVIG) as the recommended treatment for prevention of CMV infection. Many protocols recommend intravenous ganciclovir, followed by oral ganciclovir. Oral ganciclovir has poor bioavailability and must be taken in large doses three times daily. Valganciclovir has superior bioavailability to oral ganciclovir, with a pharmacokinetic profile similar to intravenous ganciclovir. The standard duration of prophylactic therapy is 100 days, although many centers have extended prophylactic therapy to the first 6–12 months post-transplant given data suggesting significant reduction in late CMV-infection with this strategy.

Table 77-2

Typical infectious complications, by organism type

Type	Complication
Bacterial	Urinary tract infections: usually Gram negative rods
	Wound infections: usually Staphylococcus/Streptococcus
	Central line infections
	Pneumonia
	Mycobacterium tuberculosis
	Bartonella henselae
Viral infections	Cytomegalovirus
	Herpes simplex virus
	Epstein Barr virus
	Varicella virus
	BK virus
Other	Pneumocystis jurevicii
	Candida
	Other fungi
	Parasitic

For preemptive therapy, intravenous ganciclovir is generally recommended, but recent studies have demonstrated good results with valganciclovir. In order for preemptive therapy to be successful frequent monitoring with reliable diagnostic assays must be performed. Detection of CMV DNA or RNA by polymerase chain reaction (PCR) and the pp65 antigenemia assay are both rapid and have reasonable predictive ability for use in preemptive therapy. Serum and whole blood DNA correlate well in case of CMV (38).

The widespread use of preventative therapy has greatly reduced the incidence of CMV disease, especially in the early post-transplant period. When CMV disease does occur, treatment with intravenous ganciclovir is the treatment of choice. Some guidelines suggest that valganciclovir, at high doses, may also be as used. The optimal duration of treatment has not yet been defined, and current protocols recommend continuing treatment till viral load becomes undetectable and perhaps for a short time thereafter.

Epstein-Barr Virus Infections and PTLD

Epstein-Barr virus (EBV) is another DNA herpes virus that causes significant morbidity post-transplantation. Like its cousin CMV, this virus commonly infects immunocompetent people sometime in childhood and establishes a prolonged latency in reticulendothelial cells. Thus, the patterns of infection are identical to CMV: primary infection (often from the graft of a seropositive donor), reactivation or superinfection. Again, like CMV, the primary infection in an immunosuppressed transplant recipient is more virulent. Unlike CMV, EBV infection does not seem to have many indirect effects except for the development of PTLD, which is an uncontrolled proliferation of immune cells (typically B cells) in the setting of post-transplant immunosuppression (39). In pediatric cases especially, most PTLD is due to Epstein-Barr virus. This condition is not a true malignancy since the immune system can regain control of B-cell proliferation if extrinsic immunosuppression is reduced and EBV-directed CD8+ T cells regain function.

EBV infection can be asymptomatic or present as a non-specific viral syndrome, similar to CMV infection. Routine PCR monitoring in recent studies suggest that the rate of EBV infection in EBV seronegative pediatric transplant recipients (as defined by systemic viremia) ranges from 50 to 80% (40–42). PTLD incidence in pediatric kidney transplantation was previously low at <1%, but then climbed over the last 10 years, concomitant with the introduction of more potent immunosuppression protocols to more than 4% (43–45).

EBV viremia, in contrast to PTLD, can be asymptomatic or associated with mild non-specific viral symptoms. In the past, the diagnosis was made by documenting seroconversion (EBV IgM positive or significant rise in IgG titer). Unlike with CMV, in the case of EBV, testing can be performed against EB nuclear antigen or viral capsid. The former turns positive early, after recent infection and the latter in more distant infection. More recently, in western countries, PCR amplification of viral DNA is the method most commonly used (46). The reader should note that PCR techniques for EBV DNA amplification vary greatly based on the type of sample and laboratory standards. Thus, PCR values from peripheral blood leucocytes and whole blood generally correlate with each other but not with PCR values from plasma (47, 48). Plasma EBNA PCR may be the best single assay for diagnosing and monitoring PTLD, while the complete PCR panel is superior for ruling out its presence (49).

PTLD can present clinically in many ways (50). Most often the patient has lymphadenopathy, fever or symptoms related to pressure on internal organs from an internal lymphoid mass. Diagnosis is made histologically, though imaging can help with appropriate tissue acquisition and staging. Monoclonal or monomorphic PTLD is generally more severe than polyclonal or polymorphic. The most severe forms are indistinguishable from lymphomas.

There is no universally accepted treatment for EBV infection post-transplant. Reduction in immunosuppression is one modality. The anti-viral agents ganciclovir and valganciclovir have activity against EBV but acyclovir is not effective against EBV. The duration and route of anti-viral treatment is not standardized but most centers will treat until the EBV PCR has turned negative. Whether all patients with acute EBV seroconversion need reduction in immunosuppression or anti-viral treatment is a controversial question in pediatric transplantation (51, 52). Children in particular can develop a chronic high load carrier state without ever progressing to PTLD (50). Nevertheless, the majority of reports indicate that higher EBV PCR values are associated with a greater risk for subsequent PTLD (53–55).

Oral ganciclovir or valganciclovir are also used for prevention of EBV disease. These agents seem to delay the onset of infection rather than reduce the incidence. IVIg does not add any benefit (56). An alternative concept is pre-emptive therapy, i.e., the initiation of anti-viral agents at treatment doses as soon as the EBV PCR load

rises. An EBV vaccine, directed against an EBV-glycoprotein, is under testing in the United Kingdom.

Treatment of PTLD usually involves a sequential process (57, 58). Immunosuppression reduction is typically the first intervention, followed by anti-CD20 antibody or interferon-alpha. Chemotherapy is usually reserved for higher grade cases, though some centers will use rituximab with low dose chemotherapy.

Varicella Infections

Varicella-zoster virus (VZV) is the most infectious of the human herpesviruses. Primary infection with VZV results in chickenpox. Following primary infection, the virus remains in the body in a latent state from which it may be reactivated, resulting in cutaneous herpes zoster, or shingles. Incidence of all VZV infections in adult kidney transplant recipients was 7.4% in one study (59). Children are morel likely to be VZV seronäive at the time of transplantation and primary infection is a significant cause of morbidity and mortality (60, 61). Routine VZV vaccination has been documented to reduce the incidence of primary VZV infection post-transplantation (62). All transplant candidates over 9–12 months of age should receive immunization with the VZV vaccine (63). Studies in children with chronic kidney disease and those who are being treated with dialysis suggest that two doses, rather than one, may be necessary to elicit protective antibody levels. Therefore, antibody levels be obtained at least four weeks following immunization, and a second dose be given if necessary (63, 64). Although some studies have evaluated the use of this vaccine in post-transplant patients, both American Academy of Pediatrics Committee on Infectious Diseases and the Centers for Disease Control and Prevention's (CDC) Advisory Committee on Immunization Practices (ACIP) advise against the use of this live-viral vaccine in immunocompromised patients. Where possible, such vaccination should thus be provided, and protective antibody levels documented, prior to transplant (65, 66).

Patients who are varicella-näive at the time of transplant (not immunized or did not respond to immunization), should receive prophylactic therapy if they are exposed to varicella. Varicella zoster immune globulin (VZIG) is no longer manufactured as of October 2004. In February 2006, the FDA approved expanded access to an investigational VZIG product, VariZIG (Cangene Corporation, Winnipeg, Canada) which became available under an investigational new drug application. The ACIP recommends that use of this product may be requested in immunocompromised patients exposed to varicella infection (67). If this product is not available, intravenous immune globulin (IVIG), which contains some antivaricella antibody, may be given (67). Any prophylactic therapy should be given as soon as possible, up to 96 hours after exposure (67). Prophylactic acyclovir may be used after exposure, especially if the window for VariZIG has passed, though data are limited to a few healthy children only (American Academy of Pediatrics Red Book 2006). Patients who develop infection, either primary or secondary, should receive treatment with intravenous acyclovir (68, 69). Oral acyclovir has limited bioavailability in children, so should not be the first option in immunocompromised children.

BK Virus Infection

The BK virus (BKV) was first isolated from the urine of a renal transplant recipient in the 1970s (70). However, this virus did not represent a significant complication of kidney transplantation until the late 1990s (6, 71). Though BKV is a polyoma virus, it shares some characteristics of the herpesviruses: (1) infecting most immunocompetent people during childhood; and (2) establishing a prolonged latency. Unlike the herpesviruses, the BK virus does not establish in the reticuloendothelial cells but prefers the uroepithelium. This propensity for the uroepithelium is responsible for the clinical manifestations: hemorrhagic cystitis in bone marrow transplant recipients and allograft nephropathy in kidney transplant recipients. The incidence of BKVAN in pediatric renal transplantation appears to be the same as in adult kidney transplant recipients at 3–8% (7, 72). Risk factors from adult kidney transplant data include the intensity of immunosuppression (73, 74), recent treatment for acute rejection (75) and placement of a ureteral stent (76), though the data implicating specific immunosuppressive agents is conflicting. In a recent multicenter NAPRTCS special study, use of antibody induction and zero mismatch kidney allografts were the only two risk factors for BKVAN in multivariate analysis (7).

BKV infection and BKV disease are two separate entities. Serial PCR surveillance has shown that urine PCRs turn positive earlier and much more often than peripheral blood PCR. Currently the diagnosis of BKVAN depends on demonstration of the virus in blood or kidney tissue (either by PCR or immunostaining) and the presence of nephropathy (raised serum creatinine or tissue inflammation). Urine positivity without the other features represents infection without disease, as discussed in the recent

guidelines for study monitoring by the American Society of Transplantation (77). Generally viruria is not associated with renal dysfunction (78).

BKVAN represents a diagnostic challenge because the condition may resemble acute rejection. Symptoms are often minimal or absent. Serum creatinine elevations are found on clinical laboratory monitoring. Since the treatment of acute rejection (intensifying immunosuppression) is the opposite of the treatment of BKVAN (reduction in immunosuppression), making the correct diagnosis is critical.

Simple BK viremia, without nephropathy, may not need treatment or may be manageable by reduction in immunosuppression. Like the CMV and EBV infections, reduction of immunosuppression is usually the first step in the treatment of full-fledged BKVAN (71, 79, 80). However, by the time BKVAN is diagnosed, the serum creatinine is significantly raised and subsequent graft survival is worse. Thus, two different approaches are advocated, much as with EBV disease: pre-emptive monitoring and therapy; or simultaneous anti-viral therapy while maintaining some immunosuppression (79). There are virtually no randomized controlled trials to test any of these strategies head to head for most of the viral infections. Anti-viral therapy against BK virus is more complicated than for CMV or EBV, since acyclovir, ganciclovir nor their analogues have any activity against BK virus. Cidofovir is one anti-viral drug that has been tried with some success (81, 82). Higher doses of cidofovir can be very nephrotoxic. Probenecid combination with the higher dose cidofovir or intermediate dose cidofovir ameliorates the nephrotoxicity (83). Some centers switch mycophenolate mofetil to leflunomide (84, 85). This agent is unique in possessing both anti-viral and immunosuppressive properties.

There is no vaccine against BK virus. A preventive strategy that has been suggested is serial urine/blood BK PCR monitoring and pre-emptive reduction in immunosuppression.

Pneumocystis

Infections with *pneumocystis carinii* (now renamed *pneumocystis jiroveci*) have fortunately become rarer with the widespread use of cotrimoxazole prophylaxis in the immediate post-transplant period. The diagnosis is established by demonstration of pneumocystis in lung secretions obtained from bronchoalveolar lavage or in tissue from lung (86). Gomori stain or toluidine blue staining will demonstrate the cysts and Giemsa staining will identify the sporozoites. CMV infection is the major differential diagnosis. Many children may have dual infection, in which CMV infection predisposed to superadded pneumocystis pneumonia (PCP) infection. The antimicrobial agents cotrimoxazole and pentamidine form the mainstay of treatment. Cotrimoxazole may be given either orally or intravenously and is less toxic, whereas pentamidine is only available as a parenteral preparation and has more side effects. Chemoprophylaxis with three times per week oral cotrimoxazole (5 mg/kg trimethoprim component/dose) reduced the incidence of PCP disease from 3.7 to 0% (87). This prophylaxis is now recommended in all transplant recipients during the periods of high risk, typically the first six to twelve months post-transplant. Some centers also advocate its use after anti-rejection therapy, particularly with anti-T cell antibodies. Some centers suggest a lower dose given daily at bedtime (88).

Parasitic

Reports of parasitic infections in pediatric kidney recipients are few. *Strongyloides stercoralis* is an intestinal nematode with worldwide distribution, endemic in tropical/sub-tropical regions, and infects tens of millions of people. The southeast states have the highest incidence within the United States (89). Similar to viruses, *S. stercoralis* may initially remain in the human intestinal tract without symptoms, and then disseminate with the introduction of immunosuppressive medication post-transplant (89). In addition strongyloidiasis transmission has been reported through the allograft kidney in an adult recipient (90). Among calcineuirn inhibitors, cyclosporine (but not tacrolimus) has effects against *S. stercoralis* and may reduce the risk for disseminated strongyloidiasis (91, 92). Active infection manifests with cutaneous, gastrointestinal and pulmonary symptoms as well as eosinophilia (93). Fever, hypotension, and central nervous system symptoms suggest dissemination (93). In uncomplicated infections, diagnosis is made by detection of larvae in stool, although 25% of infected patients may have negative stool examinations (94). In disseminated disease, larvae may be found in stool, sputum, bronchoalveolar lavage fluid, peritoneal and pleural fluid (89, 95). Serologic testing using ELISA may also be of value, although may be falsely negative in immunocompromised hosts (95). Ivermectin has replaced thiabendazole as the treatment of choice for *S. stercoralis,* with albendazole as an alternative (96).

Other parasitic infections that have been transmitted by the renal allograft include Chagas' disease (97) and post-transplant malaria (98). Chagas' disease (caused by

Trypanosoma cruzi) is found only in the southern United States, Mexico and Central and South America. The manifestations of Chagas' disease classically include megaesophagus, megacolon, and cardiac disease, although CNS involvement has been reported in kidney transplant recipients (97). The diagnosis is serological and treatment typically consists of benznidazole or nifurtimox. Post transplant malaria can be frequent in high-endemic areas, so suspicion clinically should based on local region or travel to such a region (98). Screening recipients and donors for these and other parasitic infections may be worthwhile, based on the presence of risk factors including residence in or travel to an endemic area.

Fungal Infections

In general, serious invasive fungal infections such as aspergillosis are less common in pediatric kidney transplant recipients than thoracic organ recipients. Two studies reported a retrospective incidence of 4–10% overall (including milder candidial infections) in adult kidney transplant recipients (20, 99). In studies restricted to the intensive care unit, the incidence is higher at 16.5% (100). Candida is the most common organism affecting kidney transplant recipients, either as oral thrush, vaginitis, nail infection, UTI, or rarely as systemic fungemia (101). The diagnosis of thrush is made by clinical examination or demonstration of hyphae on a smear. Candidial UTI is diagnosed by urine culture. Treatment for topical candida is by topical nystatin or clotrimazole. Prophylactic measures include nystatin liquid or clotrimazole lozenges. True invasive fungal disease, though rare, increases the risk of mortality substantially (100) and needs systemic treatment with drugs such as amphotericin. Among pediatric recipients, hospitalization for fungal infection represented 0.2–2.7% of all infection-related hospitalization in the NAPRTCS registry, but was associated with a 1.64-fold higher risk for graft loss (102).

Cardiovascular Complications

Cardiovascular disease (CVD) is a major obstacle to improving long-term outcomes after transplantation. In pediatric kidney transplant recipients, death due to CVD is uncommon. However, many of the cardiovascular risk factors are already present in pediatric transplant recipients and if not addressed will likely lead to CVD in later life. Changes in the intima-media thickness of the carotid arteries have been observed in pediatric kidney transplant recipients as young as 8 years of age. Although here has been a reduction in cardiovascular related mortality over the last several years in adult kidney transplant recipients, (103) the prevalence of CVD is still high and accounts for 40% of late mortality after adult kidney transplantation (104). In children, cardiopulmonary disease accounts for 15.4% of mortality after kidney transplantation (NAPRTCS 2007 Annual Report), which is dramatically higher than the incidence in otherwise healthy children.

Cardiovascular events in transplant recipients are the result of a combination of causes which may begin pre-transplant and before clinical findings are present. The prevalence of conventional atherogenic risk factors such as hypertension (HTN), diabetes, dyslipidemia, and obesity are much higher in the transplant population. Additional pre-kidney transplant risk factors include renal insufficiency and dialysis, hyperhomocysteinemia, chronic anemia and disorders of calcium and phosphorous metabolism. The accelerated atherosclerosis and coronary artery disease leading to CVD precipitates changes in the blood vessel walls. These alterations occur early in the course of chronic renal failure and are directly related to duration of chronic renal failure and particularly treatment with dialysis (105). Transplant-specific risk factors are primarily related to the exposure of immunosuppressant medications, which are discussed in Chapter 84.

Hypertension

The prevalence of HTN is very high, occurring in over 70% of adult kidney transplant recipients (106). Data from the 2007 Annual NAPRTCS Report indicates that in the immediate post-transplant period, 79% of live donor recipients and 85% of deceased donor recipients were receiving anti-hypertensive medications. At 5 years post-transplant, the rates decreased similarly, but were still significant for both groups, to 59 and 69% (NAPRTCS 2007 report). Other studies in children with kidney transplants have shown that anti-HTN drug use is a risk factor for earlier graft loss (107). In children, casual blood pressure and ambulatory blood pressure monitoring (ABPM) have been used to establish the prevalence of post-transplant HTN (108). Usually, a higher prevalence of HTN has been observed when using ABPM criteria. Giordano and Calzolari found HTN was present in 43–50% of patients by casual measurements (109, 110). However, the prevalence rose to 62–75% when using ABPM. ABPM is now accepted as the method of choice for evaluating HTN in adult and pediatric patients.

Left ventricular hypertrophy (LVH), an early marker of hypertensive cardiomyopathy, is present in 56–82% of

children post-transplant. One study (111) observed a correlation between left ventricular mass index (LVMI) with the mean 24-hour systolic blood pressure. A prospective study by Mitsnefes et al. studied 23 children with echocardiogram while on dialysis and at least 6 months after transplant (112). The prevalence of LVH was similar, occurring in 52% during dialysis and 56% after transplant. However, in 61% of patients, LVMI decreased post-transplant indicating that patients with good blood pressure control had regression of LVH. A recent study by Silverstein et al. reported a lower prevalence of abnormal echocardiography changes (19%) when compared with the above studies (113), suggesting that the lower rates of LVH may reflect a growing awareness of the potential risks for CVD in pediatric kidney transplant patients.

Treatment should include non-pharmacologic interventions, which include weight reduction, dietary sodium restriction and exercise. However, simultaneous pharmacologic treatment should be considered. There are no randomized controlled trials of anti-hypertensive medications in children and all classes of anti-hypertensives have been used after transplantation. The best medication choice will depend on the presence of drug interactions and coexisting conditions such as proteinuria, diabetes and heart disease.

The calcium channel blockers are commonly used as first line therapy. Calcium channel blockers have been shown to counteract the vasoconstrictive effects of CNIs (114) and when used with angiotensin converting enzyme inhibitors (ACEi) have an added antiproteinuric effect (115). The non-dihydropyridine classes of calcium channel blockers interfere with the cytochrome P450 system and CNI dosage reduction is required. A retrospective study of adult transplant patients found that calcium channel blockers were associated with an increased risk of ischemic heart disease (116). However, this increased risk was not observed in a prospective randomized controlled trial in adult hypertensive patients (117). In children, the relationship of ischemic heart disease and calcium channel blockers has not been studied, but calcium channel blockers have been used in adolescent patients after myocardial infarction (118).

Beta blockers may be used as initial agents as well, particularly if there is a preexisting cardiovascular disease. However, they may contribute to dyslipidemia and insulin resistance. The ACEi and ARBs have antiproteinuric and cardioprotective effects. They are not widely used post-transplant because they may decrease renal blood flow and glomerular filtration rate in patients treated concomitantly with a CNI. Still, in adult transplant recipients, ACE and ARBs were found to be generally effective in controlling blood pressure and were not associated with a rise in serum creatinine concentrations (119). Diuretics are useful in patients with sodium and fluid excess especially if allograft function is reduced. However, diuretics may contribute to dyslipidemia and insulin resistance.

Adjustment of immunosuppressive medications can be a reasonable alternative when hypertension is associated to such therapy. Corticosteroid reduction and withdrawal studies in adults and children have reported short-term efficacy and safety with beneficial impact on post-transplant blood pressure profiles (120–122). However, the potential side effects of these medications must be weighed against the risks of acute rejection and chronic graft dysfunction when minimizing or eliminating corticosteroids.

The choice of CNI appears to affect the prevalence of hypertension, with tacrolimus (TAC) seemingly having a more favorable cardiovascular profile over cyclosporine A (CsA) (123, 124), though prospective studies haven not substantiated this obervation (125). Also, since mycophenolate mofetil (MMF) and mTOR inhibitors are devoid of intrinsic nephrotoxicity and hypertensive effects attention has been directed towards avoiding or withdrawing CNI by using these newer agents. However, mTOR inhibitors are associated with dyslipidemia, so the reduction in a cardiovascular risk factor is replaced by increased incidence of another. The combination of MMF/mTOR is associated with diarrhea and overall poor tolerability which may lead to suboptimal compliance. Overall, the risks and benefits of CNI-free regimens have to be considered since studies have indicated variable results and long term follow up data are lacking.

Transplant Renal Artery Stenosis

Transplant renal artery stenosis is a relatively less common cause of post-transplant hypertension and accounts to 1–5% of cases (126). It usually appears between 3 months and 2 years after transplantation, but it can present at any time (127). Renal artery stenosis arising early and involving the surgical anastomosis is likely the result of trauma to the vessel during harvesting (128). If a stenosis occurs several years post-transplant it may arise as a result of atherosclerosis. The mechanism of hypertension is volume-mediated with suppression of the renin-angiotensin system, similarly to what occurs in the Goldblatt one kidney model. However, the transplanted kidney is denervated and does not elicit sympathetic activation.

Doppler ultrasound is an excellent screening test (87–94% sensitivity and 86–100% specificity), which can asses the severity of the renal artery stenosis by evaluating

the peak systolic velocity at the stenotic site and the resistive index in the post-stenotic arteries (126, 129). In small children, this modality may be challenging due to patient movement. CT and MR angiography can provide superior images of the vasculature and may be used if sonography is inconclusive (130). However, both are more costly and nephrotoxicity can occur even with the newer non-ionic contrast media used with CT. Arteriography provides the definitive diagnosis of renal artery stenosis (131). Carbon dioxide can be used as a negative contrast agent in order to avoid nephrotoxicity (132). For hemodynamically significant stenoses or uncontrolled hypertension, percutaneous transluminal angioplasty (PTA) is the treatment of choice. Surgery is indicated for restenosis or lesions that cannot be treated with PTA.

Post-Transplant Diabetes Mellitus

Abnormalities in glucose homeostasis may develop for the first time after transplant and occur as a result of insulin resistance, increased insulin metabolism or diminished insulin secretion. The incidence of post-transplant diabetes mellitus (PTDM) in adult transplant patients is high. Kasiske et al. determined from a retrospective large scale analysis of the USRDS database that the cumulative incidence of PTDM was 9.1, 16 and 24% at 3, 12 and 36 months post-transplant (133). The development of PTDM in the pediatric population is less common and data are limited. A retrospective analysis of the NAPRTCS indicated an incidence of PTDM at 2.6% with the majority of the cases occurring in the first 6 months post-transplant (134). African-American children were at higher risk, and contrary to adults, Hispanics were at lower risk to develop PTDM.

Epidemiologic studies have established that diabetes promotes cardiovascular disease and other long-term complications (135) in the general population and it is believed that these same risks apply to transplant recipients with PTDM. Further rationale for treatment is highlighted in a study by Cosio et al. in which PTDM correlated with an unfavorable cardiovascular profile and reduced patient survival in adult patients (136). A similar adverse effect on patient survival was also seen for patients with pre-existing diabetes and PTDM by other investigators (137). The importance of optimizing glycemic control is underscored by recent data indicating that treatment aimed at achieving near normoglycemia decreased the risk of any cardiovascular disease event by 42% (138). The impact of PTDM on survival has not been evaluated in the pediatric transplant population.

Management of PTDM requires a multidisciplinary approach which includes collaborations with nephrology, endocrinology and dietetics services. Lifestyle changes primarily involve calorie reduction by decreasing carbohydrate intake, particularly in obese individuals. The dietary changes should address and meet the individual's nutritional needs while taking into account personal and cultural preferences. Promoting weight loss through exercise is very effective in improving insulin sensitivity and physical activity should be an important component of the overall management.

Early steroid withdrawal reduces the incidence of PTDM (139). Steroid-free immunosuppression was also associated with a lower incidence of PTDM (0.4% vs. 5.4%) (140). However, acute rejection episodes are higher in the steroid-free (31.5%) and steroid withdrawal groups (26.1%) when compared to a steroid control group (14.7%), as illustrated in the FREEDOM Study (141). Of the CNI, TAC seems to have a higher diabetogenic potential (133, 142), though again not borne out in more recent pediatric studies (125). However, converting patients from CsA to TAC frequently results in a reduction of other cardiovascular risk factors including hypertension and dyslipidemia. Therefore, the choice of immunosuppression will involve a balance between the risk for rejection and the potential for complications like PTDM.

There is little published information regarding the pharmacological management of PTDM. The 2003 international consensus guidelines recommend a step-wise approach to the management of patients with PTDM, similar to that followed for patients with type 2 diabetes (143). If adequate blood glucose is not achieved with lifestyle modifications, pharmachologic monotherapy is recommended. The agent should be chosen based on safety and patient-specific factors (age, level of kidney function, level of glycemic control). Oral agent therapy can be used when hyperglycemia is not severe. However, for most oral agents, the safety and efficacy has not been established for use in children.

The sulfonylureas directly stimulate insulin secretion and should be used with caution in the setting of decreased allograft function. However, the newer generation of sulfonylureas are almost entirely metabolized by the liver (144). The meglitinides also stimulate insulin secretion and are short acting. They can be safely used in renal transplant recipients since they are hepatically metabolized (145). Thiazolidinediones promote peripheral insulin sensitivity and have a reduced risk of hypoglycemia compared to other oral agents. The biguanides decrease hepatic glucose production, but they are largely cleared by renal tubular secretion and should be avoided in renal

transplant recipients with allograft dysfunction (143). Glucagon-like peptide-1 receptor agonists are approved for clinical use in the United States. Its use in kidney transplant is limited since there are few data concerning drug interactions and dose adjustments may be needed since it has significant effects on gastric emptying (146).

Insulin is the safest agent in the pediatric transplant population. Insulin does not interact with immunosuppressive medications. However, insulin metabolism occurs in the kidney, and dosage adjustments may be needed with changes in allograft function (147). The modern insulin regimens use a long acting agent to provide basal glycemic control and rapid-acting insulin analogues to be given at the time of meals (148).

Dyslipidemia

Dyslipidemias play a role in the development of atherosclerosis and cardiovascular disease and are becoming a greater concern for children. Earlier studies have indicated that fatty streaks in vessels are present in individuals as young as 10 years (149). More recent data have confirmed that atherosclerotic lesions were present in more than half of the right coronary arteries of adolescent individuals (150). In children, the extent of atherosclerotic lesions correlated significantly with serum total cholesterol concentrations, serum LDL cholesterol concentrations and serum triglyceride concentrations (151). In transplant patients, many factors such as genetic predilection, age, gender, medical conditions (such as proteinuria), and medications influence the prevalence of dyslipidemia.

Dyslipidemia is common after kidney transplantation. Total cholesterol has been found to be elevated in 51–66% of patients and LDL cholesterol in up to 84% of patients in several studies (152). More recent studies indicated hypercholesterolemia in 20% of patients and elevated triglycerides in 45–50% of patients (153, 154). In this report, about one third of the study population was receiving corticosteroid free immunosuppression. The prevalence of dyslipidemia post-transplant is thought to decrease over time and may reflect changes in immunosuppression. At 10 years post-transplant, Milliner et al. found that the prevalence of hypercholesterolemia decreased from 70.4 to 35% and hypertriglyceridemia from 46.3–15% (155). However, the mean lipid values were not different over the course of 20 years and the decreased prevalence was the result of increasing normal values with advancing age.

The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (K/DOQI) Work Group created guidelines for the management of dyslipidemias in kidney transplant patients (152). Since there are few studies of dyslipidemia in children, the Work Group considered that adolescents be included in the guidelines and that children before the onset of puberty be managed according to the National Cholesterol Expert Panel on Children (NCEP-C) (156). The K/DOQI guidelines recommend that a fasting lipid profile (total cholesterol, LDL, HDL and triglycerides) be measured during the first 6 months post-transplant, at 1 year after transplant and annually thereafter. A lipid profile should also be measured if 2–3 months after stopping or starting an immunosuppressive medication known to affect lipid levels. If dyslipidemia is detected, evaluation and if indicated modification/treatment of secondary causes (medications, nephrotic syndrome, hypothyroidism, diabetes) is recommended.

For adolescents with adequate nutrition, treatment with therapeutic lifestyle changes (TLC) should be considered if fasting triglycerides are $\geq$500 mg/dL. These include changes in diet, physical activity and habits. Pharmacological therapy with fibrates or nicotinic acid may be warranted if isolated hypertriglyceridemia persists after 6 months. However, the safety and efficacy of these medications has not been well established in adolescents so their routine use is not recommended. For LDL levels between 130–159 mg/dL, TLC should be the first line therapy. Treatment with a statin should be considered if after TLC the LDL level remains above 130 mg/dL, if the initial LDL is above 160 mg/dL or if there is hypertriglyceridemia and an elevated non-HDL cholesterol level. If the desired target is not achieved, a bile acid sequestrant can be considered as long as triglyceride levels allow its use.

The NCEP-C guidelines are recommended for the management of dyslipidemia in younger children. However, they are not specific for kidney transplant recipients or patients with chronic kidney disease. The NCEP-C recommends diet therapy as the primary approach for treating dyslipidemia in children. If LDL levels are >130 mg/dL, a Step 1 AHA diet is prescribed, followed in 3 months by a Step 2 AHA diet if the target levels are not achieved. Pharmacological therapy is recommended if LDL level is >160 mg/dL and there is a positive family history of CVD or if two or more CVD risk factors are present in the child.

Obesity

The prevalence of obesity in children has increased over the last decade and is a major concern for health care

providers. Obesity is a recognized cardiovascular risk factor and its impact post-transplant is significant. Weight gain after transplant occurs as a result of multiple factors including, increased appetite from corticosteroids and elimination of uremia, lack of physical activity, genetic predisposition, age, gender and race (157).

Data collected from the United Network of Organ Sharing (UNOS) described the prevalence of overweight and obesity in individuals undergoing kidney transplantation (158). Between 1987 and 2001, the number of patients classified as overweight (BMI 25–29.9 kg/m^2) increased by 32% and those obese (BMI $\geq$30 kg/m^2) rose 116%. Furthermore, nearly 60% of current kidney transplant recipients are classified as overweight or obese. In children, a similar trend has been observed. Data from the NAPRTCS indicated that 9.7% of children were obese at the time of transplantation (159). Of importance, is that the percentage of children with obesity increased from 8.2% between 1987 through 1995 to 12.4% between 1996 to 2002. After transplant, the incidence of overweight and obesity doubles (160).

The negative role of obesity on outcome of renal transplant has been documented by several investigators. Meier-Kriesche et al. found that an elevated BMI was associated with increased mortality, particularly for those with a BMI; >36 kg/m^2. However, this association held true even for patients with mild obesity (BMI >25 kg/m^2) (161, 162). In a NAPRTCS report, obese children ages 6–12 years had a higher risk for death than non-obese transplant recipients (159). In this age group, death from cardiopulmonary disease was more common in obese recipients (27%) as compared with non-obese individuals (17%).

The treatment of obesity generally involves TLC (dietary modifications and exercise) and requires a multidisciplinary approach. Corticosteroid avoidance has been associated with a lower incidence of obesity by some investigators (163). However, other studies indicated that body weight increase following transplantation occurs even in the absence of corticosteroids (164). In children, the combination of TLC and pharmacological therapy to achieve weight loss has not been studied. In adults, limited data on chronic kidney disease patients have shown a positive impact on weight loss (165).

Musculoskeletal Complications

The skeletal complications of transplantation include impairment of linear growth, loss of bone mass, fractures and avascular necrosis. Factors such as chronic illness and renal osteodystrophy have a negative impact on bone before transplantation, so that at the time of transplant, a significant preexisting metabolic bone disease may exist. During childhood, skeletal growth and the development of peak bone mass occur, both of which are affected by renal failure and subsequent post-transplant medications.

Growth

Growth retardation in children with chronic kidney disease occur as a result of inadequate caloric intake, metabolic acidosis, renal osteodystrophy and abnormalities of the growth hormone (GH)- insulin-like-growth factor (IGF) hormonal axis (166). GH and IGF levels are normal, but the IGF bioactivity is low as a result of excess IGF binding proteins. At the time of transplantation, the mean height deficit for children is 1.79 standard deviations (SD) below the appropriate age and adjusted height level (NAPRTCS 2007 Annual Report). In 1987, the mean height deficit was 2.4 SD, so height pre-transplant has improved, but not by much. It was initially anticipated that a successful renal transplant would improve growth velocity and induce catch-up growth. Data from the NAPRTCS indicates that improvement in height delta *z*-score does occur in children younger than 6 years of age at the time of transplant. However, recipients between 6 and 12 years of age exhibited linear growth that is consistent with that of the normal population, and adolescents fail to show improvement in height delta *z*-score (NAPRTCS 2007 Annual report).

The major risk factors affecting linear growth post-transplant are age at the time of transplant, level of allograft function and corticosteroid therapy. The reason why younger children experience a greater improvement in linear growth post-transplant is not very clear. However, children with renal insufficiency undergoing transplantation have a diminished pubertal growth spurt. In prepubertal children, the height velocity increases in both boys and girls after transplant, surpassing the values in normal children. The onset of pubertal growth spurt is delayed, but the duration is shortened by 1.6 years compared to normal children, reducing the total pubertal height gain by 20% (167). Mean adult height is lower than mid-parental height by 5.2 cm in boys and 13 cm in girls. However, for children transplanted after the onset of puberty, mean adult height is below mid-parental height by 12.6 cm in both boys and girls (167).

Tejani et al. showed that renal allograft dysfunction has an adverse effect on growth. The investigators found that each increase in serum creatinine concentration of

1 mg/dL was associated with -0.17 decrease in the Z-score (168). A more recent, retrospective analysis of the NAPRCTS by Fine et al. confirmed that allograft dysfunction over time as well as well as renal function at baseline (pre-transplant) are important predictors of linear growth (169).

A firm relationship exists between corticosteroid exposure and growth retardations following transplantation. Corticosteroids suppress linear growth through various mechanisms which include abnormalities in GH, gonadotrophin secretion as well as increased IGFBP-3 levels (170). Also, corticosteroids reduce bone formation leading to bone turnover cycles in which bone resorption exceeds bone formation (171).

Maximizing growth and minimizing renal osteodystrophy pre-transplant is an initial first step in addressing growth retardation. The above data indicate that performing a kidney transplant at a younger age could have a positive effect on growth. Furthermore, minimizing time on dialysis before transplantation or pre-emptive transplantation may also confer benefits. Recombinant human growth hormone (rhGH) has been effectively used to improve linear growth. Fine et al. performed a randomized, multi-center, double-blind, placebo-controlled study that confirmed the efficacy and safety of rhGH in children with chronic renal failure (172). A subsequent review of the NAPRTCS database indicated that side effects from rhGH were infrequent and similar in treated and untreated children (173). However, a recent report evaluated the association between PTLD and rhGH use pre and post-transplant (174). The investigators indicated that the use of rhGH during CRI pre-dialysis was associated with a higher risk for PTLD post-transplant (odds ratio 1.88, 95% CI = 1.00–3.55). Hence, further research and careful monitoring is indicated to confirm these findings. Recombinant growth hormone has been effectively used post-transplant to improve linear growth (172). Further trials confirmed the efficacy of rhGH and indicated a significant increase in growth velocity in the treated group compared with the untreated group without adverse effects on graft function (175, 176).

Reducing or avoiding corticosteroid treatment will have a beneficial impact on linear growth. Alternate day corticosteroid dosing has revealed improvement in height delta *z*-score when compared to daily therapy (177). Furthermore, steroid avoidance protocols have demonstrated improvement in linear growth (122).

Post-transplant allograft function may also predict growth, so strategies aimed at maximizing allograft function may be another form of therapy towards improving growth. Of the CNIs, TAC seems to be associated with a more favorable kidney function when compared to CsA. An analysis of the NAPRTCS indicated that patients treated with TAC/MMF/corticosteroids had a significantly higher GFR at 1 and 2 years post-transplant when compared to those treated with CsA/MMF/corticosteroids (123).

Bone Loss and Fracture Risk

Chronic kidney disease and transplantation have significant effects on bone and future fracture risk, since peak bone mass is achieved following sustained childhood growth. Using dual energy X-ray absorptiometry (DEXA), several investigators have identified a decreased bone mineral density (BMD) during the first few months and in some cases years after transplant (178, 179). However, in these studies, osteopenia may have been overestimated, since measurements of BMD were compared to age-matched controls, and children undergoing transplant are usually shorter. When adjusting for height, post-transplant osteoporosis is not a prominent finding in pediatric renal transplant recipients (180, 181). However, height-adjusted DEXA yields inappropriately elevated *z*-scores since older transplant subjects may be compared to younger and skeletally less mature subjects. Alternative methods such as quantitative computed tomography and magnetic resonance imaging may allow for more accurate measurements of bone density following renal transplant but have other limitations.

Across all age groups, a United States Renal Data System (USRDS) analysis indicated that the relative risk of hip fracture is four times greater in dialysis patients independent of age and gender (182). Children post-kidney transplant have approximately a 2% risk of suffering a fracture. Corticosteroid use post-transplant is a major factor contributing to bone disease. Corticosteroids decrease intestinal calcium absorption, increase renal calcium excretion, decrease osteoblast number and activity, increase PTH concentration and increase the number of remodeling sites (183). Predominantly, corticosteroids result in a reduction in bone formation early post-transplant. The CNIs have been also associated with osteopenia mostly by increasing bone resorption (184). However, the mTOR inhibitors do not appear to have significant clinical effects on bone. Other factors that play a role in bone disease include inactivity, poor allograft function, hyperparathyroidism and the primary disease (cystinosis and oxalosis).

Adequate nutrition post-transplant is essential for bone health and calcium should be supplemented if necessary. Exercise is beneficial for bone strength and should be encouraged. Vitamin D stores should be adequate and the administration of calcium and active vitamin D may

be necessary if secondary hyperparathyroidism persists. Studies in adult transplant recipients have confirmed the value of bisphosphonates in the treatement of osteopenia and osteoporosis, but data on children are scarce (185, 186). In one study of pediatric kidney transplant recipients, bisphosphonate therapy improved BMD and was safe, tolerable and easy to administer (187). Clearly, more data are needed, particularly since the long term effects of these therapies in children are uncertain. Reduction of corticosteroids may be considered in selected subjects while assessing the potential risk of rejection and to overall outcome.

Avascular Necrosis

Avascular necrosis (AN) is a reported complication of kidney transplantation and occurs in about 1% of patients at 3–4 years post-transplant (183). Reports with longer follow up have indicated higher prevalence rates, but overall the incidence of AN is decreasing as a result of better control of renal osteodystrophy prior to transplant and lower corticosteroid dosing after transplant (188).

AN most commonly affects the epiphysis of long bones such as the femur, but may affect the humerus, talus or hand. Occasionally, individuals may be asymptomatic and have abnormal radiographic studies. However, most patients with abnormalities on MRI or bone scan have symptoms and will eventually require surgical intervention.

Conservative management with restriction of activity is used in early cases. Core decompression, were the internal bone pressure is relieved is used in selected cases. If the previous treatments fail or if pain persists, then total hip replacement is performed.

Gastrointestinal Complications

Gastrointestinal complaints in renal transplant recipients are common and all levels of the gastrointestinal tract may be involved (189). Most gastrointestinal complications including oral lesions, esophagitis, gastritis/peptic ulcer, diarrhea and abdominal pain, are either due to infections or medication toxicity.

Oral and Esophageal Lesions

Apthous ulcers may be single or multiple and can involve all areas of the oral mucosa with the exception of the hard palate, gingival and vermillion border. They are typically caused by viral infections such as CMV and HSV. HSV may also cause gingivostomatisis. Oral ulcers have also been seen in a significant number of patients receiving steroid free immunosuppression with a combination of SRL/MMF (190). Therapy consists in reducing immunosuppresion or discontinuing the offending drug, topical steroids and antiviral therapy. Histological examination of the lesions may be required if there is no response to therapy.

Oral candidiasis usually occurs early post-transplant, when immunosuppression is more intense, or after aggressive antibiotic therapy. *Candida albicans* and *Candida tropicalis* are the most common organisms involved. Nystatin or clotrimazole are effectively used for prophylaxis during the first months post-transplant and after treatment of a rejection episode.

Esophagitis may be secondary to chemical irritation of the esophageal mucosa from medications or may occur with infections such as Candida, CMV and HSV. Most cases present during periods of most intense immunosuppression, like after the treatment of acute rejection. The most common complaint is dyspepsia, but dysphagia, odynophagia and cough may also occur. Endoscopic examination is required to confirm the diagnosis. Therapy will depend on the etiology. Generally, mild cases of candidial esophagitis will respond to nystatin, but some cases require oral triazoles or amphotericin B (191). The treatment of herpetic esophagitis includes acyclovir or ganciclovir if there is a concomitant CMV infection.

Gastrointestinal Disorders

Gastric discomfort with nausea, vomiting, diarrhea and abdominal pain are the most common side effect of several medications. In particular MMF and AZA can lead to nausea and gastric discomfort (192). Gastroduodenal lesions are frequently associated with *Helicobacter pylori* infection in pediatric renal transplant candidates (193). However, the incidence of *H. pylori* colonization post-transplant in children is not known, but occurs in about one third of adult recipients (194). Overall, the incidence of peptic ulcer is low with the common use of prophylactic H_2-receptor antagonists and proton pump inhibitors.

Since many transplant medications that are toxic to the gastrointestinal tract are used in combination, it is difficult to determine relative contribution of each medication. However, dosage adjustment of the offending agent is usually required to improve the gastrointestinal symptoms. Dyspepsia can be minimized by the concomitant use of H_2-receptor antagonists or proton pump inhibitors. Therapy targeted towards *H. Pylori* should be provided in cases where the gastroduodenal lesions are associated with this infection.

Lymphoproliferative disorders are one of the most common post-transplant malignancies and may involve the gastrointestinal tract. Gastrointestinal PTLD symptoms may be mild and non-specific initially, but can lead to bleeding, obstruction and perforation (191). PTLD is discussed with greater detail earlier in this chapter.

Hematologic Complications

The most common abnormalities in the hematological parameters after kidney transplant are anemia and leucopenia. However, all three cell lines of the hematopoietic system may be affected in various ways.

Anemia

The incidence of anemia after kidney transplant is high and has been reported to occur at rates of 30–80% at 1 and 5 years post-transplant (195, 196). Anemia tends to occur early after transplant, followed by recovery and a later increased risk in the longer term (197).

Several factors play a role in the development of anemia in the early post-transplant period. Blood loss from the surgical procedure coupled with cessation of erythropoietin administration and use of certain medications leading to bone marrow suppression will all contribute. OKT3 and anti-thymocyte globulin are induction immunosuppressive agents that cause anemia by direct bone marrow suppression. Of the medications used for maintenance immunosuppression, AZA and MMF also suppress the bone marrow by direct nucleic acid synthesis inhibition (198). Anemia has also been correlated to the use of mycophenolate sodium (199). Very rarely, TAC has been associated with anemia secondary to hemolytic uremic syndrome (200). The mTOR inhibitors may cause anemia by blocking signal transduction of the cytokines needed for maturation and proliferation of bone marrow cells and may interfere with iron homeostasis (201).

Many other medications given in the post-transplant period have also been associated with anemia including, the sulfa containing drugs, dapsone and the anti-viral agents acyclovir/ganciclovir/valacyclovir/valganciclovir. The renin-angiotensin-aldosterone system is also an important regulator of erythropoiesis. Hence, ACE inhibitors and ARB have a hematocrit lowering effect (202).

Hemolytic anemia may be seen in cases of post-transplant HUS. However, hemolytic anemia can occur as a result of an anti-rhesus immune response, when a rhesus-positive recipient receives a transplant, with transfer of plasma cells, from a rhesus-negative female donor who developed anti-rhesus antibodies during a pregnancy (203).

Other factors such as poor nutritional intake may lead to iron and vitamin deficiencies and nutritional anemia. Viral infections, particularly parvovirus B19, can cause pure red cell aplasia and chronic anemia by entering the cells via the P blood antigen receptor and destroying them (204).

A few months post-transplant, in the absence of iron deficiency and with good allograft function, the anemia tends to improve or resolve. Over time, as GFR gradually decreases, anemia once again develops with a greater prevalence when compared to chronic kidney disease subjects with similar creatinine clearance.

Prevention of anemia through adequate nutrition and erythropoietin use is important prior to transplant. Treatment of anemia post-transplant depends on the identified etiology. If the anemia is medication induced, changes in dosing or drug discontinuation should be considered. Generally, use of erythropoietin in the early post-transplant period is not effective in increasing the hematocrit since there is a systemic inflammatory response and already a large increase in erythropoietin production.

Leukopenia and Thrombocytopenia

There are two main causes of leukopenia after transplant: medication toxicity and infection. Post-transplant infections are discussed earlier in this chapter.

The polyclonal antilymphocyte antibodies are associated with leukopenia in the early post-transplant period. In a randomized, double-blinded comparison of the horse and rabbit antithymocyte globulin formulations, leukopenia was more common in those patients treated with the rabbit product (205). Thrombocytopenia also occurs commonly and usually transient by may require dose adjustments. Hematologic disturbances are less frequent with the use of IL-2R antagonists.

Of the maintenance immunosuppresants, MMF and AZA cause bone marrow suppression and the risk of leukopenia is dose related (206). Using MMF at a dose of 600 mg/m^2 twice daily, leukopenia was more common in children less than 6 years of age. Subjects receiving AZA at low doses may develop leucopenia if they have a genetic defect of thiopurine methyltransferase, one of the catabolic routes for the drug. A similar effect is seen if allopurinol is given concomitantly since it inactivates xanthine–oxidase which is important in the catabolism of the active metabolites of AZA (207).

Patients receiving maintenance therapy with SRL at 5 mg per day had a higher incidence of leukopenia and

thrombocytopenia when compared to those receiving 2 mg per day. The incidence of leukopenia is also higher among patients receiving valganciclovir from day one after transplantation, especially at higher doses (208). Leukopenia and thrombocytopenia may also be seen with trimethoprim-sulfa and the administration of parenteral pentamidine.

Neurologic Complications

Post-transplant neurological complications may occur *de novo* or be the result of a previous condition that developed during the period of kidney failure and dialysis. The neurological complications can be compiled into five different categories: (1) Medication toxicities, (2) Cerebrovascular accident, (3) Peripheral neuropathy, (4) Infections, (5) Malignancy. A review on these complications has been presented by Ponticelli and Campise (209).

Neurotoxicity from CNI can be subtle, causing tremor, paresthesias and headache. Symptoms may be severe causing hallucinations, seizures, cerebral edema, demyelination and a posterior leukoencephalopathy. Often, the symptoms of CNI neurotoxicity are reversible with dose reduction or medication withdrawal. In some cases, the complications may be permanent or even fatal.

Corticosteroids administered at high doses may cause emotional lability, while prolonged corticosteroid use is associated with brain atrophy. Both, corticosteroids and growth hormone are associated with the development of pseudotumor cerebri. OKT3 administration can lead to a cytokine release syndrome manifested by aseptic meningitis and in severe cases encephalopathy with cerebral edema.

Cerebrovascular accidents in children following transplant are rare when compared to adults and data on its prevalence are lacking. Peripheral neuropathy can occur as a result of compression of the femoral nerve, when the allograft is transplanted in the iliac fossa, and compression of the lumbosacral plexus with dual kidney transplantation (210). The symptoms usually develop within the first 48 hours after the procedure and may persist for several months.

Listeria monocytogenes, *Cryptococcus neoformans* and *Aspergillus fumigatus* account for most of the central nervous system infections post-transplant (211).

Other System Complications

Pulmonary complications of renal transplantation in children are mostly confined to drug-induced pulmonary edema or infections such as pneumocystis. Skin pathology relates mainly to higher risk for squamous cell and basal cell carcinomas, which can be minimized by sunblock protection. Viruses can lead to cutaneous warts. Cyclosporine A leads to hirsuitism with a leonine facies, especially in conjunction with corticosteroids. Conversely, tacrolimus has been associated with alopecia. Hyperuricemia and gout can occur post-renal transplant, with cyclosporine increasing the risk (212). Hyperuricemia is also prevalent in obesity and hypertension. While hyperuricemia may remain silent, gout symptoms are similar to those in the general population. Allopuinol is generally more effective than uricosuric therapy because its antihyperuricemic effect is independent of renal function.

Pediatric Nephrology Around The World

78 Overview

Isidro B. Salusky · Matthias Brandis · Ira Greifer

The subspecialty of pediatric nephrology has developed within the last 40–50 years. Sophisticated diagnostic and therapeutic standards have been achieved for the care of children with congenital or acquired renal diseases. The technical equipment developed for adults has been adapted to children.

A series of reports titled "Pediatric Nephrology around the World" was first presented in the second edition of this book to draw attention to the clinical spectrum of renal disease in children across various parts of the world, with particular emphasis on differences from the disease patterns seen in Europe and North America (1). Cameron (2), reviewing the historical, social, and geographic factors affecting the pattern of renal disease in children, used the challenging phrase "pediatric nephrology in an unjust world" (describing the fact that most of contemporary pediatric nephrology arose from and was relevant to only a minority of the world's children). The situation has hardly changed since that time. The only difference is that more and more pediatricians around the world have become interested in this field of patient care and clinical research (3, 4). There has recently been an impressive change in the growth of competence and knowledge in the care of children with renal problems through the establishment of different training centers around the world. The establishment of the International Pediatric Nephrology Association (IPNA) in 1971 has played a critical role in promoting knowledge and communication among those interested in pediatric kidney disease, and improving care and treatment of diseases of the kidney and urinary tract in children throughout the world. The different regional societies from around the world, such as the African Society of Pediatric Nephrology, American Society of Pediatric Nephrology, Asian Pediatric Nephrology Association, Australia/New Zealand Society of Pediatric Nephrology, European Society of Pediatric Nephrology, Japanese Society of Pediatric Nephrology, and Latin America Society of Pediatric Nephrology, are represented within the IPNA Council. More recently, the Pan-Arabic Pediatric Nephrology Association, including almost 150 members from different countries, has been incorporated within the Asian Pediatric Nephrology Association. In separate chapters, the different regional societies are represented to provide an overview of the specific geographic, ethnic, and socioeconomic aspects of pediatric renal disease around the world. The productive and efficient organization within each of them has led to rising numbers of participants engaging in regional activities (see Appendix) and to an increase in growth and expertise in the care of children with kidney disease. These activities are all signs of increasing attention to and concern for the care of children with kidney disease. Furthermore, there is a growing interest among young pediatricians in the field of nephrology prompted by the sincere desire to provide better care for children with renal disease and to achieve this goal by pursuing better and more adequate training.

Children have a right to treatments and to resources that are as sophisticated and as well developed as those available to adults; yet in countries in transition to new demographic and economic patterns, children still have difficulty competing with adults for limited resources, as the contributions from Latin America (see Chapter 83) and Africa (see Chapter 82) in "Pediatric Nephrology around the World" clearly show. Many of the old problems remain. The proper management of renal disease in children is expensive, particularly the provision of renal replacement therapy for end-stage renal disease. Poor countries are doubly deprived: not only is their gross national product low, but also a smaller fraction of it is made available for health care (5). Nevertheless, a concern about renal disease in children has developed in all regional societies and working groups. The newest regional society of IPNA, the African Society of Pediatric Nephrology, is slowly making progress in its efforts to reach pediatricians with interest in this subspecialty within the African continent, despite the presence of a wide variety of cultural and economic barriers. The extreme geographical distances as well as differences in social, economic, and political structures between South African and North African countries, and the quite different structures within Central Africa, define only some of the ongoing challenges, even independently of the difficult economic questions. Notwithstanding these obvious issues, there is an increasing awareness of the need and a willingness to deliver better care for children. Different incidences and epidemiologic characteristics of diseases in

© Springer-Verlag Berlin Heidelberg 2009

developing and tropical countries from those in developed countries reinforce the interest of the field of nephrology in the pathogenesis and outcome of similar diseases in various parts of the world. One can conclude that, in spite of the economic differences and difficult political situations, the pediatric nephrology societies have an increasing professional commitment to studying the clinical and pathologic differences in kidney diseases in various parts of the world (6–10).

To address the prevailing problem of economic limitations to the equitable distribution of high-quality diagnostic and therapeutic services in all parts of the world, the community of pediatric nephrologists has a growing conviction that they must help to increase the knowledge of basic care for children with renal disease (11). Sophisticated research and introduction of efficacious technical procedures are not on the main worldwide agenda and thus for the near future are not achievable. Therefore, in order to fulfill its mission, IPNA has established teaching courses around the world in which a group of pediatric nephrologists with a wide range of knowledge attend the courses in coordination with a local group of physicians to facilitate education and the future establishment and recognition of pediatric nephrology in those specific countries. In addition, IPNA has initiated a fellowship training program with the primary objective of providing basic clinical training in pediatric nephrology. The goal of the program is to disseminate knowledge of pediatric nephrology to different regions of the world. For example, in India, this fellowship program is currently the only source of funding for the training of future pediatric nephrologists.

The modern structure of the specialty can be traced to the formation of the International Study of Kidney Disease in Children in the mid to late 1960s (12, 13). Such multicenter studies are of value not only for the power that they bring to the resolution of a clinical problem, such as nephrotic syndrome, by virtue of the large numbers of cases available for study, but also for the professional relationships, understanding, and standards that they foster. This study was naturally followed by the formation of several regional pediatric nephrology societies and IPNA, which held its first congress in Paris in 1971. The European Society for Pediatric Nephrology (see Chapter 79) and the American Society of Pediatric Nephrology (see Chapter 81) have the longest tradition. Both are associated with registries that maintain databases of children on renal replacement programs: the registry of the European Dialysis and Transplantation Association and European Renal Association, and the registry of the North American Pediatric Renal Transplant Cooperative Study (14, 15), which in particular developed the best resource of actual data not only on transplantation but on other renal diseases as well. There is no other registry in the world of comparable quality.

The European Society for Pediatric Nephrology is addressing the issues that arise from the harmonization of standards within the European Community, with particular focus on the adaptation of countries in Eastern Europe. Special training courses have been implemented within the Eastern European community in Russia, Rumania, and the Baltic states. This program has been received with enthusiasm by local pediatric nephrologists.

The American Society of Pediatric Nephrology has taken the lead in defining the requirements for pediatric nephrologists in developed countries (16). The Japanese Society for Pediatric Nephrology is the oldest and largest of the regional pediatric nephrology societies (See Chapter 80). A unique feature of pediatric nephrology in Japan is that children are screened annually by urinalysis in a nationwide program (17). The screening has provided invaluable epidemiologic information and the opportunity to set up clinical trials involving children in the early stages of disease.

Asia accounts for 57% of the world's population and an even higher proportion of its children because of that region's demographic characteristics. The Asian Pediatric Nephrology Association has developed into a well-recognized society worldwide, with annual conferences that are well attended. Educational courses have been introduced to expand competence into areas of limited financial and technical resources. Because of this achievement, generous space has been allocated to this region in this section of the book (see Chapter 85). The Asian Pediatric Nephrology Association and the Latin American Association of Pediatric Nephrology (see Chapter 83) are principally concerned with the problems of delivering health care to children with renal disease in countries in transition to new demographic and economic structures. The Australia/New Zealand Pediatric Nephrology Association is a well-organized, smaller regional society, which organized the IPNA Congress in 2004 (see Chapter 84). The youngest society, the African Society of Pediatric Nephrology, had its first congress in Cairo, Egypt, in 2000, and its second congress in 2002 in Nigeria, with participants primarily from Nigeria but also from South Africa and Egypt (see Chapter 82).

IPNA provides a coordinating framework for the regional associations. The global association has nearly 1,600 members in 89 countries around the world. It promotes the specialty of pediatric nephrology by holding a triennial international congress, supporting other meetings and teaching ventures, and publishing the journal *Pediatric*

Nephrology. In the Appendix of this Overview, we highlight select research- and training-related activities that serve to clarify the IPNA mission. We encourage everyone with an interest in pediatric nephrology to visit the IPNA web site for additional information on current activities and opportunities in this field, association membership, and links to affiliate organizations worldwide:

http://ipna-online.org/

Appendix

The International Pediatric Nephrology Association (IPNA) is a nonprofit organization with the overarching goal of promoting knowledge and communication among those interested in pediatric kidney disease so as to improve care and treatment of diseases of the kidney and urinary tract in children throughout the world. To accomplish this mission, IPNA pursues the following activities in support of research and training in pediatric nephrology:

A. Publication of the monthly scientific journal *Pediatric Nephrology*, which serves both scientific and educational goals.
B. International triennial congress: All members from the basic science, clinical science, and clinical care disciplines convene to disseminate knowledge of pediatric nephrology. The last IPNA Congress took place in Budapest, Hungary, in 2007, with more than 1,100 participants from 83 countries. The next congress will take place in New York City in 2010; and thereafter in Shanghai, China, in 2013.
C. Regional medical meetings and training facilities: The goal is to disseminate information on pediatric nephrology to all areas around the world, with an emphasis on underserved regions. Examples of IPNA-supported regional meetings include the Latin American Association of Pediatric Nephrology, in Buenos Aires, Argentina, 2008; European Society of Pediatric Nephrology, in Lyon France, 2008; and Asian Pediatric Nephrology Association, in Bangkok, Thailand, 2008. In addition, IPNA has supported the annual International Seminars in Pediatric Nephrology organized by the University of Miami, including travel fellowship grants.
D. Clinical and basic science workshops: The goal is to stimulate interest in and disseminate information on new and innovative research, and provide a forum to encourage young physicians in pediatric nephrology research. For example, IPNA supports the triennial workshops on growth retardation in children with chronic kidney disease, which typically draw 150–200 participants from around the world. The next symposium will be held in Oviedo, Spain, in 2009. Summaries of the scientific presentations are published in the journal *Pediatric Nephrology*. In 2012, this meeting will take place in San Diego, California.
E. Satellite symposia: Immediately prior to each IPNA triennial international congress, there is a satellite symposium called the "developmental meeting." Prior to the 2007 congress in Budapest, the developmental meeting was held in Pecs, Hungary. The next developmental symposium will be held at the Mohonk Mountain Resort, in New York State, in August 2010, just prior to the triennial congress in New York City. The goal of the developmental meetings is to provide a comprehensive state-of-the-art exploration of issues relevant to the developing kidney and urinary tract. IPNA assembles an interdisciplinary group of scientists and clinicians, approximately 120 individuals in total, to exchange information and perspectives on new knowledge and techniques relating to the biology, physiology, and genetics of the developing kidney in health and in disease. It is important to emphasize that congenital renal anomalies are the major cause of renal failure during childhood, and that the morbidity and mortality resulting from malformation of the kidney and urinary tract are considerable. The symposium is designed to foster dynamic exchange and in-depth discussion.
F. Instructional courses: In response to specific areas of instructional need around the world, IPNA supports the development and implementation of teaching courses, in different countries around the world, for example, Morocco, Japan, Venezuela, Brazil, and Bolivia, with others in Eastern Europe. During these teaching courses, usually conducted over a period of 3–5-days, a group of 3–5 pediatric nephrologists with a wide range of knowledge in nephrology as well as outstanding teaching credentials participate in the program as well as in case discussions with the local physicians. IPNA selects specific areas of the world, mainly underserved locales, based on need. The courses are organized in collaboration with a local group of physicians, who are responsible for all of the logistics and guest accommodations. In some areas of the world, such as Eastern Europe, these courses have provided the basis for the establishment and recognition of pediatric nephrology in the country or region.
G. Fellowship training program: The primary objective of this program is to provide basic clinical training in pediatric nephrology for pediatricians with limited or no training in this specialty and who work far from a

pediatric nephrology training center. The goal is to disseminate knowledge of pediatric nephrology to different regions of the world. The period of training is a minimum of 6 months and a maximum of 12 months, with the 12 months' duration encouraged. Afterward, each trainee is expected to disseminate the new knowledge at his or her home institution. The program supports a limited number of fellows for advanced training in pediatric nephrology or research training. IPNA provides approximately US $4,000–$ 8,500 per 6 months' period, depending on the cost of living at the training site, as determined by the director of the proposed training center. IPNA also provides funds for travelling expenses to and from the training site. The trainees are asked to prepare a detailed report of their training activities upon completion of the fellowship, and to report on their activities at 1- and 5-year intervals thereafter. Each trainee receives a certificate of completion from IPNA, a copy of the current edition of the textbook *Pediatric Nephrology*, and funds for travel expenses to attend one national or regional meeting in pediatric nephrology. For example at the Asian Pediatric Nephrology meeting held in Bangkok, Thailand, in August 2008, a total of 17 fellows from different countries (e.g., India, Pakistan, and Vietnam) participated in the proceedings. As evident from their contributions and discussions, the fellowship program had significant impact in advancing pediatric nephrology in their respective countries.

The fellowship program is advertised in the journal *Pediatric Nephrology*, with application deadlines in April and October of each year. Applicants are requested to send via e-mail the following documents to the IPNA secretary: (1) a curriculum vitae, (2) a letter of recommendation from the program director of the home institution, and (3) a letter of acceptance from the director of the proposed training center. A fellowship committee reviews all completed applications and recommends acceptance or rejection to the IPNA Secretary General, who renders the final decision. Since different regions of the world have differing needs for expertise in pediatric nephrology, the regional assistant secretaries and the senior nephrologists of the region determine the minimum requirements for a training center. As of August 2008, a total of 50 fellows have graduated, from 29 different countries: Albania, Bangladesh, Belarus, Benin, Bolivia, Brazil, Chile, China, Columbia, Egypt, El Salvador, India, Iraq, Jordan, Kazakhstan, Kenya, Lithuania, Mongolia, Myanmar, Nepal, Nicaragua, Nigeria, Pakistan, Philippines, RD Congo, Slovenia, Sudan, Uganda, and Vietnam.

79 Europe

Christer Holmberg

During the last decade, pediatric nephrology and treatment of renal diseases in Europe has greatly improved such that more countries can help their child population. This is partly due to the European Union (EU) and end of the cold war. Thus, traveling and cooperation over national borders is easier and the European Academy of Pediatrics (EAP, former C.E.S.P.) has had a major impact on standardizing specialization programs. In Pediatric Nephrology, the EAP has developed the syllabus for the training of Pediatric Nephrologists in Europe (1). Still there are differences in availability of care and treatment of end-stage renal disease between different countries depending on their economical, social, and political stability. However, these borders and differences diminish. In the more developed countries children with renal diseases are mostly taken care of by well trained pediatric nephrologists, in some countries by pediatricians with a special interest in renal diseases or by internist nephrologists. Less often, children with severe kidney disease are treated by general practitioners.

ESPN

The European Society for Pediatric Nephrology (ESPN), founded in 1967, is the representative body for pediatric nephrology in Europe and represents Europe on the council of the International Society for Pediatric Nephrology (IPNA). The Council of ESPN has representatives from the different parts of Europe, including the former east European countries and Russia. Thus, the interests of all children with renal diseases in Europe at large are taken into account in the policy of ESPN. The membership of ESPN is growing and currently includes 490 members from 42 countries. Most of the ESPN members were previously from France, Germany, UK, and the more developed central and south European countries, whereas countries like Turkey and Poland have become very active during the last decade. Their increased membership has stimulated increased research into all areas of Pediatric Nephrology, and is reflected in the number of publications emanating from these countries in journals like Pediatric Nephrology and other international publications. Turkey hosted the annual meeting of ESPN in 2005 and will serve as the host for the annual meeting of the International Pediatric Transplant Society in 2009.

Training

The annual meetings of ESPN are the major teaching occasions and they attract participants from the USA, Africa, and Asia with an increasing number of active participants. In 2008, there were over 700 attendees from more than 60 countries at the meeting held in Lyon, France. At ESPN meetings, the latest research in pediatric nephrology is presented in addition to clinical seminars and state-of-the-art lectures. Additionally, the national societies for pediatric nephrology organize annual teaching courses and many centers have annual seminars for European researchers in renal diseases. The presidents/representatives of the National societies for pediatric nephrology in Europe at large meet annually at the ESPN annual meeting and discuss common problems in health care for renal patients, the syllabus, requirements and demands for training centers, and registry matters. Thus, cooperation and harmonization has improved in Europe. To help establish pediatric nephrology in the economically weaker countries in Europe at large, ESPN has sponsored a training program where it helps local centers to organize training courses with ESPN- sponsored and local speakers. Such courses have recently been held in many parts of Russia, (Moscow, St. Petersburg, Orenburg, and Vladivostok), in the Baltic countries and in Belarus. Some of these teaching courses have been in collaboration with IPNA, ISN, and ERA/EDTA. The last such teaching course was in Morocco in 2008 and was organized together with IPNA, the African Society for Pediatric Nephrology, and the Moroccan Society for Pediatric Nephrology, who were responsible for the practical arrangements.

© Springer-Verlag Berlin Heidelberg 2009

Centers

In 2007, ESPN conducted a survey among 48 institutions from 11 European countries of which 13 were from the UK, 9 from Italy, and 7 from Germany. Of these 72% were in university hospitals 62% were in divisions of pediatric nephrology, and 23% were in divisions of pediatrics. Most centers had 3–6 pediatric nephrologists and 4–9 nurses. Only four centers had over nine nephrologists and over ten nurses. More than 70% had trainees both in pediatrics and in pediatric nephrology, 17% had trainees in internal medicine nephrology. The mean numbers of hospital beds were 15. Most centers had performed 40–120 renal biopsies during the last 36 months and only 7 had over 200. Sixty-seven percent of the centers performed renal transplantations but ninety-seven percent performed chronic and acute dialysis, including neonates. This gives some idea about the size of most centers within Europe but cannot be generalized for the whole continent.

Registry

The European Dialysis and Transplantation Society (EDTA) has, since 1965, gathered data on renal replacement therapy (RRT) in children and adults with end-stage renal failure (2). The pediatric registry collapsed in the late 1990s, but has been reinstituted during the last years with a half-time ESPN employee. The ERA-EDTA Registry office moved in June 2000 to the Academic Medical Centre in Amsterdam (3). Today, 26 national registries are reporting data to the registry and results from the first 12 were published in 2004 (4). The incidence of RRT increased from 7.1 per million age related population (pmarp) in 1980–1984 to 10 pmarp thereafter. The biggest increase was in the 0–4 year age group where Finland with many infants with hereditary nephropathies showed an incidence of 15.5 pmarp in 1995–2000. In the youngest patients, hypoplastic and dysplastic kidneys and hereditary diseases were most common and glomerulonephritis increased with age. HD was the first choice of treatment in the French speaking countries and Spain whereas PD was common in Finland, The Netherlands, and Scotland. Preemptive transplantation was most common in Norway. Long term survival probability was over 85% during dialysis and 95% after transplantation. The mean incidence of children under 15 years in Europe with a population of 728 million in 2005 was 19.8% of the general population in 2006, the highest being in Turkey (29%) and lowest in Spain (13%). The mean prevalence of renal replacement therapy in 2006 pmarp in the now 26 reporting countries was 23.2, but varied from 5.2 in Serbia to about 40 in most countries and 88.5 in Finland. Infants are still the group with the lowest prevalence of treatment 10.8, except for some countries with a larger number of infants with rare congenital renal diseases presenting at birth like Finland with the Finnish type of congenital nephrosis (prevalence 66.3 pmarp in the 0–4 year old) (5).

Development

Today, there are many excellent training and teaching centers in Europe. Urinary tract infections and their long term effects are today well handled in most European countries and do not constitute a major risk in the long term for the child. Renal stones and infection related glomerulopathies are still a major problem in the poorer countries. Renal biopsies are done more commonly in Russia and the east European countries are improving diagnostics and classification of renal diseases. Many congenital diseases have been characterized during the last decades and their genes isolated. This has helped us to understand the pathophysiology of these diseases and helped us to select those patients who are helped by specific therapeutic regimens. Idiopathic nephrotic syndrome, especially FSGS still constitutes a major challenge. Dialysis, nutrition, and ESRD care has been developed and guidelines on PD, HD, nutrition, growth, and osteodystrophy have been produced (http://espn.uwcm.ac.uk). Renal transplantation has today a patient survival of over 95% and a graft survival of over 90% in every age group in the short term with most of the modern immunosuppressive protocols. Still, the youngest patients should be handled by the most specialized centers.

Cooperation with other transplant centers that perform liver transplantation has become more important with the finding that some inherited diseases with primary liver defects also cause renal pathology. Further, certain diseases with liver and kidney involvement can be cured by combined liver and kidney transplantation. Examples are atypical HUS with factor H mutations, oxalosis, and autosomal recessive polycystic kidney with congenital hepatic fibrosis. As more and more younger children are treated with dialysis and renal transplantation and subsequently with life-long, stronger immunosuppression, the side effects and the long-term effects on the child and his or her quality of life becomes more important. Short-term survival is similar with many protocols, but those regimens with the least long-term side effects and with good graft survival should be chosen. Multi-center studies

are now being planned in Europe, and data will be entered in the newly re-established and functioning registry.

80 Japan

Takashi Igarashi

Most of the pediatric nephrologists in Japan are academic pediatricians who work in academic pediatric departments in University Hospitals, pediatric nephrology departments in Children's Hospitals, and less commonly, in pediatric departments of general hospitals or private clinics. They advocate for pediatric patients with renal diseases and their families.

The Japanese Society for Pediatric Nephrology

The Japanese Society for Pediatric Nephrology (JSPN; http://www.jspn.jp/) was founded in 1967 to promote optimal care for children with renal disease and to spread advances in the clinical practice and basic science of pediatric nephrology to all the members and pediatricians in Japan. JSPN aims to develop guidelines for the diagnosis and treatment for renal diseases. They are (1) the revised guidelines for the diagnosis and treatment of hemolytic uremic syndrome (HUS) following enteropathogenic *Escherichia coli* gastrointestinal infection published in 2000, (2) treatment guidelines for idiopathic nephrotic syndrome in children published in 2006, and (3) treatment guideline for IgA nephropathy (IgAN) in children published in 2007. They are accessible on the JSPN homepage (1).

JSPN was composed of 1,100 active members as of April 2009. JSPN organizes an annual national scientific meeting where pediatric nephrologists and other health care providers learn new advancements in the care and knowledge of pediatric nephrology and related fields. In 2007, the 43rd annual scientific meeting of JSPN was held in Yokohama. Over 800 pediatric nephrologists attended the meeting. The 44th annual scientific meeting took place in Fukuoka in 2008.

JSPN promotes clinical and basic scientific research in pediatric nephrology and supports training of pediatric nephrologists. JSPN and the members surveyed the methods and complications of percutaneous renal biopsy in Japanese children. They demonstrated that the overall complication rate of renal biopsy was 5.8%; gross hematuria was 2.7% and perirenal hematoma was 0.9%. They also showed that the use of the automated biopsy needle with ultrasound guidance provided a safe method for pediatric renal biopsies in Japan (2). JSPN and the members surveyed the clinical features and outcome of antineutrophil cytoplasmic autoantibody (ANCA)-associated glomerulonephritis in Japanese children. They identified that 87% of the patients were female and median age of onset was 12 years old. 84% of the patients achieved remission with immunosuppressive treatment and serum ANCA titers correlated with the response to the treatment and disease activity (3).

JSPN has satellite study groups in eight local areas in Japan. They have scientific and clinical study meetings once or twice a year. JSPN financially and educationally supports their activity. JSPN started a special educational program for trainees and young pediatric nephrologists in 2008. JSPN collaborates with other related pediatric nephrology societies including: International Pediatric Nephrology Association (IPNA), Asian Society for Pediatric Nephrology (ASPN), Japanese Society of Nephrology (JSN), Association of Pediatric Renal Failure, Study Group of Pediatric Peritoneal Dialysis, Study Group of Chinese Herbs for Pediatric Kidney Diseases, Association of Developmental Nephrology and Association of Pediatric Hypertension. JSPN also belongs to Science Council of Japan.

JSPN has supported a Japanese-Korean Pediatric Nephrology Seminar once a year since 2003. The Fifth Seminar was held in Sakai-city in 2007. The Sixth Korean-Japanese Pediatric Nephrology Seminar was held during the period of JSPN meeting in Fukuoka in 2008.

Chronic kidney disease (CKD) is common and affects about 10% of the adult population worldwide. CKD is known to increase the risk of heart disease, vascular disease, stroke and early mortality (4). JSPN has had an active collaboration with the Japan Association of CKD Initiative (JCKDI) since 2006 (http://j-ckdi.jp/index.html).

JSPN publishes two issues of Journal of JSPN (in Japanese) a year. JSPN developed guidelines for handling potential conflicts of interest for authors in 2007.

School Urine Screening Rogram

Urinalysis is one of the most effective methods to achieve early detection of glomerulonephritis (5). Urinary screening programs for elementary and junior high school children started nationwide in Japan in 1974. School children bring their first-voided early morning urine to school, where they are collected and sent to centralized examination centers. Proteinuria and hematuria are detected by a simple dipstick method. When a urine test results in positive (proteinuria; +/− 15 mg/dL or more, hematuria: + or more), children with a positive finding received a second urine test in the same manner. The goal of the program is to identify school children with chronic glomerulonephritis and permit early therapeutic intervention.

Table 80-1 summarizes the result of the first urine examination by the school urinary screening program for school children in Tokyo in 2005. This revealed that elementary school children aged between 6 and 11 years had proteinuria, hematuria, or both abnormalities at prevalence of 0.86, 1.73 and 0.11%, respectively. The corresponding prevalence was 2.33, 3.99 and 0.41%, respectively in junior high school children aged between 12 and 14, and 1.88, 2.30 and 0.36%, respectively in high school children aged between 15 and 17. The second urine examination for school children with positive urine findings at the first urine examination revealed that the prevalence of proteinuria, hematuria, or both abnormalities was 0.19, 0.67, and 0,05% respectively in elementary school children, 0.62, 0.87, and 0.15% respectively in junior high school children, and 0.43, 0.40, and 0.12% respectively in high school children (*Table 80-2*). This school urine screening program revealed that chronic glomerunephritis was found in 61.2% of the children with hematuria and proteinuria, 1.0% of the children with isolated proteinuria and 2.2% of the children with isolated hematuria.

Now, urinary screening programs are routine for school children in Korea, Taiwan, Philippine and Singapore (6–9). However, this urinary screening program has not been adapted by other countries, as its cost-effectiveness is not proven. We could not disclose the distinct evidence that the urine screening program for school children reduced the incidence of childhood or adult end stage renal failure (ESRF). However, the urine screening program for school children permits early detection of children with severe IgAN or membranoproliferatiove glomerulonephritis (MPGN) and permits controlled therapeutic trials to ameliorate disease development.

IgAN is the most common form of chronic glomerulonephritis in the world (10). IgAN has been generally regarded as a benign form of glomerulonephritis, with approximately 25–30% of patients reaching ESRF after 10 years (11). However, IgAN is the leading cause of ESRF due to chronic glomerulonephritis in Japan; 40% of all ESRF is due to IgAN (12). Despite its prevalence and clinical importance, there is no consensus for the treatment of IgAN. Recently, immunosuppressive therapies showed a dramatic impact on renal survival. A controlled study demonstrated that combination treatment with prednisolone, azathiopurine, heparin-warfarin, and dipyridamole for two years early in the course of the IgAN reduced the severity of immunologic renal injury and prevented any increase in the percentage of sclerosed glomeruli in patients with severe IgAN that showed diffuse mesangial proliferation (13). However, treatment with prednisolone alone for 2 years increased the percentage of sclerosed glomeruli in patients with severe IgAN (14). Despite aggressive and prolonged steroid therapy for

Table 80-1

Result of the first urine examination in Tokyo in 2005

Age (year)	Sex	Number of children	Number of children with hematuria	Number of children with proteinuria	Number of children with hematuira and proteinuria
6–11	Male	113,874	572	1,142	62
	Female	111,322	1,362	2,754	186
			(0.86%)	(1.73%)	(0.11%)
12–14	Male	46,412	1,154	600	94
	Female	48,562	1,061	3,194	300
			(2.33%)	(3.99%)	(0.41%)
15–17	Male	5,262	112	43	13
	Female	12,634	225	369	51
			(1.88%)	(2.30%)	(0.36%)

Table 80-2

Result of the second urine examination in Tokyo in 2005

Age (year)	Percentage of children with hematuria	Percentage of children with proteinuria	Percentage of children with hematuira and proteinuria
6–11	0.19	0.67	0.05
12–14	0.62	0.87	0.15
15–17	0.43	0.40	0.12

Table 80-3

Disease categories that cause end stage renal failure

Year	Number of patients	Disease categories	
		Glomerulonephritis (%)	Congenital renal disease (%)
1968–1979	720	81.6	7.5
1980–1986	710	60.6	14.7
1998–2003	347	29.1	50.4

36 months, approximately 15% of patients experienced a recurrence of proliferative IgAN within 3 years (15). This treatment intervention, if adopted widely, might reduce the incidence of ESRF caused by IgAN in Japan. IgAN is an immune complex glomerulonephritis that involves intense deposition of dimeric and polymeric forms of IgA1 within the mesangium of the glomerulus. Although the true pathogenesis of IgAN is unknown, aberrant glycosylation of IgA or IgG anti-IgA1 autoantibodies may have a role in the development of the disease (16). Those mechanisms and natural history of IgAN suggest a genetic background in the pathogenesis of IgAN. Therefore, lifelong effective therapy that is acceptable for the patients must be established.

The outcome of MPGN is poor in children, irrespective of type, with 50% losing renal function by 10 years and 90% by 20 years in western countries (17). The presentation of MPGN generally falls into three categories; nephrotic syndrome, acute nephritic syndrome, or asymptomatic hematuria and proteinuria discovered by chance. However, this is not the case in Japan, where many children have been identified by urine screening at an early stage of the disease. Only one patient progressed into ESRF after the treatment among 41 patients for 9-year follow-up period (18). Superior outcome of the patients with MPGN in Japan may be the result of earlier detection by urine screening and treatment.

In addition, a population-based study suggested that the number of new patients with ESRF due to glomerulonephritis reduced after the school urinary screening program started (19). This study also showed that the proportion of Japanese patients with glomerulonephritis who are less than 45 years old decreased after urinary screening program for school children started. A similar decrease has not been observed in Western Europe and the U.S., where screening is uncommon. The reasons for these differences in data are not clear, but may suggest benefits of mass urinary screening. Dent disease is an X-linked renal tubular disorder characterized by low molecular weight proteinuria, hypercalciuria, nephrocalcinosis/nephrolithiasis and progressive renal failure. Almost all of the Japanese patients with Dent disease are school children. They are identified by the school urine screening program every year. Dent disease is due to the mutations in *CLCN5* or *OCRL1*. Molecular abnormalities were dentified in more than 60 families with Dent disease in Japan (20, 21).

JSN and JSPN collaboratively developed guidelines for patients with hematuria in 2006 (22). The Study Group for Early Detection, Diagnosis, and Treatment of Intractable Renal Diseases developed a school urine screening guidebook for doctors and health care providers in 2007 (23).

National Registry Data for Children Undergoing Peritoneal Dialysis

The Japanese Pediatric Peritoneal Dialysis Study Group has produced an annual report on pediatric end stage renal disease (ESRD) since 1987. This provides valuable information on epidemiology, types of therapy, complications, morbidity, and mortality in pediatric patients with ESRF (24). The 1998 report was published in English in 2002 (25). 105 patients with ESRD were introduced to renal replacement therapy (RRT) in Japan in 1998. The prevalence rate of the ESRD patients already on the treatment was 22 per million of age-related population (pmarp) aged between 0 and 19 years in 1998. The annual incidence of RRT was 3 pmarp in Japan. In contrast, it was 10 in U.S.A and 7 in Europe (26, 27). Older patients had a higher prevalence rate than younger ones. The major disease categories causing ESRF were congenital renal diseases and glomerulonephritis. The proportion of congenital renal diseases is increasing (*Table 80-3*). Renal hypoplasia/dysplasia and focal segmental glomerulosclerosis are predominant causes of ESRD during childhood.

Peritoneal dialysis (PD) was used more frequently than hemodialysis under the age of 15. 46.9% of the patients with ESRD received renal transplantation and 96% of the transplanted kidneys were from living kidney donors. 83.1% were transplanted by the third dialysis year. The transplant rate in 1998 was 10 per 100 dialysis patient-years in patients aged between 0 and 19 years. Preemptive renal transplantation for children with ESRD started in Japan in 1998 and by 2005 totaled 46 children. Preemptive renal transplantation comprised 15.4% of all renal transplantation for children with ESRD in 2005. The death rate was 15.6 per 1,000 dialysis patient year in patients with ESRD aged between 0 and 19 years. This rate was similar to that in Europe (27). The leading causes of death were cardiovascular diseases and infections.

The ultimate goal of the care provided to children with ESRD is the achievement of normal growth and development. Attention to dialysis adequacy, control of osteodystrophy, nutrition, and correction of anemia is mandatory to attain this goal (28, 29). The Association of Pediatric Renal Failure and Study Group of Pediatric Peritoneal Dialysis developed guidelines for PD in children in 2004, in collaboration with JSPN.

81 Pediatric Nephrology Around the World – North America

Lisa M. Satlin · Sharon P. Andreoli · H. William Schnaper

Introduction

Pediatric nephrologists in North America care for children who have a wide variety of acute and chronic kidney diseases. Two registries provide insight into the current state of chronic kidney disease in pediatric patients: the North American Pediatric Renal Trials Cooperative Study (NAPRTCS), previously called the North American Pediatric Renal Transplant Cooperative Study; and the United States Renal Data System (USRDS), which produces an annual report on end stage renal disease that includes pediatric patients.

NAPTRCS was organized in 1987 (1). Scientific objectives included capturing information about current practice and identifying trends in immunosuppressive therapy, with an ultimate goal of improving the care of pediatric renal allograft recipients. In 1992, the registry was expanded to include pediatric dialysis patients and in 1994 it was further expanded to include pediatric patients with chronic kidney disease (CKD) (estimated GFR less than 75 ml/min/1.73 m^2 as calculated by the Schwartz formula). The goal is to register, follow and study the large majority of the children receiving dialysis and/or renal allografts and to determine the clinical course and natural history of patients with renal dysfunction as they progress to end stage renal disease. This voluntary collaborative effort has recorded data from over 16,000 patients in 130 pediatric renal centers in the United States, Canada, Mexico and Costa Rica.

In the three NAPTRCS registries, renal dysplasia with or without obstructive uropathy is the most common cause of CKD or the need for dialysis or a kidney transplant. Focal segmental glomerulosclerosis is a common acquired cause of CKD and is particularly prevalent in the pediatric dialysis population. The NAPTRCS data base also reports graft survival, morbidity, and the relationship that these end points have to patient characteristics such as race/ethnicity, sex and primary renal disease; and to transplant characteristics such as age at transplantation, donor source, immunosuppressive treatment, and HLA mismatches. Analogous patient and event characteristics are described in the CKD and dialysis populations.

Since 1988, the USRDS report has provided valuable information on the demographics, epidemiology, modes of therapy, morbidity and mortality in patients with end stage renal disease. The 2007 USRDS Annual Report describes underutilization of growth hormone in pediatric CKD patients with growth failure, as well as overutilization of percutaneous catheters for hemodialysis access; since catheters are associated with infectious complications and increased morbidity this was noted as a major concern (2). Alarmingly, the 2007 USRDS reported that there has been no progress in the 5-year survival of pediatric end stage kidney disease patients. In fact, in some populations the likelihood of survival declined slightly between the 1991–1995 and 1996–2000 periods. Children with a transplant have the best chance of surviving 5 years at 0.93 while children who are maintained on hemodialysis or peritoneal dialysis have 5-year survival rates of 0.79 and 0.82, respectively (2). Detailed reports of USRDS data are published yearly.

Organization of North American Pediatric Nephrologists

North American pediatric nephrologists are affiliated with the International Pediatric Nephrology Association (IPNA) through the American Society of Pediatric Nephrology (ASPN). The ASPN presently has approximately 700 members. One-fifth of these are trainees and another 15% are emeritus members. The Society conducts an annual scientific meeting each May in association with the Pediatric Academic Societies meeting. Standing committees of the Society address such issues as policy, research, workforce needs, clinical matters, and education and training.

One of the major problems confronting pediatric nephrology in the United States is the limited number of pediatricians choosing to enter careers in pediatric nephrology. The median age of pediatric nephrologists who are certified by the American Board of Pediatrics® exceeds that of the next "oldest" subspecialty by approximately 2 years. In recent years, efforts to attract trainees into the

© Springer-Verlag Berlin Heidelberg 2009

field have yielded some success, with 40–50 new Fellows entering training each year. However, some of these candidates either do not complete their training or do not sit for the certifying examination. The causes of this attrition are myriad, and include lifestyle issues, debt incurred during the course of education and training, and the relatively lower salaries received by academic physicians compared with those in the private, general practice of pediatrics. It should be noted that the median age of pediatric nephrologists has not increased over the past few years, indicating that the situation has been stabilized and may be improving.

Another major concern is the relative lack of funding for research in pediatric nephrology in the United States, reflecting a trend in overall Federal funding for research over the past 7 years. Research funding in the U.S. is primarily dependent upon support from the National Institutes of Health and the National Science Foundation, which support mostly research programs proposed by individual investigators. Limitation of this funding in recent years has meant that many promising young academicians have struggled to establish or continue their careers. Alternative sources, such as charitable foundations and industry, have mitigated this problem to some extent, but the extent of available funds does not equal that previously derived from Government support for the academic biomedical research enterprise. One positive aspect of Federal funding is that the ASPN and other organizations have collaborated with the National Institute of Diabetes, Digestive and Kidney Diseases (NIDDK) to develop initiatives to support national collaborative studies of kidney disease in childhood. These are described in more detail below.

Public Policy

The ASPN has evolved into a proactive organization regarding public policy and legislative issues. The ASPN advocates for policies and programs that advance the interests of pediatric nephrologists, patients and their families. The Public Policy Committee (PPC) and the Washington representatives of the ASPN represent the interests of the ASPN, patients and their families before the U.S. Congress and federal agencies, in coalition with similar organizations.

In its public policy activities, the ASPN interacts extensively with other nephrology and pediatric organizations, with government agencies and with industry. Coalitions and caucuses have been formed to speak with a stronger voice to advocate for patient care, research, and other issues important to our members. Collaborators include the American Society of Nephrology (ASN), the Renal Physicians Association (RPA) and the National Kidney Foundation (NKF). As an example of promoting public policy and patient care issues, the ASPN, NKF, RPA, and ASN each submitted testimony to the U.S. Congress related to the safety concerns of Erythropoiesis Stimulating Agents (ESA) dosing in June 2007 following the warnings issued by the FDA for ESA. ASPN also joined with the RPA, American Association of Kidney Patients (AAKP), and the Renal Support Network (RSN) in submitting testimony to the FDA related to appropriate use and labeling of ESA and assuring that "black box" warnings are patient- and population specific. These joint efforts among the nephrology societies have been very successful in advocating for adult and pediatric patients with kidney disease.

ASPN, ASN, NKF, and RPA joined together to recognize World Kidney Day, 8 March 2007, with an editorial authored by the current president of each of the organizations, to disseminate the message that chronic kidney disease is common, harmful and treatable (3). ASPN joined the ASN and NKF in promoting World Kidney Day, 13 March 2008, with several representatives from each of the organizations visiting lawmakers and staff to discuss the growing epidemic of kidney disease and to advocate for expansion of NIH-funded kidney disease research and surveillance and prevention programs.

Political issues in Canada differ significantly from those in the United States. Health care in Canada is funded by the provinces, consistent with federally established, overriding principles involving universal access to health care. Given that the political/governmental systems are quite different, the role of public lobbying as a contributor to governmental decisions also is very different.

Research in Pediatric Kidney Disease in North America

A major mission of the ASPN is to promote clinical and basic science research activities in the pediatric nephrology community and to participate in the development of new strategies for encouraging and supporting research by pediatric nephrologists. In the late 1990s, the U.S. House of Representatives and the Senate encouraged the NIDDK to develop and implement plans to address the special research needs of children with kidney disease. A task force comprised of NIDDK and ASPN representatives who are experienced in basic, clinical and translational research analyzed the research needs in pediatric nephrology and produced a document ("Research Needs in Pediatric Kidney Disease, 2000 and Beyond") that has served as a blueprint for implementing several NIH-supported,

multicenter observational studies, clinical trials and registries related to pediatric nephrology.

Widespread participation in these studies is critical to their success, given the limited number of patients with a specific disease at any single center. Accordingly, the NIDDK has sought to expand support of investigator-initiated, multicenter clinical studies to systematically investigate the causes, early diagnoses, improved treatment and, where possible, prevention of kidney diseases endemic to the pediatric population. A successful mechanism that has evolved to support such research is that of the multicenter clinical cooperative agreement (U01). This cooperative agreement is characterized by substantial NIH programmatic involvement with the awardees in a partnership role. The UO1 consortia generally include Clinical Centers (CC), responsible for subject recruitment and development and implementation of a common protocol, and a Data Coordinating Center (DCC), which organizes the Clinical Centers, specifically focusing on the biostatistical analyses and data management aspects of the clinical trials. NIDDK encourages investigator-initiated research project applications for ancillary studies to these ongoing, Institute-supported clinical trials, epidemiological studies and disease databases.

The NIDDK has supported three pediatric multicenter studies in recent years, including the (1) Clinical Trial in Children and Young Adults with FSGS (FSGS-CT); (2) Prospective Study of Chronic Kidney Disease in Children (CKiD); and (3) Clinical Study of Vesicoureteral Reflux in Children (RIVUR). Preliminary findings from the observational studies over the next several years will likely inform the designs of clinical trials in pediatric kidney disease patients in the near future.

The *FSGS-CT* (http://fsgstrial.org) began as a Phase III, randomized clinical trial of therapy of biopsy-proven focal segmental glomerulosclerosis (FSGS) in children and young adults. This ongoing study, aimed at comparing the efficacy of treatment with cyclosporine (CsA) to treatment with mycophenolate mofetil (MMF) combined with oral pulse dexamethasone in patients with steroid-resistant FSGS, is being conducted at 65 participating sites in North America which are divided among three core networks with principal investigators, study coordinators, and a central DCC. Eligible patients are randomly assigned to one of the two active treatment arms. The target period for each therapeutic intervention is 12 months. Both study groups are also treated with either lisinopril or losartan for 18 months and low dose, alternate-day steroids for 6 months. The primary outcome to be measured is attainment of partial or complete remission of proteinuria and the main secondary outcome is the persistence of remission in patients who achieved a complete or partial remission after 12 months on therapy, 6 months following withdrawal of immunosuppressive agents. Patient enrollment began in November 2004 and ended in May 2008; the total randomized sample size is 138. To date, 17 ancillary studies have been approved, of which 11 have received NIH support. It is expected that the results of this study, the largest FSGS randomized trial ever to be performed, will establish a standard of therapy for steroid-resistant primary FSGS. Additional benefits of the trial are the establishment of an infrastructure for the study of FSGS, the creation of a national repository of biospecimens for investigations on the pathogenesis of FSGS and the role of histological subclassifications of FSGS in the response to therapies, and the evaluation of the efficacy of withdrawing immunosuppressive drugs while maintaining ACE inhibitors/ARBs. A logical extension of the trial is the initiation of a Pediatric Nephrology Clinical Trials Group to facilitate new investigations, innovations and faculty development in translational research.

The *CKiD* study (http://www.statepi.jhsph.edu/ckid/), begun in October 2003, is a prospective observational cohort study aimed at defining risk factors for chronic kidney disease (CKD) progression and the effects of CKD progression on cognition, behavior, cardiovascular risk factors and growth (4, 5). This study, being conducted at 44 participating sites in North America led by an East Coast and Midwest Clinical Coordinating Center, a Data Coordinating Center, and a Central Biochemistry Laboratory, has enrolled 574 children ranging in age from 1 to 16 years, all with moderately impaired renal function (GFR 30–90 ml/min/1.73 m^2); the enrollment period, which began in April 2005, ended in March 2008. The study protocol consists of annual study visits; as of May 2008, 548 baseline studies and 442 6-month, 333 1-year-, 131 2-year-, and 6 3-year follow-up visits have occurred. Using iohexol plasma disappearance and a newly developed GFR-estimating equation (6, 7), CKiD has demonstrated improved precision and accuracy in GFR measurement and estimation in children. Associations between known risk factors for CKD progression (e.g., proteinuria) and level of GFR have been demonstrated, as have associations between low levels of GFR and known complications of CKD in children, including growth failure, anemia (8), hypertension, abnormalities of ambulatory blood pressure monitoring, left ventricular hypertrophy, and deficits in attention and quality of life. The collection of biological samples for banking at study entry and annually at follow-up will provide a valuable resource to explore other risk factors. To date, 14 ancillary studies have been approved of which four have received NIH

support. It is expected that the extension of CKiD (CKid II) will allow for an analysis of additional novel risk factors for CKD progression and associated morbidity, including low birth weight, inflammation, environmental factors, and nutritional Vitamin D deficiency.

The most recent study to be launched is the *RIVUR* study (http://www.cscc.unc.edu/rivur/). This multicenter, randomized, double-blind, placebo-controlled trial is designed to determine whether daily antimicrobial prophylaxis with trimethoprim and sulfamethozazole (TMP/SMZ) is superior to daily placebo in children less than 6 years old with grade I–IV vesicoureteral reflux (VUR) in reducing the frequency of urinary tract infection (UTI) and renal scarring (9). Patients are randomly assigned to treatment for 2 years with daily TMP/SMZ or placebo. The study is designed to recruit 600 children (approximately 300 in each treatment group) ranging in age from 2 months to 6 years over an 18–24 month period. The primary endpoint is recurrence of UTI. In addition, patients will be evaluated for secondary endpoints related to renal scarring and antimicrobial resistance. Scarring will be determined based on renal scintigraphy by 99mTc dimercaptosuccinic (DMSA) scans. Dysfunctional voiding symptom score, constipation surveys, quality of life, compliance, safety parameters, utilization of health resources, and change in VUR will be assessed periodically throughout the study. Currently there are a total of 15 clinical sites in North America participating in the study and these include five core sites. The patient recruitment started in late 2007 and about 120 patients have so far been enrolled in the study. The study involves pediatric nephrologists, pediatric urologists and primary care pediatricians, and the patients are being recruited from private offices, hospital admissions, emergency room visits, and nephrology or urology consult referrals.

The NIH has also fostered research related to pediatric kidney disease by supporting three Interdisciplinary Research Centers of Excellence. Two new Centers focus largely on polycystic kidney diseases (PKD), the most common renal genetic diseases of adults and children. The Research Center of Excellence in Pediatric Nephrology at the Medical College of Wisconsin (P.I. Ellis D. Avner, MD; http//:www.chw.org/research) focuses on delineating of the pathophysiology of PKD, with an ultimate goal of developing new therapeutic targets for clinical trials. Because events in the pediatric age range are critical for determining the outcome of kidney disease, investigators are examining early cellular and molecular abnormalities in PKD which may be amenable to therapeutic intervention. The genetic and metabolic determinants of glomerular and systemic hemodynamics in ischemic renal disease and PKD are being studied in an effort to understand how acute and chronic renal injury in childhood progress to end-stage disease. The ultimate goal of these studies is to identify mechanisms to delay or prevent the loss of kidney function in genetic and acquired renal diseases. A unique feature of this Center is a robust Pilot and Feasibility grant program, which was specifically developed to draw new investigators into childhood kidney disease research. At the University of Alabama at Birmingham (UAB) Recessive Polycystic Kidney Disease (RPKD) Core Center, (P.I. Lisa Guay-Woodford, MD; http://www.rpkdcc.uab.edu/), the main objective is to stimulate interdisciplinary research into the diagnosis, pathogenesis, and therapeutics of ARPKD. To stimulate such research, the Core makes PKD research technologies and methodologies, intellectual resources, and research infrastructure available to local and national investigators. These resources may be applied to new multidisciplinary projects, interactions, and collaborations. It further extends an observational study of ARPKD initiated by the North American ARPKD Database, provides a mechanism for genetic evaluation of unusual recessive PKD phenotypes, and provides educational tools for physicians and patients regarding the natural history, pathogenesis, and genetic testing in ARPKD. A unique product of this Center is the development of a HIPAA-compliant, web-based portal for data entry, which makes use of a unique data collection instrument that could serve as a model for other databases once its effectiveness has been proven. This instrument makes use of an IRB-approved algorithm for data entry that obviates the need for the contributing physician to obtain local IRB approval. The Research Center of Excellence in Pediatric Nephrology at Vanderbilt University is now in its 17th year of funding, and is focused on the Fibrotic Sequelae of Childhood Renal Disease (P.I. Agnes Fogo MD; http://www.mc.vanderbilt.edu/research).This Center focuses on the basic pathophysiology of various aspects of CKD, including tubulointerstitial fibrosis, podocyte injury and repair, atherosclerosis, and chronic inflammation. Such studies continue to provide novel insights about progressive childhood renal injury and potential therapeutic interventions.

In addition to its registry components, *NAPTRCS* initiated randomized, prospective clinical trials in the mid 1990s. These include a study of OKT3 induction therapy in children and adolescents undergoing renal transplant, trials to investigate the use of growth hormone in dialysis patients, transplant patients and children and adolescents with chronic kidney disease, and recent randomized trials designed to evaluate potential complete withdrawal of steroid therapy in transplant patients. NAPRTCS has served to document

and influence practice patterns, clinical outcomes, and changing trends in renal transplantation and the care of children with CRI. Information about NAPTRCS, including a bibliography of the numerous publications generated from this cooperative study, can be found at https://web.emmes.com/study/ped/announce.htm.

Each year, the ASPN Research and Public Policy Committees generate, with input from the general membership of the Society, legislative language summarizing priorities for research related to the care of children with kidney disease. The statement for fiscal year 2009, inserted into the *Congressional Record* by members of Congress, identifies the urgent need to promote translational and clinical research aimed at understanding the mechanisms involved in kidney injury and progression, a crucial step to develop and test new interventions and therapies in children. Additional areas of high interest for the pediatric nephrology community of North America are understanding factors that contribute to, or impede, patient adherence to treatment regimens; transition from pediatric to internal-medicine caregivers; and developing a stable infrastructure for clinical research in pediatric kidney disease.

Acknowledgments

The contributions of Susan Furth, Rick Kaskel, Tej Mattoo, Lisa Guay-Woodford, William Harmon and Ellis Avner are greatly appreciated.

82 Africa

Felicia U. Eke

Africa remains the world's poorest and most underdeveloped continent. The continent includes 53 countries including all the island groups. Despite many similarities, African nations are heterogeneous, with varying cultural and socioeconomic differences.

The African Pediatric Nephrology Association, AFPNA is the official representative of the International Pediatric Nephrology Association in Africa. It has currently 71 members from 29 African countries. There are no members from 24 countries. AFPNA was born in 1999, and affiliated with IPNA in 2000. Its first congress was in Cairo in March 2000, with the subsequent congresses in Nigeria (2002), and South Africa (2006). Dr Bahia Moustafa, Director of Pediatric Nephrology, Cairo University Egypt was the initial Secretary General of AFPNA, with Egypt, Nigeria, Libya, Sudan, Mali, Cameroon, and South Africa constituting the founding countries which developed AFPNA's Constitution. Through 2000–2006 Prof. Moustafa represented AFPNA at IPNA council and two additional African IPNA councilors were elected to represent Central Africa (Prof Felicia Eke; who was also elected Secretary General in 2006) and South Africa (Dr Mignon McCulloch). AFPNA supports a newsletter, workshops, and training programs. Communication with members and global colleagues, and updates of activities are regularly reported via AFPNA's website (http://www.afpna.org). AFPNA maintains three regional training centers in Cairo, Cape Town and Johannesburg. With regular recruitment of new members, it is hoped that all 53 countries of Africa will be represented in AFPNA by the next IPNA International Congress in 2010 (New York, USA).

Many children with kidney disease in Africa do not receive appropriate medical care, and there are critical shortages of Pediatric Nephrologists (PN) and resources in many African countries. In Egypt there is one PN per 500,000 child population, in Nigeria there is one PN per 4.5 million children and in South Africa there is one PN per 1.5 million. Therefore pediatricians and general practitioners commonly treat children with kidney disease (1). In the last two decades pediatric nephrology units have developed throughout the continent. They are concentrated mainly: (1) in the northern region in Egypt, Tunisia, Algeria, Libya, and Morocco; (2) in the eastern region in Kenya, Sudan, and Ethiopia; (3) in the western region in Nigeria and Cameroon; and (4) in the southern region in South Africa. Most of these units provide primary and secondary renal care. Some provide tertiary care (i.e., comprehensive dialysis and transplantation). In North Africa dialysis and transplantation programs are well developed; however, they are run by internist nephrologists in many areas because of the high ratio of internist nephrologists to pediatric nephrologists. This situation is slowly changing as more PNs are being trained. In Egypt, university-related pediatric nephrology units act as regional centers for training and treatment. There are pediatric hemodialysis units in national hospitals. National medical insurance covers the costs for patients treated in university or national hospitals.

In the east, only Kenya has organized renal services including peritoneal dialysis, hemodialysis, and renal transplantation. In the western and central zones, Nigeria is the largest and richest country. At this writing, there are 13 PNs serving a child population of approximately 80 million. Six hundred of these children are expected to develop end-stage renal failure per year. There are 20 adult hemodialysis units, with variable experience in treating children. There are three transplantation centers, but no child has received a transplant to date. Children requiring hemodialysis are dialyzed in adult units; peritoneal dialysis is available for children with acute renal failure (ARF). Continuous ambulatory peritoneal dialysis (CAPD) is not undertaken. There are no national medical insurance programs which cover the expense of end stage renal therapy. Children with chronic renal failure (CRF) whose parents can afford the costs travel to other regions for dialysis and transplantation. In South Africa, despite the shortage of trained pediatric nephrologists, there are several centers that provide secondary levels of renal care, and most have facilities and expertise for peritoneal dialysis. Care for children with end-stage renal disease (including dialysis and transplantation) is centralized in three major centers: Cape Town, Johannesburg, and Durban. In Durban, renal replacement therapy is limited to older children, but with the recent commissioning of the Inkosi Albert Luthuli Central Hospital, tertiary and quaternary renal care will be offered to all age groups.

© Springer-Verlag Berlin Heidelberg 2009

The policy of the country is to centralize quaternary care to limited designated sites for the entire country, such that provision of renal replacement therapies will remain limited to a small number of centers.

Childhood Renal Disease in Africa

The profile of renal diseases prevalent in Africa is unique with respect to etiology and clinical presentation. Endemic infections are a major cause of many renal diseases. The low socioeconomic status in many areas, coupled with the lack of clean water (secondary to poor sanitation and irrigation systems), and overcrowded housing promote endemic infections such as schistosomiasis, malaria, tuberculosis, hepatitis, streptococcus, salmonella, shigella, and filarial. A number of social and political factors, including poor control of drug abuse and prostitution, contribute to a high rate of HIV and other infections. Other factors contributing to the unique pattern of renal diseases in Africa includes use of alcohol, drugs of abuse, herbal and traditional medicines, toxins from bites, and local environmental pollutants. Obviously the dry environment and tropical climate with inadequate water supply leads to a high incidence of nephrolithiasis in the population. Racial differences are also seen particularly in South Africa where blacks are more prone to severe renal diseases.

Clinically, infection and malnutrition commonly complicate the presentation and treatment of renal disorders. Infection either may be the primary cause of kidney disease or may be acquired during treatment. The higher morbidity and mortality observed in African children with renal disease can often be attributed to late diagnosis and late referral to specialized units. Moreover, the poor intradialyic care children receive because of limited resources or insufficient staff explains the poor quality of life compared to that of similarly treated children in developed countries. The most prevalent renal disorders in Africa include nephrotic syndrome (NS), urinary tract infections (UTIs), acute renal failure (ARF) and chronic renal failure (CRF), (*Fig. 82-1*).

Nephrotic Syndrome (NS)

NS (see Chapters 27–28 Nephrotic Syndrome) is the most common childhood renal disorder in Africa. It accounts for 14.6% of renal disorders in eastern Nigeria (2), 40% in Sudan (3), and 40% in Egypt. In North Africa etiologies resemble those in western countries: minimal change NS (MCNS) constitutes 88% in Egypt, 85% in Libya (4), and 37% in Sudan (3). Steroid responsiveness is common in Egypt. Frequently relapsing nephrotic syndrome (FRNS) and steroid-dependent nephrotic syndrome (SDNS) occur in 42% and 36% of MCNS in Cairo and 21% and 15% in Mansoura, respectively. Relapse is often associated with noncompliance with steroid therapy or superimposed infection. Mortality, often from infections, is approximately 2%. In Egyptian children with other pathology underlying NS, focal segmental glomerulosclerosis (FSGS) occurred with equal prevalence as mesangial proliferative glomerulonephritits (MPGN) (22.7%) in 394 biopsies analyzed over 10 years but FSGS predominated in the 1980s (5).

Secondary forms of NS are uncommon in North Africa accounting for 6.6% of cases (4). The most common is postinfectious schistosomal nephropathy, which is endemic in the Nile delta in Egypt, Ethiopia, and Sudan. The causative parasite is Schistosoma haematobium which together with Schistosoma mansoni is also found in East, West, and Central Africa. Such patterns correlate with prevalence of the snail host and poor hygiene. Infected children present with haematuria, glomerulonephritits, NS, or renal failure. Hepatosplenomegaly with the presence of bilharzial ova in urine or stools commonly point to the diagnosis. Patients demonstrate unselective proteinuria, marked reduction in total serum levels of proteins with a characteristic high gamma globulin fraction, normal serum cholesterol level, normal to low serum complement profile, low urine osmolality, and normal to low glomerular filtration rate (GFR). Many such patients are chronic Salmonella carriers with intermittent bacteriuria, especially those with refractory anemia and persistent fever. Urinary tract imaging may reveal bladder calcification and/ or obstructive uropathies and vesicoureteral reflux (VUR); renal biopsies show diffuse MPGN (20%), membranous nephropathy (12%), focal MPGN (7%), or mesangiocapillary glomerulonephritits (18%). Different immune mechanisms have been implicated in the pathogenesis of these lesions (6). The recent aggressive use of chemotherapy among school children and extensive snail eradication have led to a fall in schistosomal infections. There are hopes for the development of a schistosomal vaccine (7).

Hepatitis B accounts for 44% of secondary forms of NS in Egypt; Hepatitis C is uncommon. Tuberculosis and filariasis are now less prevalent in the northern region. Lupus erythematosus nephropathy is found in 8%. Sickle cell nephropathy is rare in North Africa although the disease is not rare. Ochratoxins and aflatoxins, which are

common constituents of food in Africa, were detected in urine, serum, and kidney biopsy specimens of children with NS or renal failure in Tunisia and Egypt (8). Cadmium and aluminum which are common environmental pollutants in Africa were recorded as toxic causes for NS in Africa. Although specific data are not available, it is a clinical impression that HIV nephropathy is a largely undiagnosed cause of NS and renal failure in African children as noted below.

In west and Central Africa the profile of NS is unlike that of the Western world. Idiopathic NS is not common. When it affects black children it is often associated with a high rate of steroid unresponsiveness. This is true in Togo, West Africa (9), western Nigeria (10), northern Nigeria (11), Uganda (12), and Zaire (13). In Port Harcourt, South Eastern Nigeria (14), and Yaounde, Cameroon (15), however, steroid responsiveness is not uncommon. Infections play a major role in the pathogenesis of NS in west and Central Africa (11). Quartan malarial nephropathy, first described in Ibadan, western Nigeria, was detected in up to 81% of renal biopsy specimens in children (10) in the 1970–1980s. Quartan malaria; nephropathy is predominantly associated with *Plasmodium malariae* and also with *Plasmodium falciparum* infection. Typically there is focal and segmental glomerulonephritits with thickening of capillary walls but without endothelial cell proliferation. Finding of P. malariae or P falciparum antigen in the glomeruli by, immunofluorescence is diagnostic. Malaria induced acute renal failure is an important complication of malaria infection. Recent studies however have questioned a dominant role of a chronic malaria glomerulopathy (16). In eastern Nigeria, MCNS is the most common pathologic diagnosis in cases undergoing biopsy. In Nigeria the recent upsurge of HIV infection has been associated with HIV nephropathy mainly from vertical transmission but manifesting with NS or CRF around the age of 7–10 years (17). Other infections reported in Zimbabwe, West and Central Africa include hepatitis B and C with membranous nephropathy (18). NS often complicates post streptococcal glomerulonephritits. Schistosomiasis, filariasis, and leprosy are also recorded.

In eastern Nigeria, sickle cell nephropathy is common and sickle cell anemia is common with a heterozygous carrier rate of 25%. FSGS and renal papillary necrosis are explained by endothelial damage caused by occlusion by sickled cells and microinfarcts. There are numerous cases of unexplained renal pathology, with NS possibly caused by toxins found in herbal remedies or environmental contamination.

In South Africa the epidemiology of NS disease has undergone considerable change since first reported during the 1970s and 1980s, (*Table 75.E1*). Black children had a paucity of minimal change disease and the majority was steroid resistant (19). Indian, white and children of mixed race had MCNS similar to that reported from developed countries with a high rate of steroid responsiveness. Membranous nephropathy with a strong male predominance was seen in 40% of black children in Durban; FSGS in up to 50% in Johannesburg; MCNS in black children accounted for only 14% of all cases of N.S (20–22). The introduction of hepatitis B vaccine in April 1995 dramatically reduced the incidence of Hepatitis B virus associated nephropathy.

Another interesting finding is the distinct difference in the response to therapy in black and Indian children with steroid resistant nephrotic syndrome. While over 80% of Indian children with steroid resistant nephrotic syndrome responded to a trial or oral cyclophosphamide and prednisone therapy, none of the black children achieved remission. Black children also showed a poorer response to other forms of intensive therapy (intravenous methylprednisolone, intravenous cyclophosphamide, cyclosporine and tacrolimus) (23). Steroid resistance in none of the nonblack children predicted FSGS as 50% had MCNS on biopsy. Seventy percent of Indian children with SRNS responded to oral cyclophosphamide whereas none of those with focal segmental glomerulosclerosis on histology responded to therapy.

Table 82-1

Histologic pattern of nephrotic syndrome before and after 1995 in Durban, South Africa

Histologic findings	1976–1994	1995–2000
Minimal change disease	95	11
Focal segmental glomerulosclerosis	41	43
Membranous nephropathy	44	6
Membranous nephropathy (hepatitis B associated)	63	24
Diffuse mesangial proliferative glomerulonephritits	26	1
Focal mesangial proliferative glomerulonephritits	13	2
Mesangiocapillary glomerulonephritits	4	1
Total	286	88

Urinary Tract Infections (UTI)

UTIs (See Chapter 54 UTI) are common in Africa, in both rural and urban areas and among neonates, preschool children, and school – aged children. Symptomatic UTIs show a prevalence of 22% in Egypt; while the presence of asymptomatic bacteruria is 4.2% in girls and 2.8% in boys among schoolchildren in urban Egypt and 11% in girls and 3.6% in boys in rural Egypt (24). In Central and West Africa, UTIs have an incidence from 8.2 to 72% in symptomatic children (25) and 48% in an asymptomatic rural community. In Cape Town, approximately 1,000 cases of UTIs are seen yearly. Because of the nonspecific complaints in neonates and young children with UTIs, many cases are missed, especially in rural areas. The microbiology of UTIs in Africa is consistent over the continent (26). In Nigeria the predominant organism is *Klebsiella* resistant to amoxicillin and cotrimoxazole (26); in Egypt *Escherichia coli* is found in 70%, *Proteus* 10% *Klebsiella* 5%, and *Pseudomonas* 5% (27). Schistosomiasis is considered a common predisposing factor for UTIs in Egypt, Senegal (28) and Cameroon (29). Stones, developmental anomalies of the urinary tract, and VUR are common underlying common structural lesions which predispose children to UTIs with prevalences of 2.5, 12, and 17%, respectively in Egypt. VUR is rare in West and Central Africa whereas posterior urethral valves and meatal and urethral strictures are reported to have an incidence of 29.3% among children with UTIs (26). In South Africa, local predisposing factors include malnutrition, congenital anomalies, immunodeficiency states, and VUR (29). The latter is rare in black children but common in whites (30). Renal growth and GFR are commonly affected in African children with UTIs because of late diagnosis and referral, as well as patient noncompliance with treatment. For example, impaired renal growth was reported in 36% of cases referred to the Cairo University unit in a recent unpublished analysis. *E. coli* strains resistant to amoxicillin and co-trimoxazole are commonly reported in Africa. For example, 88 and 86% resistance to these drugs, respectively, is seen in Cape Town.

Acute Renal Failure (ARF)

ARF (see Chapter 64–66 ARF) has unique epidemiology in African children. Infection is the major cause. Bacterial infections commonly reported include streptococci, cholera, salmonellosis, shigellosis, leptospirosis, tetanus, and diphtheria. Viral infections include rotavirus, HIV infection, hepatitis A, B and C, and cytomegalovirus infections. Common parasitic infections are malaria and schistosomiasis. Among all pathogen-related causes, diarrhoeal diseases, schistosomiasis, and malaria remain the most common. Infection precipitates ARF through immune mechanisms and alteration of kidney hemodynamics. Toxins after snakebites, scorpion or other insect stings, or following ingestion of herbal medicines or illicit drugs are also unique causes of ARF in Africa. *Table 82-2* summarizes causes of ARF in Egypt, Nigeria (31), and South Africa (32). Septicemia, gastroenteritis, and hemolytic uremic syndrome (HUS) are common causes in the three regions. Epidemic forms of ARF after use of native herbal medicines and "holy water" were reported in Nigeria (33). In Sub-Saharan Africa an epidemic of shigella dysentery type1 occurred in 1994–1996 starting in Burundi and progressing to the Cape (32). One hundred and fifty-nine cases of HUS occurred in black children during this epidemic. Among 81 cases of post-Shigella-induced HUS in Durban, complications included ARF in 90.1%, encephalopathy in 37%, convulsions in 14.8%, hemiplegia in 2.3%, intestinal perforation in 9.9%, protein-losing enteropathy in 32.1%, toxic megacolon in 4.9%, rectal prolapse in 6.2%, hepatitis in 13.6%, myocarditis in 6.2%, disseminated intravascular coagulation in 21%, CRF in 32.1%, impaired renal function in 9.9%, ESRD in 1.2%, and death in 17.3% (32). Since 2000, *E. coli*-induced HUS, especially coexistent with HIV infection, has been increasingly reported in Cape Town.

Chronic Renal Failure (CRF)

The pattern of CRF(see Chapter 68–71 Chronic Renal Failure) in African children is unique with respect to its etiology, clinical presentation, and management. Causes of CRF in Egypt, Nigeria (2), and South Africa are summarized in *Table 82-2*. Obstructive uropathies and reflux nephropathy are prevalent causes in Egypt; glomerulonephritis in Nigeria (34) and South Africa. Some uncommon causes of CRF such as Takayasu arteritis (35) and cystinosis are found predominantly in South African blacks. The recent pandemic of HIV/AIDS in sub Saharan Africa has resulted in increasing cases of CRF from HIV nephropathy (17). Late referral of cases is common. Signs of CRF in African children are aggravated by four distinct elements: infection (whether causing CRF or acquired during dialysis), malnutrition (especially deficiencies of iron, vitamin D, and trace elements), late diagnosis and poor management (which aggravate anemia, growth retardation, and bone disabilities).

Table 82-2

Causes of acute and chronic renal failure in selected locations in Africa

	Egypt (%)		Nigeria (%)		Cape Town (%)		Durban blacks (%)

HIV Related Chronic Kidney Disease (see Chapter 52 HIV nephropathy)

Following the onset of the HIV epidemic in the late 1980s, over three million children are now infected in sub-Saharan Africa. KwaZulu-Natal is one of the epicenters of the epidemic. To date Durban has 37 patients with HIV-related renal disorders. Renal biopsy undertaken in 13 black patients showed FSGS in 11: membranous in one. Fifteen biopsies in Cape Town showed HIV associated nephropathy, HIVAN in 13, mesangioproliferative glomerulonephritis in two and tuberculous granulomata complicating one case. In Nigeria, most cases with vertical transmission present approximately at the age of 7–10 years with NS or CRF with increased echogenicity and strikingly bright appearance on ultrasound. Histology in a recent series was predominantly collapsing glomerulonephritis and markedly dilated tubules and tubular cysts (17).

Dialysis and Transplantation (See Chapters 72–77)

Acute peritoneal dialysis is the most common type of dialysis in Africa and is more readily available than acute hemodialysis. Chronic intermittent peritoneal dialysis is the most common technique used in end stage renal failure (ESRF). The use of continuous cycling peritoneal dialysis is less common. In developed areas such as Cape Town, however, use of CAPD is predominant. Efficiency

of dialysis varies among pediatric nephrology centers. It depends on the availability of funds as well as trained staff. Many children with ESRD experience poor quality of life, dialyzing once a week. Factors that contribute to their poor outcome include deficient dialysis, malnutrition, and lack of appropriate interdialytic care due to unavailability of erythropoietin, iron, active vitamin D, and growth hormone (1).

Although renal transplantation is more cost effective than dialysis, it is available for children only in South Africa (27) Egypt, Tunisia, Morocco, Libya, Algeria, Sudan, and Kenya. Nigeria has transplanted adults since 2000 but no child has been transplanted to date. Since 2004 there have been an average of 10–15 renal, and 5–10 liver transplants yearly in children at the Red Cross Children's Hospital in Cape Town (personal communication). Ethical and religious factors in each country determine whether cadaveric or living donor grafts are used. In South Africa, cadaver organ-based programs are widely used, whereas in Egypt, only living related donor-based programs are permitted. Morbidity and mortality of patients undergoing renal transplantation is higher in Africa than in developed countries, due mainly to infections, lack of compliance with therapy, lack of funds for immunosuppressive and other therapy, and lack of trained staff.

Most African countries lack national kidney foundations as well as medical insurance systems. To date there is no national Registry though some individual centers have a Renal Registry (2). Funding for ESRD therapy remains a significant handicap for most African countries. Prevention of ESRD is the best strategy when approaching the problem of CRF in Africa. Simple measures include health education to combat unhygienic habits and inappropriate use of traditional remedies, many of which are nephrotoxic. Additional measures include infection control through antischistosomal and antimalarial campaigns; early treatment of streptococcal infections and obligatory vaccination against tuberculosis and hepatitis. Screening for renal disease among school children might identify patients early in the course of the disease and maximize appropriate intervention.

The previously described development of the African Pediatric Nephrology Association (with its affiliation to the International Pediatric Nephrology Association) affords new opportunities for upgrading the practice of pediatric nephrology in Africa. Training programs supported by IPNA exist in Cape Town and Johannesburg and more are envisaged in Northern and Central Africa to increase the number of trained pediatric nephrologists. Shortage of specialists and trained staff as well as restricted financial resources remain a major challenge in many areas. There has been a recent upsurge in the development of regional African pediatric nephrology societies such as the Egyptian Society of Pediatric Nephrology, the Nigerian Association of Paediatric Nephrology, the Moroccan Society of Pediatric Nephrology and the South African transplantation and pediatric nephrology groups. These societies as well as improved education offer promise for dramatic improvements in pediatric nephrology care in Africa over the next decade.

Acknowledgments

The authors would like to thank Prof. M. Adhikari (Durban) and Dr. M. McCulloch and Dr. P. Sinclair (Red Cross Children's Hospital, Cape Town) for providing valuable data from their centers. The authors also offer special thanks to colleagues in different pediatric nephrology units throughout the continent for their assistance in data collection.

83 Latin America

Nelson Orta-Sibu · Ramon A Exeni · Clotilde Garcia

Demography

The Latin America subcontinent consists of 20 nations in North, Central, South America and the Caribbean, in which the prevailing languages – Spanish and Portuguese-derive from Latin. It encompasses an extensive territory with many common characteristics and also with significant cultural and socioeconomic differences. Latin America's population is a composite of ancestries, ethnic groups and races, making the region, arguably, the most diverse in the world. Race composition varies from country to country and includes population of mixed, Amerindian, European and African ancestry. Most Latin American countries also have Asian minorities. Europeans and groups with part-European heritage make nearly 80% of the population (1).

Living conditions for the aboriginal inhabitants of the subcontinent are generally poor, while social imbalances are prevalent in urban areas. However, noteworthy features, such as hospitality, tolerance, and respect for ethnic differences, that characterize Latin America's population, come from the fusion between the ancient indigenous cultures and the European influences.

Concentrated primarily in urban areas (78%) and growing at an annual rate of 1.3%, Latin America's population reached 558 million in 2006. Life expectancy at birth is 72 years; in 2002 32% of the population was 14 years old or younger. By 2010 and 20020, however, the average age is expected to decrease by 28% and 25% respectively (2). The infant mortality rate (per thousand live births) for the 2005–2006 period is 24/1000, ranging from 7.2 in Chile to 45.6 in Bolivia (3).

Latin American Association of Pediatric Nephrology (Alanepe)

The Latin American Association of Pediatric Nephrology (ALANEPE) was founded in 1981 in Buenos Aires, Argentina, by 48 founding members. The organization's main objective is to promote the knowledge and science of pediatric nephrology and to improve the care of children affected with kidney diseases in Latin America. It also contributes, in conjunction with other similar societies affiliated to the International Pediatric Nephrology Association (IPNA), to the worldwide improvement of Pediatric Nephrology as a field of study (4).

From a practical/operational stand point of view ALANEPE is divided into three regions:

- Region 1: Mexico, Guatemala, El Salvador, Costa Rica, Nicaragua, Honduras, Panama, Caribbean islands, Cuba, Dominican Republic and Puerto Rico. (Despite being an English speaking country, Belize has been added due to its geographical situation).
- Region 2: Venezuela, Colombia, Ecuador, Peru, Bolivia
- Region 3: Chile, Argentina, Brazil, Paraguay, Uruguay.

The official Journal of ALANEPE is Pediatric Nephrology (the official journal of IPNA). However to accommodate languages spoken in the subcontinent, the publication of *Archivos Latinoamericanos de Nefrologia Pediátrica* [Latin American Archives of Pediatric Nephrology], was initiated in 2001, and is published three times a year both a printed and electronic journal. This Journal includes invited reviews, practical nephrology items, guidelines for common nephrological entities, news, and reports of meetings and other activities which take place in different countries in the region. The publication has increased the interest of pediatricians in the specialty, and has served as a continuing medical education tool for pediatric nephrologists and related professionals. Like the triennial ALANEPE congress, the Journal is a symbol of ALANEPE's commitment to its mission.

Pediatric Nephrology Development in Latin America

The development of Pediatric Nephrology in Latin America can be traced back to the 1950's, when Gustavo Gordillo created the Department of Pediatric Nephrology at Mexico City's Children's Hospital, and Carlos Gianantonio championed the specialty in the southern Argentina. Gianantonio dedicated extraordinary effort to understanding the basic pathophysiology, clinical course and

© Springer-Verlag Berlin Heidelberg 2009

management of hemolytic uremic syndrome (HUS), which is endemic in the region. Contemporaneously, Julio Toporovsky started the development of Pediatric Nephrology in Brazil. The influence of these pioneers promoted the development of pediatric nephrology centers in these countries that subsequently were emulated throughout Latin America. Their nephrology units became early educational centers for nephrologists from the entire region.

Additionally, the development and promotion of pediatric nephrology as a field of study in the subcontinent has been crucially influenced of other nephrologists, such as Pierre Royer, Renee Habib and Michelle Broyer (France), Juan Rodriguez Soriano (Spain), Cyril Chantler and T Martin Barrat (England), Ira Greifer (USA) and other North American nephrologists.

Currently, there are Pediatric Nephrology educational centers in Argentina, Brazil, Colombia, Chile, Mexico, Costa Rica and Venezuela. Some of them have achieved recognition from prestigious universities.

ALANEPE has grown from 48 to 500 members in the region. The emergence of Pediatric Nephrology in Latin America is well documented by the incremental number of Latin American abstracts submitted to the last six congresses of the International Pediatric Nephrology Association, from 22 in Jerusalem (1992) to almost 100 in Budapest (2007), and by the growing number of Latin American papers published over the past 20 years in Pediatric Nephrology.

Specific Areas of Clinical and Research Interest: Hemolytic Uremic Syndrome (HUS)

The world's highest incidence of HUS is reported in Argentina, with more than 14 cases per 100,000 children younger than 5 years of age. In this country, approximately 400 new cases are reported annually. Nearly all cases are secondary to infections caused by verotoxin-producing Escherichia coli O 157:H7. After Gasser's description in 1955, a study of 64 cases was published in 1964 by Gianantonio and co-workers. A seminal achievement was the implementation of peritoneal dialysis to treat acute renal failure in these children, which reduced the acute mortality from 50 to 5% (5).

The Nephrology Committee of the Argentinean Society of Pediatrics registered 7570 HUS patients in 11 public centers in Argentina between 1965 and 2001. In that period, mortality varied between 2 and 5.6% during the acute phase. There were no significant differences between November and March (summertime). The high incidence of HUS in Argentina is related to high rate of ingestion of contaminated, undercooked beef meat and its early introduction in young children's diets (6). Several studies are in progress in this region to understand aspects of HUS, such as the role of polymorphonuclear leukocytes in the pathophysiology of typical HUS (7), the functional state of neutrophils and its correlation with the severity of renal dysfunction in children with HUS (8), and the involvement of the fractalkine pathway in the pathogenesis of childhood HUS (9).

Collaborative Studies

National Collaborative Studies

Venezuela

The Pediatric Nephrology Chapter of the Venezuelan Society of Pediatrics and the Venezuelan Society of Nephrology reported epidemiological data on renal diseases in children in recent years.. Information was obtained from 14 centers with at least one pediatric nephrologist. A total of 3,624 patients were evaluated during a period of one year, either through a first outpatient consultation or at a first hospital admission.

The patients were grouped into the following categories: (1) urinary tract infection (32%), with detection of abnormalities of urinary tract in 25%; (2) metabolic disorders (28%) mainly idiopathic hypercalciuria and hyperuricosuria; (3) glomerulonephritis (9.5%), (4) urolitihiasis (7%), (5) nephritic syndrome (4.5%), (6) "primary" hematuria (4.2%), (7) acute renal failure (2.8%), with 43% of cases secondary to acute dehydration, 15% due to birth asphyxia, (14% secondary to septicemia, and 23% due to multiple factors), (8) chronic renal failure (1.6%) and (9) miscellaneous diseases (4.8%) (10, 11).

Recently a national study of renal transplantation in children has been published in Venezuela, reporting the experience of 25 years in the four centers that perform this technique in the country. Results showed that during the period 1982–2006 a total of 268 patients with end-stage renal disease received 275 renal transplants, the age of patients was 11.1± 7.3 years. 70% of the grafted kidneys were obtained from cadaveric donors and 30% from live related donors. Most important causes of mortality included: septicemia 34%, cardiovascular and acute hemodynamic complications 22%, metabolic complications 17%, hematological complications 12% and miscellaneous causes 8%. Graft lost was due to chronic rejection

in 60% of the cases, thrombosis of renal vessels 20%, recurrence of renal disease in the graft 13%, and acute tubular necrosis 7%. Actuarial survival of patients was: 98% at 6 months, 98% at 1 year, 90% at 3 years and 85% at 5 years. There was no statistically significant difference between patients transplanted from live donors and patients with kidneys from cadavers ($p > 0.05$). The first graft actuarial survival was: 97% at 6 months, 90% at one year, 80% at 3 years and 70% at 5 years. These results confirm the feasibility of kidney transplantation programs for the rehabilitation of children with end stage renal disease in Latin American countries, with satisfactory actuarial survival (12).

Chile

Chronic Peritoneal Dialysis in Chile – A Multicenter Study

A multicenter study of continuous ambulatory peritoneal dialysis (CAPD) in five centers was carried out in Chile: One hundred and twenty-nine children younger than 18 years of age were evaluated; 97 of them, with at least 6 months of follow-up, were included in the analysis. Causes of end stage renal disease were renal hypoplasia or dysplasia (26%), glomerulopathies (17%), reflux nephropathy (15%), obstructive uropathy (15%), vascular diseases (15%), and other disorders (12%). Staphylococcus aureus accounted for the majority of episodes of peritonitis, and the incidence of this complication was 0.67 episodes per patient per year, a rate similar to that reported in the literature (13).

Argentina

National Register of Chronic Renal Disease, Dialysis, and Transplantation

In 1996, Argentina initiated a centralized Registry of pediatric patients with end-stage renal failure undergoing conservative management, dialysis and transplantation. Registry data of 710 patients, under the age of 19 years demonstrated that the etiologies of chronic renal failure were: obstructive uropathy 18%, reflux nephropathy 16%, hemolytic uremic syndrome 14%, renal aplasia/dysplasia/hypoplasia 14% and focal segmental glomerulo sclerosis 9%. The incidence of end–stage renal disease was 6.5 patients/total million inhabitants. Of the patients on dialysis treatment, 63% were undergoing hemodialysis and 37% were treated with chronic peritoneal dialysis. 16% of patients received kidney transplants, with 46% from live donors (14).

Brazil

The experience in pediatric renal transplantation in various Latin American countries is growing, and several centers in Mexico, Colombia, Venezuela, Brazil, Chile and Argentina, among others (12, 14–18) perform routine kidney transplantation in children. In certain countries pediatric transplantation is positively impacted by the adoption of a priority policy for assignment of cadaver kidneys to pediatric patients (19, 20), however, renal transplantation is limited in young children. A collaborative study from Brazil reported the results in 38 children (40 transplants), ages 1–5 years, transplanted between 1989 and 2005. Mean age at transplantation was 3.3 ± 1.3 years, and mean weight was 14 kgs (range, 5.7–25 kgs); etiology of end-stage renal disease was uropathic/vesicoureteral reflux (45%) glomerulopathies (25%), congenital/hereditary diseases (10%), and hemolytic uremic syndrome (12.5%). Prior to transplantation, 5% were on hemodialysis, 85% on peritoneal dialysis, and 10% were performed pre-emptively. All children were followed for at least 6 months post transplantation, except two who died in the first month. In 75% of cases, kidneys were obtained from living-related donors and cadaveric in 25%. Thirty-nine kidneys were extraperitoneally placed. Primary immunosuppressant therapy consisted of cyclosporine (61%), tacrolimus (39%), mycophenolate (49%), and azathioprine (51%). A steroid-free protocol was used in 17% of patients. In the last 21 cases, basiliximab or daclizumab was added. There were 13 (32.5%) graft losses (4 artery/vein thromboses, 3 chronic rejections, 3 deaths, 3 other causes). The 5-year patient and graft survival rates were 89.6% and 72.2%. These data demonstrate that renal transplantation can be performed with good long-term results in children younger than 6 years old (21).

International Latin American Collaborative Studies

Hypercalciuria and Nephrolithiasis in Children

A study on the epidemiology of Nephrolithiasis was done, including 13 centers in Latin America. Eight hundred and seventy children were recruited; 552 (63%) were boys and 318 (37%) were girls. The age at which the disease was detected ranged from 2 months to 17 years. Only 4% of the subjects were asymptomatic. The initial symptoms reported most frequently were gross hematuria in 337 (39%) patients, abdominal and/or lumbar pain in 235

(39%) patients, hematuria associated with pain in 147 (17%). Additional findings were dysuria in 17 (8%), recurrent urinary tract infection in 146 (17%), and elimination of calculi in 28 (3%). Kidney malformations were found in 78 (8.9%) (22).

Given the epidemiological data showing a high frequency of hypercalciuria and urolitihiasis in several areas of Latin America (23, 24), several studies are in progress in order to determine the normal values of urinary excretion of calcium and other electrolytes, and aspects of bone and metabolic status of these children. Such studies will determine, for example: the role of the hypocitraturia as a risk factor for reduced bone mineral density in children with idiopathic hypercalciuria (25, 26).

Epidemiologic Aspects of Chronic Renal Failure in Latin American Countries

A study on the epidemiology of CRF in several Latin American countries (Argentina, Brazil, Colombia, Mexico, Uruguay, Chile and Argentina) was performed. Data demonstrated that the incidence of CRF shows a wide variability, ranging between 2.8 and 15.8 new cases per 1 million inhabitants.

The causes of CRF were glomerulopathies in 36%, obstructive uropathies and reflux nephropathy in 31% systemic diseases in 9%, and other disorders in 15%. The histopathologic entity most frequently associated with CRF is focal segmental glomerulosclerosis. HUS is an important cause of CRF -but not the most frequent- in Argentina (27).

Antibodies against Streptococcal Zymogens in the Sera of Patients with Acute Glomerulonephritis-A Multicenter Study

In this study, one hundred and fifty patients with acute poststreptococcal glomerulonephritis from Argentina, Chile and Venezuela were studied (10); 140 were male and 49 were female. The source of infection was the skin in 84 patients, the throat in 44, and unknown in the remaining 14. Furthermore, 23 patients with streptococcal infections without glomerulonephritis and 93 healthy controls were also studies.

Antizymogen and antiproteinase titers were determined. The conclusion was that Antizymogen antibody titer is the best available marker for streptococcal infections associated with glomerulonephritis (28).

Continuous Ambulatory Peritoneal Dialysis in Children: a Collaborative Analysis of Results in Latin American Countries

Data concerning clinical practice and long-term outcome on peritoneal dialysis (PD) in Latin America are scarce, although regional registries are increasing in number and quality. The prevalence of Hemodialysis (HD) and PD replacement therapy in this region, included in the Registry of the Latin American Society of Nephrology and Hypertension (adults and pediatric patients), was 198 and 81 patients per million population respectively, corresponding to 92,875 hemodialysis and 37,732 peritoneal dialysis patients (18). By extrapolation of local data, we assume that between 20–30% of the total PD population in Latin America represents pediatric patients; in Venezuela, among 500 PD patients, 31 are children, In Argentina, among 409 dialyzed children in 32 Medical Centers, 154 of them are being treated with peritoneal dialysis. In Chile and Uruguay, for 71 of 339 and 12 of 126 PD patients are children. The main underlying renal disorders for starting PD include: renal dysplasia, reflux nephropathy, hemolytic uremic syndrome, obstructive uropathy and chronic glomerulonephritis. In some countries like Chile, most of the patients are treated with automated modalities of PD, while in Venezuela at least a half of the patients are under CAPD regimen.

Currently, most of the PD programs include routine measurement of growth, dialysis dose (Kt/V) and Peritoneal Equilibration Test (PET) according to DOQI recommendations. Some of our Centers are performing routine measurement of Protein Equivalent of Urea Nitrogen Appearance (PNA) and other kinetic measures of dialysis. To date, the recommended values for those variables in the pediatric population are under revision. In that sense, local communications in Latin America have shown that the mean 4-h D/P creatinine ratio was 0.78 ± 0.02 and 0.74 ± 0.13 initially and at 12 months of follow-up respectively, and the mean D/D_0 glucose ratio was 0.35 ± 0.11 and 0.34 ± 0.08 during the same observation period. Nutritional studies have shown that, for PD children with a positive growth, the mean PNA was 1.31 ± 0.40, and the daily protein and caloric intake were 114.6 ± 31.5 (DOQI %) and 108 ± 15 (RDA %) respectively. Latin America represents a very important region in PD, although clinical practice and dialysis approach are heterogeneous throughout the different countries. These data present an overview of the current situation of pediatric PD in Latin America (29).

Latin American Registry of Pediatric Renal Transplantation

Recently this Registry was started under the coordination of C Garcia (Brazil), A Delucchi (Chile) and N Orta (Venezuela). The reporting of data takes place every two years. The first report showed data on renal transplants in 13 countries and the main conclusions from the registry, comprising 21 centers in Latin America, have been compiled. Data from 401 renal transplants performed in pts <21 years-old, from Jan 2004 to Dec 2005, were analyzed. Mean follow-up was 18m. Mean age was 11.8y (53% female). Main etiology of ESRD was glomerulopathy (33%, of which 34% FSGS), followed by uropathy (25%). The donor was deceased (DD) in 55.4%. One year actuarial graft survival (Kaplan Meier) was 88.6% in DD and 92% in Live Donors (LD). There were 43 graft losses (23 from DD), mainly due to arterial or venous thrombosis (28%), with similar rates of thrombosis between DD and LD. Other causes of graft loss were death with functioning kidney (23.2%), acute rejection (11.6%), recurrence of kidney disease (11.6%), and chronic allograft nephropathy (9.3%). According to the recipient age at renal transplant, one year graft survival was 80% in 0–5 year-old recipients (death: 37.5%; vascular thrombosis: 11%), 90% in 6–2 year-olds (thrombosis: 31.5%) and 92% in 13–21 year-olds (thrombosis: 26.7%). One year graft survival was 91% in patients receiving steroids (n = 344), 93% in the steroid withdrawal group (n = 31) and 87% in the steroid-free group (n = 23). One year patient survival was 96.3%; 16 patients died due to infection. Although one year patient and graft survival are comparable to the international experience, there is a relatively high rate of graft loss due to vascular thrombosis (30).

The collection of data for the Registry corresponding to the renal transplants performed during the years 2006 and 2007 is in progress.

Organization and Resources

The nephrological care of children in Latin America varies; countries range from those having medical systems that provide care to all patients who need dialysis procedures to others offering no possibilities to provide dialysis or transplantation to children with end-stage renal disease. Even in countries in which hemodialysis, CAP, and kidney transplantation programs are available, such services are markedly hampered by economic problems. Health authorities appropriately give priority to prevention and treatment of common diseases. Despite the fact that this is improving, it is difficult to obtain funds for children with chronic renal disease-a small number of patients in need of expensive resources. This is worsened by the current state of devaluation of Latin American currencies, because the relative cost of the materials for treatment of end-stage renal disease, all of which are of foreign origin, constantly increases (31). To determine the situation in each of these countries, in 2002 an investigation about these topics was done. A questionnaire was sent that was answered by nephrologists skilled in these procedures. Results showed that Argentina, Brazil, Venezuela, Chile and Mexico have well-structured programs. Peritoneal Dialysis and hemodialysis programs, as well kidney transplantation programs, have and adequate infrastructure. Uruguay has adequate hemodialysis programs, was a pioneer in Chronic Peritoneal Dialysis and has a growing program of transplantation in public hospitals. Cuba and Costa Rica have adequate programs of hemodialysis and transplantation; chronic peritoneal dialysis was not used at the time of this investigation. Other countries, such as Paraguay, Ecuador, and Colombia, were developing new programs for hemodialysis, CAPD, and renal transplantation (32).

Since then, ALANEPE has decided to identify areas which need major support in Pediatric Nephrology in order to develop teaching courses and cooperation between countries. There are four areas with this profile: Central America, Bolivia-Paraguay, Ecuador-Peru and some Caribbean islands (e.g. Cuba). Several programs are under development in these specific geographical areas, including the introduction of a program of chronic peritoneal dialysis in Cuba, several teaching courses of Pediatric Nephrology in Ecuador, Bolivia, Paraguay, Panama; and the development, of important programs with support from organizations such as "Associazione Bambino Nefropatico" and the Lombardia Region, (Milan Italy). With the preliminary work developed in Nicaragua, Honduras, El Salvador, Guatemala, and Costa Rica a large program is under development to improve education and prevent pediatric chronic renal disease.

Medical Education Systems

Pediatric Nephrology residency programs exist in Argentina, Brazil, Chile, Colombia Mexico, Costa Rica, and Venezuela. Besides the residency in public hospitals, there are university Pediatric Nephrology residencies in Argentina, Chile, Mexico and Venezuela.

In conclusion, there is still a great discrepancy in the quality of care available for children with renal disease among different Latin American countries. Many challenges remain. However, dramatic improvement has been made in the care of children with renal disease over the past fifteen years in this area of the world.

84 Pediatric Nephrology in Australia and New Zealand

William Wong · Stephen Alexander

Introduction

Pediatric nephrology programs were established in a number of Australian state capital cities in the early 1970s. In 1980, New Zealand's pediatric end stage renal failure program was formed. The Australasian Paediatric Nephrology Association was formed during the International Pediatric Nephrology Association (IPNA) meeting in Toronto in 1989 and within 2 years the name was changed to the Australian and New Zealand Paediatric Nephrology Association (ANZPNA) to recognize New Zealand's contribution to the organization. In 1993, ANZPNA became officially affiliated to IPNA as a regional society. The association has maintained representation on the Council of IPNA over the past two decades. The membership of the society has steadily grown over the past 15 years.

Pediatric Nephrology in New Zealand

The country is served by a single comprehensive pediatric nephrology service based in the largest city, Auckland. It provides the entire range of diagnostic services and renal replacement therapy. There is presently a ratio of 1 specialist per 318,000 children under the age of 15 years. The service undertakes outreach clinics to all main centers and provides long distance care to children with end stage renal disease. The increasing use of telepediatrics has helped to improve access to nephrology care around the country. A nationwide network of general pediatricians with an interest in pediatric renal diseases, assist in the management of children with renal disease. Since 1998, a regular program of biennial workshops in pediatric nephrology and transplantation has been held to assist in the continuing education of pediatricians.

Epidemiology of Childhood Renal Disease in New Zealand

Glomerular Diseases

New Zealand has a high incidence of post streptococcal glomerulonephritis affecting mainly Maori and Pacific Island children. Lennon et al. (1), published an epidemiologic longitudinal study of rheumatic fever and APSGN in Auckland and estimated the rates were in excess of 100 per 100,000 age appropriate population amongst Maori and Polynesian Pacific Islanders. She calculated the overall prevalence rate for Auckland children at 16 per 100,000 with the rates of 50.5 and 46.5 for Maori and Pacific Island children respectively. A number of retrospective studies over the past 25 years have shown this to be a continuing problem. A prospective nationwide study is presently being conducted to determine precise incidence and prevalence rates.

The incidence of chronic glomerulonephritis in adult Maoris and Pacific Islanders was found to be significantly higher than in adults of European descent (2). A retrospective biopsy series of children with nephrotic syndrome by Simpson et al. (3) showed that there was an increased incidence of membranoproliferative glomerulonephritis, post streptococcal glomerulonephritis and focal segmental glomerulosclerosis (FSGS). Maori children were more likely to have membranoproliferative glomerulonephritis followed by minimal change disease, whereas Caucasian and Pacific Island children tended to have minimal change disease followed by FSGS. It was also of interest that lupus nephritis occurred predominately in Maori and Pacific Island children.

A prospective nationwide surveillance study of idiopathic nephrotic syndrome in children showed that the incidence is 1.9 children per 100,000 under the age of 15 years with no significant difference between ethnic

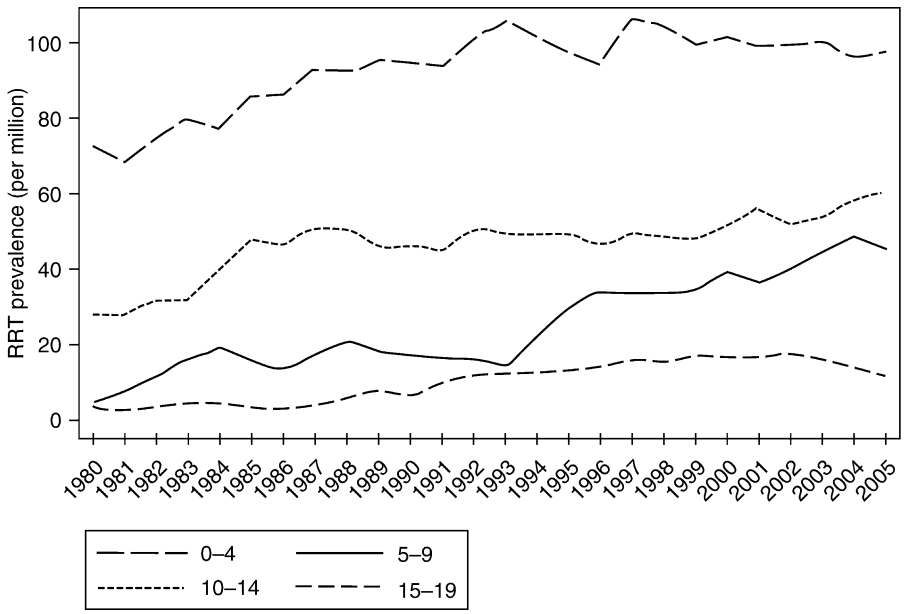
groups (4) (*Fig. 84-1*). Eighty percent were steroid responsive. Three quarter of those biopsied showed minimal change disease and 17% were focal segmental glomerulosclerosis (FSGS). The proportion of children with FSGS was the same as that reported by Simpson et al. in their retrospective biopsy study (3) (*Fig. 84-2*).

Congenital nephrotic syndrome in New Zealand also appears to have different natural history to that described in Finland and other countries in the Northern Hemisphere. Affected infants tend to become less proteinuric with increasing age with a much later onset of chronic renal failure. Recent mutation analysis of a group of eight

Figure 84-3

Prevalence of renal replacement therapy in Australia in age 0–19 from 1980 to 2005 (ANZDATA registry report 2006) (6).



children revealed that five had mutations which had not been previously described. There was however a common haplotype associated with a novel *p.R711S* mutation supporting a founder effect (5).

Acute Renal Failure in New Zealand

Beyond the first 3 months of life, hemolytic uremic syndrome (HUS) is the most common cause of acute kidney injury requiring acute renal replacement therapy (*Fig. 84-3*). A 10 year prospective study of HUS in New Zealand by the author showed 82% were diarrhea related with 75% of the cases occurring in the upper North Island of New Zealand. *E coli* 0157 was the most common serotype identified. Pneumococcal sepsis was the most common cause of non diarrhea related HUS. The annual incidence of diarrhea associated HUS was 1.1 per 100,000 in children under the age of 5 years and 0.8 per 100,000 in children under 15 years of age. No seasonal relationship was observed in contrast to the North Hemisphere. Mortality in diarrhea related HUS is 1% and pneumococcal HUS is 8% (unpublished observations).

Pediatric Renal Care in Australia

Currently there are seven pediatric renal centers in the five larger states of Australia. In addition Tasmania is served by Victoria and the Northern Territory is served by South Australia. All centers are based at the major pediatric teaching hospitals in their state and each provides comprehensive diagnostic and therapeutic services for children with acute and chronic kidney disease, including acute and chronic dialysis and transplantation. Most centers have a team including 2–4 nephrologists, renal nurses, dieticians, and social workers. There are differing models of care across the different states with on-site hemodialysis available in most units. In others, dialysis services are offered in affiliation with associated adult facilities.

Acute Care

In addition to hemodialysis and peritoneal dialysis, treatment of acute renal failure frequently involves the use of continuous veno-venous hemofiltration. This is delivered in pediatric intensive care units by intensivists and nephrologists. There has been a shift from the use of

systemic anticoagulation with heparin to local anticoagulation with citrate.

Peritoneal dialysis is delivered almost exclusively as continuous cycling peritoneal dialysis using a number of platforms and is utilized as the primary mode of dialysis in young children and for patients in remote locations. Hemodialysis is largely delivered "in center" Occasionally older adolescents, and rarely smaller children, are treated with home hemodialysis. Home therapies have been developed in some centers with increasing expertise in appropriate blood volume monitoring.

Transplantation is largely done in pediatric centers with dedicated transplant surgeons. The majority of donors are living related, with an increasing number of nonparental donors including aunts, uncles and grandparents. An increasing number of donor kidneys are harvested laparoscopically.

Transplantation Outcomes

All renal transplants in Australia and New Zealand are reported and followed six monthly by the ANZDATA registry (www.anzdata.org.au). Thus all pediatric data on renal transplants have been collected since 1963. The outcomes for children transplanted between 1963 and 2002 have been reported. The long-term survival rate among children requiring renal-replacement therapy was 79% at 10 years and 66% at 20 years. Mortality rates were 30 times as high as for children without end-stage renal disease. Dialysis was associated with a four fold risk compared to renal transplantation. Transplant outcome results have improved steadily over this time (7).

Etiology of Renal Disease

Australia and New Zealand both have a similar profile of renal disease with younger children presenting with renal dysplasia, structural renal anomalies including posterior urethral valves, and congenital renal disease, and older children presenting with glomerulonephritis secondary to systemic disease such as SLE. Increasingly there has been recognition of the growing number of cases with a genetic basis including ARPKD, cystinosis and CAKUT (8) (*Tables 84-1* and *84-2*). There is also increasing recognition of familial and genetic forms of nephrotic syndrome leading to renal failure with identification of WT-1, podocin, nephrin and LAMB-2 mutations in children in Australia and New Zealand (9–11). Like NZ, Australia has a significant proportion of postinfectious glomerulonephritis including poststreptococcal glomerulonephritis which particularly is endemic in indigenous aboriginal communities. In indigenous communities renal failure occurs at some of the highest rates in the world. and There is great interest in establishing whether unique genetic or acquired conditions in aboriginal children such as postinfectious GN may contribute to this high prevalence of chronic kidney disease. HUS has also been a major cause of ARF and has been associated with epidemics. The most severe outbreak was reported from Adelaide and associated with contaminated salami (12).

Immunosuppression

The majority of pediatric transplants receive a calcineurin inhibitor, mycophenylate mofetil, steroids and an IL-2R

Table 84-1

Causes of end stage renal disease 1996–2005 in Australia and New Zealand (ANZDATA registry report 2006) (6)

Table 84-2

Causes of end stage renal failure by age group in Australia and New Zealand, 2000–2005 (ANZDATA registry report 2006) (6)

Causes of end stage kidney disease by age group 2000–2005					
Primary renal disease	Age groups				Total
	0–4	5–9	10–14	15–19	
Glomerulonephritis	3(6)	15(21)	19(28)	74(44)	111(31)
Familial glomerulonephritis	–	–	2(3)	10(6)	12(3)
Reflux nephropathy	1(2)	6(8)	3(4.5)	32(19)	42(12)
Polycystic kidney disease	–	3(4)	3(4.5)	1(<1)	7(2)
Medullary cystic disease	1(2)	3(4)	5(7)	8(5)	17(5)
Posterior urethral valve	12(24)	6(8)	6(9)	6(4)	30(8)
Haemolytic uraemic syndrome	–	2(3)	1(1)	3(2)	6(2)
Hypoplasia/dysplasia	14(28)	14(20)	10(15)	1(<1)	39(11)
Diabetes	–	–	–	1(<1)	1(1)
Cortical necrosis	3(6)	2(3)	3(4.5)	4(2)	12(3)
Interstitial nephritis	–	1(1.5)	–	6(4)	7(2)
Cystinosis	–	4(6)	3(4.5)	–	7(2)
Uncertain	1(2)	1(1.5)	4(6)	5(3)	11(3)
Miscellaneous/other	15(30)	14(20)	9(13)	17(10)	55(15)
Total	50(100)	71(100)	68(100)	168(100)	357(100)

Values in parentheses indicate percentages

antagonist. A number of patients have been switched to Rapamycin (13). Acute rejection has become much less common. However, infectious problems including BK virus have increased (14).

Research

Throughout ANZ there has been a strong interest in clinical and basic research in pediatric nephrology and transplantation (*Fig. 84-4*). This has included research into the antecedents of renal disease in aboriginal communities, the establishment of the renal Cochrane library based in Australia and New Zealand, the development and participation in clinical trials related to CMV prophylaxis and treatment with erythropoietin and antibody prophylaxis for urinary tract infection (the PRIVENT trial). A number of studies derived from the ANZDATA registry including adolescent outcomes and the development of chronic allograft nephropathy in pediatric patients have been reported (15). In basic science there have been a number of studies related to mechanisms of fibrosis, the development of tolerance strategies involving Tregs, dendritic cells and mesenchymal stem cells as well as direct patient studies in children with ESRD, and following transplantation (16, 17). Increasingly there have been genetic studies aimed at the identification of known renal genetic defects and discovery of novel disease genes. A Kidney Gene Bank has been established to facilitate such studies. Finally work on clinical outcomes such as growth and long term outcomes such as cardiac disease in renal failure and post transplantation in children have been studied in Australia and New Zealand (18–20).

Training

Pediatric nephrology training is offered at a number of the centers and attracts both local and overseas trainees. In addition there has been a long history of nephrology training post fellowship overseas in North America and Europe, particularly in the UK.

Figure 84-4

Stars show the eight pediatric nephrology centers in Australia and New Zealand.

85 Pediatric Nephrology in Asia

Hui-Kim Yap · Arvind Bagga · Man-Chun Chiu

Overview

Asia is the largest continent in the world with an estimated population approaching 4 billion, of which children under the age of 19 years constitute more than 1 billion (1). Moreover, Asia includes the world's most populated countries, China and India. Unfortunately, health care delivery across the Asian continent is very heterogeneous. Childhood mortality and morbidity are important indicators of the quality of health care delivery. Most childhood deaths occur in less developed countries and poorer sectors of the community in more developed countries, reflecting enormous disparities among different geographical areas and population groups. The more urgent issues in child health in many Asian countries encompass the control of infections, malnutrition and diarrheal diseases. However, with improvements in public health especially in urban communities, the pattern of childhood disorders has changed, resulting in a shift in the causes of mortality from infections to other chronic diseases. Although the major challenges in pediatric nephrology practice still include the management of children with acute kidney injury due to severe dehydration, sepsis and toxins, the prevention and treatment of children with chronic kidney disease is emerging as the new challenge for this millennium.

The first Working Group for Pediatric Nephrology in Asia was formed in 1986, and the first scientific meeting addressing the "Epidemiology and Treatment of Renal Diseases in Asian Countries" was held in Tokyo, Japan in 1988. The Asian Society of Pediatric Nephrology (AsPNA) was officially inaugurated in 1996 with members from 10 Asian countries/regions. Its mandate was to promote the development of pediatric nephrology in Asia and foster regional cooperation amongst member countries. With regional education and training as one of the main focus, quality care including both acute and chronic renal replacement therapies, as well as strategies for the prevention of chronic kidney disease, will be available more widely to the pediatric population in Asia. Currently, the AsPNA has 15 member countries from East Asia, South Asia and South-East Asia, and further expansion with representation from West Asia, in particular the Middle East, will enable AsPNA to extend its mission throughout the continent.

Data on childhood end-stage renal disease in Asia are scarce. A survey on renal replacement therapy by Chiu et al. in 2005 which included 12 Asian countries, namely, China, Hong Kong SAR, India, Indonesia, Japan, Malaysia, Pakistan, Philippines, Singapore, South Korea, Taiwan, and Thailand, reported 2,874 cases on renal replacement therapy (2). Among the 1,033 reported cases of renal transplants, 63.5% were from live donors and 36.5% were from deceased donors. Patient survival rates were 98 and 92% at 1 and 5 years respectively, while kidney graft survival rates were 92 and 81% at 1 and 5 years respectively, comparable to those of the North American Pediatric Renal Transplant Collaborative Studies (NAPRTCS) for the same period.

Children on chronic peritoneal dialysis were predominantly on continuous ambulatory peritoneal dialysis (64%), followed by automated peritoneal dialysis (30%) and intermittent peritoneal dialysis (6%). Chronic hemodialysis was more commonly practiced than peritoneal dialysis in a few countries such as Indonesia, Pakistan, Philippines, Malaysia, and Taiwan. Other than center preference and funding, this might also be related to the inclusion of adolescents. On the whole, renal replacement therapy is expensive and financial support is an important issue in the care of children with end-stage renal disease, especially in the developing countries. On the other hand, in the more developed centers in Asia, overall graft survival, peritonitis rates and provision of renal replacement therapy are quite comparable to global standards.

East Asia

China

China is a vast country with a 1.3 billion population, 28.6% of which are 19 years and below. In recent years, the country has experienced rapid economic growth and development, including that of health care. However, distribution of health resources still varies greatly, especially between urban and rural areas. Unfortunately, prevalence

© Springer-Verlag Berlin Heidelberg 2009

data on childhood renal diseases are lacking. A national project supported by the Ministry of Science and Technology to study the nephro-urological abnormality rates in urban children is presently underway.

Retrospective studies on hospitalized children with renal diseases are being conducted to help understand the epidemiology of childhood renal diseases in China. Some of the completed studies examined renal diseases requiring hospitalization (3), systemic lupus erythematosus, acute renal failure (4), renal biopsy findings (5), and glomerular diseases (6). A nationwide urinary screening program in children aged 2–14 years showed that 0.85% of 224,291 children screened had urinary abnormalities, including asymptomatic hematuria, nephritis, urinary tract infection, asymptomatic bacteriuria, urinary stones, hydronephrosis, and urinary malformations (7). Another urinary screening program done among school children in Shanghai showed a 1% prevalence of urinary abnormalities (8).

The Chinese Society of Pediatric Nephrology conducted a retrospective analysis of children from 91 hospitals admitted with chronic renal failure from 1990 to 2002 (9). Using a criterion of creatinine clearance less than 50 ml/min per 1.73 m^2, 1,658 hospitalized children were diagnosed with chronic renal failure during this period, giving a mean prevalence of 1.25% of hospitalized children with renal diseases. Onset of renal failure was mainly at school-age. There was a significant increase in number of cases admitted with chronic renal failure comparing the two 6-year periods from 1990 to 1996 and 1997 to 2002. The main primary renal diseases causing chronic renal failure were chronic glomerulonephritis and nephrotic syndrome (52.7%). One-third of all cases were congenital and hereditary renal diseases, with hypoplastic or dysplastic kidneys comprising the majority. Most of the patients were managed conservatively and only 15.8% received renal replacement therapy. Hemodialysis (66.5%) was the predominant dialysis modality. Only 29 of the dialyzed patients underwent renal transplantation, with a 1-year graft survival of 93.1%. The mortality of patients with chronic renal failure over the 13-year review period was approximately 10%, with cardiac failure, infections and uremia being the main causes.

A nationwide retrospective study from 33 hospitals on IgA nephropathy in 2006, reported a total of 1,349 cases of renal biopsy-proven IgA nephropathy in children 1–14 years of age (10). This accounted for 1.37% of the hospitalized nephro-urological diseases and 11.8% of renal biopsies. Family history of renal disease was present in 9.31% cases of IgA nephropathy. Renal pathology studies showed that the majority of IgA nephropathy were graded as WHO class III (41.4%) and class II (28.51%). No standard treatment regimen was utilized to treat these children.

Hong Kong Special Administrative Region (SAR)

Hong Kong SAR has a population of 6.86 million of which 1.20 million are 19 years and under. The health care system in Hong Kong is quite different from that in mainland China. About 90% of patients requiring hospitalization are in public hospitals which are heavily subsidized, with the remaining 10% in private hospitals. Children with renal diseases are cared for in most major public hospitals. A pediatric renal center for dialysis and transplantation has been established since 1999, offering children with chronic renal failure a centralized multidisciplinary end-stage renal disease program.

The Hong Kong Society for the Study of Kidney Diseases was formed in the 1980s to bring together pediatricians working on pediatric renal diseases to promote the specialized practice of pediatric nephrology. Several surveillances and a renal registry have been set up for hospitalized pediatric renal patients. It had been reported that the number of new cases per year of nephrotic syndrome, lupus nephritis, cystic kidney diseases, and hereditary tubular disorders were 57, 10, 12, and 2 respectively, and an average of seven new cases per year of chronic renal failure with glomerular filtration rate lower than 25 ml/1.73 m^2/min were seen in children under 15 years old (11). A collaborative multi-center study on primary nocturnal enuresis involving 105 Chinese children showed that the combined use of an enuresis alarm and oral desmopressin was most effective and yielded a lower relapse rate than any other regimen (12). Another multicenter study of 128 Chinese children with lupus nephritis showed that 70% of the patients had Class III and IV nephritis and this series of Chinese children had a good medium term survival rate and chronic morbidity rates which were similar to that reported in the Caucasian population (13).

The incidence of end-stage renal disease in children younger than 15 years of age was estimated to be four per million children in the early 1990s (14). The common causes were chronic glomerulonephritis (26%), hypoplastic or dysplastic kidneys (18%), chronic pyelonephritis (18%) and hereditary or familial diseases (9%). In recent years, according to the electronic Hong Kong Renal Registry, the incidence and prevalence for those less than 20 years of age with end-stage renal disease (ESRD) was

about 5 and 28 per million children respectively. ESRD was six times more common in children between 11 and 20 years of age compared to younger children (15).

Continuous ambulatory peritoneal dialysis was started in the 1980s, and since 1996, automated peritoneal dialysis has been the modality of choice to nearly all children on chronic peritoneal dialysis. In a recent review on 30 children on automated peritoneal dialysis, a relatively low peritonitis rate of 1 in 54.2 patient-months was reported (16). Chronic hemodialysis was offered to older children or those deemed clinically unsuitable for peritoneal dialysis. Although available for young children below the age of 3 years, vascular access remains a major challenge. A review of the outcome of 25 transplanted kidney grafts in 2004 showed that 1 and 3-year actuarial graft survival rates were 93.8 and 70.3% for cadaveric grafts, and both 100% for live donor grafts respectively (17). A recent review in 2007 of 61 grafts including 37 cadaveric and 24 live donor grafts, the overall 5-year patient and graft survival rates were 100% and above 90% respectively. Even the 18 transplanted adolescents (age 13–17 years) had excellent 5-year graft survival rate at 90% (18).

South Korea

South Korea has a population of 47 million, of which 24.4% are younger than 19 years of age. There are 37 pediatric nephrologists giving a ratio of approximately 1:140,000 pediatric population. A nationwide hospital discharge survey of pediatric patients less than 18 years old was conducted in 2007. Of 826,896 patients hospitalized between 2004 and 2006, diseases of the genito-urinary system accounted for 4.1%. Urinary tract disorders (45.8%), glomerulopathies (17.3%) and tubulo-interstitial diseases (10.6%) were the main underlying etiologies. The common renal presentations of glomerular diseases were nephrotic syndrome (40.6%), recurrent and persistent hematuria (33.1%) and unspecified nephritic syndrome (17.4%).

A national surveillance system for diarrhea-associated hemolytic uremic syndrome has been in operation since 2003 by the Korean Society of Pediatric Nephrology in concert with the Korea Center for Disease Control. The nationwide annual incidence is about 20 per 9.6 million children under the age of 15 years. More than 80% of the patients were younger than 6 years old, and about a quarter underwent dialysis for acute renal failure. The overall mortality rate was 6%.

The Korean Society of Pediatric Nephrology established a web-based pediatric chronic kidney disease registry in 2004. The registry includes data of patients with chronic kidney disease stages 3–5, including transplantation. More than 530 children were enrolled in the registry by the end of 2007.

In Korea, the school screening program for urinary abnormalities has been mandated by law since 1998. Over 5 million students have been screened since its inauguration. Isolated proteinuria was detected in 0.2%, occult blood in 0.8%, and glucosuria in 0.07% from January 1998 to December 2004 (19). Of the patients referred for renal biopsy, 63.1% had isolated hematuria, 10.5% isolated proteinuria and 69.9% hematuria with proteinuria. Histopathological findings included IgA nephropathy in 43.8%, mesangial proliferative glomerulonephritis in 38.4%, Henoch-Schönlein nephritis in 2.7%, membranoproliferative glomerulonephritis in 1.6%, lupus nephritis in 0.5% and Alport syndrome in 0.6%.

Taiwan

Taiwan has a population of 22,973,622 with more than 5 million in the pediatric age group 19 years and below. A biannual mass urinary screening of elementary and junior high school students has been in operation in 1990. Results from the screening of 2.6 million children showed that 0.10 –0.35 had proteinuria and 0.07–0.21 had hematuria. In a retrospective evaluation for prevalence of proteinuria and chronic renal insufficiency to identify factors related to disease progression, 10,288,630 urinary screenings of elementary and junior high-school students were reviewed (20). The 4-year prevalence of proteinuria was higher in girls than in boys, however, the disease progression to chronic renal insufficiency was higher in boys. Further analysis showed that persistent serum cholesterol greater than 220 mg/dl, serum albumin level lower than 3.5 g/dl, total protein greater than 6 g/dl, and diastolic blood pressure higher than 90 mmHg were significant risk factors for disease progression. Therefore early detection of heavy proteinuria by mass urinary screening with early appropriate treatment, and monitoring of significant risk factors were considered helpful to decrease or delay progression to chronic renal failure.

Genetic studies in Taiwan on gene polymphisms associated with severity of vesico-ureteric reflux showed that C3123A of the angiotensin-2 receptor gene was associated with both the development and severity of vesicoureteric reflux in 100 children (21). Studies on HLA class I gene polymorphisms in Taiwanese children with steroid-sensitive nephrotic syndrome showed that the frequency of A11, B39, B48, B60, B62, CW4 and CW7 were

significantly higher than controls, suggesting that the immunogenetic background of steroid-sensitive nephrotic syndrome in Taiwanese children may be different from other populations (22).

In a survey of dialysis and kidney transplantation in patients under the age of 21 years, 110 patients were on chronic peritoneal dialysis, 264 patients on chronic hemodialysis, and 161 were transplanted. For patients on chronic peritoneal dialysis, namely continuous ambulatory peritoneal dialysis and automated peritoneal dialysis, the peritonitis rate was 1 in 24.5 patient-months. The majority of patients (95.5%) on chronic hemodialysis have arterio-venous fistulae as vascular access, with the remaining (4.5%) using permanent catheters. With regards to kidney transplantion, there were 135 cadaveric transplants (83.8%) and 26 live donor transplants (16.2%). The 1 and 3-year graft survival rates were 100 and 87.7% respectively; and the 1 and 3-year patient survival rates were 100 and 94.4% respectively.

South Asia

Bangladesh

Bangladesh has a population of 153 million, with close to 66 million children in the pediatric age group 19 years and under. There are only 14 certified pediatric nephrologists in the country, or one pediatric nephrologist per 5.7 million children. During the last two decades of the twentieth century, there was an outbreak of acute renal failure with very high mortality. Epidemiological investigations incriminated ingestion of paracetamol syrup contaminated with diethylene glycol as the cause (23). Another study (1988–1992) reported a mortality rate of 77% in 1,837 children with acute renal failure (24). Diarrheal losses were the most common cause of ischemic acute kidney injury. Poverty, illiteracy and ignorance were responsible for delays in seeking medical advice and the resultant lack of adequate treatment contributed to the high mortality. Diarrhea-related hemolytic uremic syndrome was also an important cause of renal failure (25). The incidence of acute renal failure secondary to these causes has now declined.

Although there is no national registry of childhood diseases, hospital records show that nephrotic syndrome constituted the major cause of admissions to the pediatric nephrology ward during 2005–2007, with 12% having steroid-resistant nephrotic syndrome. Obstructive uropathy and hydronephrosis (7%), chronic renal failure (6%), urinary tract infection (5%) and acute glomerulonephritis (4%) comprised the other causes. The chief causes of chronic kidney disease stage 4 and 5 in 106 patients admitted to Bangabandhu Sheikh Mujib Medical University (BSMMU, Dhaka) during 2005–2007, were posterior urethral valves, unilateral hydronephrosis, neurogenic bladder, glomerulonephritis and lupus nephritis.

Dialysis facilities are available at BSMMU, Bangladesh Institute of Child Health and National Institute of Kidney Diseases & Urology, but kidney transplantation for children is only available in one facility, at BSMMU. Regulations for kidney transplantation were enacted in 1999, with provision for live-related donation.

India

India has close to 1.15 billion people in 2008, with children 19 years and below comprising about 40% of the population. A network of state-managed health centers, and district and referral hospitals has been in place for more than 45 years. The resources available at those centers are often limited, and a large proportion of the population obtains medical care through a parallel private sector. The Indian Society of Pediatric Nephrology has more than 300 active members and has published national guidelines for management of nephrotic syndrome, urinary tract infections, hematuria, hypertension and antenatally detected hydronephrosis (26–30). A Chronic Kidney Disease Registry has also been formed.

Idiopathic nephrotic syndrome is a common problem, although its exact incidence is unknown. The clinicopathological features and response to therapy are similar to those reported from developed countries. However, the incidence of serious infections, which complicate the course of the illness, is higher (31). Levamisole has been found effective and safe, and is widely used as a steroid-sparing agent for patients with frequent relapses and steroid dependence (32). Case series also support the utility of mycophenolate mofetil as an effective medication for these patients (33). The therapy of patients with steroid-resistant nephrotic syndrome is challenging and limited by economic factors. Treatment with intravenous dexamethasone, which is less expensive, has been found as effective as methylprednisolone for inducing remission in these patients (34). Therapy with intravenous "pulse" cyclophosphamide has been used with promising results (35, 36). A multicentre study examining the efficacy and safety of tacrolimus with intravenous cyclophosphamide in patients with steroid-resistant nephrotic syndrome is currently underway.

The incidence of poststreptococcal acute glomerulonephritis, high during the 1970s, has gradually declined. Acute kidney injury caused by severe hypovolemia

from acute gastroenteritis has also decreased due to the widespread use of oral rehydration therapy (37). Acute intravascular hemolysis in individuals with glucose-6-phosphate dehydrogenase deficiency, snakebite and leptospirosis in coastal regions and rural areas, and malaria are important causes of acute renal failure. While diarrhea-associated hemolytic uremic syndrome was the most common cause of acute renal failure in the 1990s (38), its incidence has also declined. Clinical and epidemiologic evidence suggests that most patients with typical hemolytic uremic syndrome are associated with infection due to *Shigella dysenteriae*; infection caused by verotoxin producing *Escherichia coli* is rare in the Indian subcontinent. Perinatal asphyxia, septicemia and injudicious use of medications are important causes of acute kidney injury in the newborn period. Peritoneal dialysis is the most commonly used dialysis modality for children with acute renal failure.

The incidence of hepatitis B nephropathy is low, although the carrier rate of hepatitis B antigenemia is 1.5–2%. The incidence of familial and genetic disorders, collagen vascular diseases, IgA nephropathy and renal tubular disorders is similar to that in developed countries. Takayasu disease (idiopathic aortoarteritis) is an important cause of hypertension in children (39).

The chief causes of chronic renal failure include obstructive uropathy, reflux nephropathy and chronic glomerulonephritis (40). The management of patients with progressive kidney disease is challenging. Although facilities for dialysis and renal transplantation are available in all metropolitan cities, their utilization is limited by socioeconomic factors (41, 42). The Human Organ Transplantation Act became law in 1994, but the cadeveric transplant program is not well developed. Most of the live donor transplants are from parents, most often the mothers (42). Neither the state nor insurance companies subsidize the costs of therapy, which are high especially in relation to per capita income.

Pakistan

The population of Pakistan is estimated as 168 million with a pediatric population 19 years and under comprising 48%. Pakistan has a large rural population (66%) that is served by inadequate medical facilities. Larger cities with university hospitals have well-equipped centers. In 1997, the Pakistan Pediatric Nephrology Group was formed under the umbrella of the Pakistan Pediatric Association. It has approximately 100 members, including pediatricians with special interest in nephrology.

Nephrotic syndrome is one of the most common renal diseases seen in the country (43). Its clinical features and response to steroid therapy are similar to those in developed countries. Recurrent infections, affecting the upper respiratory and gastrointestinal tracts, are associated with frequent relapses (44). The seroprevelance of hepatitis B virus is high in Pakistan, but its association with nephrotic syndrome has not been demonstrated. Post-streptococcal acute glomerulonephritis has shown a decline compared to that in previous studies, while renal calculi are recognized more frequently (45). Vesicoureteric reflux and posterior urethral valves are the most common structural abnormalities, accounting for 60% of congenital anomalies of the urinary tract.

Urolithiasis is an important cause of renal morbidity, particularly in southern parts of the country. The province of Sindh has the highest prevalence of stone disease in the world, attributed to multiple factors, including hot and humid climate, inadequate fluid intake, consumption of a chiefly cereal-based diet, and recurrent diarrhea in malnourished children (45). Urolithiasis is an important cause of acute and chronic renal failure (46) and was responsible for end-stage renal failure in 20% children who underwent renal transplantation (47).

Of 4,392 patients in the National Dialysis Registry, 2.3% were less than 15 years old (48). Approximately 15 centers provide facilities for peritoneal dialysis and evaluation of children with renal problems; facilities for hemodialysis are limited to five centers. The majority of pediatric kidney transplants are performed at the Sindh Institute of Urology and Transplantation (Karachi). An act governing "Transplantation of Human Organs and Tissues" became law in 2007, whereby deceased donor organ transplants were legalized and live unrelated donor transplants declared illegal.

Sri Lanka

Sri Lanka has an estimated population of 21 million, with the population 19 years and under comprising 32%. Based on hospital records and published reports, urinary tract infections are an important cause of renal disease in children. Post-streptococcal acute glomerulonephritis is common in rural areas, though the overall incidence is decreasing. The spectrum and course of nephrotic syndrome is similar to that reported in developed countries. The majority of children with nephrotic syndrome in Sri Lanka respond to corticosteroid therapy. However, the proportion of children with steroid-resistant disease has increased significantly over the past two decades.

Nephrotic syndrome due to other diseases and syndromes are uncommon. The chief cause of acute kidney injury requiring dialysis is diarrheal dehydration or shock. The incidence of diarrhea-related hemolytic uremic syndrome has also declined.

Efforts have been made to maintain a registry of patients with chronic renal failure in the country. Congenital abnormalities account for the majority of patients with chronic kidney disease. Focal and segmental glomerulosclerosis, nephrocalcinosis, reflux nephropathy and hemolytic uremic syndrome are other causes. Pediatric renal transplants are done at the Teaching Hospital, Peradeniya. Since September 2004, 27 live donor transplantations have been performed. Since facilities for dialysis are limited, most transplants are preemptive.

South-East Asia

Indonesia

Indonesia is a densely-populated nation with more than 235 million people, and a pediatric population 19 years and under of more than 88 million. The ratio of pediatric nephrologists to the pediatric population is approximately 1:3,684,210 with 19 trained pediatric nephrologists. Based on a multicentre study in 2000–2004 involving seven pediatric institutions, the top three kidney diseases affecting children were nephrotic syndrome (35%), acute post-streptococcal acute glomerulonephritis (26%), and urinary tract infections (23%). Other renal disease entities from most to least common included acute renal failure, chronic renal failure, nephrolithiasis, enuresis, and congenital renal disease. Urinary incontinence was an increasingly recognized problem. The underlying etiologies identified were spinal dysraphism, malignant osteolytic vertebral lesions, non-neurogenic neurogenic bladder and anatomical abnormalities. More than 50% of these children developed chronic renal failure (49).

Among the causes of acute renal failure in older children, jengkol bean intoxication was an important cause, accounting for 31% of children hospitalized for acute renal failure in a large general hospital in Jakarta (50). Jengkol bean is widely consumed in Indonesia, especially in rural areas. The pathophysiologic mechanism of kidney injury include obstruction of renal tubules by jengkolic acid crystals, as well as a direct toxic effect on renal tubular cells.

Studies on frequent relapsing nephrotic syndrome in Indonesia children have shown an association with certain HLA class II haplotypes, including HLA-DRB1*12 (protective haplotype) and DQB1*02 (at risk haplotype) (51). Other studies in Indonesian children on genetic variants of the Th2 cytokine genes IL-13 and IL-4 showed some association with minimal change nephrotic syndrome (52).

Malaysia

Malaysia has a population of approximately 25 million, of which more than 40% are 19 years and under. Pediatric nephrology services in Malaysia, similar to other pediatric subspecialities, are provided on a regional basis across the country. The Ministry of Health of Malaysia has set a norm of one pediatric nephrologist for every 300,000 children, which translates to 33 pediatric nephrologists for the country. In 2007, Malaysia has about 10 trained pediatric nephrologists in institutional practice.

Based on the National Renal Biopsy Registry, primary glomerular disease accounted for 51% of all biopsies and secondary glomerular disease 44%. The main primary glomerular diseases seen include focal segmental glomerulosclerosis in 62%, and minimal change disease in 26%. Lupus nephritis accounted for 58% of renal biopsies done for secondary causes of glomerular disease, followed by post-infectious acute glomerulonephritis at 30% and Henoch-Schönlein at 10%. Proliferative features (WHO class III or IV) constituted 82% of the cases of lupus nephritis.

The incident and prevalent rate of treated end-stage renal failure in patients younger than 20 years of age has been about 8 and 54 per million age-related population respectively in 2006 (53). Transplant rate was at two per million age-related population. Glomerular diseases excluding lupus nephritis accounted for 42% of all new cases of end-stage renal failure, with lupus nephritis accounting for 8%.

Philippines

Philippines has a population of approximately 93 million, of which more than 40% are children under the age of 19 years. There are 63 pediatric nephrologists per 39 million children under the age of 15 years in the country. The Philippine Nephrology Society of the Philippines study group, comprising the four training institutions for pediatric nephrology in the country, examined the distribution of kidney and urinary tract diseases referred to accredited tertiary medical centers. Unpublished data from January 1995 to December 2007

showed a total of 15,057 admissions for pediatric nephrology. The top renal causes for admissions included primary nephrotic syndrome (20%), post-infectious acute glomerulonephritis (9.5%), acute and chronic renal failure (18.5%), complicated and uncomplicated urinary tract infections (15.7%), bladder dysfunction (8.6%), secondary glomerulonephritis (6%) such as systemic lupus erythematosus, Henoch-Schönlein purpura, hypertension and renal tubular diseases (5.5%), IgA nephropathy (1.9%), tumors (1.7%), congenital or inherited disorders (1.6%), and urolithiasis (0.7%).

From 2003 to 2007, a total of 291 pediatric patients were diagnosed to have end stage renal disease. Peritoneal dialysis remained the renal replacement therapy of choice (71.4%) compared to hemodialysis (28.6%). Unpublished data from the National Kidney and Transplant Institute, Department of Pediatric Nephrology showed that from 1984 to 2007, there were 94 pediatric kidney transplants in children aged 0–15 years. The majority of these transplants was from live-related donors (65%), followed by live non-related donors (19%) and cadaveric donors (16%).

Singapore

Singapore has a population base of 4.6 million, with the pediatric population 19 years and under comprising 20%. The country has a ratio of approximately 1:360,000 pediatric nephrologists in institutional practice to pediatric population. Over the last two decades, the pattern of renal diseases in Singapore children has changed drastically. Similar to other South-East Asian countries, post-streptococcal acute glomerulonephritis was the most common type of glomerulonephritis. However, like its counterpart acute rheumatic fever, post-streptococcal acute glomerulonephritis is a disease that is known to be influenced by socioeconomic and environmental factors. Singapore's rapid urbanization in the 1970s to 1980s resulted in a decrease in significant streptococcal skin infections and a concomitant decrease in the incidence of acute glomerulonephritis (54). In fact, idiopathic nephrotic syndrome has taken on increasing prominence as a cause of morbidity in children with more than 60% developing steroid-dependency (55). Renal biopsy data showed that minimal change disease and focal segmental glomerulosclerosis were the major causes of steroid-dependent and steroid-resistant nephrotic syndrome in childhood (56).

Singapore has seen a change in the pattern and modalities of treatment of acute kidney injury in children. An 18-year study of children requiring acute dialysis showed that 91% were dialyzed for acute renal failure, while 9% had metabolic disorders (57). The main causes of acute kidney injury were ischemic injury (62.2%), hepatorenal syndrome (15.1%), acute glomerulonephritis (4.5%), hemolytic-uremic syndrome (7.6%) and obstructive uropathy (1.5%). Analysis of 146 infants and children dialyzed in the pediatric intensive care unit over the last 25 years revealed that dialysis was exclusively by the peritoneal route in the first 15 years, whereas continuous venovenous hemodiafiltration was the modality of choice over the last 10 years. This option allowed an increasing number of critically ill children to be dialyzed across all age groups. The overall mortality rate was 53%.

Data from the Singapore Renal Registry over the 10-year period from 1997 to 2006 showed that the age-specific standardized rate of end-stage renal failure in pediatric patients ranged from 4.5 to 13.5 per million population 19 years and under. The two leading causes of end-stage renal failure in pediatric patients were glomerulonephritis (33.4%), and congenital renal malformations (obstructive uropathy, renal hypoplasia/dysplasia and reflux nephropathy) (37.9%). The dialysis acceptance rate was 9.4 per million age-related population in 2006, with a dialysis prevalence rate of 28.1 per million age-related population. Peritoneal dialysis remained the preferred mode of dialysis, with more than 90% of pediatric end-stage renal failure patients on automated peritoneal dialysis. Data from the Singapore Renal Registry showed a transplant rate of 4.3 per million age-related population in 2006. The early 5-year cumulative survival of the pediatric patients with end-stage renal failure was excellent at 91% for dialysis patients and 88% for transplant patients. However, with longer periods of follow-up, survival of dialysis patients declined to 83% at 10 years as compared to a cumulative survival of 80% at 10 years for transplant patients. More than 90% of the pediatric transplants were live donor transplants, where the 1-year and 5-year allograft survival of 94 and 89% respectively.

Screening programs aimed at detecting renal disease at an early stage have been initiated in several Asian countries. Of 9,479 children screened in a pilot Singapore school screening program for urinary abnormalities, 1,048 or 11.1% were found to be positive for proteinuria on one dipstick examination. Further evaluation established that the prevalence of clinically significant proteinuria was 1.25 per 1,000 children screened, where about 90% was due to an underlying glomerulonephritis (58). Multivariate analysis looking at the predictors of proteinuria in the school population showed that low body weight, presence of persistent newly detected hypertension and lack of sports activity were significant predictors for persistent proteinuria (59). In fact, low body weight

was associated with a 1.8-fold greater risk for proteinuria after adjusting for confounding factors, suggesting that low renal mass together with additional environmental influences resulting in decreased body weight may result in earlier manifestation of renal disease.

Thailand

Thailand has a population of more than 65 million with approximately 30% in the pediatric age group 19 years and under. The country currently has 58 trained pediatric nephrologists, with an approximate ratio of 1:275,000 pediatric population. Common renal diseases seen include urinary tract infection, nephrotic syndrome, poststreptococcal acute glomerulonephritis, lupus nephritis and tropical acute renal failure. The most common histopathological cause of primary nephrotic syndrome in children is mesangial proliferative glomerulonephritis with IgM deposition. Common etiologies of tropical renal failure are dengue shock syndrome and wasp stings. The prevalence of chronic renal failure in children below 15 years of age is four per million age-related population. Congenital abnormalities of the kidney and urinary tract are the most common cause of chronic renal failure, with obstructive uropathies and renal hypoplasia or dysplasia forming almost 25% of the cases (60).

Systemic lupus erythematosus has a high prevalence in Thailand with about 150–200 new cases diagnosed each year. In a multi-center study involving 13 tertiary care hospitals between 2002 and 2006, the hospital admission rate for newly diagnosed pediatric patients with systemic lupus erythematosus was 1:754 children. Lupus nephritis was seen in 81% of these 500 patients. In a review of the clinicopathologic features of 82 pediatric patients with lupus nephritis, the age range at onset of disease was 2–12 years (61). Almost 50% had severe proliferative lupus nephritis (WHO class IV classification), with a patient mortality rate of 26% over 5 years, of whom 65% died of serious infections, 15% of cardiovascular complications, and 10% of end-stage renal disease. Cyclophosphamide was the main second-line immunosuppressive medication, either oral or intravenous administration, and infectious complications were noted in those patients who were maintained on concomitant higher doses of prednisolone (62).

Vietnam

Vietnam has a population of 86 million, of whom 36% are 19 years or under. Similar to the other South-East Asian nations, the common renal diseases in children include primary nephrotic syndrome, acute glomerulonephritis, lupus nephritis, urinary tract infection and congenital abnormalities of the kidney and urinary tract. Of the children with idiopathic nephrotic syndrome, 10% were corticosteroid-resistant. Pathologic findings frequently found in patients with corticosteroid-resistant nephrotic syndrome were focal segmental glomerulosclerosis, minimal change disease, and mesangial proliferation (63). Corticosteroid-resistant nephrotic syndrome was the main cause of end-stage renal failure. Five percent of children with nephrotic syndrome were secondary to systemic lupus erythematosus, Henoch-Schönlein purpura, hepatitis B, and malaria. Nephrotic syndrome in the first year of life is rare in Vietnam.

The most common cause of acute glomerulonephritis in childhood is poststreptococcal glomerulonephritis but its incidence appears to have declined in recent years. Other common causes of glomerulonephritis in Vietnam include IgA nephropathy lupus nephritis. Diffuse proliferative glomerulonephritis was found in 33% of renal biopsies (64–66). Methylprednisone, intravenous cyclophosphamide pulse therapy and mycophenolate mofetil have been used to treat severe cases.

The main causes of acute renal failure in Vietnam are septicemia and wasp and bee stings. Hemolytic uremic syndrome as a cause is rare. The chief causes of chronic renal failure include focal segmental glomerulosclerosis, obstructive uropathy, reflux nephropathy, and renal hypoplasia or dysplasia.
