Although suppression of FSH and LH is the primary mechanism by which COCs prevent ovulation, there are other mechanisms by which these hormones work to prevent pregnancy. Other mechanisms include reduced penetration of the egg by sperm, reduced implantation of fertilized eggs, thickening of cervical mucus to prevent sperm penetration into the upper genital tract, and slowed tubal motility, which may delay transport of sperm.¹ Thus, in addition to inhibiting ovulation, COCs induce changes in the cervical mucus and endometrium that make sperm transport and implantation of the embryo unlikely.¹

Table 48-2 contains a partial listing of the many oral contraceptives available in the United States today.⁸ Since the mid-1960s, EE has been the primary estrogen used in most COCs. However, the amount of EE used in COCs has decreased progressively since that time, and most now contain 35 mcg or less of EE. In addition, to reduce side effects and improve tolerability associated with oral contraceptive use, new progestins and different routes of administration have been explored. In an attempt to minimize the undesirable androgenic side effects associated with the progestins of COCs, the original synthetic progestins were modified to create “third generation” progestins (e.g., desogestrel and norgestimate), and newer progestins with anti-androgenic properties (e.g., drospirenone) have been discovered. Overall, the synthetic progestins found in today’s COCs are extremely potent in their ability to inhibit ovulation and prevent pregnancy.

COCs are available in monophasic, biphasic, triphasic, and quadruphasic preparations. Monophasic preparations contain fixed doses of estrogen and progestin in each active pill. Although all four preparations contain both estrogens and progestins, biphasic, triphasic, and quadruphasic preparations contain varying proportions of one or both hormones during the pill cycle. These preparations were introduced to reduce a patient’s cumulative exposure to progestins, as well as to mimic more closely the hormonal changes of the menstrual cycle. However, there is no evidence to suggest that the multiphasic preparations offer any significant clinical advantage over monophasic pills.⁸

Most traditional COCs are packaged as 21/7 cycles (i.e., 21 days of active pills and 7 days of placebo). However, newer regimens offer either fewer hormone-free days per traditional, 28-day pill cycle or extended (or in some cases continuous) cycles, which may allow for fewer withdrawal bleeds per year and fewer menstrual-related side effects (e.g., menstrual pain, bloating, headaches) for some women.

► Noncontraceptive Benefits of Combination Oral Contraceptives

In addition to preventing pregnancy, there are several non-contraceptive benefits associated with the use of COCs. Some of these potential benefits are highlighted next.

Table 48-2

Some Available Oral Contraceptives			Triphasic Preparations		
Brand Name	Estrogen (mcg/Tablet)	Progestin (mg/Tablet)			
Monophasic Preparations					
Junel Fe 1/20	EE (20)	Norethindrone acetate (1)	Estrostep Fe	EE (20, 30, 35)	Norethindrone acetate (1)
Loestrin Fe 1/20	EE (20)	Norethindrone acetate (1)	Tilia Fe	EE (20, 30, 35)	Norethindrone acetate (1)
Loestrin 24 Fe	EE (20)	Norethindrone acetate (1)	Tri-Legest Fe	EE (20, 30, 35)	Norethindrone acetate (1)
Microgestin Fe 1/20	EE (20)	Norethindrone acetate (1)	Enpresse	EE (30, 40, 30)	Levonorgestrel (0.50, 0.075, 0.125)
Alesse	EE (20)	Levonorgestrel (0.1)	Triphasil	EE (30, 40, 30)	Levonorgestrel (0.05, 0.075, 0.125)
Yaz	EE (20)	Drospirenone (3)	Trivora	EE (30, 40, 30)	Levonorgestrel (0.05, 0.075, 0.125)
Beyaz ^a	EE (20)	Drospirenone (3)	Enpresse	EE (30, 40, 30)	Levonorgestrel (0.05, 0.075, 0.125)

Norinyl 1 + 50	Mestranol (50)	Norethindrone (1)			
Biphasic Preparations					
Lo Loestrin Fe	EE (10, 10)	Norethindrone acetate (1, 0)			
Kariva	EE (20, 0, 10)	Desogestrel (0.15)			
Mircette	EE (20, 0,10)	Desogestrel (0.15)			

EE, ethinyl estradiol.

^aEach tablet also contains 451 mcg of levomefolate calcium.

Data from Anonymous. Choice of contraceptives: Treatment Guidelines from The Medical Letter. Med Lett 2010;8:89-96.

Reduction in the Risk of Endometrial Cancer The risk of endometrial cancer among women who have used oral contraceptives for at least 1 year is approximately 40% less than the risk in women who have never used oral

contraceptives.⁹ There is additional evidence to suggest this benefit is detectable within 1 year of use, and the reduced risk may persist for years following discontinuation of oral contraceptives.¹⁰

Reduction in the Risk of Ovarian Cancer When compared with women who have never used oral contraceptives, women who have used oral contraceptives for up to 4 years are 30% less likely to develop ovarian cancer. There is also additional evidence to suggest that the longer the duration of oral contraceptive use, the greater the reduction in the risk of ovarian cancer. Women who have taken oral contraceptives for 5 to 11 years are 60% less likely to develop ovarian cancer, and women who have taken oral contraceptives for more than 12 years are 80% less likely to develop ovarian cancer than those who have never used oral contraceptives. As with the reduced risk of endometrial cancer, there is evidence to suggest the reduced risk of ovarian cancer may persist for years following discontinuation of oral contraceptives.^{11,12}

Improved Regulation of Menstruation Women who take oral contraceptives typically experience more regular menstrual cycles. In general, oral contraceptive use is associated with less cramping and **dysmenorrhea**.^{1,8} Also, women who take oral contraceptives have a smaller volume of menstruum and experience fewer days of menstruation each month and consequently experience less blood loss with each menstrual period.^{1,13} Some studies suggest that oral contraceptive use decreases overall monthly menstrual flow by 60% or more, which may be particularly beneficial in women who are anemic.¹

Relief from Symptoms Associated with Premenstrual Dysphoric Disorder COCs have been widely used for the treatment of premenstrual dysphoric disorder (PMDD). Current evidence suggests that these agents are most effective at targeting the physical symptoms associated with the disorder and less effective in treating mood-related symptoms.¹⁴ Although multiphasic COCs have been used effectively in the treatment of PMDD, monophasic preparations may yield fewer mood swings and are generally easier to manage. Yaz, which contains the progestin, drospirenone, carries an FDA-approved indication for PMDD.^{8,15}

Relief of Benign Breast Disease Women who use oral contraceptives are less likely to develop benign breast cysts or **fibroadenomas**.^{1,8}

Prevention of Ovarian Cysts Because oral contraceptives suppress ovarian stimulation, women who take them are less likely to develop ovarian cysts.⁸

Reduction in the Risk of Symptomatic Pelvic Inflammatory Disease The risk of hospitalization owing to symptomatic **pelvic inflammatory disease** (PID) caused by gonorrheal infection is reduced in oral contraceptive users.^{4,16} Although the exact protective mechanism is unknown, it is believed that thickening of the cervical mucus and/or reduction in the ability of pathogens to enter the fallopian tubes may contribute to the lower incidence of PID experienced by oral contraceptive users.¹

Improvement in Acne Control All COCs can improve acne by increasing the quantity of sex hormone-binding globulin and thereby decreasing free testosterone concentrations.⁸ Third-generation progestins, such as desogestrel and

norgestimate, are believed to have less androgenic activity compared with older progestins, and drospirenone is considered to be antiandrogenic.⁸ However, it is not clear that COCs containing any of these progestins confer any advantage over other COCs with respect to their ability to improve acne control. Ortho Tri-Cyclen (EE and norgestimate), Estrostep Fe (EE and norethindrone acetate), Yaz, and Beyaz (EE and drospirenone) each carry an FDA-approved indication for the treatment of acne.^{1,8}

► Potential Risks of Combination Oral Contraceptives

- Although there are many noncontraceptive benefits associated with the use of COCs, their use is not without risk or potential for adverse effects.

Sexually Transmitted Diseases Because the use of COCs may decrease the use of selected barrier contraceptive methods (e.g., latex condoms) that do protect against STDs, one of the most common potential risks associated with the use of oral contraceptives is the increased risk of acquiring an STD.⁴

Cardiovascular Events and Hypertension A World Health Organization (WHO) collaborative study found that high-dose (50 mcg or more of EE) oral contraceptive users with uncontrolled hypertension have an increased risk of experiencing a myocardial infarction or stroke.^{8,17} In this study, women who had the lowest risk for experiencing a myocardial infarction or stroke were those who did not smoke, took low-dose oral contraceptives, and had their blood pressure checked prior to beginning oral contraceptives.^{18–20} Hypertension secondary to oral contraceptive use is thought to occur in up to 3% of women and is believed to be attributed to the effect that estrogens and progestins can have on aldosterone activity.¹ Given this and the risk for cardiovascular events, women should have their blood pressure checked prior to initiating oral contraceptives, as well as periodically throughout oral contraceptive use. If significant elevations in blood pressure are noted, oral contraceptives should be discontinued. Estrogen-containing contraceptives are not recommended for smokers who are 35 years of age or older, for women with hypertension (especially if untreated), or for women who experience migraine headaches (especially those with focal neurologic symptoms).^{4,8}

Venous Thromboembolism It is believed that the estrogen component of COCs stimulates enhanced hepatic production of clotting factors. COCs have been associated with a two- to threefold increase in the risk of venous thromboembolism compared with women who do not use oral contraceptives.⁸ Contraceptive users at greatest risk for the development of venous thromboembolism include those who are obese, smoke, have hypertension, have diabetes complicated by end-organ damage, are immobile, have experienced recent trauma or surgery, or have a history of prior thromboembolism. It is important to note, however, that the increase in risk of venous thromboembolism in oral contraceptive users is lower than that associated with

pregnancy and the postpartum period.^{8,21} Newer, less androgenic progestins, such as desogestrel and drospirenone, have been reported to be associated with a higher risk of venous thromboembolism.^{22–25} Currently available studies validating this risk have produced conflicting results. A large prospective surveillance study including more than 142,000 women years of observation reported similar rates of venous thromboembolism occurrence among women taking levonorgestrel, drospirenone, and other progestins, including desogestrel.²⁶ However, two more recent studies published in 2011 reported a two- to threefold greater risk of venous thromboembolic events in women using oral contraceptives containing drospirenone when compared with women using levonorgestrel-containing contraceptives.^{27,28} In general, progestin-only contraceptives are preferred for women who are at increased risk of cardiovascular or thromboembolic complications, including women with a prior history of thromboembolic disease.^{4,8}

Glucose Intolerance Older oral contraceptive formulations containing higher doses of hormones were shown in some cases to induce hyperglycemia.¹ Because estrogens may inhibit the release of insulin from pancreatic islet cells, low-dose estrogen formulations may be preferred in patients with diabetes. Progesterone competes with insulin for binding to its receptor. Although it is thought that progestins may increase insulin resistance, the newer progestins are thought to be less androgenic and have little effect on carbohydrate and lipid metabolism. In general, the use of COCs is relatively contraindicated in patients with diabetes.

Gallbladder Disease In women with preexisting gallstones, low-dose estrogen-containing oral contraceptives may enhance the potential for the development of symptomatic gallbladder disease and may worsen existing gallbladder disease.^{1,4} Although this risk has not been demonstrated with the use of higher-dose oral contraceptives, COCs containing estrogen should be used with caution in patients with a history of gallbladder disease.

Hepatic Tumors Although the use of oral contraceptives is not associated with an increased risk for the development of hepatocellular carcinoma, long-term use of high-dose oral contraceptives has been associated with the development of benign liver tumors.¹ Because even benign liver tumors may pose significant risk to the patient, oral contraceptives should be discontinued if liver enlargement is noted on physical examination. In cases of hepatoma (malignancy), the use of COCs is contraindicated.⁴

Cervical Cancer There appears to be an increased risk for the development of cervical cancer among long-term users of oral contraceptives.¹ It is uncertain whether this increase in risk is directly attributed to the use of oral contraceptives. Data suggest that oral contraceptive users tend to have more sexual partners and use condoms less frequently, and as a result, this may increase their susceptibility to infection with human papilloma virus (HPV), a known risk factor for cervical cancer.

Breast Cancer Most recent studies evaluating the relationship between oral contraceptive use and the risk for breast cancer suggest little, if any, association between the two. The baseline risk for the development of breast cancer in women with a positive family history is greater than for women without a family history. However, current data suggest that COC use (either past or current) does not further raise the risk for breast cancer in such patients.^{4,29,30} Women with breast cancer susceptibility genes also have a higher baseline risk for breast cancer compared with women who do not carry such genes. Current evidence evaluating the impact of COC use on the risk for breast cancer development in women who carry the breast cancer susceptibility genes suggests that COC use does not further modify the risk in such women.^{4,31} Women with a current or recent breast cancer diagnosis should not take COCs, as breast cancer tumors are sensitive to estrogen, and COC use may worsen the prognosis for such patients.⁴

❶ *Absolute and relative contraindications to the use of oral contraceptives are listed in Table 48–3.*^{1,4,32}

Table 48–3

Contraindications to the Use of Combined Oral Contraceptives (COCs)

Absolute Contraindications

- History of thromboembolic disease
- History of stroke (or current cerebrovascular disease)
- History of (or current) coronary artery disease, ischemic heart disease, or peripheral vascular disease
- History of carcinoma of the breast (known or suspected)
- History of any estrogen-dependent neoplasm (known or suspected)
- Undiagnosed abnormal uterine or vaginal bleeding
- Pregnancy (known or suspected)
- Heavy smoking (defined as 15 cigarettes or more per day) by women who are 35 years of age or older
- History of hepatic tumors (benign or malignant)
- Active liver disease
- Migraine headaches with focal neurologic symptoms
- Postpartum (during the first 21 days, as well as during days 21 through 42 in women with additional risk factors for thromboembolism, including age greater than or equal to 35 years, history of previous venous thromboembolism, preeclampsia, recent cesarean delivery, obesity, and smoking)

Relative Contraindications

- Smoking (less than 15 cigarettes per day) at any age
- Migraine headache disorder without focal neurologic symptoms
- Hypertension (NOTE: WHO considers health risk posed by COC use to be “unacceptable” when either systolic blood pressure 160 mm Hg or more, or diastolic blood pressure 90 mm Hg or more)
- Fibroid tumors of the uterus
- Breast-feeding
- Diabetes mellitus
- Family history of dyslipidemia
- Sickle cell disease
- Active gallbladder disease
- Age greater than 50 years
- Elective major surgery requiring immobilization (planned in the next 4 weeks)

Data from Refs. 1, 4, and 32.

Patient Encounter, Part 1

LM, a 24-year-old nulliparous woman, presents to your clinic requesting information on contraception. She specifically inquires about options that allow for fewer or no menstrual periods. You begin to take a history and determine that the patient is currently sexually active and is not using any method of birth control. She weighs 150 pounds (68 kg), is 66 inches (168 cm) tall, and has a blood pressure of 110/72 mm Hg. She has no history of smoking. LM does have migraines without aura, for which she takes propranolol. On further questioning, you discover that she has a positive family history of breast cancer (both her mother and maternal aunt), but no personal history. As you discuss various contraceptive options with the patient, it is clear that she has a preference for an oral contraceptive agent.

What additional information do you need to know before recommending a contraceptive for this patient?

Based on the information provided by the patient, what oral contraceptive agent would you recommend for the patient and why?

What education would you provide to this patient regarding risks associated with oral contraceptive use?

► Adverse Effects of Oral Contraceptives and Their Management

- As with all medications, there are potential adverse effects with COCs. **2** Many side effects can be minimized or avoided by adjusting the estrogen and/or progestin content of the oral contraceptive. It is also important to individualize the selection of oral contraceptives, because some women are at increased risk for potentially serious side effects.

Common complaints with COCs include headaches, nausea, vomiting, **mastalgia**, and weight gain; although studies have shown a similar percentage of patients taking placebo experience these side effects.³³ Given that oral contraceptives often are discontinued owing to side effects, proper counseling before initiation of COCs is necessary.

Between 30% and 50% of women complain of breakthrough bleeding or spotting when oral contraceptives are initiated. These side effects tend to resolve by the third or fourth cycle.¹ Before changing formulations, other more serious causes of bleeding or spotting, such as pregnancy, infection, and poor absorption of the oral contraceptive owing to drug interaction or GI problems, should be ruled out. Once these causes have been ruled out, the timing of the spotting must be determined in order to adjust the formulation appropriately.

- Women who have spotting or bleeding before they finish their active pills need a higher progestin content to increase endometrial support. Either a monophasic formulation with a higher progestin or a triphasic formulation with an increasing dose of progestin would be appropriate. Women with continued bleeding after menses need more estrogen support.

Either increasing the estrogen component or having a lower early progestin component (in triphasic pills) should be sufficient. If midcycle bleeding occurs, it is more difficult to determine the cause. It may be best to increase both the estrogen and progestin component for such women.¹

- Hormonal methods of contraception usually decrease the amount of withdrawal bleeding quite significantly. Lower dose estrogen formulations may increase the risk of breakthrough bleeding. Switching to a higher estrogen formulation or to a triphasic formulation will help to minimize breakthrough bleeding and will increase the amount of withdrawal bleeding.
- Acne, PMDD, and **hirsutism** are all side effects that may be related to progestins with higher androgenicity, such as norgestrel and levonorgestrel, although these claims have not been documented in controlled trials. Norgestimate and norethindrone have less androgenicity and claim to have greater improvement in acne. Drospirenone has both antiandrogenic and antimineralocorticoid activity and has shown improvement in PMDD, hirsutism, and acne. If patients are complaining of such side effects, switching to a product with a lower risk of androgenic effects may be appropriate.⁸

- GI complaints are seen often with oral contraceptives. Estrogen can induce nausea and vomiting via the CNS, whereas progesterone slows peristalsis, causing constipation and feelings of bloating and distention.¹ Most women will adjust to the symptoms, and the symptoms often will resolve within 1 to 3 months. Taking the pill at bedtime or with food may be a potential strategy to help cope with nausea. If women are unable to tolerate the GI side effects, then either a decrease in EE to a low-dose 20-mcg formulation may minimize nausea or a decrease in progestin may minimize bloating and constipation. Progestin-only products may be considered if even low-dose EE causes nausea.

- Headaches are a common occurrence for women, and they must be evaluated because they can be a major warning sign for stroke. If headaches begin or become worse after initiation of COCs, all differential diagnoses must be considered. Blood pressure should be evaluated to rule out hypertension. If any neurologic symptoms or blurred vision occur with the headache, the oral contraceptive should be stopped immediately. Migraine headaches with aura showed a significant increase in the risk for ischemic stroke in one WHO study.¹⁷ If the headaches are not serious but still are troublesome to the patient, the following changes are suggested: (a) discontinue the oral contraceptive, (b) lower the dose of estrogen, (c) lower the dose of progestin, or (d) eliminate the pill-free interval for two to three consecutive cycles (for women with headaches during the pill-free interval only).¹

- Although rare, some women may complain of a decrease in libido. This often is found to coincide with feelings of depression. Alterations to vaginal lubrication and free testosterone levels may occur with some COCs, and both can relate to decreased libido.³⁴ Low levels of estrogen can decrease vaginal lubrication as well and make intercourse painful. Use of the vaginal hormonal ring (NuvaRing) may help with lubrication problems.¹

- Dyslipidemias can occur from hormone therapy. Estrogen is known to cause an increase in high-density lipoprotein

cholesterol (HDL-C), triglycerides, and total cholesterol levels and to decrease low-density lipoprotein cholesterol (LDL-C). Androgenic progestins are more likely to decrease HDL-C and triglycerides and increase LDL-C. Depending on the ratio of estrogen to progestin content, the HDL-C, LDL-C, and triglyceride levels may fluctuate up or down. In women with no risk factors for dyslipidemias (e.g., women who do not smoke, have hypertension, or have a family history of heart disease), it is not necessary to obtain a baseline lipid panel. However, if the lipid panel is monitored, and if dyslipidemia occurs, then it is recommended to replace an androgenic progestin with a more estrogenic progestin. In women with triglycerides more than 350 mg/dL (3.96 mmol/L) at baseline, estrogen-containing formulations should be used only with caution, and low doses of 20 to 25 mcg EE, or a progestin-only formulation might be preferred.¹

Mastalgia can occur in up to 30% of women taking oral contraceptives and is most likely due to the estrogen component. The average woman has a 20% increase in breast volume in the luteal phase owing to venous and lymphatic engorgement. Estrogen also causes adipose cell hypertrophy in the breast.¹ Lower dose pills (20 mcg) produce less mastalgia than those with 35 mcg of EE.³⁵ If tenderness occurs prior to menses, switching to a contraceptive that offers extended cycle length (see **Unique Oral Contraceptives**, later) may minimize problems as well.

Women often are concerned about using oral contraceptives for fear of gaining weight. It has been proven that low-dose EE oral contraceptives do not increase the risk of weight gain in women compared with placebo.³⁶ Estrogen can cause hypertrophy of adipose cells, and therefore, women see an increase in measurement of their breasts, hips, and thighs.¹ Weight gain associated with premenstrual fluid retention may also occur with the combination of estrogen and a higher androgenic progestin. Switching to a lower-dose estrogen and a progestin with less androgenic activity may be beneficial in this situation.¹

Additional side effects have been noted in some women. Women wearing contact lenses may have visual changes and more disturbances with lenses. If normal saline eye drops do not help, referral to an ophthalmologist is recommended. **Melasma** and **chloasma** can occur secondary to estrogen stimulation of melanocyte production. Women with darker pigmentation are more susceptible to hyperpigmentation effects. The melasma may not be completely reversible on discontinuation. Progestin-only products may be preferable, and sunscreen use is highly recommended.¹

As described earlier, many of the side effects of COCs may be minimized by adjusting the estrogen or progestin content of the preparation. However, although low-dose COCs may cause fewer side effects, it is important to note that in the event that doses are missed, such COCs may be more likely to result in contraceptive failure.

Progestin-Only Pills

For women unable to take estrogen-containing oral contraceptives, there is an alternative: oral contraceptives contain-

ing only the progestin, norethindrone. These agents are slightly less effective than COCs but have other advantages over COCs. Progestin-only products have not shown the same thromboembolic risk as estrogen-containing products. Therefore, women at increased risk for or with a history of thromboembolism may be good candidates for progestin-only oral contraceptives. Also, these products can minimize menses, and many women have **amenorrhea** after six to nine cycles. These products have also been found safe to use in women who are nursing, so they are a viable option for women who breastfeed and desire hormonal contraception. In such patients, it should not be initiated until 6 weeks postpartum. Spotting does not subside in some women, and this is a common cause for discontinuation. These products should be taken at the same time every day, and there is no pill-free or hormone-free period.

Unique Oral Contraceptives

Along with varying doses of estrogen and different progestins, there are also formulation modifications that may benefit various patient situations. In the United States, these formulations include products such as Loestrin-24 Fe and Lo-Loestrin Fe; Seasonale, Quasense, and Introvale; Seasonique and Lo Seasonique; Yasmin, Yaz, and Beyaz; Ortho Tri-Cyclen and Estrostep Fe; Mircette; Ovcon 35; and Lybrel. Each of these products may show benefit in certain women owing to their unique characteristics.

Loestrin-24 Fe and Lo-Loestrin Fe (norethindrone/EE) are extended-cycle preparations that contain a low-dose estrogen, a high amount of progestin, and medium androgenic activity. Similar to other low-dose estrogen COCs, Loestrin-24 Fe and Lo-Loestrin Fe may offer a smaller margin of error when pills are missed but provide the potential advantage of fewer estrogen-related side effects (e.g., nausea and breast tenderness). Unlike the typical 28-pill packs that contain 21 active tablets and seven placebo tablets, Loestrin-24 Fe contains 24 active tablets and four placebo (iron-only) tablets, and Lo-Loestrin Fe contains 24 combination hormone tablets, two estrogen-only tablets, and two placebo (iron-only) tablets. These products provide shorter hormone-free intervals and allow for shorter menstrual periods and fewer menstrual-related symptoms, such as menstrual-related headaches, menorrhagia, and anemia.

Seasonale, Quasense, and Introvale (levonorgestrel/EE) are each monophasic combinations that are packaged as a 91-day treatment cycles with 84 active tablets that are taken consecutively followed by seven placebo tablets. The extended cycle length of these products allows for one menstrual cycle per “season,” or four per year. This type of formulation may be appealing to women with perimenstrual side effects or those at higher risk for anemia with menstrual bleeding. Seasonale, Quasense, or Introvale may improve anxiety, headache, fluid retention, dysmenorrhea, breast tenderness, bloating, and menstrual migraines. However, in the SEA 301 clinical trial comparing the efficacy of Seasonale with that of an equivalent-dosage 28-day cycle regimen, 7.7% versus 1.8% of women discontinued prematurely for

unacceptable bleeding.³⁷ The risk of intermenstrual bleeding and/or spotting may be higher for patients taking these extended-cycle combinations than for patients taking typical 28-day-regimen COCs.

Seasonique and Lo Seasonique (levonorgestrel/EE) are also extended cycle preparations that are similar to Seasonale, Quasense, and Introvale, but instead these preparations contain seven tablets with low-dose estrogen rather than placebo. Menstruation-related problems that may improve with Seasonique or Lo Seasonique include menstrual-related headaches, menorrhagia, and anemia. In addition, endometriosis-related menstrual pain may be relieved by providing a continuous regimen without a pill-free interval.³⁸

Yasmin and Yaz (drospirenone/EE) are unique oral contraceptives that contain the progestin drospirenone. This hormone not only has antiandrogenic properties, but also showed antiminerlocorticoid activity in preclinical trials. It has a unique application in young women who experience problems associated with producing too much androgen. Drospirenone is a spironolactone analog, and the 3-mg dose available in COC preparations has antiminerlocorticoid activity equal to 25 mg of spironolactone. It can affect the sodium and water balance in the body, although it has not shown superior efficacy for side effects such as bloating compared with other oral contraceptives. Caution should be used in women with chronic conditions or in women taking other medications that may affect serum potassium.³⁹ Yaz (drospirenone/EE) is an extended-cycle preparation that contains a low-dose estrogen and antiminerlocorticoid and antiandrogenic activity. Like Loestrin-24 Fe, Yaz contains 24 active tablets and four placebo tablets, allowing for shorter menstrual periods and fewer menstrual-related symptoms, such as menstrual-related headaches, menorrhagia, and anemia.

In 2003, the FDA Advisory Committee for Reproductive Health Drugs recommended the development of a COC tablet containing folic acid in order to minimize the risk of neural tube defects in cases of contraceptive failure. Beyaz and Safyral, which were FDA approved in 2010, are combination tablets containing drospirenone and EE (like Yaz and Yasmin) and 451 mcg of levomefolate calcium, the primary metabolite of folic acid. Similar to Yaz, Beyaz is an extended-cycle preparation, which may allow for shorter menstrual periods and fewer menstrual-related symptoms.

In addition to the prevention of pregnancy, Yaz, Beyaz, Ortho Tri-Cyclen (norgestimate/EE), and Estrostep Fe (norethindrone acetate/EE) each carry an approved indication for treatment of moderate acne vulgaris in females 15 years of age or older desiring contraception who have not responded adequately to conventional anti-acne medication. This can help clinicians to streamline medications by serving dual purposes.

Mircette (desogestrel/EE) has a unique dosing schedule. After the usual 21 active tablets, there are only two tablets with inert ingredients. The last five tablets in the package have 10 mcg of EE. In theory, this may minimize bleeding during the menstrual cycle, although the clinical significance of this dosing schedule has not been established.⁴⁰ It is important to counsel patients to complete the entire pack and not to discard the last 7 days of medication.

Patient Encounter, Part 2: Adverse Effects

After 2 months of taking LoSeasonique, LM returns to your clinic complaining of breakthrough bleeding during her sixth week of active pills. She reports no change or increase in frequency of her migraine headaches, and her blood pressure is 112/70 mm Hg. She is frustrated with the breakthrough bleeding and wants to explore other contraceptive options.

What are some potential causes of the breakthrough bleeding that the patient has been experiencing?

What strategy would you recommend to eliminate or minimize the potential adverse effects experienced by the patient?

Another unique formulation is a chewable tablet available to women who have difficulty swallowing medications. Ovcon 35 (norethindrone/EE) has all 28 tablets in chewable form and has added spearmint flavoring.⁴¹

Finally, Lybrel (levonorgestrel/EE) is the first continuous-cycle COC approved by the FDA. Active pills are taken every day throughout the year with no pill-free interval. The major advantage of this product is elimination of menstrual periods, resulting in improvement in or elimination of menstrual-related symptoms. The most bothersome side effect associated with Lybrel is a high incidence of spotting and breakthrough bleeding during the initial months of use. It appears as though the incidence of breakthrough bleeding with Lybrel decreases with continued use.⁴²

Drug Interactions with Oral Contraceptives

EE is metabolized in the liver primarily via cytochrome P450 (CYP450) 3A4. When reviewing drug interactions of oral contraceptives, **3** *clinicians should be aware of the many drugs that may potentially interact with contraceptives—especially those that may reduce the effectiveness of contraceptives.* Refer to [Table 48–4](#) for a list of some of the most common drug interactions seen with oral contraceptives.^{1,43,44}

Nonoral Hormonal Contraceptives

4 *As an alternative to oral contraceptive pills, which must be taken daily in order to reliably prevent pregnancy, nonoral contraceptives in the form of transdermal, transvaginal, and injectable preparations are available and offer patients safe and effective alternatives to the pills for prevention of pregnancy. These formulations also do not require daily administration, making them more convenient than the pill formulations.*

Ortho-Evra is a transdermal patch that contains both an estrogen (20 mcg of EE) and a progestin (150 mcg of norelgestromin). A new patch is applied to the abdomen, buttocks, upper torso, or upper (outer) arm once weekly for 3 weeks, followed by seven patch-free days.⁸ Although some women

Table 48-4

Commonly Seen Drug Interactions With COCs

Medication	Mechanism	Clinical Effect
Anticonvulsants (carbamazepine, oxcarbazepine, phenytoin, phenobarbital, primidone, topiramate, and felbamate)	Increase metabolism of COCs via induction of various cytochrome P450 enzymes	Decrease efficacy of COCs (EE doses less than 35 mcg are not recommended in women on these medications)
Benzodiazepines (alprazolam)	COCs may inhibit oxidative metabolism	Increase side effects of benzodiazepines
Bosentan	Increase metabolism of COCs via induction of cytochrome P450 3A4 enzyme	Decrease efficacy of COCs
Colesevelam	Reduce absorption of COCs by nonspecific binding with colesevelam	Decrease efficacy of COCs
Corticosteroids (hydrocortisone, methylprednisolone, prednisone)	COCs may inhibit metabolism of corticosteroids	Increase side effects of corticosteroids
Griseofulvin	Increase metabolism of COCs	Decrease efficacy of COCs; backup method of contraception is recommended
Lamotrigine	COCs increase metabolism of lamotrigine via induction of glucuronidation	Decrease efficacy of lamotrigine; dose adjustment may be necessary
Modafinil	Increase metabolism of COCs	Decrease efficacy of COCs; alternative method of contraception is recommended
Penicillins (amoxicillin, ampicillin); tetracyclines (doxycycline, minocycline, tetracycline); Non-nucleoside reverse transcriptase inhibitors (delavirdine, efavirenz, etravirine, nevirapine)	Broad-spectrum antibiotics may alter intestinal flora, reducing enterohepatic circulation of estrogen metabolites; although the drop in estrogen levels has been shown to be only statistically significant, rather than clinically significant; Increase metabolism of COCs	Decrease efficacy of COCs; backup barrier method of contraception is controversial ^a
Rifampin, rifabutin	Increase metabolism of COCs	Decrease efficacy of COCs; backup method of contraception is recommended
Selegiline	COCs decrease metabolism of selegiline	Increase side effects of selegiline; may adjust dose of selegiline if needed
St. John's wort	Increase metabolism of COCs via induction of various cytochrome P450 enzymes	Decrease efficacy of COCs; avoid use with COCs
Theophylline	COCs decrease theophylline clearance by 34% and increase half-life by 33%	Increase side effects of theophylline

^aAlthough package inserts warn of this potential interaction, no scientific literature exists to support that concomitant antibiotics and COCs is associated with contraceptive failure.⁴⁴

Data from Refs. 1, 43, and 44.

have noted irregular bleeding during the first two cycles of patch use, the patch has been demonstrated to provide similar menstrual cycle control and contraceptive efficacy to that of COCs.⁴⁵ It is important to note, however, that higher contraceptive failure rates are seen when the patch is used in women weighing more than 90 kg (about 200 lb).^{8,45} Further, manufacturer prescriber information indicates that women who take Ortho-Evra are exposed to approximately 60% more estrogen than women who take COCs with 35 mcg of estrogen.⁴⁶ Although the clinical significance of this is not well defined, studies have suggested a link between the use of the patch and an increased risk for venous thromboembolism. A slightly higher reported incidence of breast discomfort and local skin irritation has also been reported with the patch.^{8,47}

NuvaRing is a unique transvaginal delivery system that provides 15 mcg of EE and 120 mcg of etonogestrel for the prevention of ovulation. NuvaRing is inserted into the vagina

on or before day 5 of the menstrual cycle and is removed from the vagina 3 weeks later.⁸ Seven days after the ring is removed, a new ring should be inserted. In clinical trials, NuvaRing demonstrated comparable efficacy and cycle control to COCs as well as a similar side effect profile.^{8,48} NuvaRing should not be removed during intercourse. If the ring is dislodged or removed for more than 3 hours, efficacy could be compromised, and a backup method of contraception is recommended until a new ring has been in place for 7 days.

Depo-Provera is a progestin-only, injectable contraceptive that contains depot medroxyprogesterone acetate. Depo-Provera is administered intramuscularly as a 150-mg injection once every 3 months. An advantage of Depo-Provera is that it provides an estrogen-free method of contraception either for women in whom estrogens are contraindicated or for women who cannot tolerate estrogen-containing preparations. Depo-Provera is extremely effective in preventing pregnancy. However, the incidence of menstrual

irregularities (including amenorrhea) and weight gain appears to be much greater than that seen with COCs. The use of Depo-Provera also has been demonstrated to result in significant loss of bone mineral density (BMD).⁴⁹ Although the effect is known to be reversible following product discontinuation, a black box warning within the product labeling cautions against the risk of potentially irreversible BMD loss associated with long-term use (e.g., greater than 2 years) of the injectable product. Although the extended duration of activity of this product may offer women the advantage of less frequent administration, it is important to note that on discontinuation of Depo-Provera, the return of fertility can be delayed by approximately 10 to 12 months (range 4–31 months).⁸

Depo-SubQ Provera 104 is also an injectable contraceptive product that contains only progestin (depot medroxyprogesterone acetate). This product differs from Depo-Provera in that it is given subcutaneously rather than intramuscularly, and it contains only 104 mg of medroxyprogesterone acetate (approximately 30% less hormone) administered every 3 months for the prevention of pregnancy.⁵⁰ Clinical trials have demonstrated that the subcutaneous formulation of depot medroxyprogesterone acetate is as effective as the intramuscular formulation in the prevention of pregnancy.⁵¹ This product carries the same warning in its package labeling regarding possible effects on BMD as Depo-Provera.⁵⁰

Long-Acting Reversible Contraception

There are currently four implantable contraceptive (three progestin-containing and one nonhormonal) devices available, also known as long-acting reversible contraception (LARC). After insertion, Mirena, a levonorgestrel-releasing intrauterine device (IUD), can provide contraceptive protection for up to 5 years.⁵² ParaGard T 380A, a copper IUD, can provide contraceptive protection for up to 10 years.⁵³ Implanon and Nexplanon, the newest of the implantable devices, are both etonogestrel-releasing systems that can be surgically implanted under the skin of the upper arm and are effective for up to 3 years.^{54,55} Surveys have shown that LARC has the highest satisfaction rate among patients using reversible contraceptives, and use within the United States is on the rise.²

Although the mechanism of action for IUDs is not completely understood, several theories have been suggested. The original theory is that the presence of a foreign body in the uterus causes an inflammatory response that interferes with implantation. It is believed that copper-containing IUDs may interfere with sperm transport and fertilization and prevent implantation.⁵³ Progestin-containing implantable contraceptives can have direct effects on the uterus, such as thickening of cervical mucus and alterations to the endometrial lining.⁵² Mirena, Implanon, and Nexplanon can inhibit ovulation because they contain a progestin, but Paragard T 380A does not prevent ovulation.

It is important to evaluate a patient to determine whether she is an appropriate candidate for an implantable contraceptive. Implantable contraceptives are recommended for women with at least one child, in a monogamous relationship, who

have no history of pelvic inflammatory disease (PID) and no history or risk of **ectopic pregnancy**. Contraindications with Implanon, the etonogestrel implant, are similar to those with COCs and include (a) known or suspected pregnancy, (b) current or past history of thrombosis or thromboembolic disorders, (c) hepatic tumors or active liver disease, (d) undiagnosed abnormal genital bleeding, (e) known or suspected carcinoma of the breast or personal history of breast cancer, and (f) hypersensitivity to any of the components of Implanon. There are also multiple contraindications to IUD use. Evaluation of the patient is essential because IUDs cannot be used in the following situations: (a) pregnancy or suspicion of pregnancy, (b) anatomically abnormal or distorted uterine cavity, (c) acute PID or current behavior suggesting a high risk for PID, (d) postpartum **endometritis** or infected abortion in the past 3 months, (e) known or suspected uterine or cervical malignancy, (f) genital bleeding of unknown etiology, (g) untreated acute **cervicitis**, (h) acute liver disease or liver tumor, (i) woman or her partner has multiple sexual partners, (j) previously inserted IUD still in place, (k) conditions associated with increased susceptibility to infections (e.g., leukemia or acquired immune deficiency syndrome), (l) hypersensitivity to any component of the IUD, (m) known or suspected carcinoma of the breast, and (n) **Wilson's disease**.^{52,53}

There are potential side effects of IUD use. The most common adverse effects are abdominal/pelvic cramping, abnormal uterine bleeding, and expulsion of the device. Other side effects seen are ectopic pregnancy, sepsis, PID, embedment of the device, uterine or cervical perforation, and ovarian cysts.^{52,53}

Nonpharmacologic Contraceptive Methods

► Barrier Contraceptives

As an alternative to hormonal contraceptives, several barrier contraceptive options are available for the prevention of pregnancy. Although barrier contraceptives are associated with far fewer adverse effects compared with hormonal contraceptives, their efficacy is highly user-dependent. Overall, compared with both hormonal contraceptives and IUDs, barrier contraceptives are associated with much higher accidental pregnancy rates⁸ (Table 48–1).

Diaphragms and Cervical Caps Diaphragms and cervical caps are dome-shaped rubber caps that are placed over the cervix to provide barrier protection during intercourse. Both diaphragms and cervical caps require fitting by a healthcare professional, and they must be refitted in the event of weight gain or weight loss. Diaphragms or cervical caps typically can be placed over the cervix as much as 6 hours prior to intercourse. They must be left in place for at least 6 hours after intercourse before they can be removed. Diaphragms should not be left in place longer than 24 hours, and smaller cervical caps should not be left in place longer than 48 hours owing to the risk of toxic shock syndrome (TSS). Diaphragms and cervical caps are used along with spermicides to prevent pregnancy. When sexual intercourse is repeated with the diaphragm, reapplication of the spermicide is necessary.

However, when sexual intercourse is repeated with a cervical cap, reapplication of the spermicide typically is not necessary.⁸ Whether or not diaphragms or cervical caps provide adequate protection against STDs remains unclear.⁵⁶

Spermicides Nonoxynol-9, a surfactant that destroys the cell membranes of sperm, is the most commonly used spermicide in the United States.^{8,57} Nonoxynol-9 is available in a variety of forms, including a cream, foam, film, gel, suppository, and tablet. Spermicides may be used alone, with a barrier method, or adjunctively with other forms of contraceptives to provide additional protection against unwanted pregnancy.⁵⁷ To be used most effectively, spermicides must be placed in the vagina not more than 1 hour prior to sexual intercourse, and they must come in contact with the cervix.⁸

Although the efficacy of spermicides depends largely on how consistently and correctly they are used, their efficacy is enhanced when they are used in combination with a barrier contraceptive device.⁵⁶ Clinical trials assessing the ability of spermicides to protect against STDs have failed to produce positive results.⁵⁷ Further, there exists some evidence to suggest that frequent use of spermicides actually may increase risk for transmission of human immunodeficiency virus (HIV) secondary to vaginal mucosal tissue breakdown, which may allow a portal of entry for the virus.⁸ In December 2007, the FDA issued a statement requiring manufacturers of nonoxynol-9 products to include a warning on the product label indicating that the spermicide does not provide protection against infection from HIV or other STDs.

Condoms Condoms, which are available for both male and female use, act as physical barriers to prevent sperm from coming into contact with ova.⁵⁷ Condoms are easy to use, available without a prescription, and inexpensive. Most condoms are made of latex. When used correctly, condoms can be very effective in prevention of unwanted pregnancy.

Condoms should be stored in a cool, dry place, away from exposure to direct sunlight. When stored improperly or when used with oil-based lubricants, however, latex condoms can break during intercourse, increasing the risk of pregnancy.⁸ For latex-sensitive individuals, condoms made from lamb intestine (“natural membrane” condoms) and synthetic polyurethane condoms are available. Unlike latex condoms, condoms made from lamb intestine contain small pores that may permit the passage of viruses and therefore do not provide adequate protection against STDs.⁵⁸

5 *Both latex and synthetic condoms can provide some protection against many STDs. Data from one meta-analysis suggested that HIV transmission can be reduced by as much as 90% when condoms are consistently used.⁵⁹ This is in contrast to hormonal contraceptives (oral, transdermal, or vaginal), IUDs, and most other barrier contraceptives, which do not protect against STDs.*

Relative to male condoms, female condoms may offer even better protection against STDs because they provide more extensive barrier coverage of external genitalia, including the labia and the base of the penis.⁵⁷ It is important to note that the male and female condoms are not recommended to be used together because they may adhere to one another, causing displacement of one or both condoms.⁵⁷

Sponge The Today sponge is a small, pillow-shaped polyurethane sponge impregnated with nonoxynol-9.⁵⁶ It is an over-the-counter barrier contraceptive that has been shown to be generally less effective at preventing pregnancy than diaphragms.⁶⁰ The sponge is moistened with water and then is inserted and placed over the cervix for up to 6 hours prior to sexual intercourse. The sponge then is left in place for at least 6 hours following intercourse.⁵⁷ Although the sponge maintains efficacy for 24 hours (even if intercourse is repeated), as with diaphragms, the sponge should be removed after 24 hours owing to the risk of TSS.⁸

► Fertility Awareness–Based Methods

Fertility awareness–based methods (natural methods) represent another nonpharmacologic means of pregnancy prevention. Although failure rates of such methods can be high, some couples still prefer these types of approaches. Fertility awareness–based methods depend on the ability of the couple to identify the woman’s “fertile window,” or the period of time in which pregnancy is most likely to occur as a result of sexual intercourse.⁶¹ During the fertile window, the couple practices abstinence, or avoidance of intercourse, in order to prevent pregnancy. In some cases, rather than practicing abstinence during the fertile period, some couples may prefer to employ barrier methods or spermicides as a means of preventing pregnancy rather than to avoid intercourse altogether.⁸ In order to identify the fertile window, a number of different fertility awareness–based methods may be tried. The calendar (rhythm) method involves counting the days in the menstrual cycle and then using a mathematical equation to determine the fertile window.⁶¹ The temperature method involves monitoring changes in the woman’s basal body temperature using a basal thermometer.⁶¹ The cervical mucus (or Billings ovulation) method involves observing changes in the characteristics of cervical secretions throughout the cycle.⁶¹ Around ovulation, the mucus becomes watery. The symptothermal method, which is considered to be the most difficult to learn but potentially the most effective, is a combination of both the temperature method and the cervical mucus method.⁸ In general, fertility awareness–based methods are not recommended for women who have irregular menstrual cycles or who have difficulty interpreting their fertility signs correctly.⁶¹

Emergency Contraception

Emergency contraception (EC) is used to prevent pregnancy after known or suspected unprotected sexual intercourse. There are three FDA-approved oral agents available for use as EC, with two being available for nonprescription sale to patients 17 years of age and older. The two over-the-counter options contain the progestin levonorgestrel and are Plan B One Step and Next Choice, both of which are available via prescription for those younger than 17 years of age. Plan B One Step allows patients to take one dose of 1.5 mg of levonorgestrel within 72 hours of unprotected intercourse. Next Choice is a two-step process of 0.75 mg of levonorgestrel

Patient Encounter, Part 3: Missed Doses

LM calls your clinic in a panic today because she forgot to take her oral contraceptive for the past 3 days, beginning the third week of active pills. Three days have elapsed since she took her last active pill, and she reports having had unprotected sexual intercourse last night. The patient is very concerned about her risk of pregnancy and is interested to learn more about emergency contraception and what her options are.

Given this patient's reported imperfect use of her oral contraceptive, what information can you provide to the patient regarding her risk of pregnancy?

What additional education should be provided to LM regarding her risk of STDs related to unprotected intercourse?

Provide appropriate patient education regarding the use of various forms of emergency contraception, in the event she decides to use EC.

- taken within 72 hours of intercourse and a second equal dose taken 12 hours later. The newest EC option is ella (ulipristal acetate), a progesterone-receptor agonist/antagonist that can delay follicular rupture if taken just before ovulation and may cause endometrial changes to interfere with implantation.
- It is dosed as a single 30-mg tablet that can be taken up to 5 days after unprotected intercourse.⁸ It is available only via prescription. It is important to note that EC is more effective the earlier it is used after unprotected intercourse. Common side effects include headache, nausea, abdominal pain, dysmenorrhea, fatigue, and dizziness. If severe abdominal pain occurs, patients should be referred to their physician for risk of an ectopic pregnancy. Patients should also contact their physician if their menstrual cycle is more than 1 week late after taking EC.

OUTCOME EVALUATION/MONITORING

Side effects of contraceptives tend to occur in the first few months of therapy. Thus schedule a follow-up visit 3 to 6 months after initiating a new contraceptive. Yearly checkups usually are sufficient for patients who are doing well on a particular product.¹ At each follow-up visit, assess blood pressure, headache frequency, and menstrual bleeding patterns, as well as compliance with the prescribed regimen. Strict adherence to the prescribed hormonal contraceptive regimen is essential for effective prevention of unintended pregnancy. **6** *When a contraceptive dose is missed, the risk of accidental pregnancy may be increased. Depending on how many doses were missed, the contraceptive formulation being used, and the phase of the cycle during which doses were missed, counseling regarding the use of additional methods of contraception may be warranted.*

Patient Care and Monitoring

1. Obtain a thorough medical and family history and carefully evaluate each patient's risk factors prior to prescribing contraceptives.
2. Educate all women taking hormonal contraceptives to prevent pregnancy regarding self-monitoring for early warning signs that may precede adverse events. Healthcare professionals can easily recall the major warning signs by using the following two simple pneumonics:
 - ACHES**—for women taking hormonal contraceptives
 - A** = Abdominal pain. This may be an early warning sign of the presence of an abdominal thromboembolism, liver adenoma, or gallbladder disease.
 - C** = Chest pain. The presence of chest pain may indicate pulmonary embolism, angina, or myocardial infarction.
 - H** = Headaches. Headaches (particularly those associated with focal neurologic symptoms, such as blurred vision, speech impairment, and/or weakness) may represent stroke-like symptoms. Headaches also may indicate poorly controlled blood pressure.
 - E** = Eye problems. Blurred vision and/or ocular pain may be early warning signs for stroke and/or blood clots. In addition, visual changes may occur in patients wearing contact lenses (secondary to changes in corneal shape).
 - S** = Severe leg pain. Patients taking hormonal contraceptives who complain of severe leg pain should be evaluated for the presence of venous thromboembolism.
 - PAINS**—for women with an IUD
 - P** = Period late
 - A** = Abdominal pain, pain with intercourse
 - I** = Infection, abnormal or odorous vaginal discharge
 - N** = Not feeling well, fever, chills
 - S** = String (missing, shorter, longer)
3. In addition to the preceding, monitor patients taking hormonal contraceptives for missed periods, signs of pregnancy, appearance of jaundice, and/or severe mood changes. Instruct patients to consult a healthcare professional upon noticing or experiencing any of these warning signs.¹
4. Stress the importance of adherence to the patient's chosen method of contraception in order to reliably prevent pregnancy. Educate the patient on what to do in the event of missed doses with hormonal contraception.

Abbreviations Introduced in This Chapter

BMD	Bone mineral density
COC	Combined oral contraceptive
CYP450	Cytochrome P450
EC	Emergency contraception
EE	Ethinyl estradiol
FSH	Follicle-stimulating hormone
GnRH	Gonadotropin-releasing hormone
HDL	High-density lipoprotein
HIV	Human immunodeficiency virus
HPV	Human papilloma virus
IUD	Intrauterine device
LARC	Long-acting reversible contraception
LDL	Low-density lipoprotein
LH	Luteinizing hormone
PID	Pelvic inflammatory disease
PMDD	Premenstrual dysphoric disorder
STD	Sexually transmitted disease
TSS	Toxic shock syndrome
WHO	World Health Organization

Self-assessment questions and answers are available at <http://mhpharmacotherapy.com/pp.html>.

Menstruation-Related Disorders

Jacqueline M. Klootwyk and Elena M. Umland

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Describe the underlying etiology and pathophysiology of dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia and how they relate to selecting effective treatment modalities.
2. Describe the clinical presentation of dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia.
3. Recommend appropriate lifestyle and dietary modifications and pharmacotherapeutic interventions for patients with dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia.
4. Identify the desired therapeutic outcomes for patients with dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia.
5. Design a monitoring plan to assess the effectiveness and adverse effects of pharmacotherapy for dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia.

KEY CONCEPTS

- 1 Nonsteroidal anti-inflammatory drugs (NSAIDs) are the treatment of choice for dysmenorrhea due to their effect on prostaglandins. In addition to their analgesic properties, NSAIDs also inhibit prostaglandin production, decreasing uterine contractions.
- 2 Intrauterine devices (IUDs) are considered therapeutic options in a variety of menstrual-related disorders. Guidelines from the American College of Obstetricians and Gynecologists states that any woman (regardless of parity), including adolescents, at low risk of sexually transmitted diseases (and thus pelvic inflammatory disease) is a good candidate for IUD use.
- 3 Unrecognized pregnancy remains the most common cause of amenorrhea, and a urine pregnancy test should be one of the first steps in the evaluation of this disorder.
- 4 For most conditions associated with primary and secondary amenorrhea, estrogen treatment (along with a progestin to minimize the risk of endometrial hyperplasia) is utilized.
- 5 Anovulatory bleeding, also referred to as dysfunctional uterine bleeding, is secondary to the effects of unopposed estrogen and does not include bleeding owing to an anatomic lesion of the uterus.
- 6 The use of metformin and thiazolidinediones for anovulatory bleeding associated with polycystic ovary syndrome is beneficial for anovulatory bleeding and fertility and also improves glucose tolerance and decreases overall cardiovascular risk.
- 7 Causes of menorrhagia can be divided into systemic disorders and reproductive tract abnormalities.
- 8 Intrauterine pregnancy, ectopic pregnancy, and miscarriage must be at the top of the differential diagnosis list for any woman presenting with heavy menses.
- 9 The reduction in menorrhagia-related blood loss with the use of NSAIDs and oral contraceptives is directly proportional to the amount of pretreatment blood loss.

Women of reproductive age commonly experience menstrual cycle-related maladies. The disorders in this chapter are most frequently encountered and include dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia. The need to effectively treat these disorders stems from their impact on a reduced quality of life, negative effects on reproductive health, and/or the potential for detrimental health effects over time, notably osteoporosis with amenorrhea and cardiovascular disease with polycystic ovary disease.

DYSMENORRHEA

Dysmenorrhea is pelvic pain, generally described as cramping, that occurs during or just prior to menstruation. Primary dysmenorrhea is pain in the setting of normal pelvic anatomy and physiology, whereas secondary dysmenorrhea is associated with underlying pelvic pathology.¹

Epidemiology and Etiology

Rates of dysmenorrhea range from 20% to 90%.^{2,3} Dysmenorrhea is associated with significant interference in work and school attendance for as many as 15% of women.^{1,3,4} Risk factors for dysmenorrhea include young age, menarche prior to age 12, irregular or heavy menses, body mass index (BMI) less than 20 kg/m², smoking, and **nulliparity**.^{1,2} Causes of secondary dysmenorrhea may include cervical stenosis, endometriosis, pelvic infections, pelvic congestion syndrome, uterine or cervical polyps, and uterine fibroids.^{1,5}

Pathophysiology

1 The most significant mechanism for primary dysmenorrhea is elevated levels of arachidonic acid in the menstrual fluid leading to increased concentrations of prostaglandins and leukotrienes in the uterus. In turn, this induces uterine contractions, stimulating pain fibers, reducing uterine blood flow, and causing uterine hypoxia.^{1,3-5} This prostaglandin-mediated reaction contributes to the resulting symptoms.^{1,4,5}

Clinical Presentation and Diagnosis of Dysmenorrhea

General

- Patient may or may not be in acute distress depending on the severity of menstrual pain experienced.

Symptoms

- Complaints of crampy pelvic pain beginning shortly before or at menses onset. Symptoms typically last 1 to 3 days.
- Associated symptoms may include nausea, vomiting, diarrhea, hypertension, and/or tachycardia.

Laboratory Tests

- Sexually active females should receive a pelvic examination to screen for sexually transmitted diseases.
- Gonorrhea, chlamydia cultures or PCR, wet mount.

Other Diagnostic Tests

- Pelvic ultrasound may be used to identify anatomic abnormalities such as masses/lesions or to detect ovarian cysts and endometriomas.

Patient Encounter 1, Part 1

CO is a 14 year-old white female who presents to her physician with complaints of severe pelvic pain and cramping during menses that result in 1 to 2 missed school days each menstrual cycle. She is not sexually active and does not take any routine medications. She has recently begun high school and is a member of the field hockey team.

What menstrual related disorder does this patient have?

What are the potential risk factors and etiologies for this condition?

Treatment

► Desired Outcomes

- The medical management of dysmenorrhea should relieve the related pelvic pain and result in a reduction in lost school and work days. **Table 49–1** identifies agents used to manage dysmenorrhea, their recommended doses, and their common side effects. **Figure 49–1** is a treatment algorithm for dysmenorrhea management.

► Nonpharmacologic Therapy

- Several nonpharmacologic interventions exist for the management of dysmenorrhea. Among these, topical heat therapy, exercise, and following a low-fat vegetarian diet all have been shown to reduce the intensity of dysmenorrhea.^{2,4,11} Dietary changes may also shorten dysmenorrhea duration. Such interventions require little time, minimal cost, and are associated with little risk. Other nonpharmacologic options that may be considered before or after a trial of pharmacologic interventions include transcutaneous electric nerve stimulation (TENS), acupressure, and acupuncture.²

► Pharmacologic Therapy

Nonsteroidal Anti-inflammatory Drugs (NSAIDs) **1**

- NSAIDs are the treatment of choice for dysmenorrhea due to their effect on prostaglandins. In addition to their analgesic properties, NSAIDs also inhibit prostaglandin production, decreasing uterine contractions. Although there is not a clear difference in efficacy between the agents, switching agents may be of benefit if relief is not obtained from an initial trial (e.g., ibuprofen to mefenamic acid).^{1,5} Choice of one agent over another is based on cost, convenience, and patient preference.¹⁻⁵ The most commonly used agents are naproxen and ibuprofen.

A loading dose (twice the usual single dose) of the NSAID is recommended, followed by the usually recommended dose until symptoms resolve.¹¹ An alternative recommendation is to begin the NSAID at menses onset or 1 to 2 days prior and continue treatment around the clock instead of

Table 49–1

Therapeutic Agents for Selected Menstrual Disorders

Specific Menstrual Disorders(s)	Agent(s)	Dose Recommended	Common Adverse Effects
Amenorrhea (primary or secondary)	CEE ^a	0.625–1.25 mg by mouth daily on days 1–25 of the cycle ⁶	Thromboembolism, breast enlargement, breast tenderness, bloating, nausea, GI upset, headache, peripheral edema
Amenorrhea (secondary)	Ethinyl estradiol patch ^a	50 mcg/24 hours ⁶	Edema, anorexia, depression, insomnia, weight gain or loss, increase in serum total and LDL cholesterol, may reduce HDL cholesterol
	Oral CHC ^a	30–40 mcg formulations	
Amenorrhea related to hyperprolactinemia	Oral medroxyprogesterone acetate ^a	5–10 mg by mouth on days 14–25 of the cycle ⁶	Hypotension, nausea, constipation, anorexia, Raynaud's phenomenon
	Bromocriptine	2.5 mg by mouth 2–3 times daily ⁷	
Anovulatory bleeding	Oral CHC ^a	Optimal dose unknown ⁸ For acute bleeding, product containing 35 mcg ethinyl estradiol; take one tablet by mouth 3 times daily × 1 week; then one tablet by mouth daily × 3 weeks. ⁹	As noted above for CEE, ethinyl estradiol, and oral CHC (progesterone side effects with the CHC depend on agent chosen)
	Oral medroxyprogesterone acetate ^a	For acute bleeding, 20 mg by mouth 3 times daily × 1 week; then 20 mg by mouth once daily × 3 weeks. ⁹	
Dysmenorrhea	Oral CHC ^{10,a}	Less than 35 mcg formulations + norgestrel or levonorgestrel ¹¹ ; use of extended-cycle formulations are beneficial for this indication	As noted above for CEE, ethinyl estradiol, and oral CHC (progesterone side effects with the CHC depend on agent chosen)
	Depo-medroxyprogesterone acetate ^a	150 mg intramuscularly every 12 weeks	Irregular menses, amenorrhea
	Levonorgestrel IUD ^{12,a}	20 mcg released daily	Irregular menses, amenorrhea
	NSAIDs—any are acceptable; the most commonly studied/cited are included in this table ^{1,2,4,5,10}	Diclofenac 50 mg by mouth 3 times daily ^b	GI upset, stomach ulcer, nausea, vomiting, heartburn, indigestion, rash, dizziness
		Ibuprofen 800 mg by mouth 3 times daily ^a	
		Mefenamic acid 500 mg by mouth as a loading dose, then 250 mg by mouth up to 4 times daily as needed ^b Naproxen 550-mg loading dose by mouth started 1–2 days prior to menses, followed by 275 mg by mouth every 6–12 hours as needed ^c Treatment should begin 1–2 days prior to the suspected onset of menses	
Menorrhagia	Oral CHC ^a	Optimal dose unknown	As noted above
	Levonorgestrel IUD ^a	20 mcg released daily	As noted above
	Medroxyprogesterone acetate (oral) ^a	5–10 mg by mouth on days 5–26 of the cycle or during the luteal phase ¹²	As noted above
PCOS-related amenorrhea and/or anovulatory bleeding	NSAIDs	Doses as recommended for above; therapy should be initiated with the onset of menses ¹²	As noted above
	Clomiphene ¹¹	50 mg by mouth daily × 5 days starting 3–5 days after the start of menses; doses up to 100 mg by mouth daily have been used in significantly obese patients.	Hot flashes, ovarian enlargement, thromboembolism, blurred vision, breast discomfort
	Depo-medroxyprogesterone acetate ^a	150 mg intramuscularly every 12 weeks	As noted above

(Continued)

Table 49-1

Therapeutic Agents for Selected Menstrual Disorders (Continued)

Specific Menstrual Disorders(s)	Agent(s)	Dose Recommended	Common Adverse Effects
PCOS-related amenorrhea and/or anovulatory bleeding	Medroxyprogesterone acetate (oral) ^a	10 mg by mouth × 10 days ^b	As noted above
	Metformin ^a	1,500–2,000 mg by mouth daily in 2–3 divided doses ^{10,a,d}	Anorexia, nausea, vomiting, diarrhea, flatulence, lactic acidosis
	Thiazolidinediones ^{b,e}	Pioglitazone 15–45 mg by mouth daily; rosiglitazone 4–8 mg by mouth daily	Weight gain; increase in total, LDL, and HDL cholesterol; edema; headache; fatigue; hepatic injury (rare)

CEE, conjugated equine estrogen; CHC, combination hormonal contraceptive; HDL, high-density lipoprotein; LDL, low-density lipoprotein; IUD, intrauterine device.

^aUse is contraindicated in patients with severe hepatic impairment.

^bNot recommended in patients with severe renal impairment.

^cUse is contraindicated with creatinine clearance less than 30 mL/min (0.5 mL/s).

^dContraindicated in males with serum creatinine more than 1.5 mg/dL (133 μmol/L); females with serum creatinine more than 1.4 mg/dL (124 μmol/L); caution with creatinine clearance less than 60 mL/min (1 mL/s).

^eContraindicated in patients with active liver disease or if transaminases more than 2.5 times upper limit of normal at baseline, discontinue therapy if ALT is more than 3 times upper limit of normal.

Data from Refs. 1, 2, 4–14.

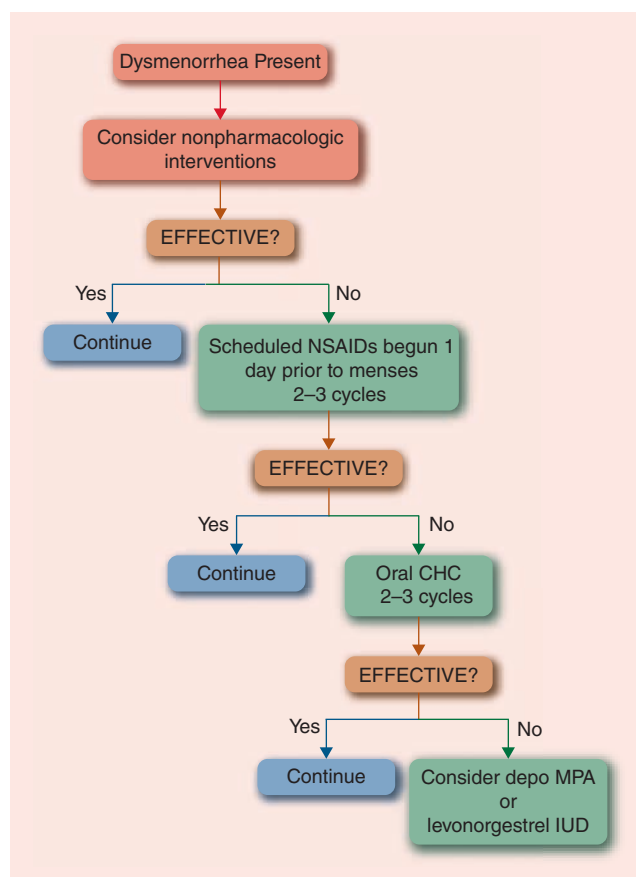

FIGURE 49-1. Treatment algorithm for dysmenorrhea. (NSAID, nonsteroidal anti-inflammatory drug; CHC, combination hormonal contraceptive; MPA, medroxyprogesterone acetate; IUD, intrauterine device.)

waiting until symptom onset. For patients in whom NSAID use is contraindicated, the agents discussed next should be considered.^{1,5} The use of acetaminophen is inferior to NSAIDs for treating this disorder.²

- Combination Hormonal Contraceptives (CHCs)** CHCs help to improve dysmenorrhea by inhibiting the proliferation of endometrial tissue. This reduction in tissue reduces the endometrial-derived prostaglandins that contribute to the pelvic pain.^{1,3-5,11} A trial of 2 to 3 months of CHC dosing is required to establish whether the patient will be a responder or not. Significant improvements in mild, moderate, and severe dysmenorrhea have been noted with CHC use. These agents have other benefits, including pregnancy prevention, improving acne, and reducing ovarian cancer risk. Although monophasic formulations are purported to be more efficacious for this indication, the evidence supporting this is limited.^{2,15} If no response occurs after 6 months of therapy, the patient should be evaluated for secondary causes.¹
- Progestins** The benefit of depo-medroxyprogesterone acetate in dysmenorrhea is related to its ability to render most patients amenorrheic within 1 year of use.² This is an expected side effect. Since the pelvic pain is related to prostaglandins released during menses, in the setting of amenorrhea, this underlying cause of dysmenorrhea is removed.

Observational data illustrate a reduction in dysmenorrhea from 60% to 29% with 3 years of levonorgestrel-releasing intrauterine device (IUD) use.^{2,3} As with depo-medroxyprogesterone acetate, this reduction is likely secondary to the increasing incidence of amenorrhea observed with its use. Although data are limited, this is an option for dysmenorrhea management.¹⁵

Patient Encounter 1, Part 2

Additional workup of CO reveals:

PMH: seasonal allergic rhinitis

PSH: none

FH: Mother and father are alive and well. She has two younger siblings (ages 12 and 10) who are alive and well.

SH: The patient participates in high school field hockey. She denies smoking cigarettes or drinking alcohol.

Meds: Loratadine 10 mg by mouth as needed for seasonal allergies

Past Gynecologic Hx: Menarche at age 11; never pregnant and never on contraception; (–) sexual activity; (+) history of painful menses beginning at age 12; (+) heavy menstrual flow; menstrual cycle 28 to 30 days in length.

ROS: (–) fatigue; (–) headaches; (+) mild acne on shoulders; (+) moderate to severe pelvic pain with menses.

PE:

General: Thin-appearing white female, in no acute distress

VS: BP 118/62, P 74, RR 16, weight 123 lbs (55.9 kg), height 5'6" (168 cm), BMI: 19.9 kg/m²

HEENT: (–) hirsutism

Breasts: (–) galactorrhea

Pelvic exam: normal appearance of external genitalia and vagina, cervix without lesions, uterus midposition without masses, adnexa without masses

Labs:

None ordered.

Given this information, what is your assessment of this patient's condition?

Identify your treatment goals for this patient.

What therapeutic options exist for this patient? Identify those that would be most appropriate.

What monitoring parameters are necessary to employ in assessing efficacy and safety of the therapeutic options?

Dysmenorrhea in Adolescents

Dysmenorrhea is very common in adolescent females, with an incidence of 60% to 90%.¹ Any of the treatment measures discussed for dysmenorrhea would be appropriate in this population. Although NSAIDs and oral CHCs are among the top choices, levonorgestrel IUD use is also an option.¹⁵ **2** *The American College of Obstetricians and Gynecologists (ACOG) states that any woman, including adolescents (regardless of parity) at low risk of sexually transmitted diseases and thus pelvic inflammatory disease, is a good candidate for IUD use.*^{16,17}

AMENORRHEA

Amenorrhea is either primary or secondary in nature. **Primary amenorrhea** is the absence of menses by age 15 in the presence of normal secondary sexual development or within 5 years of **thelarche** (if occurring before age 10).^{18,19} **Secondary amenorrhea** is the absence of menses for three cycles or 6 months in a previously menstruating woman. The initial evaluation of amenorrhea is often the same regardless of age of onset, except in unusual clinical situations.²⁰

Epidemiology and Etiology

- 3** *Unrecognized pregnancy remains the most common cause of amenorrhea, and a urine pregnancy test should be one of the first steps in the evaluation of this disorder.* Amenorrhea not related to pregnancy, lactation, or menopause occurs in 3% to 4% of women.¹⁹ After pregnancy, the five most common causes of secondary amenorrhea, in descending order of prevalence, include hypothalamic suppression (33%), chronic anovulation (28%), hyperprolactinemia (14%), ovarian failure (12%), and uterine disorders (7%).²¹

Pathophysiology

In organizing an approach to amenorrhea diagnosis and treatment, the organs involved in the menstrual cycle, including the uterus, ovaries, anterior pituitary, and hypothalamus, should be considered. Normal menstrual cycle physiology depends on a coordinated system of hormonal interactions that involve the hypothalamus, anterior pituitary gland, ovary, and endometrium. **Figures 49–2** and **49–3** summarize these points. Pulsatile gonadotropin-releasing hormone (GnRH) secretion from the hypothalamus stimulates the anterior pituitary to secrete follicle-stimulating hormone (FSH) and luteinizing hormone (LH). In the

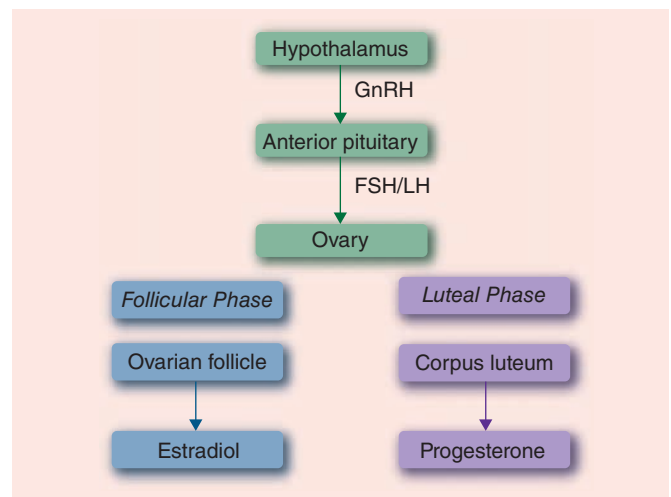

FIGURE 49–2. Summary of normal menstrual cycle. (FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.)

FIGURE 49-3. Hormonal fluctuations with the normal menstrual cycle. (FSH, follicle-stimulating hormone; LH, luteinizing hormone.) (Data from Umland EM, Weinstein LC, Buchanan E. Menstruation-related disorders (Chapter 89). In: Pharmacotherapy: A Pathophysiologic Approach, 8th ed. New York, NY: McGraw-Hill, 2011, with permission.)

specialized cells of the ovarian follicle, FSH and LH stimulate estradiol's release. Estradiol stimulates endometrial growth during the follicular phase of the cycle. Following the LH surge and ovulation, the follicle transforms into the corpus luteum. Progesterone secreted by the corpus luteum during the luteal phase of the cycle causes endometrial "organization." If conception does not occur, the drop in estrogen and progesterone stimulates endometrial shedding.^{5,20,22} **Table 49-2** illustrates amenorrhea pathophysiology relative to the organ system(s) involved, as well as the condition(s) resulting in amenorrhea. Amenorrhea is an expected, potential side effect resulting from use of low-dose oral CHCs, extended-cycle oral CHCs, or depot medroxyprogesterone acetate.²⁸ Many women experience delayed return of menses after CHC discontinuation. Postpill amenorrhea usually is a self-limited condition. Further evaluation for other conditions such as polycystic ovary syndrome (PCOS) should be considered if spontaneous resolution of amenorrhea does not occur within 3 to 6 months following CHC discontinuation.

Treatment

► Desired Outcomes

- Therapeutic modalities for amenorrhea are targeted at restoring the normal menstrual cycle. The goals of treatment are to preserve bone density, prevent bone loss, and restore ovulation, thus improving fertility as desired. Amenorrhea resulting from conditions contributing to hypoestrogenism affects quality of life via hot flash induction (e.g., premature ovarian failure), dyspareunia, and, in prepubertal females, absence of secondary sexual characteristics and menarche.

► Nonpharmacologic Therapy

- Nonpharmacologic therapy for amenorrhea varies depending on its underlying cause. Amenorrhea secondary to undernutrition or anorexia may respond to weight gain.¹⁹

Clinical Presentation and Diagnosis of Amenorrhea

General

- Patients may be concerned about cessation of menses and fertility implications but generally are not in acute distress.

Symptoms

- Cessation of menses
- Possible complaints of infertility, vaginal dryness, decreased libido

Signs

- Absence of menses by age 15 in the presence of normal secondary sexual development or within 5 years of thelarche (if occurs before age 10).
- Recent significant weight loss or gain
- Presence of acne, hirsutism, hair loss, or **acanthosis nigricans** may suggest androgen excess.

Laboratory Tests

- Pregnancy test
- TSH
- Prolactin
- If PCOS is suspected, consider free or total testosterone, 17-hydroxyprogesterone, fasting glucose, and fasting lipid panel.
- If premature ovarian failure is suspected, consider FSH and LH measurements.

Other Diagnostic Tests

- Progesterone challenge
- Pelvic ultrasound to evaluate for polycystic ovaries

Table 49–2

Pathophysiology of Selected Menstrual Bleeding Disorders

Organ System	Condition	Pathophysiology/Laboratory Findings
Amenorrhea ^{1,20,24}		
Uterus	Asherman's syndrome Congenital uterine abnormalities	Postcurettage/postsurgical uterine adhesions Abnormal uterine development
Ovaries	Turner's syndrome Gonadal dysgenesis Premature ovarian failure Chemotherapy/radiation	Lack of ovarian follicles Other genetic anomalies Early loss of follicles Gonadal toxins
Anterior pituitary	Pituitary prolactin-secreting adenoma Hypothyroidism	↑ Prolactin suppresses HPO axis TRH causing ↑ prolactin, other abnormalities
Hypothalamus	Medications—antipsychotics, verapamil “Functional” hypothalamic amenorrhea Disordered eating Exercise Anovulation/PCOS	↑ Prolactin suppresses HPO axis ↓ Pulsatile GnRH secretion in the absence of other abnormalities ↓ Pulsatile GnRH secretion, ↓ FSH and LH secondary to weight loss ↓ Pulsatile GnRH secretion, ↓ FSH and LH secondary to low body fat Asynchronous gonadotropin and estrogen production, abnormal endometrial growth
Anovulatory Bleeding ^{1,8,25,26}		
Physiologic causes	Adolescence Perimenopause	Immature hypothalamic-pituitary-ovarian axis: no LH surge Declining ovarian function
Pathologic causes	Hyperandrogenic anovulation—PCOS Hypothalamic dysfunction (physical or emotional stress, exercise, weight loss) Hyperprolactinemia (pituitary gland tumor, psychiatric medications) Hypothyroidism Premature ovarian failure	Hyperandrogenism: high testosterone, high LH, hyperinsulinemia, and insulin resistance Suppression of pulsatile GnRH secretion and estrogen deficiency: low LH, low FSH High prolactin High TSH High FSH
Menorrhagia ²⁷		
Hematologic	von Willebrand's disease Idiopathic thrombocytopenic purpura	Factor VII defect causing impaired platelet adhesion and increased bleeding time Decrease in circulating platelets—can be acute or chronic
Hepatic	Cirrhosis	Decreased estrogen metabolism, underlying coagulopathy
Endocrine	Hypothyroidism	Alterations in HPO axis
Uterine	Fibroids Adenomyosis Endometrial polyps Gynecologic cancers	Alteration of endometrium, changes in uterine contractility Alteration of endometrium, changes in uterine contractility Alteration of endometrium Various dysplastic alterations of endometrium, uterus, cervix

↑, high; ↓, low; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; HPO, hypothalamic-pituitary-ovarian axis; LH, luteinizing hormone; PCOS, polycystic ovary disease; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

Data from Refs. 1, 7, 18, 21, and 23–25.

- Such patients also would benefit from psychotherapy. In young women for whom excessive exercise is an underlying cause, exercise reduction is recommended.

► Pharmacologic Therapy

- Estrogen/Progestin Replacement Therapy** ⁴ For most conditions associated with primary or secondary amenorrhea, estrogen treatment (along with a progestin to minimize the risk of endometrial hyperplasia) is utilized. The purpose of estrogen therapy in this patient population is multifactorial: to reduce osteoporosis risk, stimulate and maintain secondary sexual characteristics, and improve quality of life.^{6,13,19} Table 49–1 identifies therapeutic options for amenorrhea,

including recommended doses. **Figure 49–4** illustrates a treatment algorithm for amenorrhea management.

- Bromocriptine** If hyperprolactinemia is the cause of amenorrhea in women who desire conception, use of a dopamine agonist, most commonly, bromocriptine, results in a reduction in prolactin concentrations and resumption of menses.^{7,19} Bromocriptine normalizes prolactin levels in 90% of women, and fertility is restored in 80% of women.²⁹
- Progestins** Progestins have long been used to induce withdrawal bleeding in women with secondary amenorrhea. Several factors predict progesterone's efficacy for this purpose.³⁰ These factors include estrogen concentrations greater than or equal to 35 pg/mL (128 pmol/L) and endometrial

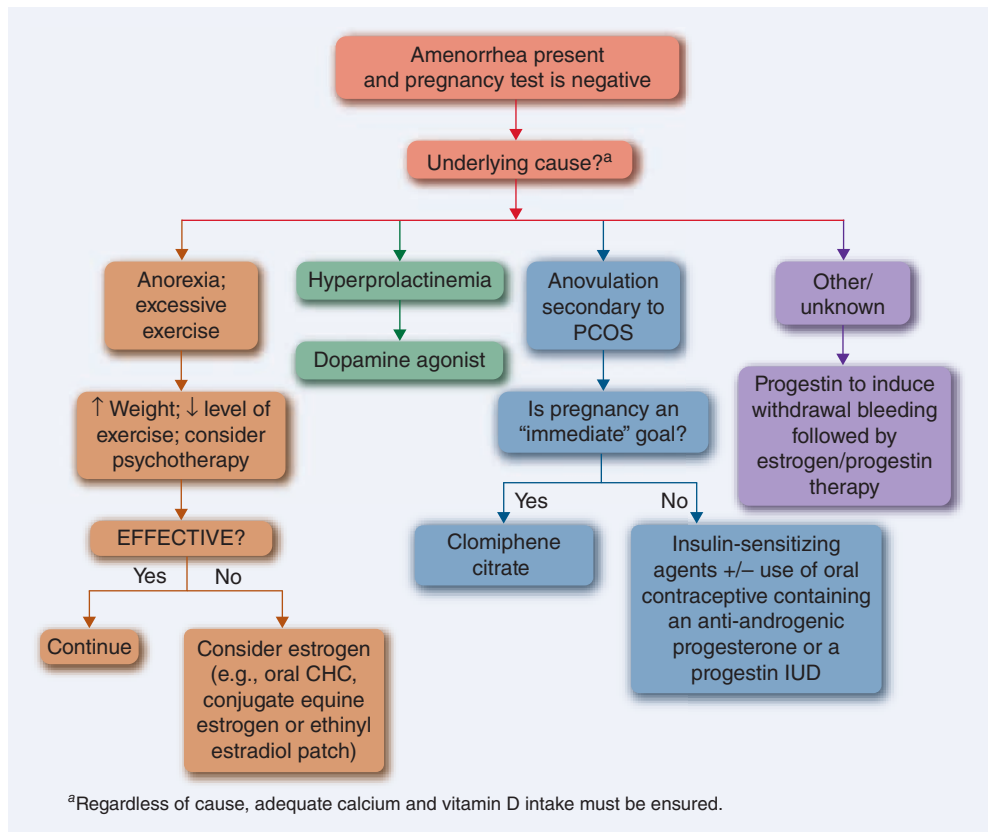

FIGURE 49-4. Treatment algorithm for amenorrhea. (CHC, combination hormonal contraceptive; IUD, intrauterine device; PCOS, polycystic ovarian syndrome.)

thickness (the greater it is, the greater the amount of withdrawal bleeding).

Progestin efficacy for secondary amenorrhea also varies depending on the formulation used. For example, progesterone in oil administered intramuscularly results in withdrawal bleeding in 70% of treated patients, whereas oral medroxyprogesterone acetate induces withdrawal bleeding in 95% of treated patients.³⁰ Table 49-1 identifies the types and doses of progestins used for inducing withdrawal bleeding in secondary amenorrhea. Figure 49-4 illustrates when to consider progestins for amenorrhea treatment.

• **Insulin-Sensitizing Agents** Amenorrhea related to anovulation and PCOS may respond to the use of insulin sensitizing agents.⁸ The use of metformin for this purpose will be discussed in the following anovulatory bleeding section.

For all patients experiencing amenorrhea, owing to the negative impact this has on bone health, a diet rich in calcium and vitamin D must be followed.

Amenorrhea in Adolescents

Amenorrhea in the adolescent population is very important, as this is when peak bone mass is achieved. The cause of amenorrhea and appropriate treatment must be identified promptly in this population because hypoestrogenism contributes negatively to bone development.¹⁹ Estrogen replacement, typically via a CHC, is important. Although some recent data suggest that CHCs and depo-medroxyprogesterone acetate may reduce bone mineral density (BMD) short-term,

their long-term effects on fractures are unknown. Additionally, these negative BMD effects appear to be reversible; therefore, CHC use is still recommended in the adolescent population.³¹ Ensuring adequate dietary calcium and vitamin D intake in this population is imperative.

ANOVULATORY BLEEDING

Anovulatory bleeding is irregular menstrual blood flow from the endometrium that ranges from light spotting to heavy blood flow.³² 5 *Anovulatory bleeding, also referred to as dysfunctional uterine bleeding, is secondary to the effects of unopposed estrogen and does not include bleeding owing to an anatomic lesion of the uterus.* It includes noncyclic menstrual bleeding due to anovulation or oligo-ovulation.²⁶ Anovulatory bleeding is a diagnosis of exclusion and includes PCOS, which typically presents with irregular menstrual bleeding, **hirsutism**, obesity, and/or infertility.⁸

Epidemiology

Anovulatory bleeding is the most common form of noncyclic uterine bleeding.³² Patients often seek medical care to regulate their menstrual cycle or improve fertility. All women of reproductive age should have a pregnancy test when presenting with irregular menstrual bleeding. Anovulation may be secondary to physiologic or pathologic causes. It is common at menarche and in the perimenopausal period. During adolescence, ovulatory menstrual cycles may not be regular for 12 to 18 months after menarche.³² Ovulation frequency

is related to the age at and time since menarche.¹⁸ In the year following menarche, the feedback mechanism in the hypothalamic-pituitary-ovarian (HPO) axis may be immature, and the LH surge needed for ovulation fails to occur.³² During perimenopause, anovulatory cycles may occur due to declining quality and quantity of ovarian follicles. As ovarian function declines, estrogen secretion continues, and progesterone secretion decreases. Chronic anovulatory cycles and unopposed estrogen secretion lead to endometrial proliferation and increased risk of polyps, endometrial hyperplasia, and endometrial carcinoma.²⁶

Anovulation also may occur at any time during the reproductive years due to a pathologic cause. The most common causes of nonphysiologic ovulatory dysfunction and their prevalence rates²⁶ are:

- PCOS (70%)
- Hypothalamic amenorrhea (10%)
- Hyperprolactinemia (10%)
- Premature ovarian failure (10%)

PCOS, although responsible for 55% to 91% (depending on the definition) of ovulatory dysfunction cases, occurs in approximately 7% of women.⁸

Etiology

Anovulation results from dysfunction at any level of the HPO axis. In addition to physiologic life stages such as adolescence, perimenopause, pregnancy, and lactation, other causes of anovulation include the following^{18,26}:

- Hyperandrogenic anovulation (PCOS, congenital adrenal hyperplasia, androgen-producing tumors)
- Hypothalamic dysfunction (anorexia nervosa, physical or emotional stress)
- Hyperprolactinemia
- Hypothyroidism
- Primary pituitary disease
- Premature ovarian failure

Pathophysiology

A normal ovulatory cycle includes follicular development, ovulation, **corpus luteum** development, and **luteolysis**. During the cycle, the endometrium proliferates and undergoes secretory changes and desquamation. This is influenced by the effects of estrogen alone, then by estrogen and progesterone, and culminates with estrogen and progesterone withdrawal. Progesterone stops endometrial growth and stimulates endometrial differentiation. In anovulatory women, a corpus luteum is not formed, and the ovary does not secrete progesterone. Without progesterone, there is no endometrial desquamation or differentiation. Chronic unopposed estrogen causes endometrial proliferation, and the endometrium becomes vascular and fragile, resulting in noncyclic menstrual bleeding. The endometrium may also become hyperplastic and progress to a precancerous state, increasing

the woman's risk of endometrial cancer.¹ See Table 49–2 for the pathophysiology of anovulatory bleeding relative to the specific conditions contributing to it.

- The most common pathologic cause of anovulation is PCOS. Although PCOS does not have a universal definition, consensus criteria have been updated to include the presence of polycystic ovaries on ultrasound. The Rotterdam criteria identify PCOS as a syndrome of ovarian dysfunction diagnosed by when two of the following characteristics exist: (a) **oligoanovulation** or anovulation; (b) clinical signs (hirsutism, acne) or laboratory evidence of hyperandrogenism (total testosterone and sex hormone-binding globulin); and (c) polycystic ovary morphology on ultrasound.^{8,33} The Androgen Excess Society (AES) recognizes hyperandrogenism as a mandatory component of diagnosis in addition to oligoanovulation or anovulation, polycystic ovaries on ultrasound, or both.^{8,33} No gene or environmental substance appears to cause PCOS.⁸ However, familial clustering of PCOS cases suggests that genetics play a role. Insulin resistance, hyperandrogenism, and changes in gonadotropins also influence PCOS development. The underlying cause for increased androgens is unknown.^{35,36}

Recently, discussion regarding the link to cardiovascular disease has been emphasized. PCOS is associated with a two to five times increased risk of developing type 2 diabetes.⁸ In women with PCOS, approximately 60% to 80% have impaired glucose tolerance (IGT). In obese women with PCOS, IGT prevalence increases to 95%,³⁷ and 70% have dyslipidemia.^{8,37} Although rates of cardiovascular disease mortality directly related to PCOS are unknown, women with PCOS should be screened for IGT, diabetes, hypertension, and dyslipidemia.⁸ If any of these are present, there is an increased risk of cardiovascular events.^{37,38}

Treatment

► Desired Outcomes

- The desired, short-term outcome of therapy is to stop acute bleeding. The long-term goals include preventing future episodes of noncyclic bleeding, decreasing long-term complications of anovulation (e.g., osteopenia and infertility), and improving overall quality of life.²⁶ Table 49–1 identifies the agents used in anovulatory bleeding management, their doses, and common side effects.

► Nonpharmacologic Therapy

- Nonpharmacologic treatment options for anovulatory bleeding depend on the underlying cause. For all women with PCOS, weight loss may be beneficial. In overweight or obese women, a 5% reduction in weight has been associated with resumption of menses, improved pregnancy rates, and decreased hirsutism, glucose, and lipid levels.⁸ In women who have completed childbearing or who have failed medical management, endometrial ablation or resection and hysterectomy are surgical options. It is unclear which procedure is preferred. Short term, it appears that ablation or resection

Clinical Presentation and Diagnosis of Anovulatory Bleeding

General

- May or may not be in acute distress

Symptoms

- Irregular, heavy, or prolonged vaginal bleeding, perimenopausal symptoms (hot flashes, etc.)

Signs

- Acne, hirsutism, obesity

Laboratory Tests

- If suspect PCOS, consider free or total testosterone, fasting glucose, fasting lipid panel.
- If suspect perimenopause, FSH.

Other Diagnostic Tests

- Pelvic ultrasound to evaluate for polycystic ovaries

results in less morbidity and shorter recovery periods.³⁹ However, a significant number of these women eventually undergo hysterectomy in the following 5 years.²⁶

► Pharmacologic Therapy

- **Estrogen** Estrogen is the recommended treatment for managing acute bleeding episodes because it promotes endometrial growth and stabilization.²⁶ Its use via CHC regimens has averted emergency surgical procedures in 95% of patients.⁹ Following estrogen's initial use to control acute bleeding

episodes, it should be continued to prevent future occurrences. CHC use fulfills this role.

- In addition to controlling acute bleeding, CHC use also aids in preventing recurrent anovulatory bleeding. They suppress ovarian hormones and adrenal androgen production and indirectly increase sex hormone-binding globulin (SHBG). This, in turn, binds and reduces circulating androgen.^{8,26,40} For women with high androgen levels and related signs (e.g., hirsutism), low-dose CHCs (less than or equal to 35 mcg ethinyl estradiol) are the treatment of choice.²⁶ In theory, one may consider a CHC with a progestosterone such as drospirenone that has greater impact on increasing SHBG and antiandrogenic effects.⁴¹ However, to date there is no consensus regarding the best CHC choice for treating PCOS.⁸

- **Medroxyprogesterone Acetate** Depot and intermittent oral medroxyprogesterone acetate suppresses pituitary gonadotropins and circulating androgens in women with PCOS.⁸ Furthermore, cyclic progesterone use may benefit women over age 40 with anovulatory bleeding.²⁶ Similar to the use of CHCs, oral medroxyprogesterone acetate use has been observed to avert emergency surgical procedures in 100% of patients for acute uterine bleeding justifying immediate medical attention.⁹

- **Insulin-sensitizing Agents** The use of metformin and the thiazolidinediones, pioglitazone and rosiglitazone, results in improved insulin sensitivity. In patients with PCOS, this is associated with reduced circulating androgen concentrations, increasing ovulation rates, and improving glucose tolerance.⁸ These improvements can be attributed to the SHBG increase that occurs via increased insulin sensitivity.

6 *These agents are of benefit not only for anovulatory bleeding and fertility, but also because they improve glucose tolerance and decrease overall cardiovascular risk.*⁸ Metformin has an additional benefit of potentially promoting weight loss, whereas the thiazolidinediones may cause weight gain. The thiazolidinediones have fallen out of favor in recent years due to the potential negative cardiovascular effects.⁴² There are no well-controlled trials lasting longer than 1 year in women with PCOS.⁸ If pregnancy is a desired outcome, it is important to note that metformin is a pregnancy category B agent, whereas pioglitazone and rosiglitazone are category C.

Clomiphene Citrate Although insulin-sensitizing agent use may improve fertility, if the treatment goal is to induce ovulation, then the treatment of choice is clomiphene citrate. It is approximately three times more effective than metformin at achieving live births.⁸ A recent meta-analysis has shown that combination therapy with an insulin-sensitizing agent such as metformin plus clomiphene citrate may be more effective in increasing pregnancy rates, especially in obese women with PCOS.^{8,43,44} Treatment with clomiphene citrate 50 mg/day for 5 days can be initiated between days 3 and 5 of the menstrual cycle. This is often recommended following withdrawal bleeding induction with medroxyprogesterone acetate, 10 mg/day by mouth for 10 days.

Patient Encounter 2, Part 1

TP, a 32-year-old woman, presents to your office for a routine gynecologic examination. She entered menarche at the age of 12. Her last menstrual period was 3 months ago. Her periods are often irregular and occur about every 2 to 3 months. She has had all normal Pap smears in the past and no history of sexually transmitted infections. She has had a total of four sexual partners. She has never been pregnant. She is married and has noted that she is not using any form of contraception, as she and her husband have been trying, unsuccessfully, to become pregnant for the past 12 months. As you examine the patient, you note facial and chest acne, increased facial and abdominal hair, and obesity.

What anovulatory disorder is most likely present?

What signs/symptoms support this conclusion?

What diagnostic tests should be done?

Patient Encounter 2, Part 2

PMH: Obesity; acne

FH: Father is living and has hypertension. Mother is living and has diabetes mellitus and hypercholesterolemia. Both parents are obese.

SH: The patient works as a secretary. She lives with her husband. She denies any tobacco or recreational drug use. She drinks 1 to 2 alcoholic beverages per week. She denies regular exercise.

Meds: None

ROS: (+) acne, (+) hirsutism, (–) dysmenorrhea, (–) breast tenderness, (–) vaginal discharge

PE:

VS: blood pressure 128/82, pulse 80 beats per minute, respiratory rate 18, weight 170 lb (77.3 kg), height 5 ft, 3 in (160 cm), BMI 30.2 kg/m²

Abd: Obese, soft, nontender, nondistended, (+) bowel sounds, no hepatosplenomegaly

Gyn: Normal external appearance; vaginal walls normal; cervix well visualized and without lesions; midposition uterus; no cervical motion tenderness; no **adnexal** masses palpated

Labs: Urine HCG negative, free testosterone 100 ng/dL (3.47 nmol/L) (elevated), TSH 2.1 μ IU/mL (2.1 milliunits/L) (within normal limits), prolactin 9 ng/mL (9 mcg/L) (within normal limits), fasting glucose 120 mg/dL (6.7 mmol/L). Fasting lipid panel: total cholesterol 181 mg/dL (4.68 mmol/L), HDL cholesterol 58 mg/dL (1.50 mmol/L), triglycerides 65 mg/dL (0.73 mmol/L), LDL cholesterol 110 mg/dL (2.84 mmol/L).

Pelvic ultrasound

15 follicles in right ovary, 14 follicles in left ovary, increased ovarian volume of 12 mL

What treatment options are available for this patient?

Anovulatory Bleeding in Adolescents

Anovulatory cycles are common in the perimenarchal reproductive years. Ovulation typically is established a year or more following menarche. When anovulatory bleeding occurs in this population, it may be excessive. In this case, the patient should be evaluated for blood dyscrasias, including von Willebrand's disease, prothrombin deficiency, and idiopathic thrombocytopenia purpura.^{26,27}

In the adolescent population, specific blood dyscrasias should be treated. In addition, acute, severe bleeding is managed with high-dose estrogen. Low-dose CHCs (less than or equal to 35 mcg ethinyl estradiol) are the treatment of choice in adolescents with chronic anovulation.²⁶

MENORRHAGIA

The term **menorrhagia** describes prolonged menstrual bleeding or cyclic, heavy blood loss. Menstrual cycles lasting greater than 7 days are considered prolonged, and heavy menstrual bleeding is menstrual blood loss greater than 80 mL per cycle.^{25,32} The latter definition has been questioned for several reasons, including difficulty with quantifying menstrual blood loss in clinical practice. Many women with “heavy menses,” but who experience less than 80 mL of blood loss, merit consideration for treatment because of containment flow problems, unpredictable heavy flow days, and other associated dysmenorrhea symptoms.^{45,46}

Epidemiology and Etiology

Menorrhagia rates in healthy women range from 9% to 14%.

7 *Causes of menorrhagia can be divided into systemic disorders and reproductive tract abnormalities.* **8** *Intrauterine pregnancy, ectopic pregnancy, and miscarriage must be at the top of the differential diagnosis list for any woman presenting with heavy menses.* Additionally, genital tract malignancies and infection may present with abnormal bleeding.²⁵ Sys-

Clinical Presentation and Diagnosis of Menorrhagia

General

- Patient may or may not be in acute distress.

Symptoms

- Complaints of heavy/prolonged menstrual flow and fatigue and light-headedness in the case of severe blood loss. These symptoms may or may not occur with dysmenorrhea.

Signs

- Orthostasis, tachycardia, and pallor may be noted, especially with significant acute blood loss.

Laboratory Tests

- Complete blood count (CBC) and ferritin levels; hemoglobin and hematocrit results may be low.
- If the history dictates, testing may be done to identify coagulation disorder(s) as a cause.

Other Diagnostic Tests

- Pelvic ultrasound
- Pelvic magnetic resonance imaging (MRI)
- Pap smear
- Endometrial biopsy
- Hysteroscopy
- Sonohysterogram

temic disorders include coagulation dysfunction such as von Willebrand's disease and platelet function disorders.^{25,27,32}

- Hypothyroidism is also associated with heavy menses. Specific reproductive tract causes of menorrhagia are more common in older childbearing women, and they include fibroids, adenomyosis, endometrial polyps, and gynecologic malignancies.³²

Pathophysiology

Table 49–2 illustrates the pathophysiology of menorrhagia relative to the organ system(s) involved and the specific conditions resulting in menorrhagia.

Treatment

► Desired Outcomes

- Menorrhagia therapy should reduce menstrual blood flow, improve the patient's quality of life, and defer the need for surgical intervention. Table 49–1 identifies agents used in managing menorrhagia. It also includes their dosing and common side effects. **Figure 49–5** illustrates which treatment(s) to use and when.

► Nonpharmacologic Therapy

- Nonpharmacologic interventions for menorrhagia include surgical interventions that are reserved for patients nonresponsive to pharmacologic treatment. These interventions vary from conservative endometrial ablation to hysterectomy.³⁹

► Pharmacologic Therapy

- **Nonsteroidal Anti-inflammatory Drugs (NSAIDs)** Nonsteroidal anti-inflammatory drugs (NSAIDs) are first-line treatments for menorrhagia associated with ovulatory cycles.⁴⁰ They have the advantage of being taken only during menses, and their use is associated with a significant reduction in menstrual blood loss. A 20% to 50% reduction in blood loss has been observed in 75% of treated women.^{12,40} In some patients, as much as an 80% reduction has been observed. **9** *This reduction is directly proportional to the amount of pretreatment blood loss.*¹²
- **Combination Hormonal Contraceptives** CHC use is beneficial to women with menorrhagia who do not desire pregnancy. A 40% to 50% menstrual blood loss reduction has been observed in 68% of menorrhagia patients treated with oral CHCs containing greater than or equal to 35 mcg estradiol.^{12,15}

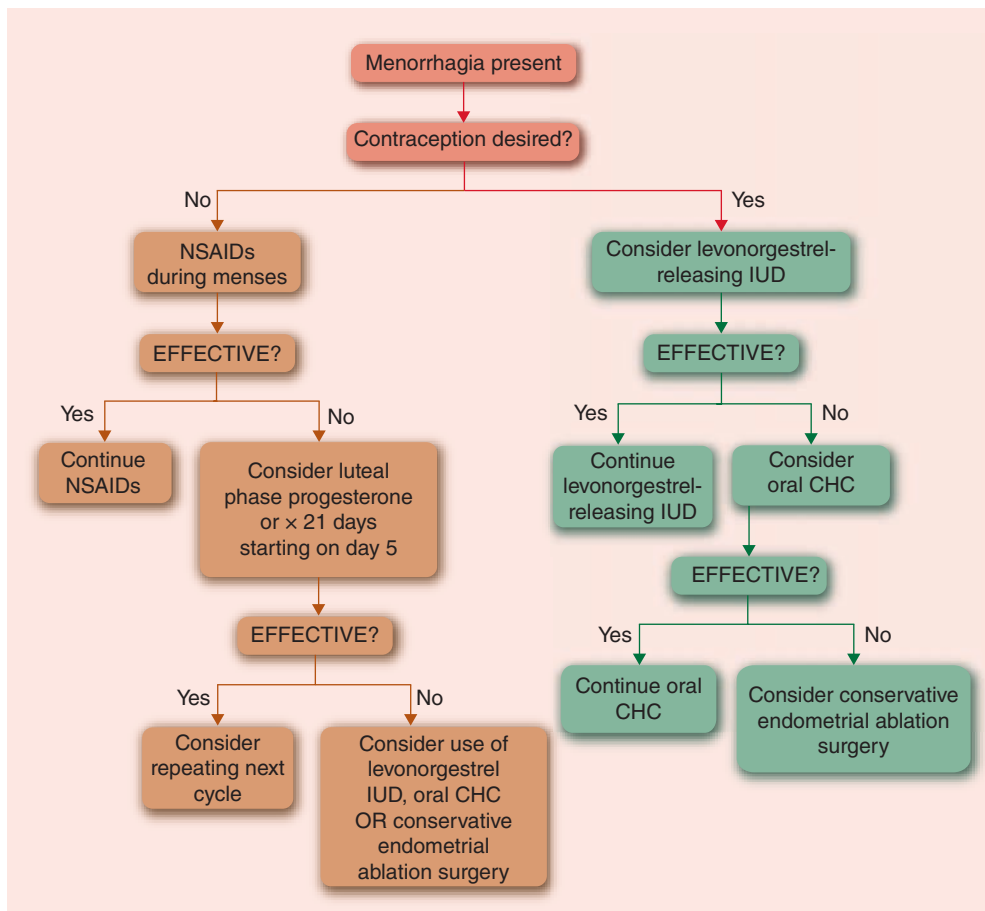

FIGURE 49–5. Treatment algorithm for menorrhagia. (CHC, combination hormonal contraceptive; IUD, intrauterine device; NSAID, nonsteroidal anti-inflammatory drug.)

Continuous and extended cycle options may also reduce the number of menstrual cycles.¹⁵ As with NSAID use, **9** *the reduction in blood loss is proportional to pretreatment blood loss.*

● **Progesterone** Menorrhagia also may be treated with the levonorgestrel-releasing IUD. This treatment is effective and consistently reduces menstrual flow by 75% to 95%, and after 12 months, 20% to 80% of women experience amenorrhea.^{12,15,16,40,47} When compared with endometrial ablation, the progesterone IUD has similar menstrual blood loss reductions after 6, 12, and 24 months.⁴⁸ Its use has also resulted in postponing or canceling scheduled endometrial resection surgery or hysterectomy. Specifically, 60% of treated patients have avoided hysterectomy.^{16,49,50}

The progesterone IUD is more effective than oral norethindrone administered cyclically.^{15,51} In a small open-label study, the levonorgestrel IUD resulted in a greater menstrual blood loss reduction and number of lost days compared with oral CHCs.⁵²

● Progesterone therapy either during the luteal phase of the menstrual cycle or for 21 days starting on day 5 after menses onset results in a 32% to 50% menstrual blood loss reduction.¹² Its use is not superior to other medical treatments, including NSAIDs.¹² In addition, it is not associated with contraceptive benefits.

Menorrhagia in Adolescents

● In several studies of adolescents with acute menorrhagia, underlying bleeding disorders accounted for 3% to 13%

of emergency room visits.²⁸ Further, 20% of adolescent females requiring hospitalization for excessive menstrual bleeding have an underlying coagulopathy.²³ Although von Willebrand's disease has a 1% incidence in the general population, it is estimated that 5% to 36% of adolescents presenting with heavy menses have von Willebrand's disease.^{27,28} Platelet function disorders exist in 2% to 44% of adolescents with menorrhagia.²⁷

OUTCOME EVALUATION

Treatment success for menstruation-related disorders is measured by the degree to which the care plan (a) relieves or reverses the disorder's symptoms, (b) prevents or reverses the disorder's complications (e.g., osteoporosis, anemia, and infertility), and (c) results in minimal side effects. Resumption of regular menstrual cycles with minimal premenstrual or dysmenorrhea symptoms should occur. Depending on the desire for conception and related therapy, these cycles may be ovulatory or anovulatory.

Assess treatment efficacy in resuming normal menstrual cycles with minimal side effects after an appropriate treatment interval (1 to 2 months). Assess improvement in quality-of-life measures such as physical, psychological, and social functioning and well-being. Evaluate the patient for adverse drug reactions, drug allergies, and drug interactions. Table 49–1 illustrates the common side effects that require monitoring. Table 49–3 illustrates the expected outcome measures for each menstruation-related disorder discussed in this chapter.

Table 49–3

Expected Outcome Measures for Selected Menstrual Bleeding Disorders

Menstrual Disorder	Expected Outcome Measures
Amenorrhea	Efficacy: Normal breast development (especially primary amenorrhea in adolescents); BMD preservation/improvement; return of menses. Time to relief/effect: Menses should occur within 1–2 months of therapy.
Anovulatory bleeding	Efficacy: Alleviation of acute bleeding when present; ovulation and subsequent pregnancy in women desiring this; reduced risk of developing the long-term complications of PCOS (e.g., diabetes and cardiovascular disease); improved quality of life. Time to relief/effect: The acute treatment of heavy bleeding should reduce bleeding within 10 days of therapy onset; return of ovulation may require several months of therapy; when oral CHCs are used, abnormal bleeding control can be expected within 1–2 treatment cycles.
Dysmenorrhea	Efficacy: Reduction in menses-related pelvic pain; reduction in time lost from work/school; improved quality of life. Time to relief/effect: Improvement in pain may be observed within hours of NSAID therapy; improvement with other options such as oral CHCs may be observed after a full 1–3 cycles of use.
Menorrhagia	Efficacy: Decline in amount of blood loss with menses (monitor a decline in the number of times feminine hygiene products such as pads and tampons require changing during menses); increase in hemoglobin/hematocrit if anemia was present as because of menorrhagia. Time to relief/effect: A decline in menstrual blood loss should be realized within 1–2 cycles of therapy initiation.

BMD, bone mineral density; NSAID, nonsteroidal anti-inflammatory drug; CHCs, combination hormonal contraceptives; PCOS, polycystic ovary syndrome.

Data from Ref. 18, 25–28, 45.

Patient Care and Monitoring

1. Assess symptoms to determine whether patient-directed therapy is appropriate (e.g., NSAIDs for dysmenorrhea) or whether the patient should be evaluated by a physician (e.g., amenorrhea, menorrhagia, anovulatory bleeding, or premenstrual dysphoric disorder). Does the patient have any related complications, such as symptoms of anemia in patients presenting with menorrhagia or complaints of difficulty conceiving in women with amenorrhea or anovulatory bleeding?
2. Review any available diagnostic data, as appropriate, to determine hormonal, reproductive, and pregnancy status.
3. Obtain a thorough history of prescription, nonprescription, and natural drug product use. Determine which treatments have been helpful to the patient in the past.
4. Educate the patient on lifestyle modifications that will improve symptoms and prevent complications.
5. Is the patient taking the appropriate dose of the prescribed medication? If not, why not?
6. Develop a plan to assess effectiveness of the prescribed medication after 1 to 2 months of therapy.
7. Determine whether long-term maintenance treatment is necessary.
8. Assess improvement in quality-of-life measures such as physical, psychological, social functioning, and well-being.
9. Evaluate for adverse drug reactions, drug allergies, and drug interactions.
10. Stress the importance of adherence with the therapeutic regimen, including lifestyle modifications. Recommend a therapeutic regimen that is easy for the patient to adhere to.
11. Provide patient education regarding disease state, lifestyle modifications, and drug therapy by noting the following:
 - a. What causes the menstruation-related disorder?
 - b. What are the possible complications of the menstruation-related disorder?
 - c. What lifestyle modifications may help to reduce the risk associated with these complications?
 - d. When and how should patients take their medications?
 - e. What potential adverse effects may occur?
 - f. Which drugs may interact with their therapy?

Self-assessment questions and answers are available at <http://mhpharmacotherapy.com/pp.html>.

PCOS	polycystic ovarian syndrome
PID	pelvic inflammatory disease
SHBG	sex hormone-binding globulin
TENS	transcutaneous electrical nerve stimulation
ULN	upper limit of normal

Abbreviations Introduced in This chapter

ACOG	American College of Obstetricians and Gynecologists
BMD	bone mineral density
BMI	body mass index
CBC	complete blood count
CEE	conjugated equine estrogen
CHC	combination hormonal contraceptive
FSH	follicle-stimulating hormone
GI	Gastrointestinal
GnRH	gonadotropin-releasing hormone
HCG	human chorionic gonadotropin
HPA	hypothalamic-pituitary-adrenal
HPO	hypothalamic-pituitary-ovarian
IUD	intrauterine device
LH	luteinizing hormone
MPA	medroxyprogesterone acetate
MRI	magnetic resonance imaging
NIH	National Institutes of Health
NSAID	nonsteroidal anti-inflammatory drug
OC	oral contraceptive

Hormone Therapy in Menopause

Nicole S. Culhane and Kelly R. Ragucci

LEARNING OBJECTIVES

● **Upon completion of the chapter, the reader will be able to:**

1. Explain the physiologic changes associated with menopause.
2. Identify the signs and symptoms associated with menopause.
3. Determine the desired therapeutic outcomes for a patient taking hormone therapy (HT).
4. Explain how to evaluate a patient for the appropriate use of HT.
5. Recommend nonpharmacologic therapy for menopausal symptoms.
6. List the adverse effects of and contraindications to HT.
7. Differentiate between topical and systemic forms of HT.
8. Explain the risks and benefits associated with HT.
9. Educate a patient regarding the proper use and potential adverse effects of HT.
10. Describe the monitoring parameters for a patient taking HT.
11. Describe the circumstances under which nonhormonal therapies for menopausal symptoms should be considered.

KEY CONCEPTS

- 1 Common symptoms of menopause include hot flashes, night sweats, vulvovaginal atrophy, vaginal dryness, and dyspareunia. Women less commonly may experience mood swings, depression, insomnia, arthralgia, myalgia, urinary frequency, and decreased libido.
- 2 Hormone therapy (HT) remains the most effective treatment for vasomotor symptoms and vulvovaginal atrophy and can be considered, especially for women experiencing moderate to severe symptoms.
- 3 Women should receive a thorough history and physical examination, including assessing for coronary heart disease (CHD) and breast cancer risk factors before HT is considered. If a woman does not have any contraindications to HT, including CHD or significant CHD risk factors, and also does not have a personal history of breast cancer, HT may be an appropriate therapy option.
- 4 Oral or transdermal estrogen products should be prescribed at the lowest effective dose and for the shortest duration possible to provide relief of vasomotor symptoms. Topical vaginal products in the form of creams, tablets, or rings should be prescribed for women exclusively experiencing vulvovaginal atrophy.
- 5 Women who have an intact uterus should be prescribed a progestogen in addition to estrogen in order to decrease the risk of endometrial hyperplasia and endometrial cancer.
- 6 HT is also indicated for the prevention of osteoporosis, but is not recommended for long-term use. Traditional osteoporosis therapies such as bisphosphonates should be considered as first-line therapy for the prevention and treatment of osteoporosis, in addition to appropriate doses of calcium and vitamin D.
- 7 Combined estrogen plus progestogen should not be used in the prevention of chronic diseases because it increases the risk of CHD, stroke, breast cancer, venous thromboembolism (VTE), and dementia. Estrogen alone administered to women without a uterus does not increase the risk of breast cancer. Colorectal cancer and rates of fracture are reduced with combined hormonal treatment.
- 8 HT improves overall well-being and mood in women with vasomotor symptoms but has not demonstrated an improvement in quality of life (QOL) in women without vasomotor symptoms.
- 9 When treating moderate to severe postmenopausal symptoms, the benefit-to-risk ratio appears to be best

when HT is started close to the time of menopause. Therapy should be tapered before discontinuation in order to limit the recurrence of hot flashes.

- 10 Since the publication of the Women's Health Initiative (WHI) study, there has been an increase in the use of alternative and nonhormonal therapies for the management of menopausal symptoms, particularly for women with CHD and/or breast cancer risk factors. A wide range of therapies, both prescription and herbal, have been studied with varying degrees of success.

Menopause is the permanent cessation of menses following the loss of ovarian follicular activity. The diagnosis of menopause is primarily a clinical one and is made after a woman experiences amenorrhea for 12 consecutive months. The loss of ovarian follicular activity leads to an increase in follicle-stimulating hormone (FSH), which, on laboratory examination, may help to confirm the diagnosis.

The role of hormone therapy (HT) has changed dramatically over the years. HT has long been prescribed for relief of menopausal symptoms and, until recent years, has been purported to protect women from coronary heart disease (CHD). The reason behind recommending HT in postmenopausal women revolved around a simple theory: If the hormones lost during menopause were replaced through drug therapy, women would be protected from both menopausal symptoms and chronic diseases that often follow after a woman experiences menopause. Recent studies have disproved this theory.

In 1996, the United States Preventive Services Task Force first published its recommendations that not all postmenopausal women should be prescribed HT, but that therapy should be individualized based on risk factors. This recommendation was further supported with publication of the Heart and Estrogen/Progestin Replacement Study (HERS) in 1998, which demonstrated that women who had established CHD were at an increased risk of experiencing a myocardial infarction within the first year of HT use compared with a similar group of women without CHD risk factors. As a result, the authors concluded that HT should not be recommended for the secondary prevention of CHD.¹ Then, in 2002, the Women's Health Initiative (WHI) study was published. This trial demonstrated that HT was not protective against CHD but rather could increase the risk in women with underlying CHD risk factors. The risk of breast cancer was also increased after a woman was on combination estrogen and progestogen for approximately 3 years. It should be noted that this was not the case with estrogen alone. As a result of this study, the FDA issued a statement that HT, in general, should not be initiated or continued for the primary prevention of CHD.²

This series of trials led to dramatic changes in how HT is prescribed and greater understanding of the associated risks. HT, once thought of as a cure-all for menopausal symptoms, is now a therapy that should be used primarily to reduce the frequency and severity of moderate to severe **vasomotor symptoms** associated with menopause in women without

risk factors for CHD or breast cancer. The changes that have occurred over the years in the use of HT further support the importance of evidence-based practice and judicious medication use.

EPIDEMIOLOGY AND ETIOLOGY

Menopause is a period of time marked by loss of ovarian follicular activity, inadequate estradiol production, and the subsequent cessation of menses. It occurs in all women usually between the ages of 40 and 58 years. The median age for a woman to experience menopause is 52 years. However, women who have undergone a total abdominal hysterectomy with bilateral salpingo-oophorectomy (surgical menopause) generally experience menopause earlier compared with women who experience natural menopause. Some other factors that may be associated with early menopause include low body weight, increased menstrual cycle length, **nulliparity**, and smoking. Smokers generally experience menopause approximately 2 years earlier than nonsmokers.³

The usual transitional period prior to menopause, known as **perimenopause** or the *climacteric*, is a period when hormonal and biologic changes begin to occur. These changes may begin 2 to 8 years prior to menopause and eventually lead to irregular menstrual cycles, an increase in cycle interval, and a decrease in cycle length. During this time, women also may experience physical symptoms similar to menopausal symptoms, which may require treatment depending on symptom severity.³

Because the perimenopausal and postmenopausal periods are marked by many biologic and endocrinologic changes, women should inform their healthcare provider when they experience any signs and symptoms in order to discuss the most appropriate therapeutic approach.

PHYSIOLOGY

Reproductive physiology is regulated primarily by the hypothalamic-pituitary-ovarian axis. The hypothalamus secretes gonadotropin-releasing hormone (GnRH), which stimulates the anterior pituitary to secrete FSH and luteinizing hormone (LH). FSH and LH regulate ovarian function and stimulate the ovary to produce sex steroids. All of these hormones are influenced by a negative-feedback system and will increase or decrease based on the levels of estradiol and progesterone.

The physiologic changes that occur during the perimenopausal and menopausal periods are caused by the decrease and eventual loss of ovarian follicular activity. As women age, the number of ovarian follicles decreases, and the remaining follicles require higher levels of FSH for maturation and ovulation. During perimenopause, anovulatory cycles are more likely, and the lack of progesterone production leads to irregular and unpredictable menses. During menopause, FSH concentrations increase 10- to 15-fold, LH concentrations increase fivefold, and levels of circulating estradiol decrease by more than 90%.⁴

Clinical Presentation and Diagnosis of HT in Menopause

1 Menopausal Symptoms

- Vasomotor symptoms (**hot flashes**, night sweats)
- Irregular menses
- Episodic amenorrhea
- Sleep disturbances
- Mood swings
- Vaginal dryness, dyspareunia
- Depression

Less Common Symptoms

- Fatigue

- Irritability
- Migraine
- Arthralgia
- Myalgia
- Decreased libido

Diagnosis

- Amenorrhea for 1 year
- FSH greater than 40 milliunits/mL (40 units/L)
- Fivefold increase in LH

1 Common symptoms of menopause include vasomotor symptoms (hot flashes, night sweats), vulvovaginal atrophy, vaginal dryness, and **dyspareunia**. Women less commonly may experience mood swings, depression, insomnia, arthralgia, myalgia, urinary frequency, and decreased libido. Menopausal symptoms tend to be more severe in women who undergo surgical menopause compared with natural menopause because of the more rapid decline in estrogen concentrations.³ Women who seek medical treatment should undergo laboratory evaluation to rule out other conditions that may present with similar symptoms, such as abnormal thyroid function or pituitary adenoma. Once symptoms have been evaluated and other conditions have been excluded, HT may be considered.

Patient Encounter, Part 1

RJ, a 52-year-old woman with a history of hypertension, osteoarthritis, and hypothyroidism, presents to the clinic complaining of hot flashes, vaginal dryness, and insomnia. She states that she experiences approximately three hot flashes per day and is awakened from sleep at least three to four times a week in a “pool of sweat” requiring her to change her clothes and bed linens. Her symptoms began about 3 months ago, and over that time, they have worsened to the point where they have become very bothersome. On questioning, she states her last menstrual period was 1 year ago.

Which of the patient’s symptoms and past medical history are consistent with menopause?

What additional information do you need to know in order to make an appropriate therapeutic plan for this patient?

TREATMENT

Desired Outcomes

2 HT remains the most effective treatment for vasomotor symptoms and vulvovaginal atrophy and can be considered, especially for women experiencing moderate to severe symptoms.

- The goals of treatment are to alleviate or reduce menopausal symptoms and to improve the patient’s quality of life (QOL) while minimizing adverse effects of therapy. The appropriate route of administration should be chosen based on individual patient symptoms, and therapy should be continued at the lowest dose for the shortest duration consistent with treatment goals for each patient.

General Approach to Treatment

There are a number of national and international guidelines and consensus statements available on the management of menopause.⁵⁻⁹ The most current guidelines should always be consulted before making pharmacotherapeutic recommendations for women. Women suffering from vasomotor symptoms should attempt lifestyle or behavioral modifications before seeking medical treatment. Women who seek medical treatment usually suffer from symptoms that diminish their QOL, such as multiple hot flashes per day or week, sleep disturbances, vaginal dryness, or mood swings. HT should be considered for these women, but is not the most appropriate choice for all women. 3 Women should receive a thorough history and physical examination, including assessing for CHD and breast cancer risk factors and contraindications, before HT is considered. They should be informed of the risks and the benefits of HT and encouraged to be involved in the decision-making process. If a woman does not have any contraindications to HT, including CHD or significant CHD risk factors, and also does not have a personal history of breast cancer, HT could be an appropriate therapy option (Fig. 50-1). Women who have undergone a hysterectomy need only be prescribed estrogen. A progestogen should be added to the estrogen only

Patient Encounter, Part 2: Medical History, Physical Exam, and Diagnostic Tests

RJ's workup reveals the following additional information:

PMH: Osteoarthritis of the lower back for 5 years controlled on acetaminophen 500 mg two tablets by mouth 3 to 4 times daily; hypertension since age 45, currently controlled; hypothyroidism since age 25, currently controlled

FH: Father: Alive with HTN and CHD (MI at age 60). Mother: Alive with hypothyroidism and GERD. Siblings: Two sisters alive and well.

SH: Occupation: nurse; nonsmoker; drinks one to two glasses of red wine with dinner on the weekends; denies illicit drug use

Meds: Acetaminophen 500 mg two tablets by mouth 3 to 4 times daily; lisinopril/HCTZ 20/12.5 mg once daily; Synthroid 0.075 mg by mouth once daily; multivitamin by mouth once daily

ROS: (+) hot flashes, night sweats, vaginal dryness and itching; (+) insomnia, myalgias, bowel changes, weight gain, constipation

PE:

VS: BP 128/78, P 78, RR 16, T 37.0°C (98.6°F), wt 74.5 kg (164 lb)

HEENT: WNL

Neck: Supple; no bruits, no adenopathy, no thyromegaly.

Breasts: Supple; no masses

CV: RRR, normal S₁ and S₂; no murmurs, rubs, or gallops

Abd: Soft, nontender, nondistended; (+) BS, no masses

Genitourinary: Pelvic examination normal except (+) mucosal atrophy

Labs:

FSH: 76 mIU/mL (76 IU/L)

TSH: 2.5 µU/mL (2.5 mIU/L)

Chem-7: Na 135 mEq/L (135 mmol/L), K 4.5 mEq/L (4.5 mmol/L), Cl 109 mEq/L (109 mmol/L), CO₂ 25 mEq/L (25 mmol/L), BUN 9 mg/dL (3.21 mmol/L), SCr 0.9 mg/dL (80 µmol/L), Glucose 98 mg/dL (5.44 mmol/L)

CBC: Hgb 13 g/dL (130 g/L or 8.06 mmol/L), Hct 39% (0.39 volume fraction), WBC $5.5 \times 10^3/\text{mm}^3$ ($5.5 \times 10^9/\text{L}$), platelets $234 \times 10^3/\text{mm}^3$ ($234 \times 10^9/\text{L}$)

Fasting lipid levels: TC 232 mg/dL (6 mmol/L), low-density lipoprotein (LDL) 145 mg/dL (3.76 mmol/L), high-density lipoprotein (HDL) 45 mg/dL (1.17 mmol/L), Triglycerides (TG) 200 mg/dL (2.26 mmol/L)

Assess the patient's condition based on this additional information.

What are the goals of treatment for this patient?

Assess the patient's risk factors for heart disease and breast cancer.

Recommend nonpharmacologic and pharmacologic treatment for this patient. Justify your recommendations.

for women with an intact uterus. Alternative and nonhormonal treatment options are available for women who are not candidates for HT, but they are less effective than hormonal therapies. These treatments should be chosen based on the efficacy and safety profile of the treatment and the patient's past medical history and current medications.

Nonpharmacologic Therapy

Nonpharmacologic therapies for menopause-related symptoms have not been studied in large randomized trials, and evidence of benefit is not well documented. Due to the minimal adverse effects of these interventions, patients should try lifestyle or behavioral modifications before and in addition to pharmacologic therapy. The most common nonpharmacologic interventions for vasomotor symptoms include the following^{3,12,13}:

- Smoking cessation
- Limit alcohol and caffeine
- Limit hot beverages (e.g., coffee/tea, soup)
- Limit spicy foods

- Keep cool, and dress in layers
- Stress reduction (e.g., meditation, relaxation exercises)
- Increase exercise
- Paced respiration

Exercise demonstrated an improvement in QOL but did not improve vasomotor symptoms. Paced respiration, a form of deep, slow breathing, improved vasomotor symptoms in a small group of patients.

Dyspareunia may result from vaginal dryness. Water-based lubricants may provide relief for several hours after application. Moisturizers may provide relief for a longer period of time and potentially can prevent infections by maintaining the acidic environment in the vagina. Both these treatments require frequent application.

A decline in estrogen concentrations also may be associated with urinary stress incontinence. **Kegel exercises** are recommended as a first-line intervention for stress incontinence, although pharmacologic therapy also may be necessary. Kegel exercises strengthen the pelvic floor muscles and help to keep the urethral sphincter from relaxing at inappropriate times, such as when lifting heavy objects, coughing, or sneezing.

FIGURE 50-1. Treatment algorithm for postmenopausal women. (CHD, coronary heart disease; HT, hormone therapy.) (Data from Refs. 2, 10, and 11.)

These exercises have no adverse effects, take little time, may be done inconspicuously, and when done correctly, may help to restore normal urine flow.

Pharmacologic Therapy

► Estrogens

Estrogen is indicated for the treatment of moderate to severe vasomotor symptoms and vulvovaginal atrophy associated with menopause. In addition, it is indicated for the prevention of postmenopausal osteoporosis in women with significant risk; however, it is recommended that nonestrogen medications be used long-term. **4** *Oral or transdermal estrogen products should be prescribed at the lowest effective dose and for the shortest duration possible to provide relief of vasomotor symptoms. Topical vaginal products in the form of creams, tablets, or rings should be prescribed for women exclusively experiencing vulvovaginal atrophy.*

Many systemically administered estrogen products are available in the United States. Transdermal estrogen preparations are also available and usually are prescribed for patients who experience adverse effects, elevated triglycerides (TG), or liver function abnormalities while taking an oral product. Although there have been no randomized controlled trials published, one case control study suggests that transdermal preparations have a lower incidence of venous thromboembolism (VTE) than oral preparations.^{5,14}

► Progestogens

5 *Women who have an intact uterus should be prescribed a progestogen in addition to estrogen in order to decrease the risk of endometrial hyperplasia and endometrial cancer.⁵* Progestogens should be prescribed for at least 12 to 14 days of the month and often are prescribed continuously. Even low doses of oral estrogen therapy, as well as some vaginal preparations, require daily or intermittent administration of a progestogen in order to provide endometrial protection. **Table 50-1** lists estrogen and progestogen preparations and dosages.

► Adverse Effects

Therapy with estrogen with or without a progestogen should be initiated at the lowest dose in order to minimize adverse effects. Because the adverse effects of these preparations can be similar, it may be difficult to assess whether the estrogen or the progestogen is the cause. Changing preparations, particularly the progestogen, or changing the method of administration may help to alleviate adverse effects. **Table 50-2** lists the adverse effects that may be associated with estrogen and progestogen preparations.

► Contraindications

HT should not be prescribed to women with a history of or active thromboembolic disease, breast cancer or estrogen-dependent neoplasm, pregnancy, liver disease, or undiagnosed vaginal bleeding. It also should not be used for the

prevention or treatment of cardiovascular disease, cerebrovascular disease, or dementia.³

► Methods of Administration

Cyclic Estrogen and Progestogen Estrogen is administered daily, and progestogen is administered for 12 to 14 days of the month. The disadvantage of this method of administration is the return of monthly menses in approximately 90% of women 1 to 2 days following the last progestogen dose. However, the withdrawal bleeding does not last as long and is not as heavy as a typical menstrual period. Women may view this scheduled bleeding as an advantage to this method of administration as it limits spotting or soiling of undergarments.

Continuous Combined Estrogen and Progestogen

Estrogen and progestogen are administered daily and result in endometrial atrophy. Therefore, women do not experience a withdrawal bleed but may experience unanticipated breakthrough bleeding or spotting during the month. Although this may sound more appealing than a withdrawal bleed, women may view the unpredictable bleeding or spotting as a disadvantage to this type of administration. If bleeding persists beyond 6 to 12 months, women should seek medical attention to rule out endometrial hypertrophy or carcinoma.

► Low-Dose HT

There is an increasing body of evidence proving the effectiveness of low-dose HT regimens in the management of menopausal symptoms. The Women's Health, Osteoporosis, Progestin/Estrogen (HOPE) trial demonstrated that lower doses of conjugated equine estrogen (CEE) ± medroxyprogesterone acetate (MPA) (CEE 0.45 mg or 0.3 mg ± MPA 2.5 mg or 1.5 mg) decreased hot flashes comparable with standard HT, improved vulvovaginal atrophy, increased bone mineral density (BMD) at the spine and hip, and provided sufficient endometrial protection.¹⁸⁻²¹ Currently, no data are available on the effects of low-dose HT on the incidence of VTE, breast cancer, or CHD. Although many women have switched to low-dose HT, time will tell if lower doses translate into lower risks.

► Bioidentical HT

Bioidentical hormones are exogenous hormones that are identical to those produced in a woman's body (e.g., estradiol, estrone, estriol, and progesterone). They are either commercially manufactured or chemically compounded in pharmacies into formulations such as topical creams, gels, and suppositories. The commercially manufactured prescription products are subject to regulation by the FDA and have been tested for potency, purity, efficacy, and safety (Table 50-1). Conversely, pharmacist-compounded formulations are not subject to the same regulations and therefore, the efficacy and safety may be questionable. Often women view bioidentical hormones, particularly the pharmacist-compounded formulations, as "natural" and assume these formulations are safer than currently marketed prescription hormone products.

Table 50-1

Estrogen and Progestogen Formulations and Dosages

Product	Available Strengths	Common Dosages
Oral estrogens		
CEE (Premarin)	0.3–1.25 mg	0.3–0.625 mg/day
Synthetic conjugated estrogens (Cenestin; Enjuvia)	0.3–1.25 mg	0.3–0.625 mg/day
Esterified estrogens (Menest)	0.3–2.5 mg	0.3–0.625 mg/day
Estradiol (Estrace ^a ; Femtrace ^a)	0.5–2 mg; 0.45–1.8 mg	0.5–1 mg/day
Estropipate (Ogen ^a ; Ortho-Est ^a)	0.625–5 mg; 0.625–1.25 mg	0.625 mg/day
Transdermal estrogens		
Estradiol patch (Alora, Climara, Estraderm, Vivelle, Vivelle Dot)	0.025–0.1 mg/24 hours	0.025–0.05 mg, changed weekly (Climara) or changed twice weekly
Menostar ^b	14 mcg/24 hours	14 mcg once weekly
Estradiol gel (Elestrin, Estrogel)	0.06%	0.87 g/day; 1.25 g/day
(Divigel)	0.1%	0.25, 0.5, 1 mg packets/day
Estradiol spray (Evamist)	1.53 mg/actuation	1–3 sprays/day
Topical estrogens		
<i>Vaginal creams</i>		
CEE (Premarin)	0.625 mg/g	0.5–2 g/day
Estradiol (Estrace)	0.01% estradiol	1g 1–3 times/week
Estropipate (Ogen)	1.5 mg/g	2–4 g/day
<i>Vaginal rings</i>		
Estradiol (Estring; Femring)	0.0075 mg/24 hours; 0.05–0.1 mg/24 hours	1 ring every 3 months
<i>Vaginal tablet</i>		
Estradiol (Vagifem)	10 mcg estradiol	1 tablet 2 times/week
<i>Emulsions</i>		
Estradiol (Estrasorb)	0.25%	3.84 g applied daily
Oral progestogens^{c,d}		
MPA (Provera)	2.5–10 mg	
Micronized progesterone	100–200 mg	
Transdermal progestogens^{c,d}		
Levonorgestrel	0.015 mg	
Norethindrone acetate	0.25–1 mg	
Norgestimate	0.09 mg	
Combination products		
<i>Oral</i>		
CEE + MPA (Prempro; Premphase)	0.3 /1.5 mg–0.625 /5 mg; 0.625/5 mg	0.3–0.625/2.5–5 mg/day
Estradiol + norethindrone (Activella)	0.5/0.1 mg–1/0.5 mg	1 tablet daily
Estradiol + drospirenone (Angeliq)	1/0.5 mg	1 tablet daily
Ethinyl estradiol + norethindrone (FemHRT)	2.5 mcg/0.5 mg; 5 mcg/1 mg	1 tablet daily
Estradiol + norgestimate (Prefest)	1/0.09 mg	1 tablet daily
Esterified estrogens + methyltestosterone (Covaryx, Covaryx HS)	1.25/2.5 mg; 0.625/1.25 mg	1 tablet daily
<i>Transdermal</i>		
Estradiol + norethindrone (Combipatch)	0.05/0.14–0.05/0.25 mg/24 hours	Apply one patch twice weekly
Estradiol + levonorgestrel (Climara Pro)	0.045/0.015 mg/24 hours	Apply one patch once weekly

CEE, conjugated equine estrogens; MPA, medroxyprogesterone acetate.

^aFDA approved commercially available bioidentical product.

^bIndicated for the prevention of postmenopausal osteoporosis only.

^cMay be administered cyclically or continuously.

^dDose varies based on daily or weekly administration.

Data from Refs. 10, 15, and 17.

Table 50–2

Adverse Effects of Estrogens and Progestogens**Estrogens***Common adverse effects*

Nausea

Headache
Weight gain
Bleeding
Irritability
Depression

Serious adverse effects

Venous thromboembolism
Decreased bone mineral density

Data from Refs. 4, 10, 16, and 17.

Women may feel more comfortable using compounded products that are formulated based on individual hormone levels, however, due to a lack of regulation, these products may potentially cause more harm than benefit. In addition, pharmacist-compounded formulations can result in higher costs, as they are generally not covered by third-party payers. There is little evidence comparing the safety and efficacy of conventional HT to prescription bioidentical HT, and thus the same risks and benefits should be assumed.^{5,22}

► Benefits of HT

Vasomotor Symptoms HT remains the most effective treatment for vasomotor symptoms, and systemic HT should be considered only in women experiencing these symptoms. Women with mild vasomotor symptoms may benefit from nonpharmacologic therapy alone; however, many women will seek medical treatment for these symptoms. Benefits must outweigh risks, and decisions should be made only after careful consideration by the woman and her health care provider. If it is decided to use HT, it should be prescribed at the lowest dose that relieves or reduces menopausal symptoms and should be recommended only for short-term use (generally less than 5 years). Women should be reassessed every 6 to 12 months, and discontinuation of therapy should be considered.

Vulvovaginal Atrophy Approximately 50% of postmenopausal women experience vulvovaginal atrophy and seek medical attention. Vulvovaginal atrophy is associated with vaginal dryness and dyspareunia and also may be associated with recurrent urinary tract infections, urethritis, and

urinary urgency and frequency. Topical vaginal preparations generally should be prescribed as first-line therapy unless the patient is also experiencing vasomotor symptoms. Local vaginal estrogen has demonstrated increased efficacy over systemic estrogen and generally does not require supplementation with a progestogen in women with an intact uterus using low or ultralow doses.⁵ Women using regular or high doses of topical estrogen products may require intermittent treatment with a progestogen. Although few data are available on the appropriate progestogen dose, some data indicate that 10 days every 12 weeks may be sufficient to prevent endometrial hyperplasia.²³ Estradiol in the form of a tablet or a ring is not significantly absorbed systemically and may be used safely in a woman with contraindications to estrogen therapy and symptoms of vulvovaginal atrophy.⁵

Osteoporosis Prevention Postmenopausal osteoporosis is a condition that affects millions of women. Fractures, particularly hip fractures, are associated with a high incidence of morbidity and mortality and a decrease in QOL. Before the WHI study, only observational data were available regarding the association of HT and the reduction of fractures. The WHI was the first randomized controlled trial (RCT) that demonstrated a reduction in total fractures, including the hip, spine, and wrist.^{2,24}

6 Because HT should be maintained only for the short term, traditional therapies such as bisphosphonates should be considered as first-line therapy for the prevention of postmenopausal osteoporosis, in addition to appropriate doses of calcium and vitamin D. Because of the associated risks, HT should not be prescribed solely for the prevention of osteoporosis.

Colon Cancer Retrospective observational studies suggested that HT was associated with lower rates of colorectal cancer. The mechanism was suspected to be related to reduced production of bile acids and inhibition of the growth of colon cancer cells. The WHI was the first and largest RCT to confirm that HT decreases the risk of colorectal cancer.² However, in the WHI estrogen alone arm, the cases of colorectal cancer were not lower in the estrogen group compared with the placebo group.²⁵ Data from a new analysis of the WHI suggest that there is not strong evidence for a reduction in the incidence of colorectal cancer or on mortality after 8 years with either combination HT or estrogen alone.²⁶ Because of these data, estrogen therapy should not be used long-term for prevention of colon cancer.

► Risks of HT

Cardiovascular Disease CHD is the leading cause of death among women in the United States. Retrospective data indicated that HT was associated with a decrease in risk of CHD by 30% to 50%.²⁵ However, the results of RCTs demonstrate that HT does not prevent or treat CHD in women and that it actually may cause an increase in CHD events. The HERS was the first RCT conducted in women with established CHD. This trial demonstrated an increased incidence of CHD events within the first year of treatment with HT and an increased risk of VTE and gallbladder disease. There was

a trend of decreasing incidence of CHD death in years 3 to 5 that prompted a discontinuation of the study.¹ A follow-up HERS II trial also showed no difference in CHD events after 2.7 years.²⁷ The WHI was the first RCT conducted in women without established CHD. Women aged 50 to 79 years with an intact uterus were assigned to receive HT (CEE 0.625 mg + MPA 2.5 mg) daily for 8.5 years. The trial was stopped after only 5.2 years owing to an increased incidence of invasive breast cancer in women taking HT compared with those taking placebo. The WHI demonstrated an increased risk of CHD in the HT group compared with the placebo group (hazard ratio [HR] 1.24, 95% confidence interval [CI] 1.00–1.54). This translates into six more cases of CHD per 10,000 women years. There also was an increased risk of stroke in the HT group compared with placebo (HR 1.31, 95% CI 1.02–1.68), which translates into seven more cases of stroke per 10,000 women years.^{28,29}

The estrogen-alone arm of the WHI, which included women aged 50 to 79 years with a history of hysterectomy, continued for another 1.6 years (average follow-up 6.8 years). This arm of the study did not demonstrate an increased risk of CHD compared with placebo. However, there was an increased risk of stroke in the estrogen-alone group compared with placebo (HR 1.39, 95% CI 1.10–1.77). This translates into 12 more strokes for every 10,000 women treated per year with estrogen therapy.²⁵ Women who initiated hormone therapy 10 or more years after menopause tended to have an increased cardiovascular risk compared with women who initiated therapy within 10 years of menopause.^{30,31}

The results of these trials demonstrate that HT should not be prescribed for the prevention of CHD or in patients with preexisting CHD. It is important to note that the average age of women included in the HERS and the WHI trials was 67 and 63 years, respectively, and they started HT a mean of 10 years after menopause. Therefore, these trials were unable to assess the true risk in younger, potentially healthier women with fewer cardiovascular risk factors.²⁵

Breast Cancer Breast cancer is the most common cancer in women in the United States. Observational data indicated an association between HT and breast cancer risk. The WHI was the first RCT to demonstrate an increased risk of invasive breast cancer among women taking HT. There were eight more cases of invasive breast cancer for every 10,000 women treated per year with HT (HR 1.24, 95% CI 1.01–1.54).^{2,32} The increase in risk did correlate with increased age of the women, and the risk appears to be greater in those who initiate therapy within 5 years of the start of menopause. These results are overall supported by results from a follow-up study of the WHI. During approximately 11 years of follow-up, there were 385 cases of invasive breast cancer in the combination HT group compared with 293 cases in the placebo group (95% CI 1.07–1.46, $P = 0.004$). There were also more deaths from breast cancer in the combination group than in the placebo group (95% CI 1.00–4.04, $P = 0.049$) and in deaths overall (95% CI 1.01–2.48, $P = 0.045$). This translates to 2.6 versus 1.3 deaths from breast cancer per 10,000 women years and 5.3 versus 3.4 deaths from all causes

after breast cancer diagnosis per 10,000 women per year.³³ It should be noted that any increase in risk for breast cancer appears to dissipate over 2 to 3 years after hormone therapy is discontinued.^{5,34} Whether hormone therapy is associated with an increased risk for breast cancer recurrence is still questionable.

Breast cancer was not increased in the estrogen-alone arm of the WHI.²⁷ These data point to a possible link of progestogen with breast cancer risk. Whether or not the risk differs between continuous and sequential use of progestogens is questionable. Some evidence suggests that sequential use may be safer than taking progestogen each day.^{5,35}

Because the WHI is the best evidence to date linking HT with breast cancer, women with a personal history of breast cancer and possibly even a strong family history of breast cancer should avoid the use of HT and consider alternative and nonhormonal therapies for the treatment of vasomotor symptoms.

Other Cancers A post-hoc analysis from the WHI suggests that combination HT therapy could be associated with an increased risk of death from lung cancer and an increased risk for certain lung tumors. However, this association was observed primarily in those who were smokers (past or present) and in women 60 years old or older.²⁵ The theory is that estrogen plus progestogen may promote growth of existing lung cancer in older women with a history of smoking. Data from another large observational trial suggests that the relative risk of lung cancer could be increased by approximately 50% in postmenopausal women who use combination HT for 10 years or longer.³⁶ Hormone therapy with estrogen alone does not appear to have this same risk.

Observational data suggested an increased risk of ovarian cancer with the use of HT in postmenopausal women. However, this increase was observed only after more than 5 years of therapy and was not seen 3 to 4 years after therapy was stopped.⁵ Data from the WHI did not show an increased risk for ovarian cancer.²

Venous Thromboembolism The WHI demonstrated an increased risk for VTE in the HT group compared with placebo (HR 2.06, 95% CI 1.58–2.82). This translates into 18 more cases of venous thromboembolic events for every 10,000 women treated per year with HT.² The risk for deep vein thrombosis was also increased in the estrogen-alone arm of the WHI, but pulmonary embolism was not increased significantly.²⁵ The risk of thromboembolism may be dose related, and the oral route of administration is associated with a higher risk compared with the transdermal route.¹⁴

7 *In summary, combined estrogen plus progestogen should not be used for the prevention of chronic diseases because it increases the risk of CHD, stroke, breast cancer, and VTE. However, colorectal cancer and rates of fracture were reduced with combined hormonal treatment.*

► Other Effects of HT

QOL and Cognition Although women generally consider QOL measures when deciding whether to use HT, the effects

of HT on overall QOL have been inconsistent. HT did not demonstrate a clinically meaningful effect on QOL; however, women taking HT did have a small improvement in sleep disturbances, physical functioning, and bodily pain after 1 year of therapy.³⁷ Results from the HERS demonstrated that HT did improve emotional measures such as depressive symptoms, but only if women suffered from flushing at trial entry.³⁸

Observational studies suggested a potential benefit of HT on cognitive functioning and dementia. However, the WHI Memory Study (WHIMS), conducted in postmenopausal women aged 65 years or older, failed to demonstrate an improvement in cognitive function and demonstrated a dementia rate, including Alzheimer's disease, two times greater compared with placebo.^{39,40} The estrogen-alone arm of the WHIMS also demonstrated similar results.^{41,42}

8 *HT improves overall well-being and mood in women with vasomotor symptoms, but it has not demonstrated an improvement in QOL in women without vasomotor symptoms.*

► Discontinuation of HT

9 *When treating moderate to severe postmenopausal symptoms, the benefit-to-risk ratio appears to be best when HT is started close to the time of menopause. Therapy should be tapered before discontinuation in order to limit the recurrence of hot flashes.* Although vasomotor symptoms in most women will subside within 4 years, approximately 10% of women continue to experience symptoms that interfere with their QOL. Literature suggests that one of every four women needs to be reinitiated on HT due to persistent and bothersome symptoms.^{43,44}

Limited evidence is available to guide healthcare providers regarding the least disruptive way to taper HT. Slowly discontinuing HT over 3 to 6 months may be associated with less risk of symptom return. Tapering HT may be done by a dose taper or day taper. The dose taper involves decreasing the dose of estrogen over several weeks to months and

Patient Encounter, Part 4

RJ has been in good health for the past 7 years. She reports adherence with her medications, a healthy diet and exercise routine, and her medical conditions are controlled. However, 1 month ago she was diagnosed with stage 1 breast cancer following a routine mammogram. RJ is concerned that her hormone therapy may have caused the breast cancer.

Educate RJ regarding the risk of breast cancer and hormone therapy.

monitoring closely for symptom return. If symptoms recur, the next reduction in dose should not occur until symptoms resolve or stabilize on the current dose. The day taper involves decreasing the number of days of the week that a woman takes the HT dose, for example, decreasing a daily dose of 0.3 mg estrogen to 0.3 mg estrogen 5 days a week. Again, if symptoms recur, continue on the current dose until symptoms resolve or stabilize before trying a subsequent decrease. These tapering regimens have not been studied in clinical trials and may not prove to be beneficial in individual women.⁴⁴

► Nonhormonal and Alternative Treatments

10 *Since publication of the WHI study, there has been an increase in the use of alternative and nonhormonal therapies for the management of menopausal symptoms, particularly for women with CHD and/or breast cancer risk factors. A wide range of therapies, both prescription and herbal, have been studied with varying degrees of success.* In choosing a particular therapy, it is important to match patient symptoms with a therapy that is not only effective, but also safe.

A variety of nonhormonal and alternative therapies (Table 50–3) have been studied for symptomatic management of vasomotor symptoms.^{45,46} The limited and often conflicting evidence demonstrates that these agents are only modestly effective.

SSRIs and venlafaxine are theorized to reduce the frequency of hot flashes by increasing serotonin in the central nervous system and by decreasing LH. Of the SSRIs, fluoxetine, citalopram, paroxetine, and sertraline have published data demonstrating a reduction in hot flashes while treating other symptomatic complaints such as depression and anxiety.⁴⁷ These antidepressant medications offer a reasonable option for women who are unwilling or cannot take hormonal therapies, particularly those who suffer from depression or anxiety.

Phytoestrogens are plant sterols that are structurally similar to human and animal estrogen. Soy protein is a common source of phytoestrogens.^{45,46} If used, at least 60 mg/day of isoflavone content is necessary for any possible benefit. Because the effect of isoflavones on breast cancer and other female related cancers is unknown, phytoestrogens should not be

Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for RJ's hot flashes and vaginal dryness. The plan should include:

- a statement identifying the patient problem and its severity*
- goals of therapy*
- a therapeutic plan based on individual patient-specific factors*
- subjective and objective monitoring parameters*
- a follow-up evaluation to assess for adverse effects and adherence and to determine whether the goals of therapy have been achieved*

Table 50-3

Nonhormonal Therapies for Menopause

Agent	Demonstrated Efficacy	Dosing	Adverse Effects/Precautions
Citalopram	Nonrandomized trial demonstrated efficacy in hot flash reduction	20–60 mg daily	Nausea, dizziness, somnolence
Fluoxetine	One RCT demonstrated significant reduction in hot flashes; one RCT found drug no better than placebo	20 mg daily	Nausea, insomnia, nervousness, fatigue
Paroxetine	Two RCTs demonstrated significant reduction in and severity of hot flashes (approximately 30%)	10–20 mg daily	Headache, nausea, insomnia
Sertraline	Case series demonstrating efficacy in hot flash reduction	25–50 mg daily	Nausea, dizziness, somnolence
Venlafaxine	Two RCTs reported short-term significant reductions in and severity of hot flashes	12.5 mg twice daily	Nausea, dry mouth
Soy protein	Eighteen small RCTs demonstrated conflicting findings; modestly effective in relieving menopausal symptoms	At least 60 mg of isoflavones daily	GI upset; other adverse effects unknown; do not use in those with history of or high risk of estrogen-dependent cancer
Black cohosh	Seven small, short-term RCTs demonstrated benefit in mild-moderate hot flashes, especially when associated with sleep and mood disturbances	Varied dosing based on herbal product combination; most studied: Remifemin 40–80 mg twice daily	GI upset (take with food); potential hepatotoxicity; not recommended to be taken over a 6-month period of time
Gabapentin	Four RCTs concluded that drug was significantly more effective than placebo at reducing the frequency and severity of hot flashes (approximately 50%), including those with breast cancer	900 mg daily	Dizziness and somnolence
Clonidine	Eleven studies, seven of which demonstrated significant reductions in frequency and severity of hot flashes	0.1–0.4 mg daily	Dry mouth, blood pressure lowering; monitor blood pressure
Dong quai	No demonstrated efficacy in one RCT	Not recommended	Structurally similar to coumarins—avoid with warfarin because INR can increase
Evening primrose oil, passion flowers, sage, valerian root, and wild yam	No demonstrated efficacy for any product in RCTs	Not recommended	Caution with all plant products in women with hay fever and plant allergies

INR, international normalized ratio; RCT, randomized controlled trial.

Data from Refs. 45–47.

considered in women with a history of estrogen-dependent cancers.⁴⁸ A recent trial compared the effect of dietary soy supplementation (90 mg isoflavones) with estrogen (1 mg of estradiol and 0.5 mg of norethisterone acetate) or placebo in 60 healthy, symptomatic, postmenopausal women aged 40 to 60 years.⁴⁹ The comparison between groups revealed a statistically significant improvement in hot flashes and urogenital symptoms with both soy and estrogen. There was no statistically significant difference between the groups with respect to overall menopausal symptoms. After reviewing hundreds of studies, the North American Menopause Society (NAMS) determined that soy-based isoflavones are modestly effective in relieving menopausal symptoms.⁴⁸ The efficacy of isoflavones on bone, cognitive improvement, and cardiovascular health has not been proven.

Black cohosh has been one of the most studied alternative therapies for vasomotor symptoms, but it has not demonstrated a substantial benefit over placebo. The mechanism of action, safety profile, drug–drug interactions, and adverse effects of black cohosh remain unknown. However, there have been case reports of hepatotoxicity with its use.^{46,50} In non–placebo-controlled trials conducted for 6 months or less, black cohosh (40 to 80 mg/day) demonstrated small reductions in vasomotor symptoms.^{45–47} Caution should be exercised when considering the use of this product, and it is not recommended for more than a 6-month period of time.

Gabapentin and clonidine have also been studied for the management of menopausal symptoms. In RCTs, gabapentin at doses of 900 mg/day demonstrated significant reductions in severity and frequency of hot flashes compared with

placebo. Clonidine has been studied in several small RCTs at doses of 0.1 to 0.4 mg/day and has demonstrated statistically significant reductions in hot flashes.⁴⁷ Overall, alternative and nonhormonal therapies are less effective in treating vasomotor symptoms than HT but do offer another option for women experiencing menopausal symptoms who cannot or are unwilling to take HT. SSRIs and soy isoflavones have the best evidence for efficacy. However, healthcare providers should weigh the benefits and risks of all therapies, and women should be advised to discuss their options with their physicians and pharmacists.

OUTCOME EVALUATION

Evaluating the outcomes of any therapy for menopausal symptoms focuses primarily on the woman's report of symptom resolution. Ask women to report the resolution or reduction of hot flashes, night sweats, and vaginal dryness and any improvement or change in sleep patterns. Also ask women taking hormonal therapies to report any breakthrough bleeding or spotting. If abnormal or heavy bleeding occurs, refer the woman to her primary care provider. Monitor subjective parameters such as adverse effects and adherence to the therapy regimen, as well as monthly breast self-examinations. In addition, monitor objective parameters, including blood

pressure, at every outpatient visit; encourage yearly clinical breast examinations, mammograms, lipid panel, and thyroid-stimulating hormone (TSH) determination, particularly for women with hypothyroidism on thyroid therapy, and conduct a BMD test every 2 to 5 years as indicated. Also perform endometrial studies, as necessary, in women with undiagnosed vaginal bleeding. Lastly, evaluate the patient's overall QOL. Because the management of menopause is largely symptomatic, it is important to document symptoms at the beginning of therapy and monitor symptom improvement and potential adverse effects at each visit. Frequent follow-up, proper monitoring, and education will help to ensure that the woman achieves optimal results from any therapy chosen to treat menopausal symptoms.

Patient Encounter, Part 5

It has been 6 months since RJ completed chemotherapy and radiation for breast cancer. She presents to her PCP for follow-up with a chief complaint of recurrent hot flashes. She denies recurrence of vaginal dryness or insomnia.

Recommend the most appropriate therapy for RJ's recurrent hot flashes.

Patient Care and Monitoring

1. Assess the patient for use of HT by evaluating for the presence of vasomotor symptoms. If the patient is experiencing bothersome vasomotor symptoms, consider the use of HT only after assessing for risk factors for heart disease and breast cancer. If vasomotor symptoms are tolerable and/or the patient has risk factors for heart disease and/or breast cancer, consider alternative, nonhormonal treatments for vasomotor symptoms.
2. Obtain a thorough medication history, including the use of over-the-counter and herbal products.
3. Educate the patient on lifestyle or behavioral interventions that may help to alleviate vasomotor symptoms.
4. Discuss methods of HT administration, and have the patient decide in conjunction with the healthcare provider which one she feels will work best for her.
5. Recommend the appropriate dose of HT, and use the lowest effective dose for the shortest duration of time.
6. Educate the patient regarding the proper administration, potential adverse effects, and expectations of HT.
7. Monitor the patient for a reduction in vasomotor symptoms, vaginal dryness, and improvement in sleep. Also monitor for breakthrough bleeding and spotting, adverse effects of HT, and improvement in QOL.
8. Monitor the following objective parameters:
 - Blood pressure at every outpatient visit
 - Yearly lipoprotein panels
 - Yearly fasting plasma glucose determinations
 - Yearly breast examinations and mammograms
 - Yearly TSH determinations, particularly for women with hypothyroidism on thyroid therapy
 - Endometrial studies in women with undiagnosed vaginal bleeding
9. Educate the patient regarding the importance of adhering to the medication regimen.
10. Educate the patient regarding the importance of obtaining a yearly mammogram and Papanicolaou (Pap) smear (if applicable), as well as performing a monthly breast self-examination.
11. Assess patient symptoms every 6 to 12 months, and consider tapering the HT dose and discontinuing treatment after 5 years. If vasomotor symptoms return, determine whether a longer tapering schedule is warranted or if long-term treatment is necessary. If treatment beyond 5 years is necessary, consider switching to a nonhormonal product.

Abbreviations Introduced in This Chapter

BMD	Bone mineral density
CEEs	Conjugated equine estrogen
CHD	Coronary heart disease
FSH	Follicle-stimulating hormone
GnRH	Gonadotropin-releasing hormone
HDL	High-density lipoprotein
HERS	Heart and Estrogen/Progestin Replacement Study
HOPE	Women's Health, Osteoporosis, Progestin/Estrogen trial
HT	Hormone therapy
LDL	Low-density lipoprotein
LH	Luteinizing hormone
MPA	Medroxyprogesterone acetate
NAMS	North American Menopause Society
NNTH	Number needed to treat to harm
QOL	Quality of life
PCP	Primary care provider
RCT	Randomized controlled trial
SSRI	Selective serotonin reuptake inhibitor
TG	Triglycerides
TSH	Thyroid-stimulating hormone
VTE	Venous thromboembolism
WHI	Women's Health Initiative
WHIMS	Women's Health Initiative Memory Study

Erectile Dysfunction

Cara Liday

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Identify the structures of the male reproductive system and describe the normal physiology of a penile erection.
2. Explain the pathophysiology of the different types of erectile dysfunction (ED).
3. Recognize risk factors and medications associated with the development of ED.
4. Identify the goals of therapy when treating ED.
5. Define the essential components of history, physical examination, and laboratory data needed to evaluate the patient presenting with ED.
6. Describe current nonpharmacologic and pharmacologic options for treating ED and determine an appropriate first-line therapy for a specific patient.
7. Compare and contrast the benefits and risks for the current phosphodiesterase (PDE) inhibitors.
8. Identify patients with significant cardiovascular risk and recommend an appropriate treatment approach for their ED.

KEY CONCEPTS

- 1 Erectile dysfunction (ED) can be classified as organic, psychogenic, or mixed. Many patients may initially have organic dysfunction, but develop a psychogenic component as they cope with their inability to achieve an erection.
- 2 In addition to a physical exam, a thorough medical, social, and medication history with emphasis on cardiac disease must be taken before starting any treatment for ED to assess for ability to safely perform sexual activity and to assess for possible drug interactions.
- 3 Treatment options for ED include medical devices, pharmacologic treatments, lifestyle modifications, surgery, and psychotherapy. Reversible causes of ED should be identified first and treated appropriately.
- 4 When determining the best treatment for an individual, the role of the clinician is to inform the patient and his partner of all available options while understanding his medical history, desires, and goals. The choice of treatment is primarily left up to the couple, but most often treatment is initiated with the least invasive option and then progresses to more invasive options if needed.
- 5 Vacuum erection devices (VEDs) and intracavernosal injections are highly effective for many patients, but side effects, lack of spontaneity, and fear of needles limit their widespread use as first-line therapies.
- 6 Effectiveness of the three available phosphodiesterase (PDE) inhibitors is essentially comparable, but differences exist in duration of action, absorption with a fatty meal and, to a small degree, incidence of side effects and drug interactions.
- 7 Androgens are important for general sexual function and libido, but testosterone supplementation is only effective in patients with documented low serum testosterone levels.

INTRODUCTION

Erectile dysfunction (ED) is defined as the inability to achieve or maintain an erection sufficient for sexual intercourse. The definition is very subjective due to differences in desired or needed rigidity in patients of different ages and in different types of relationships. ED is the most prominent sexual problem in men, and it can lead to lower quality of life and

self-esteem.¹ Patients may also develop **libido** or ejaculatory disorders, but these are not considered ED.

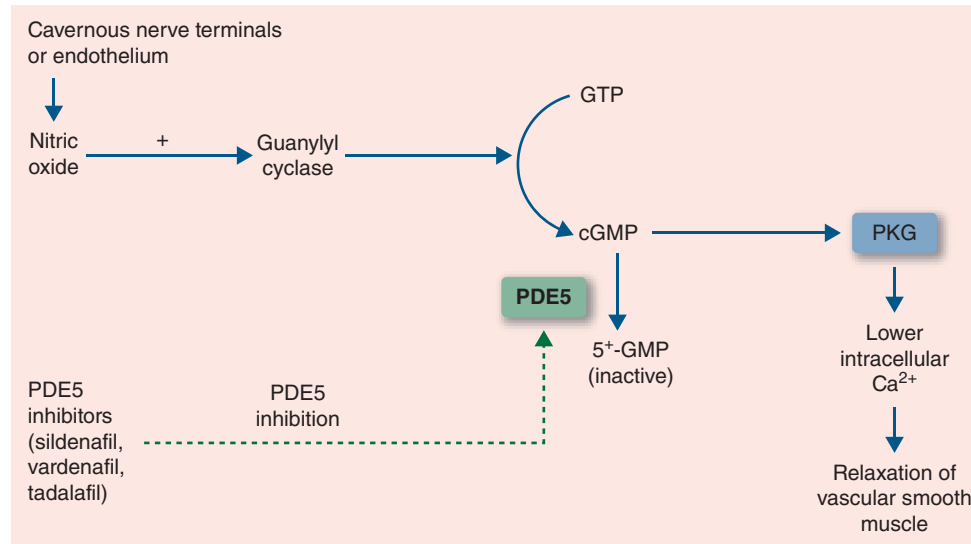

EPIDEMIOLOGY AND ETIOLOGY

ED becomes increasingly frequent as men age. Few men report erection problems before the age of 40, but the percentage of men experiencing ED increases to 26% in men aged 50 to 59 years and 40% in men aged 60 to 69 years.² The increase in incidence could be due to physiologic changes that occur with aging, the onset of chronic disease states associated with ED, increased medication use, lifestyle factors, or a combination of the above.

PATHOPHYSIOLOGY

The penis consists of three components, two dorsolateral corpora cavernosa and a ventral corpus spongiosum that surrounds the penile urethra and distally forms the glans penis. The corpora cavernosa consist of blood-filled sinusoidal or lacunar spaces, which are lined with endothelial cells, supported by trabecular smooth muscle, and surrounded by a thick fibrous sheath called the tunica albuginea. The cavernosal arteries, which are branches of the penile artery, penetrate the tunica albuginea and supply blood flow to the penis.

Sympathetic and parasympathetic nerves innervate the penis. In the flaccid state, α_2 -adrenergic receptors mediate tonic contraction of the arterial and corporal smooth muscles. This maintains high penile arterial resistance, and a balance exists between blood flow into and out of the corpora. With sexual stimulation, nerve impulses from the brain travel down the spinal cord to the thoracolumbar ganglia. A decrease in sympathetic tone and an increase in parasympathetic activity then occurs, causing a net increase in blood flow into the erectile tissue. Erections may also occur as a result of a sacral nerve reflex arc while patients are sleeping (nocturnal erections). Acetylcholine-mediated parasympathetic activity leads to production of the nonadrenergic–noncholinergic transmitter nitric oxide (NO). By enhancing the activity of guanylate cyclase, NO increases the production of cyclic guanosine monophosphate (cGMP). Vasoactive peptide and prostaglandins E_1 and E_2 stimulate increased production of cyclic adenosine monophosphate (cAMP). Both cAMP and cGMP ultimately lead to a decrease in calcium concentration within smooth muscle cells of the penile arteries and the sinusoidal spaces, leading to smooth muscle relaxation and increased blood flow. As the sinusoidal spaces become engorged, intracavernosal pressure increases, subtunical venules are compressed, and the penis becomes rigid and elongated (**Fig. 51-1**).

- **FIGURE 51-1.** Mechanism of erection and sites of action of various treatment modalities for erectile dysfunction (ED). Penile erection is achieved through relaxation of smooth muscle cells lining arterial vessels and sinusoidal spaces in the corpora cavernosa, which leads to increased arterial inflow and pressure, decreased venous outflow, and increased intracavernosal pressure. Smooth muscle relaxation is mediated by intracellular generation of cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP) via activation of guanylate cyclase by nitric oxide. Treatment modalities for ED include oral phosphodiesterase type 5 (PDE-5) inhibitors, which inhibit the breakdown of cGMP, and local vasoactive agents. Nitric oxide–cGMP signaling in cavernous smooth muscle. (cGMP, cyclic guanosine monophosphate; GTP, guanosine triphosphate; PDE5, phosphodiesterase 5; PDE, phosphodiesterase; PKG, protein kinase G.) (Reproduced, with permission, from Setter SM, Iltz JL, Fincham JE, Campbell RK, Baker DE. Phosphodiesterase 5 inhibitors for erectile dysfunction. *Ann Pharmacother*. 2005;39(7-8):1286-95.)

Detumescence occurs with sympathetic discharge after ejaculation. Sympathetic activity induces smooth muscle contraction of arterioles and vascular spaces leading to a reduction in blood inflow, decompression of the sinusoidal spaces, and enhanced outflow.

Testosterone also plays a significant albeit complex role in erectile function. Testosterone is responsible for much of a man's libido. With low serum concentrations, libido declines. Additionally, testosterone helps with stabilization of intracavernosal levels of NO synthase, the enzyme responsible for triggering the NO cascade. Interestingly, some patients with low or borderline-low serum concentrations of testosterone will have normal erectile function, whereas some with normal levels will have dysfunction.

Normal penile erections are complex events that require the full function of the vascular, neurologic, and hormonal systems. Anything that affects the function of these systems may lead to ED. **1** *ED can be classified as organic, psychogenic, or a mixture of these.* Organic dysfunction includes abnormalities in the three systems responsible for a normal erection or may be medication-induced (**Tables 51-1** and **51-2**). It is estimated that 25% of ED cases are due to medications.⁴ Note that many of the risk factors for

ED are the same as risk factors for cardiovascular (CV) disease, including hypertension, diabetes, dyslipidemia, smoking, obesity, metabolic syndrome, and sedentary behavior.⁵ In many patients, ED is the first indication of the endothelial dysfunction associated with cardiovascular disease, with two-thirds of patients with coronary artery disease having symptoms of ED before the onset of coronary symptoms.⁴ The presence of ED risk factors leads to the assumption that the patient has organic dysfunction. Most commonly, medical conditions that impair arterial flow into or out of the erectile tissue or affect the innervation will be strongly associated with ED. Patients with diabetes mellitus have exceptionally high rates of ED as a result of vascular disease and neuropathy. Additionally, a relationship has been found between low testosterone levels and an increased incidence of metabolic syndrome and type 2 diabetes.⁶

Psychogenic dysfunction occurs if a patient does not respond to psychological arousal. It occurs in up to 30% of all cases of ED. Common causes include performance anxiety,

strained relationships, lack of sexual arousability, and overt psychiatric disorders such as depression and schizophrenia.⁷

① *Many patients may initially have organic dysfunction, but develop a psychogenic component as they try to cope with their inability to achieve an erection.*

CLINICAL PRESENTATION AND DIAGNOSIS

TREATMENT

Desired Outcomes

ED is not a life-threatening condition, but left untreated it can be associated with depression, loss of self-esteem,

• poor self-image, and marital discord.⁹ The primary goal of therapy is achievement of erections suitable for intercourse and improvement in patient and partner quality of life. Additionally, the ideal therapy should have minimal side effects, be convenient to administer, have a quick onset of action, and have few or no drug interactions.¹⁰

General Approach to Treatment

After determining whether the ED is organic or psychogenic, the initial step in management is to identify associated disease states and lifestyle activities that adversely affect erectile function and treat them optimally. ② *In addition to*

Clinical Presentation and Diagnosis of ED

The introduction of oral medications and direct-to-consumer advertising has made patients feel more comfortable approaching practitioners for treatment advice. Despite this, some patients may only discuss their dysfunction when questioned directly by their provider or if their partner initiates the interaction. Patients may still feel that a loss in erectile function translates into a loss of masculinity.

Possible Signs and Symptoms

- Embarrassment
- Anxiousness
- Anger
- Marital difficulties
- Low self-confidence or morale, depression
- Full inability to achieve erections
- Ability to achieve partial erections, but not suitable for intercourse
- Erections sufficient for intercourse, but early **detumescence**
- The problem may have a slow or acute onset, or may wax and wane

Diagnosis

ED may be the presenting symptom of other chronic disease states.

Full medical, social, and medication histories should be taken to determine areas that can cause or exacerbate ED and to assess the patient's ability to safely perform intercourse.

- Medical history with emphasis on cardiovascular and psychiatric disorders, diabetes, trauma, and surgical procedures
- Social history including history of smoking, recreational drug use, exercise, and alcohol consumption

- Medication history including prescription, nonprescription, and dietary supplements

Physical Examination

- Review for hypogonadism (gynecomastia, testicular atrophy, reduced body hair, increase in body fat)
- Digital rectal exam to determine whether prostate is enlarged
- Vital signs
- Abnormalities of the penis or impaired vasculature and nerve function to the penis

Labs

- Fasting glucose or HbA1c
- Serum testosterone
- Fasting lipid panel
- Further cardiac testing if warranted

Determine Severity

- Use an abridged, five-item version of the International Index of Erectile Dysfunction (IIEF-5) as a diagnostic tool¹²:
 - How do you rate your confidence that you could get and keep an erection?
 - When you had erections with sexual stimulation, how often were your erections hard enough for penetration?
 - During sexual intercourse, how often were you able to maintain your erection after you had penetrated (entered) your partner?
 - During sexual intercourse, how difficult was it to maintain your erection to completion of intercourse?
 - When you attempted sexual intercourse, how often was it satisfactory for you?
 - Questions scored 1 to 5, very low to very high respectively. Score of 21 or less indicates ED likely.

a physical exam, a thorough medical, social, and medication history with emphasis on cardiac disease must be taken before starting any treatment for ED to assess for ability to safely perform sexual activity and to assess for possible drug interactions. Medications suspected to cause or worsen ED should be discontinued if possible. In patients with intermediate or high cardiovascular risk, additional testing should occur to determine whether sexual activity is safe.

③ Treatment options for ED include medical devices, pharmacologic treatments, lifestyle modifications, surgery, and psychotherapy. Reversible causes of ED should be identified first and treated appropriately.

④ When determining the best treatment for an individual, the role of the clinician is to inform the patient and his partner of all available options while understanding his medical history, desires, and goals. The choice of treatment is primarily left up to the couple, but most often treatment is initiated with the least invasive option and then treatment progresses to more invasive options if needed. Ultimately, the choice of therapy should be individualized, taking into account patient and partner preferences, concomitant disease states, response, administration route, cost, tolerability, and safety. Common drug treatment regimens for ED are listed in **Table 51-3**.

Table 51-3

Common Drug Treatment Regimens for ED

Route of Administration	Generic Name	Brand Name	Typical Dosing Range ^a	Maximum Dosing Frequency
Oral	Sildenafil	Viagra	25–100 mg 1 hour prior to intercourse	Once daily
	Tadalafil	Cialis	5–20 mg prior to intercourse or daily dose of 2.5–5 mg	Once daily
Intracavernosal	Vardenafil	Levitra	5–20 mg 1 hour prior to intercourse	Once daily
	Yohimbine ^b	Aphrodyne, Yocon	5.4 mg 3 times daily	N/A
	Alprostadil	Caverject, Caverject Impulse, Edex N/A	1.25–60 mcg 5–20 minutes prior to intercourse ^c	3 times weekly, 24 hours between injections
	Papaverine ^b	N/A	Typically used in combination at variable doses ^c	3 times weekly, 24 hours between injections
Intraurethral	Alprostadil	MUSE	125–1,000 mcg 5–10 minutes prior to intercourse ^c	2 times daily
		Depo-Testosterone	50–400 mg every 2–4 weeks	Once weekly
Intramuscular	Testosterone cypionate	Delatestryl	50–400 mg every 2–4 weeks	Once weekly
	Testosterone enanthate			
Topical	Testosterone patches	Testoderm	4–6 mg/day applied to scrotum	Once daily
		Testoderm TTS	4–6 mg/day applied to arm, back, or upper buttocks	Once daily
		Androderm	2.5–5 mg/day applied to back, abdomen, upper arms, or thighs	Once daily
	Testosterone gel	AndroGel 1%, Testim	5–10 g gel per day (50–100 mg testosterone) to shoulders, upper arms, abdomen (AndroGel 1% only)	Once daily
		AndroGel 1.62%	40.5–81 mg/day to shoulders or upper arms	Once daily
		Fortesta Axiron	10–70 mg/day to thigh 30–120 mg/day to axilla	Once daily Once daily
Buccal	Testosterone	Striant	30 mg every 12 hours to gum region above incisor; rotate to alternate sides with each dose	Twice daily
Subcutaneous implantable pellet	Testosterone	Testopel	150–450 mg (150 mg for every 25 mg testosterone propionate required weekly)	Every 3–6 months

MUSE, medicated urethral system for erection.

^aUse the lowest effective dose to limit adverse effects.

^bNot FDA-approved for this indication.

^cInitial dose must be titrated in physician's office.

Patient Encounter 1, Part 1

CB, a 52-year-old man with type 2 diabetes, coronary artery disease, hypertension, and dyslipidemia, returns to your clinic for follow-up on his chronic disease states. When reviewing his history, he describes problems with his erections. After further questioning, you determine that his dysfunction has progressively gotten worse over the last year. He is quite emotional and states that the problem is distressing and has caused significant marital discord. He wonders about “those ads on television” suggesting a pill.

Based on the available information, how would you classify his ED?

What additional information do you need before establishing an appropriate treatment regimen and determining his ability to safely perform intercourse?

► Nonpharmacologic Therapy

Lifestyle Modifications Lifestyle modifications should always be addressed in the management of ED. A healthy diet, increase in regular physical activity, and weight loss are associated with higher International Index of Erectile Dysfunction (IIED) scores and an improvement in erectile function.¹¹ The clinician should also recommend smoking cessation, reduction in excessive alcohol intake, and discontinuation of illicit drug use.

Psychotherapy Psychotherapy is an appropriate treatment approach for patients with psychogenic or mixed dysfunction. It should address immediate causes of dysfunction, and if possible the partner should attend sessions as well. Effectiveness is not well documented for organic dysfunction unless combined with other therapies. Advantages include noninvasiveness and partner participation, whereas disadvantages include increased cost and time commitment.

Vacuum Erection Devices Vacuum erection devices (VEDs) induce erections by creating a vacuum around the penis; the negative pressure draws blood into the penis by passively dilating arteries and engorging the corpora cavernosa. The erection is maintained with a constriction band placed at the base of the penis to reduce venous outflow (Fig. 51–2). They may be used as often as desired, but it is recommended that the constriction band not be left in place longer than 30 minutes at a time.

5 VEDs are highly effective treatment modalities for ED and are considered a second-line therapy. Efficacy rates are as high as 90% in obtaining an erection sufficient for *coitus*, and satisfaction rates are between 27% and 94%.^{5,13} Rigidity may be improved by using a double pump technique in which the vacuum is applied for a couple of minutes, removed, then reapplied for another few minutes. Higher efficacy rates can also be achieved by combining VEDs with other therapies.

Onset of action is slow at around 30 minutes, which limits spontaneity. In addition, patients and partners may complain

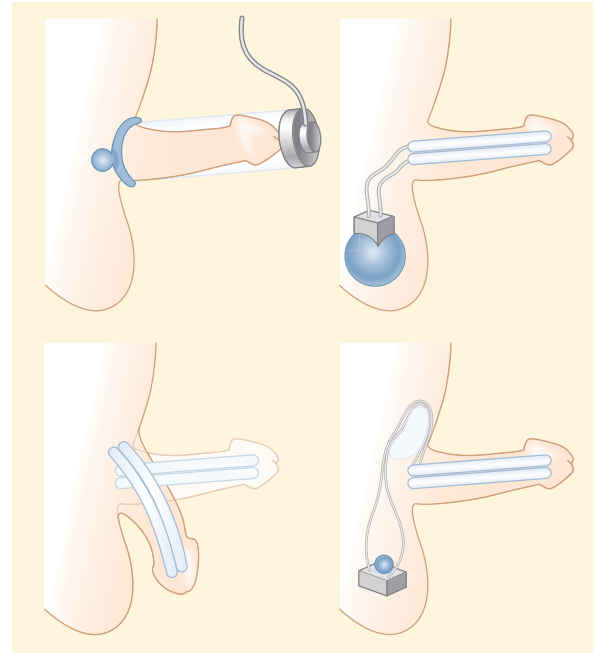

FIGURE 51–2. Available devices and prostheses used to treat ED. (From Wagner G, Saenz de Tejada I. Update on male erectile dysfunction. *BMJ* 1998;316:678–682.)

of a cold, lifeless, discolored penis that has a hinge-like feel. Painful ejaculation or inability to ejaculate are additional adverse effects. VEDs are contraindicated in persons with sickle cell disease and should be used with caution in patients on oral anticoagulants or who have bleeding disorders due to the increased possibility of **priapism**. VEDs are generally more acceptable to older patients in stable relationships and with infrequent sexual encounters.¹³

Prostheses Penile prostheses are semirigid malleable or inflatable rods, which are inserted surgically into the corpus cavernosa to allow erections (Fig. 51–2). The malleable rods are rigid at all times, but may be bent into position by the patient when desired. The inflatable prostheses remain flaccid until the pump within the scrotum moves fluid from a reservoir to the cylinders within the penis. Detumescence is achieved when the fluid is then transferred back to the reservoir by activating a release button.

Because prostheses are the most invasive treatment available, they are only considered in patients who do not respond to medications or external devices, or those who have significant adverse effects from other therapies. Patient satisfaction rates can be as high as 95%, with partner satisfaction rates just slightly lower.¹⁴ The primary risk of insertion is infection, although this only happens in 3% of first-time prostheses. Semirigid malleable rods may interfere with urination, are difficult to conceal, and have a higher likelihood of erosion.¹⁴ Most devices need replacement after 10 to 15 years.

► Pharmacologic Therapy

Phosphodiesterase Type 5 Inhibitors Sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra) act by selectively

inhibiting phosphodiesterase (PDE) type 5, an enzyme that breaks down cGMP. By inhibiting the breakdown of cGMP, smooth muscle relaxation is induced, leading to an erection (Fig. 51-1). However, the PDE inhibitors are only effective in the presence of sexual stimulation to drive the NO/cGMP system, making them facilitators of an erection, not initiators. Patients must be informed of the need for sexual stimulation to induce an erection, as it will not occur spontaneously.

6 *Effectiveness of the three available PDE inhibitors is essentially comparable, but differences exist in duration of action, absorption with a fatty meal and, to a small degree, incidence of side effects and drug interactions (Table 51-4).* Review of available data for each individual agent shows a 50% to 80% response rate depending on the dose of agent used and the etiology of dysfunction. Response rates tend to be lower in patients with radical prostatectomy as well as those with diabetes, severe nerve damage, or severe vascular disease.¹⁵ Although efficacy rates appear to be similar between agents, there are some data to suggest that continuation rates are higher and patient preference greater with tadalafil.¹⁶ The PDE inhibitors are considered first-line

therapies due to high efficacy rates, convenience of dosing, and minimal severe adverse effects.

The most dramatic difference among the three agents is tadalafil's extended duration of action, earning it the nickname "the weekender drug." Although sildenafil and vardenafil have average half-lives of 3 to 4 hours, tadalafil's half-life is approximately 18 hours. The extended half-life allows for more spontaneous sexual activity over a couple of days, but may increase the duration of adverse effects and likelihood of drug interactions. Tadalafil has been approved for use as a daily medication at a lower dose (2.5 to 5 mg) than the as-needed dose. The dosing efficacy appears to be similar to as-needed dosing, but cost will be prohibitive for many patients.

The most common side effects experienced with PDE inhibitors include headache, facial flushing, nasal congestion, dyspepsia, myalgia, back pain, and, rarely, priapism. Vardenafil and sildenafil may also cause difficulty in discriminating blue from green, bluish tones in vision, or difficulty seeing in dim light due to cross-reactivity with PDE 6 in the retina. Labeling for all PDE inhibitors includes a warning about nonarteritic ischemic optic neuropathy (NAION) in a small number of patients. This is a condition in which blood flow

Table 51-4

Comparison of PDE Inhibitors

	Sildenafil (Viagra)	Tadalafil (Cialis)	Vardenafil (Levitra)
Available strengths	25-, 50-, 100-mg tabs	2.5-, 5-, 10-, 20-mg tabs	2.5-, 5-, 10-, 20-mg tabs
Initial dosage in healthy adults	50 mg up to once daily taken 1 hour prior to sexual activity	10 mg up to once daily taken 1 hour prior to sexual activity or 2.5 mg daily at the same time each day	10 mg up to once daily taken 1 hour prior to sexual activity
Dosing range for healthy adults	25–100 mg	5–20 mg	5–20 mg
Dosage in the elderly	25 mg	5–10 mg	5 mg
Dosage in renal impairment	50 mg (moderate ^a) 25 mg (severe ^b)	5 mg (moderate ^a and severe ^b)	5–20 mg
Dosage in hepatic impairment	25 mg	10 mg ^c	5–10 mg ^d
Time to onset	30 minutes	15 minutes	Less than 1 hour
Onset delayed by high-fat meal?	Yes	No	Yes
Duration of effect	Up to 4 hours	Up to 36 hours	Up to 4 hours
Half-life	3–4 hours	18 hours	4–5 hours
Metabolism	CYP3A4 (major) CYP2C9 (minor)	CYP3A4	CYP3A4 (major) CYP3A5 (minor) CYP2C (minor)
Clinically relevant drug interactions	Nitrates, protease inhibitors, azole antifungals, erythromycin	Nitrates, α_1 -blockers ^e , azole antifungals, erythromycin	Nitrates, antiarrhythmic agents, ^f α_1 -blockers, ^e erythromycin

CYP, cytochrome P450 isoenzyme.

^aModerate renal impairment = creatinine clearance (CrCl) 31 to 50 mL/min (0.51 to 0.83 mL/s).

^bSevere renal impairment = CrCl less than 30 mL/min (0.50 mL/s).

^cMild to moderate only—contraindicated in severe liver disease.

^dMild to moderate only—not yet evaluated in severe liver disease.

^eSelective α_1 -blockers (such as alfuzosin, silodosin, and tamsulosin) are appropriate in combination.

^fVardenafil can cause QT-interval prolongation; this effect in combination with certain antiarrhythmic agents can lead to life-threatening arrhythmias.

is blocked to the optic nerve. If patients experience sudden or decreased vision loss, they should call a healthcare provider immediately.

Concern exists about the safety of renewing sexual activity and using PDE inhibitors in patients with cardiovascular disease. Due to the coexistence of ED and coronary artery disease, a management approach was developed to give recommendations for the use of PDE inhibitors as well as to determine the safety of intercourse in patients with cardiovascular disease^{17,18} (Table 51–5). In addition to the inherent risk of renewing sexual activity, PDE inhibitors can lead to significant hypotension. Patients taking organic nitrates are at highest risk, as these drugs potentiate the drop in blood pressure. All three PDE inhibitors are absolutely contraindicated in patients taking any form of nitrate, whether scheduled or sublingual for acute situations. Caution should be used when using a PDE inhibitor in patients taking α -blockers due to an increased risk of hypotension. In addition, the labeling for vardenafil contains a precautionary statement about the possibility of QT prolongation with the use of the drug. Other drug interactions and cautions vary slightly between agents and are described in Table 51–4.

The introduction of the oral PDE inhibitors has dramatically changed the treatment of ED. Direct-to-consumer advertising has informed patients of the availability of oral drugs for treatment. However, patients must be fully informed of side effects, drug interactions, mechanism of action, and dosing before being prescribed the medication. In addition, they need to understand the need for sexual stimulation

to achieve the desired result and that a single trial is not adequate. It is estimated that six to eight attempts with a medication and specific dose may be needed before successful intercourse results.⁵

Alprostadil Alprostadil is a prostaglandin E₁ analog that induces an erection by stimulating adenylyl cyclase, which leads to an increase in smooth muscle relaxation, rapid arterial inflow, and increased penile rigidity. Alprostadil is available as an intracavernosal injection (Caverject or Edex) or a transurethral suppository (MUSE, medicated urethral system for erection), but the injectable form is more effective (Fig. 51–3).^{4,5} Both forms of alprostadil are considered more invasive than oral medications or VEDs and are therefore second-line therapies.

MUSE consists of a urethral pellet of alprostadil with an applicator. Onset of action is within 5 to 10 minutes and it is effective for 30 to 60 minutes. Initial dose titration should occur in a physician's office to ensure correct dose and prevent adverse events. Although effectiveness rates in clinical trials have been as high as 65%,¹⁹ its success in practice has been lower.²⁰ Aching in the penis, testicles, legs, and perineum; warmth or burning sensation in the urethra, minor urethral bleeding or spotting, priapism, and lightheadedness are all possible adverse effects. In addition, partners may experience vaginal burning or itching. Disadvantages include lower effectiveness, high cost, adverse effects, complicated insertion technique, and a contraindication against use with a pregnant partner unless using a condom.

Table 51–5

Recommendations of the Second Princeton Consensus Conference for Cardiovascular Risk Stratification of Patients Being Considered for PDE Inhibitor Therapy

Risk Category	Description of Patients' Conditions	Management Approach
Low risk	Has asymptomatic CV disease with less than three risk factors for CV disease Has well-controlled hypertension Has mild, stable angina Has mild congestive heart failure (NYHA Class I) Has mild valvular heart disease Had a myocardial infarction more than 6 weeks ago	Patient can be started on PDE inhibitor
Moderate risk	Has greater than or equal to three risk factors for CV disease Has moderate, stable angina Had a recent myocardial infarction or stroke within the past 6 weeks Has moderate congestive heart failure (NYHA Class II)	Patient should undergo complete CV workup and treadmill stress test to determine tolerance to increased myocardial energy consumption associated with increased sexual activity
High risk	Has unstable or symptomatic angina, despite treatment Has uncontrolled hypertension Has severe congestive heart failure (NYHA Class III or IV) Had a recent myocardial infarction or stroke within the past 2 weeks Has moderate or severe valvular heart disease Has high-risk cardiac arrhythmias Has obstructive hypertrophic cardiomyopathy	PDE inhibitor is contraindicated; sexual intercourse should be deferred

CV, cardiovascular; NYHA, New York Heart Association; PDE, phosphodiesterase.

From Gupta BP, Murad MH, Clifton MM, et al. The effect of lifestyle modification and cardiovascular risk factor reduction on erectile dysfunction. *Arch Intern Med* 2011;171:1797–1803.

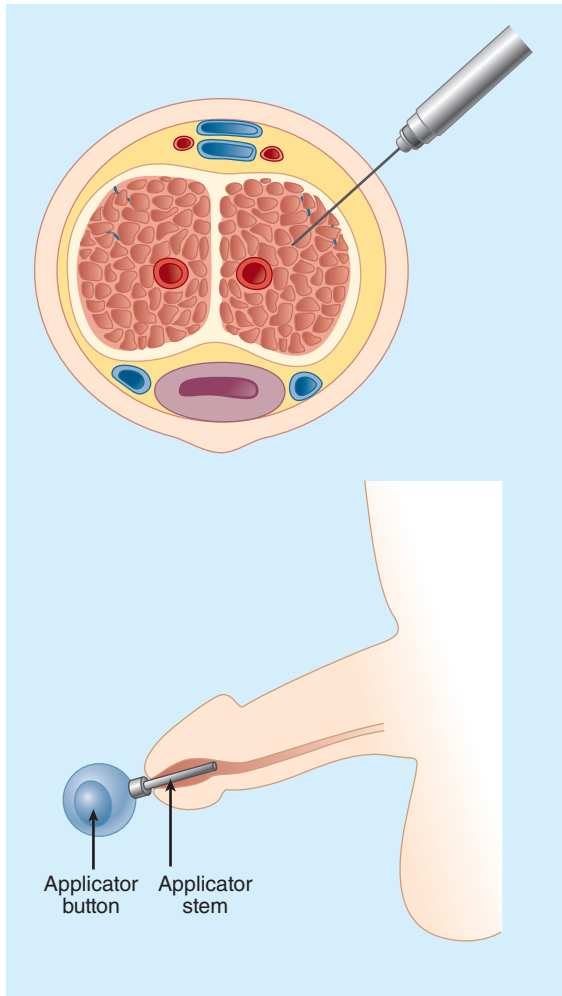

FIGURE 51-3. Intraurethral and intracavernosal administration of alprostadil. (From Wagner G, Saenz de Tejada I. Update on male erectile dysfunction. *BMJ* 1998;316:678–682.)

Alprostadil Alprostadil injected into the corpus cavernosum is the more effective route and is the only FDA-approved injection for ED. The onset of action is similar to transurethral alprostadil, but duration varies with dose and must be titrated in a physician's office to achieve an erection lasting no more than 1 hour. Injections should be done into one side of the penis directly into the corpus cavernosum, and then the penis should be massaged to distribute the drug. Because of cross-circulation, both corpora will become erect when massaging. Education is extremely important with intracavernosal injections. Patients must be adequately informed of technique, expectations, side effects, and when to seek help. **5** *Intracavernosal injections are effective in up to 90% of patients, but side effects, lack of spontaneity, and fear of needles limit their widespread use as first-line therapy, and therefore this therapy is most appropriate for patients in long-term stable relationships. Adverse effects include pain with injection, bleeding or bruising at the injection site, fibrosis, or priapism. Use with caution in patients with sickle cell disease, those on anticoagulants, or those who have*

bleeding disorders, due to an increased risk of priapism and bleeding.

Papaverine and Phentolamine Papaverine and phentolamine are non-FDA-approved agents used for intracavernosal injection. Papaverine is a nonselective PDE inhibitor that induces an erection by relaxing smooth muscle and increasing blood flow. Phentolamine is a competitive α_2 -adrenergic receptor antagonist that increases arterial inflow by opposing arterial constriction. Both drugs are rarely used alone and are most often mixed in various concentrations with alprostadil for increased effectiveness and in an effort to reduce adverse effects with smaller doses of each medication. Patients typically must see a specialist for use of these medications in mixtures, as the providers are most likely to compound them and adjust dosages.

Yohimbine Yohimbine is an indole alkaloid produced in the bark of yohimbe trees. It selectively inhibits α_2 -adrenergic receptors in the brain that are associated with libido and penile erection. Because there are only limited data supporting its efficacy, yohimbine is not a recommended treatment for any form of ED.⁵ Adverse effects of the drug include nausea, irritability, headaches, anxiety, tachycardia, and hypertension.

Testosterone Supplementation **7** *Androgens are important for general sexual function and libido, but testosterone supplementation is only effective in patients with documented low serum testosterone levels. In patients with hypogonadism, testosterone replacement is the initial treatment of choice, as it corrects decreased libido, fatigue, muscle loss, sleep disturbances, and depressed mood. Improvements in ED may occur, but they should not be expected to occur in all patients. The initial trial should be for 3 months. At that time, re-evaluation and the addition of another ED therapy is warranted. Dosage forms include oral, intramuscular, topical patches or gel, an implanted pellet, and a buccal tablet.*

Injectable esters of testosterone offer the most inexpensive replacement option. Testosterone cypionate and enanthate have the longest duration of action and are therefore the preferred agents. There are several drawbacks associated with parenteral testosterone, including the need to administer deep intramuscular injections every 2 to 4 weeks. In addition, levels of hormone are well above physiologic values within the first few days. Concentrations then decline and eventually dip below physiologic levels just before the next dose. These extreme changes in concentration may lead to mood swings and a reduced sense of well-being.²¹

Treatment with topical products is attractive to patients due to convenience, but they tend to be more expensive than the injections. In a review of studies including patients with ED and primary hypogonadism, transdermal testosterone resulted in significantly higher response rates than intramuscular administration.⁴ Testosterone patches and gels are administered daily and result in serum levels within the physiologic range during the 24-hour dosing period.²¹ Most patients prefer the nonscrotal patch or the gel because the scrotal patch requires shaving of the area, and the patch has a tendency to fall off. Care must be taken with the use of

Patient Encounter 1, Part 2

PMH: Type 2 diabetes for 15 years; not controlled due to his stressful profession; he often works late, eats on the run, and has no time for exercise. Coronary artery disease; myocardial infarction with stent placement 6 months ago. Hypertension for 8 years, currently controlled. Dyslipidemia for 8 years, currently controlled.

SH: Works long hours as a business executive; drinks alcohol only occasionally; has a 20-pack-per-year smoking history, but quit 6 months ago.

Meds: Metformin 1,000 mg orally twice daily; metoprolol XL 50 mg orally once daily; lisinopril/hydrochlorothiazide 40/25 mg once daily; simvastatin 20 mg orally once daily; aspirin 81 mg once daily.

ROS: (–) Morning, nocturnal, or spontaneous erections suitable for intercourse; (–) nocturia, urgency, symptoms of prostatitis; (–) chest pain or anginal symptoms; (+) significant life stressors; (+) mild pain in feet.

PE:

VS: BP 128/78 mm Hg, P 85 beats/min, RR 18 breaths/min, Wt 249 lb (113 kg), Ht 70 in (178 cm)

CV: Normal exam

Genital/Rectal: Normal scrotum and testicles w/o masses; penis without discharge or curvature

Labs: lipid panel: total cholesterol, LDL, HDL, triglycerides at goal; HbA1c 8% (0.08; 64 mmol/mol hemoglobin), total testosterone 700 ng/dL (24 nmol/L)

Given this additional information, what are his risk factors for ED?

Identify treatment goals for this patient.

Perform a cardiovascular risk assessment to determine risk.

What pharmacologic and nonpharmacologic alternatives are available for this patient?

the gel to wash hands thoroughly after use and avoid baths or showers within 2 to 6 hours of application. The most common side effects of topical testosterone are dermatologic reactions caused by the absorption enhancers.

Oral testosterone products are also available for supplementation. Unfortunately, testosterone has poor oral bioavailability and undergoes extensive first-pass metabolism. Alkylated derivatives such as methyltestosterone and fluoxymesterone have been formulated to compensate for these problems, but this modification makes them considerably more hepatotoxic. This adverse effect makes oral replacement undesirable, and this route of administration should not be used.

An alternative to the oral route is the buccal mucoadhesive system. The Striant buccal system adheres to the inside of the mouth and the testosterone is absorbed through the oral mucosa and delivered to the systemic circulation. There is no first-pass effect, as the liver is bypassed by this route of administration. Patients apply a 30-mg tablet to the upper gum twice daily. The cost is similar to that of the patch or gel. Side effects unique to this dosage form include oral irritation, bitter taste, and gum edema.

General side effects of testosterone include gynecomastia, dyslipidemia, polycythemia, and acne. Weight gain, hypertension, edema, and exacerbations of heart failure also occur due to sodium retention. Before initiating testosterone, the patient should undergo evaluation for benign prostatic hypertrophy and prostate cancer. Routine follow-up includes yearly prostate-specific antigen, digital rectal exam, and hemoglobin and liver function, in addition to assessment of response.

OUTCOME EVALUATION

Successful therapy for ED results in an increase in erections suitable for intercourse and, most importantly, in an

improvement in the patient's quality of life. Ideally, the therapy chosen is free of significant adverse effects, discomfort, and inconvenience. Laboratory evaluation and a physical exam are not necessary for evaluation of effectiveness, but may be necessary to determine whether adverse events are occurring.

Evaluate satisfaction and effectiveness after a 4-week trial unless the patient initiates follow-up sooner. Some therapies such as intracavernosal injections will require multiple visits over the long term to determine the correct dose and to detect adverse effects. If the initial therapy is not effective, the patient must be further evaluated to determine whether the initial assessment of comorbid disease states, type of dysfunction, and patient goals were appropriate. After providing further education, ensuring the patient is using the therapy appropriately and determining their goals are realistic, providers can then increase the dose of drug if not at maximum, switch to another therapy, or add a therapy if indicated.

Patient Encounter 1, Part 3

CB was referred to his cardiologist, and it was determined that he may safely resume sexual activity at this time. Based on the information available, create a treatment plan for this patient's ED.

Which of the available options will be your treatments of choice based on degree of invasiveness, ease of use, and side-effect profile?

What are the safety and efficacy monitoring parameters for the chosen treatment?

Patient Encounter 2, Part 1

WW is a 62-year-old man with a history of type 2 diabetes, dyslipidemia, hypertension, and ED. When in the office for a routine follow-up, he states the pill recently prescribed for his ED is not “doing the trick” so he has not been using it. He also complains that he is tired all the time, does not have much of a libido anymore, and is gaining weight.

Meds: glimepiride 4 mg orally twice daily, metformin 1,000 mg orally twice daily, losartan/hydrochlorothiazide 100/25 mg orally once daily, vardenafil 20 mg orally as needed.

ROS: (–) Morning, nocturnal, or spontaneous erections suitable for intercourse; (–) nocturia, urgency, symptoms of prostatitis.

PE:

VS: BP 132/74 mm Hg, P 82 beats/min, Wt 214 lb (97.3 kg), Ht 75 in (191 cm)

Labs: lipid panel: total cholesterol, LDL, and HDL at goal, triglycerides 191 mg/dL (2.16 mmol/L); HbA1c 8.5% (0.085; 69 mmol/mol hemoglobin)

Based on the information provided, what is your assessment of the patient’s ED?

What should be recommended as the next step in treatment of his ED?

Patient Care and Monitoring

1. Assess the patient’s specific symptoms to determine the type of dysfunction. Does the patient have ED or an ejaculatory or libido disorder?
2. If problems are with erectile ability, ask specific questions related to onset, frequency, and sexual relationships. Does the patient history imply psychogenic, organic, or mixed dysfunction?
3. Perform a thorough medical and social history as well as a physical exam to diagnose ED and to determine potential causes that may be treatable.
4. Perform a thorough history of prescription and nonprescription medications. Are any of the patient’s medications associated with ED or are they contraindicated with possible ED therapies?
5. Generally treatment is started with the least invasive option and then progresses to more invasive options, but ultimately patient and partner preferences determine the initial therapy.
6. Discontinue medications that may cause ED if possible and optimally treat associated disease states.
7. If the patient and partner are not satisfied, provide further counseling to ensure that they are using the therapy appropriately and that they have realistic goals.
8. Provide patient education with regard to disease state, lifestyle modifications, drug therapy, and device technique:
 - The causes of ED
 - The fact that therapy will not cure ED, but may be helpful in improving erections; it is important to have realistic expectations
 - The appropriate use of medications and devices
 - Typical adverse effects
 - Drug interactions
 - Warning signs and their management (e.g., vision changes, fibrosis, pain, priapism, or hypotension)
 - The importance of frequent follow-up with the provider

Abbreviations Introduced in This Chapter

cAMP	Cyclic adenosine monophosphate
cGMP	Cyclic guanosine monophosphate
ED	Erectile dysfunction
GTP	Guanosine triphosphate
IIED	International Index of Erectile Dysfunction
MUSE	Medicated urethral system for erection
NAION	Non-arteritic ischemic optic neuropathy
PDE	Phosphodiesterase
VED	Vacuum erection device

Benign Prostatic Hyperplasia

Mary Lee and Roohollah Sharifi

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiologic mechanisms underlying the symptoms and signs of benign prostatic hyperplasia (BPH).
2. Recognize the symptoms and signs of BPH in individual patients.
3. List the desired treatment outcomes for a patient with BPH.
4. Identify factors that guide selection of a particular α -adrenergic antagonist for an individual patient.
5. Compare and contrast α -adrenergic antagonists versus 5α -reductase inhibitors in terms of mechanism of action, treatment outcomes, adverse effects, and interactions when used for management of BPH.
6. Describe the indications, advantages, and disadvantages for single drug versus combination drug treatment of BPH.
7. Describe the indications for surgical intervention of BPH.
8. Formulate a monitoring plan for a patient on a given drug treatment regimen based on patient-specific information.
9. Formulate appropriate counseling information for patients receiving drug treatment for BPH.

KEY CONCEPTS

- 1 The lower urinary tract symptoms (LUTS) and signs of benign prostatic hyperplasia (BPH) are due to static, dynamic, or detrusor factors. The static factor refers to anatomic obstruction of the bladder neck caused by an enlarged prostate gland. The dynamic factor refers to excessive stimulation of α -adrenergic receptors in the smooth muscle of the prostate, prostatic urethra, and bladder neck. The detrusor factor refers to irritability of hypertrophied detrusor muscle as a result of long-standing bladder outlet obstruction.
- 2 Drug treatment goals for BPH include relieving obstructive and irritative voiding symptoms, preventing complications of disease, and reducing the need for surgical intervention.
- 3 Watchful waiting is indicated for patients with mild symptoms that are not bothersome.
- 4 Single-drug treatment with an α -adrenergic antagonist is preferred for patients with moderate or severe symptoms of BPH. Single-drug treatment with a 5α -reductase inhibitor should be reserved for patients with moderate or severe symptoms and significantly enlarged prostates of at least 30 g (1.05 oz).
- 5 Surgical intervention should be reserved for patients with severe LUTS due to BPH and those with complications of disease, such as recurrent urinary tract infections, recurrent severe gross hematuria, renal failure, and bladder calculi.
- 6 α -Adrenergic antagonists reduce the dynamic factor. They competitively antagonize α -adrenergic receptors, thereby causing relaxation of the bladder neck, prostatic urethra, and prostate smooth muscle. They do not shrink an enlarged prostate. The onset of action is days to weeks, depending on the need for up-titration of the daily dose to achieve a therapeutic response. Dose-limiting adverse effects include orthostatic hypotension and syncope. In addition, delayed or retrograde ejaculation has been reported. Combined use with antihypertensives, diuretics, or phosphodiesterase inhibitors can increase the risk of hypotensive episodes, particularly with immediate release formulations of second-generation α -adrenergic antagonists.

- 7 Among the α -adrenergic antagonists, modified-release alfuzosin is considered functionally uroselective because usual therapeutic doses produce relaxation of the bladder neck and prostatic smooth muscle with minimal peripheral vascular relaxation. Although alfuzosin appears to produce less hypotension than immediate-release formulations of terazosin and doxazosin, it is not clear whether it has the same cardiovascular profile as tamsulosin. Although not uroselective, controlled-release doxazosin produces less hypotension than the immediate-release formulation. Tamsulosin and silodosin are pharmacologically uroselective and exert greater antagonism of α_{1A} -receptors, which comprise the majority of adrenergic receptors in the prostate, prostatic urethra, and bladder neck; and α_{1D} -receptors, which predominate in bladder detrusor muscle as compared with vascular α_{1B} -receptors. Therefore, tamsulosin and silodosin can be initiated with a full therapeutic dose, which achieves peak effects sooner than with immediate-release formulations of terazosin and doxazosin, which must be up-titrated. Tamsulosin appears to have the lowest potential to cause hypotension. In various clinical trials, tamsulosin is well tolerated in the elderly and in patients taking diuretics and antihypertensives. It is also commercially available in a controlled-release dosage formulation. Therefore, with chronic use, tamsulosin can be taken once daily at the patient's convenience. Fewer clinical data are available concerning silodosin than tamsulosin. Also, clinical advantages of silodosin over tamsulosin have yet to be documented. For this reason, tamsulosin is preferred over silodosin.
- 8 **5 α -Reductase inhibitors** shrink an enlarged prostate by approximately 20% to 25%, reducing symptoms caused by the static factor. They do so by inhibiting 5 α -reductase that is responsible for intraprostatic conversion of testosterone to dihydrotestosterone, the active androgen that stimulates prostate tissue growth. The onset of action is slow, with peak shrinkage of the prostate taking up to 6 months. Unlike treatment with α -adrenergic antagonists, 5 α -reductase inhibitors have been shown to reduce the incidence of acute urinary retention and need for prostate surgery in patients with significantly enlarged prostate glands (more than 30 g [1.05 oz]) and those with prostate-specific antigen (PSA) serum levels of 1.5 ng/mL (1.5 mcg/L) or more. Because 5 α -reductase inhibitors do not produce cardiovascular adverse effects, they are preferred for treatment of moderate to severe symptoms of BPH when the patient is at risk of hypotension, but wants to be treated medically. Adverse effects include gynecomastia, decreased libido, erectile dysfunction, and ejaculation disorders. Drug interactions are uncommon.
- 9 The combination of an α -adrenergic antagonist and a 5 α -reductase inhibitor is a preferred drug regimen in patients with moderate to severe voiding symptoms and an enlarged prostate (more than 30 g [1.05 oz]) and who

are at risk of complications of BPH as suggested by a PSA of 1.5 ng/mL (1.5 mcg/L) or more. The α -adrenergic antagonist quickly reduces the severity of obstructive voiding symptoms, and the 5 α -reductase inhibitor slowly shrinks the enlarged prostate. At 2 and 4 years after the start of the combination regimen, clinical trials show that treated patients have a lower frequency of developing acute urinary retention or needing prostate surgery than patients treated with single drug therapy. Also, in patients with severe symptoms, the combination enhances the effectiveness of the α -adrenergic antagonist after the first year.

- 10 When monitoring efficacy of drug treatment for BPH, subjective end points include relief of obstructive and irritative voiding symptoms. Objective end points include improvements of urinary flow rates, decreased postvoid residual urinary volume, and decreased complications of disease.

INTRODUCTION

The prostate is a heart-shaped, chestnut-sized organ that encircles the portion of the proximal urethra that is located at the base of the urinary bladder. The prostate produces secretions, which are part of the ejaculate.

Benign prostatic hyperplasia (BPH) is the most common benign neoplasm in males who are at least 40 years of age. BPH can produce lower urinary tract voiding symptoms that are consistent with impaired emptying of urine from and storage of urine in the bladder. Medications are a common mode of treatment to reduce symptoms and/or delay complications of the disease. For this reason, clinicians should be knowledgeable about the medical management of this disease.

EPIDEMIOLOGY AND ETIOLOGY

BPH is present as microscopic disease in many elderly males. The prevalence increases with advancing patient age. However, only about 50% and 25% of patients with microscopic BPH disease develop an enlarged prostate on palpation and clinical voiding symptoms, respectively.^{1,2} It is estimated that 25% of males 40 years of age or more have voiding symptoms consistent with BPH, and 20% to 30% of all male patients who live to the age of 80 years will require a **prostatectomy** for severe voiding symptoms of BPH.²

Two etiologic factors for BPH include advanced patient age and the stimulatory effect of androgens.

- Prior to 40 years of age, the prostate in the adult male stays the same size, approximately 15 to 20 g. However, in males who have reached 40 years of age, the prostate undergoes a growth spurt, which continues as the male advances in age. Enlargement of the prostate can result in clinically symptomatic BPH.
- The testes and adrenal glands produce 90% and 10%, respectively, of circulating testosterone. Testosterone enters prostate cells, where predominantly type II 5 α -reductase activates testosterone to

dihydrotestosterone, which combines with a cytoplasmic receptor. The complex enters the nucleus and induces changes in protein synthesis that promote glandular tissue growth of the prostate. Thus 5 α -reductase inhibitors (e.g., finasteride and dutasteride) directly interfere with one of the major etiologic factors of BPH.

- The prostate is composed of two types of tissue: (a) glandular or epithelial tissue, which produces prostatic secretions, including prostate-specific antigen (PSA), and (b) muscle or stromal tissue, which can contract around the urethra when stimulated. Whereas androgens stimulate glandular tissue growth, androgens have no direct effect on stromal tissue. It has been postulated that stromal tissue growth may be stimulated by estrogen. Because testosterone is converted to estrogen in peripheral tissues in males, testosterone may be associated indirectly with stromal hyperplasia. Stromal tissue is innervated by α_{1A} -receptors. When stimulated, prostatic stroma contracts around the urethra, narrowing the urethra and causing obstructive voiding symptoms.

PATHOPHYSIOLOGY

- **1** Lower urinary tract symptoms (LUTS) and signs of BPH are due to static, dynamic, and/or detrusor factors. The static factor refers to anatomic obstruction of the bladder neck caused by an enlarged prostate gland. As the gland grows around the urethra, the prostate occludes the urethral lumen. The dynamic factor refers to excessive stimulation of α_{1A} -adrenergic receptors in the smooth muscle of the prostate and urethra, which results in smooth muscle contraction. This reduces the caliber of the urethral lumen. The detrusor factor refers to bladder detrusor muscle instability, in which bladder muscle fibers have decompensated as a result of excessive hypertrophy in response to prolonged bladder outlet obstruction. Patients with obstruction of the bladder neck or a narrowed urethral lumen due to static or dynamic factors, respectively, will develop obstructive voiding symptoms, such as decreased force of the urinary stream, urinary dribbling, an inability to completely empty the bladder. Patients with detrusor muscle instability will develop irritative voiding symptoms, such as urinary urgency and frequency.^{1,3} Detrusor muscle fibers are embedded with α_{1D} -receptors. Therefore, it has been proposed that some α_{1D} -adrenergic antagonists may be particularly useful for controlling these symptoms.⁴

In an enlarged gland, the epithelial/stromal tissue ratio is 1:5.⁵ Androgens stimulate epithelial, but not stromal tissue hyperplasia. Hence androgen antagonism does not induce a complete reduction in prostate size to normal. This explains one of the limitations of the clinical effect of 5 α -reductase inhibitors.

Stromal tissue is the primary locus of α_1 -adrenergic receptors in the prostate. An estimated 98% of the α -adrenergic receptors in the prostate are found in prostatic stromal tissue. Of the α_1 -receptors found in the prostate, 70% of them are of the α_{1A} -subtype.⁴ This explains why α -adrenergic antagonists are effective for managing symptoms of BPH.

- Symptoms of BPH are classified as obstructive or irritative. Obstructive symptoms result from failure of the urinary bladder to empty urine when the bladder is full. The patient will complain of reduced force of the urinary stream, urinary hesitation, dribbling, and straining to empty the bladder. Irritative symptoms result from the failure of the urinary bladder to store urine until the bladder is full. With long-standing bladder outlet obstruction, detrusor muscle fibers undergo hypertrophy so that the bladder can generate higher pressure to overcome the bladder outlet obstruction and empty urine from the bladder. Once maximal bladder muscle hypertrophy occurs, the muscle decompensates. The detrusor becomes irritable, contracting abnormally in response to small amounts of urine in the bladder. As a result, the patient complains of urinary frequency and urgency.³

The natural history of untreated BPH is unclear in patients with mild symptoms. It is estimated that up to 38% of untreated men with mild symptoms will have symptom improvement over a 2.5- to 5-year period.⁶ It may be that such patients attribute their symptoms to aging, grow tolerant of their symptoms, or adopt behavioral changes in their lifestyle that minimize their voiding symptoms. On the other hand, a significant portion of patients with mild symptoms will likely experience disease progression. Patients with moderate to severe symptoms can experience a decreased quality of life as daily activities are adjusted because of urinary incontinence. Also, such patients may develop complications of BPH, which include acute refractory urinary retention, renal failure, urinary tract infection, urinary incontinence, bladder stones, large bladder diverticuli, and recurrent gross hematuria. Predictors of disease progression include an enlarged prostate of at least 30 g (1.05 oz) or PSA of at least 1.5 ng/mL (1.5 mcg/L).⁷⁻⁹

TREATMENT

Desired Outcomes^{9,10}

- **2** Reducing or eliminating obstructive and irritative voiding symptoms. Drug treatment with an α -adrenergic antagonist or 5 α -reductase inhibitor is expected to reduce the American Urological Association (AUA) Symptom Score by 30% to 50% (or a minimum decrease of 3 or more points), improve peak and mean urinary flow rate by 1 to 3 mL/s, and decrease PVR to normal (less than 50 mL total) when compared with pretreatment baseline values. The AUA Symptom Score may not correlate with response to therapy.
- Slowing disease progression. When compared with baseline, symptoms and serum blood urea nitrogen (BUN) and creatinine should improve, stabilize, or decrease to the normal range with treatment.
- Preventing disease complications and reducing the need for surgical intervention.
- Avoiding or minimizing adverse treatment effects.
- Providing economical therapy.
- Maintaining or improving quality of life.

Clinical Presentation and Diagnosis of BPH

General

Patients may or may not be in acute distress. In early stages of disease, the patient may complain of obstructive voiding symptoms. If untreated, in late stages of disease the patient may complain of irritative voiding symptoms or acute urinary retention, which is painful due to maximal distention of the urinary bladder. Also, the patient may be symptomatic of disease complications, including urosepsis, pyelonephritis, cystitis, or overflow urinary incontinence.

Symptoms

Patients may complain of obstructive voiding symptoms (e.g., urinary hesitancy, decreased force of urinary stream, straining to void, incomplete bladder emptying, dribbling, and intermittency) and/or irritative voiding symptoms (e.g., urinary frequency, nocturia, dysuria, urgency, and urinary incontinence). Severity of symptoms should be assessed by the patient using a standardized instrument (e.g., the American Urological Association [AUA] Symptom Scoring Index; [Table 52-1](#)). However, it is important to recognize that a patient's perception of the bothersomeness of his voiding symptoms may not match with the AUA Symptom Score. In this case, after thorough evaluation of the signs and complications of BPH disease, if present, the physician and patient should discuss the bothersomeness of the patient's symptoms and decide together on the most appropriate course of treatment for the patient.^{1,10} Lower urinary tract symptoms (LUTS) is a term that refers to the collection of obstructive and irritative voiding symptoms characteristic of, but not specific for, BPH. That is, other urologic diseases (e.g., urinary tract infection, prostate cancer, prostatitis, or neurogenic bladder) can also cause LUTS.

Signs

- Enlarged prostate on digital rectal exam (DRE); check for prostate nodules or induration, which would suggest prostate cancer instead of BPH as the cause of the patient's voiding symptoms
- Distended urinary bladder
- Rule out meatal stenosis or urethral stricture, which could cause voiding symptoms similar to LUTS
- Check anal sphincter tone as an indirect assessment of peripheral innervation to the detrusor muscle of the bladder

Complications of Untreated BPH

Upper and lower urinary tract infection, urosepsis, urinary incontinence refractory urinary retention, chronic renal failure, bladder diverticula, bladder stones, or recurrent gross hematuria.

Medical History

- Check the patient's general health, including previous surgery, presence of diabetes mellitus, or medications that

may cause or worsen voiding symptoms.

- Have the patient provide a diary of his voiding pattern for the past week: date and time of each voiding, volume voided, and whether or not the patient had urinary leakage during the day.

Laboratory Tests

- Serum PSA: The combination of PSA and DRE of the prostate is used to screen for prostate cancer, which could also cause an enlarged prostate. Also, PSA is a surrogate marker for an enlarged prostate due to BPH. Using a PSA greater than 1.5 ng/mL (1.5 mcg/L) suggests that a patient has a prostate volume greater than 30 mm³ (30 g or 1.05 oz).¹¹
- Urinalysis to rule out infection as a cause of the patient's voiding symptoms; also check urinalysis for microscopic hematuria, which typically accompanies BPH.
- Plasma blood urea nitrogen (BUN) and serum creatinine may be increased as a result of long-standing bladder outlet obstruction. These tests are not routinely performed but rather are reserved for those patients in whom renal dysfunction is suspected.

Other Diagnostic Tests ([Table 52-2](#))

- Decreased peak and mean urinary flow rate (less than 10 to 15 mL/s) on uroflowmetry; decreased urinary flow rate is not specific for BPH; it can also be due to other urologic disorders (e.g., [urethral stricture](#), [meatal stenosis](#), or [bladder hypotonicity](#))
- Increased postvoid residual urine volume (PVR) (more than 50 mL)
- DRE to check for an enlarged prostate (more than 15 to 20 g [0.5 to 0.7 oz])
- Transurethral cystoscopy reveals an enlarged prostate, which decreases urethral lumen caliber; information from this procedure helps the surgeon decide on the best surgical approach.
- Transrectal ultrasound of the prostate; a transrectal probe is inserted to evaluate prostate size and best surgical approach.
- Transrectal prostate needle biopsy to be done if the patient has areas of nodularity or induration on DRE; tissue biopsy can document the presence of prostate cancer, which can also cause enlargement of the prostate.
- IV pyelogram (IVP) will show retention of radiocontrast in the bladder if the patient has bladder outlet obstruction due to an enlarged prostate; this is only indicated in patients with recurrent hematuria, recurrent urinary tract infection, renal insufficiency, and urolithiasis.
- Filling cystometry provides information on bladder capacity, detrusor contractility, and the presence of uninhibited bladder contractions, which could also cause LUTS.

General Approach to Treatment

Until recently, the principal approach to treatment focused on reducing BPH symptoms (Fig. 52-1, Tables 52-1, 52-2, and 52-3). However, treatment should also slow disease progression and decrease complications of BPH.⁹

3 For patients with mild symptoms that the patient does not consider to be bothersome, watchful waiting is a reasonable approach to treatment. The patient is instructed to schedule

return visits to the clinician every 3 to 6 months. At each visit, the patient's symptoms are reassessed using the AUA Symptom Scoring Index, and results are compared with baseline (Table 52-1). In addition, the patient is educated about avoiding factors that worsen obstructive and irritative voiding symptoms (Table 52-4). The digital rectal exam (DRE) is repeated annually. If the patient's symptoms are unchanged, then watchful waiting is continued. If the patient's symptoms worsen, then specific treatment is initiated.¹⁰

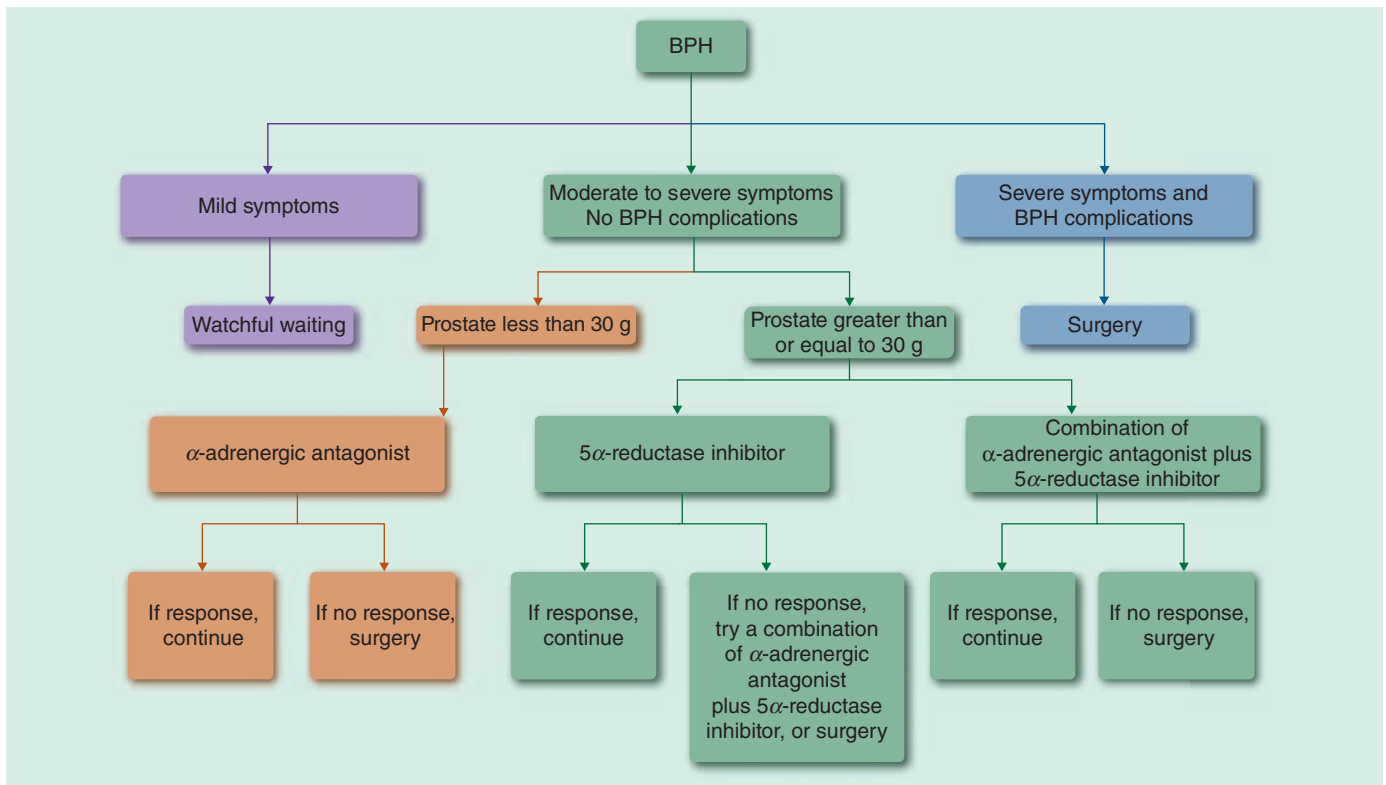

FIGURE 52-1. Algorithm for selection of treatment for BPH based on symptom severity and presence of disease complications.

Table 52-1

Questions to Determine the AUA Symptom Score

Directions for the patient: The patient should be asked to respond to each question based on the absence or presence of symptoms over the past month. For each question, the patient can respond using a 1–5 scale, where 0 = not at all or none; 1 = less than 1 time in 5; 2 = less than half of the time; 3 = about half of the time; 4 = more than half of the time; and 5 = almost always

Directions for the clinician: After the patient completes the questionnaire, the scores for individual items should be tallied for a final score. Scores of 0–7 = mild symptoms; scores of 8–19 = moderate symptoms; scores more than 20 = severe symptoms

Questions to Assess Obstructive Voiding Symptoms

1. How often have you had a sensation of not emptying your bladder completely after you finished urinating?
2. How often have you found you stopped and started again several times when you urinated?
3. How often have you had a weak urinary stream?
4. How often have you had to push or strain to begin urinating?

Questions to Assess Irritative Voiding Symptoms

5. How often have you found it difficult to postpone urination?
6. How often have you had to urinate again less than 2 hours after you finished urinating?
7. How many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?

From AUA Practice Guidelines Committee. AUA guideline on the management of benign prostatic hyperplasia (2010). www.auanet.org/content/guidelines-and-quality-care/clinical-guidelines.cfm?sub=bph (last accessed 8/31/2012).

Table 52-2

Objective Tests Used to Assess the Severity and Complications of BPH

Test	How the Test Is Performed	Normal Test Result	Test Result in Patients With BPH
DRE of the prostate	Prostate is palpated through the rectal mucosa; the physician inserts an index finger into the patient's rectum	Prostate is soft, symmetric, mobile; size is 15–20 g (0.5–0.7 oz)	Prostate is enlarged, more than 20 g (0.5 oz); no areas of induration or nodularity
Peak and mean urinary flow rate	Patient drinks water until bladder is full; patient empties bladder; volume of urine output and time to empty the bladder are measured; the flow rate (mL/s) is calculated	Peak and mean urinary flow rate are at least 10 mL/s	Peak and mean urinary flow rates are less than 10 mL/s
PVR	Measurement of urine left in the bladder after the patient has tried to empty out his bladder; assessed by urethral catheterization or ultrasonography	PVR should be 0 mL	PVR greater than 50 mL is a significant amount of retained urine; this is associated with recurrent urinary tract infection
Urinalysis	Midstream urine is analyzed microscopically for white blood cells and bacteria	Urine should have no white cells or bacteria in it	Urine with white blood cells and bacteria is suggestive of inflammation and infection; if positive, urine is sent for bacteriologic culture
Prostate needle biopsy	Transrectally, a biopsy needle is inserted into the prostate; tissue core is sent to a pathologist for analysis	A normal prostate should have no evidence of BPH or prostate cancer	The biopsy is consistent with BPH
PSA	Blood test for this chemical, which is secreted by the prostate	Less than 4 ng/mL (4 mcg/L)	A PSA greater than 1.5 ng/mL (1.5 mcg/L) is a surrogate marker for an enlarged prostate greater than 30 g (1.05 oz)

DRE, digital rectal exam; PVR, postvoid residual urine volume; PSA, prostate-specific antigen.

Table 52-3

Staging the Severity of BPH Based on AUA Symptom Score and Example Signs of Disease

	AUA Symptom Score	Signs of Disease
Mild	Less than or equal to 7	Enlarged prostate on DRE, peak urinary flow rate less than or equal to 10 mL/s
Moderate	8–19	All of the above, PVR greater than 50 mL, irritative symptoms
Severe	Greater than or equal to 20	All of the above plus one or more complications of BPH

AUA, American Urological Association; BPH, benign prostatic hyperplasia; DRE, digital rectal exam; PVR, postvoid residual urine volume.

The AUA Symptom Score focuses on seven items (incomplete emptying, frequency, intermittency, urgency, weak stream, straining, and nocturia) and asks that the patient quantify the severity of each complaint on a scale of 0 to 5. Thus the score can range from 0 to 35.

Table 52-4

Drugs That Can Cause Irritative or Obstructive Voiding Symptoms

Pharmacologic Class	Example Drugs	Mechanism of Effect
Androgens	Testosterone	Stimulate prostate enlargement
α -Adrenergic agonists	Phenylephrine, pseudoephedrine	Stimulate contraction of prostatic and bladder neck smooth muscle
Anticholinergic agents	Antihistamines, phenothiazines, tricyclic antidepressants, antiparkinsonian agents	Block bladder detrusor muscle contraction, thereby impairing bladder emptying
Diuretics	Thiazides diuretics, loop diuretics	Produce polyuria

Table 52-5

Comparison of α -Adrenergic Antagonists and 5 α -Reductase Inhibitors for Treatment of BPH

Characteristic	α -Adrenergic Antagonists	5 α -Reductase Inhibitors
Relaxes prostatic smooth muscle	Yes	No
Reduces size of enlarged prostate	No	Yes
Useful in patients with enlarged prostates	No (works independent of the size of the prostate)	Yes
Efficacy in relieving voiding symptoms and improving flow rate	++	+
Reduces the frequency of BPH-related complications	No	Yes
Reduces the frequency of BPH-related surgery	No	Yes
Frequency of daily dosing	Once or twice daily, depending on the agent and the dosage formulation	Once daily
Requirement for up-titration of dose	Yes (for terazosin and doxazosin immediate-release); no (for alfuzosin or silodosin; possibly for doxazosin extended-release and tamsulosin)	No
Peak onset of action	Days–6 weeks, depending on need for dose titration	6 months
Decreases PSA	No	Yes
Cardiovascular adverse effects	Yes	No
Drug-induced sexual dysfunction	Ejaculation disorders	Decreased libido, erectile dysfunction, ejaculation disorders

PSA, prostate-specific antigen.

4 For patients with moderate to severe symptoms, the patient is usually offered drug treatment first. α -Adrenergic antagonists are preferred over 5 α -reductase inhibitors because the former have a faster onset of action (days to a few weeks) and improve symptoms independent of prostate size. 5 α -reductase inhibitors have a delayed onset of action (i.e., peak effect may be delayed for up to 6 months) and are seldom effective in patients with smaller size prostate glands (less than 30 g or 1.05 oz). Therefore, 5 α -reductase inhibitors should be reserved for patients with an enlarged prostate gland, of at least 30 g, and moderate to severe symptoms. Drug treatment must be continued as long as the patient responds (Table 52-5).¹⁰

5 For patients with complications of BPH disease (e.g., recurrent urinary tract infection, urosepsis, urinary incontinence, refractory urinary retention, chronic renal failure, large bladder diverticuli, recurrent severe gross hematuria, or bladder calculi secondary to prolonged urinary retention), surgery is indicated. Although it is potentially curative, surgery can result in significant morbidity, including erectile dysfunction, retrograde ejaculation, urinary incontinence, bleeding, or urinary tract infection.¹² The gold standard is a prostatectomy, which can be performed transurethral or as an open surgical procedure, which can be performed suprapubically or retropubically. To avoid complications of prostatectomy, minimally invasive surgical procedures, such as transurethral incision of the prostate, transurethral needle ablation, or transurethral laser ablation, are options.^{10,12,13} However, minimally invasive surgical procedures are associ-

ated with a higher reoperation rate than a prostatectomy. Drug treatment is used in patients with severe disease when the patient refuses surgery or when the patient is not a surgical candidate because of concomitant diseases.

6 In the Multiple Treatment of Prostate Symptoms Study (MTOPS), selected patients with moderate to severe symptoms benefited from a combination of α -adrenergic antagonist plus 5 α -reductase inhibitor drug therapy.¹⁴ Specifically, the use of doxazosin plus finasteride was more effective than doxazosin alone or finasteride alone in relieving symptoms, reducing the need for prostatectomy, and decreasing the incidence of BPH complications in patients at highest risk of developing disease complications (i.e., those with prostate size of at least 40 g [1.4 oz]). In the Combination of Avodart and Tamsulosin (CombAT) Study, which compared tamsulosin, dutasteride, and the combination of tamsulosin and dutasteride in patients with large prostates, mean volume of

Patient Encounter 1

AB is a 65-year-old man with an AUA Symptom Score of 7, urinary hesitancy, a slow urinary stream, urinary frequency, and nocturia. He wakes up three times every night to void. A DRE reveals a prostate of 40 g (1.4 oz). His PSA is 4 ng/mL (4 mcg/L). A urinary flow rate is 7 mL/s.

What stage of BPH does this patient have?

55 g (1.9 oz), and elevated PSA (mean of 4 ng/mL [4 mcg/L]), similar results were documented at 1, 2, and 4 years of follow-up.¹⁵ Combination therapy is more expensive and also produces more adverse effects than monotherapy. Therefore, the clinician should discuss the advantages and disadvantages of combination therapy with a patient before deciding on a final treatment regimen.¹⁶

Nonpharmacologic Therapy

To reduce nocturia, patients should be instructed to stop drinking fluids several hours before going to bed and then void before going to sleep. During the day, patients should avoid excessive caffeine and alcohol intake, as these may cause urinary frequency. Patients should avoid taking nonprescription medications that can worsen obstructive voiding symptoms (e.g., antihistamines or decongestants) (Table 52–4). In addition, toilet mapping (knowing the location of toilets on the way to and from various destinations) may help reassure the patient that he can still continue with many of his routine daily activities. Patients are also advised to lose weight, if overweight. Because testosterone is converted to estrogen in adipose tissue, an alteration in the testosterone:estrogen ratio occurs in overweight men, similar to that which occurs in elderly males, which may contribute to the development of BPH.¹⁷

Although a variety of herbal agents are used for symptomatic management, including pygeum (African plum), secale cereale (rye pollen), and hypoxis rooperi (South African star grass), objective evidence of efficacy is lacking.^{18,19} Also, in a randomized, double-blind, and placebo-controlled clinical trial, saw palmetto was no different than placebo in improving symptoms or increasing peak urinary flow rate.²⁰

Pharmacologic Therapy

► *α-Adrenergic Antagonist Monotherapy*²¹

6 *α-Adrenergic antagonists reduce the dynamic factor causing BPH symptoms. These drugs competitively antagonize α-adrenergic receptors, thereby causing relaxation of the bladder neck, prostatic urethra, and prostate smooth muscle.*^{10,21} A secondary mechanism of action may be that α-adrenergic antagonists induce prostatic apoptosis,²² which suggests that these agents may cause some shrinkage of an enlarged prostate. However, the clinical importance of this remains to be elucidated.

All α-adrenergic antagonists are considered equally effective in relieving symptoms.^{10,21} In various clinical trials, 30% to 80% of patients experience improvement in AUA Symptom Score by 30% to 45%, and 20% to 40% of patients experience urinary flow rate increases of 2 to 3 mL/s. The onset of action is days to weeks, depending on the need for titration of the dose from a subtherapeutic starting dose to a therapeutic maintenance dose. An adequate clinical trial is considered to be at least 1 to 2 weeks of continuous treatment at a full maintenance dose with any of these agents.¹⁰ Durable

responses have been demonstrated for up to 5 years of continuous use of terazosin,²³ 10 years with doxazosin,²⁴ and 6 years with tamsulosin.²⁵ However, some patients will develop disease progression despite treatment. α-Adrenergic antagonists are hepatically metabolized. Therefore, in patients with significant hepatic dysfunction, these drugs should be used in the lowest possible dose. With the exception of silodosin, these drugs do not require dosage modification in patients with renal dysfunction.

These agents can be differentiated by their adverse effect profile. Dose-limiting adverse effects include hypotension and syncope, which are more common with immediate-release terazosin and doxazosin, less frequent with extended-release doxazosin and alfuzosin, and least frequent with pharmacologically uroselective α_{1A}-adrenergic antagonists.^{26,27} Ejaculation disorders have been reported most often with tamsulosin 0.8 mg orally once a day. Combined use with antihypertensives, diuretics, or phosphodiesterase inhibitors can lead to additive blood pressure-lowering effects; however, this appears to be less of a problem with tamsulosin and silodosin.^{23,26,27}

• α-Adrenergic antagonists are recommended as first-line treatment for moderate to severe voiding symptoms of BPH. The agents in this pharmacologic class can be classified by several characteristics (Table 52–6):

- **Generation of α-adrenergic antagonist.** First-generation agents (e.g., phenoxybenzamine) block presynaptic and postsynaptic α-adrenergic receptors. Whereas blockade of postsynaptic α-adrenergic receptors is desirable for BPH management, blockade of presynaptic α-adrenergic receptors is undesirable, as it results in release of catecholamines and tachycardia. Thus first-generation α-adrenergic antagonists are not used for treatment of BPH.²⁸ Second-generation α-adrenergic antagonists (e.g., terazosin, doxazosin, and alfuzosin) are pharmacologically not selective in blocking the subtypes of α-adrenergic receptors, which include α_{1A}-receptors in the genitourinary tract, α_{1D}-receptors in the coronary arteries and bladder, and α_{1B}-receptors in the peripheral vasculature. Hypotensive adverse effects are dose-related and common. An extended-release formulation of doxazosin and a modified-release formulation of alfuzosin produce lower peak serum concentrations and less hypotension than immediate release formulations. Third-generation α-adrenergic antagonists (e.g., tamsulosin, silodosin) selectively block postsynaptic α_{1A}-receptors, which predominate in the prostate. As a result, hypotensive adverse effects are less common with third-generation agents than with second-generation agents.
- **7 Uroselectivity.** Pharmacologic uroselectivity refers to preferential inhibition of α_{1A}-receptors, which predominate in the prostatic stroma, prostatic urethra, and bladder neck, and α_{1D}-receptors, which predominate in the bladder detrusor muscle.²¹ Pharmacologically uroselective α_{1A}-adrenergic antagonists have the potential to produce less hypotension, as they have a lower

Table 52-6

Comparison of Pharmacologic Properties of α -Adrenergic Antagonists

	Terazosin	Doxazosin	Alfuzosin	Tamsulosin	Silodosin
Brand name	Hytrin	Cardura	Uroxatral	Flomax	Rapaflo
Generation	Second	Second	Second	Third	Third
Uroselective	No	No	Functionally and clinically uroselective	Pharmacologically and clinically uroselective	Pharmacologically and clinically uroselective
Need for up-titration	Yes	Yes (with immediate-release); possibly (with extended-release)	No	Minimal	No
Daily oral dose (mg)	5–20	2–8, immediate-release; 4–8, extended-release	10	0.4–0.8; (0.8 mg/day dose has not consistently produced clinical improvement over 0.4 mg/day)	8
Recommended dose reduction in patients with renal dysfunction	None needed	None needed	Manufacturer recommends caution in patients with severe renal insufficiency. No specific dosing recommendations provided.	If creatinine clearance greater than 10 mL/min (0.17 mL/s), none needed. Tamsulosin has not been studied in patients with creatinine clearance less than 10 mL/min (0.17 mL/s)	If creatinine clearance 30–50 mL/min (0.50–0.83 mL/s), use 4 mg/day. Contraindicated in patients with creatinine clearance less than 30 mL/min (0.50 mL/s)
Recommended dose reduction in patients with hepatic dysfunction	Manufacturer provides no specific recommendation. Terazosin should be used cautiously as it undergoes extensive hepatic metabolism.	Manufacturer provides no specific recommendation. Doxazosin should be used cautiously as it undergoes extensive hepatic metabolism.	Contraindicated in patients with moderate/severe hepatic impairment. Alfuzosin should be used cautiously in patients with mild hepatic impairment.	Patients with mild/moderate hepatic impairment require no dosage adjustment. Tamsulosin has not been studied in patients with severe hepatic impairment.	Patients with mild/moderate hepatic impairment require no dosage adjustment. Contraindicated in patients with severe hepatic impairment.
Best time to take doses	At bedtime	Immediate-release: anytime during the day; however, it is typically given at bedtime. Extended-release: anytime during the day	After meals for best oral absorption	On an empty stomach for best oral absorption; if taken 30 minutes after a meal, as recommended by the manufacturer, extent of absorption is reduced, thereby further reducing the potential for hypotensive adverse effects.	Take with a meal, which decreases extent of absorption. Theoretically, this would help decrease hypotensive adverse effects.
Half-life (hours)	12	22	5	10	13
Formulation	Immediate-release	Immediate-release and extended-release	Extended-release	Modified-release	Immediate-release
Cardiovascular adverse effects	++	++	+	0 to +	0 to +
Ejaculation disorders	+	+	+	++	++
Rhinitis	+	+	+	+	+
Malaise	+	+	+	+	+

+, minimal; ++ moderate

propensity to antagonize α_{1B} -adrenergic receptors in the peripheral vasculature. Tamsulosin and silodosin are the only commercially available α -adrenergic antagonists with pharmacologic uroselectivity. In contrast, despite the potential of inhibiting α -adrenergic receptors in both the prostate and peripheral vasculature, functionally uroselective α -adrenergic antagonists in usually prescribed doses produce effective relaxation of prostatic smooth muscle with minimal vascular vasodilation. *Thus blood pressure-lowering effects are mild or absent. The only functionally uroselective α -adrenergic antagonist is alfuzosin extended-release tablets. The mechanism of functional uroselectivity is unclear. It may be related to the drug formulation, which produces a higher concentration in target tissues than in nontarget tissues.*²⁸

Both pharmacologically and functionally uroselective agents appear to be clinically uroselective, in that they improve BPH symptoms without causing cardiovascular adverse effects in humans.²¹

Pharmacologic and functional uroselectivity are dose-related phenomena. Large daily doses of tamsulosin, silodosin, or alfuzosin may cause loss of uroselectivity, with resultant hypotension and dizziness in some patients.

- **Need for up-titration of daily dose.** Up-titration is required for immediate-release terazosin and doxazosin. It is minimally required for extended-release doxazosin and tamsulosin. It is not required for extended-release alfuzosin or silodosin. The need for up-titration with a particular α -adrenergic antagonist delays its peak onset of action and the time when the patient can experience maximal clinical benefit.
- **Plasma half-life.** α -Adrenergic receptors with short plasma half-lives (e.g., prazosin) require multiple doses during the day. This is challenging for most patients, and thus prazosin is not recommended for BPH.¹⁰
- **Dosage formulation.** Immediate-release formulations of terazosin and doxazosin are quickly absorbed and produce high peak plasma levels. Modified- or extended-release formulations of doxazosin, alfuzosin, and tamsulosin produce lower peak levels, but more sustained therapeutic plasma levels, than immediate-release formulations and have less potential for producing hypotensive episodes. This allows for initiation of treatment with a therapeutic dose, a shorter time to peak onset of clinical effects, and once daily dosing.^{29,30}
- **Adverse effects.** Hypotensive adverse effects of α -adrenergic antagonists can range from asymptomatic blood pressure reductions to dizziness and syncope. This adverse effect is most commonly associated with immediate-release terazosin and doxazosin; is less commonly associated with extended-release alfuzosin and extended-release doxazosin, and silodosin; and least commonly associated with tamsulosin.^{26,29} To minimize first-dose syncope from terazosin and

doxazosin immediate-release, a slow up-titration from a subtherapeutic dose of 1 mg/day to a therapeutic dose is essential. The first dose should be given at bedtime so that the patient can sleep through the peak serum concentration of the drug when the adverse effect is most likely to occur. A 3- to 7-day interval between each dosage increase should be allowed, and the patient should be maintained on the lowest effective dose of an α -adrenergic antagonist. If the patient is noncompliant with his regimen of terazosin or doxazosin, and he skips or interrupts treatment, the α -adrenergic antagonist should be restarted using the usual starting dose and then retitrated up. He should not be instructed to simply double up on missed doses or resume treatment with his currently prescribed daily dose, as this can lead to significant hypotension.

Ejaculation disorders, including delayed, an- and retrograde ejaculation, occur with all adrenergic antagonists. Although largely thought to be due to pharmacologic blockade of peripheral α -adrenergic receptors at the bladder neck (i.e., the bladder neck is unable to close during ejaculation in the presence of α -adrenergic blockade), a central nervous system mechanism of action cannot be discounted.³¹ The incidence appears to be dose-related and highest with tamsulosin 0.8 mg daily, occurring in up to 26% of treated patients. Ejaculation disorders generally do not necessitate discontinuation of treatment. Although they may decrease the patient's satisfaction with the quality of sexual intercourse, ejaculation disorders are not harmful to the patient.

Rhinitis and malaise occur with α -adrenergic antagonists and are an extension of the pharmacologic blockade of α -adrenergic receptors in the vasculature of the nasal mucosa and in the central nervous system, respectively. Tolerance often develops to these adverse effects and they rarely require discontinuation of treatment. Avoid use of topical or oral decongestants, as these may exacerbate obstructive voiding symptoms. Cautious use of antihistamines with anticholinergic adverse effects is also recommended in patients with severe BPH and large residual urine volumes, as these drugs may cause acute urinary retention in patients with an obstructed bladder neck.

Floppy iris or small pupil syndrome has been reported with α -adrenergic antagonists, most often with tamsulosin. In response to tamsulosin, the iris dilator muscle relaxes and the pupil constricts. As a result, when the α -adrenergic antagonist-treated patient undergoes cataract surgery, the iris can become flaccid, billow out, or floppy. This plus the papillary constriction interfere with the surgical procedure and increase the risk of intraoperative and postoperative complications. A patient who plans to undergo cataract surgery is advised to inform his ophthalmologist that he is taking an α -adrenergic antagonist. Although the drug will not need to be held or discontinued, the ophthalmologist can plan to use certain surgical techniques, for example, iris hooks or iris expansion rings, to deal with the drug's effect on the iris dilator muscle.^{32,33}

Patient Encounter 2

DD has essential hypertension and has been taking valsartan 160 mg and hydrochlorothiazide 12.5 mg orally every day for the past 2 years. The patient tolerates this regimen well, and his blood pressure is now 140/80 mm Hg. However, DD was recently diagnosed with moderately severe BPH, and he began taking doxazosin immediate-release tablets. Over the course of several weeks, he was slowly titrated up from an initial dose of 2 mg orally every day up to 8 mg every day. Although the patient has experienced significant improvement in his obstructive voiding symptoms, he also complains of dizziness, lightheadedness, and periodically feels like fainting.

How should this patient be managed?

Alfuzosin has been linked to two cases of hepatitis.^{34,35} The cause-effect relationship remains to be elucidated.

- **Potential for drug interactions.** Hypotensive adverse effects of terazosin and doxazosin can be additive with those of diuretics, antihypertensives, and phosphodiesterase inhibitors (e.g., sildenafil). In patients at greatest risk for hypotension, or in those patients who tolerate hypotension poorly, including those with poorly controlled coronary artery disease or severe orthostatic hypotension, tamsulosin 0.4 mg appears to be the safest choice.^{36,37} In patients who cannot tolerate tamsulosin, a 5 α -reductase inhibitor or prostatectomy should be considered. When initiating sildenafil, tadalafil, or vardenafil, patients who are taking α -adrenergic antagonists should be stabilized first on a fixed dose of the α -adrenergic antagonist, and then patients should be started on the lowest effective dose of phosphodiesterase inhibitor to minimize the likelihood of hypotensive effects.

7 Among the α -adrenergic antagonists, tamsulosin and silodosin are unique in that they are third-generation α -adrenergic antagonists. They are pharmacologically uroselective and exert greater antagonism of α_{1A} - and α_{1D} -receptors than α_{1B} -receptors. Tamsulosin exerts comparatively low antagonism of peripheral vascular α_{1B} -receptors. Therefore, tamsulosin can be started with a therapeutic dose, which achieves peak effects sooner than terazosin and doxazosin immediate-release, which must be up-titrated. Tamsulosin appears to have the lowest potential to cause hypotension.^{26,36} In various clinical trials, tamsulosin had minimal hypotensive adverse effects and was well tolerated in the elderly, as well as in patients taking diuretics, antihypertensives, or phosphodiesterase inhibitors. Also, the commercially available product is a modified-release dosage formulation, which is dosed at 0.4 mg orally once a day. With chronic use, tamsulosin can be taken at any time of the day and at the patient's

convenience. Although the package insert states that the dose can be increased to 0.8 mg daily, no consistent improvement in clinical efficacy has been observed in patients taking the higher dose. At this time, no difference in clinical efficacy or adverse effects between tamsulosin and silodosin has been documented. In addition, the amount of clinical data documenting the efficacy of silodosin is less than that with tamsulosin. For these reasons, silodosin is not considered to offer advantages over tamsulosin.²⁷

In patients with BPH and hypertension, it is not recommended to use an α -adrenergic antagonist alone to treat both disorders. In the ALLHAT study,³⁸ where doxazosin was compared with other agents for treatment of essential hypertension, doxazosin was associated with a higher incidence of congestive heart failure. Therefore, in patients with hypertension and moderate to severe BPH, it is recommended that an appropriate antihypertensive be added to an α -adrenergic antagonist.²⁶

► 5 α -Reductase Inhibitor Monotherapy

8 5 α -Reductase inhibitors reduce the static factor, which results in shrinkage of an enlarged prostate by approximately 20% to 25%. They do so by inhibiting 5 α -reductase, which is responsible for intraprostatic conversion of testosterone to dihydrotestosterone, the active androgen that stimulates prostate tissue growth. In the prostate, there are two subtypes of 5 α -reductase; the majority is the type II isoenzyme and the minority is the type I isoenzyme.^{10,21} The onset of action is slow, with peak shrinkage of the prostate taking up to 6 months.¹⁰ Unlike α -adrenergic antagonists, 5 α -reductase inhibitors are used to prevent BPH-related complications and disease progression. Finasteride has been shown to reduce the incidence of acute urinary retention and need for prostate surgery in patients with significantly enlarged prostate glands (greater than 40 g [1.4 oz]),^{14,15} and those with serum levels of PSA of at least 1.5 ng/mL (1.5 mcg/L).¹¹ Because 5 α -reductase inhibitors do not produce cardiovascular adverse effects, they are preferred for men with moderate to severe BPH who are at risk of developing complications of BPH (i.e., the patient has an enlarged prostate of at least 30 g [1.05 oz]), and have a PSA of greater than 1.5 ng/mL (1.5 mcg/L).^{8,11,39}

With regard to their use for the symptomatic treatment of BPH, 5 α -reductase inhibitors relieve BPH symptoms in 30% to 70% of patients and increase the urinary flow rate by 1 to 2 mL/s, which is less improvement than that seen with α -adrenergic antagonists.^{10,14} A minimum of 6 months is required to evaluate the effectiveness of treatment. This is a disadvantage in patients with moderate to severe symptoms, as it will take that long to determine whether the drug is or is not effective. Durable responses have been demonstrated in responding patients treated up to 6 years with finasteride and 4 years with dutasteride.^{40,41} These agents are hepatically metabolized. No specific recommendations for dosage modification are currently available in patients with significant hepatic dysfunction; however, due to drug specificity for its enzyme target, it is unlikely that any dosage adjustment

Table 52-7

Comparison of Pharmacologic Properties of 5 α -Reductase Inhibitors

	Finasteride	Dutasteride
Brand name	Proscar	Avodart
Subtype inhibition of the 5 α -reductase enzyme	Type II	Types I and II
Percentage of inhibition of serum dihydrotestosterone level	70–76	90–95
Percentage of patients with reduction in serum dihydrotestosterone	49	Greater than 85
Time to peak onset of reduction in serum dihydrotestosterone level	6 months	1 month
Percentage of inhibition of intraprostatic dihydrotestosterone	85–90	Greater than 95
Half-life	6.2 hours	3–5 hours
Daily dosage (mg)	5	0.5
Recommended dose reduction in patients with renal dysfunction	None needed	None needed
Recommended dose reduction in patients with hepatic dysfunction	Manufacturer provides no specific recommendation. Finasteride should be used cautiously as it undergoes extensive hepatic metabolism	Manufacturer provides no specific recommendation. Dutasteride should be used cautiously as it undergoes extensive hepatic metabolism

From Keam SJ, Scott LJ. Dutasteride: a review of its use in the management of prostate disorders. *Drugs* 2008;68:463–485.

will be required. No dosage adjustment is needed in patients with renal impairment. Adverse effects include decreased libido, erectile dysfunction, and ejaculation disorders, which generally decrease in frequency with continued use, and gynecomastia and breast tenderness. Serum testosterone levels increase by 10% to 20% in treated patients; however, the clinical significance of this is not clear at this time.¹⁰ Drug interactions are uncommon. These drugs do produce a mean 50% decrease in serum levels of PSA. Therefore, to preserve the usefulness of this laboratory test as a diagnostic and monitoring tool, it is recommended that prescribers obtain a baseline PSA prior to the start of treatment and repeat it at least annually during treatment. A significantly elevated PSA in treated patients suggests that the patient is not compliant with his prescribed 5 α -reductase inhibitor regimen or is an indicator for further diagnostic workup for prostate cancer. Exposure to 5 α -reductase inhibitors is contraindicated in pregnant females, as the drugs may cause feminization of a male fetus. Pregnant females should not handle these drugs unless they are wearing gloves.

Patient Encounter 3

CC has moderately severe obstructive voiding symptoms of BPH. A DRE reveals a prostate of 20 g (0.7 oz) and a PSA of 1.2 ng/mL (1.2 mcg/L). He is started on dutasteride 0.5 mg daily by mouth. After 6 months, the patient complains that his symptoms have not significantly improved.

Explain why the patient has not responded to treatment.

Identify an alternative treatment regimen for this patient.

5 α -Reductase inhibitors include finasteride and dutasteride. Finasteride is a selective type II 5 α -reductase inhibitor, whereas dutasteride is a nonselective type I and II 5 α -reductase inhibitor. When compared with finasteride, dutasteride produces a faster and more complete inhibition of 5 α -reductase in prostate cells. However, no difference in clinical efficacy or adverse effects has been demonstrated between these two agents.³⁹ Thus finasteride and dutasteride are considered therapeutically interchangeable (Table 52-7).

By reducing serum levels of dihydrotestosterone, which is linked to the development of prostate cancer, it has been hypothesized that 5 α -reductase inhibitors may prevent the development of prostate cancer. The Prostate Cancer Prevention Trial reported that finasteride reduced the detection of prostate cancer with prostatic needle biopsy by 25%; however, higher grade tumors were more common in treated patients.⁴² This finding is likely due to the fact that the drug-induced shrinkage of the prostate increased the probability that the prostate needle biopsy procedure was able to obtain cancerous tissue.⁴² The Reduce Trial compared dutasteride, tamsulosin, and the combination of dutasteride and tamsulosin. Results showed that patients treated with the combination had greater symptom improvement after 9 months and less disease progression at 4 years than patients treated with single drug therapy.⁴³

► Combination Therapy

- A combination of an α -adrenergic antagonist and 5 α -reductase inhibitor may be considered in symptomatic patients at high risk of BPH complications, which are defined as those with an enlarged prostate of at least 30 g (1.05 oz) and a PSA of at least 1.5 ng/mL (1.5 mcg/L). In such patients, combination therapy will relieve voiding symptoms and also may reduce the risk of

Patient Encounter 4

EE has BPH. His prostate gland is estimated to be 40 cc (1.4 oz) in size and his PSA is 3 ng/mL (3 mcg/L). The patient also suffers from recurrent urinary tract infection, renal impairment with an estimated creatinine clearance of 25 mL/min (0.42 mL/s), and gross hematuria. The patient's peak urinary flow rate is 5 mL/s, and his postvoid residual urine volume is 200 cc (200 mL). The patient's AUA Symptom Score is 25. The patient prefers medical management for his BPH.

What is the best treatment option for this patient?

developing BPH-related complications and reduce the need for prostatectomy by 67%.^{14,15} Because combination therapy is more expensive and associated with the array of adverse effects associated with each drug in the combination, clinicians should discuss the advantages and disadvantages of each treatment regimen with the patient before a final decision is made.^{10, 14,15}

To streamline and reduce the cost of treatment regimens, it has been suggested that the α -adrenergic antagonist may be discontinued after the first 6 to 12 months of combination therapy. However, in patients with severe symptoms and an enlarged prostate gland, the combination regimen should be continued as long as the patients are responding.⁴⁴

Another enhancement to BPH symptom management is the addition of an anticholinergic agent to an α -adrenergic antagonist. The rationale for the anticholinergic agent is that irritative symptoms (e.g., urinary urgency and frequency) are thought to be due to hyper-reactive bladder detrusor muscle contraction, which can be ameliorated by blockade of acetylcholine receptors.^{45,46} Also, α_{1D} -adrenergic receptors in the detrusor muscle, which cause muscle contraction when stimulated, can be blocked by α -adrenergic antagonists. As a result, use of an α -adrenergic antagonist may also decrease involuntary bladder muscle contraction and increase the bladder's compliance. Thus the combination may have an additive pharmacologic effect on relieving irritative voiding symptoms.⁵¹ A recent study documenting the addition of tolterodine to tamsulosin showed significant irritative symptom improvement, more than what was observed with tamsulosin alone. No cases of urinary retention were reported. Patients at the highest risk of anticholinergic agent induced acute urinary retention include those with a high postvoid residual urine volume (250 mL or more). Thus anticholinergic agents should be used precautiously in these patients.

Finally, tadalafil is approved for treatment of LUTS. It may be prescribed alone or along with an α -adrenergic antagonist or 5 α -reductase inhibitor. It is postulated that its mechanism may be due to relaxation of smooth muscle of the urethra, prostate, and bladder neck, which is mediated by inhibiting the Rho/Rhokinase pathway or by enhancing the action of nitric oxide. Tadalafil is comparable to α -adrenergic antagonists in relieving LUTS, however, it does not increase urinary

flow rate or reduce post void residual urine volume. Because tadalafil is expensive, the best candidates for treatment are those with BPH and erectile dysfunction.

OUTCOME EVALUATION

9 *Once the peak effects of drug treatment are expected to occur, monitor the drug for effectiveness. Assess symptom improvement using the AUA Symptom Scoring Index. A reduction in symptom score by a minimum of 3 points is anticipated with symptom improvement. However, it should be noted that the AUA Symptom Score may not match the patient's perception of the bothersomeness of his voiding symptoms. If the patient perceives his symptoms as bothersome, independent of the AUA Symptom Score, consideration should be given to modifying the patient's treatment regimen. Similarly, a patient may regard his symptoms as not bothersome even though the AUA symptom score is high. In this case, the physician should objectively assess symptoms at baseline and during treatment by performing a repeat uroflowmetry, which can detect an improvement in peak and mean urinary flow rate. If the patient shows a response to treatment, instruct the patient to continue the drug regimen and have the patient return at 6-month intervals for monitoring. If the patient shows an inadequate response to treatment, the dose of α -adrenergic antagonist can be increased (except for extended-release alfuzosin and silodosin) until the patient's symptoms improve or until the patient experiences adverse drug effects.*

For the α -adrenergic antagonists, the severity of hypotensive-related adverse effects, which may manifest as dizziness or syncope, may require a dosage reduction or a slower up-titration of immediate-release terazosin or doxazosin, or halting the up-titration of the α -adrenergic antagonist. If the patient develops adverse effects at this dose, the drug should be discontinued. Other adverse effects of α -adrenergic antagonists are nasal congestion, malaise, headache, and ejaculation disorders. None of these generally require discontinuation of treatment, and these often improve as treatment continues. For the 5 α -reductase inhibitors, the most bothersome adverse effects are decreased libido, erectile dysfunction, and ejaculation disorders. In sexually active males, erectile dysfunction may be improved with erectogenic drugs; however, this adverse effect may necessitate discontinuation of treatment.

During continuing treatment of BPH, the patient should undergo an annual repeat PSA and DRE. A rising PSA level suggests that the patient has worsening BPH, new-onset prostate cancer, or that the patient is noncompliant with his regimen of 5 α -reductase inhibitor. An abnormal DRE suggestive of prostate cancer would reveal a nodule or area of induration on the prostate, or a gland that is fixed in place. In such a case, a prostate biopsy is required to rule out prostate cancer.

Drug treatment failures may result from a variety of factors. Initial failure to respond to α -adrenergic antagonists occurs in 20% to 70% of treated patients. It is likely in these patients that the static factor may predominate as the cause of symptoms in these patients. In these patients, adding a 5 α -reductase inhibitor may be helpful. Initial failure to respond to 5 α -reductase inhibitors occurs in 30% to 70%

Table 52-8

Summary of Adverse Effects of α -Adrenergic Antagonists and 5 α -Reductase Inhibitors and Management Suggestions

Drug Class	Adverse Reaction	Management Suggestion
α -Adrenergic antagonist	Hypotension	Start with lowest effective dose, give doses at bedtime, and slowly up-titrate at 0.5- to 1-week intervals to a full therapeutic dose, if using immediate-release terazosin or doxazosin Use tamsulosin, silodosin, extended-release doxazosin, or alfuzosin, as alternatives to immediate-release products, particularly in patients taking other antihypertensives
	Malaise	Educate the patient that this is a common adverse effect; tolerance may develop to malaise. Usually does not require discontinuation of treatment
	Rhinitis	Educate the patient that this is a common adverse effect; tolerance may develop to rhinitis. Usually does not require discontinuation of treatment
	Ejaculation disorders	Educate the patient that this is a common adverse effect and it is not harmful
5 α -Reductase inhibitor	Gynecomastia	Educate the patient that this may be bothersome, but not harmful
	Decreased libido	If the patient is sexually active, sexual counseling may be helpful. May be reversible despite continued use of the 5 α -reductase inhibitor
	Erectile dysfunction	The addition of sildenafil or another erectogenic drug may be helpful. May be reversible despite continued use of the 5 α -reductase inhibitor
	Ejaculation disorders	Educate the patient that this may occur but it is not harmful. May be reversible despite continued use of the 5 α -reductase inhibitor

Patient Care and Monitoring

1. Monitor the patient for the drug's effectiveness in relieving symptoms by using the AUA Symptom Scoring Index. Ensure that the score improves (by a minimum decrease of 3 points) and that the patient subjectively feels that symptoms have improved. If the patient has no improvement after several weeks of a therapeutic dose of α -adrenergic antagonist or after 6 months of a 5 α -reductase inhibitor, consider surgical intervention. Alternatively, if the patient was on a 5 α -reductase inhibitor alone, it may be reasonable to consider adding an α -adrenergic antagonist.
2. If the patient is started on an α -adrenergic antagonist, monitor the patient for hypotension, dizziness, or syncope. If present, assess the severity of each symptom. Reduce the drug dose, switch to a uroselective α -adrenergic antagonist, or discontinue the drug, as necessary. If the patient has malaise or rhinitis, reassure the patient that these are usual, but bothersome, adverse effects that often improve with continued therapy.
3. If the patient is started on a 5 α -reductase inhibitor, monitor the patient for drug-induced decreased libido, erectile dysfunction, or ejaculation disorders. If severe, discontinue the drug.

of treated patients. It is likely that the dynamic factor may predominate as the cause of symptoms in these patients. In these patients, switching to or adding an α -adrenergic antagonist may be helpful. In contrast, drug treatment failures after an initial good response to drug therapy will likely be an indication of progressive BPH disease. In such patients, modifying the drug regimen or surgical intervention may be indicated.

Table 52-8 summarizes the adverse effects of the agents used to treat BPH and includes management suggestions for these situations.

Abbreviations Introduced in This Chapter

AUA	American Urological Association
BPH	Benign prostatic hyperplasia
BUN	Blood urea nitrogen
CombAT	Combination of Avodart and Tamsulosin Study
DRE	Digital rectal exam
IVP	Intravenous pyelogram
LUTS	Lower urinary tract symptoms
MTOPS	Multiple Treatment of Prostate Symptoms Study
PSA	Prostate specific antigen
PVR	Postvoid residual urine volume
TURP	Transurethral resection of the prostate

Urinary Incontinence and Pediatric Enuresis

David R.P. Guay and Sum Lam

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiology of the major types of urinary incontinence (UI, urge, stress, overflow, and functional) and pediatric enuresis.
2. Recognize the signs and symptoms of the major types of UI and pediatric enuresis in individual patients.
3. List the treatment goals for a patient with UI or pediatric enuresis.
4. Compare and contrast anticholinergics/antispasmodics, α -adrenoceptor agonists, dual serotonin-norepinephrine reuptake inhibitors, vaginal estrogens, cholinomimetics, tricyclic antidepressants (TCAs), and vasopressin analogues in terms of mechanism of action, treatment outcomes, adverse effects, and drug–drug interaction potential when used to manage UI or pediatric enuresis.
5. Identify factors that guide drug selection for an individual patient.
6. Formulate a monitoring plan for a patient on a given treatment regimen based on patient-specific information.
7. Describe indicators for combination drug therapy of UI or pediatric enuresis.
8. Describe nonpharmacologic treatment approaches (including surgery) for UI or pediatric enuresis.
9. Formulate appropriate patient counseling information for patients undergoing drug therapy for UI or pediatric enuresis.

KEY CONCEPTS

- 1 Accurate diagnosis and classification of urinary incontinence (UI) type is critical to the selection of appropriate drug therapy.
- 2 Many medications can influence the lower urinary tract, including those not used for managing genitourinary disorders, and can precipitate new onset or aggravate existing voiding dysfunction and UI.
- 3 Patient-specific treatment goals should be identified. This frequently requires reaching a compromise between efficacy and tolerability of drug therapy. These goals are not static and may change with time.
- 4 Nonpharmacologic treatment can allow the use of lower drug doses. The combination of both therapies may have at least an additive effect on UI signs and symptoms.
- 5 The anticholinergic/antispasmodic drugs are the pharmacologic first-line treatments for urge UI. They are the most effective agents in suppressing premature detrusor contractions, enhancing bladder storage, and relieving symptoms.
- 6 Patient characteristics (e.g., age, comorbidities, concurrent drug therapies, and ability to adhere to the prescribed regimen) can also influence drug therapy selection.
- 7 Careful dose titration is necessary to maximize efficacy and tolerability.
- 8 If therapeutic goals are not achieved, a switch to an alternative agent should be made.
- 9 Vaginally administered estrogen plays only a modest role in managing stress urinary incontinence (SUI, urethral underactivity), unless it is accompanied by local signs of estrogen deficiency (e.g., atrophic urethritis or vaginitis).
- 10 The major impediment to using the α -adrenoceptor agonist class in SUI is the extensive list of contraindications.
- 11 The use of duloxetine in SUI is complicated by (a) the potential for multiple clinically relevant drug–drug interactions with CYP-450 2D6 and 1A2 inhibitors, (b) withdrawal reactions if abruptly discontinued,

(c) high rates of nausea and other side effects, (d) hepatotoxicity that contraindicates its use in patients with any degree of hepatic impairment, and (e) its mild hypertensive effect. Another disconcerting finding is the high discontinuation rate when duloxetine is used in a “usual use” clinic environment (66%, two-thirds due to adverse events and one-third due to lack of efficacy).

- 12 In overflow UI due to atonic bladder, a trial of bethanechol may be reasonable if contraindications do not exist.
- 13 In overflow UI due to obstruction, the goal of treatment is to relieve the obstruction.
- 14 Considering that pharmacotherapy is inferior to select nonpharmacologic treatment modalities in pediatric enuresis, pharmacotherapy will be most valuable in patients who are not candidates for nonpharmacologic therapy due to nonadherence or who do not achieve the desired outcomes on nonpharmacologic therapy alone.
- 15 Desmopressin (DDAVP) is the first-line drug choice in pediatric enuresis.

URINARY INCONTINENCE

INTRODUCTION

Urinary incontinence (UI) is defined as the complaint of involuntary leakage of urine.¹ It is often associated with other bothersome lower urinary tract symptoms such as urgency, increased daytime frequency, and **nocturia**. Despite its prevalence across the lifespan and in both sexes, it remains an underdetected and underreported health problem that can have significant negative consequences for the individual’s quality of life. Patients with UI may be depressed due to a perceived loss of self-control, loss of independence, and lack of self-esteem, and often curtail or substantially modify their activities for fear of an “accident.” Serious medical and economic consequences may also occur in untreated or undertreated patients, including perineal dermatitis and infections, worsening or lack of healing of pressure ulcers, urinary tract infections (UTIs), falls, and the need for long-term institutionalization in extended-care facilities (including skilled nursing facilities [SNFs], or nursing homes).

EPIDEMIOLOGY AND ETIOLOGY

The true prevalence of UI has been difficult to determine because of methodologic issues such as varying definitions of UI and reporting bias.² Although the condition occurs across the lifespan, the peak prevalence, at least in women, is around the age of menopause (approximately 50 years), which is followed by a slight decrease in the 55- to 60-year-old age group, and then a steadily increasing prevalence after age 65. In general, the median prevalences of UI are as follows³:

- 20% to 30% in young females
- 30% to 40% in middle-aged females

- 30% to 50% in elderly females (50% to 75% in female SNF residents)
- 10% in adult males (more than 50% in elderly male SNF residents)

UI can result from abnormalities within (intrinsic to) and outside of (extrinsic to) the urinary tract. Within the urinary tract, abnormalities may occur in the urethra (including the bladder outlet and urinary sphincters), the bladder, or a combination of both structures. Focusing on abnormalities in these two structures, a simple classification scheme emerges for all but the rarest intrinsic causes of UI.

1 *Accurate diagnosis and classification of UI type is critical to the selection of appropriate drug therapy.*

PATHOPHYSIOLOGY

Stress Urinary Incontinence Related to Urethral Underactivity⁴

In stress urinary incontinence (SUI), the urethra and/or urethral sphincters cannot generate enough resistance to impede urine flow from the bladder when intra-abdominal pressures (that are transmitted to the bladder, which is an intra-abdominal organ) are elevated. Intra-abdominal pressures are suddenly elevated by exertional activities like exercise, running, lifting, coughing, and sneezing. The amount of urine lost is generally small with each episode. Nocturia and **enuresis** are rarely seen. The factors responsible for urethral underactivity are incompletely understood, although the loss of the **trophic** effects of estrogen on the uroepithelium at menopause is thought to be important. The peak of SUI prevalence in the perimenopausal years supports this hypothesis. Clearly established risk factors for SUI include⁵:

- Pregnancy (increased risk with increased parity)
- Childbirth (vaginal delivery)
- Menopause
- Cognitive impairment
- Obesity
- Increasing age

Unless the sphincter mechanism is compromised by surgery or trauma, SUI is exceedingly rare in males. The most common surgeries predisposing to SUI in males are radical prostatectomy for prostate cancer and transurethral resection of the prostate for benign prostatic hyperplasia (BPH).

Urge Urinary Incontinence Related to Bladder Overactivity⁴

In urge urinary incontinence (UUI), the detrusor (bladder) muscle is overactive and contracts inappropriately during the filling phase. Stimulation of muscarinic cholinergic receptors (especially M2 and M3 subtypes) in the bladder muscle is responsible for these contractions. The amount of urine lost per episode can be as large as the entire contents of the bladder may empty. Sleep may be disrupted by nocturia and enuresis.

Patient Encounter 1, Part 1

A 60-year-old white woman presents to the clinic complaining of urinary urgency that occurs almost every day. She often experiences a strong, sudden urge to urinate with barely adequate time to make it to the bathroom. She makes at least eight trips to a bathroom while awake on a daily basis. She reports no clothes-wetting accidents so far, but is fearful of the embarrassment, especially if she should be at her painting lessons. Because of the urinary condition, she has avoided several social and family gatherings in fear of “not making it to the bathroom in time.” She denies any urinary leakage when she coughs, laughs, or exercises. She has no or little postvoid residual volume (PVR less than 10 mL). She is diagnosed with overactive bladder without urinary incontinence.

List symptoms that are consistent with her diagnosis.

What additional information do you need to know before creating a treatment plan for this patient?

In most patients, the cause of bladder overactivity is unknown (idiopathic). Clearly established risk factors for UUI include:

- Increasing age
- Neurologic disorders (e.g., stroke, Parkinson’s disease, multiple sclerosis, and spinal cord injury)
- Bladder outlet obstruction (e.g., benign or malignant prostatic enlargement or hyperplasia)
- Hysterectomy
- Recurrent UTIs

Overactivity may be myogenic or neurogenic in origin or a combination of both. These etiologies appear to be interconnected and complementary.

Overflow Urinary Incontinence Related to Urethral Overactivity and/or Bladder Underactivity⁴

- In overflow urinary incontinence (OUI), an important but uncommon form of UI in both sexes, the bladder is filled to capacity at all times but cannot empty, causing urine to leak out episodically. If caused by bladder underactivity, the detrusor muscle has weakened, in some cases enough to lose the ability to voluntarily contract. In this case, the bladder cannot be emptied completely, and large volumes of residual urine remain after **micturition**. Clinically, this is most commonly seen in the setting of long-term chronic bladder outlet obstruction due to benign or malignant prostatic enlargement. However, this may also be a manifestation of neurogenic bladder, frequently being seen in patients with diabetes, lower spinal cord injury, multiple sclerosis, or following radical pelvic surgery. If due to urethral overactivity, the resistance of the urethra and/or

Clinical Presentation of SUI Related to Urethral Underactivity⁴

General

The patient usually notes UI during activities like exercise, running, lifting, coughing, or sneezing. This type of UI is much more common in females (seen only in males with lower urinary tract surgery or injury compromising the sphincter).

Symptoms

Urine leakage with physical activity (volume is proportional to activity level). No UI with physical inactivity, especially when supine (no nocturia). May develop urgency and frequency as a compensatory mechanism (or independently as a separate component of bladder overactivity).

Diagnostic Tests

Observation of urethral meatus (opening) while patient coughs or strains

sphincters cannot be overcome by detrusor contractility. This functional or anatomic obstruction results in incomplete bladder emptying. Clinically, in males this most frequently occurs in the context of long-term chronic bladder outlet obstruction, as outlined previously. In females, urethral overactivity is rare, but may result from **cystocele** formation

Clinical Presentation of UUI Related to Bladder Overactivity⁴

General

Can have bladder overactivity and UI without urgency, if sensory input from the lower urinary tract is absent. Can have bladder overactivity without UI (called overactive bladder or OAB).

Symptoms

OAB is a clinical condition characterized by urinary urgency with/without incontinence, urinary frequency, and nocturia. Patients with OAB typically present with symptoms of sudden and compelling need to urinate, which is difficult to defer (urgency), involuntary urine leakage with sensations of urgency (UUI), frequency (eight or more micturitions in 24 hours), and nocturia (one or more awakening per night to void).²

Diagnostic Tests

Urodynamic studies are the gold standard for diagnosis. Also urinalysis and urine culture should be negative (rule out urinary tract infection [UTI] as cause of frequency).

Clinical Presentation of OUI Related to Urethral Overactivity and/or Bladder Underactivity⁴

General

Important but rare type of UI in both sexes. Urethral overactivity usually due to prostatic enlargement (males) or cystocele formation or surgical overcorrection following antiurethral underactivity (SUI) surgery (females).

Symptoms

Lower abdominal fullness, hesitancy, straining to void, decreased force of stream, interrupted stream, sense of incomplete bladder emptying. May have urinary frequency and urgency, too. Abdominal pain if acute urinary retention is also present.

Signs

Increased postvoid residual urine volume.

or surgical overcorrection during anti-SUI surgery. In both sexes, systemic neurologic diseases such as multiple sclerosis or spinal cord injury may be the etiology.

Functional UI⁴

Functional UI is not generally caused by intrinsic urinary tract pathology. It is usually caused by factors extrinsic to the urinary tract. Examples of factors predisposing to functional incontinence include:

- Immobility (due to pain, traction, or use of nonportable medical devices)
- Lack of or slowed access to toileting facilities
- Cognitive impairment (difficulty with recognition of the urinary urge and proper response to it)
- UTIs
- Postmenopausal atrophic urethritis and/or vaginitis
- Diabetes mellitus (glucosuria leading to polyuria)
- Diabetes insipidus (polyuria due to decreased antidiuretic hormone [ADH])
- Pelvic malignancy (extrinsic pressure on urinary tract structures causing obstruction)
- Constipation or fecal impaction
- Congenital malformations
- CNS disorder resulting in a decreased level of consciousness
- Depression (apathy leading to recognition and response difficulties)

Mixed and Drug-Induced UI⁴

Frequently, two or more types of UI may coexist in a given patient, combinations termed mixed UI. This can lead to

diagnostic and therapeutic difficulties due to the confusing array of presenting signs and symptoms and the opposing effects that a given treatment can have in different types of UI (i.e., a given drug may reduce the signs and symptoms of one type of UI but worsen those of other types). Another interesting type of mixed UI is coexisting bladder overactivity (UUI) and impaired bladder contractility (OUI). Most common in the elderly, this combination is called *detrusor hyperactivity with impaired contractility* (DHIC).

2 Many medications can influence the lower urinary tract, including those not used for managing genitourinary disorders, and can precipitate new onset or aggravate existing voiding dysfunction and UI (Table 53-1).

CLINICAL PRESENTATION AND DIAGNOSIS

- The clinical presentation of UI depends on the underlying pathophysiology. The literature evaluating the prevalences of different UI types by age and sex has produced widely varying results due to a number of factors. The clinician should thus consider a given patient as having virtually any type of UI until ruled out during diagnostic evaluation.

A complete medical history and targeted physical examination are essential to correctly classify the type(s) of UI present. It is important to assess the degree of annoyance of the patient due to UI signs and symptoms. The degree of annoyance of the patient may not correlate well with the results of quantitative tests such as symptom frequency/severity, use of absorbent products, frequency/severity of neurologic signs, and postvoid residual urine volume. This is especially the case in “hypersensitive” and “stoic” individuals. Items to address during the evaluation are illustrated in Table 53-2. Components of the physical examination include⁴:

- Abdominal examination (look for distended bladder, organomegaly, and masses)
- Neurologic evaluation of perineum and lower extremities to evaluate lumbosacral nerve function (includes digital rectal exam to check rectal tone, reflexes, ability to perform a voluntary pelvic muscle contraction in females and size and surface quality of prostate in males)
- Pelvic exam (females) (look for evidence of prolapse of bladder, small bowel, rectum, or uterus, or estrogen deficiency)
- Genital/prostate exam (men)
- Urinalysis, postvoid residual
- Direct observation of urethral meatus (opening) when patient coughs/strains (urine spurt consistent with SUI) (cough stress test)
- Perineal exam (looking for skin maceration, redness, breakdown, ulceration, and evidence of fungal skin infection)
- Optional: voiding diary, assessment of incontinence severity, quality-of-life measures

Table 53-1

Medications Influencing Lower Urinary Tract Function

Medication	Effect
Diuretics	Polyuria, frequency, urgency
α -Adrenoceptor antagonists	Urethral relaxation: may relieve obstruction in males, induces/worsens SUI in females
α -Adrenoceptor agonists	Urethral constriction: aggravates obstruction in males (may cause urinary retention), potential SUI treatment in females
Calcium channel blockers (dihydropyridines)	Urethral constriction (may cause urinary retention), especially in males
Opioid analgesics	Impaired bladder contractility (may cause urinary retention)
Sedative-hypnotics	Functional UI due to immobility, delirium, sedation
Psychotherapeutics with anticholinergic properties; anticholinergics	Urinary retention due to impaired bladder contractility or potential UUI treatment
TCA	Combination of anticholinergic and α -adrenoceptor blocking activities can lead to unpredictable effects on UI
Ethanol	Polyuria and frequency (via effects on ADH), functional UI (delirium, sedation), urgency
ACEIs	Cough leading to SUI (ARBs do not induce cough)
Cyclophosphamide	Hemorrhagic cystitis due to acrolein metabolite (prevent with MESNA)

ACEIs, angiotensin-converting enzyme inhibitors; ADH, antidiuretic hormone (or vasopressin); ARB, angiotensin II receptor blocker; MESNA, sodium 2-mercaptoethanesulfonate; SUI, stress urinary incontinence; TCA, tricyclic antidepressant; UI, urinary incontinence; UUI, urge urinary incontinence.

Table 53-2

Items to Address During Diagnostic Evaluation of UI

Item	Comments
Urine leakage	
Use of absorbent products	Yes/no, type(s), quantity, times of day worn Quantity may relate more to personal preference and hygiene than to UI type and severity (e.g., use of large number of pads by a fastidiously hygienic patient with low volume loss)
Quantity lost per episode	Dribbling versus small volumes intermittently versus large volumes Consistent or varied quantities
Precipitants	Yes/no, physical activity, excessive fluid intake, drug(s)
Times of day	Daytime/nighttime/both
Symptoms	
Urgency	Yes/no, how often, how severe, duration from urge onset to micturition
Frequency	Yes/no, daytime/nighttime/both, how often
Nocturia	Yes/no, how often, proportion associated with UI
Obstructive symptoms	Yes/no, type(s) (hesitancy, strain to void, decreased force of stream, start and stop stream, sense of incomplete emptying), severity
Lower abdominal fullness	Yes/no, how often, how severe
Comorbidities	
Current medication use	See Table 53-1. Remember CAMs , OTCs
Evidence of preexisting or new-onset:	
Diabetes mellitus	
Metastatic or genitourinary malignancy	
Multiple sclerosis or other neurologic disease	
CNS disease above the pons	Usually UUI
Spinal cord injury	UUI or OUI, depending on level and degree of completeness of injury
Recent nongenitourinary surgery	Functional UI
Previous local surgery/radiation	Prostate surgery, lower abdominal cavity surgery (direct injury versus denervation), radiation (direct injury)
Gynecologic history	Childbirth (vaginal versus cesarean section), prior gynecologic surgery, hormonal status (pre- versus peri- versus postmenopausal)
Pelvic floor disease	Constipation, diarrhea, fecal incontinence, dyspareunia , sexual dysfunction, pelvic pain
UTI	Dysuria, CVA tenderness, frequency
Gross hematuria	Possible bladder or other genitourinary cancer

CAM, complementary and alternative medications; CVA, costovertebral angle; OTC, over-the-counter; OUI, overflow urinary incontinence; SUI, stress urinary incontinence; UTI, urinary tract infection; UUI, urge urinary incontinence.

The methods adopted for evaluating symptoms include evaluation via questioning, responses of patients to uniform questionnaires, and records in bladder diaries (recommended length of 3 days to 1 week). The Overactive Bladder Symptom Score (OABSS, see [Table 53–3](#)) has been used for the evaluation of symptoms in patients diagnosed with OAB. The recommended diagnostic criteria for OAB are “an urgency score for Question 3 of 2 or greater, and an OABSS of 3 or greater.” OABSS may also be used for assessing the severity of OAB: a total score of 5 or less (mild), 6 to 11 (moderate), and 12 or more (severe). A simplified form of the OABSS can be used to screen for OAB in the general population. This three-item questionnaire has high sensitivity but low specificity for OAB.⁶

TREATMENT

3 *Patient-specific treatment goals should be identified. This frequently requires reaching a compromise between efficacy and tolerability of drug therapy. These goals are not static and may change with time.*

Desired Outcomes

- Restoration of continence
- Reduction of the number of UI episodes (daytime and nighttime) and frequency of nocturia (must produce a minimum reduction of 50% to be clinically important)
- Prevention of disease complications (e.g., dermatologic infections and skin breakdown, delay institutionalization)
- Avoidance or minimization of adverse consequences of treatment

- Minimization of treatment costs
- Improvement in patient’s quality of life

Nonpharmacologic Treatment

At the primary care level, nonpharmacologic treatment of UI constitutes the chief approach to UI management. In patients in whom pharmacologic or surgical management is inappropriate or undesirable or refused, nonsurgical nonpharmacologic treatment is the only option. Nonpharmacologic therapy has no adverse reactions, is minimally invasive, and can be utilized adjunctively with other modalities. Examples of patients fitting this scenario include:

- Those not medically fit for surgery
- Those who plan future pregnancies (as pregnancy/childbirth can compromise the long-term results of certain types of continence surgery)
- Those with OUI whose condition is not amenable to surgical or drug treatment
- Those with comorbidities that place them at high risk for significant side effects to drug therapy
- Those who wish to delay or avoid surgery
- Those with mild to moderate symptoms who do not wish to undergo surgery or take medication

Nonpharmacologic approaches include lifestyle modifications, scheduled voiding regimens, pelvic floor muscle rehabilitation (PFMR), anti-incontinence devices, and supportive interventions.^{4,7} Many of these are best utilized through attendance at multidisciplinary UI clinics staffed by healthcare

Table 53–3

Overactive Bladder Symptom Score (OABSS)

Question	Symptom	Score	Frequency over the past
1	How many times do you typically urinate from waking in the morning until going to bed in the evening?	0	7 or less
		1	8–14
		2	15 or more
2	How many times do you typically wake up to urinate from going to sleep at night until waking in the morning?	0	0
		1	1
		2	2
3	How often do you have a sudden compelling desire to urinate, which is difficult to postpone?	3	3 or more
		0	Not at all
		1	Less than once week
4	How often do you leak urine because you cannot postpone the sudden desire to urinate?	2	Once a week or more
		3	About once a day
		4	2–4 times a day
		5	5 times a day or more
		0	Not at all
Sum of scores		1	Less than once week
		2	Once a week or more
		3	About once a day
		4	2–4 times a day
		5	5 times a day or more

The sampling period is usually defined as “the past week” but, depending on the usage, it can be amended to, for example, “the past 3 days” or “the past month.” Whatever the case, it is necessary to specify the sampling period.

Patient Encounter 1, Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH: Hypertension, dyslipidemia, type 2 diabetes mellitus, and osteoarthritis

FH: Mother died of breast cancer at age 70; father died of a myocardial infarction at age 65

SH: Retired certified public accountant; now volunteers as an instructor for water-color painting classes at a local senior center. Married and lives with husband. Two married daughters (ages 30 and 32 years) live in the neighborhood. Denies tobacco or alcohol use; drinks 4 cups of coffee daily

All: Erythromycin (rash)

Medications: Insulin glargine 40 units subcutaneously at bedtime; Regular insulin 10 units subcutaneously before meals; metoprolol 50 mg once daily; enalapril 5 mg once daily; atorvastatin 10 mg once daily; acetaminophen 650 mg every 6 hours as needed for knee pain

ROS: Alert, sociable, and pleasant. (–) UI, history of UTIs; (–) nocturia, enuresis, dysuria, lower abdominal fullness, decreased force of stream

PE:

Gen: Postmenopausal white woman with mild kyphosis; NAD; A & O 3

VS: BP 120/70 mm Hg, HR 65 beats/min, RR 20 breaths/min, Temp 98.3°F (36.8°C), Wt 60 kg, Ht 5 ft 5 in (165 cm)

HEENT: PERRLA; EOMI, TMs WNL

Neck/LN: Supple w/o LAD or masses

Lungs/Thorax: CTA

CV: RRR w/o murmurs, rubs, gallops

Abd: Soft, NT/ND w/o masses; (+) BS; bladder not palpable

GU: WNL; no atrophic vaginitis or uterine prolapse

MS/Ext: WNL, no edema

Neuro: DTRs 2+, CN II – XII intact

Labs:

Na: 134 mEq/L (134 mmol/L)

K: 3.8 mEq/L (3.8 mmol/L)

Cl: 100 mEq/L (100 mmol/L)

CO₂: 22 mEq/L (22 mmol/L)

BUN: 9 mg/dL (3.2 mmol/L)

SCr: 1.0 mg/dL (88 μmol/L)

Random glucose: 180 mg/dL (10.0 mmol/L)

Hb: 12 g/dL (120 g/L; 7.45 mmol/L)

Hct: 37% (0.37)

Plts: 300,000/mm³ (300 × 10⁹/L)

WBC: 6.1 × 10³/mm³ (6.1 × 10⁹/L) with normal differential

Hemoglobin A1c 8.5% (0.085; 69 mmol/mol hemoglobin)

LFTs within normal limits

UA (–)

Given this additional information, what is your assessment of the patient's condition?

What are the goals of pharmacotherapy for this patient?

What nonpharmacologic and pharmacologic alternatives are available to the patient?

providers. Behavioral interventions are among the first-line treatment approaches for SUI, UUI, and mixed UI. However, these lifestyle modifications, scheduling regimens, and PFMR methods require a motivated patient and/or caregiver who can play an active role in developing the treatment plan. Anything that interferes with active participation (including cognitive dysfunction) will render these approaches suboptimal. Patients/caregivers also must attend regular follow-up visits to monitor outcomes. Of interest, nonpharmacologic treatment may even be superior to pharmacologic treatment in select cases. For example, the short-term (6 months) and long-term (21 months) results of a combination of PFMR plus behavioral training produced statistically superior results compared with anticholinergic therapy in women with UUI.^{8,9} Even if the results of nonpharmacologic treatment have not fully achieved the desired outcomes, if it has provided at least some improvement in UI signs and symptoms, it should be continued during pharmacologic treatment. **4** *Nonpharmacologic treatment can allow the use of lower drug doses. The combination of both therapies may have at least an additive effect on UI signs and symptoms.*

In the recent systematic review of nonsurgical treatments for UI by Shamliyan et al., the only nonpharmacologic treatment for which true objective evidence of benefit exists is the combination of PFMR plus behavioral training (restored continence with an effect size of 0.13 [95% CI, 0.07 to 0.20], but improvement in continence was not consistent between trials). Although PFMR alone or combined with biofeedback restored and improved continence, the effect size was not consistent between trials.¹⁰ Weight loss of 5% to 10% in overweight or obese women has an efficacy similar to that of other nonpharmacologic treatments.

Surgery is rarely a first-line treatment for UI. Surgery is generally considered only when the degree of bother or lifestyle compromise is sufficient and other nonoperative therapies are either undesired or have been ineffective. Surgery can be used to manage urethral overactivity due to benign prostatic enlargement and bladder outlet obstruction (via endoscopic incision using a cystoscope). Bladder underactivity cannot be managed surgically and rarely is surgery considered for UUI. Surgery is most

effective in the management of SUI. Surgery for SUI is directed toward stabilizing the urethra and bladder neck and/or augmenting urethral resistance. This can be accomplished by injection of periurethral bulking agents, midurethral or pubovaginal sling surgeries, and lap or retropubic suspension surgeries. In males, SUI is best treated by implanting an artificial urinary sphincter.⁴

Unaddressed issues regarding nonpharmacologic therapy include uncertain long-term results, lack of standardized protocols for specific procedures in each treatment method, insurance coverage, and reimbursement concerns.⁶

Pharmacologic Treatment

► Urge Urinary Incontinence

5 *The anticholinergic/antispasmodic drugs are the first-line pharmacologic treatment for UUI. They are the most effective agents in suppressing premature detrusor contractions, enhancing bladder storage, and relieving symptoms.* It must be emphasized that the improvements in clinical and urodynamic parameters are modest at best, although still considered by experts in the field to be positive.¹¹ In the recent systematic review/meta-analysis of 50 clinical trials in UUI by Novara et al., there were no clinically important or relevant differences found among different anticholinergics.¹² Antimuscarinic agents are also the mainstay therapy for urinary symptoms, including UUI, associated with OAB. Their efficacy can be maximized by combination with nonpharmacologic therapy. These agents should be considered for patients who are bothered by OAB symptoms and have no major contraindications to therapy. They are considered equally effective based on statistical superiority over placebo or active controls, with small absolute reductions in symptom measures in most clinical trials.¹³

Currently there are few head-to-head trials that directly compare these agents, and there are no objective data suggesting the first-line drug to initiate for OAB. In the recent systematic review of Shamliyan et al., data for analysis were adequate only for oxybutynin IR (5 to 10 mg/day) and tolterodine LA (4 mg/day). Both of these agents restored continence with an effect size of 0.18 (95% CI, 0.13 to 0.22), although neither was demonstrated to be superior.¹⁰ The ideal agent for UUI must have clinical efficacy and safety, minimal side effects, minimal drug-drug/drug-disease interactions, convenient administration, and low cost.

6 *Patient characteristics (e.g., age, comorbidities, concurrent drug therapies, and ability to adhere to the prescribed regimen) can also influence drug therapy selection.* Table 53–4 compares the pharmacokinetics, contraindications, precautions, and dosing of available agents (oxybutynin, tolterodine, trospium chloride, solifenacin, darifenacin, and fesoterodine) approved for OAB.^{13–16}

All antimuscarinic agents have similar contraindications and precautions, including urinary retention, gastric retention, and uncontrolled narrow-angle glaucoma.¹³ Older agents, such as oxybutynin IR and tolterodine IR, have been associated with higher rates of adverse effects such

as dry mouth, constipation, headache, dyspepsia, dry eyes, cognitive impairment, tachycardia, and urinary retention. Older patients are especially susceptible to adverse events associated with these agents. Significant dry mouth can be associated with dental caries, ill-fitting dentures, and swallowing difficulty. Orthostatic hypotension and sedation can be particularly troublesome to patients with cognitive impairment or at risk for falls. Issues with tolerability and multiple daily dose administration associated with IR products may jeopardize medication adherence and can prevent dose titration to achieve optimal clinical response. Thus, these products are not preferred in elderly patients with functional limitations and/or those who are already

being treated with complicated drug regimens. Nevertheless, adverse events are not universal and their severity varies with individuals. Therefore, older agents (start at the lowest possible doses) are reasonable to consider in patients who cannot otherwise afford drug therapy. Extended-release agents (oxybutynin XL, tolterodine LA, trospium ER, darifenacin ER, fesoterodine ER) cause less dry mouth compared with IR products,^{4,12,13} but patients are required to swallow the product whole, as these agents cannot be chewed, crushed, or divided. Oxybutynin TD patch and topical gel are alternatives for patients who cannot take or tolerate oral drugs, but they are associated with application site reactions. Similar to newer agents, they are four to five times more costly than generic oxybutynin.¹³

Most antimuscarinic agents (oxybutynin, tolterodine, fesoterodine, solifenacin, darifenacin) are tertiary amines, which can penetrate the blood–brain barrier and may lead to CNS side effects (sedation, mental status changes). Oxybutynin is also highly lipophilic, which may contribute to a greater potential for CNS side effects. Trospium chloride is a hydrophilic, positively charged quaternary amine that does not readily cross into the CNS. These characteristics have been often used to explain its lower CNS side effect potential compared with oxybutynin.¹⁷ However, this benefit has not been confirmed in clinical studies. Patients receiving any antimuscarinic agent should be informed about sedation as a possible side effect and warned against operating heavy machinery, such as driving, especially during the initial phase of therapy. Patients with existing cognitive dysfunction or difficulty with balance should be monitored closely for mental status changes and falls, respectively. Older individuals are more likely to experience drug-induced constipation because of polypharmacy and age-related physiologic changes. A study demonstrated that solifenacin was most associated with constipation, followed by trospium chloride, oxybutynin, fesoterodine, darifenacin, and tolterodine, which was least associated with constipation.¹⁸ Patients should be advised to contact their physician if they experience severe abdominal pain or become constipated for 3 or more days.

The appropriate dosing of drug therapy for OAB is based on drug–drug interactions and renal or hepatic function. All available OAB agents, except trospium chloride, are metabolized by CYP450 3A4 and/or 2D6

Table 53-4

Anticholinergic/Antispasmodic Drugs Recommended for UUI

Parameter	Oxybutynin	Tolterodine	Trospium Chloride	Solifenacin	Darifenacin	Fesoterodine
Dosage forms	IR tablets, solution SR-ER tablets, SR-TD patch, topical gel	IR tablets SR-LA capsules	IR tablets ER tablets	IR tablets	ER tablets	ER tablets
Dosing	IR: 2.5–5 mg 2–4 times daily (pediatrics 0.3–0.5 mg/kg/ day in 3 doses) SR (oral): 5–30 mg once daily (pediatrics: 0.3–0.5 mg/kg/day) SR (TD): 3.9 mg/day patch applied twice weekly SR (gel): 1 sachet (100 mg) applied once daily	IR: 1 or 2 mg twice daily (pediatrics: 1 mg twice daily) SR: 2 or 4 mg once daily (pediatrics: 2 mg once daily)	IR: 20 mg twice daily ER: 60 mg once daily	5–10 mg once daily	7.5–15 mg once daily	4–8 mg once daily
Kinetics	Active metabolite (N-desethyl) Not altered in renal or hepatic disease or advanced age	Active metabolite (5-hydroxymethyl) Polymorphic metabolism (CYP 2D6) Not altered in advanced age. Significantly altered in hepatic disease (decreased CL in cirrhosis) and renal disease (decreased CL)	Food: decreased BA by 70–80% Significantly altered in renal disease (decreased CL) but not in hepatic disease or advanced age	Metabolized via CYP 3A4 but only one active metabolite (4-hydroxy) Significantly altered in severe renal impairment, moderate hepatic impairment (Child-Pugh B), and advanced age (decreased CL in all)	Complex metabolism (polymorphic CYP 2D6, CYP 3A4) Not altered in advanced age, renal impairment, mild hepatic impairment (Child-Pugh A) Significantly altered in moderate hepatic impairment (Child- Pugh B) (decreased CL)	Prodrug (for 5-hydroxymethyl tolterodine) Inactive metabolites Not altered in advanced age Significantly altered in renal disease (decreased CL) and moderate hepatic impairment (Child-Pugh B) (decreased CL)
Contraindications and precautions	Use with caution if CYP 3A4 inhibitors are also being taken (decreased oxybutynin CL)	Reduce dose 50% in those taking CYP 3A4 inhibitor(s) or with hepatic cirrhosis or with CrCl less than 30 mL/ min (0.50 mL/s) Antacid-SR (oral) prep, interaction (dose-dumping) (not seen with PPIs)	Give on empty stomach Decrease dose 50% when CrCl less than 30 mL/ min (0.50 mL/s) and use IR formulation	Do not exceed 5 mg/ day if CrCl less than 30 mL/min (0.50 mL/s), patient has moderate hepatic impairment, or patient is taking CYP 3A4 inhibitor(s) If severe hepatic impairment, do not use	Do not exceed 7.5 mg/day if patient is taking potent CYP 3A4 inhibitor(s) Use caution if patient is taking moderate CYP 3A4 inhibitor(s) or CYP 3A4 or 2D6 substrate(s) Do not chew, divide, or crush the ER tablets	Do not exceed 4 mg/day if CrCl less than 30 mL/ min (0.50 mL/s) or patient is taking potent CYP 3A4 inhibitor(s) If severe hepatic impairment, do not use

BA, bioavailability; CL, total body clearance; CrCl, creatinine clearance; CYP450, cytochrome P450; TD, transdermal; ER, extended release; IR, immediate release; LA, long acting; PPIs, proton pump inhibitors; SR, sustained release.

Patient Encounter 1, Part 3: Creating a Care Plan

Patient prefers to try a once-daily oral drug for her urinary symptoms.

Based on the information presented, create a care plan for this patient's OAB. Your plan should include:

- (a) A statement of the drug-related needs and/or problems
- (b) The goals of therapy
- (c) A patient-specific detailed therapeutic plan, including patient counseling to enhance medication adherence, ensure successful therapy, and minimize adverse effects
- (d) A plan for follow-up to evaluate therapeutic outcome and drug tolerability

isoenzymes. Tolterodine, solifenacin, darifenacin, and fesoterodine require dose reduction when used concurrently with CYP 3A4 inhibitor(s). In addition, darifenacin also interacts with drugs via the CYP 2D6 system. Trospium chloride, solifenacin, and fesoterodine require dose reduction in patients with CrCl less than 30 mL/min (0.50 mL/s). Tolterodine requires a 50% dose reduction in patients with hepatic cirrhosis, whereas solifenacin and fesoterodine should be avoided in patients with severe hepatic dysfunction. An important drug–drug interaction to avoid is the concurrent use of acetylcholinesterase inhibitors for dementia and anticholinergic agents of any kind due to pharmacologic antagonism.¹⁹

Treatment with a selected agent should be initiated at the lowest possible dose and gradually titrated upward based on clinical response; not to exceed the maximum recommended dose. A trial of at least 4 weeks is required to evaluate the efficacy of the agent. Consider switching to another agent if the patient reports intolerable side effects or inadequate relief from OAB symptoms despite optimized dose.

► Stress Urinary Incontinence

The goal of pharmacologic therapy of urethral underactivity is to improve the urethral closure mechanism by one or more of the following:

- Stimulating α -adrenoceptors in the smooth muscle of the proximal urethra and bladder neck
- Enhancing the supportive structures underlying the urethral mucosa
- Enhancing the positive effects of serotonin and norepinephrine in the afferent and efferent pathways of the micturition reflex

It is generally felt that there is no role for pharmacologic therapy in SUI in males resulting from surgery or trauma.²⁰ Initial data, however, suggest a possible role for duloxetine added to nonpharmacologic treatment (PFMR), rather than

PFMR alone, in males postradical prostatectomy, at least over the first 4 to 6 months.²¹ It should be kept in mind that SUI (in contrast to UUI) is frequently curable by surgery, thus obviating years of drug therapy that may be incompletely effective in symptom relief.

Estrogens⁴  *Vaginally administered estrogen plays only a modest role in managing SUI (urethral underactivity), unless it is accompanied by local signs of estrogen deficiency (e.g., atrophic urethritis or vaginitis).*

Although not supported by rigorous clinical trial evidence, local (PV) and systemic estrogens have been considered mainstays of pharmacologic management since the 1940s. They are believed to work by a trophic effect on uroepithelial cells and underlying collagenous subcutaneous tissue, enhancement of local microcirculation by increasing the number of periurethral blood vessels, and enhancement of the number and/or sensitivity of α -adrenoceptors. Open trials have supported the use of estrogens administered by the oral, TD, and local routes of administration. However, randomized controlled trials have found no significant clinical or urodynamic effects of oral estrogen compared with placebo in SUI. In fact, most trials have found that oral estrogen/hormone replacement therapy actually increases the risk of new-onset UI (SUI, UUI, mixed UI).¹⁰ Open trials of local estrogens (estriol [not available in the United States] tablets, CEE cream, and estradiol rings) have demonstrated subjective improvement in SUI symptoms as well as positive urodynamic effects (significantly increased maximum urethral pressure, urethral closing pressure, and abdominal pressure transmission ratio to proximal urethra).²² Systemic estrogen therapy also carries numerous short- and long-term side effect risks (mastodynia, uterine bleeding, nausea, thromboembolism, cardiac and cerebrovascular ischemic events, and enhanced breast and endometrial cancer risks). If estrogens are to be used in SUI management, only locally administered products should be used (Table 53–5). Even with locally administered products, improvement of continence has been inconsistent between trials.¹⁰ Vaginal tablets and rings have greater acceptability than creams.

► α -Adrenoceptor Agonists⁴

Open and randomized controlled trials utilizing clinical and urodynamic end points have supported the use of a variety of α -adrenoceptor agonists, including phenylpropanolamine, ephedrine, and pseudoephedrine, in the therapy of mild and moderate SUI. In addition, several studies have demonstrated clinical and urodynamic benefits for combination estrogen– α -adrenoceptor agonist use over those of the individual agents. However, in the recent systematic review of Shamliyan et al., monotherapy with this class failed to restore continence or improve incontinence compared with placebo or PFMR.¹⁰ Phenylpropanolamine was removed from the U.S. market in late 2000 due to the risk of ischemic stroke in women taking this drug. However, this drug is still available via the Internet, so clinicians need to monitor and discourage its

Table 53-5

Drugs Used for SUI^a

Parameter	Estrogens	Pseudoephedrine	Duloxetine
Dosage forms	Avoid systemic (parenteral, oral, TD); use vaginal: tablet, cream, intravaginal ring	Tablets, solution	DR capsules
Dosing	Estradiol 25 mcg vaginal tablets (insert one PV daily for 14 days, then one PV twice weekly) Estradiol vaginal cream (0.1mg/gm) (2–4 g daily PV for 1–2 weeks; then 1 g PV daily or less frequently) CEE vaginal cream (0.625 mg/gm) (0.5–2 g daily PV; consider 3 weeks on, 1 week off; may be able to decrease frequency of use over time) Estradiol 2, 12.4, 24.8 mg vaginal rings (1 ring PV every 3 months)	15–60 mg 3 times daily	40–80 mg/day in one or two doses (optimal regimen from a tolerability perspective is 20 mg twice daily for 2 weeks, then titrate to 40 mg twice daily)
Kinetics	Use local route to minimize systemic BA and side effects Estradiol less likely to be absorbed; CEE 1 mg or more daily sufficiently absorbed to cause systemic side effects	Less than 1% of dose is metabolized (inactive metabolites) Primarily renal elimination of unchanged drug Would not expect hepatic impairment to have an effect (no data) Expect significant effect if renal impairment and no effect if advanced age (beyond decreased CrCl with age) (no data)	Extensive metabolism via CYP 2D6 and 1A2 (inactive metabolites) Not altered in advanced age, mild to moderate renal impairment (CrCl 31–80 mL/min [0.51–1.34 mL/s]), mild hepatic impairment (Child-Pugh A) Significantly altered in severe renal disease (CrCl less than 30 mL/min [less than 0.50 mL/s]) and moderate hepatic impairment (Child-Pugh B) Systemic exposure to duloxetine decreased by 1/3 in smokers (dose change not recommended) Multiple drug–drug interactions possible with CYP 2D6 and 1A2 substrates/inhibitors Avoid if CrCl less than 30 mL/min (0.50 mL/s) and in all patients with hepatic disease Can raise BP Do not discontinue abruptly (withdrawal syndrome) Suicide risk even in patients without psychiatric disease Avoid in uncontrolled narrow-angle glaucoma (causes mydriasis) Hepatotoxic; avoid in alcoholics even if signs/symptoms of hepatic disease are absent
Contraindications/precautions	Contraindications include known or suspected breast or endometrial cancer Abnormal genitourinary bleeding of unknown etiology Active thromboembolism (or history of TE associated with previous estrogen use)	Contraindications include hypertension, tachyarrhythmias, coronary artery disease, MI, cor pulmonale, hyperthyroidism, renal failure, narrow-angle glaucoma	

BA, bioavailability; BP, blood pressure; CEE, conjugated equine estrogens; CrCl, creatinine clearance; CYP, cytochrome P-450; DR, delayed-release; MI, myocardial infarction; PV, per vagina; TD, transdermal; TE, thromboembolism.

^aNone of these agents are FDA-approved for treatment of SUI.

use. Although still available by prescription, ephedrine is considerably more toxic than other α -adrenoceptor agonists and its use is not recommended. Although phenylephrine is now available in oral formulations, the lack of data regarding its use in SUI and the reported lack of efficacy in maximum recommended doses for rhinitis suggest that this agent should be avoided at present.

This leaves the clinician with only one practical agent to use: pseudoephedrine (Table 53-5). Side effects include hypertension, headache, dry mouth, nausea, insomnia, and restlessness.²³ **10** *The major impediment to using the α -adrenoceptor agonist class is the extensive list of contraindications (Table 53-5).* In the past, α -adrenoceptor agonist therapy was generally added to estrogen therapy

in those insufficiently improved with estrogen alone and in whom its use was not contraindicated. With the recent availability of duloxetine, treatment is now available for estrogen non- or hypo-responders whether they can or cannot take α -adrenoceptor agonists.

Duloxetine²⁴ Duloxetine is a selective serotonin-norepinephrine reuptake inhibitor similar pharmacologically to venlafaxine approved for the treatment of major depression, painful diabetic peripheral neuropathy, fibromyalgia, selected musculoskeletal pain states, and generalized anxiety disorder. Its use in SUI is off-label in the United States. Duloxetine enhances central serotonergic and adrenergic tone, which is involved in ascending and descending control of urethral smooth muscle and the internal urinary sphincter. Urethral and urinary sphincter smooth muscle tone during the filling phase are thus enhanced.^{25,26} The pharmacokinetics, contraindications/precautions, and dosing of duloxetine are illustrated in Table 53–5.²⁴ Clearly, duloxetine has demonstrated modest efficacy in SUI, and a major question is its role in SUI compared with estrogen and α -adrenoceptor agonists as well as potentially curative surgery. In the absence of head-to-head clinical trial data, this is a difficult question to answer, at least for the comparison of duloxetine to α -adrenoceptor agonists. In the recent systematic review of Shamliyan et al., duloxetine improved incontinence with an effect size of 0.11 (95% CI, 0.07 to 0.14) but failed to restore continence.¹⁰ Duloxetine is not the treatment of first choice in males with SUI after radical prostatectomy for prostate cancer, despite the availability of data from four clinical trials (one randomized and controlled, three case series).²⁷ **11** *The use of duloxetine in stress UI is complicated by (a) the potential for multiple clinically relevant drug–drug interactions with cytochrome P450 (CYP) 2D6 and 1A2 inhibitors, (b) withdrawal reactions if abruptly discontinued, (c) high rates of nausea and other side effects, (d) hepatotoxicity contraindicating its use in patients with any degree of hepatic impairment, and (e) its mild hypertensive effect. Another disconcerting finding is the high discontinuation rate when duloxetine is used in a “usual use” clinic environment (66% at 1 year, two-thirds due to adverse events and one-third due to lack of efficacy).*²⁸ Surgery (tension-free vaginal tape sling) was a more cost-effective therapy of SUI than duloxetine in women failing PFMR, due to the lower efficacy and high discontinuation rates with duloxetine.²⁹

► Overflow Incontinence Due to Bladder Underactivity⁴

12 *In overflow UI due to atonic bladder, a trial of bethanechol may be reasonable if contraindications do not exist.* There is no established effective pharmacologic therapy for OUI due to poor bladder contractility (atonic bladder). The efficacy of the cholinomimetic bethanechol (25 to 50 mg three or four times daily) is uncertain, and,

in well-done clinical trials, it has had mixed results. In addition, its cholinomimetic effect is not urospecific, and its side effects are bothersome, including muscle and abdominal cramping, hypersalivation, diarrhea, and potentially life-threatening bradycardia and bronchospasm. α -Adrenoceptor antagonists such as silodosin, prazosin, terazosin, doxazosin, tamsulosin, and alfuzosin may benefit this condition by relaxing the bladder outflow tract and hence reducing outflow resistance. If pharmacologic therapy fails, intermittent urethral catheterization by the patient or caregiver three or four times per day is recommended. Less satisfactory alternatives include indwelling urethral or suprapubic catheters or urinary diversion.

► Overflow Incontinence Due to Obstruction

13 *In overflow UI due to obstruction, the goal of treatment is to relieve the obstruction.*

► Mixed Urinary Incontinence

Mixed urinary incontinence (MUI, usually a combination of UUI plus SUI) accounts for one-third of UI cases in women. For treatment to be considered successful, both components of the problem must be improved. Often, one component will be dominant. In such patients, a reasonable approach is a combination of lifestyle modifications and PFMR (the foundation of treatment for the individual UI types) with pharmacotherapy appropriate to the dominant type of UI (anticholinergics in UUI-predominant MUI and duloxetine or, perhaps, local estrogen and oral α -adrenoceptor agonist in SUI-predominant MUI). In some patients, the less dominant form of UI may respond, but usually not to a degree that is considered adequate by the patient.

Most experts feel that SUI-predominant MUI is best treated initially using the nonpharmacologic approach just outlined plus anti-SUI surgery. Unfortunately, SUI success rates with surgery are lower in this patient subgroup compared with patients having pure SUI. In addition, the urge component may get better, stay the same, or get worse after surgery. There is no a priori way to predict the response in a given individual.^{30,31}

In UUI-predominant MUI, little improvement can be expected in the SUI symptoms with anticholinergic therapy alone. Local estrogens improve the frequency and urgency symptoms of UUI but are thought to have no effect on the nocturia and incontinence symptoms. However, the latest Cochrane review suggests that local estrogens may actually improve incontinence (relative risk, 0.74; 95% CI, 0.64 to 0.86), with reductions in the numbers of micturitions, frequency episodes, and urgency episodes per day.²² The prolongation in the interval between micturitions in pilot research in UUI patients suggests that duloxetine may help the UUI component as well. It should be emphasized that comparative trials of anticholinergic monotherapy versus anticholinergic plus

local estrogen or duloxetine combination therapies have not been conducted.^{30,31}

OUTCOME EVALUATION

- Monitor the patient for symptom relief. Have the desired outcomes jointly developed by the healthcare team and the patient/caregiver been achieved? If so, to what degree? Inspect the daily diary completed by the patient/caregiver since the last clinic visit and quantitate the clinical response (e.g., number of micturitions, number of incontinence episodes, and pad use). If a diary has not been used, ask the patient how many incontinence pads have been used and how they have been doing in terms of “accidents” since the last visit. If appropriate, administer a short-form instrument used to measure symptom impact and condition-specific quality of life and compare with previous result(s).
- Elicit adverse effects of drug therapy using a non-leading approach and ask the patient/caregiver to judge their severity and what measures, if any, the patient/caregiver used to ameliorate them. Assess adherence (ask patient/caregiver about missed doses or do a pill count if the prescription container was brought to the visit).
- The balance of clinical response and tolerability will dictate the approach to adjusting drug dosage. Potential approaches include dosage increase, maintenance, or decrease. If adverse effects are quite bothersome to the patient and patient safety and/or adherence are compromised, stop, or taper, the offender and initiate another drug option.

PEDIATRIC ENURESIS

INTRODUCTION

Pediatric enuresis is not a disease but a symptom, which can present alone or at the same time as other disorders, in children and adolescents. It is defined as the repeated voiding of urine into bed or clothes at least twice a week for at least 3 consecutive months in a child at least 5 years old (per the *Diagnostic and Statistical Manual of Mental Disorders, 4th ed., Text Revision*).^{32,33} Enuresis can still be present even if the above frequency and duration parameters are not met, provided that associated distress or functional impairment exists. The terms “nocturnal” and “diurnal” refer to periods during sleep and while awake, respectively. Primary enuresis refers to a process wherein the patient has never been consistently dry throughout the night. Secondary enuresis refers to a process wherein the patient has resumed wetting after a period of dryness of at least 6 months in duration. Lastly, monosymptomatic and polysymptomatic enuresis should be differentiated. Monosymptomatic enuresis refers

Patient Care and Monitoring: UI

1. Identify urinary symptoms and assess their severity. Identify exacerbating factors and complications that may be related to UI. Based on patient factors, determine whether patient-directed therapy and/or triage to physician are required.
2. Review concurrent medical conditions and assess whether or not urinary symptoms could be disease-related.
3. Obtain a thorough medication history, including use of prescription, nonprescription, and complementary/alternative drug products. Determine which, if any, treatments in the past had been helpful as judged by the patient. Assess whether or not urinary symptoms could be related to drug use.
4. Educate the patient on lifestyle modifications that may improve symptoms: smoking cessation (for patients with cough-induced SUI), weight reduction (for those patients with SUI and UUI), prevention of constipation in patients at risk, caffeine reduction, and modification of diet and fluid intake (e.g., timing and quantity of fluid intake and avoidance of foods or beverages that worsen UI).
5. Evaluate whether or not the patient is taking an appropriate regimen (drug choice, dosage) for his or her type(s) of UI. If not, why?
6. Develop a plan to assess efficacy after a minimum of 4 weeks.
7. Assess changes in quality of life (physical, psychological, social functioning, and well-being).
8. Evaluate the patient for medication adherence, drug-related adverse events, allergies, and drug interactions with concomitant medications or disease states.
9. In cognitively intact elderly patients, focus communications to elicit the preferences of the patient, not those of potential proxies.
10. Stress the importance of adherence with the prescribed regimen, including lifestyle modifications. Recommend the most “patient-friendly” treatment regimen possible.
11. Provide patient education regarding the disease state, lifestyle modifications, and drug therapy:
 - Causes of UI and suggested interventions (see 2 and 4 above)
 - Possible UI complications
 - Timing of medication intake
 - Potential adverse events (limit to most frequent and/or clinically relevant)
 - Potential drug–drug or drug–disease interactions

to wetting at nighttime with no other urinary tract and no daytime symptoms. Polysymptomatic enuresis refers to wetting at nighttime associated with other urinary tract symptoms (e.g., urge or frequency without any other urinary symptoms) and daytime symptoms as well.

Enuresis is not a benign disorder that children will just “grow out of.” Emotional and/or physical abuse of the child by adult caregivers lead to secondary problems such as chronic anxiety, low self-esteem, and delayed developmental milestones such as attending camp or going on “sleepovers” at the homes of friends. The emotional and developmental damage produced by enuresis may be more significant to the child than the enuresis itself.

EPIDEMIOLOGY AND ETIOLOGY

Five to seven million children and adolescents in the United States suffer from nocturnal enuresis. Primary enuresis is twice as common as secondary enuresis. Enuresis is twice as common in boys as compared with girls. The incidence of enuresis varies as a function of age^{32,33}:

- 40% in 3-year-olds
- 12% to 25% in 4-year-olds
- 15% to 20% in 5-year-olds
- 10% in 6-year-olds
- 6% to 10% in 7- and 8-year-olds
- 5% in 10-year-olds
- 2% to 3% in 12-year-olds
- 1% to 3% in adolescents
- 0.5% in adults

Five to ten percent of children with enuresis will suffer from the condition as adults. It may also predispose to UUI in adults. In the enuretic population, 80% to 85% are monosymptomatic, 5% to 10% are polysymptomatic, and less than 5% have an organic cause. The spontaneous annual cure rate (i.e., restoration of continence) ranges from 14% to 16% (exception: at about 4 or 5 years of age, it may be as high as 30%).

Patient Encounter 2, Part 1

A 9-year-old female is brought into your clinic, her mother seeking advice regarding her daughter's frequent (2 to 3 nights/week) bedwetting and whether there are any nonprescription therapies that would help. After questioning both individuals separately, you determine that the child has had this problem for almost a year. It began shortly after her parent's acrimonious divorce was settled.

What should you do at this point?

The etiology of enuresis is poorly understood, but there is a clear genetic link. The incidence in children from families in whom there are no members with enuresis, where one parent had enuresis as a child, and where both parents had enuresis as children are 14%, 44%, and 77%, respectively. Loci for enuresis have been located on chromosomes 12, 13, and 22. Sleep disorders are not considered major contributors, with the exception of sleep apnea. Enuresis occurs in all sleep stages in proportion to the time spent in each stage. However, a small proportion of individuals are not aroused from sleep by bladder distention and have uninhibited bladder contractions preceding enuresis.

PATHOPHYSIOLOGY

- There are potentially treatable organic causes of enuresis, as outlined in [Table 53–6](#). However, the vast majority of children with enuresis have normal urodynamics, including nocturnal bladder capacity. Functional bladder capacity can be estimated using the formula: age in years +2 equals the ounces of capacity. In some children, there appears to be a relationship between developmental immaturity (motor and language milestones) and enuresis, but the mechanism is unknown. There is evidence that affected individuals have an attenuated vasopressin circadian rhythm (females more so than males) with lower vasopressin plasma concentrations.³⁴ Other contributors include detrusor overactivity at night and an increased threshold for arousal. Drugs like lithium, clozapine, risperidone, valproic acid, selective serotonin reuptake inhibitors, and theophylline can rarely cause and aggravate enuresis. However, caffeine ingestion does not correlate with enuresis ($r = 0.05$, $p = \text{NS}$).³⁵ Psychological factors are clearly contributory in only a minority of individuals. The most frequent example of this is secondary enuresis precipitated by a stressor such as divorce, school trauma, sexual abuse, or hospitalization. In rare cases, the family may be so dysfunctional that the child has never been properly toilet-trained.

Table 53–6

Major Potentially Treatable Organic Causes of Enuresis

Potentially Treatable by Surgery

- Ectopic ureter
- Lower UTI (correct congenital anomalies)
- Neurogenic bladder
- Bladder calculus (stone) or foreign body
- Obstructive sleep apnea

Potentially Treatable by Drugs

- UTI
- Diabetes mellitus
- Diabetes insipidus
- Fecal impaction
- Constipation

UTI, urinary tract infection.

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical Presentation and Diagnosis: Pediatric Enuresis

Proper assessment of the child or adolescent with enuresis should explore every aspect of UI, especially the genitourinary and nervous systems. The minimum assessment should include^{41,42,50}:

- Interview of child and parent(s), being sensitive to the emotional consequences of the enuresis.
- Direct physical examination, looking for enlarged adenoids/tonsils, bladder distention, fecal impaction, abnormal genitalia, spinal cord anomalies, and abnormal neurologic signs (look for an organic cause amenable to surgery or drugs; see **Table 53–6**).
- Obtain a urinalysis for sugar, protein, WBC, or leukocyte esterase (consider a urine culture at the same time if urinalysis is positive or has symptoms consistent with urinary tract infection).
- A 7 or more day diary of wet and dry nights prior to intervention is useful in that it can be used to monitor the response to treatment. A first-morning urine specific gravity may help to predict response to DDAVP therapy. Polysymptomatic presentation may require a more elaborate workup, including voiding cystourethrogram, renal and/or bladder ultrasound, urodynamics, and sleep studies.

Patient Encounter 2, Part 2: Medical History, Physical Examination, Diagnostic Tests, and Creating a Care Plan

PMH: Unremarkable pregnancy/delivery. All developmental milestones within normal limits. Three episodes of AOM treated with no sequelae. Current on all immunizations

FH, SH: Acrimonious divorce of parents 1 year prior, o/w noncontributory

Meds: None

ROS: (+) nocturnal incontinence 2 or 3 nights/week; (–) vaginal itching, UTIs, urgency, frequency, dysuria, lower abdominal fullness

PE:

VS: BP 90/65 mm Hg, P 72 beats/min, RR 16 breaths/min, T 37.0°C (98.6°F)

Resp: WNL

CV: WNL

Abd: Soft, nontender, nondistended; (+) bowel sounds; bladder not palpable

Neuro: WNL (gross sensory, motor, reflexes)

GU, Rectal: Deferred

Labs: Urinalysis WNL

Given this additional information, what is your assessment of this patient's condition?

Identify your treatment goals for this patient.

What nonpharmacologic and pharmacologic alternatives are available to the patient?

What initial treatment would you suggest?

TREATMENT

Desired Outcomes

- Restoration of continence, which may not initially be a realistic outcome
- Reduction in the number of enuresis episodes
- Prevention or amelioration of disease complications, including adverse psychological effects on the patient and caregivers or delay in developmental milestones
- Avoidance or prevention of adverse treatment effects
- Minimization of treatment costs
- Improvement in the patient's and caregivers' quality of life

General Approach to Treatment

Treatment is guided by the findings of the patient assessment. Daytime wetting, abnormal voiding such as unusual posturing, discomfort, straining, or poor stream, history of recurrent UTIs, and abnormalities of the genitalia suggest

the need for referral to a urologist. In the rare circumstance of a true psychological cause, individual and/or family psychotherapy and crisis intervention are recommended.

In the absence of an identified cause and comorbidities, monosymptomatic nocturnal enuresis is present, which can be amenable to nonpharmacologic and pharmacologic therapies (**Fig. 53–1**). Nonpharmacologic therapy should be utilized initially, provided that the patient and family are sufficiently motivated. Use of one nonpharmacologic method at a time is reasonable, provided that each is given an adequate trial period. If response is suboptimal after 6 months, a different method should be substituted or added. There is some evidence to justify combination therapy. There is no consensus as to when pharmacologic therapy should be added to or substituted for nonpharmacologic therapy. ¹⁴ *Considering that pharmacotherapy is inferior to select nonpharmacologic treatment modalities in pediatric enuresis, pharmacotherapy will be most valuable in patients who are not candidates for nonpharmacologic therapy due to nonadherence or who do not achieve the desired outcomes on nonpharmacologic therapy alone.*

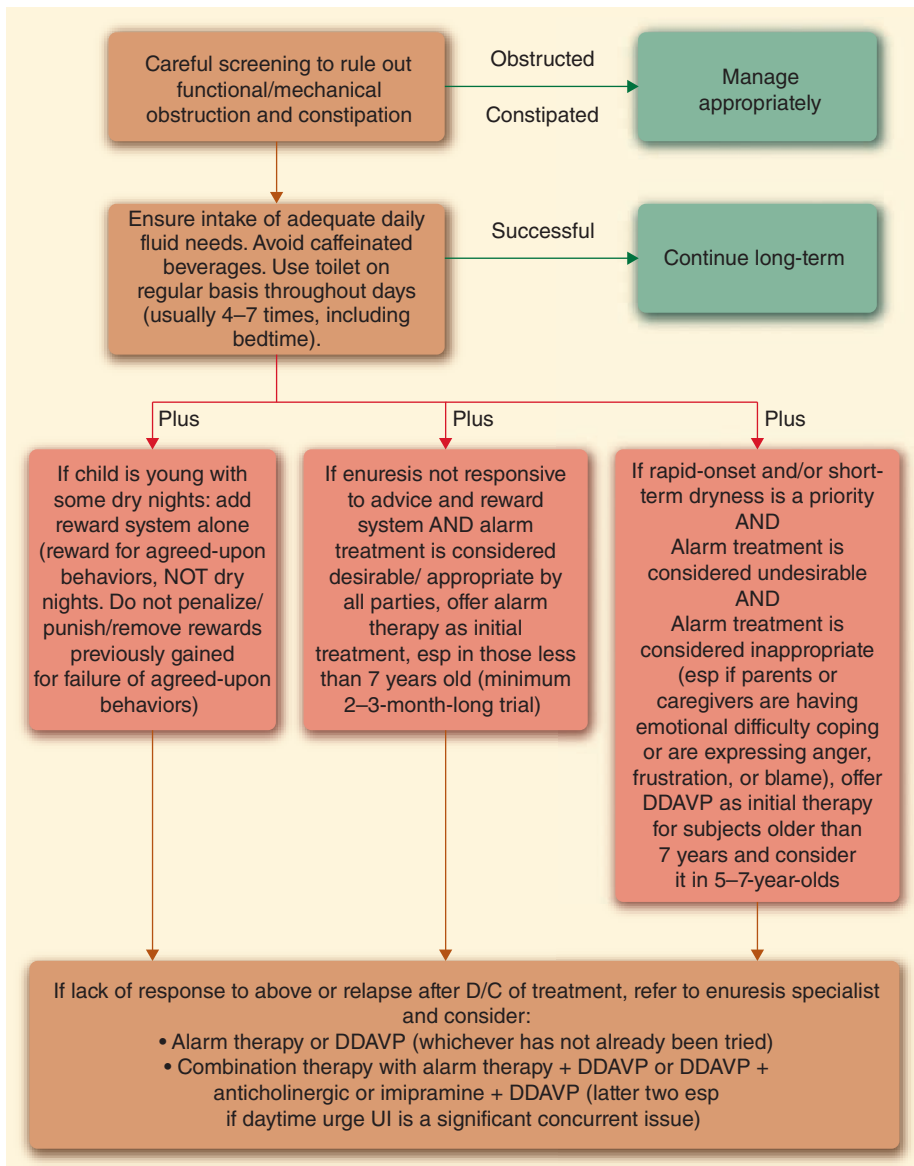

FIGURE 53-1. Enuresis treatment protocol. (DDAVP, desmopressin; HS, at bedtime; D/C, discontinuation; UI, urinary incontinence.) (Modified from Nunes VD, O’Flynn N, Evans J, Sawyer L; Guideline Development Group. Management of bedwetting in children and young people: summary of NICE guidance. *BMJ* 2010; 341:c5399.)

► Nonpharmacologic Treatment³⁶

The standard first-line therapy is supportive in nature. This involves education about the condition, demystification, and assurance that the parents do not punish the child for enuresis. Journal keeping, fluid restriction, and nighttime awakenings of the child to preempt “accidents” make for a high level of caregiver involvement. The behavioral treatments of enuresis are explained in [Table 53-7](#). Alarms, overlearning, and dry-bed training are the most complex and effective nonpharmacologic treatments available and compare favorably to pharmacologic therapy. A 3- to 6-month trial is recommended. Once dryness is achieved, relapse rates are low. In addition, adding alarm therapy to pharmacologic therapy can be an effective approach in partial or nonresponders to pharmacologic therapy alone. The converse applies as well.^{37,38}

Measures that *do not* help or are of questionable value include:

- Bladder stretching exercises (done by delaying voiding despite the urge to do so)
- Hypnotherapy
- Dietary changes
- Desensitization to allergens
- Acupuncture³⁹
- Chiropractic

► Pharmacologic Treatment

The two primary agents used to treat enuresis are DDAVP and imipramine ([Table 53-8](#)). ¹⁵ *DDAVP is the drug of choice in pediatric enuresis.* Anticholinergics have a limited role ([Table 53-8](#)). Other agents have been studied with inconclusive results.⁴⁰

Table 53-7

Behavioral Treatments for Enuresis

Lifting	Procedure wherein the caregiver takes the child to the toilet at regular intervals during the night to urinate without fully awakening him or her
Night awakening	Procedure wherein the caregiver fully awakens the child to void shortly before he or she would usually have wet the bed; once the child is consistently dry, the frequency of awakening drops or (for single awakenings) the time of awakening is gradually moved to earlier in the night (i.e., closer to bedtime) until the child is dry when awakened 1 hour after going to bed
Alarm	An alarm device and a moisture-sensitive sensor are used in combination, with the sensor being placed under the sheets, or more commonly, attached to the child's pajamas or underwear near the urethra
Overlearning	This is commenced at a minimum of 2 weeks after the alarm has rendered the child dry; the child drinks 500 mL (about 16 oz) during the hour before going to bed; alarm use is continued until he or she is dry for 14 consecutive nights with the extra fluid intake; is used to reduce relapse rates seen with alarm use alone
Dry-bed training	This begins with an intensive first night of training that involves increased fluid consumption, hourly awakenings, praise when the bed is dry at hourly awakenings, and, when the alarm goes off, a mild reprimand and cleanliness training (child changes wet clothes and bed linens, remakes the bed, resets the alarm); before going to bed and after each wetting, the child engages in 20 practice trials of appropriate toileting (i.e., positive practice): for each practice trial, the child lies in bed, counts to 50, arises and attempts to urinate in the toilet, then returns to bed; on subsequent nights, child is woken only once, usually about 3 hours after the child has gone to bed; after a dry night, the night awakening moves up 30 minutes earlier; it is discontinued when it is scheduled to occur 1 hour after bedtime; after 7 consecutive dry nights, the alarm is discontinued, but is reinstated if two episodes of wetting occur in a 1-week period

Desmopressin⁴¹ A synthetic analogue of ADH, DDAVP was first studied in enuresis in the 1970s. It was approved by the FDA in 1990 for the treatment of nocturnal enuresis in children at least 6 years of age. It decreases the number of wet nights per week by a mean of 1.34. The between-study variability in response to DDAVP is quite large, with a frequency of wetting ranging from 10% to 91% of patients. Only 25% to 30% become completely dry on the drug, whereas an additional 25% to 30% have a partial response. Response is dose-independent for the nasal formulation (20 = 40 = 60 mcg); however, 20 mcg is the minimum dose

resulting in therapeutic benefit. Response is dose-dependent for the oral formulation (e.g., the number of wet nights fell 27%, 30%, and 40% with 0.2-, 0.4-, and 0.6-mg doses, compared with 10% with placebo in one study). Benefit exists only as long as the patient takes DDAVP, with relapse rates of up to 94% after discontinuation. Insufficient data are available to judge the relative efficacies of the two formulations. DDAVP appears to work better with monosymptomatic versus polysymptomatic enuresis and in the presence of nocturnal polyuria with a normal voided volume. The oral route is generally preferred since nasal congestion and sinusitis can reduce the bioavailability (BA) of the nasal formulation. DDAVP is an ideal agent for rapid-onset, short-term use such as attendance at camp or going on a "sleepover." If the desire is for long-term therapy and if it is sufficiently effective short term, a 3- to 6-month trial is reasonable. At the end of this period, the drug should be tapered off by 0.1 mg (oral) or 10 mcg (nasal) per month. Relapse is less likely with a tapered withdrawal compared with an abrupt discontinuation. The following factors should be considered in individuals with partial responses to DDAVP: suboptimal dosing, poor adherence, poor BA (change nasal to oral preparation), and poor fluid/dietary habits (i.e., fluid restriction and high protein intake during the day and liberal salt and fluid intake after suppertime).⁴² In individuals with presumed DDAVP resistance (i.e., poor response to usual doses or deterioration after a good response has been established), oral furosemide 0.5 mg/kg in the early morning may be useful. Furosemide works by reversing the abnormal circadian rhythm of renal tubular sodium handling, which is common in such individuals.⁴³ In 12 patients with DDAVP-resistant enuresis, furosemide 0.5 mg/kg once daily in the morning was added to DDAVP therapy. In 9 of 12 (75%), enuresis events were reduced to less than one wet night per month. In the remaining three patients,

Table 53-8

Dosing of Pharmacologic Treatments of Enuresis

Desmopressin	Nasal: Start with 10 mcg 1 hour before bedtime and titrate upward in 10 mcg increments every week to a maximum of 40 mcg/day Oral: Start with 0.2 mg 1 hour before bedtime and titrate upward in 0.1 mg increments every week to a maximum of 0.6 mg/day
Imipramine	Start with 1 mg/kg/day (approximately 25 mg in 5- to 8-year-olds and 50 mg in older children and adolescents). Add desmopressin to augment efficacy. Only titrate in 0.5 mg/kg/day increments every 2 weeks to a maximum of 2.5 mg/kg/day if low-dose imipramine plus desmopressin combination is suboptimally effective
Anticholinergics	Refer to Table 53-4

although events were reduced from baseline (7 wet nights/week), they were still wet 2, 3, and 6 nights per week. Two of these three patients exhibited signs/symptoms of overactive bladder, and one of the two patients had to discontinue furosemide therapy due to the increased frequency of daytime symptoms.⁴³ With this exception, diuretics play little role in the treatment of enuresis.^{43,44} Side effects to DDAVP are minor and infrequent.⁴⁵ The most serious complication, water intoxication, is extremely uncommon when DDAVP is used to treat enuresis, with only 48 reported cases, all due to the nasal formulation.⁴⁵ However, electrolyte monitoring is recommended if intercurrent illness complicates the situation. Children should also not drink more than 8 ounces (about 240 mL) of fluid at supertime, 8 ounces (240 mL) in the evening, and none in the 2 hours prior to bed in order to reduce the risk of water intoxication.

Imipramine⁴⁶ The TCA imipramine was first used in the treatment of enuresis in the 1960s. Although trials involving other TCAs have been performed over the years, there is insufficient evidence to assess the relative performance of these agents versus imipramine, and the latter is considered the gold standard TCA in enuresis management. Its mechanism of action is unclear, although it is an anticholinergic and antispasmodic and may increase plasma ADH concentrations. About 50% of unselected patients may respond. A patient can expect approximately one less wet night per week with imipramine use. As with DDAVP, benefit only occurs as long as the drug is being taken, with relapse rates after discontinuation of therapy of up to 50%. There is no significant correlation of drug concentration with response. The usual imipramine dosage is 25 to 50 mg at bedtime, with the latter dose being used in patients greater than 9 years old. After 1 month of therapy, if some response can be discerned, DDAVP at the usual dosage should be added (but only if fluid intake can be restricted). If this combination therapy proves successful, the clinician can taper imipramine to the lowest effective dose and attempt drug holidays of 2 weeks in duration every third month to reduce the otherwise high risk of tolerance. There is a high frequency of neurologic side effects in children, including lethargy, dizziness, and headache in 5%; irritability in 11%; anxiety in 10%; and sleep disturbances in 16%.⁴⁵ GI symptoms occur in about 25% of pediatric patients.⁴⁵ It is due to these adverse event/safety issues that imipramine has been relegated to third-line treatment status.

Anticholinergics Oxybutynin and related agents (see adult UI section of this chapter) should be used only if the patient has concurrent daytime urgency or frequency. Before adding these agents, the presence of postvoid residual urine, dysfunctional micturition, and low micturition frequency must be ruled out using frequency/volume diary, uroflowmetry, and bladder ultrasound assessments. Usual initial doses of oxybutynin and tolterodine are 5 mg and 2 mg at bedtime, respectively, and these doses can be doubled, if necessary. Maximal therapeutic effects are seen within 2 months and sometimes much sooner. Major adverse

events to be avoided include urinary retention (leads to urinary tract infections) and constipation (worsens urinary tract dysfunction). Combination therapy with DDAVP may also be worthwhile in patients refractory to combinations incorporating alarm therapy, DDAVP, and/or imipramine.

Comparison of Therapies Most of the comparisons between treatments have been made by means of meta-analyses conducted by the Cochrane Enuresis Collaborative.^{40,41,46-48} Unfortunately, most enuresis treatment studies have been so poorly designed that they compromise the ability to pool studies for meta-analysis. With this in mind, the comparative efficacies of monotherapy and combination therapies using the best data available follow.

- The most effective nonpharmacologic method is the use of bed alarms. Defining success as less than 1 wet night per month, the initial success rate for alarms is 66%, with long-term success after discontinuation occurring in 45% (versus 1% with no treatment). However, this method requires highly motivated families, and the development of improvement is slow (over 4 to 12 or more weeks). Data are inadequate to compare the various commercial brands of alarms available to consumers or to compare alarms to other behavioral interventions. Supplementing this method with either overlearning or dry-bed training significantly reduces the already low relapse rates seen with alarms. Alarm therapy is also significantly more effective than DDAVP, evaluated at both the end of therapy and long-term. However, a recent trial documented the equi-effectiveness of DDAVP and alarm therapy, both as primary and secondary therapies. As documented previously, relapse rates were significantly lower with alarm therapy.⁴⁹ Similar findings are noted for the alarm-versus-imipramine comparison. There are conflicting data regarding the value of supplementing the alarm method with DDAVP.

The year 2010 saw the introduction of the revised International Children's Continence Society (ICCS) and the National Institute for Health and Clinical Excellence (NICE) (UK) guidelines for the diagnosis and management of monosymptomatic nocturnal enuresis.^{33,50} The algorithm (Fig. 53-1) within the NICE guideline is inclusive of the most potentially useful treatments and distinguishes approaches based on the child's age, maturity, and abilities; the frequency of enuresis; and the motivation and needs of the family.⁵⁰

OUTCOME EVALUATION

- Monitor the patient for symptom relief. Have the desired outcomes jointly developed by the healthcare team, the patient, and his or her parents/guardians been achieved and to what degree? Evaluate the daily diary completed by the patient or parents/guardians since the last clinic visit and quantitate the clinical response (the number of dry nights versus the total number of nights, and the frequency of nights with greater than or equal to two enuresis episodes). If a diary has not been used,

Patient Care and Monitoring: Pediatric Enuresis

1. Assess the patient's symptoms to determine whether or not patient-directed therapy is appropriate or whether or not the patient should be evaluated by a physician. Assessment includes the types and severities of symptoms and the presence or absence of exacerbating factors. Does the patient have any enuresis-related complications?
2. Review any available diagnostic data to determine disease status.
3. Obtain a thorough medication history, including use of prescription, nonprescription, and complementary and alternative drug products. Determine which, if any, treatments in the past had been helpful as judged by the patient and/or caregiver(s). Could any of the patient's current medications be contributing to enuresis?
4. Educate the patient and/or caregiver(s) on lifestyle modifications that may improve symptoms or assist the clinician in monitoring the responses to therapy, including but not limited to, fluid restriction and journal keeping. The patient and/or caregiver(s) should be referred to local enuresis clinics (if available) for training in nonpharmacologic treatments such as use of bed alarms, overlearning, and dry-bed training.
5. Is the patient taking the appropriate drug(s) for his or her enuresis? Is/are the dose(s) appropriate? If no (to either question), why?
6. Develop a plan to assess efficacy after a minimum of 3 months.
7. Assess changes in quality of life (physical, psychological, and social functioning and well-being).
8. Evaluate the patient for drug-related adverse events, allergies, and interactions (drug–drug and drug–disease).
9. Stress the importance of adherence with the prescribed regimen, including lifestyle modifications and nonpharmacologic treatment. Recommend the most “patient-friendly” treatment regimen possible.
10. Provide the patient and/or caregiver(s) with education regarding the disease state, lifestyle modifications, and drug therapy:
 - The causes of enuresis and what things the patient and/or caregiver(s) can do to reduce its frequency
 - Possible enuresis complications
 - Timing of medication intake
 - Potential adverse events (limit to most frequent and/or clinically relevant)
 - Potential drug–drug interactions

elicit the clinical response, in general terms, since the last visit.

- Elicit adverse events of therapy in a nonleading manner, and ask the patient to judge their severity. Ask the patient or parents/guardians what measures if any were used to ameliorate them. Assess adherence (ask patient or parents/guardians about missed doses; do pill counts if the prescription vial is available).
- The balance of clinical response, tolerability, and burden on the family will dictate the approach to management. As most nonpharmacologic approaches are “all or none” and drug dosages after an initial titration period are fixed, the major decision process involves either changing therapy if clinical results are inadequate or beginning or continuing tapering-off and discontinuation of therapy after success. There is no consensus on which treatment approach to withdraw first, although the ICCS recommends the nonpharmacologic (alarm) therapy first, then pharmacologic (DDAVP) therapy.³³

Abbreviations Introduced in This Chapter

ADH	Antidiuretic hormone
BA	Bioavailability
CAM	Complementary and alternative medicine
CL	Total body clearance
CrCl	Creatinine clearance
CVA	Costovertebral angle
CYP	Cytochrome P-450
DDAVP	Desmopressin
DHIC	Detrusor hyperactivity with impaired contractility
ER	Extended release
ICCS	International Children's Continence Society
IIQ	Incontinence Impact Questionnaire
IR	Immediate release
LA	Long acting
MESNA	Sodium 2-mercaptoethanesulfonate
OTC	Over the counter
OUI	Overflow urinary incontinence
PV	Per vagina
SNF	Skilled nursing facility
SR	Sustained release
SUI	Stress urinary incontinence
TCA	Tricyclic antidepressant
TD	Transdermal
UDI	Urogenital Distress Inventory
UI	Urinary incontinence
UTI	Urinary tract infection
UUI	Urge urinary incontinence

Self-assessment questions and answers are available at <http://mhpharmacotherapy.com/pp.html>.

54 Allergic and Pseudoallergic Drug Reactions

J. Russell May and Philip H. Smith

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Describe the potential incidence of allergic and pseudoallergic reactions and why it is difficult to obtain accurate numbers.
2. Describe the Gell and Coombs categories of reactions.
3. Identify the classes of drugs most commonly associated with allergic and pseudoallergic reactions.
4. Recommend specific treatment for a patient experiencing anaphylaxis.
5. Recommend an approach to drug selection in patients with multiple drug allergies.
6. Describe drug desensitization procedures for selected drugs.

KEY CONCEPTS

- 1 Approximately 6% to 10% of adverse drug reactions are allergic or immunologic; however, allergic and pseudoallergic reactions represent 24% of reported adverse drug reactions in hospitalized patients. These reactions are costly and cause considerable morbidity and mortality.
- 2 Allergy is an adverse immune response to a stimulus and has been traditionally placed in the Gell and Coombs categories: type I (immediate hypersensitivity), type II (complement-mediated antibody reactions), type III (immune complex reactions), and type IV (cellular or delayed-type hypersensitivity). Drug exposures often stimulate several or all of these types of reactions, and clinical symptoms do not always fit neatly into the categories. Only type I reactions may cause anaphylaxis.
- 3 The well-known symptoms of immediate hypersensitivity include urticaria, rhinitis, bronchoconstriction, and anaphylaxis.
- 4 Reactions that clinically resemble allergic reactions but lack an immune basis have been referred to as “pseudoallergic.” They include almost the entire range of immediate hypersensitivity clinical patterns and range in significance from the alarming but trivial anxiety or vasovagal reactions caused by local dental anesthetics to potentially fatal reactions to ionic radiocontrast media.
- 5 Penicillins and cephalosporins both have a β -lactam ring joined to an S-containing ring structure (penicillins, a thiazolidine ring; cephalosporins, a dihydrothiazine ring). Because of this structural difference, the extent of cross-allergenicity appears to be relatively low. Cross-allergenicity is less likely with newer generation cephalosporins compared with the first-generation agents.
- 6 Reactions to sulfonamide antibiotics, ranging from mild (most common) to life-threatening (rare), occur in 2% to 4% of healthy patients, with rates as high as 65% in patients with AIDS.
- 7 IgE-mediated urticarial/angioedema reactions and anaphylaxis are associated with aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs). Urticaria is the most common form of IgE-mediated reaction. However, most reactions are the result of metabolic idiosyncrasies, such as aspirin-induced respiratory disease, which may produce severe and even fatal bronchospasm. This class is second only to β -lactams in causing anaphylaxis.
- 8 Radiocontrast media may cause serious immediate pseudoallergic reactions such as urticaria/angioedema, bronchospasm, shock, and death. These reactions have been reduced with the introduction of nonionic, lower osmolality products.
- 9 Opiates (morphine, meperidine, codeine, hydrocodone, and others) stimulate mast cell release directly, resulting in pruritus and urticaria with occasional mild wheezing. Though these reactions are not allergic, many patients state that they are “allergic” to one or more of the opiates. Pretreatment with an antihistamine may reduce these reactions. These pseudoallergic reactions are rarely, if ever, life-threatening.

- 10 Drug desensitization is a potentially life-threatening procedure and requires continuous monitoring in a hospital setting, with suitable access to emergency treatment and intubation. It should only be undertaken under the direction of a physician with suitable training and experience and only when a suitable alternative is not available. In such hands, desensitization may present less risk than treatment failure with a less effective alternative medication.

INTRODUCTION

Allergic and pseudoallergic drug reactions are reported together. They are rarely confirmed by testing, making statistical analysis imprecise, with both over-reporting and under-reporting. 1 *Approximately 6% to 10% of adverse drug reactions are allergic or immunologic; however, allergic and pseudoallergic reactions represent 24% of reported adverse drug reactions in hospitalized patients.*^{1,2} *These reactions are costly and cause considerable morbidity and mortality.*

Between 10% and 20% of hospitalized patients incur drug reactions (7% in the general population), with about one-third possibly due to hypersensitivity; however, most of these reactions are not reported, especially in pediatrics.^{1,3,4} Patients experiencing an allergic drug reaction in the hospital result in increased costs of \$275 to \$600 million annually.⁵ This financial burden can occur due to several reasons, including increased indirect cost of (a) time and lost labor; (b) the use of costlier alternative medications; and (c) treatment failures. Outpatient rates are not well studied and are much harder to collect. Relying on a patient's history without an attempt to verify the relationships between drugs taken and symptoms experienced results in confusion. Healthcare professionals and patients use the term "drug allergy" in such a general way that it is not medically useful and, further, perpetuates a level of fear and concern in the public and in medical practice that is inappropriate and costly. This same confusion and anxiety sometimes leads medical personnel to ignore or forget "drug allergy" with potentially catastrophic results. Clearly, an understanding of how allergic and pseudoallergic reactions occur and how they might be managed or prevented is important to healthcare professionals and their patients.

PATHOPHYSIOLOGY

Drug allergies are immune responses resulting from different mechanisms of immunologic recognition and activation, and reactions are produced by multiple physiologic pathways. This produces a confusing spectrum of clinical pictures and complex pathophysiologic mechanisms. 2 *Allergy is an adverse immune response to a stimulus and has been traditionally placed in the Gell and Coombs categories: type I (immediate hypersensitivity), type II (complement-mediated antibody reactions), type III (immune complex reactions), and type IV (cellular or delayed-type hypersensitivity).*⁶ *Drug exposures often stimulate several or all of these types of reactions, and*

clinical symptoms do not always fit neatly into the categories. Only type I reactions may cause anaphylaxis.

The immune system uses many tools, such as blood vessel dilation or constriction, causing fluid to flood an infected area, or even producing special cells to kill bacteria or the infected cells in which they are harbored. The pattern of these responses is either inborn (the innate immune response) or learned from previous infections and injuries (the adaptive immune response). Most drug reactions involve the adaptive response and, in the sense that they cause more harm than good, are "mistakes."

T cells control these "learned" responses and decide which "tools" to use in each reaction. Sometimes they utilize several different tools at once, and several different reactions ensue, as when a person becomes sensitized to penicillin and may have not only anaphylaxis but hemolytic anemia and **serum sickness**, as well. There are different types of T cells, and they communicate either directly with other cells or by chemical messages, called "**cytokines**." The pattern of cytokines released is one way T cells may activate different responses. They are broadly called Th1 or Th2 responses, with Th1 mostly responding to infections and Th2 sometimes producing allergy or asthma. Here too, drug reactions often include both types of T-cell response.

Immunologic drug reactions generally represent T-cell activation. The type of T cell activated determines the type of reaction to the drug. Th1 cytokines (largely interferon- γ) produce many more chronic, and at times serious, skin reactions and destruction of cells, as in hemolytic anemia or thrombocytopenia. Sometimes these responses can damage tissues, such as the kidney (interstitial nephritis). Th2 cytokines tend to cause any antibodies produced to be switched to the immune globulin E (IgE) or allergic antibody class, which can result in hives or anaphylaxis. Other classes of antibodies are also often made, and these can produce serum sickness or indirect destruction of cells (thrombocytopenia). T-cell receptors respond to one peptide only, which makes each activation response exclusive to the original stimulus (drug) or to chemical structures with very close resemblance.

Antigens

Antigen-presenting cells recognize complex, three-dimensional protein molecules of at least 1,000 Daltons (Da) in size. Most drugs are much smaller than this and cannot be recognized on their own. Only proteins such as insulin, exogenous **sera**, or monoclonal antibodies are identified and their peptides presented directly to T cells.

Smaller drugs that are chemically reactive may bond covalently to body proteins, altering them and forming large enough molecules for antigen-presenting cells to recognize. This process is called **haptenation**, and the smaller reactive molecule, a hapten. Some other drugs are inert until they are partially metabolized (prohaptens), and it is their breakdown products that bind native proteins to serve as antigens. Metabolic variations in some patients may produce more active haptens or

Table 54-1

Reaction Classification, Clinical Symptoms, and Potential Causative Drugs^{7,8}

Gell and Coombs Classification	Immune Response	Clinical Symptoms	Potential Causative Drugs ^a
Type I	IgE	Anaphylaxis, urticaria	β -Lactam antibiotics penicillins (primarily), cephalosporins, carbapenems Non- β -lactam antibiotics: sulfonamides, vancomycin Others: insulins, heparin
Type II	IgG	Hemolytic anemia thrombocytopenia	Quinidine, methyldopa penicillins, heparin
Type III	IgG, IgM	Vasculitis, serum sickness lupus	Penicillins, sulfonamides, radiocontrast agents, phenytoin
Type IV			β -Lactam antibiotics, sulfonamides, phenytoin See text for examples
IVa	Th1 cytokines	Tuberculin reaction eczema	
IVb ^b	Th2 cytokines	Maculopapular and bullous exanthema	
IVc ^b	Cytotoxic T cells (CD4 and CD8)	Same as IVb, also eczema, pustular exanthema	
IVd	T cells (IL-8)	Pustular exanthema	

^aThese drugs represent a list of causative agents. Many drugs can cause these reactions.

^bIVb and IVc reactions may combine to produce erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis.

prevent these fragments from being detoxified, causing them to accumulate and make binding proteins and allergic sensitization more likely.

Gell and Coombs

Type I reactions occur when the drug or its bound hapten incites an IgE antibody response. IgE binds to high-affinity receptors on mast cells and basophils. **3** When the original antigen cross-links cell-bound IgE, the effector cell releases enormous amounts of preformed mediators, producing the well-known symptoms of immediate hypersensitivity: **urticaria**, rhinitis, bronchoconstriction, and anaphylaxis.

Type II reactions are produced by IgG (or IgM) antibody. The drug or hapten that elicited the antibody response binds to target cells. When antibody attaches to a cell-bound drug, complement activation destroys the cell. **Blood dyscrasias** like thrombocytopenia or hemolytic anemia are the most common examples of type II reactions.

Type III or immune complex reactions also involve IgG antibody production. In this case, when the concentration of the sensitizing drug or hapten is in slight excess to the antibody, the two combine in the serum, producing lattices of antigen-antibody complexes. These complexes are deposited, particularly in vessel walls. Deposits of drug-antibody complexes activate complement, causing vasculitis. The classic forms of type III reaction are serum sickness (usually including arthralgias, fever, malaise, and urticaria that develop 7 to 14 days after exposure to the causative antigen) and the localized **Arthus reaction**, a local inflammatory response due to deposition of immune complexes in tissues.

Type IV reactions are mediated by T cells themselves. “Delayed-type hypersensitivity” reactions from positive tuberculin tests to allergic contact dermatitis are typical

type IV reactions, but understanding T-cell function allows us to further define this category, as shown in **Table 54-1**.^{7,8}

Pseudoallergic Drug Reactions

4 Reactions that clinically resemble allergic reactions but lack an immune basis have been referred to as “pseudoallergic.” They include almost the entire range of immediate hypersensitivity clinical patterns. Pseudoallergic reactions range in significance from the alarming but trivial anxiety or vasovagal reactions caused by local dental anesthetics to sometimes fatal reactions to ionic radiocontrast media. However, cytotoxic reactions, serum sickness, and severe dermatologic reactions (e.g., **Stevens-Johnson syndrome** and **toxic epidermal necrolysis**) are immunologic processes that are not likely to be mimicked by nonimmune processes seen with pseudoallergic reactions.

Pseudoallergic reactions are important in patient counseling and management considerations. The reactions represent common biological functions (direct histamine [H] release by vancomycin, opiates), whereas immunologic (allergic) reactions are based on the structure of the drug. Even a mild drug allergy may carry significant potential for anaphylaxis on readministration. In contrast, pseudoallergic reactions tend to remain constant whether mild or severe and are dose-related.

Pseudoallergic reactions, then, are reactions where the tools of the immune system are used in exactly the same way, but without the “learning” response by T cells and generally without the much greater danger that true immunologic sensitization implies. Pseudoallergic reactions may be thought of as a subtype of idiopathic reactions, rather than an activation of the patient’s immune system. The pathophysiology of pseudoallergic reactions is generally unknown, but indicators of immune activation are not seen when they occur.

Clinical Presentation and Diagnosis of Allergic and Pseudoallergic Drug Reactions

The clinical presentation of a patient experiencing an allergic reaction varies greatly. The primary reactions are as follows:

Anaphylaxis

Anaphylaxis is an acute life-threatening allergic reaction. Signs and symptoms involve the skin (e.g., pruritus, urticaria), respiratory tract (e.g., dyspnea, wheezing), gastrointestinal tract (e.g., nausea, cramping), and cardiovascular system (e.g., hypotension, tachycardia). Onset is usually within 30 minutes, but can be as long as 2 hours. Treatment must begin immediately. Anaphylaxis may recur 6 to 8 hours after exposure, so patients experiencing anaphylaxis should be observed for at least 12 hours.

Cytotoxic Reactions

These reactions usually take the form of hemolytic anemia, thrombocytopenia, granulocytopenia, or agranulocytosis.

Immune Complex Reactions

These reactions usually involve a serum sickness-like syndrome (e.g., arthralgias, fever, malaise, and urticaria) that usually develops 7 to 14 days after exposure to the causative antigen.

Dermatologic Reactions

Rashes may range from mild to life-threatening.

- *Urticaria*: These are itchy, raised, swollen areas on the skin. Also known as hives.
- *Maculopapular rash*: A rash that contains both macules and papules. A macule is a flat, discolored area of the skin, and a papule is a small raised bump. A maculopapular rash is usually a large area that is red and has small bumps.
- *Erythema multiforme*: A rash characterized by papular (small raised bump) or vesicular lesions (blisters) and reddening or discoloration of the skin often in concentric zones about the lesion.
- *Stevens-Johnson syndrome*: A severe expression of **erythema multiforme** (also known as erythema multiforme major). It typically involves the skin and the mucous membranes with the potential for severe morbidity and even death.
- *Toxic epidermal necrolysis*: A life-threatening skin disorder characterized by blistering and peeling of the top layer of skin.

PROBLEMATIC DRUG CLASSES AND TREATMENT OPTIONS

The first priority is to avoid doing serious harm by administering a drug that the patient cannot tolerate. We can generally establish the likelihood of a relationship between the suspected drug and the observed reaction, and also whether it is likely to be an immune or idiopathic reaction by examining the time course and specific signs and symptoms as precisely and objectively as possible. Reevaluating the patient's physical findings and laboratory values (taking into account preexisting diseases) allows further clarification of the need to change treatments and to add therapy for the reaction itself.

Reviewing the original indications for the treatment that caused the reaction is important. For example, in many respiratory illnesses, a prescribed antibiotic may be unnecessary. If the disease persists and indications for some treatment are established, alternatives must be sought, either by adjusting dose or administration rate, finding effective and unrelated alternative medication, or desensitizing the patient to the original drug.

When adverse drug reactions occur, the healthcare provider should carefully describe all aspects of the reaction and assess the potential for it to reoccur. Many patients have frightening associations of the term "allergy" with severe and unpredictable anaphylaxis. It is difficult to undo fears created by injudiciously labeling a patient as allergic in the medical record. Labeling a person "allergic" may hamper future medical care, as patients may refuse treatment or fail to adhere to medication regimens. If the original reaction is

clearly documented, healthcare providers can appropriately counsel patients about any true dangers.

Anaphylaxis is a true medical emergency and must be treated promptly. Otherwise, managing allergic reactions begins with stopping the offending agent. Understanding the allergic reaction and potential for **cross-allergenicity** between similar drugs will assist in selecting an alternative medication. Desensitization is a management option if the patient truly needs the medication and alternative drugs are not available. Although any drug may cause an allergic or pseudoallergic reaction, several drugs and drug classes are strongly associated with such reactions (**Table 54-2**). These classes will be discussed individually.

β -Lactam Antibiotics

Hypersensitivity reactions with β -lactam antibiotics, especially penicillin, may encompass any of the type I through IV Gell-Coombs classifications. The most common reactions are **maculopapular** and urticarial eruptions.⁹ Although rare (lesser than 0.05%), anaphylactic reactions to penicillins cause the greatest concern, as they are responsible for the majority of all drug-induced anaphylaxis deaths in patients, accounting for 75% of all anaphylaxis cases in the United States.^{7,10}

- The treatment of anaphylaxis is given in **Table 54-3**.^{11,12}

The healthcare professional is faced with a difficult task when approaching a patient who claims a history of penicillin allergy. Although as many as 12% of hospital patients state they have an allergy to penicillin, about 90% will have negative skin tests.¹³ **Table 54-4** shows the traditional protocol for penicillin skin testing.¹⁴ This test only evaluates

Table 54-2

Problematic Drug Classes

β -Lactam antibiotics
 Sulfonamide antibiotics
 Aspirin and nonsteroidal anti-inflammatory drugs
 Radiocontrast media
 Opiates
 Cancer chemotherapy
 Insulin
 Anticonvulsants

IgE-mediated reactions. A patient with a history of other serious reactions such as erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis should not receive penicillins and should not be tested.

5 Penicillins and cephalosporins both have a β -lactam ring joined to an S-containing ring structure (penicillins: a thiazolidine

ring, cephalosporins: a dihydrothiazine ring). The extent of cross-allergenicity appears to be relatively low, with an estimate of approximately 4%.¹⁵ Cross-allergenicity is less likely with newer generation cephalosporins compared with the first-generation agents. Anaphylactic reactions to cephalosporins are rare, with a predicted range of 0.0001% to 0.1%. Minor skin reactions including urticaria, **exanthem**, and pruritus are the most common allergic reactions with cephalosporins, showing severe reactions less often than with penicillins.¹⁶

For other β -lactam agents, the recommendations are fairly straightforward.¹¹ Carbapenems should be considered cross-reactive with penicillins. Monobactams (e.g., aztreonam) do not cross-react with any β -lactam drugs except ceftazidime because they share an identical R-group side chain.

Sulfonamide Antibiotics

Sulfonamides are compounds that contain a sulfonamide moiety (i.e., SO_2NH_2). This group includes sulfonamide antibiotics (sulfonarylaminines), and nonarylamine

Table 54-3

Pharmacologic Management of Anaphylactic Reactions**Immediate Intervention**

Epinephrine 1:1000 (1 mg/mL)
 Adults: Give 0.2–0.5 mg intramuscularly (IM), repeat every 5 minutes as needed
 Pediatrics: 0.01 mg/kg (maximum 0.3 mg) IM, repeat every 5–15 minutes as needed

Subsequent Interventions

Normal saline infusion
 Adults: 1–2 L at a rate of 5–10 mL/kg in the first 5 minutes, followed by slow infusion
 Pediatrics: 20 mL/kg bolus repeat to a total maximum of 60 mL/kg as needed for hypertension

Epinephrine infusion

If patient is NOT responding to epinephrine injections and volume resuscitation:

Adults: epinephrine infusion (1 mg in 250 mL D5W): 1–4 mcg/min, titrating based on clinical response or side effects
 Pediatrics: epinephrine 1:10,000 (0.1 mg/mL): 0.01 mg/kg (up to 0.3 mg) over several minutes

Other Considerations After Epinephrine and Fluids

Diphenhydramine
 Adults: 25–50 mg IV or IM
 Pediatrics: 1–1.25 mg/kg (maximum of 300 mg/24 hours)
 Ranitidine
 Adults: 50 mg in D5W 20 mL IV over 5 minutes
 Pediatrics: 1 mg/kg (up to 50 mg) in D5W 20 mL IV over 5 minutes
 Inhaled β -agonist (bronchospasm resistant to epinephrine)
 2–5 mg in 3 mL of normal saline, nebulized, repeat as needed
 Dopamine (hypotension refractory to fluids and epinephrine)
 2–20 mcg/kg/min titrated to maintain systolic blood pressure greater than 90 mm Hg
 Hydrocortisone (severe or prolonged anaphylaxis)
 Adults: 250 mg IV (prednisone 20 mg can be given orally in mild cases)
 Pediatrics: 2.5–10 mg/kg/24 hours

D5W, dextrose 5% in water.

Adapted from Refs. 11 and 12.

Table 54-4

Procedure for Performing Penicillin Skin Testing**A. Percutaneous (prick) skin testing**

Materials	Volume
Pre-Pen 6 x 10 ⁶ M	1 drop
Penicillin G 10,000 Units/mL	1 drop
β -Lactam drug 3 mg/mL	1 drop
0.03% albumin-saline control	1 drop
Histamine control (1 mg/mL)	1 drop

- Place a drop of each test material on the volar surface of the forearm.
- Prick the skin with a sharp needle inserted through the drop at a 45° angle, gently tenting the skin in an upward motion.
- Interpret skin responses after 15 minutes.
- A wheal at least 2 x 2 mm with erythema is considered positive.
- If the prick test is nonreactive, proceed to the intradermal test.
- If the histamine control is nonreactive, the test is considered uninterpretable.

B. Intradermal skin testing

Materials	Volume
Pre-Pen 6 x 10 ⁶ M	0.02 mL
Penicillin G 10,000 Units/mL	0.02 mL
β -Lactam drug 3 mg/mL	0.02 mL
0.03% albumin-saline control	0.02 mL
Histamine control (0.1 mg/mL)	0.02 mL

- Inject 0.02 to 0.03 mL of each test material intradermally (amount sufficient to produce a small bleb).
 - Interpret skin responses after 15 minutes.
 - A wheal at least 6 x 6 mm with erythema and at least 3 mm greater than the negative control is considered positive.
 - If the histamine control is non-reactive, the test is considered uninterpretable.
- Antihistamines may blunt the response and cause false-negative reactions.**

Adapted from Sullivan TJ. Current Therapy in Allergy. St. Louis, MO: Mosby; 1985:57–61.

Patient Encounter 1

A 10-year-old boy (38 kg [84 lb]) is admitted to the pediatric intensive care unit with an acute exacerbation of chronic bronchitis. The parents are questioned about potential allergies, but they are too upset about their child's condition to remember anything other than a mild rash with an antibiotic about 2 months ago. Ampicillin/sulbactam injection is prescribed. As the drug is infusing, the child complains of difficulty swallowing. Within seconds, he is gasping for air.

Which of the four types of allergic reactions is the child most likely having?

What treatment (dose and route) would be indicated first?

If there is no response after the first dose, how soon can a second dose be administered?

What are the subsequent interventions for this child's reaction?

sulfonamides such as furosemide, thiazide diuretics, sulfonyleureas, and celecoxib. The sulfonamide antibiotics contain an aromatic amine at the N4 position and a substituted ring at the N1 position. Most allergists agree that most, but not all patients allergic to antimicrobial sulfonamides will tolerate nonarylamine sulfonamides.¹⁷ Predisposition to allergic reactions is a more likely reason than cross-reactivity between these differing molecules.¹⁸ The term “sulfa allergy” should not be used as it can be confusing to patients and healthcare providers. The sulfonamide antibiotics are significant because they account for the largest percentage of antibiotic-induced toxic epidermal necrolysis and Stevens-Johnson syndrome cases.¹⁹

6 *Reactions to sulfonamide antibiotics, ranging from mild (most common) to life-threatening (rare), occur in 2% to 4% of healthy patients, with rates as high as 65% in patients with acquired immunodeficiency syndrome (AIDS).*²⁰ Anaphylaxis or **anaphylactoid** reactions almost always occur within 30 minutes but may be up to 90 minutes after exposure, most commonly after parenteral administration. Isolated **angioedema** or urticaria can occur within minutes to days. Serum sickness occurs within 1 to 2 weeks. Fixed drug eruptions (lesions) occur within a half hour to 8 hours. These lesions resolve within 2 to 3 weeks after drug removal. The more severe conditions of Stevens-Johnson syndrome and toxic epidermal necrolysis tend to occur 1 to 2 weeks after initiation of therapy. Because trimethoprim-sulfamethoxazole is the drug of choice for patients with *Pneumocystis jirovecii* pneumonia, desensitization may be necessary. A history of Stevens-Johnson syndrome or toxic epidermal necrolysis is an absolute contraindication for the desensitization procedure.

Patients with Multiple Antibiotic Allergies

Dealing with patients who claim to have multiple antibiotic allergies can be challenging. Combining knowledge of cross-allergenicity with a careful assessment of patient history may

Table 54–5

Multiple Antibiotic Allergies: Obtaining Background Information

For **each** antibiotic to which the patient claims to be allergic, gather the following information:

- What type of infection was being treated?
- Have you ever received the drug without experiencing a reaction?
- How many times have you received the drug and experienced a reaction?
- What was the drug dose and route of administration with the last reaction?
- How many doses did you take before the onset of the last reaction?
- How many doses did you take after the last reaction?
- Can you describe the adverse reaction?
- What was the duration of the reaction?
- What treatment was given for the reaction?
- Was there any permanent damage?

For **each** antibiotic that the patient has received and does not claim allergy, gather the following information:

- What was the last type of infection being treated?
- What was the drug dose and route of administration?
- Have you received this drug more than once without reactions?

Other information to be gathered:

- Have you had adverse reactions to any other drugs? If so, give dates and describe the reaction.
- Document any risk factors for allergic reactions such as chronic urticaria, liver or kidney disease, HIV (human immunodeficiency virus), or any other immune deficiencies.

Adapted from Macy E. Multiple antibiotic allergy syndrome. *Immunol Allergy Clin North Am* 2004;24:533–543.

be helpful in designing an antimicrobial regimen. **Table 54–5** outlines a series of questions that can be useful in developing an effective treatment plan.²¹ If available and indicated, skin testing may be useful to complete the puzzle. Often with careful assessment, an antibiotic of choice may be used when the patient's initial history would have ruled it out. Based on data gathered, the patient's record should reflect antibiotics safe to use if needed, antibiotics to be avoided, and antibiotics that can be used only after desensitization. Although Table 54–5 was designed with antibiotics in mind, it can be modified for multiple allergy situations.

Aspirin and Nonsteroidal Anti-Inflammatory Drugs

Aspirin and the nonsteroidal anti-inflammatory drugs (NSAIDs) can induce allergic and pseudoallergic reactions. Because these drugs are so widely used, with much over-the-counter use, the healthcare professional must have a basic understanding of the types of reactions that can occur and how to prevent them. Three types of reactions occur: bronchospasm with rhinoconjunctivitis, urticaria/angioedema, and anaphylaxis. Remember that patients with gastric discomfort or bruising from these agents may describe themselves as being allergic; however, these are not allergic or pseudoallergic reactions.

Patient Encounter 2

A 47-year-old woman is admitted to the hospital for treatment of community-acquired pneumonia. She is a nonsmoker, has no history of cardiopulmonary disease, and is otherwise healthy. When asked about drug allergies, she states she is allergic to penicillin, one of the “floxacin” drugs, vancomycin, and erythromycin. During your interview with the patient, the reactions are described as follows:

Penicillin: When receiving penicillin as a child, she developed “hives.”

Quinolone: When receiving a drug that ended in “floxacin” for a urinary tract infection 2 years ago, she was treated in the emergency room for severe itching, shortness of breath, and nausea.

Vancomycin: When receiving vancomycin for a skin infection last year, she got a red rash on her upper body the first two times she received the drug. The nurses told her they “adjusted her dose,” and she did not experience the reaction again but still believes she is allergic to it.

Erythromycin: She develops an upset stomach every time she takes a dose of erythromycin. She received it 10 years ago for bronchitis.

The physician asks you what can be used for empiric therapy pending culture results. Your hospital’s treatment guidelines for community-acquired pneumonia in an otherwise healthy individual include the following choices: ceftriaxone plus azithromycin or levofloxacin (monotherapy) or ampicillin/sulbactam plus azithromycin.

Are any of the hospital’s recommended regimens acceptable for this patient? If yes, which one should be recommended?

Describe your justification for your recommendation.

Two specific conditions—*aspirin-exacerbated respiratory disease (AERD)* and *chronic idiopathic urticaria*—are important because they are commonly seen. AERD may include asthma, rhinitis with nasal polyps, and aspirin sensitivity.²² Upon exposure to aspirin or an NSAID, patients with AERD experience rhinorrhea, nasal congestion, conjunctivitis, laryngospasm, and asthma. Chronic idiopathic urticaria may also be seen with aspirin or NSAID-induced pseudoallergic reactions.²³ Patients with a history of chronic idiopathic urticaria are likely to see a flare of urticaria if aspirin or a cyclooxygenase (COX)-1 inhibiting NSAID is given. Cross-reactions between aspirin and older COX-1 inhibiting NSAIDs exist in patients with AERD and chronic idiopathic urticaria. Even though product warning labels for COX-2 inhibitors state that these agents should not be used in these two conditions, there are no reports of cross-reactivity in AERD and only rare reports in patients with chronic idiopathic urticaria.²⁴

7 *IgE-mediated urticarial/angioedema reactions and anaphylaxis are associated with aspirin and NSAIDs. Urticaria is the most common form of IgE-mediated reaction. However, most reactions are the result of metabolic idiosyncrasies, such as aspirin-induced respiratory disease which may produce severe and even fatal bronchospasm. This class is second only to β -lactams in causing anaphylaxis. Most reactions in this class are due to a complex metabolic pattern, which causes increasingly recurrent and severe nasal polyps and often refractory asthma. The metabolic problem is constant once it emerges, accounting for the persistence and difficulty of these clinical problems. The metabolic problem is also capable of causing severe, sometimes fatal, acute reactions to aspirin or many if not all other NSAIDs. Rare reports of non-cross-reactive severe reactions suggest possible specific IgE-mediated reactions to individual NSAIDs, and there are some occurrences of urticaria related to NSAIDs as well. Because aspirin therapy is highly beneficial in primary and secondary prevention in coronary artery disease (CAD), aspirin desensitization should be considered in patients who have had reactions to aspirin. Desensitization is contraindicated in patients who have experienced aspirin-induced anaphylactoid reaction, hypotension, tachypnea, or altered consciousness. Alternate agents must be used. A comprehensive approach to aspirin-sensitive patients with CAD has been described.²⁵*

Radiocontrast Media

8 *Radiocontrast media may cause serious, immediate pseudoallergic reactions such as urticaria/angioedema, bronchospasm, shock, and death. These reactions have been reduced with the introduction of nonionic, lower osmolality products. Because a small percentage of patients who have reacted previously to radiocontrast media will react if re-exposed, several steps (listed below) should be taken to prevent reactions in these patients. These steps should also be followed in patients with high-risk factors: asthmatic patients, patients on β -blockers, and patients with cardiovascular disease.⁵ The steps are as follows:*

- Determine whether the study is essential.
- Be sure the patient understands the risks.
- Ensure adequate hydration.
- Use nonionic, lower osmolar agents.
- Pretreat with prednisone 50 mg orally 13, 7, and 1 hour(s) before the procedure and diphenhydramine 50 mg orally 1 hour before the procedure.

Delayed reactions with these agents occur in 1% to 3% of patients.²⁶ Although reactions are occasionally severe, most are mild and manifest as maculopapular rashes, fixed eruptions, erythema multiforme, and urticarial eruptions.

Opiates

9 *Opiates (morphine, meperidine, codeine, hydrocodone, and others) stimulate mast cell release directly, resulting in*

Patient Encounter 3

A 27-year-old man presents to the emergency room with severe abdominal pain. He states his pain score is 10 out of 10. After relief of his pain with hydromorphone, you are able to obtain the following information: He has no known drug allergies. His home medications include loratadine 10 mg daily, ibuprofen 400 mg three times daily as needed for tennis elbow, albuterol inhaler 4 puffs as needed for wheezing, and flunisolide inhaler 2 puffs twice daily. The patient is being sent to radiology for a computed tomography (CT) scan.

What are your recommendations for radiocontrast media?

pruritus and urticaria with occasional mild wheezing. Though these reactions are not allergic, many patients state that they are “allergic” to one or more of the opiates. Pretreatment with an antihistamine may reduce these reactions. These pseudoallergic reactions are rarely, if ever, life-threatening.⁷ Avoiding other mast cell degranulating medications while patients require opiates also reduces the chances of frightening and uncomfortable reactions. Patients may state they are allergic if they have experienced gastrointestinal upset, a common side effect to opiates, with previous exposures. Obtaining a thorough history from the patient will prove useful. If a more serious reaction has occurred, a nonnarcotic analgesic should be selected.

Cancer Chemotherapy

Hypersensitivity reactions have occurred with all chemotherapy agents. Reactions are most common with the taxanes, platinum compounds, asparaginases, and epipodophyllotoxins.⁹ Reactions range from mild (flushing and rashes) to severe (dyspnea, bronchospasm, urticaria, and hypotension). IgE-mediated type I reactions are the most common. To reduce the risk, patients are routinely premedicated with corticosteroids and H₁ and H₂ receptor antagonists. The platinum compounds have produced anemia, probably via a cytotoxic immunologic mechanism.

Insulin

Insulin is one of a very few medications that is itself a whole protein and can induce IgE sensitivity directly. This can result in anaphylaxis. Adverse reactions to insulin also include erythema, pruritus, and indurations, which are usually transient and may be injection site-related.²⁷ For the sensitivity reactions, treatment options include dexamethasone or desensitization. If the reaction is injection site-related, a change in delivery system (i.e., insulin pump or inhaled insulin) may be helpful.

Anticonvulsants

A wide range of hypersensitivity reactions, ranging from mild maculopapular skin eruptions to severe life-threatening

reactions, can occur with anticonvulsants.²⁸ Aromatic anticonvulsants, primarily phenytoin, carbamazepine, and phenobarbital as well as some of the newer agents (lamotrigine, oxcarbazepine, felbamate, and zonisamide) can cause a life-threatening syndrome with symptoms including fever, a maculopapular rash, and evidence of systemic organ involvement. The rash may be mild at first but can progress to **exfoliative dermatitis**, erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis. This syndrome is known as anticonvulsant hypersensitivity syndrome (AHS) or drug rash with eosinophilia and systemic symptoms (DRESS). The causative agent should be withdrawn immediately. Cross-sensitivity among aromatic anticonvulsant drugs ranges between 40% and 80%.²⁹ If a patient is hypersensitive to an aromatic anticonvulsant, a nonaromatic agent (ethosuximide, gabapentin, levetiracetam, topiramate, and valproic acid) or the benzodiazepines may be useful.²⁹

Drug Desensitization

Drug desensitization may be undertaken for some drugs in the absence of useful alternative medications. The risk of severe systemic reactions and anaphylaxis associated with desensitization must be compared with the risk of not treating the patient. Thorough evaluation should establish that the drug probably caused the reaction by an allergic mechanism. Because of the dangers involved with drug desensitization, an expert review of the patient's indication for the drug should be conducted. Consider the possibility that the patient does not really need the drug.

10 *Desensitization is a potentially life-threatening procedure and requires continuous monitoring in a hospital setting, with suitable access to emergency treatment and intubation if required. It should only be undertaken under the direction of a physician with suitable training and experience. In such hands, desensitization may present less risk than treatment failure with a less effective alternative medication.*

The possibility of readministering a suspected drug may be safely tested by gradual dose escalation in some cases, and there are certainly many more patients who are harmed by inappropriately withholding medications than there are those who suffer significant harm from testing and desensitization.³⁰

Only type I IgE-mediated allergy may be treated by classical desensitization. Desensitization may occur within hours to several weeks, unlike specific immunotherapy injections for inhalant allergy (i.e., “allergy shots,” which may take months of therapy before a patient realizes any benefit and years to complete). The mechanism of drug desensitization is poorly understood, but produces temporary drug-specific tolerance of the offending drug. Any interruption of therapy of 24 hours or more requires full repeat desensitization, and abrupt significant increases of dosage have been reported to break through the tolerance with some drugs.

The process probably involves either: (a) cross-linking small subthreshold numbers of bound IgE molecules gradually depleting mast cells of their mediators, or (b) binding of the IgE by monomers or haptent-protein entities that cannot

cross-link the antibody. The low doses used at the beginning of all protocols would provide small amounts of antigen, favoring these mechanisms. Both drug-specific IgE and IgG serum concentrations increase after successful desensitization, but skin test positivity generally decreases.³¹

Oral and IV protocols are available for most drugs in this category, with the oral route producing somewhat milder reactions, but the IV route providing more precision in dosing. IV administration can also be used in unresponsive patients for whom the oral route is not feasible. Protocols generally begin at about 1% of the therapeutic dose and increase in intervals defined by the patient's reaction and the distribution and metabolism of the drug itself. Half-log₁₀ dose increases (about threefold) are often tolerated.

Penicillin desensitization is the most common drug desensitization protocol and is required for penicillin-allergic patients when penicillin is clearly the only treatment option, for example, when syphilis is present in pregnancy. Protocols have been adapted to most antibiotics. **Tables 54-6** and **54-7** describe procedures for oral and IV penicillin desensitization, respectively.³²

Aspirin desensitization is useful in diseases for which low-level antiplatelet action is needed and in the care of patients with aspirin sensitivity and intractable nasal polyps. Lysine aspirin availability in Europe allows desensitization by inhalation at greatly reduced risk. New procedures utilizing ketorolac as a nasal topical application may allow similar reduction of risk in the United States.³³ As with all desensitizations, constant daily administration must be maintained once the

- desired dose is reached. **Table 54-8** summarizes several similar aspirin desensitization protocols.³⁴ **Table 54-9** depicts a 2-day alternative protocol.³⁵

All desensitization procedures are expected to produce mild symptoms in the patient at some point, and the patient must be made to understand this before doses are started. Mild sensitivity to the drug still remains, and large dose increases as well as missing doses should be avoided. Late complications, such as urticaria, may occur with type I desensitization, and serum sickness or hemolytic anemia

^aDoses are administered every 3 hours, with patient observed for 3 hours after final dose.

Adapted from Stevenson DD, Simon R. Sensitivity to aspirin and non-steroidal anti-inflammatory drugs. In: Middleton E, Reed CE, Ellis EF, et al., eds. *Allergy Principles and Practice*. St. Louis, MO: Mosby; 1998:1225.

may also occur with high-dose therapy in allergic, desensitized patients.

Some regimens are designed for outpatient administration over much longer time periods and have been used, for example, with allopurinol dermal reactions. Such late-onset morbilliform reactions, sometimes overlapping with erythema multiforme minor, are difficult to evaluate, as it is often unclear to what extent the patients were at risk for recurrent reaction.

Severe life-threatening reactions not mediated by IgE, such as Stevens-Johnson syndrome and toxic epidermal necrolysis, are absolute contraindications to testing, desensitization attempts, and readministration.

OUTCOME EVALUATION

To successfully treat a patient with a drug allergy or pseudo-allergy, several goals must be accomplished:

- If a reaction occurs, it must be identified and managed quickly.
- The patient should be educated about the reaction.
- True drug contraindications should be avoided if at all possible.
- Patients should receive the medications they need or a suitable alternative. If this is not possible due to an allergy, desensitization should be considered.
- Patients should always be monitored for adverse drug reactions.

CONCLUSION

Allergic and pseudoallergic reactions may be mild or life-threatening. Efforts to manage these reactions or change the patient's treatment due to the reactions may increase costs and prevent best therapeutic outcomes. The healthcare professional should carefully explore all available information to accurately assess potential risks from drugs after an apparent reaction to guide both avoidance and alternative treatments.

Patient Care and Monitoring

1. Before administering any medication, take a thorough drug history to establish any past allergic or adverse reactions experienced by the patient.
2. For any reaction, use questions given in Table 54-5 to establish the nature of the reaction and the likelihood it was caused by the suspected drug. For nonantibiotics, the first question regarding infection type is not needed.
3. Document the reaction, in detail, in the patient's medical record.
4. Recommend an alternative choice if the prescribed drug is contraindicated, and develop a plan to assess safety and effectiveness.
5. Consult with a physician trained in desensitization if the patient has a true allergy and no acceptable alternative medication is available.
6. Educate the patient about the allergy or pseudoallergy, so they are able to work with healthcare providers to avoid the reaction in the future.

The healthcare professional should partner with the patient to document reactions so the patient can avoid drugs that present dangers to them if possible and receive the best drug choices when needed.

Abbreviations Introduced in This Chapter

AERD	Aspirin-exacerbated respiratory disease
AHS	Anticonvulsant hypersensitivity syndrome
AIDS	Acquired immunodeficiency syndrome
CAD	Coronary artery disease
COX	Cyclooxygenase
CT	Computed tomography
Da	Dalton
D5W	Dextrose 5% in water
DRESS	Drug reaction with eosinophilia and systematic symptom
H (H1, H2)	Histamine
HIV	Human immunodeficiency virus
ID	Intradermal
Ig	Immune globulin (followed by the specific type of immune globulin: E, G, or M)
IM	Intramuscular
NSAIDs	Nonsteroidal anti-inflammatory drugs
SC	Subcutaneous

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Solid Organ Transplantation

Steven Gabardi, Spencer T. Martin, and Ali J. Olyaei

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Describe the reasons for solid organ transplantation.
2. Differentiate between the functions of cell-mediated and humoral immunity and how they relate to organ transplant.
3. Describe the roles of the antigen-presenting cells (APCs) in initiating the immune response.
4. Compare and contrast the types of rejection, including hyperacute, acute, chronic, and humoral rejection.
5. Define the terms “host–graft adaptation” and “tolerance,” paying close attention to their differences.
6. Discuss the desired therapeutic outcomes and appropriate pharmacotherapy utilized to avoid allograft rejection.
7. Compare and contrast the currently available immunosuppressive agents in terms of mechanisms of action, adverse events, and drug–drug interactions (DDIs).
8. Design an appropriate therapeutic regimen for the management of immunosuppressive drug complications based on patient-specific information.
9. Develop a therapeutic drug-monitoring plan to assess effectiveness and adverse events of the immunosuppressive drugs.
10. Write appropriate patient education instructions and identify methods to improve patient adherence following transplantation.

KEY CONCEPTS

- 1 T cells are the chief component initiating the immune response against the allograft. The activity of T cells is mediated by a complex system of pathways resulting from the presence of antigen and the release of multiple inflammatory markers known as cytokines.
- 2 Antigen-presenting cells (APCs) are vital in initiation of the immune response and play a role in both direct and indirect allorecognition.
- 3 The goal of pharmacotherapy in transplantation is to induce immunosuppression with a multidrug approach to target various points of the immune system with resultant long-term allograft and patient survival, while minimizing the complications of suppressing the immune system and drug toxicity.
- 4 The goals of induction therapy are to improve short-term allograft and patient survival and to reduce the incidence of acute rejection in the immediate post-transplant period.
- 5 The calcineurin inhibitors, cyclosporine and tacrolimus, block T-cell activation by inhibiting the production of interleukin 2 (IL-2). They are associated with significant adverse events, such as nephrotoxicity, cardiovascular disease, posttransplant diabetes, and neurotoxicity.
- 6 The antiproliferatives, azathioprine and the mycophenolic acid derivatives, inhibit T-cell proliferation. Myelosuppression is the most significant adverse event associated with these agents.
- 7 Sirolimus and everolimus, target of rapamycin (ToR) inhibitors, work by decreasing the ability of T cells to respond to IL-2. The major adverse events associated with these agents are decreased wound healing, hyperlipidemia, and myelosuppression. The promising effects of allowing calcineurin inhibitor withdrawal have been limited by the significant toxicity profile

of the ToR inhibitors. However, interest in this drug class as an immunosuppressant currently surrounds its potential cardiovascular and skin malignancy protective properties.

- 8 Corticosteroids induce a nonspecific immunosuppression. Due to their overwhelming incidence of adverse events, many practitioners attempt to use low-dose maintenance therapy or, in some cases, complete steroid withdrawal. These agents are also effective in reversing acute rejection.
- 9 Belatacept is an intermittent, IV maintenance immunosuppressive agent that blocks the costimulatory pathway of T-cell activation. This agent may contribute to improved glomerular filtration rates in renal transplant recipients; however, these patients are at an increased risk of acute rejection. This medication should be avoided in patients who are Epstein-Barr virus (EBV) negative, as it is associated with an increased risk of posttransplant lymphoproliferative disorders (PTLD).
- 10 Long-term patient and allograft survival is complicated by several factors, including drug–drug interactions (DDIs) with the immunosuppressive agents, infectious disease, cardiovascular disease, new-onset diabetes after transplant, and malignancy. The goals of treating these complications are to prevent allograft damage and improve patient survival.

INTRODUCTION

The earliest recorded attempts at organ transplant date back thousands of years.¹ More than a few apocryphal descriptions exist from ancient Egypt, China, India, and Rome describing experimentation with transplantation. However, it wasn't until the early 1900s that French surgeon, Alexis Carrel, pioneered the art of surgical techniques for transplantation.¹ Together with Charles Guthrie, Carrel experimented in artery and vein transplantation. Using revolutionary methods in **anastomosis** operations and suturing techniques, Carrel laid the groundwork for modern transplant surgery. He was one of the first to identify the dilemma of rejection, an issue that remained insurmountable for nearly half a century.¹

Prior to the work of Alexis Carrel, malnourishment was the prevailing theory regarding the mechanism of **allograft** rejection.¹ However, in 1910, Carrel noted that tissue damage in the transplanted organ was likely caused by multiple, circulating biological factors. It was not until the late 1940s with the work of Peter Medawar that transplant immunology became more understood. Medawar was able to define the immunologic nature of rejection using skin allografts. In addition, George Snell observed that grafts shared between inbred animals were accepted but were rejected when transplanted between animals of different strains.¹

The seminal work by early transplant researchers eventually led to the concept of histocompatibility.^{1,2} Histocompatibility describes the process by which polymorphic genes encode cell membrane antigens that serve as targets for

immune response, even within a species. Further research in transplant immunobiology has led to a more accurate understanding of the alloimmune response.^{1,2}

Joseph Murray performed the first successful organ transplant in 1954.¹ It was a kidney transplant between identical twins. This was a success in large part because no immunosuppression was necessary due to the fact that donor and recipient were genetically identical. Murray's success laid the groundwork for modern-day transplantation.

EPIDEMIOLOGY AND ETIOLOGY

Heart

Nearly six million Americans are afflicted with heart failure.^{1,3} Cardiac transplantation is the treatment of choice for patients with severe end-stage heart failure. Candidates for cardiac transplantation generally present with New York Heart Association (NYHA) class III or IV symptoms and have an ejection fraction of less than 20%. The general indications for cardiac transplantation include rapidly declining cardiac function, requirement of IV inotropes, and having a projected 1-year mortality rate of greater than 75%. Mechanical support with an implantable left ventricular assist device may be appropriate as bridge therapy while patients await the availability of a viable organ.^{1,3} Most heart transplants are **orthotopic**; however, in certain situations, **heterotopic** cardiac transplants have been performed. There were 2,322 heart transplant procedures done in the United States in 2011.³ Indications for heart transplant include:

- Cardiomyopathy (i.e., dilated myopathy, hypertrophic cardiomyopathy, restrictive myopathy)
- Congenital heart disease
- Coronary artery disease
- Valvular heart disease

Intestine

An intestine transplant may involve the use of an entire intestine or a shortened segment. Most intestine transplants completed in the United States have involved the transplant of the full organ and are often performed in conjunction with liver transplantation. Although most intestine transplants involve organs harvested from a deceased donor, recent advances in the field have made it possible for living donor intestinal segment transplants. There were 129 intestine transplants (128 deceased donors, 1 living donor) done in 2011.³ Reasons for intestine transplant include:

- Functional bowel problems (i.e., Hirschsprung's disease, neuronal intestinal dysplasia, pseudoobstruction, protein-losing enteropathy, microvillous inclusion disease)
- Short gut syndrome (i.e., intestinal atresia, necrotizing enterocolitis, intestinal volvulus, massive resection secondary to inflammatory bowel disease, tumors, mesenteric thrombosis)

Kidneys

More than 26 million Americans have chronic kidney disease (CKD), with another 20 million more considered to be at increased risk for the development of kidney disease. End-stage renal disease (ESRD) only constitutes a small portion of those patients with CKD, with more than 450,000 patients currently diagnosed with ESRD throughout the United States. However, the ESRD population continues to increase, with projections estimating that more than 700,000 people will carry a diagnosis of ESRD by 2012. All patients with ESRD should be considered for renal transplantation if they are healthy enough to undergo the transplant surgery. A successful kidney transplant offers advantages in terms of both quality and duration of life compared with other renal replacement therapies. It is also more effective than dialysis from a medical and economic perspective.

Most kidney transplants are heterotopic, where the kidney is implanted above the pelvic bone and attached to the patient's iliac artery and vein. The ureter of the transplant kidney is attached directly to the recipient's bladder or native ureter. The native kidneys are usually not removed, and data have shown that under most circumstances, removal of the native kidneys does not influence **patient** and **allograft survival**.^{1,3} There were 16,814 (11,043 deceased donors, 5,771 living donors) kidney transplants performed in 2011.³ Reasons for kidney transplant include:

- Congenital, familial, and metabolic disorders (i.e., congenital obstructive uropathy, Fabry's disease, medullary cystic disease, nephrolithiasis)
- Diabetes mellitus (DM)
- Glomerular diseases (i.e., antiglomerular basement membrane disease, focal segmental glomerular sclerosis, IgA nephropathy, hemolytic uremic syndrome, systemic lupus erythematosus, Alport's syndrome, amyloidosis, membranous nephropathy, Goodpasture's syndrome)
- Hypertension
- Neoplasm (i.e., renal cell carcinoma, Wilms' tumor)
- Polycystic kidney disease
- Renovascular disease
- Tubular and interstitial diseases (i.e., analgesic nephropathy, drug-induced nephritis, oxalate nephropathy, radiation nephritis, acute tubular necrosis, sarcoidosis)

Liver

A liver transplant may involve the use of the entire organ or a segment. The majority of cases involve utilizing the full organ. In recent years, segmental transplants have been conducted using living donors. This procedure requires donation of the left hepatic lobe, which accounts for nearly 60% of the overall liver mass. This type of procedure is possible because the liver can regenerate; therefore, both the donor and recipient, in theory, will have normal liver function shortly after the transplant procedure.^{1,3} There were 6,342 (6,095 deceased

donors, 247 partial lobe-living donors) liver transplants done in 2011.³ Reasons for liver transplant include:

- Acute hepatic necrosis (i.e., chronic or acute hepatitis B or C)
- Biliary atresia
- Cholestatic liver disease/cirrhosis (i.e., primary biliary cirrhosis)
- Metabolic disease (i.e., Wilson's disease, primary oxalosis, hyperlipidemia)
- Neoplasms (i.e., hepatoma, cholangiocarcinoma, hepatoblastoma, bile duct cancer)
- Noncholestatic cirrhosis (i.e., alcoholic cirrhosis, postnecrotic cirrhosis, drug-induced cirrhosis)

Lungs

Lung transplants may involve deceased donation of two lungs or a single lung. More recently, lobar transplants from blood group-compatible living donors have been performed for a small segment of the population. Most of the lobar transplants have been performed on cystic fibrosis patients. On rare occasions, a simultaneous heart-lung transplant occurs. This type of procedure is reserved for patients with severe pulmonary and cardiac disease. There were 1,822 (1,821 deceased donors, 1 living donor) lung transplants and 27 simultaneous heart-lung transplant procedures done in 2011.³ Reasons for lung transplant include:

- α -1-Antitrypsin deficiency
- Congenital disease (i.e., Eisenmenger's syndrome)
- Cystic fibrosis
- Emphysema/chronic obstructive pulmonary disease
- Idiopathic pulmonary fibrosis
- Primary pulmonary hypertension

Pancreas

The exact nationwide prevalence of all diseases of the pancreas has not been fully quantified; however, DM, both types 1 and 2, affects nearly 21 million people in the United States. Some people suffering from DM may also be afflicted with ESRD. A small percentage of these patients undergo a simultaneous pancreas-kidney (SPK) transplant, which may be accomplished using organs from deceased or living donors. Transplant of a pancreas may involve either the entire organ or a pancreas segment. Currently, whole-organ transplant is the most common procedure, with a portion of the duodenum often transplanted along with the pancreas. Living donors are often the source of segmental transplants. In recent years, isolation and transplantation of β -islet cells alone have been completed. Islet transplantation is intended to treat organ dysfunction by replacing nonfunctioning islet cells with new ones. Islet transplants are still considered experimental, and long-term benefit and/or risk of this procedure needs to be studied extensively. Future success of islet cell transplantation is dependent on identifying a nontoxic

immunosuppressive combination. There were 287 pancreas transplants and 795 SPK procedures done in 2011.³ Reasons for pancreas transplants include:

- DM (i.e., type 1 and 2, DM secondary to chronic pancreatitis or cystic fibrosis)
- Pancreatic cancer

PATHOPHYSIOLOGY

Major Histocompatibility Complex

The primary target of the immune response against a transplanted organ is the major histocompatibility complex (MHC).^{1,2} The MHC is a region of highly polymorphic genes located on the short arm of chromosome six. The human MHC is referred to as human leukocyte antigen (HLA). HLA is a set of glycoproteins that are expressed on the surface of most cells. These proteins are involved in immune recognition, which is the discrimination of self from nonself, but are also the principal antigenic determinants of allograft rejection.^{1,2}

The protein products of the HLA have been classified into two major groups, class I and II:

- Class I: expressed on the surfaces of all nucleated cells and are recognized by CD8⁺ cells (i.e., cytotoxic T cells).
 - The three subclasses of MHC class I are HLA-A, HLA-B, and HLA-C.
- Class II: expressed solely on the surfaces of antigen-presenting cells (APCs). The APCs serve to stimulate CD4⁺ cells (i.e., helper T cells).
 - The three subclasses of MHC class II are HLA-DP, HLA-DQ, and HLA-DR.

T and B Lymphocytes

Lymphocytes are one of the five kinds of white blood cells. Mature lymphocytes are astonishingly diverse in their functions. The most abundant of the lymphocytes are T lymphocytes (i.e., T cells) and B lymphocytes (i.e., B cells).

► T Lymphocytes

1 *T cells play a major role in the cell-mediated immune response.* These cells are produced in the bone marrow, but their final stage of development occurs in the thymus, hence the abbreviation “T.” There are three recognized subclasses of T cells: cytotoxic T cells (CD8⁺), helper T cells (CD4⁺), and regulatory T cells (suppressor T cells):

- Cytotoxic T cells (CD8⁺) promote target cell destruction by activating cellular **apoptosis** or aggressively killing the target cell via the release of cytotoxic proteins.
- Helper T cells (CD4⁺) are the great communicators of the immune response. Once activated, they proliferate and secrete cytokines that regulate **effector cell** function. Some helper T cells secrete cytokines that recruit cytotoxic T cells, B cells, or APCs, whereas others secrete

cytokines that turn off the immune response once an antigen has been destroyed.

- Regulatory T cells, or suppressor T cells, suppress the activation of an immune response. The activity of these cells in organ transplant is not well elucidated.

► B Lymphocytes

- B cells play a large role in the humoral immune response. In humans, B cells are produced and mature in the bone marrow. The human body produces several types of B cells. Each B cell is unique, with a distinctive cell surface receptor protein that binds to only one particular antigen. Once B cells encounter their antigen and receive a cytokine signal from helper T cells, they can further differentiate into one of two cells, plasma B cells or memory B cells. Plasma B cells secrete antibodies that induce the destruction of target antigens through complement recruitment and/or **opsonization**. Memory B cells play an important role in long-term immunity. Once formed to a specific antigen, memory B cells are capable of rapidly responding to subsequent exposures to their target antigen.

Antigen-Presenting Cells

- 2 *APCs are vital in initiation of the immune response. An APC is a cell that displays a foreign antigen complexed with MHC on its cell surface.* Its major responsibility is to present these foreign antigens to T cells. T cells can identify this complex using their T-cell receptors (TCRs). There are three main types of APCs: dendritic cells (DCs), macrophages, and activated B cells. DCs are present in tissues that are in contact with the environment, such as the skin and the lining of the nose, lungs, stomach, and intestines. They are responsible for antigen **phagocytosis**. After phagocytosis, they express the foreign antigen on their cell surface and then migrate to the lymphoid tissues to interact with T and B cells to initiate the immune response. Macrophages’ main role is in the removal of pathogens and necrotic debris. However, like DCs, macrophages also phagocytize antigens and express them on their cell membranes to present to T cells to initiate an immune response. The first time an antigen is encountered, the DCs and macrophages act as the primary APCs. However, if the same antigen is encountered again, memory B cells become the most important APC because they initiate the immune response quickly after antigen presentation. It appears that both the DCs and macrophages have the most activity in terms of **allorecognition**.

Allorecognition

1 2 *Recognition of the antigens displayed by the transplanted organ (alloantigens) is the prime event that initiates the immune response against the allograft.* There are currently two accepted pathways for T-cell allorecognition:

- Direct pathway: Donor APCs migrate out of the allograft into the recipient’s lymph nodes and present donor MHC molecules to the TCRs of the recipient’s T cells.

Table 55-1

Organ-Specific Signs and Symptoms of an Acute Rejection Episode^{1,2}

Organ	Clinical Symptoms	Laboratory Signs
Heart	Fever, lethargy, weakness, SOB, DOE, hypotension, tachycardia, atrial flutter, ventricular arrhythmias	Leukocytosis, endomyocardial biopsy positive for mononuclear infiltrates
Kidney	Fever, graft tenderness and swelling, decreased urine output, malaise, hypertension, weight gain, edema	Increased SCr, BUN, leukocytosis, renal biopsy positive for lymphocytic infiltration
Intestine	Fever and GI symptoms (i.e., bloating, cramping, diarrhea, increased stomal output)	There are no reliable biochemical markers for intestine transplant rejection, but biopsies may be helpful.
Liver	Fever, lethargy, change in color or quantity of bile in patients with biliary T-tube, graft tenderness and swelling, back pain, anorexia, ileus, tachycardia, jaundice, ascites, encephalopathy	Abnormal LFTs, increased bilirubin, alkaline phosphate, transaminases, biopsy positive for mononuclear cell infiltrate with evidence of tissue damage
Lung	Fever, impaired gas exchange, SOB, malaise, anxiety	Decreased FEV, infiltrate on CXR, biopsy positive for lymphocytic infiltration
Pancreas	Fever, graft tenderness and swelling, abdominal pain, ileus, and malaise	Increased FBS, leukocytosis, decreased human C-peptide and urinary amylase levels

BUN, blood urea nitrogen; CXR, chest x-ray; DOE, dyspnea on exertion; FBS, fasting blood sugar; FEV, forced expiratory volume; GI, gastrointestinal; LFTs, liver function tests; SCr, serum creatinine; SOB, shortness of breath.

- Indirect pathway: Recipient APCs migrate into the graft and phagocytize alloantigens. The donor MHC molecules are then expressed on the cell surface of the recipient's APCs and presented to recipient T cells in the lymph nodes.

T-Cell Activation

① *Whether it is by the direct or indirect pathway, in order for a T cell to become activated against the allograft, two interactions or signals must take place between the APCs and the recipient's T cells^{1,2}:*

- Signal 1 is the interaction of the TCR with the foreign antigens presented by the APCs.
- Signal 2 is an interaction between one of several costimulatory receptors and paired ligands on the cell surfaces of the APCs and T cells, respectively. This interaction is of the utmost importance, as Signal 1, in the absence of Signal 2, induces T-cell **anergy**.

Once activated, T cells undergo **clonal expansion** under the influence of cytokines, specifically interleukin 2 (IL-2). These steps elicit an antidonor T-cell response that results in graft destruction.

Mechanisms of Acute Rejection

After activation, cytotoxic T cells emerge from lymphoid organs to infiltrate the graft and trigger the immune response. These cells induce graft destruction via two mechanisms: (a) secretion of the cytotoxic proteins perforin and granzyme B, and (b) induction of cellular apoptosis through interaction with various cell surface receptors. Besides the cytotoxic T cells, several other cell lines may play a role in allograft destruction, including B cells, granulocytes, and natural killer cells.

Types of Rejection

► Hyperacute Rejection

- Hyperacute rejection is an immediate recipient immune response against the allograft due to the presence of preformed recipient antibodies directed against the donor's HLA. This type of reaction generally occurs within minutes of the transplant. The organ must be removed immediately to prevent a severe systemic response. In the case of cardiac or lung transplantation in which the organ cannot be promptly removed, short-term mechanical circulatory support is required until an alternative organ becomes available. Those patients at highest risk for hyperacute rejection include any patients that have preformed HLA or ABO blood group antibodies, including patients with a history of previous organ transplant or multiple blood transfusions, as well as women who have had children. Hyperacute rejection has been largely eliminated due to routine surveillance testing completed pretransplant.

► Acute Rejection

- Acute rejection is a cell-mediated process that generally occurs within 5 to 90 days after transplantation; however, it can occur at any time after transplant. This reaction is mediated through alloreactive T cells, as discussed previously in the Mechanisms of Acute Rejection section. Organ-specific signs and symptoms of acute rejection can be seen in **Table 55-1**.^{1,2}

► Antibody-Mediated Rejection

- Antibody-mediated rejection (AMR) is the process of creating graft-specific antibodies.^{1,2,4} This type of rejection occurs less frequently than cell-mediated acute rejection. AMR is characterized by deposition of immunoglobulins and

complement in allograft tissues. Treatment for this type of rejection is not well defined; however, several reports have shown that treatments such as plasmapheresis, immunoglobulin therapy, rituximab, bortezomib, or eculizumab may be effective.⁶

► **Chronic Rejection**

- Chronic rejection has traditionally been thought of as a slow, insidious form of acute rejection, resulting in worsening organ function over time. The exact immunologic processes of chronic rejection are poorly understood; however, many believe that both the cell-mediated and humoral immune systems and drug-induced toxicities play a vital role in its development. Currently, retransplantation is the only effective treatment option.^{1,2,7}

► **Host–Graft Adaptation**

- The term “host–graft adaptation” describes the decreased immune response against the allograft over time.² This phenomenon is evident by the reduced incidence of acute rejection episodes seen months after transplantation. In theory, host–graft adaptation is thought to be secondary to a weakened T-cell response to donor antigens when patients are receiving maintenance immunosuppression.²

Tolerance

- Tolerance is the process that allows organ-specific antigens to be accepted as self.^{2,8} This would mean the immune system would cease to respond to the allograft and immunosuppressive medications would not be required. Immune tolerance has been achieved in the lab, but has yet to be successfully accomplished in humans.^{2,8} The definition of “achieved tolerance” is highly variable and subjective. Currently, a number of protocols focusing on testing clinically safe regimens to achieve chimerism or tolerance are being studied.

Immunologic Barriers to Transplantation

One of the more common barriers to successful transplantation is the presence of preformed HLA antibodies, acquired through pregnancy, blood transfusion, or previous transplant, or ABO blood group incompatibility. In cases in which these antibodies exist, if they are not adequately removed prior to transplant, they are likely to result in AMR and poor graft survival. To improve outcomes, assessment of pretransplant immune risk factors of recipients plays an important role in the prevention of immune-mediated allograft injuries. The introduction of pretransplant crossmatching and the use of ABO-compatible donors has largely eliminated hyperacute rejection episodes. However, these immunologic barriers remain intact for several transplant recipients with willing organ donors, and patients are left to wait on the deceased donor waiting list or undergo pretransplant immunomodulation in an attempt to prevent these antibodies from affecting the allograft.

► **ABO Incompatibility**

The expanding deceased donor waiting list encouraged some centers to evaluate the use of ABO desensitization protocols in order to transplant patients with ESRD that had willing but ABO-incompatible donors. The desensitization protocol most commonly used in the United States involves reducing ABO antibody titers through plasmapheresis with IV immune globulin (IVIG). Use of plasma exchange to achieve an ABO antibody titer of less than 1:8 to 1:32 has resulted in long-term renal transplant results that are comparable to those of ABO-compatible transplants, despite an incidence of acute AMR that approaches 10% to 30%.

► **HLA Sensitization**

Evaluation of the presence or absence of alloantibodies and T-cell activities to HLA antigens plays a significant role in individualization of immunosuppressive therapy. A patient’s degree of sensitization is often reported as the percentage of panel-reactive antibodies (PRA), which is an estimate of the likelihood of a positive crossmatch to a pool of potential donors. Advancement in HLA antibody screening and identification through flow cytometry or solid-phase multiplex platforms has overcome many of the issues stemming from the older methods of PRA calculations. Patients are considered to be highly sensitized to HLA if they have a PRA of greater than or equal to 80%, making them less likely to receive a deceased donor organ. Patients with higher PRAs and preformed antibodies have poorer long-term allograft survival. Although PRA is a sensitive test and has predictive value, lymphocytes directly obtained from the donor is a superior method of immune monitoring before and early after transplant.⁴ The assay is aimed to detect the presence of antibodies directed against the HLA antigens of the donor. In this setting, the presence of donor-specific antibodies (DSA) is identified. In one study, allograft survival was significantly lower in patients with DSA.⁵ Thus detecting DSA and the presence of high PRA may indicate the need to enhance immunosuppression to improve posttransplant outcomes and allograft survival.

Like ABO incompatibilities, it is possible to desensitize patients against a willing donor despite the presence of DSA or those awaiting a deceased donor transplant with a broad array of preformed anti-HLA antibodies (PRA greater than or equal to 30%). There are two general protocols used for HLA desensitization: high-dose IVIG and low-dose IVIG with plasmapheresis. Despite the relatively high degree of AMR seen in desensitized patients, this population of patients have acceptable short-term patient and allograft survival. Unfortunately, the long-term results for graft and patient outcomes using either of these two protocols is unknown.

TREATMENT

Desired Outcome

- **3** The major focus of pharmacotherapy in transplantation is to achieve long-term patient and allograft survival.^{2,9} Short-term

Table 55-2

Currently Available Immunosuppressive Agents^{2,8,9}

Generic Name (Brand Name)	Common Dosage	Common Adverse Effects
<i>Induction Therapy Agents</i>		
Alemtuzumab (Campath)	20–30 mg × 1–2 doses	Flu-like symptoms, chills, rigors, fever, rash, myelosuppression
Antithymocyte globulin equine (ATGAM)	15 mg/kg IV × 3–14 days	Flu-like symptoms, chills, rigors, fever, rash, myelosuppression
Antithymocyte globulin rabbit (Thymoglobulin)	1.5 mg/kg IV × 3–14 days	Flu-like symptoms, chills, rigors, fever, rash, myelosuppression
Basiliximab (Simulect)	20 mg IV × 2 doses	None reported compared to placebo
<i>Maintenance Immunosuppressants</i>		
Cyclosporine (Sandimmune, Neoral, Gengraf)	4–5 mg/kg by mouth twice a day	Neurotoxicity, gingival hyperplasia, hirsutism, hypertension, hyperlipidemia, glucose intolerance, nephrotoxicity, electrolyte abnormalities
Tacrolimus (Prograf)	0.05–0.075 mg/kg by mouth twice a day	Neurotoxicity, alopecia, hypertension, hyperlipidemia, glucose intolerance, nephrotoxicity, electrolyte abnormalities
Azathioprine (Imuran)	1–2.5 mg/kg by mouth once a day	Myelosuppression, GI disturbances, pancreatitis
Mycophenolate mofetil (CellCept)	0.5–1.5 gm by mouth twice a day	Myelosuppression, GI disturbances
Enteric-coated MPA (Myfortic)	720 mg by mouth twice a day	Myelosuppression, GI disturbances
Sirolimus (Rapamune)	1–10 mg by mouth once a day	Hypertriglyceridemia, myelosuppression, mouth sores, hypercholesterolemia, GI disturbances, impaired wound healing, proteinuria, lymphocele, pneumonitis
Everolimus (Zortress)	0.75 mg by mouth twice daily	Hypertriglyceridemia, myelosuppression, mouth sores, hypercholesterolemia, GI disturbances, impaired wound healing, proteinuria, lymphocele, pneumonitis
Prednisone (Deltasone)	Maintenance: 2.5–20 mg by mouth once a day	Mood disturbances, psychosis, cataracts, hypertension, fluid retention, peptic ulcers, osteoporosis, muscle weakness, impaired wound healing, glucose intolerance, weight gain, hyperlipidemia
Belatacept (Nulojix)	10 mg/kg on postop days 1 and 4 10 mg/kg at the end of postop weeks 2, 4, 8, and 12 5 mg/kg at the end of postop week 16 and every 4 weeks thereafter	GI disturbances, electrolyte abnormalities, headache

GI, gastrointestinal; MPA, mycophenolic acid.

outcomes (e.g., acute rejection rates, 1-year graft survival) have improved significantly since the first successful transplant due to an improved understanding of the immune system and enhancements in surgical techniques, organ procurement, immunosuppression, and posttransplant care. Despite the success in improving short-term outcomes, the overall frequency of graft loss remains higher than desired.^{1,2}

It is imperative that transplant practitioners be aware of the specific advantages and disadvantages of the available immunosuppressants, as well as their adverse reactions and drug–drug interaction (DDI) profiles. There are generally considered to be three stages of medical immunosuppression: (a) induction therapy, (b) maintenance therapy, and (c) treatment of rejection. **3** Overall, the immunosuppressive regimens utilize multiple medications that work on different targets of the immune system. Please refer to **Table 55-2** for a list of all currently available immunosuppressive agents.^{2,9,10}

Immunosuppressive Therapies—Induction Therapy

- 4** The goal of induction therapy is to provide a high level of immunosuppression in the critical early posttransplant period, when the risk of acute rejection is highest.^{2,9,11–13}

This stage of immunosuppression is initiated intraoperatively and is generally concluded within the first 1 to 10 days after transplantation. Induction therapy is not a mandatory stage of recipient immunosuppression. However, since acute rejection is a major concern in solid organ transplant recipients and its impact on chronic rejection is undeniable, induction therapy is often considered essential to optimize outcomes.^{2,9,11–13}

► Goals of Induction Therapy

- 4** First, the induction agents are highly immunosuppressive, allowing for significant reductions in acute rejection episodes and improved 1-year graft survival. Second, due to

their unique pharmacologic effect, these agents are often considered essential for use in patients at high risk for poor short-term outcomes, such as those patients with preformed antibodies, history of previous transplants, multiple HLA mismatches, or transplantation of organs with prolonged cold ischemic time, or from expanded-criteria donors. Specifically in renal transplant recipients, induction therapy plays an important role in preventing early-onset calcineurin inhibitor–induced nephrotoxicity. With the use of induction agents, initiation of calcineurin inhibitors can be delayed until the graft regains some degree of function.^{9,12,13} Transplant centers that pursue corticosteroid sparing or avoidance protocols consider induction therapy imperative due to its profound and lasting immunosuppressive effects.

The improved short-term outcomes gained from induction therapy come with a degree of risk. By using these highly immunosuppressive agents, particularly the antilymphocyte antibodies (ALA; the antithymocyte antibodies, and alemtuzumab), the body loses much of its innate ability to mount a cell-mediated immune response, which increases the risk of opportunistic infections and malignancy.^{9,12,13} Cytokine release syndrome is a common complication of T-cell depleting agents and may require methylprednisolone, diphenhydramine, and/or acetaminophen 30 to 60 minutes before infusion.

► Currently Available Induction Therapies

- **Basiliximab** Basiliximab is a chimeric monoclonal antibody with a high affinity for the IL-2 receptor, where it acts as a receptor antagonist.^{10,13} These receptors are present on almost all activated T cells. Basiliximab inhibits IL-2–mediated activation of lymphocytes, which is an important step for the clonal expansion of T cells.

- The dose of basiliximab is 20 mg IV given 2 hours prior to the transplant, followed by a second 20-mg dose on postoperative day 4.^{9,10,13} This dosing schedule can be used for both children greater than or equal to 35 kg (77 lb) and adults. Two 10-mg doses with the same dosing schedule should be used for children less than 35 kg (77 lb). There is no specific dosage adjustments needed in renal or hepatic impairment.^{9,10,13}

- The incidence of all adverse reactions with basiliximab was similar to placebo in clinical trials.^{10,13} There are no reported DDIs with basiliximab.

- **Antithymocyte Globulin Equine** Antithymocyte globulin equine (e-ATG) is a polyclonal antibody that contains antibodies against several T-cell surface markers. After binding to these cell surface markers, e-ATG promotes T-cell depletion through opsonization and complement-mediated T-cell lysis.^{9,10,12,13} The common dosing strategy for e-ATG when used for induction therapy is 10 to 30 mg/kg/day IV for 3 to 14 days.^{9,10,12,13}

- After T-cell lysis there is a cytokine release. Due to this phenomenon, e-ATG is associated with several adverse reactions.^{9,10,12,13} The most common of these include fever (63%), chills (43.2%), headache (34.6%), back pain (43.2%), nausea (28.4%), diarrhea (32.1%), dizziness (24.7%), malaise (3.7%), and myelosuppression (**leukopenia** [29.6%] and **thrombocytopenia**

[44.4%]). The overall incidence of opportunistic infections is 27.2%, with **cytomegalovirus (CMV) disease** occurring in 11.1% of patients. There are currently no reported pharmacokinetic DDIs with this agent.^{9,10,12,13}

- **Antithymocyte Globulin Rabbit** Antithymocyte globulin rabbit (r-ATG) is also a polyclonal antibody that induces T-cell clearance, but more importantly, it alters T-cell activation, homing, and cytotoxic activities. Compared with e-ATG, r-ATG causes less T-cell lysis due to its secondary mechanisms of immunosuppression. It is also believed that r-ATG plays a role in inducing T-cell apoptosis. r-ATG has been dosed between 1 and 4 mg/kg/day (typically dosed at 1.5 mg/kg/day) and is usually administered for 3 to 10 days after transplantation.^{9–13} Many renal transplant centers aim to initiate the first dose intraoperatively to reduce organ reperfusion injury.

- Adverse reactions are common and may include fever (63.4%), chills (57.3%), headache (40.2%), nausea (36.6%), diarrhea (36.6%), malaise (13.4%), dizziness (8.5%), leukopenia (57.3%), thrombocytopenia (36.6%), and generalized pain (46.3%).^{9,10,13} The incidence of infection is 36.6%, with CMV disease occurring in 13.4% of patients. There are no reported DDIs with the use of r-ATG at this time.^{9–13}

- **Alemtuzumab** Alemtuzumab is a recombinant DNA-derived monoclonal antibody that binds to CD52. CD52 is present on the surface of almost all B and T lymphocytes, many macrophages, natural killer (NK) cells, and a subpopulation of granulocytes.^{10,13} This agent's mechanism of action is believed to be antibody-dependent cell lysis following its binding to CD52 cell surface markers. When used for induction therapy, alemtuzumab produces a rapid and extensive lymphocyte depletion that may take several months to return to pretransplant levels. Although it is not FDA approved for use in organ transplantation, studies have demonstrated a dose of 30 mg IV at the time of transplant to be effective in preventing acute rejection.¹³ A recent retrospective analysis suggests that use of alemtuzumab as an induction therapy may be associated with an increased risk of graft loss as a result of AMR, but further study is warranted.¹⁴

- Alemtuzumab has been associated with serious adverse reactions that include anemia (47%), neutropenia (70%), thrombocytopenia (52%), headache (24%), dysesthesias (15%), dizziness (12%), nausea (54%), vomiting (41%), diarrhea (22%), autoimmune hemolytic anemia (rare), infusion-related reactions (15% to 89%), and infection (37%; CMV viremia occurred in 15% of patients).^{10,13} The FDA recommends that premedication with acetaminophen and oral antihistamines is advisable to reduce the incidence of infusion-related reactions.¹⁰

Comparative Efficacy—Induction Therapy Agents The improvements in short-term outcomes gained from the use of induction therapies cannot be denied. However, despite these advances, use of induction therapy has not impacted long-term allograft function or survival. There are a few studies that help to delineate the ideal induction therapy agent. Only one study has compared r-ATG to patients receiving no

induction therapy and found no benefit in acute rejection, allograft loss, or death.¹⁵ It is difficult to draw specific conclusions regarding r-ATG induction therapy from this trial due to major discrepancies in maintenance immunosuppression between the two groups. Studies comparing r-ATG and e-ATG show that r-ATG is more effective in lowering acute rejection rates and improving 1-year allograft survival.¹⁶ Conversely, studies evaluating the use of basiliximab versus r-ATG demonstrate similar short-term efficacy between both groups.¹⁷ However, more recent analyses of these two agents demonstrated similar results for allograft and patient survival, but a benefit for r-ATG in lowering the incidence of acute allograft rejection.^{18,19} A more recent analysis showed that alemtuzumab improved transplant outcomes when compared with basiliximab in patients with a low immunologic risk, and similar outcomes in comparison with high immunologic risk patients receiving r-ATG.²⁰ When choosing an agent for induction therapy, one must weigh the risks versus the benefits. For the most part, the ALAs are considered to be most effective, but are associated with a higher incidence of infectious disease and malignancy.¹³

Immunosuppressive Therapies—Maintenance Therapy

- The goals of maintenance immunosuppression are to prevent rejection episodes and to optimize patient and graft survival. Antirejection medications require careful selection and dosage titration to balance the risks of rejection with the risks of toxicities.

Common maintenance immunosuppressive agents can be divided into five basic medication classes:

- Calcineurin inhibitors (cyclosporine and tacrolimus)
- Antiproliferatives (azathioprine and the mycophenolic acid [MPA] derivatives)
- Target of rapamycin (ToR) inhibitors (sirolimus and everolimus)
- Corticosteroids (prednisolone derivatives and dexamethasone)
- Costimulatory pathway blocker (belatacept)

- Maintenance immunosuppression is generally achieved by combining two or more medications from the different classes to maximize efficacy by specifically targeting unique components of the immune response. Please refer to [Figure 55–1](#) for a schematic representation of these different drug mechanisms and [Figure 55–2](#) for an example protocol for administration of immunosuppressive medications post-transplant. This method of medication selection also helps to minimize toxicities by choosing agents with different adverse event profiles. Immunosuppressive regimens vary between organ types and transplant centers, but most often they include a calcineurin inhibitor with an adjuvant agent, plus or minus corticosteroids. Selection of an appropriate immunosuppressive regimen should be patient-specific, and one must take into account the patient's preexisting disease states, medication regimens, and preferences.

Patient Encounter Part 1

HPI: ED is a 34-year-old man who presents to your transplant center for a living unrelated renal transplant.

PMH:

- ESRD: secondary to focal segmental glomerulosclerosis
- Anxiety
- Hypertension
- Hyperlipidemia
- Insomnia
- Gout, he has had 10 episodes of gout since the age of 21
- Secondary hyperparathyroidism

FH: Father is alive and living with a history of cardiovascular disease and mother is alive and living with a history of breast cancer.

SH: The patient works as a mechanical engineer. He admits to social alcohol use (3 or 4 drinks per week) and denies any tobacco and IV drug use.

Admission Medications:

- Bisoprolol 5 mg by mouth once a day
- Amlodipine 5 mg by mouth once a day
- Irbesartan 100 mg by mouth once a day
- Furosemide 20 mg by mouth twice a day
- Atorvastatin 20 mg by mouth once a day
- Alprazolam 0.5 mg by mouth three times a day as needed for anxiety
- Zolpidem 10 mg by mouth once a day at bedtime
- Calcitriol 0.25 mg by mouth once a day
- Epo 4000 units IV every hemodialysis session

Allergies: NKDA

Misc:

- CMV Serostatus: Donor is CMV IgG positive
- CMV Serostatus: Recipient is CMV IgG negative
- Epstein Barr Virus (EBV) Serostatus: Donor is EBV IgG positive
- EBV Serostatus: Recipient is EBV IgG negative
- Patient has documented glucose-6 phosphate dehydrogenase (G6PD) deficiency

Identify your treatment goals for this patient.

Create a plan for induction therapy (i.e., would you recommend induction therapy, if so, which agent)?

► Calcineurin Inhibitors

- 5 Cyclosporine and tacrolimus belong to a class of immunosuppressants called the calcineurin inhibitors. These agents are considered by many to be the cornerstone of immunosuppressive protocols. The calcineurin inhibitors work

FIGURE 55-1. Identification of the sites of action of the various immunosuppressive medications. Allograft recognition through Signal 1 occurs when the antigen-major histocompatibility complex (MHC) molecule is recognized by the T-cell receptor (TCR). A costimulatory signal, Signal 2, initiates signal transduction with activation of second messengers, one of which is calcineurin. Together, Signal 1 and Signal 2 activate calcineurin phosphatase, which removes phosphates from the nuclear factors, allowing them to enter the nucleus, with a subsequent increase in IL-2 gene transcription. Signal 3 occurs with the interaction of IL-2, with the IL-2 receptor on the cell membrane surface. This culminates in a signal that passes through the mammalian target of rapamycin (ToR) and induces cell proliferation and production of cytokines specific to the T cell. (ATG, antithymocyte globulin; AZA, azathioprine; CsA, cyclosporine; EC-MPA, enteric-coated mycophenolic acid; EVL, everolimus; NFAT, nuclear factors; MMF, mycophenolate mofetil; SRL, sirolimus; TAC, tacrolimus.)

by complexing with cytoplasmic proteins (cyclosporine with cyclophilin and tacrolimus with FK binding protein-12).^{9,10,21,22} These complexes then inhibit calcineurin phosphatase, which results in reduced IL-2 gene transcription. The final outcome is a decrease in IL-2 synthesis and a subsequent reduction in T-cell activation.^{9,10,21,22}

Cyclosporine Cyclosporine USP was first approved in 1983, but was associated with a variable oral absorption. The development of a newer formulation, cyclosporine micro-emulsion USP (i.e., modified) introduced in 1994, allowed for a more consistent drug exposure due to a more reliable pharmacokinetic profile.²³ Cyclosporine modified is the formulation of choice for most transplant centers that use cyclosporine for maintenance immunosuppression due to the previously mentioned benefit. The two formulations are not interchangeable.

The usual oral adult dose of cyclosporine ranges from 3 to 7 mg/kg/day in two divided doses.¹⁰ The appropriate selection of the starting dose usually depends on the organ type, the patient's preexisting disease states, and other concomitant immunosuppressive agents utilized. Cyclosporine modified is available as 25-mg and 100-mg individually blister-packed capsules and an oral solution. An IV formulation of conventional cyclosporine is also available. When converting a patient from oral to IV, the dosage should be reduced to approximately one-third of the total daily oral dose.¹⁰

Cyclosporine whole-blood trough concentrations have traditionally been obtained to help monitor for efficacy and safety.

Therapeutic trough levels (C_0) may range from 50 to 400 ng/mL (50 to 400 mcg/L or 42 to 333 nmol/L). Target levels should be individualized for each patient, usually depending on the organ transplanted, patient's condition, method of assay (high-performance liquid chromatography [HPLC], monoclonal, polyclonal), and time since transplantation. Newer studies suggest that monitoring of concentrations at 2 hours post-dose (C_2) correlates better with toxicity and efficacy when compared with C_0 .²⁴

Tacrolimus Tacrolimus (also known as FK506) is the second calcineurin inhibitor and was approved in 1997. Oral starting doses of tacrolimus range from 0.1 to 0.2 mg/kg/day in two divided doses. Tacrolimus is available in 0.5-, 1-, and 5-mg capsules and as an injectable.¹⁰ Tacrolimus C_0 should be monitored (12 hours after the last administered dose) and maintained between 5 and 15 ng/mL (5 and 15 mcg/L), again depending on the transplanted organ, patient's condition, and time since transplant.¹⁰

The tacrolimus IV formulation is usually avoided due to the risk of anaphylaxis because of its castor oil component and nephrotoxicity. Doses for IV administration are recommended to start at 0.01 mg/kg/day. Most IV doses of tacrolimus are administered over 24 hours as a continuous infusion. To avoid drawing falsely elevated levels, it is important that trough levels are not drawn from the line that tacrolimus is being infused through. Because IV administration of tacrolimus is usually a continuous infusion, a "trough level" can be taken at any time during administration.

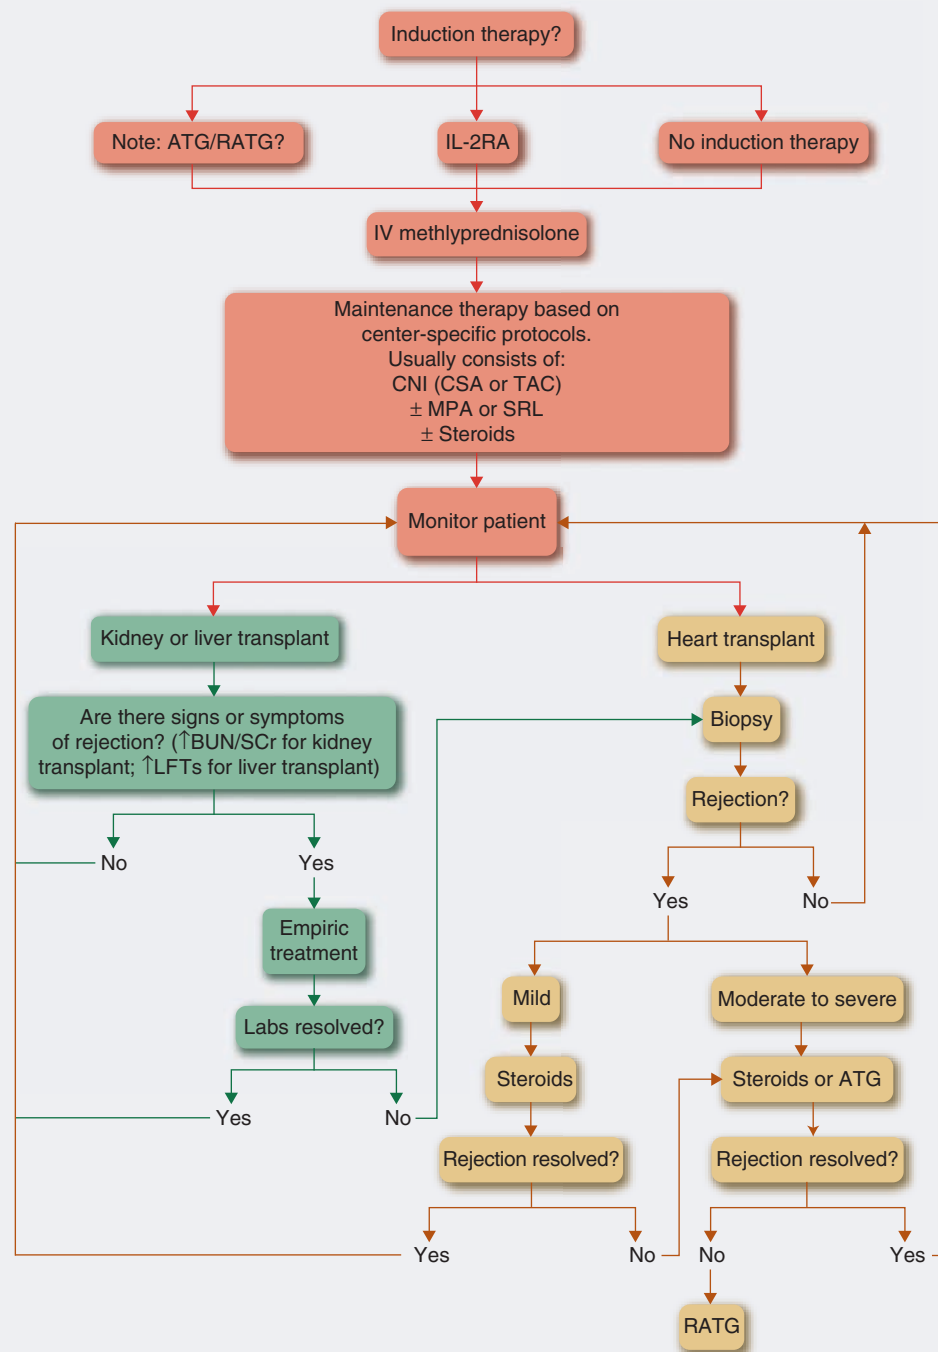

FIGURE 55-2. Example protocol of immunosuppressive medication use in organ transplantation. Center-specific protocols may use rabbit antithymocyte immunoglobulin (RATG), an interleukin-2 receptor antagonist (IL-2RA), or no induction therapy. In any situation, patients receive IV methylprednisone prior to, during, or immediately following the transplant operation. The patient then will begin the maintenance immunosuppressive regimen. The center-specific protocol will specify which calcineurin inhibitor (cyclosporine or tacrolimus) is used in combination with mycophenolate mofetil or sirolimus, with or without steroids. Patients then are monitored for signs and symptoms of rejection. If rejection is suspected, a biopsy can be done for definitive diagnosis, or the patient may be treated empirically for rejection. Empirical treatment generally involves administration of corticosteroids. If signs and symptoms of rejection are resolved with empirical therapy, the patient will continue to be monitored according to the center-specific protocol. If rejection is confirmed by biopsy, treatment may be based on the severity of rejection. High-dose corticosteroids are used most frequently for mild to moderate rejection. RATG can be used for moderate to severe rejections or steroid-resistant rejections. (ATG, antithymocyte globulin; BUN, blood urea nitrogen; CNI, calcineurin inhibitor; CSA, cyclosporine; IL-2RA, interleukin-2 receptor antagonist; LFT, liver function test; MPA, mycophenolic acid; RATG, rabbit antithymocyte immunoglobulin; SCr, serum creatinine; SRL, sirolimus; TAC, tacrolimus.) (From Schonder KS, Johnson HJ. Solid Organ Transplantation. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*. 7th ed. New York: McGraw-Hill; 2008:1466.)

Adverse Drug Reactions 5 One of the major drawbacks of the calcineurin inhibitors is their ability to cause acute and chronic nephrotoxicity. Acute nephrotoxicity has been correlated with high doses and is usually reversible.¹⁰ Chronic calcineurin inhibitor toxicity, however, is typically irreversible and is linked to chronic drug exposure. [Table 55-3](#) expands on the more common calcineurin inhibitor-induced adverse events.

Comparative Efficacy—Calcineurin Inhibitors Even though cyclosporine and tacrolimus are both calcineurin inhibitors, there are several differences between the two. First, looking at efficacy, some studies suggest that tacrolimus-based regimens are associated with improved short-term survival when compared with cyclosporine-based regimens.²⁵ To help assess the relative efficacy of tacrolimus versus cyclosporine, a 2005 meta-analysis evaluated

Table 55-3

Management of Common Adverse Effects of Calcineurin Inhibitors^{2,8,9}

Adverse Event	Most Likely Offending CNI	Monitoring Parameters	Therapeutic Management Options
Nephrotoxicity	Either	Serum creatinine BUN Urine output Biopsy-proven CNI-induced nephrotoxicity	Reduce CNI dose (if possible) Use of CCB for HTN control Modify regimen (add or change to non-CNI-containing regimen)
Hypertension ^a	Cyclosporine	Blood pressure Heart rate	Initiate patient-specific antihypertensive therapy Reduce cyclosporine dose (if possible) Change from cyclosporine to tacrolimus or sirolimus
Hyperlipidemia ^a	Cyclosporine	Fasting lipid panel	Initiate patient-specific cholesterol-lowering therapy Reduce cyclosporine dose (if possible) Change from cyclosporine to tacrolimus
Hyperglycemia ^b	Tacrolimus	Blood glucose (fasting and nonfasting) Hemoglobin A1c	Diet modifications Reduce tacrolimus dose (if possible) Reduce steroids (if patient is taking them and if possible) Initiate patient-specific glucose-lowering therapy (insulin or oral therapy)
CNS toxicities ^b	Tacrolimus	Fine hand tremor Headache Mental status changes	Reduce tacrolimus dose (if possible) Change from tacrolimus to cyclosporine or sirolimus
Hematologic	Either	WBC Platelets Hemoglobin Hematocrit Symptoms of anemia	Reduce CNI dose (if possible) Modify regimen (add or change to non-CNI containing regimen; although hematologic risk is high for all meds except steroids)
Hepatotoxicity	Either	Liver function tests	Reduce CNI dose (if possible) Modify regimen (add or change to non-CNI containing regimen)
Electrolyte Imbalance	Either	K (usually ↑) Mg (usually ↓) PO ₄ (usually ↓)	Treat electrolyte imbalance (i.e., Mg replacement) Reduce CNI dose (if possible) Modify regimen (add or change to non-CNI-containing regimen)
Hirsutism	Cyclosporine	Patient complains of excessive hair growth or male-pattern hair growth	Reduce cyclosporine dose (if possible) Cosmetic hair removal Change from cyclosporine to tacrolimus or sirolimus
Alopecia	Tacrolimus	Patient complains of excessive hair loss	Reduce tacrolimus dose (if possible) Hair growth treatments (i.e., minoxidil, finasteride—males only)
Gingival Hyperplasia	Cyclosporine	Patient complains of excessive gum growth Recommendations for therapy from the patient's dentist	Change from tacrolimus to cyclosporine or sirolimus Reduce cyclosporine dose (if possible) Oral surgery (gum resection) Change from cyclosporine to tacrolimus or sirolimus

BUN, blood urea nitrogen; CCB, calcium channel blocker; CNI, calcineurin inhibitor; CNS, central nervous system; HTN, hypertension; K, potassium; Mg, magnesium; PO₄, phosphate; WBC, white blood cell count.

^aTacrolimus is also associated with hypertension and hyperlipidemia, but to a much lower extent compared with cyclosporine.

^bCyclosporine is also associated with hyperglycemia and CNS toxicities, but to a much lower extent compared with tacrolimus.

30 trials consisting of 4,102 patients.²⁶ In this meta-analysis, tacrolimus, when compared with either formulation of cyclosporine, was associated with a significantly lower risk of allograft loss at 6 months. It also appeared that late allograft loss favored tacrolimus. In addition, lower rates of acute rejection were seen at 1 year in tacrolimus-treated patients.²⁶ In recent years, tacrolimus has become the primary calcineurin inhibitor in many transplant centers, due in large part to a more favorable adverse reaction profile.²²

► Antiproliferatives

These agents are generally considered to be adjuvant to the calcineurin inhibitors or ToR inhibitors. The medications included in this class are azathioprine and the MPA derivatives.

Azathioprine Azathioprine was originally approved in 1968 as an adjunct immunosuppressant for use in renal transplant recipients. It is available in oral and IV dosage forms.¹⁰ Prior to the advent of cyclosporine, the combination of azathioprine and corticosteroids was the mainstay of immunosuppressive therapy. Over the past 10 years, the use of azathioprine has declined markedly, due in large part to the success of the MPA derivatives, which are more specific inhibitors of T-cell proliferation. **6** *Azathioprine is a prodrug for 6-mercaptopurine (6-MP), a purine analog. 6-MP acts as an antimetabolite and inhibits DNA replication with a resultant reduction in T-cell proliferation.¹⁰ The typical oral dose of azathioprine for organ transplantation is 3 to 5 mg/kg once a day.¹⁰ The maintenance dose is usually reduced to 1 to 2 mg/kg/day within a few weeks posttransplant. Dose reductions due to severely impaired renal function may be necessary since 6-MP and its metabolites are renally eliminated.¹⁰ Trough concentrations of 6-MP are not monitored; however, most clinicians often monitor for signs of myelosuppression.*

6 *Myelosuppression (mainly leukopenia and thrombocytopenia) is a frequent, dose-dependent and dose-limiting complication (greater than 50% of patients) that often prompts dose reductions.¹⁰ Other common adverse events include hepatotoxicity (2% to 10%) and adverse gastrointestinal (GI) events (10% to 15%; mostly nausea and vomiting). Importantly, pancreatitis and venoocclusive disease of the liver occur in less than 1% of patients following chronic azathioprine therapy.¹⁰*

Mycophenolic Acid Derivatives Mycophenolate mofetil was approved in 1995 and enteric-coated MPA in 2004. Both agents are considered to be adjunctive immunosuppressants. **6** *Both mycophenolate mofetil and enteric-coated MPA are prodrugs for MPA. MPA acts by inhibiting inosine monophosphate dehydrogenase, a vital enzyme in the de novo pathway of purine synthesis. Inhibition of this enzyme prevents the proliferation of most cells that are dependent on the de novo pathway for purine synthesis, including T cells.^{9,10,27-29}*

Mycophenolate mofetil is available in 250-mg and 500-mg capsules, an oral suspension (100 mg/mL; in cherry syrup), and as an injectable.¹⁰ Usual doses of mycophenolate mofetil range from 1,000 to 3,000 mg/day in two to four divided doses. The conversion between oral and IV mycophenolate

mofetil is 1:1. Enteric-coated MPA is available in 180-mg and 360-mg tablets. The appropriate equimolar conversion between mycophenolate mofetil and enteric-coated MPA is 1,000 mg of mycophenolate mofetil to 720 mg of enteric-coated MPA.^{27,28,30} The recommended starting dose of enteric-coated MPA is 720 mg given twice daily.²⁷ Conversion of mycophenolate mofetil to enteric-coated MPA has been proven safe. MPA C_0 can be monitored; however, they are not routinely recommended.

6 *The most common adverse events associated with these agents are GI (18% to 54%; diarrhea, nausea, vomiting, and gastritis) and myelosuppression (20% to 40%).^{9,10,27-29} Despite being enteric-coated, enteric-coated MPA has produced the same degree of GI adverse events as mycophenolate mofetil.^{27,30} However, recent data suggest that there is a benefit in converting patients with documented mycophenolate-induced GI disease from mycophenolate mofetil to enteric-coated MPA.³¹*

Comparative Efficacy—Antiproliferatives Due to the results of several studies, the MPA derivatives have replaced azathioprine as the antiproliferative agent of choice in most organ transplant centers. The MPA derivatives are generally considered to provide a more specific immunosuppressive effect compared with azathioprine. Mycophenolate mofetil and enteric-coated MPA have similar safety and efficacy data in renal transplant recipients. The decision to choose one agent over another is a purely practitioner-dependent preference.

► Target of Rapamycin Inhibitors

Sirolimus **7** *Sirolimus is a macrolide antibiotic that inhibits T-cell activation and proliferation by binding to and inhibiting the activation of the mammalian ToR, which suppresses cellular response to IL-2 and other cytokines (i.e., IL-4, IL-15).^{10,32} Studies have shown that sirolimus may be used safely and effectively with either cyclosporine or tacrolimus as a replacement for either azathioprine or mycophenolate mofetil.³³ Sirolimus can also be used as an alternative agent for patients who do not tolerate calcineurin inhibitors due to nephrotoxicity or other adverse events.³⁴ **7** *At this time, the most exciting data for sirolimus point to its ability to prevent long-term allograft dysfunction when used as a substitute for the calcineurin inhibitors in renal transplant recipients.^{32,33}**

Sirolimus is available in 0.5-mg, 1-mg, and 2-mg tablets and a 1-mg/mL oral solution. The current approved dosing regimen for sirolimus is a 6-mg loading dose followed by a 2-mg/day maintenance dose.¹⁰ It was recommended that this agent does not require therapeutic drug monitoring. However, most centers do check trough concentrations and adjust doses to reach goal concentrations.³⁵ Most clinicians who use sirolimus utilize a loading dose of 5 to 15 mg/day for 1 to 3 days to more rapidly achieve adequate immunosuppression.^{30,32} Maintenance doses of sirolimus usually range from 1 to 10 mg/day given once daily. Sirolimus blood C_0 should be maintained between 5 and 20 ng/mL, depending on the institution-specific protocols.³⁵ Of note, sirolimus has a half-life of approximately 62 hours, which means that it will not reach steady state after dosage changes for several days.¹⁰

7 The most common adverse events reported with sirolimus are leukopenia (20%), thrombocytopenia (13% to 30%), and hyperlipidemia (38% to 57%).^{10,32} Other adverse effects include delayed wound healing, anemia, diarrhea, arthralgias, rash, proteinuria, pneumonitis, and mouth ulcers. 7 A recent analysis suggests that use of sirolimus in kidney transplant recipients can reduce cardiovascular risk compared with calcineurin inhibitor–based regimens.³⁶ Sirolimus has a black-box warning in newly transplanted liver and lung recipients.¹⁰ In liver transplant recipients, use of sirolimus immediately after transplant is associated with an increased risk of hepatic artery thrombosis, graft loss, and death. In lung transplant recipients, bronchial anastomotic dehiscence, including some fatal cases, has been noted in patients treated with sirolimus, tacrolimus, and corticosteroids.¹⁰

Everolimus Everolimus is a derivative of sirolimus and has the same mechanism of action.^{10,37} Everolimus is only indicated for prevention of rejection in low- to moderate-risk renal transplant recipients when given in conjunction with basiliximab induction, reduced-dose cyclosporine, and corticosteroids. This agent is available in 0.25-mg, 0.5-mg, and 0.75-mg tablets. The recommended starting dose of everolimus is 0.75 mg twice daily without the need for a loading dose. Maintenance everolimus doses should be maximized to achieve a C_0 goal of 3 to 8 ng/mL.^{37,38} With a significantly shorter half-life compared with sirolimus, everolimus steady-state can be reached within 90 to 150 hours. 7 The adverse event profile of everolimus is similar to that seen with sirolimus.^{10,37}

► Corticosteroids

Traditional triple-therapy immunosuppressive regimens have consisted of one of the following combinations:

- A calcineurin inhibitor, an antiproliferative, and a corticosteroid
- A calcineurin inhibitor, a ToR inhibitor, and a corticosteroid
- A ToR inhibitor, an antiproliferative, and a corticosteroid

In recent years, many protocols have focused on corticosteroid sparing or avoidance. Avoidance or sparing of corticosteroids has been supported in the literature, although more studies are needed to help better characterize which patients should follow these protocols.^{19,39–43} A typical taper includes a bolus of IV methylprednisolone 100 to 500 mg at the time of transplant, then tapered over days to months (depending on the type of organ) to a maintenance low dose of prednisone 5 to 10 mg/day. Although most centers still use low-dose steroids for immunologically high-risk patients, a number of renal transplant programs have developed an immunosuppression protocol that completely avoids or withdraws corticosteroids at some point posttransplantation.^{2,9} Therapeutic drug monitoring of corticosteroids is not employed. 8 Corticosteroids are associated with a variety of acute and chronic toxicities. The most common adverse events have been summarized in Table 55–4.

Table 55–4

Common Adverse Events Associated With Corticosteroids⁹

Body System	Adverse Event
Cardiovascular	Hyperlipidemia Hypertension
Central nervous system	Anxiety Insomnia Mood changes Psychosis
Dermatologic	Acne Diaphoresis Ecchymosis Hirsutism Impaired wound healing Petechiae Thin skin
Endocrine/metabolic	Cushing's syndrome Hyperglycemia Sodium and water retention
Gastrointestinal	Gastritis Increased appetite Nausea, vomiting, diarrhea Peptic ulcers
Hematologic	Leukocytosis
Neuromuscular/skeletal	Arthralgia Impaired growth Osteoporosis Skeletal muscle weakness
Ocular	Cataracts Glaucoma
Respiratory	Epistaxis

8 Corticosteroids have various effects on immune and inflammatory response systems, although their exact mechanism of immunosuppression is not fully understood. It is generally believed that at high doses, the agents are directly lymphotoxic, and at lower doses, it is believed that corticosteroids act by inhibiting the production of various cytokines that are necessary to amplify the immune response.^{2,9}

The most commonly used corticosteroids are methylprednisolone (IV and oral) and prednisone (oral), although prednisolone and dexamethasone have also been shown to be effective for organ transplantation. Corticosteroid doses vary by center-specific protocols, organ type, and patient characteristics.

► Costimulatory Pathway Blocker

Belatacept Belatacept was approved in 2011 as the first IV biologic agent for maintenance immunosuppression in renal transplant recipients. 9 Belatacept results in the blockade of the CD80 and CD86 ligands, found on APCs.⁴⁴ The CD80 and CD86 proteins are responsible for stimulating CD28 on inactive T cells, an essential costimulatory interaction (Signal 2). As detailed in the T-Cell Activation section, Signal 1, the interaction of the TCR with a foreign antigen presented by an APC, without a complementary Signal 2 induces T-cell anergy.⁴⁵

Studies have shown that in combination with mycophenolate mofetil and corticosteroids, belatacept may be used in place of calcineurin inhibitors. Studies demonstrated similar patient and allograft survival in patients receiving belatacept compared with those receiving a cyclosporine-based regimen.^{46,47} 9 *Belatacept was found to improve renal function; however, the incidence of acute rejection was found to be significantly increased.* Additional benefits of belatacept when compared with calcineurin-based regimens may include improvement in blood pressure and lipid levels.⁴⁵

Belatacept is available in a 250-mg vial that requires reconstitution prior to administration.¹⁰ The recommended dosing regimen for belatacept is 10 mg/kg on the first day of transplantation, followed by an additional dose 4 days after transplant, and again at the end of weeks 2, 4, 8, and 12, post-transplant. Beginning at the end of week 16 posttransplant, belatacept is dosed at 5 mg/kg and every 4 weeks thereafter.^{10,45} Belatacept requires access to an infusion center, a hired home infusion service, or an infusion suite to ensure appropriate IV administration.

The most common adverse effects associated with belatacept are infectious (urinary tract infection, 37%; upper respiratory infection, 15%), GI (diarrhea, 39%; constipation, 33%; nausea, 24%, vomiting, 22%), metabolic (hyperkalemia, 20%; hypokalemia 21%), and central nervous system (CNS; headache, 21%) complications.^{10,45} Other adverse effects include peripheral edema, anemia, leukopenia, hypotension, arthralgia, and insomnia. 9 *Belatacept has a black-box warning for increased risk of developing posttransplant lymphoproliferative disorders (PTLD), especially in the CNS. Due to this risk, it is recommended that belatacept only be used in patients who present with a proven preexisting immunity to Epstein-Barr virus (EBV).* An additional black box warning states that the use of belatacept in liver transplant patients is not recommended due to an increased risk of allograft loss and patient death.^{10,45}

Immunosuppressive Therapies—Future Immunosuppressive Agents

The immunosuppressant armamentarium is expanding with novel small molecules (i.e., protein kinase C and the Janus-Kinase 3 inhibitors) and other biological agents currently in clinical development. These newer agents appear promising and may represent the emergence of novel immunosuppressive agents that can deliver immunosuppression without the long-term toxicities. Some currently marketed immunosuppressants may also have beneficial effects in organ transplantation. Several agents, including alefacept, bortezomib, alemtuzumab (discussed previously), efalizumab, leflunomide and rituximab, have already been used successfully in renal transplantation.

Immunosuppressive Therapies—Treatment of Acute Rejection Episodes

Acute rejection is generally treated with a course of high-dose methylprednisolone (250 to 1,000 mg/day IV for 3 days),

which is usually sufficient to ameliorate the rejection episode. If the acute rejection episode is resistant to the initial course of steroids, a second course may be administered or the patient may begin therapy with r-ATG (1.5 mg/kg/day for 3 to 14 days).⁴⁸ Cellular acute rejection refractory to these treatments is rare and is likely due to underlying causes such as an antibody-mediated component or other diagnosis. Treatments of refractory acute rejection may include alemtuzumab, IVIG, high-dose tacrolimus, or organ irradiation. Refractory cellular acute rejections are typically related to therapeutic failures, which may require changing to an alternative protein source such as e-ATG.

Immunosuppressive Therapies—Managing Highly Sensitized Patients and Antibody-Mediated Rejection Episodes

The presence of preformed antibodies, high PRA, and donor-specific antibodies (DSA) are major barriers to successful transplantation.^{49–51} This is true, mainly because traditional immunosuppressants do not significantly affect the humoral immune system and are ineffective at management of AMR, which is a leading cause of allograft loss in kidney and heart transplant recipients. Without some form of intervention, antibody formation and rejection can be a major cause of morbidity and mortality. Two major strategies are used for reduction of DSA pretransplant: (a) high-dose IV immune globulin (IVIG), and (b) plasmapheresis plus low-dose IVIG. Each approach has advantages and disadvantages.^{49–51}

In plasmapheresis or plasma exchange, patients' plasma is removed and replaced with albumin or fresh-frozen plasma.^{49–51} Plasmapheresis produces a rapid reduction of preformed antibodies and allows transplantation to occur. The purpose of IVIG administration is to decrease anti-HLA alloantibody synthesis. The other mechanisms of IVIG are inhibition of complement-mediated injury, reduced B-cell proliferation and NK cells, and a decrease in phagocytosis. Most patients require four to five plasmapheresis sessions and use of IVIG to remove the DSA. In patients at risk for bleeding, the use of albumin should be limited, and fresh-frozen plasma or a combination of both agents should be considered.^{49–51}

In one study, Stegall compared a single dose of IVIG with two plasmapheresis sessions plus low-dose IVIG regimens. The overall success rate for desensitization was 84% to 88% in the plasmapheresis plus IVIG groups, but only 38% in the high-dose IVIG group.⁵¹ However, they also reported that patients with high titers did not respond to either treatment.

In patients who develop AMR posttransplant, there are limited therapeutic options, none of which are FDA-approved. The potential options include plasmapheresis and IVIG, rituximab, bortezomib, and/or eculizumab.⁶ All of these agents have an effect on humoral immunity, which may provide benefit to patients with AMR. The mechanisms of plasmapheresis and IVIG have been discussed earlier in this chapter. Details regarding the use of rituximab, bortezomib, and eculizumab for desensitization and treatment of AMR are provided next.⁶

Rituximab is a chimeric monoclonal anti-CD20 antibody targeting B cells.^{6,10} This agent directly inhibits B-cell proliferation and induces cellular apoptosis through complement-mediated antibody-dependent cellular cytotoxicity and cell death. In an analysis of AMR treatment, the use of rituximab in conjunction with plasmapheresis/IVIG resulted in improved 3-year graft survival (92% versus 50%) and significantly reduced DSA at 3 months compared with high-dose IVIG alone.⁵² Unfortunately, the majority of plasma cells lack CD20 and are unaffected by rituximab. However, rituximab may play an important role in reducing memory B-cell response. Overall, it appears that rituximab may provide beneficial effects in managing AMR when used in combination with other therapies.^{6,10}

Bortezomib is a proteasome inhibitor indicated for treatment of multiple myeloma.^{6,10} It works by inducing cell-cycle arrest and apoptosis of plasma cells. It also has been shown to exert numerous indirect effects on circulating B and T cells. Desensitization and treatment protocols using bortezomib have utilized doses ranging from 1 to 1.3 mg/m² from one to four cycles. Most commonly observed adverse effects include peripheral neuropathy, hematologic effects (thrombocytopenia, neutropenia, anemia), asthenia, paresthesia, and rash. Limited published data document bortezomib use in kidney transplantation protocols. When used in combination with other accepted modalities, it is difficult to discern whether there is any additional benefit when adding on bortezomib in patients at risk of AMR. The small case reports and case series in existence resulted in little to no added benefit in AMR treatment.^{6,10} A recent analysis including less than 20 patients found treatment of AMR with bortezomib to be more efficacious compared with rituximab.⁵³ Future study is warranted before bortezomib can be considered as mainstay therapy of AMR.

Eculizumab is a humanized monoclonal antibody directed against complement protein C5.^{6,10} It inhibits the cleavage to C5a and C5b, thus preventing the generation of the membrane attack complex (MAC) and reducing antibody-dependent cell lysis. One case report used eculizumab in combination with plasmapheresis/IVIG to salvage a kidney transplant from severe AMR.⁵⁴ In this analysis, there was a marked decrease in MAC deposition in the kidney.

Maintenance Immunosuppressive Therapies—Common Drug–Drug Interactions

10 *As the number of medications that a patient takes increases, so does the potential for DDIs.* Disease severity, patient age, and organ dysfunction are all risk factors for increased DDIs. In general, DDIs can be broken down into two categories: (a) pharmacokinetic, and (b) pharmacodynamic interactions.

- Pharmacokinetic interactions result when one drug alters the absorption, distribution, metabolism, or elimination of another drug.
- Pharmacodynamic interactions include additive, synergistic, or antagonistic interactions that can affect efficacy or toxicity.

► Pharmacokinetic Interactions

Pharmacokinetic DDIs pose a major dilemma with the maintenance immunosuppressants. Pharmacokinetic interactions can either result in increased concentrations of one or more agents with an increased risk for drug-induced toxicities, or lowered (i.e., subtherapeutic) drug concentrations, possibly leading to allograft rejection. As mentioned previously, pharmacokinetic DDIs can be further categorized into interactions of absorption, distribution, metabolism, and elimination.

Interactions of Absorption Most DDIs are due to altered absorption and occur within the intestines. There are a variety of potential mechanisms through which the absorption of the maintenance immunosuppressants is altered, including:

- Drug metabolism within the gut (“Interactions of Metabolism” will be discussed later)
- Alterations in the active transport process
- Changes in intestinal motility
- Chelation interactions

Active transporters (i.e., P-glycoprotein [P-gp]) play an important role in DDIs. P-gp, a plasma membrane transport protein, is present in the gut, brain, liver, and kidneys.^{55,56} This protein provides a biological barrier, eliminating toxic substances and xenobiotics that may accumulate in these organ systems. P-gp plays an important role in the absorption and distribution of many medications. In the GI tract, P-gp is located in the brush borders of mature enterocytes. The colon has the largest percentage of P-gp, whereas the stomach and jejunum-ileum contain the lowest percentage. P-gp affects the absorption of cyclosporine, tacrolimus, sirolimus, and everolimus. Some medications can alter the activity of P-gp (inhibit or induce its activity). Medications that are cytochrome P450 (CYP) 3A4 substrates, inhibitors, or inducers also tend to affect P-gp; therefore, the potential exists for several DDIs with the immunosuppressants by this mechanism.^{55,56} For example, medications that inhibit P-gp activity will increase concentrations of cyclosporine, tacrolimus, sirolimus, and everolimus due to a reduction in P-gp-dependent drug elimination from the hepatic circulation.

When looking at the ability of drugs that change intestinal motility and their effects on the maintenance immunosuppressants, you can see notable interactions between the prokinetic agents and the calcineurin inhibitors. Metoclopramide has been shown to increase the absorption of cyclosporine and tacrolimus by enhancing gastric mobility and emptying.⁵⁷

Most of the interactions with mycophenolate mofetil and enteric-coated MPA are due to reductions in intestinal absorption. Proton pump inhibitor use can decrease the oral absorption of mycophenolate mofetil, but has no effect on enteric-coated MPA.⁵⁸ Aluminum, magnesium, and calcium-containing products decrease the peak level of MPA.¹⁰ If a patient requires aluminum, magnesium, or calcium, it should be administered at least 4 hours before or after MPA. Of note, iron does not interact with the MPA preparations.⁵⁹

Interactions of Distribution Interactions of distribution tend to occur with drugs that are highly protein bound. A drug that is extensively bound to plasma proteins can be displaced from its binding site by another agent that has greater affinity for the same binding site, thereby raising free concentrations of the displaced drug. MPA is the only highly protein bound (97% bound to albumin) maintenance immunosuppressant with a reported DDI by this mechanism. It has been shown that concomitant administration of MPA with salicylates increases the free concentrations of MPA.¹⁰ The adverse sequelae of this drug interaction have not been assessed. DDI studies have not been completed evaluating the MPA derivatives, or the other highly protein bound maintenance immunosuppressants, when used with other highly protein bound drugs.

Interactions of Metabolism Oxidative metabolism by CYP isozymes is the primary method of drug metabolism.⁶⁰ The purpose of drug metabolism is to make drugs more water-soluble so they can be more easily eliminated.

Cyclosporine, tacrolimus, sirolimus, and everolimus are all substrates of the CYP3A isozyme system. The majority of CYP-mediated metabolism takes place in the liver; however, CYP is also expressed in the intestine, lungs, kidneys, and brain. Two types of interactions usually occur with medications metabolized via the CYP enzyme system: inhibitory interactions and inducing interactions. Enzyme inhibition occurs when there is enzyme inactivation or mutual competition of substrates at a catalytic site. This usually results in a reduction of drug metabolism leading to increased medication concentrations. Enzyme induction interactions are just the opposite and occur when there is increased synthesis or decreased degradation of CYP enzymes. This type of interaction can produce decreased concentrations of medications.⁶⁰ Being CYP3A substrates, it would be anticipated that cyclosporine, tacrolimus, sirolimus, and everolimus would all experience similar pharmacokinetic DDIs. **Table 55-5** details the clinically relevant DDIs that occur with the calcineurin and ToR inhibitors due to inhibition or induction of the CYP isozyme system.

One of the most often overlooked DDIs in transplant recipients is the effect corticosteroids have on drug metabolism. Dexamethasone is a CYP3A isozyme inducer, meaning that it may decrease the C_0 of cyclosporine, tacrolimus, sirolimus, and everolimus.^{10,61} Conversely, methylprednisolone is a CYP3A isozyme inhibitor, and it may increase the C_0 of cyclosporine, tacrolimus, sirolimus, and everolimus.^{10,61} This is usually not a noteworthy interaction, since doses of the immunosuppressants are titrated to achieve target concentrations in patients maintained on stable doses of corticosteroids. However, these DDIs may be problematic after pulse dose steroids for treatment of acute rejection or during steroid withdrawal.

Not all metabolic DDIs occur through the CYP system. Azathioprine has a considerable interaction with both allopurinol and febuxostat that is not mediated through CYP.⁶² Allopurinol and febuxostat inhibit xanthine oxidase, which is the enzyme responsible for metabolizing 6-MP to inactive

6-thiouric acid. Combining these agents can result in 6-MP accumulation and severe toxicities, particularly myelosuppression. It is recommended that concomitant therapy with azathioprine and allopurinol or febuxostat be avoided, but if necessary, azathioprine doses must be reduced to one-third or one-fourth of the current dose.⁶²

Interactions of Elimination There are very few interactions of elimination with the maintenance immunosuppressants. However, the major interaction through this process involves MPA. MPA is metabolized to MPA-glucuronide (MPAG) via hepatic glucuronosyltransferase.^{10,27} MPAG is excreted in the bile for elimination in the gut. Deconjugation of MPAG back to MPA by intestinal flora results in a secondary absorption of MPA several hours after its administration.^{10,27} Several medications have been shown to interfere with the biliary excretion of MPAG, thereby eliminating its reabsorption in the intestines and lowering the overall exposure to MPA. Cyclosporine has been shown to reduce the overall exposure to the MPA derivatives through competitive inhibition of MPAG enterohepatic recirculation.⁶³ MPA levels are lower when administered in cyclosporine-based immunosuppression regimens compared with tacrolimus-based regimens. The bile acid sequestrants (i.e., cholestyramine, colestipol, colesevelam) have also been shown to decrease overall MPA exposure through a similar mechanism.^{64,65}

► Pharmacodynamic Interactions

In addition to the numerous pharmacokinetic interactions seen with the maintenance immunosuppressants, there also exists the possibility for pharmacodynamic interactions. An in-depth review of pharmacodynamic interactions with maintenance immunosuppressive agents goes beyond the scope of this chapter. However, some common pharmacodynamic DDIs will be discussed. Pharmacodynamic interactions are the backbone of modern immunosuppressive therapies that employ multiple medications with different mechanisms of action resulting in additive immunosuppression. Unfortunately, pharmacodynamic interactions can also be problematic, such as when medications with similar adverse events are used concomitantly. For example, nephrotoxic agents, such as amphotericin B, aminoglycosides (i.e., gentamicin, tobramycin, amikacin), and nonsteroidal anti-inflammatory drugs (NSAIDs; i.e., naproxen, ibuprofen, ketorolac) may potentiate the nephrotoxic effects of the calcineurin inhibitors.¹⁰ The use of myelosuppressive agents, such as sulfamethoxazole-trimethoprim and valganciclovir, could enhance the myelosuppressive effects of induction therapy and the maintenance immunosuppressants.¹⁰

The potential exists for multiple DDIs in transplant recipients due to the complexity of their medication regimens. Practitioners must be diligent in reviewing all medications for potential DDIs. In addition to reviewing prescription medications, it is essential to question patients about the use of both nonprescription and complementary and alternative medicines, as these products also have the potential for significant interactions.

Table 55-5

Potential Drug–Drug Interactions with the Calcineurin Inhibitors and Target of Rapamycin Inhibitors Mediated Through the Cytochrome P-450 System 3A (CYP3A4) Isozyme^a

	Substrates ^a	Inducers ^b	Inhibitors ^c
Alfentanil	Loratadine	Carbamazepine	Boceprevir
Alprazolam	Lovastatin	Dexamethasone	Cimetidine
Amiodarone	Nevirapine	Etravirine	Clarithromycin
Amlodipine	Nicardipine	Ethosuximide	Clotrimazole
Atorvastatin	Nifedipine	Isoniazid	Delavirdine
Boceprevir	Omeprazole	Nevirapine	Diltiazem
Cilostazol	Paclitaxel	Phenobarbital	Erythromycin
Cisapride	Propafenone	Phenytoin	Fluconazole
Chlorpromazine	Progesterone	Prednisone	Fluoxetine
Clonazepam	Quetiapine	Rifabutin	Fluvoxamine
Cocaine	Quinidine	Rifampin	Grapefruit juice
Cortisol	Rilpivirine	Rilpivirine	Indinavir
Cyclophosphamide	Rivaroxaban	St. John's wort	Itraconazole
Dantrolene	Sertraline		Ketoconazole
Dapsone	Simvastatin		Miconazole
Diazepam	Tamoxifen		Nefazodone
Disopyramide	Testosterone		Nelfinavir
Enalapril	Tolvaptan		Rilpivirine
Estradiol	Triazolam		Ritonavir
Estrogen	Vandetanib		Saquinavir
Etoposide	Venlafaxine		Telaprevir
Everolimus	Vinblastine		Troleandomycin
Felodipine	Warfarin		Verapamil
Flutamide	Zolpidem		Voriconazole
Lidocaine			Zafirlukast

^aSubstrates of the CYP3A4 isozyme will compete with cyclosporine, tacrolimus, and sirolimus for metabolism; therefore, concentrations of both medications will be increased (usually by less than or equal to 20%).

^bInducers of the CYP3A4 isozyme will enhance the metabolism of cyclosporine, tacrolimus, and sirolimus; therefore, concentrations of these medications will be decreased.

^cInhibitors of the CYP3A4 isozyme will decrease the metabolism of cyclosporine, tacrolimus, and sirolimus; therefore, concentrations of these medications will be increased.

Patient Encounter Part 2

Identify your treatment goals for ED in terms of maintenance immunosuppressants.

Create a plan for maintenance therapy for ED, making sure to compare and contrast the pros and cons of the different maintenance immunosuppressants.

Identify the need to continue the patient's pretransplant medications, and identify any potential DDIs that may exist with the addition of the maintenance immunosuppressants and the medications that ED is currently taking.

Immunosuppressive Therapies—Controversies with Generic Immunosuppressants

The question of whether clinically relevant changes in drug exposure would occur with the use of generic immunosuppressants culminated with the approval of several generic formulations for cyclosporine, cyclosporine modified, mycophenolate mofetil, and tacrolimus. Generic products are considered to be therapeutically equivalent if they are both bioequivalent and pharmaceutically equivalent to the innovator product. However, bioequivalence is determined in a small group of healthy volunteers and the issue raised is would the generic products be deemed bioequivalent in a

transplant population. One concern is that given the narrow therapeutic windows of both cyclosporine and tacrolimus, would generic conversion result in significant changes in drug exposure, potentially resulting in acute rejection or drug toxicities.

Generic medications are commonplace within the US healthcare system. The availability of less expensive alternatives may allow for increased access to essential drug therapy as well as defraying associated costs. Organ transplant is not immune to the financial pressures on the healthcare system. However, with few clinical studies to help guide our decision making on the use of generic immunosuppressants, appropriate clinical decisions need to balance therapeutic outcomes, patient quality of life, and the associated financial burdens. The consensus guidelines from the American Society of Transplantation advocate for use of generic immunosuppressants if they are deemed bioequivalent to the innovator product.⁶⁶ The guidelines state that use of generics offers an opportunity to reduce direct costs to the patients and potentially improve adherence.

Immunosuppressive Therapies—Management of Immunosuppressive Drug Complications

► Opportunistic Infections

10 *Solid organ transplant recipients are at increased risk of infectious diseases, which are a chief cause of early morbidity and mortality.*⁶⁷ The prevalence of posttransplant infection depends on many factors, including clinical risk factors, environmental exposures, and the degree of immunosuppression. Antiinfectives are universally prescribed in this population, and their use can be split into three different categories:

- Prophylaxis: antimicrobials given to prevent infection
- Empiric: preemptive therapy given based on clinical suspicion of an active infection
- Treatment: antimicrobials given to manage a documented infection

Posttransplant infections generally occur in a standard pattern; therefore, prevention is a key management strategy. The information in this section is designed to only highlight prophylaxis options routinely used in organ transplant recipients. Please refer to [Table 55–6](#) for a list of agents used for the prevention of *Pneumocystis jiroveci* pneumonia and CMV disease.

- **Pneumocystis jiroveci Pneumonia** **10** *Without prophylaxis, *P. jiroveci* pneumonia occurs in 5% to 15% of transplant recipients.*⁶⁸ Antipneumocystis prophylaxis is enormously helpful and is generally used in all organ transplant recipients. The duration of prophylaxis is usually 6 to 12 months after transplant, but may be prolonged in highly immunosuppressed patients (i.e., active CMV disease, treatment for rejection) or liver or lung recipients.⁶⁸ Sulfamethoxazole-trimethoprim is the preferred agent for prophylaxis. One of its major advantages is its relatively broad spectrum of activity.

Clinical Presentation of *Pneumocystis jiroveci* Pneumonia

General

- Patients may not be in acute distress or they may feel completely run down; it is very patient specific.

Symptoms

- Patients may complain of fever, cough, and progressive dyspnea.

Signs

- The most common findings are fever and tachypnea.
- Chest examination may reveal crackles and rhonchi.

Radiographic Tests

- Chest radiographs may be normal in up to 25% of patients.
- The most common radiographic abnormalities are diffuse, bilateral interstitial, or alveolar infiltrates.

Not only is it effective against *Pneumocystis* pneumonia, but it also has activity against toxoplasmosis and other common bacterial infections. Patients who have sulfa allergies, glucose-6 phosphate dehydrogenase (G6PD) deficiency, or are unable to tolerate sulfamethoxazole-trimethoprim should be given one of the second-line treatments.¹⁰ Unfortunately, the second-line agents are antiparasitics and have no meaningful activity against common bacteria. These agents include dapsone, atovaquone, and pentamidine.⁶⁸

- **Cytomegalovirus** CMV is the most concerning opportunistic pathogen in transplantation due to its association with poor outcomes.⁶⁹ **CMV infection** is present in 30% to 97% of the general population, but CMV disease is typically restricted to immunocompromised hosts. The risk of CMV disease is highest among CMV-naïve recipients who receive a CMV-positive organ (donor+/recipient–). Other factors that augment the risk of CMV disease include organ type (lung and pancreas recipients are highest risk) and immunosuppressive agents (ALA use increases risk). CMV disease characteristically occurs within the first 3 to 6 months post-transplantation, but delayed onset disease has been seen in patients receiving antiviral prophylaxis.⁶⁹ Patients with CMV infection may present with general flu-like symptoms, including fever, chills, aches, malaise, and fatigue. CMV infection may result in more profound symptoms in the immunosuppressed patient, including leukopenia, thrombocytopenia, and organ dysfunction.

- **10** *Several antivirals have proven efficacy in preventing and treating CMV.*⁶⁹ Valacyclovir and valganciclovir, prodrugs of acyclovir and ganciclovir, respectively, have improved bioavailability compared with their parent compounds and offer the advantage of less frequent dosing. CMV prophylaxis is classically continued for the first 200 days, or longer, after

Table 55-6

Prophylactic Options for *Pneumocystis jiroveci* Pneumonia and CMV^{68,69}

Medication	Dosing	Common Adverse Events
<i>Antipneumocystis Prophylaxis</i> Sulfamethoxazole-trimethoprim (Bactrim, Septra, SMZ-TMP, cotrimoxazole)	One SS tablet by mouth once a day ^a One DS tablet by mouth once a day ^a One DS tablet by mouth every M/W/F ^a	Hyperkalemia Myelosuppression Nephrotoxicity Neutropenia Photosensitivity Rash
Pentamidine (NebuPent)	300 mg inhaled every 3–4 weeks	Bronchospasm Cough
Dapsone (Avlosulfon)	50–100 mg tablet by mouth once a day	Hypo- or hyperglycemia Hepatotoxicity Myelosuppression Nephritis
Atovaquone (Mepron)	1,500 mg suspension by mouth once a day	Elevated liver transaminases Nausea Rash
<i>Antivirals</i> Valganciclovir (Valcyte)	450–900 mg by mouth once a day ^a	Stomach upset (8–41%) Myelosuppression (2–27%) Headache (9–22%)
Ganciclovir (Cytovene)	5 mg/kg IV everyday; or 1,000 mg by mouth three times a day ^a	Stomach upset (13–40%) Myelosuppression (5–40%) Rash (10–15%)
Valacyclovir (Valtrex)	1–2 g by mouth four times a day ^a	Stomach upset (1–15%) Myelosuppression (less than 1%) Headache (14–35%)
CMV IgG (CytoGam) and polyvalent IVIG	The maximum recommended total dosage per infusion is 150 mg/kg beginning within 72 hours of transplantation. Follow-up doses and time intervals depend on the type of organ transplanted.	Stomach upset (1–6%) Fevers and chills (1–6%) Flushing (1–6%)

CMV, cytomegalovirus; DS, double-strength (800 mg SMZ, 160 mg TMP); IgG, immunoglobulin G; IVIG, intravenous immune globulin; M/W/F, Monday, Wednesday, and Friday; SS, single-strength (400 mg SMZ, 80 mg TMP); SMZ, sulfamethoxazole; TMP, trimethoprim.

^aDose adjustment required in renal insufficiency.

transplantation.^{70,71} Both IV ganciclovir and oral valganciclovir may be used for preemptive therapy or for treatment of established CMV disease. Prolonged courses of low-dose ganciclovir or valganciclovir prophylaxis may be more effective in preventing CMV infection but can increase the risk of developing ganciclovir-resistant strains. The adverse events are similar among these agents and include myelosuppression and GI effects.¹⁰

Fungal Infections Fungal infections are an important cause of morbidity and mortality in solid organ transplant recipients.⁷² Immunologic (i.e., immunosuppressants, CMV infection), anatomic (i.e., tissue ischemia and damage), and surgical (i.e., duration of surgery, transfusion requirements) factors contribute to the risk for invasive fungal infections. Mucocutaneous candidiasis (i.e., oral thrush, esophagitis) is associated with corticosteroid and ALA use. **10** *Oral nystatin or clotrimazole troches are effective prophylactic options for the prevention of thrush.* However, clotrimazole inhibits the CYP3A system in the gut and can alter immunosuppressive levels.¹⁰ The use of systemic antifungal prophylaxis, such as oral fluconazole, is controversial due to the potential for

DDIs and the risk of developing resistance. The American Society of Transplantation has recommended antifungal prophylaxis in liver, lung, intestine, and pancreas transplantation.^{73,74} The choice of agents depends on the fungal risk in that particular population. For example, liver, intestine, and pancreas transplant recipients are at high risk for candidiasis; therefore, the use of medications that cover *Candida* spp. is crucial, such as the triazole antifungals (i.e., fluconazole, itraconazole) or the echinocandins (i.e., caspofungin, micafungin, anidulafungin). Lung transplant recipients are at high risk for aspergillosis; therefore, it is imperative to use antifungal prophylaxis that covers *Aspergillus* spp., such as the echinocandins or polyenes (i.e., amphotericin B, lipid-based amphotericin B products).^{73,74}

Polyomavirus One complication of increasing significance in renal transplant recipients is polyomavirus. In humans, there are two known pathologic polyoma strains, BK and JC. These viruses are rarely associated with disease in immunocompetent individuals. During periods of immunosuppression, the virus is reactivated and can be associated with significant morbidity.⁷⁵

In renal transplant recipients, the major diseases caused by BK virus (BKV) are tubulointerstitial nephritis and ureteral stenosis. BKV-induced nephropathy (BKVN) presents with evidence of allograft dysfunction, resulting in either an asymptomatic acute or slowly progressive rise in serum creatinine concentrations. Some studies have reported the incidence of BK viremia to be as high as 29%. It is estimated that BKVN affects up to 10% of renal transplant recipients, frequently resulting in permanent renal dysfunction or allograft loss.⁷⁵

Currently, treatment options for BKV are limited, and management recommendations are formulated based on individual case reports and small case series. Pharmacologic options with activity against BKV are limited; therefore, a reduction in the degree of immunosuppression in patients with BK viremia is often thought to be the first-line option to prevent BKVN. Despite the lack of a directed antiviral intervention, there are several agents that have anti-BK activity, including IVIG, cidofovir, leflunomide, and the fluoroquinolone antibiotics. All of these agents have been reported to provide some benefit in managing BKV in anecdotal cases.⁷⁵

Vaccination Vaccination is one of the most effective means of preventing infection and related complications.⁷⁶ However, there is a valid concern that solid organ transplant recipients may mount an inadequate response to vaccination due to immunosuppression. Required vaccinations should be administered prior to transplantation so that an appropriate antibody response can develop (Table 55-7). If this strategy is pursued, the earlier a vaccine is administered, the more effective it may be, as end-stage organ failure can also contribute to a decreased immune response.⁷⁶

In general, the weakest response to vaccine is within the first 6 months posttransplantation due to the intense level of immunosuppression during this period.⁷⁶ Vaccination within 6 months of transplant may be considered on a case-by-case basis in those patients who are at high risk of developing infection. Use of inactive vaccines is preferred in transplant recipients due to the relative risk of infection associated with live vaccines. Healthcare workers and family members who are in close contact with transplant recipients and have received a live vaccine should consider use of respiratory masks for at least 7 days after vaccination and adhere to strict oral and hand hygiene.⁷⁶

Table 55-7

Recommended Vaccinations Pre- and Posttransplant⁷⁶

Vaccine	Administration		Additional Information
	Before SOT	After SOT	
Hepatitis A	X		Immunize as soon as possible during course of disease
Hepatitis B	X		Immunize as soon as possible during course of disease (before transplant, administer 40 mcg dose in a series of 3–4 doses)
Herpes Zoster	X		Live ^a virus, administer greater than or equal to 14 days before immunosuppressant agents are initiated (experts advise 1 month before)
Human Papilloma Virus	X		Recommended for females aged 9–26, no recommendations for SOT
Influenza	X	X	Annual vaccination with inactivated intramuscular formulation recommended before and after SOT
Measles-Rubella	X		Live ^a virus, administer to patients who are seronegative, <i>before</i> transplant, or in women of childbearing age for prevention of congenital rubella syndrome
Pneumococcal	X	X	23-valent polysaccharide vaccine should be given once before transplant and boosters at 3 and 5 years after initial dose
Tetanus/diphtheria	X		TDaP booster indicated for less than 65 years old (may be given less than or equal to 2 years after last TDaP booster in SOT patients)
Varicella	X		Live ^a virus, administer to patients who are seronegative, <i>before</i> transplant

TDaP, tetanus, diphtheria, and pertussis

^aAll live vaccines are contraindicated post solid organ transplant (SOT), as they can cause serious infection.

Live vaccines:

Bacillus Calmette-Guerin

Herpes zoster

Live intranasal attenuated influenza

Live oral typhoid

Measles-rubella

Vaccinia (smallpox)

Varicella

Patient Encounter Part 3

Identify your treatment goals for ED in terms of antimicrobial prophylaxis.

Create a plan for ED's antimicrobial prophylaxis, making sure to compare and contrast the pros and cons of the different agents in this patient.

► Hypertension

- 10 Cardiovascular disease has been identified as the leading causes of death in organ transplant recipients.^{77,78} Post-transplant hypertension is associated with an increase in cardiac morbidity and patient mortality in all transplant patients and is also an independent risk factor for allograft dysfunction and loss. Based on all of the available post-transplant morbidity and mortality data, it is imperative that posttransplant hypertension be identified and managed appropriately.^{77,78}

There are several underlying mechanisms responsible for posttransplant hypertension. Some causes of hypertension in transplant recipients may include renal dysfunction, increased sensitivity to endothelin-1 and angiotensin, increased density of glucocorticoid receptors in the vascular smooth muscle, and decreased production of vasodilatory prostaglandins.^{77,78} However, one of the most easily recognized causes of posttransplant hypertension is the use of corticosteroids and the calcineurin inhibitors. Corticosteroids usually cause sodium and water retention, thus increasing blood pressure, whereas calcineurin inhibitors are associated with a number of effects that may result in hypertension, including reduced glomerular filtration rate (GFR) and renal blood flow (RBF), increased systemic and intrarenal vascular resistance, sodium retention, reduced concentrations of systemic vasodilators (i.e., prostacyclin, nitric oxide), and increased concentrations of vasoconstrictive thromboxanes. When compared with cyclosporine in clinical trials, tacrolimus displayed significantly less severe hypertension, and patients taking tacrolimus required significantly fewer antihypertensive medications at both 24 and 60 months after transplant.^{77,78}

- Treatment** 10 Controlling hypertension after transplant is essential in preventing cardiac morbidity and mortality and prolonging graft survival. The target blood pressure in kidney transplant recipients should be less than 130/80 mm Hg. This goal blood pressure may not be suitable for all organ transplant recipients. In such cases, the Joint National Committee Seventh Report (JNC 7) guidelines should be followed.^{77,78}
- Lifestyle Modifications** To achieve a goal blood pressure, lifestyle modifications including diet, exercise, sodium restriction, and smoking cessation are recommended.⁷⁴ Unfortunately, lifestyle modifications alone are often inadequate to control hypertension in this high-risk population, and antihypertensive medications are usually initiated early after transplant.^{77,78}

- Immunosuppressive Regimen Modification** Because tacrolimus has shown the propensity to cause less severe hypertension when compared with cyclosporine, conversion from cyclosporine-based immunosuppression to tacrolimus-based immunosuppression may be one way to help reduce the severity of hypertension in transplant recipients. 7 Conversion to a ToR inhibitor, which is not associated with increases in blood pressure, may also be an alternative to the calcineurin inhibitors in patients with difficult-to-treat hypertension. Corticosteroid taper or withdrawal are effective strategies for lowering blood pressure, but are not warranted in all clinical situations.^{77,78}

- Antihypertensive Agents** There is no single class of antihypertensive medications recognized as the ideal agent. Numerous factors must be considered when determining appropriate treatment for a given patient, including the safety and efficacy data of the available agents, patient-specific situations and potential comorbidities, and medication cost. A large majority of patients often require multiple medications to achieve their goal blood pressure. This conclusion is supported by the recommendations of JNC 7, where combination therapy is regarded as an appropriate first-line therapy.^{77,78}

- β-Blockers and thiazide diuretics have proven benefits in reducing cardiovascular disease-associated morbidity and mortality.^{77,78} Tolerability permitting, these agents are to be considered first-line therapies in most transplant recipients.
- The angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARB) have definite benefits in patients with nephropathy and are believed to have renoprotective effects in most patients. However, due to their ability to cause an initial increase in serum creatinine, these agents should be used cautiously when used in combination with
- the calcineurin inhibitors. The dihydropyridine calcium channel blockers have demonstrated an ability to reverse the nephrotoxicity associated with cyclosporine and tacrolimus. The addition of diltiazem to patients' regimens after cardiac transplant has also been shown to retard progression of cardiac allograft vasculopathy. In general, antihypertensive therapy should focus on agents with proven benefit in reducing the progression of cardiovascular disease and should be chosen on a patient-specific basis.^{77,78}

► Hyperlipidemia

- 10 Hyperlipidemia is seen in up to 60% of heart, lung, and renal transplant patients and greater than 30% of liver transplant patients.^{79,80} As a result of elevated cholesterol levels, transplant recipients are not only at an increased risk of atherosclerotic events, but emerging evidence also shows an association between hyperlipidemia and allograft vasculopathy. Hyperlipidemia, along with other types of cardiovascular disease, is now one of the primary causes of morbidity and mortality in long-term transplant survivors.^{79,80}

Elevated cholesterol levels in transplant patients are due to a culmination of factors such as age, genetic disposition, renal dysfunction, DM, proteinuria, body weight, and immunosuppressive therapy. Many of the immunosuppressive agents can produce elevations in serum lipid levels.^{79,80}

• **Treatment** 10 *Lowering cholesterol has shown to significantly decrease severe rejection and transplant vasculopathy and improve 1-year survival in heart transplant recipients.*⁸¹

Although these results cannot be extrapolated to other transplant populations, they do demonstrate the potential benefits of aggressive cholesterol lowering in organ transplant recipients. Due to high prevalence of cardiovascular disease among organ transplant recipients, most healthcare practitioners consider these patients to fall in the highest risk category for lipid lowering as established by the National Cholesterol

• **Education Panel (NCEP) III guidelines.** These guidelines call for a calculated low-density lipoprotein cholesterol (LDL-C) target level of less than 100 mg/dL (2.59 mmol/L).⁸²

• **Lifestyle Modifications** Generally, lowering cholesterol in patients begins with therapeutic lifestyle changes. These changes are initiated either alone or in conjunction with lipid-lowering drug therapy, depending on baseline cholesterol levels and other risk factors. Therapeutic lifestyle changes entail a reduction in saturated fat and cholesterol intake and an increase in moderate physical activity.⁸² As with hypertension, lifestyle modifications alone rarely are effective enough to achieve a goal LDL-C level.^{79,80} Modification of the immunosuppressive regimen and use of cholesterol-lowering medications are often warranted in this patient population.

• **Immunosuppressive Regimen Modifications** Tacrolimus has shown the propensity to cause less severe hyperlipidemia when compared with cyclosporine. Conversion from cyclosporine-based immunosuppression to tacrolimus-based immunosuppression may be one way to counteract this disease in transplant recipients.^{79,80}

In past studies, steroid withdrawal in renal transplant patients did lower total cholesterol by 17% and LDL cholesterol by 16%; unfortunately, an 18% decrease in high-density lipoprotein (HDL) levels was also noted in these patients.^{79,80}

• **Cholesterol-Lowering Agents** 3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, or statins, are considered to be first-line therapy for hyperlipidemia in the general population.^{79,80,82} However, there is some uncertainty about the pathogenesis of cardiovascular disease in transplant recipients and whether statin therapy will have similar effectiveness in organ transplant recipients. Statins have shown definite advantages when used in heart transplantation, including a reduction in LDL-C and major adverse cardiac events (MACE), as well as an apparent cardioprotective effect. In renal transplant recipients, statins are known to lower LDL-C levels and reduce the incidence of some cardiac events; however, the ability to lower MACE may not be evident in this patient population. Despite these mixed results, statins are still considered the primary therapeutic option for hyperlipidemia in all organ transplant recipients.^{79,80} Finally, when choosing a statin for management of hyperlipidemia in the transplant recipient, a focus on potential DDIs is warranted. It is recommended that doses of atorvastatin do not exceed 10 mg daily when taken with cyclosporine due to an increased risk of myopathy and

rhabdomyolysis. Use of cyclosporine in conjunction with simvastatin is considered a contraindication due to the risk of the skeletal muscle effects aforementioned.^{79,80}

• **Fibric acid derivatives** are an excellent choice for lowering triglycerides, but are not as effective as statins at lowering LDL-C.^{79,80} These agents may play a role in conjunction with statins in patients with both elevated cholesterol and triglycerides. Nicotinic acid is very effective at improving the lipid panel, with excellent results in lowering LDL-C, as well as increasing HDL. However, patient tolerability issues are of concern with this agent. The bile acid sequestrants should be avoided in organ transplant recipients due to their high incidence of GI adverse events, as well as their propensity for pharmacokinetic DDIs with MPA. Ezetimibe has proven safe and effective in lowering LDL-C in renal transplant recipients. Future studies are needed to establish ideal regimens involving the antihyperlipidemic and immunosuppressive medications to decrease morbidity and mortality and ultimately prevent cardiovascular events.^{79,80}

► **New-Onset DM After Transplantation**

• 10 *New-onset DM after transplantation (NODAT) is a serious complication that is often underestimated by transplant practitioners.*⁸³ Kasiske and colleagues attempted to quantify the cumulative incidence of NODAT in renal transplant recipients and found that 8.3% of patients developed NODAT at 3 months posttransplant, 12.9% at 12 months, and 22.3% at 36 months.⁸⁴ Even more alarming is that recent studies have revealed an overwhelming prevalence of impaired glucose tolerance, which is also accepted as a risk factor for long-term morbidity and mortality. NODAT is associated with increases in cardiovascular events, with an approximately 22% higher risk of mortality. Patients with NODAT are also more likely to suffer acute rejection episodes and infectious complications than patients without this complication.⁸³

• **Prevention** 10 *NODAT prevention mainly consists of identifying patients at risk before transplant and controlling modifiable risk factors both before and after transplantation.*⁸³ The major modifiable risk factors are choice of immunosuppressive therapy and body mass index (BMI). For example:

- **Immunosuppressive medications:** Steroid minimization and possibly withdrawal are effective strategies for the prevention of NODAT. Also, patients with worsening (increased) blood glucose after transplantation who are receiving tacrolimus may benefit from conversion to cyclosporine.⁸³
- **Body mass index:** A reduction in body weight is always recommended in obese patients prior to the transplant procedure to help lower their NODAT risks.^{83,83}

• **Treatment** 10 *Lifestyle modifications are always in order in patients who have developed or those who are at increased risk of developing NODAT.*⁸³ Insulin therapy and oral hypoglycemic agents are often utilized in those patients in whom lifestyle modifications alone have not controlled blood glucose. Please refer to Chapter 43 for proper instruction

on choosing the appropriate treatment regimens in patients with DM.⁸³

► Neoplasia

Cancer Screening in Transplant Patients Transplant recipients are at increased risk for different types of specific cancers (Table 55–8).⁸⁶ The risk of developing Kaposi's sarcoma following transplantation is over 200 times that in the general population. In addition, the risk of nonmelanocytic and melanocytic skin cancer is 10 to 20 times higher compared with the nontransplanted population. Transplant recipients are at greatest risk for the types of cancers associated with viral infections, such as PTLT, cervical, and vulvovaginal cancers. Solid organ tumors like colorectal and lung cancers are two to three times higher in transplant recipients when compared with the general population. The American Cancer Society and American Transplant Society recommend cancer screening for most adults who have undergone transplantation (Table 55–9). Although clinical research has not yet proven that the potential benefits of testing outweigh the harms of testing in transplant recipients, most believe that transplant recipients should be tested and screened very closely.⁸⁶

Skin Cancer Skin cancer remains the most common malignancy after organ transplantation. The incidence of these types of cancers increases with time posttransplant, with one study showing a prevalence rate of 35% among patients within 10 years after transplant.⁸⁵ More alarming than the high prevalence is the activity of these cancers in patients on maintenance immunosuppression. Skin cancers

in transplant recipients tend to grow more rapidly and are more likely to metastasize.⁸⁷

The most common risk factors for skin cancer development after transplant include increased age; excessive ultraviolet (UV) light exposure; high degree of immunosuppression; Fitzpatrick skin types I, II, and III; history of skin cancers; and infection by human papillomavirus.⁸⁷ **7** A recent analysis suggests that use of sirolimus in place of a calcineurin inhibitor in kidney transplant recipients can reduce the risk of nonmelanoma skin carcinomas.⁸⁸

It is of the utmost importance that transplant practitioners be vigilant about educating their patients about excessive exposure to the sun.⁸⁷ Patients should be warned about the risk of skin cancer and be advised on simple methods to limit their risk:

- Use of protective clothing (i.e., long-sleeved shirts and long pants, dark-colored clothing)
- Use of sunscreen daily that is applied to all sun-exposed skin
- Sun protection factor (SPF) 30 or higher is recommended

► Posttransplant Lymphoproliferative Disorders

10 PTLTs are a major complication in patients following organ transplantation.⁸⁹ Large series of case reports have demonstrated that the incidence of PTLT is 1% for renal patients, 1.8% for cardiac patients, 2.2% for liver patients, and 9.4% for heart-lung patients. The risk of developing non-Hodgkin's lymphoma is 28- to 49-fold higher in solid organ transplant recipients compared with the general population. Another independent risk factor is the presence of EBV.^{85,89,90} Lymphomas are the most common form of PTLT in transplant recipients.⁸⁹

The incidence of disease depends on certain factors. These factors include the type of organ transplanted, the age of the transplant recipient, the degree of immunosuppression, the type of immunosuppression, and exposure to EBV. The mortality rate in these patients is about 50%, with most patients dying shortly after diagnosis. It has also been demonstrated that the risk of developing PTLT is greater in the population of EBV seronegative patients at the time of transplant.⁸⁹

Another risk factor for the development of PTLT is the type of immunosuppressive regimens used. Belatacept has been approved with a black box warning outlining an increased risk of PTLT, especially of the CNS. Patients who are EBV seronegative or have an unknown immunity to EBV should not be considered for therapy. ALAs have come to be widely used in the prevention and treatment of acute rejection. These agents work by causing widespread T-cell lysis. Immunosuppressive regimens utilizing the ALAs have been proven to increase the risk of PTLT.⁸⁹

Treatment **10** Treatment for PTLT is still controversial; however, the most common treatment options include reduction of immunosuppression, chemotherapy, and anti-B-cell monoclonal antibodies.⁸⁹ PTLT continues to be a long-term complication of prolonged immunosuppression. Current treatment options are all associated with certain risks.

Table 55–8

Overall Risk of Different Types of Cancer in Transplant Patients^{86,87,89,90}

Cancer	Cumulative Incidence (/100,000)	Male	Female
Kaposi's sarcoma	140	17.4	62
Kidney/ureter	1,010	14.1	14.6
Lymphoma	80	6.9	29.1
Bladder	126	1.6	3.6
Esophagus	70	2.4	2.8
Cervix	180	–	5.7
Liver	220	4.2	4.5
Melanoma	320	6.9	5.2
Lung/bronchus/ trachea	690	2.3	3.6
Colorectal	510	1.6	2.8
Breast	1,050	4	1.1
Prostate	1,740	1.6	–

Table 55-9

Cancer Screening Recommendations in Transplant Patients^{86,87,89,90}

Cancer Type	General Populations	Transplant Populations
Breast	Mammography every 1–2 years for all women greater than or equal to 50 years old. Clinical breast exam every 3 years in women 20–39 years old, yearly after age 40. Monthly self-exam.	Mammography every 1–2 years for all women greater than or equal to 50 years old. May undergo screening between 40 and 49 years old but no evidence for or against screening in this age group.
Cervical	Annual Pap smear & pelvic exam once sexually active; after 3 or more tests with normal results, may decrease frequency of exams.	Annual Pap smear & pelvic exam once sexually active.
Colorectal	Annual FOBT plus flexible sigmoidoscopy every 5 years for all patients greater than or equal to 50 years old or colonoscopy and DRE every 10 years.	Annual FOBT plus flexible sigmoidoscopy every 5 years for all transplant patients greater than or equal to 50 years old.
Prostate	Annual DRE & PSA for men greater than or equal to 50 years old with 10-year life expectancy or younger men at high risk.	Annual DRE & PSA measurement in all males greater than or equal to 50 years old.
Hepatocellular	Not recommended for average-risk individuals. α -Fetoprotein and ultrasound every 6 months in high-risk patients (no firm supporting data).	α -Fetoprotein and ultrasound every 6 months in high-risk patients (no firm supporting data).
Skin	Skin exam every 3 years between ages 20 and 40, annually thereafter.	Monthly self-exam. Total body skin exam every 6–12 months by dermatologists
Renal	Insufficient evidence to support routine screening.	No firm recommendations. Regular ultrasound of native kidneys.
Lung	Insufficient evidence to support routine screening.	No firm recommendations
Ovarian	Insufficient evidence to support routine screening.	No firm recommendations
Testicular	Insufficient evidence to support routine screening.	No firm recommendations
Endometrial	Insufficient evidence to support routine screening.	No firm recommendations

DRE, digital rectal exam; FOBT, fecal occult blood test; PSA, prostate-specific antigen.

Prevention is the most effective treatment for PTLD. A better understanding in the future of the disease process and the risk factors involved with the development of PTLD will aid in the prophylaxis and treatment of this disorder.⁸⁹

► Pregnancy

- Females of childbearing age who do not wish to become pregnant after transplantation require adequate education on preferred forms of birth control. The optimal method of birth control in this patient population is the barrier method (e.g. condom, diaphragm). Use of intrauterine devices and progestin-based oral contraceptives are controversial, and associated risks must be considered prior to initiating therapy. Intrauterine devices may be less effective in the setting of immunosuppression and predispose patients to an increased risk of infection.⁹¹ Progestin-based oral contraceptives are considered a less effective form of birth control, but may be a safe option in those patients who have well-controlled hypertension.
- Female patients considering pregnancy after transplantation should be educated extensively regarding the potential risks that transplantation and medical immunosuppression may present to a fetus. Risks to the infant include premature birth (50%) and intrauterine growth restriction (20%), which may result in death or long-term complications, including

cerebral palsy, blindness, deafness, and learning deficiencies.⁹¹ Patients hoping to become pregnant should wait at least 1 year after transplantation to ensure reconstitution of gonadal function posttransplant, as well as demonstrate a 1-year freedom from acute rejection.⁹¹

Understanding the associated risk of immunosuppressives while pregnant is paramount considering their ability to cross the placenta as well as enter breast milk (Table 55-10). Tacrolimus and cyclosporine, both Pregnancy Category C, are the backbone of immunosuppressive therapy and have been used safely and effectively in pregnancy posttransplant for decades.⁹² Side effects associated with calcineurin inhibitors such as hypertension, diabetes, and nephrotoxicity should be monitored closely in the pregnant population. Sirolimus is also Pregnancy Category C and has not been associated with fetal malformation but has been correlated with low birth weight.⁹² Corticosteroids, pregnancy category B, are recognized to be relatively safe and have been used extensively in pregnancy after transplantation. However, they carry a risk of premature membrane rupture and newborn adrenal insufficiency.⁹² More common side effects associated with corticosteroids that may cause complications in pregnancy include hypertension, diabetes, weight gain, and poor wound healing. Due to teratogenic effects in animal studies, azathioprine is considered Pregnancy Category D; however, it has been used extensively as an antimetabolite in pregnant

Patient Encounter Part 4

ED continues to have his posttransplant care at your renal transplant ambulatory care clinic. He returns to your clinic 1 month after the transplant:

Labs:

Na: 141 mEq/L (141 mmol/L)

K: 4.7 mEq/L (4.7 mmol/L)

Cl: 198 mEq/L (198 mmol/L)

CO₂: 21 mEq/L (21 mmol/L)

BUN: 21 mg/dL (7.5 mmol/L)

SCr: 1.1 mg/dL (97.2 μmol/L)

Glucose: 110 mg/dL (6.1 mmol/L)

Lipid panel: TC = 341 mg/dL (8.8 mmol/L), LDL-C = 179 mg/dL (4.6 mmol/L), HDL = 47 mg/dL (1.2 mmol/L), TG = 575 mg/dL (6.5 mmol/L)

Uric acid: 10.6 mg/dL (630.5 μmol/L)

Tacrolimus: 11.7 mg/dL

Vitals: BP 164/95 mm Hg (162/88 mm Hg repeated), HR 87 beats/min

Medications:

- Tacrolimus 6 mg by mouth twice a day
- Mycophenolate mofetil 1000 mg by mouth twice a day
- Prednisone 10 mg by mouth once a day
- Atovaquone 1500 mg by mouth once a day
- Valganciclovir 900 mg by mouth once a day
- Atorvastatin 20 mg by mouth once a day
- Metoprolol XL 100 mg by mouth once a day
- Amlodipine 5 mg by mouth once a day
- Zolpidem 10 mg by mouth once a day at bedtime
- Alprazolam 0.5 mg by mouth three times a day as needed for anxiety

Identify why ED is taking each agent listed.

What are some treatment options for ED's elevated blood pressure?

What are some treatment options for ED's elevated cholesterol?

What are some treatment options for ED's elevated uric acid?

Design a monitoring plan for ED's therapy.

thioprine, should be substituted for mycophenolate mofetil or enteric-coated MPA in patients who plan on becoming pregnant. The safety of ALAs and rituximab in transplantation has yet to be fully determined; however, IVIG has been widely used without any documented adverse events.⁹¹ Newly available immunosuppressives, belatacept and everolimus, are pregnancy category C but are not recommended for use in pregnant patients due to inadequate human data.

► Immunosuppressant Therapy Adherence

Transplant recipients require strict adherence to their medication regimens to ensure optimal allograft and patient outcomes. Nonadherence in this population can be attributed to the complexity of the regimens coupled with the variability in drug dosing, need for therapeutic drug monitoring, avoidance of potential drug-drug interactions, infectious risks, and drug toxicities. The incidence of nonadherence to immunosuppressant therapy in the first year posttransplant has been estimated to be as high as 22.6%.⁹³ This is especially alarming when one considers that 35% of all graft failures can be directly attributed to nonadherence.⁹⁴ Risk factors associated with immunosuppressant therapy nonadherence include a history of substance abuse, personality disorders, and lack of social support.⁹⁵ The roll of the pharmacist in educating patients on the importance of their medication regimens and stressing the need for adherence is paramount in optimizing both patient and allograft survival after transplantation. Previous reports have suggested that intervention by a pharmacist posttransplant improves adherence.⁹⁶

OUTCOME EVALUATION

- Successful outcomes in solid organ transplantation are generally measured in terms of several separate end points: (a) preventing acute rejection, (b) increasing 1-year graft survival, (c) preventing immunosuppressive drug complications, and (d) improving long-term allograft and patient survival.
- The short-term goals after organ transplantation revolve around reducing the incidence of acute rejection episodes and attaining a high graft survival rate. By accomplishing these goals, transplant clinicians hope to attain good allograft function to allow for an improved quality of life. These goals can be achieved through the appropriate use of medical immunosuppression and scrutinizing over the therapeutic and toxic monitoring parameters associated with each medication employed. In addition, transplant recipients should be monitored for adverse drug reactions, DDIs, and adherence with their therapeutic regimen.
- The long-term goals after organ transplant are to maximize the functionality of the allograft and prevent the complications of immunosuppression, which lead to improved patient survival. Clinicians must play multiple roles in the long-term care of transplant recipients, as not only must the patient be followed

transplant patients without extensive evidence of harm to the fetus. 6-Mercaptopurine has not been shown to cross the placental barrier.

Currently, the MPA derivatives, both Pregnancy Category D, are not considered optimal immunosuppressive agents for patients who become pregnant, and alternative therapies should be pursued.⁹² A less teratogenic antimetabolite, aza-

Table 55–10

Transplant Immunosuppressants and Pregnancy^{9,91,92}

Drug	Male Reproduction	Female Reproduction	Recommendations	Pregnancy Category
Prednisone	Prednisone may lead to decreased spermatogenesis.	Prednisone and prednisolone pose a small risk to the developing fetus. One of these risks appears to be orofacial clefts.	Female: No changes recommended. May need to decrease dose to improve spermatogenesis.	B
AZA	Treatment with azathioprine has not been associated with changes in semen quality.	Most investigators found azathioprine to be safe in pregnancy. Leukopenia and thrombocytopenia in the neonate has been seen.	Male: No changes recommended. Female: Continue during pregnancy. Dose adjustments may be made to maintain normal maternal leukocyte counts.	D
MPA	MPA resulted in an incidence of birth defects similar to that of the general population.	MPA in the first trimester is associated with increased risk for fetal death and structural defects. Malformations were external ear, facial anomalies, cleft lip/palate, and defects of limbs, heart, esophagus and kidney.	Male: No changes recommended. Female: Guidelines recommend against its use. Use contraception during therapy and for 6 weeks after therapy is stopped, switch to AZA.	D
ToR Inhibitors	Men on mammalian ToRs have been shown to have decreased fertility because of impaired spermatogenesis and azoospermia. This was reversible when switched to alternate agent.	Very limited data exist for human pregnancy in offspring of mothers on sirolimus; no data on everolimus.	Male: No changes recommended. Female: Guidelines recommend against its use. Use effective contraception before and during therapy and for 12 weeks after therapy is stopped.	C
CsA	No definitive evidence of malformations or major birth defects was seen in children fathered by patients on cyclosporine. Motility was affected in patients on cyclosporine only when levels exceeded normal therapeutic range.	Cyclosporine does not seem to be a human teratogen.	Male: Change to alternate agent when attempting to father a child. Female: May be used, recommend waiting to conceive until 12 months after transplant.	C
TAC	No definitive evidence of malformations or major birth defects was seen in children fathered by patients on tacrolimus. No information has been found to associate tacrolimus with oligospermia.	An abortive risk has been shown in animal models. However, human experience has shown low fetal/embryo risk.	Male: No changes recommended. Female: May be used, recommend waiting to conceive until 12 months after transplant.	C
Basiliximab	No studies have been done to assess basiliximab effects on male fertility.	No data	Male: No changes recommended. Female: Not recommended in pregnant females due to lack of evidence for safety.	C
r-ATG	No studies have been done to assess r-ATG effect on male fertility.	r-ATG use during five human pregnancies has been reported without apparent adverse fetal consequences.	Male: Avoid if attempting to have children. Female: Not recommended in pregnant females due to lack of evidence for safety.	C
Belatacept	No studies have been done to assess belatacept effect on male fertility.	No data	Male: Not recommended due to lack of evidence for safety. Female: Not recommended in pregnant females due to lack of evidence for safety.	C
Rituximab	No studies have been done to assess rituximab effect on male fertility.	Infants born to patients on rituximab were all born healthy (6 patients). Similar to research in monkey offspring. Immunosuppression was found in 1 infant and was normal at 4 months.	Males: No studies, use contraception while on rituximab therapy. Females: Appears to be safe.	C

AZA, azathioprine; CsA, cyclosporine; MPA, mycophenolic acid; r-ATG, rabbit antithymocyte immunoglobulin; TAC, tacrolimus; ToR, target of rapamycin.

from an immunologic perspective, but practitioners must be focused on identifying and treating the adverse sequelae associated with lifelong immunosuppression including cardiovascular disease, malignancy, infection, and osteoporosis among others. Again, limiting drug misadventures and ensuring adherence with the therapeutic regimen are important and should be stressed.

Abbreviations Introduced in This Chapter

6-MP	6-Mercaptopurine
ACE	Angiotensin converting enzyme
ALA	Antilymphocyte antibodies
AMR	Antibody mediated rejection
APC	Antigen-presenting cell

Patient Care and Monitoring

Early Management of Transplant Recipients

1. Review any available diagnostic and laboratory data to evaluate the function of the allograft and the health of the recipient.
2. Assess the patient's current medication regimen, including:
 - Induction therapy agent:
 - Assess for appropriate dose and duration of therapy
 - Therapeutic monitoring parameters (organ function)
 - Toxic monitoring parameters
 - Maintenance immunosuppressive agents:
 - Assess for appropriate dose and duration of therapy
 - Therapeutic monitoring parameters (organ function)
 - Toxic monitoring parameters
 - Antiinfective prophylaxis:
 - Assess suitability of chosen prophylactic agents (e.g., drug allergies, CMV donor, and recipient serostatus)
 - Therapeutic monitoring parameters
 - Toxic monitoring parameters
 - Medications used for comorbidities:
 - Assess appropriate selection of these medications for pharmacokinetic and pharmacodynamic DDIs, need (e.g., do renal transplant recipients need to continue to take erythropoietin?), and efficacy
 - Therapeutic monitoring parameters
 - Toxic monitoring parameters
3. Evaluate the patient for the presence of adverse drug reactions, drug allergies, or DDIs.
4. Develop patient-specific short-term and long-term therapeutic goals.
5. Provide patient education regarding the organ transplant, the complications associated with transplantation, the need for lifestyle modifications to reduce risk of complications (e.g., wear sunscreen, low-sodium diet), and drug therapy.
6. Stress importance of adherence with therapeutic regimen.

Outpatient Management of Transplant Recipients

1. Obtain a thorough history of prescription, nonprescription, and complimentary and alternative medication use.
 - Maintenance immunosuppressive agents:
 - Assess for appropriate dose and duration of therapy
 - Therapeutic monitoring parameters (organ function)
 - Toxic monitoring parameters
2. Antiinfective prophylaxis:
 - Assess suitability of chosen prophylactic agents (e.g., drug allergies, CMV donor, and recipient serostatus)
 - Does the patient need continued prophylaxis therapy?
 - When do you stop prophylaxis?
 - Therapeutic monitoring parameters
 - Toxic monitoring parameters
3. Medications used for comorbidities:
 - Assess appropriate selection of these medications for pharmacokinetic and pharmacodynamic DDIs, need, and efficacy
 - Therapeutic monitoring parameters (drug- and disease-specific)
 - Toxic monitoring parameters (drug-specific)
4. Evaluate the patient for the presence of adverse drug reactions, drug allergies, or DDIs.
5. Reassess your patient-specific short-term and long-term therapeutic goals.
6. Continue with patient education in regard to the complications associated with transplantation, the need for lifestyle modifications to reduce risk of the complications (e.g., wear sunscreen, low-sodium diet), and drug therapy.
7. Reemphasize the importance of adherence with therapeutic regimen.
8. Assess improvement in quality-of-life measures such as physical, psychological and social functioning, and well-being.

ARB	Angiotensin receptor blocker	MPA	Mycophenolic acid
ATG	Antithymocyte globulin	MPAG	MPA-glucuronide
ATGAM	Antithymocyte globulin equine	NCEP	National Cholesterol Education Program
AZA	Azathioprine	NFAT (NFAT-P)	Nuclear factors
BKV	BK virus	NK	Natural killer
BKVN	BK virus-induced nephropathy	NODAT	New-onset diabetes mellitus after transplantation
BMI	Body mass index	NSAID	Nonsteroidal anti-inflammatory drug
BUN	Blood urea nitrogen	NYHA	New York Heart Association
C ₀	Trough concentration	P-gp	P-glycoprotein
C ₂	Drug concentration 2 hours postdose	PO ₄	Phosphate
CCB	Calcium channel blocker	PRA	Panel of reactive antibodies
CD4 ⁺	Helper T cells	PSA	prostate-specific antigen
CD8 ⁺	Cytotoxic T cells	PTLD	Posttransplant lymphoproliferative disorders
CKD	Chronic kidney disease	r-ATG (RATG)	Antithymocyte globulin rabbit
CMV	Cytomegalovirus	RBF	Renal blood flow
CNI	Calcineurin inhibitor	SCr	Serum creatinine
CNS	Central nervous system	SMZ-TMP	Sulfamethoxazole-trimethoprim
CSA	Cyclosporine	SOB	Shortness of breath
CXR	Chest x-ray	SOT	Solid organ transplant
CYP	Cytochrome P-450 system	SPF	Sun protection factor
CYP3A	Cytochrome P-450 system 3A isozyme	SPK	Simultaneous pancreas-kidney
DC	Dendritic cell	SRL	Sirolimus
DDI	Drug-drug interaction	SS	Single strength
DM	Diabetes mellitus	TAC	Tacrolimus
DOE	Dyspnea on exertion	TC	Total cholesterol
DRE	Digital rectal exam	TCR	T-cell receptor
DSA	Donor-specific antibody	TDaP	Tetanus, diphtheria, and pertussis
DS	Double strength	TG	Triglycerides
e-ATG	Antithymocyte globulin equine	ToR	Target of rapamycin
EBV	Epstein-Barr virus	UV	Ultraviolet
EC	Enteric-coated	WBC	White blood cells
ESRD	End-stage renal disease		
EVL	Everolimus		
FBS	Fasting blood sugar		
FEV	Forced expiratory volume		
FOBT	Fecal occult blood test		
G6PD	Glucose-6-phosphate-dehydrogenase		
GFR	Glomerular filtration rate		
GI	Gastrointestinal		
HDL	High-density lipoproteins		
HLA	Human leukocyte antigen		
HMG-CoA	3-Hydroxy-3-methylglutaryl coenzyme A		
HPLC	High-performance liquid chromatography		
HTN	Hypertension		
IgG	Immunoglobulin G		
IL-2	Interleukin 2		
IL-2RA	Interleukin-2 receptor antagonist		
IVIG	Intravenous immune globulin		
JNC 7	Joint National Committee Seventh Report		
K	Potassium		
LDL-C	Low-density lipoprotein cholesterol		
LFT	Liver function test		
MAC	Membrane attack complex		
MACE	Major adverse cardiac events		
Mg	Magnesium		
MHC	Major histocompatibility complex		
MMF	Mycophenolate mofetil

Osteoporosis

Beth Bryles Phillips and Maria Miller Thurston

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Explain the association between osteoporosis and morbidity and mortality.
2. Identify risk factors that predispose patients to osteoporosis.
3. Describe the pathogenesis of fractures.
4. List the criteria for diagnosis of osteoporosis.
5. Recommend appropriate lifestyle modifications to prevent bone loss.
6. Compare and contrast the effect of available treatment options on reduction of fracture risk.
7. Recommend an appropriate treatment regimen for a patient with osteoporosis and develop a monitoring plan for the selected regimen.
8. Educate patients on osteoporosis and drug treatment, including appropriate use, administration, and adverse effects.

KEY CONCEPTS

- 1 Major risk factors for osteoporotic fracture as defined by the World Health Organization (WHO) are low bone mineral density (BMD), personal history of adult fracture, age, family history of osteoporotic fracture, current cigarette smoking, low body mass index, excessive alcohol use, and chronic glucocorticoid use.
- 2 A standardized approach for diagnosing osteoporosis is recommended using central dual-energy x-ray absorptiometry (DXA) measurements.
- 3 Both pharmacologic and nonpharmacologic therapies for osteoporosis are aimed at preventing fractures and their complications, maintaining or increasing BMD, preventing secondary causes of bone loss, and improving morbidity and mortality.
- 4 All men and women over age 50 should be considered for pharmacologic treatment if they meet any of the following criteria: (a) history of hip or vertebral fracture, (b) *T*-score less than or equal to -2.5 at femoral neck or spine, or (c) osteopenia and at least a 3% 10-year probability of hip fracture or at least a 20% 10-year probability of major osteoporosis-related fracture as determined by FRAX.
- 5 Adequate calcium and vitamin D intake is essential in prevention and treatment of osteoporosis. Calcium and vitamin D supplements to meet requirements should be added to all drug therapy regimens for osteoporosis.
- 6 Bisphosphonates are first-line therapy for postmenopausal and male osteoporosis due to established efficacy in preventing hip and vertebral fractures.
- 7 The American College of Rheumatology (ACR) recommends bisphosphonate therapy with alendronate or risedronate for all patients who are starting treatment with glucocorticoids (prednisone 5 mg or more daily or equivalent) that will continue for 3 months or longer.

INTRODUCTION

Osteoporosis is a common and often silent disorder causing significant morbidity and mortality and reduced quality of life. It is associated with increased risk and rate of bone fracture and is responsible for more than 1.5 million fractures in the United States annually resulting in direct healthcare costs of more than \$17 billion.¹ As the population ages, these numbers are expected to increase by two- to threefold. It is estimated that postmenopausal white women have a 50% lifetime chance of developing an osteoporosis-related fracture, whereas men have a 20% lifetime chance.¹ Common sites of fracture include the spine, hip, and wrist, although almost all sites can be affected. Only a fraction of patients with osteoporosis receive optimal treatment.

- The fractures associated with osteoporosis have an enormous impact on individual patients. In addition to the initial pain associated with a new fracture, several adverse long-term

complications can occur, including chronic pain, loss of mobility, depression, nursing home placement, and death. Patients with vertebral fractures may experience chronic pain, height loss, **kyphosis**, and decreased mobility due to limitations in bending and reaching. Multiple vertebral fractures may lead to restrictive lung disease and altered abdominal anatomy. Patients with hip fractures have added risks associated with surgical intervention to repair the fracture. Some patients never fully recover or regain preinjury independence. Death is common in the year after a hip fracture.¹

EPIDEMIOLOGY AND ETIOLOGY

Osteoporosis is the most common skeletal disorder, affecting more than 10 million Americans. Additionally, more than 34 million Americans have low bone mass. Only one in three patients with osteoporosis are diagnosed, and only one in seven receives treatment.² Osteoporosis can be classified as either primary (no known cause) or secondary (caused by drugs or other diseases). Primary osteoporosis is most often found in postmenopausal women and aging men, but it can occur in other age groups as well.

The prevalence of osteoporosis varies by age, gender, and race/ethnicity. The risk of fracture increases exponentially with each decade in age over 50.³ Residents of nursing homes may be at an even higher risk of fracture. Both men and women lose bone as they age. However, women have accelerated bone loss surrounding menopause due to loss of estrogen. Men have some protection from osteoporosis due to their larger initial bone mass and size and lack of accelerated bone loss associated with menopause.⁴ **Fragility fractures** of the hip and spine are common among men, especially as age increases. Men comprise 20% of the Americans with osteoporosis. Secondary causes of osteoporosis, such as **hypogonadism**, are found more commonly in men with fragility fractures.⁴ Most hip fractures occur in postmenopausal white women; this group also has the highest incidence of fracture when adjusted for age. The incidence of osteoporosis and low bone mass is highest in white women, followed by Asian, Hispanic, and African American women, respectively.⁵

Many of the risk factors for osteoporosis and osteoporotic fractures are predictors of low BMD, such as age and ethnicity (**Table 56-1**). **1** Major risk factors for osteoporotic fracture as defined by the World Health Organization (WHO) are low BMD, female sex, age, race/ethnicity, personal history of fragility fracture as an adult, family history of osteoporotic fracture, low body mass index, past or present oral glucocorticoid use, current cigarette smoking, and excessive alcohol use.⁶ As BMD decreases, the risk of fracture increases. However, the threshold at which individual patients develop a fracture varies, and other factors may play a role in fracture susceptibility. One such factor that can influence the development of fracture is falling.

Osteoporosis can also develop from secondary causes such as concurrent disease states and drugs (**Table 56-2**). Approximately one-third to one-half of osteoporosis cases in men and half of all cases in perimenopausal women are due to secondary causes.⁵ Common secondary causes in men

Table 56-1

Risk Factors for Osteoporosis and Osteoporotic Fractures^{1,2}

Risk Factors for Osteoporosis	Risk Factors for Falling and Fractures
Low bone mineral density ^a	Poor health/frailty
Female sex ^a	Impaired gait or balance
Advanced age ^a	Recent falls
Race/ethnicity ^a	Cognitive impairment
History of previous low trauma (fragility) fracture as an adult ^a	Impaired vision
Osteoporotic fracture in a first-degree relative (especially parental hip fracture ^a)	Environmental factors (e.g., stairs, throw rugs, pets, poor lighting)
Low body weight or body mass index ^a	
Premature menopause (before 45 years old) ^b	
Secondary osteoporosis ^b (especially rheumatoid arthritis ^a)	
Past or present systemic oral glucocorticoid therapy ^a	
Current cigarette smoking ^a	
Alcohol intake of three or more drinks per day ^a	
Low calcium intake	
Low physical activity	
Minimal sun exposure	

^aMajor risk factors used in the World Health Organization (WHO) fracture risk model.

^bSecondary causes included in the FRAX tool question are type 1 diabetes, osteogenesis imperfecta as an adult, longstanding untreated hyperthyroidism, hypogonadism, premature menopause (before 45 years of age), chronic malnutrition, malabsorption, and chronic liver disease.

Adapted from DiPiro JT et al, eds. *Pharmacotherapy: A Pathophysiologic Approach*. 8th ed. New York: McGraw-Hill; 2011:1563, Table 99-1; With permission.

include hypogonadism and alcoholism. The most common cause of drug-induced osteoporosis is glucocorticoid use.

PATHOPHYSIOLOGY

The human skeleton is comprised of both cortical and trabecular bone. Cortical bone is dense and compact and is responsible for much of bone strength. It is the most common type of bone and accounts for approximately 80% of the skeleton. It is generally found on the surfaces of long and flat bones. Trabecular or cancellous bone has a sponge-like appearance and is generally found along the inner surfaces of long bones and throughout the vertebrae, pelvis, and ribs.

Under normal circumstances, the skeleton undergoes a dynamic process of **bone remodeling**. Bone tissue responds to stress and injury through continuous replacement and repair. This process is completed by the basic multicellular unit, which includes both **osteoblasts** and **osteoclasts**. Osteoclasts are involved with **resorption** or breakdown of bone and continuously create microscopic cavities in bone

Table 56-2

Medical Conditions and Drugs Associated with Osteoporosis or Low Bone Mass

Medical Conditions	Drugs
Alcoholism	Anticonvulsants (phenytoin, phenobarbital)
Chronic kidney disease	Aromatase inhibitors (anastrozole, exemestane, letrozole)
Cushing's syndrome	Cytotoxic drugs (e.g., methotrexate, cisplatin)
Cystic fibrosis	Glucocorticoids (5 mg or more of prednisone daily or equivalent for at least 3 months)
Diabetes mellitus	Gonadotropin-releasing hormone analogs (leuprolide acetate, nafarelin, goserelin)
Eating disorders	Heparin
GI disorders (e.g., gastrectomy, malabsorption syndromes)	Immunosuppressants (e.g., tacrolimus)
Hematologic disorders (e.g., hemophilia)	Lithium
Hyperparathyroidism	Medroxyprogesterone acetate
Hyperthyroidism	Thyroid supplements (due to over-replacement)
Hypogonadal states	Total parenteral nutrition
Organ transplantation	
Skeletal cancer (e.g., myeloma)	

tissue. Osteoblasts are involved in bone formation and continuously mineralize new bone in the cavities created by osteoclasts. Until peak bone mass is achieved between the ages of 25 and 35, bone formation exceeds bone resorption for an overall increase in bone mass. Trabecular bone is more susceptible to bone remodeling in part due to its larger surface area. **Figure 56-1** illustrates the difference between normal and osteoporotic bone.

In osteoporosis, an imbalance in bone remodeling occurs. Most commonly, osteoclastic activity is enhanced, resulting

FIGURE 56-1. Normal trabecular bone (left) compared with trabecular bone from a patient with osteoporosis (right). The loss of mass in osteoporosis leaves bones more susceptible to breakage. From Barnett KE, Barman SM, Boitano S. Brooks H. Ganong's Review of Medical Physiology. 23rd ed. New York: McGraw-Hill; 2010: Figure 23-13; With permission. [cited 2011 Oct 10]. Clinical Presentation of Osteoporosis**General**

Many patients with osteoporosis are asymptomatic unless they experience a fragility fracture.

Symptoms of Fragility Fracture

Pain at the site of the fracture or immobility.

Signs

Height loss (greater than 2 cm), spinal kyphosis ("dowager's hump"), fragility fracture especially of the hip or spine.

in overall bone loss. However, a reduction in osteoblastic activity and reduced bone formation can also occur in certain types of osteoporosis. Due to a decrease in endogenous estrogen, bone remodeling accelerates during menopause, and up to 15% of bone is lost during the first 5 years after menopause. After this initial decline, bone loss continues to occur, but at a much slower rate of up to 1% per year. The resultant bone loss and change in bone quality predispose patients to low-impact or **fragility fractures**.

CLINICAL PRESENTATION AND DIAGNOSIS

See the accompanying text box for the clinical presentation of osteoporosis.

Diagnosis

Osteoporosis has been defined by the WHO as a disease characterized by low bone density and weakening of bone tissue associated with an increase in fragility and vulnerability to fracture.⁷ Because bone strength cannot be measured directly, an assessment of BMD is used, which represents 70% of bone strength. Low BMD has been associated with an increased risk of fractures. X-rays are useful only in identifying patients suspected of sustaining a fracture and are not recommended for diagnosis of osteoporosis.

► Measurement of Bone Mineral Density

BMD can be measured at various sites throughout the skeletal system and by various methods. The site of measurement can be either central (hip and/or spine) or peripheral (heel, forearm, or hand). Dual-energy x-ray absorptiometry (DXA) can be used to measure central and peripheral sites of BMD. Quantitative ultrasound, peripheral quantitative computed tomography, radiographic absorptiometry, and single-energy x-ray absorptiometry are used to measure peripheral sites.

2 The WHO recommends a standardized approach to measuring BMD for diagnosis of osteoporosis using central measurement of BMD by DXA.⁵ Central DXA is recommended for diagnosis due to inconsistencies in T-scores

Table 56-3

WHO Definition of Osteoporosis

Skeletal Disorder	T-Score ^a
Normal	Greater than or equal to -1
Osteopenia	Less than -1 to greater than or equal to -2.5
Osteoporosis	Less than -2.5

^aT-score is the number of standard deviations above or below the mean bone mineral density in young adults.

measured between different sites and by different methods.^{1,2} Current standards of practice consist of measuring BMD at the lumbar spine and hip, although the WHO suggests the hip is the preferred site for diagnosis.^{3,7}

Some instruments used for peripheral bone densitometry are portable, which allows bone density to be measured in pharmacies and health-fair screening booths. In addition to its accessibility, peripheral measurement of BMD is generally less expensive than central DXA. These factors make it an attractive option for many patients. Peripheral BMD testing is useful in identifying patients who are candidates for central DXA and who are at increased risk of fracture.

Once the BMD report is available, *T*-scores and *Z*-scores are useful tools in interpreting the data. The *T*-score is the number of standard deviations from the mean BMD in healthy young white women. Osteoporosis is defined as a *T*-score at least -2.5 (Table 56-3). **Osteopenia**, or low bone mass that may eventually lead to osteoporosis, is defined as a *T*-score between -2.5 and -1.0. The International Society for Clinical Densitometry recommends use of the WHO definition and *T*-scores for diagnosis of osteoporosis in postmenopausal women and men over the age of 50.⁸

The *Z*-score is similar to the *T*-score but is corrected for both the age and sex of the patient. The *Z*-score is defined as the number of standard deviations from the mean BMD of age- and sex-matched controls. *Z*-scores may be more clinically relevant in evaluating BMD in premenopausal women, men under the age of 50, and patients who may have secondary causes for low BMD.

► Screening and Risk Factor Assessment

Screening for low bone density is an effective way to identify individuals at risk for osteoporotic fracture. A number of published osteoporosis guidelines provide recommendations for screening based on age and risk factors.^{1,2,6,8} Routine BMD screening is generally recommended for all women over the age of 65 and men over the age of 70.¹ Many guidelines also recommend screening in individuals under these ages but over the age of 50 with specific risk factors such as previous fragility fracture, glucocorticoid or other high-risk medication use, or secondary cause of osteoporosis.

An additional tool, FRAX, was developed by the WHO to evaluate an individual's 10-year probability of developing hip and major osteoporotic fracture.¹ This probability is

calculated based on BMD *T*-score, age, and other risk factors. Its intended use is for men and women over the age of 40 and may be accessed at www.shef.ac.uk/FRAX. Although the *T*-score is helpful in calculating risk of fracture with FRAX, fracture risk may be calculated without it.

► Laboratory Evaluation

Laboratory assessment has little value in diagnosing osteoporosis, but it can be beneficial in identifying or excluding secondary causes of bone loss, such as hyperparathyroidism, low 25-hydroxyvitamin D levels, hyperthyroidism (thyroid stimulating hormone levels), hypogonadism (testosterone levels), or cancer.³ Serum creatinine, calcium, phosphorus, and complete blood count are also usually obtained. Biochemical markers of bone turnover such as pyridinoline, deoxypyridinoline, N-telopeptides, and C-telopeptides of type I collagen cross-links have been associated with an

Patient Encounter, Part 1: Patient History

HPI: AN is a frail 74-year-old white man who presents to the clinic for follow-up. He reports occasional forgetfulness. His erectile dysfunction, poor libido, and fatigue have improved since starting testosterone replacement therapy. He has no complaints with his current medication regimen for asthma. He also has no complaints about omeprazole but takes calcium carbonate (Tums) approximately once a week for heartburn after eating spicy meals. He usually spends his day inside his house watching television from his recliner. He states that milk upsets his stomach, so he usually drinks water or soda

PMH: Asthma, DM type 2, HTN, GERD, hypogonadism, lactose intolerance

FH: Father died at age 76 with Alzheimer's disease; mother died at age 92 with history of breast cancer and osteoporotic fractures of the hip; sister alive and well at age 69

SH: Retired construction worker; drinks 4 beers per day; nonsmoker

Meds: Albuterol inhaler two puffs as needed, metformin 500 mg twice daily; lisinopril 10 mg daily; testosterone cypionate 200 mg IM every 4 weeks; omeprazole 20 mg daily; calcium carbonate (Tums) 500 mg as needed

Do any symptoms suggest the presence of osteoporosis?

What risk factors for osteoporosis does this patient have as defined by the World Health Organization?

What secondary causes of osteoporosis does the patient have?

What are his recommended daily intakes for calcium and vitamin D?

How could he incorporate more calcium into his diet?

increased fracture risk in some trials. Variations in the normal ranges of these tests may be related to age, gender, food, and diurnal variation, making interpretation of these tests difficult.² For these reasons, biochemical markers of bone turnover are not recommended for diagnosis of osteoporosis.

TREATMENT

Desired Outcomes

3 Pharmacologic and nonpharmacologic therapies are aimed at the following goals: (a) preventing fractures and their

complications; (b) maintaining or increasing BMD; (c) preventing secondary causes of bone loss; and (d) reducing morbidity and mortality associated with osteoporosis.

Nonpharmacologic Therapy

The primary goal of nonpharmacologic therapy for osteoporosis is to prevent fractures. Strategies to prevent fractures include maximizing peak bone mass, reducing bone loss, and using precautions to prevent falls leading to fragility fractures (Fig. 56-2).

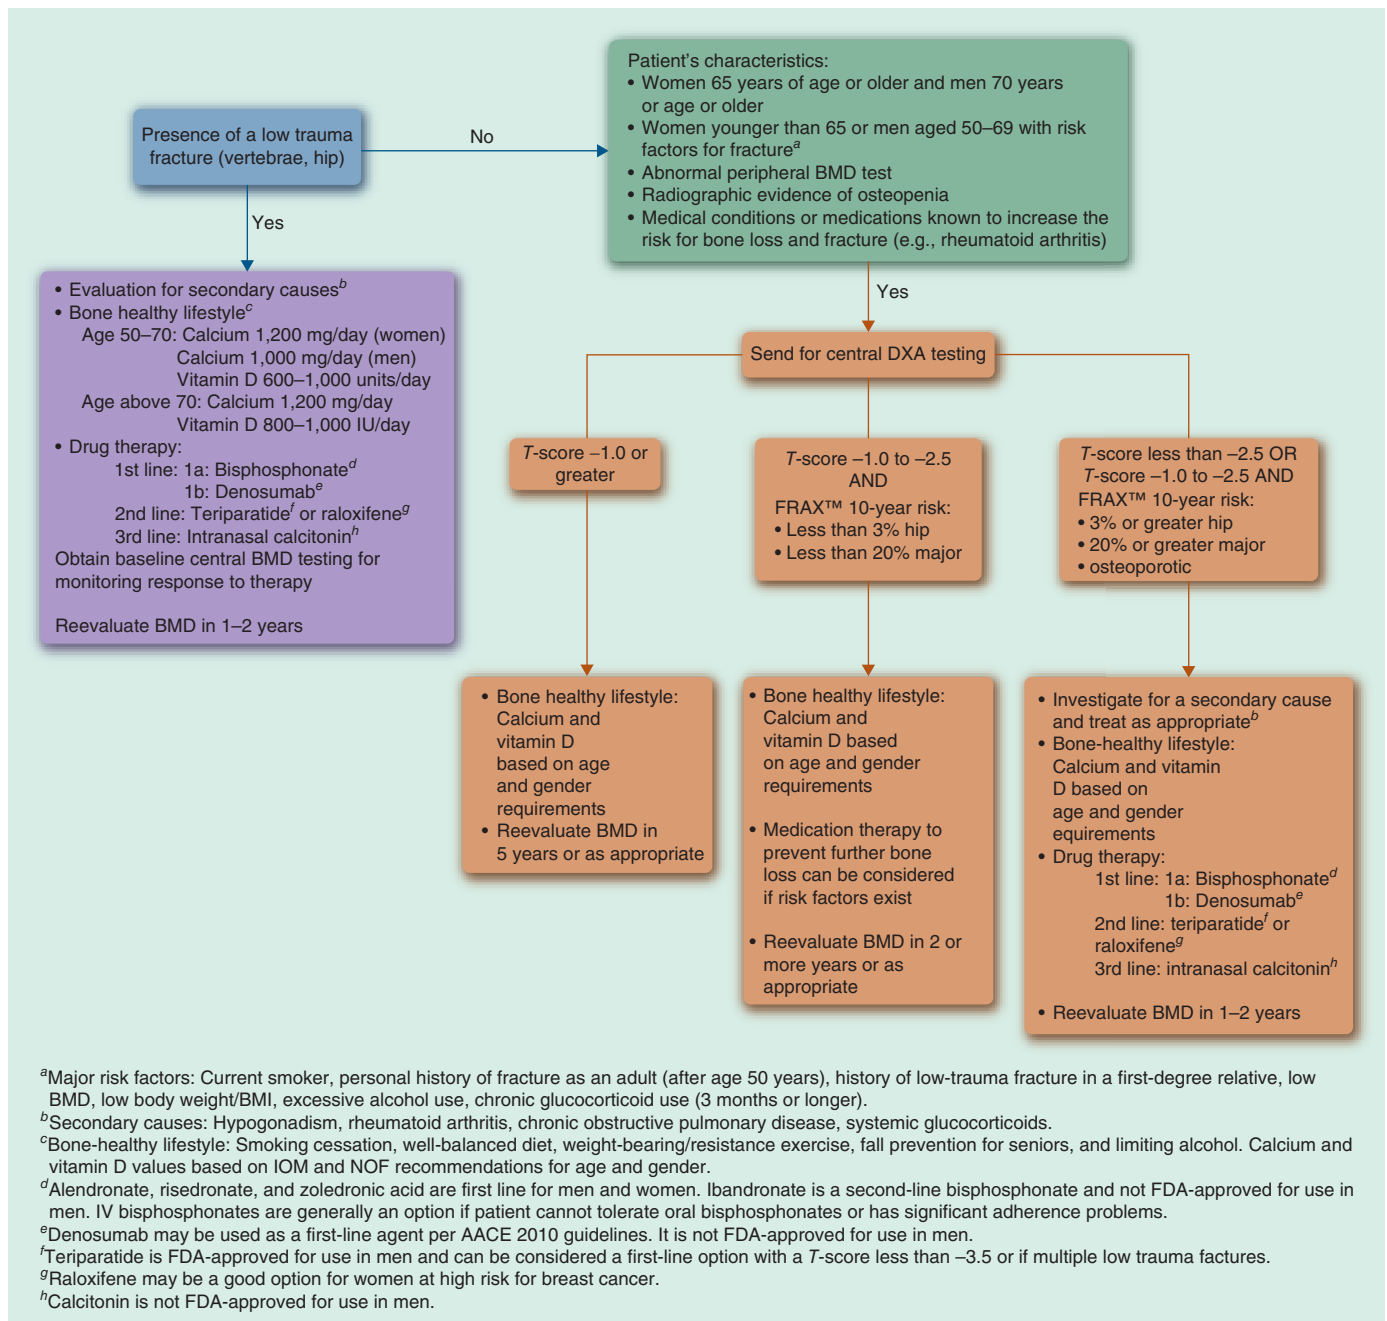

FIGURE 56-2. Algorithm for management of osteoporosis in women and in men aged 50 and older. Adapted from DiPiro JT et al., eds. Pharmacotherapy: A Pathophysiologic Approach. 8th ed. New York: McGraw-Hill; 2011:1567, Figure 99-3; With permission.

► Modification of Risk Factors

Some osteoporosis risk factors (see Tables 56–1 and 56–2) are nonmodifiable, including family history, age, ethnicity, gender, and concomitant disease states. However, certain risk factors for bone loss may be minimized or prevented by early intervention, including smoking, low calcium intake, poor nutrition, inactivity, heavy alcohol use, and vitamin D deficiency. To avoid certain risk factors and maximize peak bone mass, efforts must be directed toward osteoporosis prevention at an early age.

► Nutrition

Good nutrition is essential to ensure intake of sufficient nutrients and for maintenance of appropriate weight. Dietary calcium intake is important for achieving peak bone mass and maintaining bone density. Adequate dietary intake of vitamin D is essential for calcium absorption. The Institute of Medicine (IOM) recently updated the dietary reference intakes for calcium and vitamin D.⁹ However, the National Osteoporosis Foundation (NOF) recommends higher calcium requirements for men between the ages of 50 and 70 years and higher vitamin D requirements for both men and women over the age of 50 years.¹ In patients at risk for developing or with a diagnosis of osteoporosis, it may be prudent to follow the NOF guidelines, which offer more stringent recommendations targeted to prevention and treatment of osteoporosis. **Table 56–4** lists the IOM and NOF recommendations for calcium and vitamin D requirements.

Good dietary sources of calcium include dairy products, fortified juice, cruciferous vegetables (e.g., broccoli, kale), salmon, and sardines (**Table 56–5**). Dietary intake generally provides 600 to 700 mg per day of calcium for men and women 50 and older. Therefore, supplementation is important for primary prevention, as well as for those with a diagnosis of osteoporosis, to achieve recommended intake not attained by diet alone.¹

Table 56–4

Recommended Daily Calcium and Vitamin D Intake

Age	Institute of Medicine Dietary Reference Intakes		National Osteoporosis Foundation	
	Calcium	Vitamin D	Calcium	Vitamin D
Women 50–70	1,200 mg	600 IU	1,200 mg	800–1,000 IU
Women over 70	1,200 mg	800 IU	1,200 mg	800–1,000 IU
Men 50–70	1,000 mg	600 IU	1,200 mg	800–1,000 IU
Men over 70	1,200 mg	800 IU	1,200 mg	800–1,000 IU

From references 1 and 9.

Table 56–5

Calcium-Rich Foods^a

1 cup ^b skim milk
1 cup soy milk (calcium-fortified)
1 cup yogurt
1½ ounces ^c cheddar cheese
1½ ounces jack cheese
1½ ounces Swiss cheese
1½ ounces part-skim mozzarella
4 tablespoonfuls ^d grated Parmesan cheese
8 ounces tofu
1 cup greens (collards, kale)
2 cups broccoli
4 ounces almonds
2 cups low-fat cottage cheese
3 ounces sardines with bones
5 ounces canned salmon
1 cup orange juice (calcium-fortified)

^aFoods containing approximately 300 mg of elemental calcium.

^bOne cup is equivalent to approximately 240 mL.

^cOne ounce is equivalent to approximately 28 g.

^dOne tablespoon is equivalent to approximately 15 mL.

The most common source of vitamin D comes from exposure to sunlight. Ultraviolet rays from the sun promote synthesis of vitamin D₃ (cholecalciferol) in the skin. This generally occurs within 15 minutes of direct sunlight exposure to exposed skin without sunscreen. However, during the winter months, patients living in northern latitudes are not able to obtain the type of exposure that results in vitamin D synthesis.² It is recommended that individuals receive twice weekly sun exposure to ensure optimal synthesis. Vitamin D may also be found in some dietary sources, including fortified milk, egg yolks, salt-water fish, and liver.

► Exercise

Exercise can be beneficial in preventing fragility fractures. Weight-bearing exercise such as walking, jogging, dancing, and climbing stairs can help build and maintain bone strength. Muscle-strengthening or resistance exercises can help improve and maintain strength, agility, and balance, which can reduce falls.¹ It is important to develop and maintain a lifelong routine of weight-bearing and resistance exercise, as the benefits on bone can be lost after cessation of the exercise program.¹

► Falls Prevention

Another crucial step in avoiding fragility fractures is prevention of falls. Patients with frailty, poor vision, hearing loss, or those taking medications affecting balance are at higher risk for falling and subsequent fragility fractures.^{1,2}

A number of medications have been associated with an increased risk of falling, including drugs affecting mental status such as antipsychotics, benzodiazepines, tricyclic antidepressants, sedative/hypnotics, anticholinergics, and

corticosteroids. Some cardiovascular and antihypertensive drugs can also contribute to falls, especially those causing orthostatic hypotension.¹

Efforts to decrease the risk of falling include balance training, muscle strengthening, removal of hazards in the home, installation of fall reduction measures such as handrails in the home, and discontinuation of predisposing medications.^{1,2,10} Use of hip protectors also helps prevent hip fractures, although adherence to this measure may be problematic.¹⁰

Pharmacologic Treatment (Fig. 56–2)

4 The NOF recommends that all men and women over age 50 be considered for pharmacologic treatment if they meet any of the following criteria: (a) history of hip or vertebral fracture, (b) T-score less than or equal to -2.5 at femoral neck or spine, or (c) osteopenia and at least a 3% 10-year probability of hip fracture or at least a 20% 10-year probability of major osteoporosis-related fracture as determined by FRAX.¹

► Calcium and Vitamin D

5 Adequate calcium and vitamin D intake are essential for preventing and treating osteoporosis. Calcium and vitamin D supplements to meet requirements should be added to all drug therapy regimens for osteoporosis. Calcium and vitamin D supplementation increases BMD, and the combination decreases the risk of hip and vertebral fractures.¹¹

Calcium plays an important role in maximizing peak bone mass and decreasing bone turnover, thereby slowing bone loss. When the calcium supply is insufficient, calcium is taken from bone stores to maintain the serum calcium level. Adequate calcium consumption is essential to prevent this from occurring. Calcium supplementation may also correct secondary hyperparathyroidism in elderly patients.

The NOF recommends daily calcium intakes of 1,200 mg.¹ When these requirements cannot be achieved by diet alone, appropriate calcium supplementation is recommended. Intakes over 1,200 to 1,500 mg/day may increase the risk of developing kidney stones or cardiovascular disease,¹ and supplementation greater than 2,500 mg/day may lead to hypercalciuria and hypercalcemia.⁶

Calcium supplements are available in a variety of calcium salts and dosage forms. Daily calcium requirements are reported as elemental calcium. However, many product labels list calcium content in the salt form, so the percentage of elemental calcium must be known to calculate the elemental calcium content per tablet. A number of factors can limit calcium absorption, and special consideration must be given to calcium dosing to maximize absorption. Large amounts of calcium taken at once cannot be absorbed. Supplement doses should be limited to 500 to 600 mg of elemental calcium per dose. Healthcare providers can help patients find a suitable and tolerable supplement with good absorption and high elemental calcium content, necessitating fewer tablets per day. Table 56–6 lists widely available supplements with elemental calcium and vitamin D content.

Table 56–6

Calcium and Vitamin D Content of Common Supplements

Product (% Elemental Calcium)	Elemental Calcium per Tablet (mg)	Vitamin D per Tablet (IU)
Calcium Carbonate (40%)		
Tums 500 mg	200	—
Tums E-X 750 mg	300	—
Tums ULTRA 1,000 mg	400	—
Os-Cal 500	500	—
Os-Cal 500 + D	500	200
Os-Cal Ultra	600	200
Caltrate 600	600	—
Caltrate 600 + D	600	200
Caltrate 600 + Soy	600	200
One-A-Day Women's Multivitamin	450	400
Rolaids 550 mg	220	—
Viactiv	500	100
Calcium Citrate (24%)		
Citracal	200	—
Citracal 250 mg + D	250	62.5
Citracal + D	315	200
Calcium Phosphate, Tribasic (39%)		
Posture – D	600	125
Calcium Lactate (13%)	85	—
Calcium Gluconate (9%)	60	—

Calcium carbonate should be taken with food to maximize absorption. Elderly patients or patients receiving proton pump inhibitors or H₂-receptor antagonists may have added difficulty absorbing calcium supplements due to reduced stomach acidity. Better absorption may occur in this setting with calcium citrate because an acid environment is not needed for absorption; it may be taken with or without food.

Common adverse effects of calcium salts include constipation, bloating, cramps, and flatulence. Changing to a different salt form may alleviate symptoms for some patients. Calcium salts may reduce the absorption of iron and some antibiotics, such as tetracycline and fluoroquinolones.

Vitamin D is crucial for calcium absorption and maintenance of bone. The goal is to maintain a serum 25-hydroxyvitamin D level above 30 ng/mL (75 nmol/L).¹ The IOM recommends daily vitamin D intakes of 600 IU for men and women aged 51 to 70 years, and 800 IU for men and women greater than 70 years,⁹ whereas the NOF recommends 800 to 1,000 IU for all men and women over 50 years of age. However, higher doses may be necessary in selected patients to meet this goal (see Table 56–4).

Vitamin D is often combined in varying amounts with calcium salts and is present in many multivitamin preparations. Vitamin D is also available as a single entity. To avoid hypercalciuria and hypercalcemia, the maximum recommended dose for most patients is 4,000 IU/day.⁹ Ergocalciferol (vitamin D₂) and cholecalciferol (vitamin D₃) are available and generally reserved for patients with vitamin D deficiency. High-dose ergocalciferol is available by prescription

Patient Encounter, Part 2: Physical Exam and Diagnostic Tests

ROS: 4-cm height loss since middle age; (+) back pain

PE:

Gen: Well-developed white man in no acute distress

- BMD of lumbar spine: *T*-score = -2.1

What additional risk factor and signs of osteoporosis are present in this patient?

What are the goals of pharmacologic and nonpharmacologic therapy?

List at least three nonpharmacologic interventions important in his treatment plan.

What factors support pharmacotherapy for osteoporosis in this patient?

What type of supplement(s) would you recommend for this patient to meet his calcium and vitamin D requirements? Why?

only, whereas cholecalciferol is available over the counter. With daily dosing, there is little difference between the potency of the two formulations, but cholecalciferol is more potent when dosed weekly or monthly.²

Several patient groups are at risk for vitamin D deficiency, including elderly patients with malabsorption syndromes, chronic renal insufficiency, other chronic diseases and those with limited sun exposure.¹ Elderly patients in particular are at increased risk of deficiency due to decreased exposure to sunlight and subsequent decreased vitamin D synthesis in the skin, decreased GI absorption of vitamin D, and reduction in vitamin D₃ synthesis. Individuals living in northern

climates may have low vitamin D levels due to decreased sunlight exposure.

Many adults have low vitamin D levels, and vitamin D deficiency is an important secondary cause of osteoporosis.^{2,12} Laboratory determination of 25-hydroxyvitamin D levels should occur prior to the start of therapy to determine whether supplementation is adequate or whether treatment of deficiency is needed. The Endocrine Society Vitamin D Deficiency Clinical Practice Guideline recommends treatment with ergocalciferol or cholecalciferol 50,000 IU once weekly (or its equivalent of 6,000 IU daily) for 8 weeks.¹² After 25-hydroxyvitamin D levels have risen above 30 ng/mL (75 nmol/L), doses of 1,500 to 2,000 IU can be used to maintain 25-hydroxyvitamin D levels between 30 and 60 ng/mL (75 and 150 nmol/L).^{2,12}

► Bisphosphonates

6 *Bisphosphonates are first-line therapy for osteoporosis in both men and women due to established efficacy in preventing hip and vertebral fractures.* They are also the most commonly prescribed therapy for osteoporosis. They decrease bone resorption by binding to the bone matrix and inhibiting osteoclast activity. They remain in the bone for a prolonged period of several years and are released very slowly over time. These effects increase BMD. Although several bisphosphonates are currently available, only alendronate, ibandronate, risedronate, and zoledronic acid carry an FDA-approved indication for osteoporosis. All of these agents are approved for use in men and women, with the exception of ibandronate, which is only approved for use in postmenopausal osteoporosis. Ibandronate is generally considered a second-line bisphosphonate due to lack of documented efficacy in hip and nonvertebral fractures in prospective trials.² **Table 56-7** contains comparative dosing and cost information for the bisphosphonates.

In placebo-controlled clinical trials, bisphosphonates increased BMD by up to 5% to 8% in the lumbar spine and up to 3% to 6% in the hip.¹³⁻¹⁶ Additional data with oral bisphosphonates suggest that BMD continues to increase with long-term therapy of 7 to 10 years.^{17,18} Although increases in BMD have been reported at other sites, most of the clinically significant fractures occur in the hip or spine, and these sites have become clinically important measures in the trials. These increases in BMD at the hip and spine are an important marker of treatment effects and are probably related to the decreases in fracture risk found in larger trials.

Large, well-designed trials have proven the benefits of bisphosphonate therapy in preventing vertebral and nonvertebral fractures. Several studies have found decreases in vertebral fracture risk by as much as 40% to 50% with oral bisphosphonates and up to 70% with zoledronic acid.^{1,19} Although data suggest a similar reduction on vertebral fractures with ibandronate, only alendronate, risedronate, and zoledronic acid have been shown to decrease the incidence of hip and nonvertebral fractures as well by as much as 25% to 40%.^{2,20,21} In addition to benefits in fracture reduction, the Horizon Recurrent Fracture Trial found a 28% decrease in mortality associated with hip fracture in patients treated with IV zoledronic acid.²⁰

Table 56-7

Prescription Drug Therapy for Osteoporosis

Drug	Product Size	Indication/Usual Dose	Administration	Monthly Cost ^a
Bisphosphonates				
Alendronate (Fosamax)	5-, 10-, 35-, 70-mg tablets; 70-mg with cholecalciferol 2,800 IU; 70-mg with cholecalciferol 5,600 IU; 70-mg oral solution	Prevention of PM osteoporosis: 5 mg orally daily or 35 mg orally once weekly Osteoporosis (men and women): 10 mg orally once daily or 70 mg orally once weekly Glucocorticoid-induced osteoporosis: 10 mg once daily Avoid when CrCl less than 35 mL/min (0.58 mL/s)	Take after an overnight fast with 6–8 oz (180–240 mL) plain water while sitting or standing upright at least 30 minutes prior to morning meal. Do not lie down for 30 minutes after administration. Do not take with other medications or fluids. Do not chew or suck on the tablet.	As low as \$9 for 70-mg weekly tablet ^b
Ibandronate (Boniva)	2.5-, 150-mg tablets; 3-mg/3 mL injection	Treatment or prevention of PM osteoporosis: 2.5 mg orally daily or 150 mg orally once monthly; 3 mg IV push over 15–30 seconds every 3 months Avoid when CrCl less than 35 mL/min (0.58 mL/s)	Same as alendronate except administer at least 1 hour prior to morning meal and refrain from lying down for 1 hour after administration.	\$126 for 150-mg tablet
Risedronate (Actonel)	5-, 35-, 75-, 150-mg tablets; 35-mg with 1,250-mg calcium carbonate tablets	PM osteoporosis: 5 mg orally daily, 35 mg orally once weekly, 75 mg on 2 consecutive days each month, or 150 mg once monthly Male osteoporosis: 35 mg orally weekly or 150 mg orally monthly Glucocorticoid-induced osteoporosis: 5 mg orally daily Avoid when CrCl less than 30 mL/min (0.50 mL/s)	Same as alendronate.	\$131 for 35-mg weekly tablet \$144.50 for 150-mg monthly tablet
Zoledronic acid (Reclast)	5 mg/100 mL IV infusion	Prevention of PM osteoporosis: 5 mg infused IV over 15 minutes or longer every 24 months Treatment of osteoporosis (men and women), glucocorticoid-induced osteoporosis: 5 mg infused IV over 15 minutes or longer every 12 months Avoid when CrCl less than 35 mL/min (0.58 mL/s)	Infuse over at least 15 minutes. May premedicate with acetaminophen.	\$1,137 for 5-mg dose
Monoclonal Antibody				
Denosumab (Prolia)	60 mg/mL SC pre-filled syringe	PM osteoporosis: 60 mg SC every 6 months	Inject in the upper arm, upper thigh, or abdomen. Keep refrigerated.	Not available
Recombinant Human Parathyroid Hormone				
Teriparatide (Forteo)	250 mcg/mL, 2.4-mL pre-filled pen	Osteoporosis (men and women), glucocorticoid-induced osteoporosis: 20 mcg SC daily	Inject into thigh or abdominal wall. Keep pen refrigerated.	\$1,016 per pre-filled pen
Selective Estrogen Receptor Modulators				
Raloxifene (Evista)	60-mg tablets	PM osteoporosis: 60 mg daily	May be taken with or without food.	\$150 for 60-mg tablet
Calcitonin				
Calcitonin salmon (Miacalcin)	200 IU/0.9 mL, 3.7-mL nasal spray	PM osteoporosis: Nasal spray: 200 IU daily	Nasal spray: Alternate nostrils on a daily basis.	\$110 per 3.7-mL nasal spray

CrCl, creatinine clearance; IM, intramuscularly; PM, postmenopausal; SC, subcutaneously.

^aMonthly cost from drugstore.com.^bPrice available through select retail pharmacy prescription discount plans.

Several studies have evaluated the long-term efficacy and safety of bisphosphonates in postmenopausal women. One study evaluated the use of alendronate over a 10-year period and found no difference in adverse effects between women who received alendronate for 10 years compared with women who discontinued alendronate after 5 years. Women who discontinued alendronate after 5 years continued to experience sustained increases in BMD compared with baseline values and reduction in fracture rates.¹⁷ Another study found sustained increases in BMD after discontinuation of alendronate, albeit less than in those who continued longer term alendronate therapy.²² A 7-year follow-up study with risedronate found continued increases in BMD and no increase in adverse effects in women receiving risedronate for 7 years compared with women receiving risedronate for 2 years.¹⁸ These findings support long-term administration of bisphosphonates in patients at high risk for fracture. However, for women who must discontinue bisphosphonate therapy due to intolerance or adverse events, improvements in BMD may be sustained.

The most notable adverse effects associated with the bisphosphonates are GI, ranging from relatively mild nausea, vomiting, and diarrhea to more severe esophageal irritation, and esophagitis. However, the most common adverse reactions reported in clinical trials include dyspepsia, abdominal pain, nausea, and esophageal reflux. Clinically significant adverse events include esophageal ulceration, erosions with bleeding, perforation, stricture, and esophagitis. Upper GI adverse effects can occur in up to 20% of patients and are often related to inappropriate administration. Advanced age, previous upper GI tract disease, and use of nonsteroidal anti-inflammatory drugs also increase the risk for GI adverse events, whereas once-weekly administration of oral bisphosphonates may decrease the risk.

The parenteral bisphosphonates (ibandronate and zoledronic acid) are associated with additional adverse effects.² Up to 40% of patients receiving the first dose may experience acute-phase reactions (also referred to as flu-like symptoms) that can last for days, such as headache, arthralgia, myalgia and fever.^{1,2,20} Pretreatment with acetaminophen may prevent these symptoms.² Patients with moderate to severe renal impairment, severe dehydration, or taking concomitant diuretics or nephrotoxic drugs may be at higher risk of developing acute renal failure with zoledronic acid. Laboratory monitoring, including serum creatinine, alkaline phosphatase, phosphate, magnesium, and calcium, is recommended prior to administration of each zoledronic acid dose.

Although bisphosphonate trials have demonstrated continued efficacy over time, there may be some safety concerns associated with long-term use. Serious adverse events including **osteonecrosis** of the jaw (ONJ),^{24,25} **subtrochanteric** fractures,²⁴ and nonvertebral atraumatic fractures²⁵ have been reported in the literature. These events may be related to oversuppression of bone turnover causing weakening of bone structure related to inhibition of osteoclastic activity.^{23,26} Risk factors for development of ONJ include chemotherapy, radiotherapy, corticosteroids, infection, or preexisting dental disease. Most cases in the literature of ONJ occurred in patients receiving high doses of zoledronic acid for cancer-related

indications.²⁴ It is recommended that patients complete major dental work prior to initiation of bisphosphonate therapy. One population-based study found that older women treated with a bisphosphonate for more than 5 years had an increased risk of subtrochanteric or femoral shaft fractures.²⁷ The development of these fractures in patients treated with bisphosphonates are notable because they are not commonly associated with osteoporosis. The American Association of Clinical Endocrinologists (AACE) guidelines suggest that providers may consider a drug holiday of 1 to 2 years after 5 to 10 years of bisphosphonate treatment, depending on osteoporosis risk.² However, a recent FDA review on the risk of atypical subtrochanteric femur fractures from bisphosphonates found no clear association, and the FDA recommends to continue bisphosphonate therapy as labeled.²⁸ Esophageal cancer has also been reported with long-term therapy, but data are currently inconclusive.^{29,30}

Oral bisphosphonates are poorly absorbed (less than 5%). Taking them in the presence of food or calcium supplementation further reduces absorption. After absorption, bisphosphonate uptake to the primary site of action is rapid and sustained. Once attached to bone tissue, bisphosphonates are released very slowly over several years. They are not recommended for use in patients with renal insufficiency because they are renally excreted and not metabolized.

Proper drug administration is important for optimal absorption and prevention of adverse effects. Oral bisphosphonates should be taken 30 to 60 minutes prior to the first meal or food in the morning after an overnight fast with 6 to 8 ounces (about 180 to 240 mL) of water (or 2 ounces [60 mL] with the oral solution). Patients should remain upright and refrain from lying down for 30 to 60 minutes after administration. The tablets should be swallowed whole without chewing or sucking. Administration should be with water only and not combined with other fluids. Bisphosphonates should not be taken with other medications or dietary supplements. Bisphosphonates are not recommended for use in patients with esophageal abnormalities that may delay transit of the tablet, such as with severe GERD, **achalasia**, **stricture**, or **Barrett's esophagus**. In addition, they are not recommended in patients with hypocalcemia or renal insufficiency or failure (creatinine clearance less than 30 to 35 mL/min [0.50 to 0.58 mL/s]), or in those who are pregnant. For patients unable to tolerate oral bisphosphonates, options exist for parenteral administration with ibandronate or zoledronic acid.

► Denosumab

Denosumab is the first human monoclonal antibody FDA approved for the treatment of postmenopausal osteoporosis. It is first-line therapy and should be considered in patients who are unable to tolerate bisphosphonates.² Denosumab reduces nuclear factor-kappa B ligand (RANKL) action, which leads to selective inhibition of osteoclast formation, function, and survival. In contrast to bisphosphonates, the antiresorptive effects of denosumab are reversible.

Denosumab has been shown to increase BMD in the hip and spine by up to 6% and 9%, respectively; and decrease

hip, vertebral, and nonvertebral fracture risk by up to 40%, 68%, and 20%, respectively.³¹ In direct head-to-head trials, patients treated with denosumab had greater increases in hip and spine BMD than patients treated with alendronate, although fracture risk was not reported.^{32,33} Denosumab is a treatment alternative for patients who are unable to tolerate oral bisphosphonates due to gastrointestinal contraindications or side effects and for patients with malabsorption or adherence issues.³⁴

Common adverse effects include back pain, arthralgias, fatigue, headache, dermatologic reactions, diarrhea, and nausea. Serious adverse reactions, including hypophosphatemia, hypocalcemia, dyspnea, and skin and other infections, can occur. Patients should seek medical attention if they experience any symptoms of infection. Denosumab can worsen hypocalcemia in predisposed patients, such as those with severe kidney disease. Prior to initiation of therapy, pre-existing hypocalcemia should be corrected. Suppression of bone turnover has been associated with denosumab therapy, and ONJ has also been reported.²

Denosumab is part of a Risk Evaluation and Mitigation Strategy (REMS) program, in which the manufacturer is required by the FDA to inform patients and healthcare providers of the risks associated with its use.³⁵ Denosumab is administered as a subcutaneous injection once every 6 months and should be stored in the refrigerator until administration. Once at room temperature, the vial or pre-filled syringe must be used within 14 days. Prescribing information recommends administration of 1,000 mg of calcium and at least 400 IU of vitamin D once daily.

► Teriparatide

Teriparatide, recombinant human parathyroid hormone (1–34), is the first anabolic agent approved by the FDA for treatment of postmenopausal and male osteoporosis. It is generally reserved for patients with very high fracture risk or those in whom other therapies have been ineffective.² This agent differs from antiresorptive therapies in that it stimulates osteoblastic activity to form new bone. It is administered as a subcutaneous injection. Teriparatide increases BMD in the spine and hip by 9% and 3%, respectively, and reduces fracture risk by 65% and 35% in vertebral and nonvertebral fractures, respectively.³⁶ Significant reductions in hip fracture have not been demonstrated.

Common adverse effects include nausea, headache, leg cramps, dizziness, injection site discomfort, and hypercalcemia. Orthostatic hypotension may also occur; patients should be seated after the first several doses until drug response is predictable. Observations of osteosarcoma in animal studies has led to the inclusion of a “black box warning” in the product labeling, but no cases have been reported in humans. Teriparatide should not be used in patients with preexisting hypercalcemia. Patient-related concerns regarding the use of teriparatide include cost of therapy and need for subcutaneous injections. The labeling recommends treatment for a maximum of 2 years because it has not been studied for longer periods.

► Raloxifene

Raloxifene is currently the only selective estrogen receptor modulator (SERM) indicated for prevention and treatment of osteoporosis. It is recommended as alternative therapy after bisphosphonates, denosumab, or teriparatide.² It has estrogen-like activity on bones and cholesterol metabolism and estrogen antagonist activity in breast and endometrium. It reduces bone resorption and decreases overall bone turnover.

Raloxifene has been shown to increase BMD in the vertebra (2% to 3%) and hip (1% to 2%), and reduce vertebral fracture rates by as much as 30%.³⁷ Significant decreases in hip and nonvertebral fractures have not been demonstrated in clinical trials.² In high-risk women, raloxifene has been shown to decrease the incidence of breast cancer. Although it decreases total and low-density lipoprotein (LDL) cholesterol, a large-scale trial found no benefit on cardiovascular events but did find an increased risk of fatal stroke in women treated with raloxifene.³⁸

Adverse effects of raloxifene include hot flashes, leg cramps, and increased risk of venous thromboembolism. Hot flashes are very common and may be intolerable in postmenopausal women who are already predisposed to experiencing them. A more serious adverse effect is the significantly increased risk of venous thromboembolism that has been found in clinical trials.³⁸ A previous history of venous thromboembolism is a contraindication to therapy.

► Calcitonin

Calcitonin is a naturally occurring mammalian hormone that plays a major role in regulation of calcium levels. It inhibits bone resorption by binding to osteoclast receptors. Calcitonin is considered a last-line agent for the treatment of osteoporosis.² Calcitonin produces a modest increase in BMD at the spine of 1% to 3% and reduces vertebral fracture risk by up to 30%.³⁹ However, no benefit has been demonstrated in reducing hip or nonvertebral fractures.² Calcitonin has previously been thought advantageous for potential analgesic effects in women with back pain from vertebral fractures. However, enthusiasm for using it in this setting has waned in favor of managing fracture risk and pain separately.

Although salmon calcitonin is approved and available in injectable and intranasal formulations, only the intranasal formulation has documented benefit in clinical trials for management of osteoporosis. Adverse effects associated with the intranasal formulation include rhinitis, nasal irritation, and dryness. Hypersensitivity can develop with either formulation and should be considered before administering to patients with suspected risk of hypersensitivity.²

► Hormone Therapy

Estrogen, either alone or in combination with a progestin as hormone replacement therapy (HRT), has a long history as an effective treatment of osteoporosis. The Women’s Health Initiative (WHI) trial found a 33% reduction in both vertebral and hip fractures and a 23% reduction in other fractures in postmenopausal women receiving conjugated estrogen and medroxyprogesterone.⁴⁰ However,

significant risks associated with long-term HRT, including breast cancer and venous thromboembolism, have limited its use in osteoporosis.^{40,41}

► **Combination and Sequential Therapy**

Interest in combination therapy with two or more osteoporosis drugs is based on the idea that using agents with differing mechanisms for inhibiting bone resorption would result in greater increases in BMD and reductions in fracture rates. Although there is some evidence to suggest modest additional increases in BMD occur with combination therapy, no significant benefits have been shown in reducing fracture rates. Combination therapy is also more expensive, and concern has been raised that significant reductions in bone turnover may promote bone that is more brittle.⁴² The AACE does not recommend combination antiresorptive therapy for treating osteoporosis.²

Sequential therapy with teriparatide followed by bisphosphonate therapy has been studied. Its rationale is based on the limited duration (2 years) with which teriparatide can be used and the fact that increases in BMD decline rapidly after discontinuation of teriparatide.² Whether sequential therapy leads to reductions in fracture risk remains to be determined.

► **Other Therapies**

Investigational Agents Several anabolic and antiresorptive therapies are under investigation for treatment of osteoporosis. The most promising antiresorptive therapy may be odanacatib, a selective enzyme inhibitor of cathepsin-K.⁴³ This inhibition prevents enzymatic bone degradation in mature osteoclasts. It is thought that these actions lead to a more modest effect on suppression of bone turnover than other antiresorptive therapies.⁴³ It has been shown to progressively increase hip and spine bone BMD and reduce markers of bone resorption in postmenopausal women with low BMD. BMD levels quickly revert to baseline levels, and markers of bone remodeling rapidly increase after odanacatib discontinuation.⁴⁴

Anabolic therapies currently under investigation include calcilytic drugs and Wnt antagonists. Calcilytic drugs increase bone formation by imitating hypocalcemia and cause parathyroid hormone secretion. The most advanced compound, MK-5442, is administered orally and could have important advantages over current therapy if efficacy and safety data are positive.⁴³ Wnt inhibitors bind to and block Wnt receptors and promote osteoblastic bone formation. All of these agents are currently in phase 1 and 2 trials.⁴³ Two other therapies with anabolic properties, strontium ranelate and PTH (1–84), are available in countries outside the United States.⁴³

Complementary and Alternative Therapies Several studies have evaluated dietary supplements such as isoflavones, which are found in soy products and red clover. A well-controlled trial in more than 400 postmenopausal women evaluating a specific isoflavone, ipriflavone, found no benefits on BMD or fracture rates after 3 years.⁴⁵

Nevertheless, because these therapies are available without prescription and are not regulated by the FDA, patients may choose to self-medicate with isoflavones. Lymphocytopenia appeared in several patients treated with ipriflavone in clinical trials. Additionally, ipriflavone should be used with caution in immunocompromised patients, those with renal disease, and patients taking drugs metabolized by CYP 1A2 and 2C9, such as warfarin.

Treatment of Special Populations

► **Premenopausal Women**

The NOF recommends measuring BMD in premenopausal women with specific risk factors for osteoporosis, such as those with a predisposing medical condition or medication, in whom treatment would be considered.¹ Premenopausal women at risk for osteoporosis should follow all nonpharmacologic recommendations for exercise and adequate calcium and vitamin D intake. Currently, no good data are available regarding pharmacologic therapy on fracture reduction in this population. Bisphosphonates should be used with caution in this population due to pregnancy risks and uncertain long-term effects.

► **Glucocorticoid-Induced Osteoporosis**

Glucocorticoids play a significant role in bone remodeling. Exogenous glucocorticoid administration results in an increase in bone resorption, inhibition of bone formation, and change in bone quality. Glucocorticoids (e.g., prednisone, hydrocortisone, methylprednisolone, and dexamethasone) promote bone resorption through reduced calcium absorption from the GI tract and increased renal calcium excretion. Bone formation is reduced through inhibition of osteoblasts. They also decrease estrogen and testosterone production.

Patients receiving long-term glucocorticoids are at increased risk of fracture. This risk is greater with higher doses and longer-term therapy. Most bone is lost during the initial 6 to 12 months of therapy, and bone mass continues to decline thereafter.⁴⁶ Due to the risk of bone loss and fractures, therapy is recommended for patients receiving long-term supraphysiologic doses of glucocorticoids.⁴⁷

In addition to nonpharmacologic measures, the ACR has specific recommendations for preventing and treating patients receiving glucocorticoids.⁴⁷ Recommendations for optimal calcium and vitamin D intake are higher for patients receiving glucocorticoids. These recommendations include 1,200 to 1,500 mg daily of elemental calcium and 800 to 1,000 IU daily of vitamin D, or higher as needed to maintain adequate 25(OH)D levels, for all adults receiving glucocorticoids.

7 The ACR recommends bisphosphonate therapy with alendronate or risedronate for all patients who are starting treatment with glucocorticoids (prednisone 5 mg or more daily or equivalent) that will continue for 3 months or longer. Therapy may also be started in other patients with lower

doses or shorter duration of glucocorticoids based on risk factors for fracture. Zoledronic acid and teriparatide may also be considered for moderate- to high-risk patients. Although not FDA approved, denosumab has been studied in this population and may be considered an alternate therapy for patients nonresponsive to or intolerant of other therapies.⁴⁶

Gastrointestinal Disease

Various GI disorders, including inflammatory bowel disease, celiac disease, and postgastrectomy states, are associated with osteoporosis due to impairment of calcium and vitamin D absorption, corticosteroid-induced bone changes, and chronic inflammatory states. Management of these patients includes stabilizing the underlying disorder, BMD measurement and screening every 1 to 2 years, and treatment in appropriate patients, including those at risk for glucocorticoid-induced osteoporosis.⁴⁸

Transplantation Osteoporosis

Osteoporosis is an important health issue for post-transplantation patients. As survival continues to improve after transplantation, more patients are experiencing significant morbidity and mortality related to fragility fractures. These patients are at high risk for developing fractures due to pretransplantation risk factors for osteoporosis and rapid bone loss after transplantation. It is thought that significant decreases in BMD within 6 to 12 months after transplantation are due to high-dose glucocorticoids and the increase in bone resorption seen with calcineurin inhibitors such as cyclosporine.⁴⁹

Prior to transplantation, BMD should be measured, and any secondary causes of osteoporosis should be identified and corrected. All patients should meet daily calcium and vitamin D requirements, with supplementation of vitamin D to maintain a 25(OH) D level above 30 ng/mL (75 nmol/L). Initiating therapy with a bisphosphonate before transplantation is thought to help counteract the immediate increase in bone resorption.⁴⁹

Patient Encounter, Part 3: Development of a Treatment Plan

Considering all of the information presented, develop a treatment plan for this patient. Include the following information:

Recommendations for patient-specific drug therapy including dose and frequency.

Patient education about the chosen regimen.

Monitoring plan for efficacy and adverse effects.

Consideration of alternate therapies if the initial therapy fails or is intolerable.

OUTCOME EVALUATION

- Evaluate patients for progression of osteoporosis, including signs and symptoms of new fragility fracture (e.g., localized pain), loss of height, and physical deformity (e.g., kyphosis). Assess patients on an annual basis or more often if new symptoms present.
- Monitor for beneficial effects on bone density. The NOF recommends a follow-up DXA scan every 2 years to monitor the effects of therapy.

Patient Care and Monitoring

1. Assess patient risk factors for osteoporosis, with special attention to age, menopausal status, previous history of osteoporotic fracture, smoking status, low body weight, family history of osteoporotic fracture in first-degree relatives, and presence of secondary causes of osteoporosis.
2. Perform a thorough medication history, including prescription, over-the-counter, and alternative therapies. Pay special attention to any vitamins and calcium and vitamin D supplements the patient is taking.
3. Assess nonpharmacologic interventions for preventing osteoporotic fractures, including nutrition, weight-bearing and muscle-strengthening exercise regimens, and fall risk.
4. Determine average calcium intake from diet (Table 56–5) and supplements (Table 56–6). Compare with age-adjusted recommendations (Table 56–4). Evaluate the patient's sources of vitamin D. Recommend appropriate calcium and vitamin D supplementation.
5. Review bone densitometry (i.e., central DXA) for presence of low bone mass (i.e., *T*-score below -2.5 in the spine or hip). If *T*-score is between -1.0 and -2.5 , use the FRAX risk calculator to estimate fracture risk.
6. Educate the patient about nonpharmacologic measures to prevent osteoporotic fractures.
7. If drug therapy is indicated, assess the patient for contraindications (e.g., esophageal disease or severe renal impairment for bisphosphonate therapy).
8. Educate the patient on the drug therapy selected, including drug name, dose, method of administration, common or serious adverse reactions, adherence and monitoring. Pay special attention to administration instructions and monitoring for adverse effects. Include a discussion about the therapeutic goals and expectations (e.g., changes in individual *T*-scores may not necessarily correlate with benefit in fracture risk reduction).
9. Develop a monitoring plan, including assessment of efficacy, adverse effects, nonpharmacologic measures to prevent fractures, and appropriate drug administration.

- Assess patients for adverse effects of therapy:
 - Oral bisphosphonates: Dyspepsia, esophageal reflux, esophageal pain, or burning
 - Injectable zoledronic acid: Influenza-type symptoms related to infusion, ONJ (rare)
 - Denosumab: Arthralgias, dermatologic reactions, and hypocalcemia
 - Teriparatide: Nausea, headache, leg cramps, hypercalcemia
 - Raloxifene: Hot flushes, signs or symptoms of thromboembolic disease (e.g., pain, redness, or swelling in one extremity, chest pain, and shortness of breath)
 - Calcitonin salmon: Nasal irritation or burning

Abbreviations Introduced in This Chapter

AACE	American Association of Clinical Endocrinologists
ACR	American College of Rheumatology
BMD	Bone mineral density
BMI	Body mass index
DXA	Dual-energy x-ray absorptiometry
HRT	Hormone replacement therapy
IOM	Institute of Medicine
NOF	National Osteoporosis Foundation
ONJ	Osteonecrosis of the jaw
PM	Postmenopausal
SERM	Selective estrogen receptor modulator
WHI	Women's Health Initiative

Rheumatoid Arthritis

Susan P. Bruce

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Identify risk factors for developing rheumatoid arthritis (RA).
2. Describe the pathophysiology of RA, with emphasis on the specific immunologic components.
3. Discuss the comorbidities associated with RA.
4. Recognize the typical clinical presentation of RA.
5. Create treatment goals for a patient with RA.
6. Compare the available pharmacotherapeutic options, selecting the most appropriate regimen for a given patient.
7. Propose a patient education plan that includes nonpharmacologic and pharmacologic treatment measures.
8. Formulate a monitoring plan to evaluate the safety and efficacy of a therapeutic regimen designed for an individual patient with RA.

KEY CONCEPTS

- 1 Comorbidities with the greatest impact on morbidity and mortality associated with rheumatoid arthritis (RA) are: (a) cardiovascular disease, (b) infections, (c) malignancy, and (d) osteoporosis.
- 2 The most clinically important features associated with poor long-term outcomes include: (a) functional limitation (defined by use of standard measurement scales such as the Health Assessment Questionnaire [HAQ] score), (b) extraarticular disease, (c) positive rheumatoid factor, (d) positive anticyclic citrullinated peptide (anti-CCP) antibodies, and/or (e) bony erosions by radiography.
- 3 The goals of treatment for RA are to: (a) reduce or eliminate pain, (b) protect articular structures, (c) control systemic complications, (d) prevent loss of joint function, and (e) improve or maintain quality of life.
- 4 It is imperative that the initiation of one or more disease-modifying antirheumatic drugs (DMARDs) occurs in all patients within the first 3 months of diagnosis to reduce joint erosion.
- 5 Methotrexate is the nonbiologic DMARD of choice because of its documented efficacy and safety profile when monitored appropriately.

- 6 The risk of infection in patients treated with biologic DMARDs must be considered when selecting and monitoring therapy.
- 7 Women of childbearing potential and their partners must be counseled to: (a) use proper birth control while undergoing treatment for RA, and (b) involve healthcare providers in discussions regarding family planning to carefully consider all treatment options available.
- 8 In addition to designing an individualized therapeutic regimen to control the progression of RA, the clinician must evaluate the presence of comorbidities and implement measures to control the increased risk.

INTRODUCTION

Rheumatoid arthritis (RA) is a complex systemic inflammatory condition manifesting initially as symmetric swollen and tender joints of the hands and/or feet. Some patients may experience mild **articular** (joint) disease, whereas others may present with aggressive disease and/or extraarticular manifestations. The systemic inflammation of RA leads to joint destruction, disability, and premature death. Juvenile idiopathic arthritis (JIA), formerly known as juvenile rheumatoid arthritis (JRA), is the most common form of arthritis in children.

EPIDEMIOLOGY AND ETIOLOGY

RA affects approximately 1% of the U.S. population and 1% to 2% of the world's population.^{1,2} Patients with RA have a 50% increased risk of premature death and a decreased life expectancy of 3 to 10 years compared with individuals without RA.³ The underlying causes of increased mortality in this population remain unclear. RA arises from an immunologic reaction, and there is speculation that it is in response to a genetic or infectious antigen. Risk factors associated with the development of RA include the following:

- Female gender (3:1 females to males)
- Increasing age (peak onset 35 to 50 years of age)
- Current tobacco smoking.⁴ Tobacco users are more likely to have extraarticular manifestations and to experience treatment nonresponsiveness. This risk is reduced when a patient has remained tobacco-free for at least 10 years.
- Family history of RA. Genetic studies demonstrate a strong correlation between RA and the presence of major histocompatibility complex class II **human leukocyte antigens** (HLA), specifically HLA-DR1 and HLA-DR4.^{5,6} HLA is a molecule associated with the presentation of antigens to T lymphocytes.
- Emerging evidence suggests that stress may influence RA onset and disease activity. It appears that individual major stressful life events do not play a significant role. Instead, chronic presence of minor stressors (daily hassles, work and relationship stress, financial pressures) may affect the immune response and RA disease activity.⁹
- The prevalence of JIA is approximately 1 in 1000 children.¹⁰ There are no known risk factors for JIA.

PATHOPHYSIOLOGY

The characteristics of a **synovium** affected by RA are: (a) the presence of a thickened, inflamed membrane lining called **pannus**;

(b) the development of new blood vessels; and (c) an influx of inflammatory cells in the synovial fluid, predominantly T lymphocytes. The pathogenesis of RA is driven by T lymphocytes, but the initial catalyst causing this response is unknown. Understanding specific components of the immune system and their involvement in the pathogenesis of RA will facilitate understanding of current and emerging treatment options for RA. The components of most significance are T lymphocytes, cytokines, and B lymphocytes.^{5,11}

T Lymphocytes

The development and activation of T lymphocytes are important to maintain protection from infection without causing harm to the host.¹¹ Activation of mature T lymphocytes requires two signals. The first is the presentation of an antigen by antigen-presenting cells to the T-lymphocyte receptor. Second, a ligand-receptor complex (i.e., CD80/CD86) on antigen-presenting cells binds to CD28 receptors on T lymphocytes.

Once a cell successfully passes through all stages, the inflammatory cascade is activated.¹² Activation of T lymphocytes: (a) stimulates the release of macrophages or monocytes, which subsequently causes the release of inflammatory cytokines; (b) activates osteoclasts; (c) activates the release of matrix metalloproteinases or enzymes responsible for the degradation of connective tissue; and (d) stimulates B lymphocytes and the production of antibodies.^{5,11}

Cytokines

Cytokines are proteins secreted by cells that serve as intercellular mediators (**Table 57-1**). An imbalance of proinflammatory and anti-inflammatory cytokines in the synovium leads to inflammation and joint destruction. The proinflammatory cytokines interleukin 1 (IL-1), tumor necrosis factor- α (TNF- α), IL-6, and IL-17 are found in high

Table 57-1

Cytokines Involved in the Pathogenesis of RA^{5,7,11}

Cytokine	Source	Activity
Proinflammatory		
TNF- α	Macrophages, monocytes, B lymphocytes, T lymphocytes, fibroblasts	Induces IL-1, IL-6, IL-8, GM-CSF; stimulates fibroblasts to release adhesion molecules
IL-1	Macrophages, monocytes, endothelial cells, B lymphocytes, activated T lymphocytes	Stimulates fibroblasts and chondrocytes to release matrix metalloproteinases
IL-6	T lymphocytes, monocytes, macrophages, synovial fibroblasts	Activates T lymphocytes, induces acute-phase response, stimulates growth and differentiation of hematopoietic precursor cells; stimulates synovial fibroblasts
IL-17	T lymphocytes in synovium	Synergistic effect with IL-1 and TNF leading to increased production of proinflammatory cytokines
Anti-Inflammatory		
IL-4	CD4+ type 2 helper T lymphocytes	Inhibits activation of type 1 helper T lymphocytes, decreases production of IL-1, TNF- α , IL-6, IL-8
IL-10	Monocytes, macrophages, B lymphocytes, T lymphocytes	Inhibits production of IL-1, TNF- α , and proliferation of T lymphocytes

concentrations in synovial fluid. These proinflammatory cytokines cause the activation of other cytokines and adhesion molecules responsible for the recruitment of lymphocytes to the site of inflammation. Anti-inflammatory cytokines and mediators (IL-4, IL-10, and IL-1 receptor antagonist) are present in the synovium, although concentrations are not high enough to overcome the effects of the proinflammatory cytokines.^{5,11}

B Lymphocytes

In addition to serving as antigen-presenting cells to T lymphocytes, B lymphocytes may produce proinflammatory cytokines and antibodies.^{6,11} Antibodies of significance in RA are **rheumatoid factors** (antibodies reactive with the Fc region of IgG) and antibodies against **cyclic citrullinated peptide** (CCP).⁶ Rheumatoid factors are not present in all patients with RA, but their presence is indicative of disease severity, likelihood of extraarticular manifestations, and increased mortality.¹² CCPs are produced early in the course of disease. High levels of anti-CCP antibodies are indicative of aggressive disease and a greater likelihood of poor outcomes. Monitoring anti-CCP antibodies may be useful to predict the severity of disease and match aggressive treatment appropriately.

Comorbidities Associated with RA

RA reduces a patient's average life expectancy, but RA alone rarely causes death. Instead, specific **comorbidities** contribute to premature death independent of safety issues surrounding the use of immunomodulating medications.

1 *The comorbidities with the greatest impact on morbidity and mortality associated with RA are: (a) cardiovascular disease, (b) infections, (c) malignancy, and (d) osteoporosis.*

► Cardiovascular Disease

Half of all deaths in RA patients are cardiovascular related.¹³ Because a patient with RA experiences inflammation and swelling in his or her joints, it is likely that there is inflammation elsewhere, such as in the blood vessels, termed **vasculitis**. C-reactive protein (CRP), a nonspecific marker of inflammation, is associated with an increased risk of cardiovascular disease; CRP is elevated in patients with RA. Traditional cardiovascular risk factors alone cannot explain the increased cardiovascular mortality in patients with RA. Increasing evidence suggests that the presence of RA is a cardiovascular risk similar to diabetes. Aggressive management of systemic inflammation and traditional cardiovascular risk factors (e.g., blood pressure, cholesterol, tobacco use) may reduce cardiovascular mortality in this population.¹⁴

► Infections

RA itself leads to changes in cellular immunity and causes a disproportionate increase in pulmonary infection and sepsis.¹⁵ Because medications that alter the

immune system are linked to an increased risk of infection, it is difficult to distinguish between an increased risk of infection secondary to RA and the medications used to treat RA. Patients and clinicians must pay close attention to signs and symptoms of infection because of this increased risk.¹⁵

► Malignancy

Patients with RA have an increased risk of developing **lymphoproliferative** malignancy (e.g., lymphoma, leukemia, and multiple myeloma) and lung cancer but a decreased risk of developing cancer of the digestive tract.^{15,16} The relationship between RA and cancer is not clear. To confound the issue, medications for treating RA are undergoing review to determine whether use independently increases cancer risk. Current evidence suggests that the underlying disease process is responsible for the increased cancer risk and not the use of medications.¹⁶ Patients presenting with new onset of symptoms (e.g., fevers, night sweats, chills, or anorexia) out of proportion with disease activity and patients not responding to conventional RA treatment should be evaluated further for lymphoproliferative malignancy.^{15,17}

► Osteoporosis

Osteoporosis associated with RA follows a multifaceted pathogenesis, but the primary mechanism likely is mediated by increased **osteoclast** activity.¹⁵ The cytokines involved in the inflammatory process directly stimulate osteoclast and inhibit **osteoblast** activity. Additionally, arthritis medications can lead to increased bone loss. Bone mineral density should be evaluated at baseline and routinely using dual-energy x-ray absorptiometry.¹⁵

CLINICAL PRESENTATION AND DIAGNOSIS

See the accompanying text box for the clinical presentation of RA.

Diagnosis

Both osteoarthritis and RA are prevalent in the American population, but they differ significantly in presentation (**Table 57-2**). Because management of the two conditions differs significantly, early evaluation and diagnosis are essential to maximize an individual patient's care.

In 2010, The American College of Rheumatology (ACR) and European League Against Rheumatism (EULAR) released new classification criteria for RA (**Table 57-3**).¹ The goal was to identify a subset of patients with undifferentiated synovitis who were at high risk for chronic and erosive disease. The new criteria are intended to help identify patients earlier in the course of disease. This will allow researchers to determine whether earlier introduction of medications alters

Clinical Presentation of RA

General

- About 60% of patients develop symptoms gradually over several weeks to months.
- Patients may present with systemic findings, joint findings, or both.

Symptoms

- Nonspecific systemic symptoms may include fatigue, weakness, anorexia, and diffuse musculoskeletal pain.
- Patients complain of pain in involved joints and prolonged morning joint stiffness.

Signs

- The metacarpophalangeal (MCP), proximal interphalangeal (PIP), metatarsophalangeal (MTP), and wrist joints are involved frequently.
- Joint involvement is usually symmetric.
- There is often limited joint function.
- Signs of joint inflammation are present (tenderness, warmth, swelling, and erythema).
- Low-grade fever may be present.
- Extraarticular manifestations:
 - *Skin*: Subcutaneous **nodules**
 - *Ocular*: **Keratoconjunctivitis sicca, scleritis**

- *Pulmonary*: Interstitial fibrosis, pulmonary nodules, **pleuritis**, pleural effusions
- *Vasculitis*: Ischemic ulcers, skin lesions, **leukocytoclastic vasculitis**
- *Neurologic*: Peripheral neuropathy, **Felty's syndrome**
- *Hematologic*: Anemia, **thrombocytosis**

Laboratory Tests

- Positive rheumatoid factor (the test is negative in up to 30% of patients)
- Elevated ESR (Westergren ESR: greater than 20 mm/h in men; greater than 30 mm/h in women)
- Elevated C-reactive protein (CRP) (greater than 0.7 mg/dL or 7 mg/L)
- Complete blood count: Slight elevation in WBC count with a normal differential; slight anemia; thrombocytosis
- Positive anti-CCP antibodies

Other Diagnostic Tests

- *Synovial fluid analysis*: Straw colored, slightly cloudy, WBC 5 to 25 × 10³/mm³ (5 to 25 × 10⁹/L), no bacterial growth if cultured
- *Joint x-rays*: To establish baseline and evaluate joint damage
- *MRI*: May detect erosions earlier in the course of disease than x-rays but is not required for diagnosis

Table 57-2

Comparison of RA and Osteoarthritis

Characteristic	RA	Osteoarthritis
Speed of onset	Rapid (weeks–months)	Slow (years)
Gender prevalence (women: men)	3:1	1:1
Usual age of onset	Juvenile or adult (35–50 years)	Greater than 50 years
Most common joints affected	Small joints of hands (MCPs, PIPs), feet	Hands (DIPs), large weight-bearing joints (hips, knees)
Joint symptoms	Pain, swelling, warmth, stiffness	Pain, bony enlargement
Presence of inflammation	Local and systemic	None or mild, local
Duration of morning joint stiffness	Usually 60 minutes or longer	Usually less than 30 minutes
Joint pattern	Symmetric	Symmetric or asymmetric
ESR	Elevated	Normal
Synovial fluid	Leukocytosis, slightly cloudy	Mild leukocytosis
Systemic manifestations	Yes	No

DIPs, distal interphalangeal joints; ESR, erythrocyte sedimentation rate; MCPs, metacarpophalangeal joints; PIPs, proximal interphalangeal joints.

the disease process. The criteria were developed as a tool for research purposes, but the authors acknowledge that they are also helpful to guide clinical diagnosis. Patients with at least one joint with definite clinical synovitis that is not explained by another disease should be tested for RA.

Several clinical features of RA are associated with a worse long-term prognosis. The presence of these poor prognostic features should be considered at the time initial treatment decisions are made; more aggressive treatment may be warranted if these features are present. **2** *The most clinically important features associated with poor long-term outcomes include: (a) functional limitation (defined by use of standard measurement scales such as the Health Assessment Questionnaire [HAQ] score), (b) extraarticular disease, (c) positive rheumatoid factor, (d) positive anti-CCP antibodies, and/or (e) bony erosions by radiography.*

► Diagnosis of Juvenile Idiopathic Arthritis

Diagnostic criteria for JIA include: (a) age less than 16 years at disease onset, (b) arthritis in one or more joints for more than 6 weeks, (c) exclusion of other types of arthritis. JIA can be divided into three main types:

Table 57-3

ACR/EULAR 2010 Classification Criteria for Rheumatoid Arthritis¹

Criteria	Score
Joint involvement	
1 large joint (hips, knees, ankles, elbows, shoulders)	0
2–10 large joints	1
1–3 small joints (MCPS, PIPs, MTPs, wrists)	2
4–10 small joints	3
More than 10 joints (at least 1 small joint)	5
Serology (need at least 1 result for classification)	
Negative RF and negative anti-CCP	0
Low positive RF or low-positive anti-CCP	2
High-positive RF or high-positive anti-CCP	3
Acute-phase reactants (need at least 1 result for classification)	
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
Duration of symptoms	
Less than 6 weeks	0
More than 6 weeks	1
TOTAL: 6 or greater indicates definite RA	

ACR, American College of Rheumatology; anti-CCP, anti-cyclic citrullinated peptide; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; EULAR, European League Against Rheumatism; MCPS, metacarpophalangeal joints; MTPs, metatarsophalangeal joints; PIPs, proximal interphalangeal joints; RA, rheumatoid arthritis; RF, rheumatoid factor.

Patient Encounter, Part 1

RT is a 38-year-old white woman who presents to the neighborhood free medical clinic with a 4-month history of progressive stiffness and pain in her hands. She is a waitress at the local diner and has no medical or prescription insurance. She delayed seeking medical treatment for fear of the expenses she would incur. For the last 2 months, she has been taking acetaminophen for the pain but admits that it is no longer working and she needs something stronger so she can perform her job responsibilities. RT is a single mother of three children aged 6, 8, and 9. She lives in an apartment, but she is at risk of being evicted for late rent payments. She is missing work more often lately due to morning stiffness, joint pain, and general fatigue.

What risk factors does she have for RA?

What additional information do you need before creating a treatment plan for this patient?

What other variables in this scenario may inhibit optimal patient care?

1. *Systemic (approximately 10% of cases):* Occurs equally in girls and boys. There are characteristic fever spikes twice daily (greater than 38.3°C or 101°F) and the presence of a pale, pink, transient rash. The peak onset is between ages 1 and 6 years.
2. *Polyarticular (approximately 40% of cases):* More likely to affect girls than boys (3:1). Arthritis is present in five or more joints. The disorder resembles adult RA more than the other types of JIA.
3. *Pauciarticular (approximately 50% of cases):* More likely to affect girls than boys (5:1). Uveitis is more likely to be present. Arthritis is present in four or fewer joints. Categories are further divided into early onset and late onset. Early onset is more likely to occur in girls, whereas late onset is more common in boys.¹⁸

TREATMENT

Desired Outcomes

- 3 The goals of treatment in RA are to: (a) reduce or eliminate pain, (b) protect articular structures, (c) control systemic complications, (d) prevent loss of joint function, and (e) improve or maintain quality of life.⁸ The goals for JIA are the same, with the added goals of maintaining normal growth, development, and activity level.¹⁹ It is a common misconception that patients with JIA grow out of the disease. Many children with JIA become adults with JIA. Knowing this, it is essential that early, aggressive treatment is initiated to achieve the goals of therapy.

General Approach to Treatment

The clinician must evaluate patient-specific factors and select appropriate treatment to maximize the care of an individual patient. Joint damage accumulates over time; therefore, early diagnosis and early aggressive treatment are necessary to reduce disease progression and prevent joint damage. Aggressive treatment is defined as one or more disease-modifying antirheumatic drugs (DMARDs) at effective doses. Delaying treatment will result in more destructive disease that is very difficult to delay or reverse to preserve joint function.

- 4 It is imperative that the initiation of one or more DMARDs occurs in all patients within the first 3 months of diagnosis to reduce joint erosion. Depending on disease severity and whether poor prognostic features are present, combination therapy may be initiated at the time of diagnosis or after an adequate trial of a DMARD initiated as monotherapy. If a patient has more aggressive disease, a more aggressive treatment plan may be warranted. The following medication classes are prescribed commonly for the treatment of RA: (a) nonsteroidal anti-inflammatory drugs (NSAIDs), (b) glucocorticoids, (c) nonbiologic DMARDs, and (d) biologic DMARDs. Table 57-4 highlights dosing, safety, monitoring, and patient counseling information for the common nonbiologic and biologic DMARDs.

Table 57-4

FDA-Approved Nonbiologic and Biologic DMARDs for Treatment of RA

Drug	Dose ^a	Route	Time to Effect (weeks)	ADRs	Dosing in Hepatic Impairment	Dosing in Renal Impairment	Monitoring	Counseling Points
Methotrexate	Adults: 7.5–20 mg once weekly Polyarticular-course JIA: Recommended starting dose: 10 mg/m ² once weekly; usual max dose: 20 mg/m ² once weekly	Oral or IM	4–8	N, D, hepatotoxicity, alopecia, new-onset cough or SOB, MYL	CI	CrCl (mL/min) ^b : 61–80: 75% of dose 51–60: 70% of dose 10–50: 50% of dose Less than 10: Avoid use	CBC, creatinine, LFTs every 4–8 weeks; monitor for signs of infection	Use of folic acid concomitantly Avoid alcohol Use contraception if childbearing potential
Hydroxy- chloroquine	Adults: 200 mg twice daily	Oral	8–24	N, D, HA, vision changes, skin pigmentation	Use with caution	No change	Eye exam every 12 months	Sunscreen use
Sulfasalazine	Adults: 1,000 mg 2–3 × daily Polyarticular-course JIA: Initial: 10 mg/kg/day; increase weekly by 10 mg/kg/day; usual dose: 30–50 mg/kg/ day in 2 divided doses; max 2 g/day	Oral	8–12	N, D, rash, yellow- orange discoloration, photosensitivity, MYL	Avoid use	CrCl (mL/min) ^b : 10–30: Give twice daily; Less than 10: Give once daily	CBC every 2–4 weeks for 3 months, then every 3 months	
Leflunomide (Arava)	Adults: 100 mg daily for 3 days; then 20 mg daily	Oral	4–12	Hepatotoxicity, D, N, HTN, rash, HA, abdominal pain	Avoid use	Guidelines not available	CBC, creatinine, LFTs every months for 6 months; then every 4–8 weeks Monitor for signs of infection	Avoid alcohol Use contraception if childbearing potential
Etanercept (Enbrel)	Adults: 25 mg twice weekly or 50 mg once weekly Children ages 2–17: 0.8 mg/ kg once weekly; max 50 mg/ week	SC injection	1–4	ISR	No change	No change	Monitor for infection	ISR—topical corticosteroids, antipruritics, analgesics, rotate injection sites Screen for tuberculosis
Inflixima ^b (Remicade)	Adults: 3–10 mg/kg at 0, 2, and 6 weeks; then every 8 weeks	IV infusion	1–4	IR (rash, urticaria, flushing, HA, fever, chills, nausea, tachycardia, dyspnea)	No change	No change	Monitor for infection	Screen for tuberculosis
Adalimumab (Humira)	Adults: 40 mg every other week Children older than 4 years and weighing 15–29 kg: 20 mg every other week Children weighing 30 kg or more: 40 mg every other week	SC injection	1–4	ISR	No change	No change	Monitor for infection	Screen for tuberculosis

Golimumab (Simponi)	Adults: 50 mg once monthly Children: Safety and efficacy has not been established	SC injection	1–4	ISR	No change	No change	Monitor for infection	Screen for tuberculosis
Certolizumab (Cimzia)	Adults: 400 mg initially, at 2 weeks, 4 weeks, then every 4 weeks thereafter Children: Safety and efficacy has not been established	SC injection	1–4	ISR	No change	No change	Monitor for infection	Screen for tuberculosis
Anakinra (Kineret)	Adults: 100 mg daily	SC injection	2–4	HA, N, V, D, ISR	No data available	CrCl less than 30 mL/min ^b : consider 100 mg every other day	Monitor for infection	
Abatacept (Orencia)	Adults less than 60 kg, 500 mg; 60–100 kg, 750 mg; Adults greater than 100 kg, 1,000 mg IV on days 1, 15 and every 28 days thereafter. SC Injection: Weight-based loading dose, then 125 mg SC within 1 day, 125 mg SC once weekly; or 125 mg once weekly in patients unable to receive IV. JIA (older than 6 years of age): less than 75 kg: 10 mg/kg; 75–100 kg: 750 mg; greater than 100 kg: 1,000 mg IV on days 1, 15, 28 and every 28 days thereafter	IV infusion, SC injection	2	HA, infection, IR	No change	No change	Monitor for infection	
Rituximab (Rituxan)	Adults: Two 1,000-mg infusions separated by 2 weeks	IV infusion	4	IR	No change	No change	Monitor for infection	
Tocilizumab (Actemra)	Adults: 8 mg/kg every 4 weeks JIA (2 years and older): less than 30 kg: 12 mg/kg every 2 weeks; greater than 30 kg: 8 mg/kg every 2 weeks	IV infusion		Elevated LFTs, total cholesterol, triglycerides, and high-density lipoprotein; nasopharyngitis, infection	No data available	No data available	Monitor for infection; LFTs	

CI, contraindicated; D, diarrhea; HA, headache; HTN, hypertension; IR, infusion reactions; ISR, injection-site reactions; LFTs, liver function tests; MYL, myelosuppression (watch for fever, symptoms of infection, easy bruisability, and bleeding); N, nausea; SOB, shortness of breath.

^aGeriatric patients should receive the usual adult dose unless renal or hepatic impairment is present. Pediatric doses are provided for drugs that have FDA-approved indications for juvenile idiopathic arthritis (JIA).

^bTo convert to SI units of mL/s, multiply by 0.0167.

From Refs. 1, 2, 8, and 20–22.

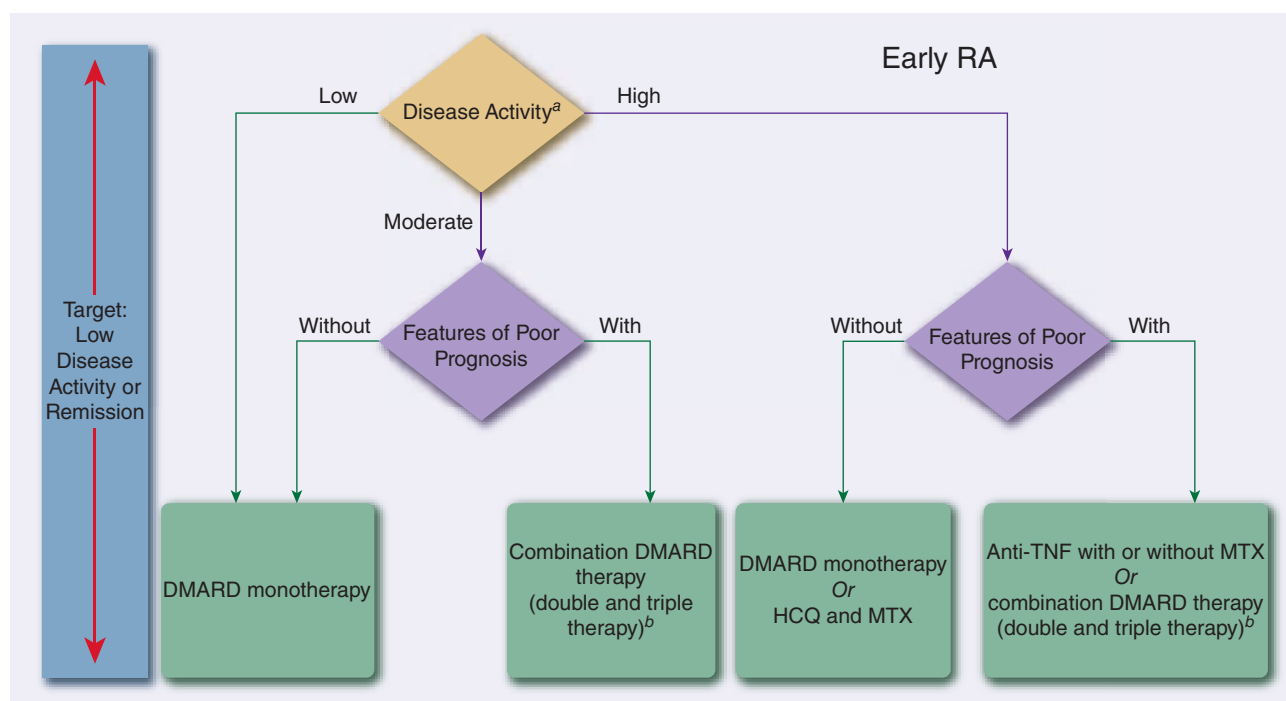

FIGURE 57-1. Recommendations for the treatment of early RA (disease duration less than 6 months). ^aSee Ref. 20 for definitions of disease activity. ^bCombination DMARD therapy: methotrexate + leflunomide, methotrexate + hydroxychloroquine, methotrexate + sulfasalazine, sulfasalazine + hydroxychloroquine. Triple DMARD therapy: methotrexate + hydroxychloroquine + sulfasalazine. (Reproduced, with permission, from Singh JA, Furst DE, Bharat A, et al. 2012 Update of the 2008 American College of Rheumatology recommendations for the use of disease-modifying antirheumatic drugs and biologic agents in the treatment of rheumatoid arthritis. *Arthritis Care Res* 2012;64:625–639.)

Figures 57-1 and 57-2 outline the course of treatment according to the ACR 2012 Recommendations.²⁰ The recommendations are based on the activity level of the patient's disease, the presence or absence of poor prognostic features, and the duration of disease activity (early vs. established). Figure 57-1 applies to patients who have had RA for less than 6 months. Patients who have early RA with low disease activity may be treated with nonbiologic DMARD monotherapy (hydroxychloroquine, minocycline, leflunomide, methotrexate, or sulfasalazine). Patients with moderate or high disease activity but without poor prognostic features may receive initial treatment with DMARD monotherapy or the combination of methotrexate and hydroxychloroquine. Patients with moderate or high disease activity and evidence of poor prognostic features may receive combination therapy with methotrexate/hydroxychloroquine, methotrexate/sulfasalazine, or methotrexate/sulfasalazine/hydroxychloroquine. Alternatively, patients with high disease activity and features of poor prognosis may be started on anti-TNF therapy with or without methotrexate.

Figure 57-2 outlines the course of treatment for patients with established RA (disease duration 6 months or longer). Biologic DMARDs are usually considered in patients with established RA following inadequate response to nonbiologic or biologic DMARDs. Figure 57-2 establishes a progression of how to switch from one biologic agent to another in a patient

who experiences an inadequate response or adverse event. Because of treatment expense, biologic DMARDs should be considered only in patients who have no limitations due to cost or insurance coverage. There is no evidence that the benefits of combination therapy with biologic DMARDs outweigh the potential risks, especially the increased risk of infections.

Nonpharmacologic Therapy

All patients should receive education about the nonpharmacologic and pharmacologic measures to help manage RA and JIA. Empowered patients take an active role in care by participating in therapy-related decisions. Certain forms of nonpharmacologic therapy benefit all levels of severity, whereas others (i.e., surgery) are reserved for severe cases only.

Occupational and physical therapy may help patients preserve joint function, extend joint range of motion, and strengthen joints and muscles through strengthening exercises. Patients with joint deformities may benefit from the use of mobility or assistive devices that help to minimize disability and allow continued activities of daily living. When appropriate, patients should also be counseled about stress management (i.e., cognitive behavioral therapy, emotional disclosure, tai chi). In situations where the disease has progressed to a severe form with extensive joint erosions, surgery to replace or reconstruct the joint may be necessary.

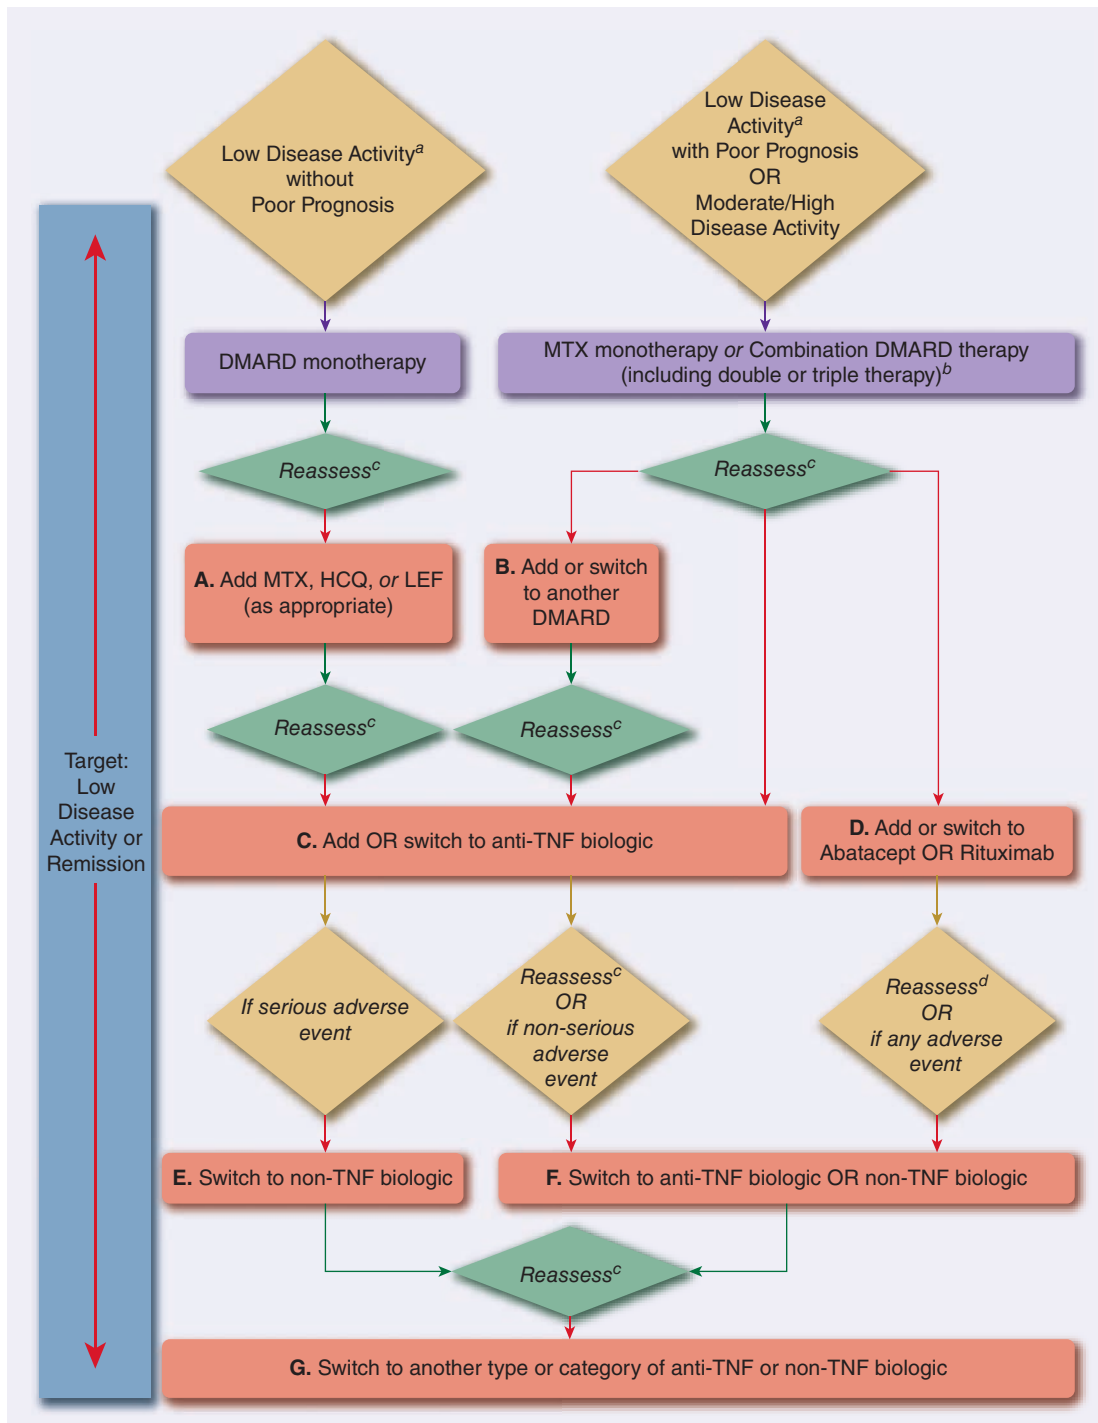

FIGURE 57-2. Recommendations for the treatment of established RA (disease duration 6 months or longer). ^aSee Ref. 20 for definitions of disease activity. ^bCombination DMARD therapy: methotrexate + leflunomide, methotrexate + hydroxychloroquine, methotrexate + sulfasalazine, sulfasalazine + hydroxychloroquine. Triple DMARD therapy: methotrexate + hydroxychloroquine + sulfasalazine. ^cReassess after 3 months of adequate therapy. ^dReassess after 6 months of adequate therapy. (Reproduced, with permission, from Singh JA, Furst DE, Bharat A, et al. 2012 Update of the 2008 American College of Rheumatology recommendations for the use of disease-modifying antirheumatic drugs and biologic agents in the treatment of rheumatoid arthritis. *Arthritis Care Res* 2012;64:625–639.)

Pharmacologic Therapy

► Nonsteroidal Anti-Inflammatory Drugs

NSAIDs provide analgesic and anti-inflammatory benefits for joint pain and swelling. However, they do not prevent joint damage or change the underlying disease. It is appropriate for a patient to begin taking an NSAID along with a DMARD for “bridge therapy” to provide symptomatic relief until the therapeutic effect of the DMARD is observed. Because of interpatient variability in response, patients may find relief from one NSAID and not another. For this reason, if a patient does not receive relief from one NSAID, it is acceptable to try a second one. Selecting another NSAID depends on multiple patient-specific factors, including cardiovascular risk, potential for GI-related adverse events, adherence to medication regimens, and insurance coverage or lack thereof. Clinicians must weigh these factors carefully to determine whether the patient will benefit from another NSAID, if he or she should receive a cyclooxygenase-2 (COX-2) inhibitor, or if another medication class should be considered.

NSAID use is associated with an increased risk of GI ulcers or hemorrhage, fluid retention, exacerbation of existing hypertension, and decreased renal function in certain patient populations.^{8,21} Factors that place a patient at a higher risk of GI-related adverse reactions include: (a) history of peptic ulcer disease, (b) high doses of NSAIDs, (c) concomitant use of other medications with an increased risk of GI hemorrhage or ulcers (e.g., anticoagulants, corticosteroids, use of multiple NSAIDs), (d) age greater than 75 years, and (e) serious underlying diseases.²⁰

If a patient has an increased risk of NSAID-induced adverse reactions, gastroprotection should be considered by coinstitution of a proton pump inhibitor, histamine-2 receptor blocker, or misoprostol. Misoprostol is effective in reducing the occurrence of gastric and duodenal ulcers. However, its tolerability is limited by adverse effects, specifically diarrhea. Histamine-2 receptor blockers effectively prevent duodenal ulcers (but not gastric ulcers) that occur more readily as a result of NSAID therapy. Proton pump inhibitors are the preferred gastroprotective agents due to greater acid suppression, prevention of both gastric and duodenal ulcers, and a tolerable adverse-effect profile.²² Alternative options include low-dose prednisone, a nonacetylated salicylate, or a COX-2 inhibitor.

NSAIDs may accentuate the increased risk of cardiovascular events inherent in patients with RA. Increases in blood pressure and fluid retention may exacerbate existing cardiovascular disease. With the evidence associating COX-2 inhibitors with cardiovascular disease, clinicians must carefully evaluate the potential risks of NSAID therapy against the potential benefits.² See Chap. 58 for additional discussion of NSAID therapy.

NSAID monotherapy is recommended as initial treatment in children with JIA with low disease activity affecting four or fewer joints. As in adults, adverse effects of NSAID therapy should be anticipated and treated accordingly in pediatrics.¹⁰

► Glucocorticoids

Low-dose glucocorticoid treatment (equivalent to prednisone 10 mg/day or less) effectively reduces inflammation through

inhibition of cytokines and inflammatory mediators and prevents disease progression.^{21,23} The goal of glucocorticoid use is to minimize adverse drug events by keeping doses low and using the drugs as infrequently as possible. Patients may receive glucocorticoids for a brief time as “bridge therapy” following DMARD initiation or via intraarticular injections to relieve symptoms of active disease. Patients taking more than 5 mg/day of prednisone or equivalent are at an increased risk for clinically significant adverse reactions, especially bone loss leading to osteoporosis. Other glucocorticoid-related adverse reactions include Cushing’s syndrome, peptic ulcer disease, hypertension, weight gain, infection, mood changes, cataracts, dyslipidemia, and hyperglycemia.^{2,23}

Intraarticular glucocorticoid injections are recommended following an adequate trial of an NSAID or if moderate or high disease activity is affecting four or fewer joints in the treatment of JIA.¹⁰

► Nonbiologic DMARDs

Nonbiologic and biologic DMARDs are the mainstay of RA treatment because they modify the disease process and prevent or reduce joint damage. In addition to relying on safety and efficacy data, the initial DMARD choice depends on disease severity, patient characteristics (i.e., comorbidities, likelihood of adherence), cost, and clinician experience with the medication.^{8,20} Methotrexate alone or in combination therapy is the initial treatment of choice for patients with aggressive disease. Patients with early, mild disease may receive monotherapy with sulfasalazine, leflunomide or hydroxychloroquine. Agents such as azathioprine, D-penicillamine, gold salts, and anakinra are used rarely today because of concerns about toxicity and reduced efficacy.^{1,20,21}

• **Methotrexate** 5 *Methotrexate is the nonbiologic DMARD of choice in RA because of its documented efficacy and safety profile when monitored appropriately.*^{1,25} Methotrexate exerts its anti-inflammatory effect through inhibition of dihydrofolate reductase, which causes the inhibition of purines and thymidylc acid and by inhibiting the production of certain cytokines.² Unless the patient has contraindications to methotrexate, once-weekly doses should be initiated within 3 months of diagnosis and increased steadily until the patient has symptomatic improvement or a maximum dose of 20 mg/week is reached. Concomitant folic acid is given routinely to reduce the risk of folate-depleting reactions induced by methotrexate therapy (e.g., **stomatitis**, diarrhea, nausea, **alopecia**, **myelosuppression**, and elevations in liver function tests).^{1,25}

Serious adverse reactions include pulmonary fibrosis and hepatotoxicity. Patients should be counseled to avoid the use of alcohol, take folic acid as directed, adhere to the laboratory monitoring schedule, and immediately report symptoms of pulmonary fibrosis (e.g., cough or dyspnea) and hepatotoxicity (e.g., jaundice or abdominal pain). If monotherapy does not produce complete resolution of symptoms, methotrexate may be used in combination with other nonbiologic or biologic DMARDs. In situations in which the clinician suspects RA but a diagnosis has not yet been made, initiation of

methotrexate was found to delay the diagnosis and halt joint damage without untoward adverse effects.²⁶

Methotrexate is recommended as initial treatment for JIA in patients with high disease activity.¹⁰ The usual dose is 5 to 15 mg/m² (based on body surface area) once weekly. There are insufficient published data to assess the risk of serious toxicity in children receiving doses greater than 20 mg/m²/wk. Patients will begin to notice a response in 3 to 4 weeks, with maximal response in 3 to 6 months. Methotrexate therapy in pediatric patients should be monitored the same way that is recommended in adults.²⁷

Hydroxychloroquine and Sulfasalazine The exact mechanism of action of these drugs is unknown, but both agents are fairly well tolerated. Hydroxychloroquine or sulfasalazine may be initiated on diagnosis of low disease activity. Because of their slow onset of action, each drug must be given at therapeutic doses for at least 6 months before it can be deemed a treatment failure. Hydroxychloroquine and sulfasalazine are relatively inexpensive compared with the new biologic agents. If patients do not respond to methotrexate monotherapy, adding one of these agents may provide the benefit necessary to reduce symptoms satisfactorily.^{2,20}

Hydroxychloroquine may cause retinal toxicity, and patients must have their eyes examined at least annually to detect this abnormality. It is not associated with renal, hepatic, or bone marrow suppression and therefore may be an acceptable treatment option for patients with contraindications to other DMARDs because of their toxicities.

Starting sulfasalazine at low doses and titrating slowly will minimize the nausea and abdominal discomfort caused by the drug. Patients receiving sulfasalazine must undergo routine blood work to monitor for leukopenia.²⁰ Patients with a sulfa allergy should not receive sulfasalazine.

In patients with JIA, sulfasalazine is recommended only for patients with the **enthesitis**-related category. Enthesitis-related arthritis is a less common form of JIA that affects boys more than girls and is characterized by lower extremity joint involvement, including heel pain and enthesitis. The dose of sulfasalazine for children older than 6 years is 30 to 50 mg/kg/day in two divided doses. Hydroxychloroquine is not recommended in patients with active arthritis associated with JIA.¹⁰

Leflunomide Leflunomide inhibits dihydroorotate dehydrogenase, an enzyme within the mitochondria that supplies T lymphocytes with the necessary components to respond to cytokine stimulation.²⁸ Thus leflunomide inhibits the T-lymphocyte response to various stimuli and halts the cell cycle. Its efficacy is similar to that of moderate doses of methotrexate or sulfasalazine.²¹ Because of its extended half-life, leflunomide therapy begins with a loading dose followed by a maintenance dose. Patients with preexisting hepatic disease or a history of heavy alcohol ingestion should not receive leflunomide.²⁸ Leflunomide may be used in combination with methotrexate, but the added efficacy comes with a dramatic rise in the risk of hepatotoxicity. Liver function tests must be followed closely to prevent or minimize liver damage.²⁰ If therapy requires abrupt discontinuation (e.g.,

due to toxicity or pregnancy), administering cholestyramine will accelerate removal of leflunomide from the body.

Leflunomide is recommended as an alternative to methotrexate in patients with JIA experiencing high disease activity in five or more joints. However, leflunomide does not have an FDA-approved indication for this use.²⁰

► **Biologic DMARDs**

- Biologic DMARDs are indicated in patients who have failed an adequate trial of nonbiologic DMARD therapy or in combination with nonbiologic DMARDs in patients with early, aggressive disease. These agents may be added to nonbiologic DMARD monotherapy (e.g., methotrexate) or replace ineffective nonbiologic DMARD therapy. The decision to select a particular agent generally is based on the prescriber's comfort level with monitoring the safety and efficacy of the medications, severity of disease activity, presence of factors suggestive of poor prognosis, the frequency and route of administration, the patient's comfort level or manual dexterity to self-administer subcutaneous injections, the cost, and the availability of insurance coverage. In general, biologic DMARDs should be avoided in patients with serious infections, demyelinating disorders (e.g., multiple sclerosis or optic neuritis), or hepatitis. TNF antagonists should be avoided in patients with heart failure.²⁰

Tumor Necrosis Factor Antagonists Etanercept is a recombinant form of human T receptor.²⁹ Etanercept provides a therapeutic effect by binding to soluble TNF and preventing its binding with TNF receptors. It is administered subcutaneously once or twice weekly; noticeable symptomatic improvement is seen in 1 to 4 weeks. Etanercept is very effective as monotherapy or in combination with other nonbiologic DMARDs. The most common adverse reactions with etanercept are injection-site reactions. If such reactions are bothersome, patients should be advised to place ice on the injection site before and after administration or apply a topical anesthetic or corticosteroid to the affected area.³⁰ Etanercept has an FDA-approved indication for treatment of JIA. The pediatric dose of etanercept is 0.8 mg/kg subcutaneously once weekly.

Adalimumab is a recombinant human IgG1 monoclonal antibody specific for human TNF.³¹ Adalimumab binds to soluble and bound TNF- α . Patients may experience symptomatic relief in as early as 1 week. Adalimumab can be administered in combination with methotrexate or other DMARDs.² Adalimumab has an FDA-approved indication for JIA. Of the TNF antagonists, only etanercept and adalimumab are recommended for treating JIA with high disease activity after an adequate trial of NSAIDs, glucocorticoids, or methotrexate.¹⁰

Infliximab is a **chimeric** IgG1 monoclonal antibody that binds to soluble and bound TNF- α .³² Methotrexate typically is given with it to suppress antibody production against the mouse-derived portion of the molecule. Infliximab is delivered via IV infusion every 4 to 8 weeks; however, patients may notice benefit within 1 to 4 weeks of receiving the first infusion.

Infusion-related reactions including rash, urticaria, flushing, headache, fever, chills, nausea, tachycardia, and dyspnea may occur during treatment. Qualified healthcare personnel must be present during the infusion to respond to the infusion-related reactions, if they occur. If patients experience any of these symptoms, the reaction may be treated by: (a) temporarily discontinuing the infusion, (b) slowing the infusion rate, or (c) administering corticosteroids or antihistamines.³⁰ Clinicians may prescribe pretreatment regimens with corticosteroids or antihistamines if the patient continues to experience infusion reactions.³⁰ Infliximab was shown in clinical trials to be effective for treatment of JIA, but it has not yet received FDA approval for this indication.

Golimumab is a human monoclonal antibody that binds to membrane-bound and soluble TNF. Golimumab can be administered in combination with methotrexate in patients with moderate to severe RA. One advantage of this agent over others in the class may be the once-monthly dosing. Golimumab is not FDA-approved for use in JIA.

Certolizumab is a humanized antibody Fab fragment conjugated to polyethylene glycol, which delays the metabolism and elimination of the medication. Certolizumab can be administered as monotherapy or in combination with methotrexate in patients with moderate to severe RA. Certolizumab is not FDA-approved for use in JIA.

Interleukin-1 Receptor Antagonist Anakinra is a recombinant form of human IL-1 receptor antagonist. Anakinra inhibits the activity of IL-1 by binding to it and preventing cell signaling. It is indicated for adults with RA who have failed one or more nonbiologic DMARDs. Patients must administer a subcutaneous injection every day, which may be less desirable than other treatment options. Anakinra may be used in combination with other nonbiologic DMARDs in patients not responding to or unable to tolerate nonbiologic DMARDs or TNF antagonists. Anakinra should not be used in combination with TNF antagonists due to the increased risk of infection. Anakinra is not included in the algorithms outlined in the 2012 treatment guidelines due to its infrequent use in RA. Regarding treatment of JIA, anakinra is recommended in patients with systemic arthritis of moderate to high disease activity with active arthritis after a trial of methotrexate.¹⁰

Costimulation Modulators Abatacept interferes with T-cell signaling, ultimately blocking T-cell activation and leading to anergy, or lack of response to an antigen.³³ Trials conducted in patients refractory to methotrexate and anti-TNF therapy demonstrated significant clinical benefit after administration of abatacept every 28 days with a dose approximating 10 mg/kg.³³ Adverse reactions reported in clinical trials were low and similar to those of placebo, with the exception of an increased incidence of headache, infections, and infusion-related reactions in the treatment group.³³

Abatacept is indicated as monotherapy or in combination with nonbiologic DMARDs. Its exact place in therapy is not yet clear; however, clinicians see a window of opportunity for patients who were intolerant to or did not receive therapeutic

benefit from other nonbiologic or biologic DMARDs or developed antibodies to adequate trials of anti-TNF agents, specifically infliximab.³³ Abatacept is FDA approved for the treatment of moderate to severe JIA. It is recommended as a treatment option for patients who received and did not respond to an adequate trial of TNF antagonists.

Anti-CD20 Monoclonal Antibody Rituximab is a genetically engineered chimeric anti-CD20 monoclonal antibody that causes B-lymphocyte depletion in bone marrow and synovial tissue. The exact role of rituximab in RA is not clearly defined, but it is indicated for patients with moderate to severe active RA and a history of inadequate response to one or more TNF antagonist therapies. Adverse effects occurring during or up to 24 hours after the first infusion may include increases or decreases in blood pressure, cough, rash, and pruritus. The infusion-related reactions subside with subsequent infusions. Rituximab carries a black-box warning of fatal infusion reactions and severe mucocutaneous reactions, even though these events did not occur during the RA clinical trials. The benefits of rituximab must be tempered against the safety concerns reported with use of rituximab in the oncology setting. Rituximab is considered a last-line treatment option for JIA (after TNF antagonists and abatacept), although the medication is not FDA approved for this purpose.¹⁰

Anti-interleukin-6 Receptor Antibody Interleukin-6 (IL-6) is produced in high amounts in patients with RA. High levels are indicative of joint damage and disease activity. In addition, IL-6 plays a significant role in the pathogenesis of anemia associated with RA.³⁷ Tocilizumab, an anti-IL-6 receptor monoclonal antibody, inhibits the binding of IL-6 to the IL-6 receptor.²⁴ Studies in patients not responding to methotrexate or TNF antagonists have demonstrated decreased disease activity and improved function and quality of life in patients with RA. The tocilizumab dose is 8 mg/kg IV every 4 weeks. Adverse reactions include nasopharyngitis, infection, and elevated lab values, including liver function tests and cholesterol parameters.³⁸ In the 2012 recommendations, tocilizumab is considered after inadequate therapeutic response or adverse event to anti-TNF agents, abatacept, or rituximab. Tocilizumab is FDA approved for the treatment of JIA, although it was not included in the recent JIA treatment recommendations.

Kinase Inhibitors Kinases (e.g., Janus kinase 3) are intracellular molecules involved in cytokine signaling. Tofacitinib is a Janus kinase 3 inhibitor undergoing clinical trials to determine safety and efficacy in RA. Tofacitinib is an oral medication that, if approved by the FDA, may provide an alternative for patients unwilling or unable to receive injectable medications.³⁹

► **Selecting a Biologic DMARD**

Developments in the treatment of RA are tempered by the lack of evidence of the long-term safety and efficacy of the biologic DMARDs. In addition, high costs can be a deterrent to

use. Longer term data are emerging that suggest that patients receiving therapy with these agents early in the course of disease (within 3 years) for a defined time period have reduced disease activity and less joint destruction. If additional evidence proves this to be true, concerns regarding the cost of biologic DMARDs may be alleviated.³⁹ Cost analyses may indicate that the increased expenses associated with these drugs are offset by the costs avoided for treatment of advanced RA.

6 *The risk of infection in patients treated with biologic DMARDs must be considered when selecting and monitoring therapy.*^{20,40,41} Influencing the immune response to reduce symptoms of RA may influence the body's response to pathogens. Of particular concern is the use of TNF antagonists in patients with a history of tuberculosis exposure. TNF is important in the formation of granulomas that wall off tuberculosis infection. In theory, if TNF is inhibited, patients with latent tuberculosis may have a reactivated infection. Patients receiving biologic DMARD therapy should be screened for tuberculosis and other infections (hepatitis B, hepatitis C). Antituberculosis therapy should be initiated in patients with active or latent tuberculosis.²⁰ Biologic therapy may be initiated after at least 1 month of antituberculosis treatment. Patients with untreated hepatitis B should not receive biologic DMARDs. Etanercept may be a potential treatment option in patients with hepatitis C.²⁰ Biologic DMARDs should not be initiated during an acute, serious infection and should be discontinued temporarily during times of infection.⁴¹

► Fertility, Pregnancy, and Fetal Development

Women of childbearing age should be counseled about the impact of antirheumatic drugs on fertility, pregnancy, fetal development, and lactation. Some women may experience a reduction in disease symptoms during pregnancy; however, many agents used to treat RA are known teratogens. In addition, some women may present with signs and symptoms of RA for the first time during the postpartum period. Women desiring motherhood must consult with their physicians to carefully plan for the pregnancy and reduce risks to the developing fetus.⁴² Treatment plans selected must also consider the potential effects on breastfeeding babies. Low-dose corticosteroids generally are safe and effective. Certain NSAIDs, hydroxychloroquine, and azathioprine may be considered in severe disease.

Methotrexate use (FDA Pregnancy Category X) is associated with spontaneous abortion, fetal myelosuppression, limb defects, and CNS abnormalities; therefore, pregnancy must be avoided.⁴² Methotrexate should be discontinued 3 months prior to attempting conception. Sulfasalazine, on the other hand, may be the drug of choice in women who are pregnant or planning to become pregnant due to its safety profile.⁴² There is limited evidence of safety and long-term effects of the use of biologic DMARDs in pregnant women. Case reports of pregnancy during biologic DMARD therapy show no increased risk of fetal toxicity, but long-term data are needed.^{29,42} Based on available data, TNF antagonists are considered safe until the time of conception, and discontinuation during pregnancy is recommended. Rituximab should be discontinued 1 year

prior to planned conception. Abatacept should be discontinued 10 weeks prior to planned conception.⁴²

Male patients with RA must receive counseling about the effects of certain medications on their fertility and potential harm to the fetus. It is difficult to establish causality between use of a medication by a male and the effect on fertility or fetal development; therefore, a conservative approach must be taken. **7** *Women of childbearing potential and their partners must be counseled to: (a) use proper birth control*

Patient Encounter, Part 2: Medical History, Physical Examination, and Laboratory Tests

PMH: Hypertension (uncontrolled), dyslipidemia (uncontrolled), depression, prediabetes (uncontrolled)

FH: Unknown, she left home at age 16

SH: She is a waitress at the local diner working 40 to 60 hours per week. She does not drink alcohol. She smokes one pack of cigarettes per day

Allergies: sulfa

Meds: She has received prescriptions for medications in the past, but she does not fill them. For the last 2 months, she has been taking acetaminophen 500 mg twice daily for joint pain. Otherwise, she takes no medications routinely

ROS: (+) fatigue, (-) N/V/D, HA, SOB, chest pain, cough

PE:

VS: BP 166/88, P 82, RR 22, T 38.0°C (100.4°F); ht 5 ft 4 in (163 cm), wt 79.5 kg (175 lb)

Skin: Warm, dry

HEENT: NC/AT, PERRLA, TMs intact

CV: RRR, normal S1 and S2, no m/r/g

Chest: CTA

Abd: Soft, NT/ND

Neuro: A & O × 3; CN II to XII intact

Ext: Bilateral tender and swollen PIPs and MCPs

Labs: ESR 82 mm/h, RF (-), HLA-DR4 (-), anti-CCP (low +)

Synovial fluid analysis: Yellow, cloudy, decreased viscosity
Hand x-rays: Soft-tissue swelling, joint space narrowing, evidence of erosions

Disease Activity Score 28 (DAS 28): 5.2

Describe whether this patient fits the classification criteria for RA.

How would you categorize this patient's disease activity—low, moderate, or high? Why? How does this affect your treatment plan?

What nonpharmacologic and pharmacologic alternatives are appropriate for this patient?

while undergoing treatment for RA, and (b) involve healthcare providers in discussions regarding family planning to carefully consider all treatment options available.⁴²

OUTCOME EVALUATION

- Rheumatologists rely on standardized criteria to assess treatment interventions through measurement of disease activity. The ACR uses criteria for improvement based on percentage improvement in tender and swollen joint count and the presence of at least three or more of the following measures: (a) pain, (b) patient global assessment, (c) physician global assessment, (d) self-assessed physical disability, and (e) acute-phase reactants.⁴² ACR20, ACR50, and ACR70 are common efficacy end points in clinical

Patient Encounter, Part 3: Creating a Care Plan

Based on the information available, create a care plan for this patient's RA. The plan should include the following:

- A statement of the drug-related needs and/or problems
- A patient-specific detailed therapeutic plan (including specific medications and associated doses)
- Monitoring parameters to assess safety and efficacy

Six months later, the patient returns because she just found out that she is pregnant. She has worked diligently to take care of her health and reports 80% adherence to her RA treatment regimen.

Does this change your treatment plan? If so, devise a new treatment plan for the patient.

Patient Care and Monitoring

- Assess the patient's symptoms to determine whether they are consistent with RA. Evaluate the duration of symptoms and their impact on daily living.
- Review available diagnostic data to determine the severity of disease and whether the patient is at risk of experiencing poor outcomes.
- Obtain a thorough medication history, including prescription drugs, over-the-counter drugs, and dietary supplement use.
- Educate the patient on nonpharmacologic measures that will improve symptoms.
- Formulate a therapeutic plan, taking into consideration patient-specific factors.
- Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
- Develop a plan to assess safety and efficacy of the pharmacologic treatment plan. Determine whether the appropriate doses of antirheumatic medications were used and whether all medications were given a sufficient trial to achieve therapeutic benefit.
- Stress importance of adherence with the therapeutic regimen, including required laboratory monitoring, medication dosing, and administration. Recommend a therapeutic regimen that is convenient and consistent with the patient's lifestyle.
- Longitudinally evaluate the patient's clinical response to therapy and the impact on quality of life and mobility.
- Evaluate the presence of comorbidities and implement measures to control the increased risk.
 - Cardiovascular:** Keep doses of NSAIDs and glucocorticoids low, consider initiation of folic acid to reduce homocysteine level elevations induced by methotrexate, consider initiation of low-dose aspirin and/or HMG-CoA reductase inhibitors (statins), and encourage smokers to discontinue tobacco use and assist with the development of a tobacco-cessation plan.^{13,15} Screen and aggressively treat elevated blood pressure. Preferred agents in this population are angiotensin-converting enzyme inhibitors and angiotensin II blockers.
 - Infection:** Wash hands routinely, limit contact with individuals who are ill, and report signs and symptoms of infection immediately (e.g., fever, weight loss, and night sweats).
 - Malignancy:** Report new onset of signs and symptoms (e.g., fever, chills, anorexia, and night sweats) immediately.¹⁷
 - Osteoporosis:** Encourage patients to ingest adequate amounts of calcium and vitamin D, encourage smokers to discontinue tobacco use, and consider initiation of medications for osteoporosis (e.g., bisphosphonates, calcitonin, and parathyroid hormone) if the patient is taking glucocorticoids chronically or if the patient has evidence of low bone mineral density.^{21,47}
- Provide patient education with regard to RA, lifestyle modifications, and drug therapy:
 - What causes RA?
 - What are the comorbidities associated with RA?
 - How will lifestyle modifications affect RA?
 - What are the goals of therapy in the treatment of RA?
 - When and how should the medications be administered?
 - What potential adverse drug reactions may occur?
 - Which drugs may interact with therapy?
 - What are the warning signs to report to the physician?

trials. The number corresponds with the percentage improvement. As drug development continues to evolve, the acceptable criteria for 20% improvement may be too low. For example, if a patient has 10 tender and swollen joints, reducing that by 20% to 8 tender and swollen joints is, by definition, an improvement by ACR20 criteria. However, further reduction in symptoms or disease remission may have greater clinical significance and effect on the patient's quality of life.

- A joint committee of ACR and EULAR is currently working to define criteria for disease remission in RA. At this time, different organizations define remission differently. Each criteria set has its strengths and weaknesses. A consensus definition will help to establish specific treatment targets for patients.⁴³
- Physical disability from RA can be measured through the Stanford HAQ.^{44,45} This patient self-assessment tool was developed to evaluate patient outcomes in five dimensions of chronic conditions: (a) disability, (b) discomfort, (c) drug adverse effects, (d) dollar costs, and (e) death. Clinicians and clinical studies in rheumatology use HAQ to assess longitudinally changes that influence the patient's quality of life.^{44,45}
- Disease activity can be measured through the Disease Activity Score in 28 joints (DAS 28). Components involved in the calculation are the number of swollen and tender joints, ESR or CRP, and a subjective measure of the patient's general health. A DAS 28 score of 3.2 or less indicates low disease activity, between 3.2 and 5.1 is considered moderate activity, and 5.1 or more is considered to be high activity.^{20,46} Remission, defined by DAS 28, is a score of less than 2.6.
- Before starting treatment for RA, assess the subjective and objective evidence of disease. For joint findings, this includes the number of tender and swollen joints, pain, limitations on use, duration of morning stiffness, and presence of joint erosions. Systemic findings may include fatigue and the presence of extraarticular manifestations. Obtain laboratory measurements of CRP and ESR. The impact of the disease on quality of life and functional status is also important.
- At follow-up visits, compare the patient's status to baseline or previous visits using standardized criteria for improvement of disease activity and the HAQ to assess longitudinally the influence on quality of life.
- Assess the patient's response to initiation of nonbiologic or biologic DMARD therapy after allowing adequate time for the medication to achieve its therapeutic effect.
- Determine whether any adverse reactions associated with each antirheumatic medication are present.
- Monitor laboratory parameters to ensure patient safety and reduce the risk of adverse reactions.
- **8** *In addition to designing an individualized therapeutic regimen to control the progression of RA, the clinician must evaluate the presence of comorbidities and implement measures to control the increased risk.*

Abbreviations Introduced in This Chapter

ACR	American College of Rheumatology
CCP	Cyclic citrullinated peptide
COX-2	Cyclooxygenase-2
CRP	C-Reactive protein
DAS	Disease Activity Score
DMARD	Disease-modifying antirheumatic drug
ESR	Erythrocyte sedimentation rate
EULAR	European League Against Rheumatism
HAQ	Health Assessment Questionnaire
HLA	Human leukocyte antigen
IL	Interleukin
JIA	Juvenile idiopathic arthritis
JRA	Juvenile rheumatoid arthritis
MCP	Metacarpophalangeal joint
MTP	Metatarsophalangeal joint
NSAID	Nonsteroidal anti-inflammatory drug
PIP	Proximal interphalangeal joint
RA	Rheumatoid arthritis
TNF	Tumor necrosis factor

Osteoarthritis

Steven M. Smith, Eric Dietrich, and John G. Gums

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiologic mechanisms involved in the development of osteoarthritis (OA).
2. Identify risk factors associated with OA.
3. Recognize the clinical presentation of OA.
4. Determine the goals of therapy for individual patients with OA.
5. Formulate a rational nonpharmacologic plan for patients with OA.
6. Recommend a pharmacologic plan for treating OA, taking into consideration patient-specific factors.
7. Modify an unsuccessful treatment strategy for OA.
8. Develop monitoring parameters to assess effectiveness and adverse effects of pharmacotherapy for OA.
9. Deliver effective disease-state counseling, including lifestyle modifications and drug therapy, to facilitate effective and safe management of OA.

KEY CONCEPTS

- 1 Osteoarthritis (OA) is the most common form of arthritis and is most prevalent in the middle to later years of life.
- 2 The most common symptoms are joint pain, reduced range of motion, and brief joint stiffness after periods of inactivity.
- 3 Treatment goals are to educate the patient and caregivers, relieve pain, maintain or restore mobility, minimize functional impairment, preserve joint integrity, and improve quality of life.
- 4 Nonpharmacologic therapy is the cornerstone of treatment; education, exercise, weight loss, and cognitive behavioral intervention are integral components.
- 5 Acetaminophen is the initial drug of choice; an adequate dose and duration of therapy should be used before resorting to other drug classes.
- 6 Nonsteroidal anti-inflammatory drugs (NSAIDs) may be initiated if acetaminophen therapy fails. At equipotent doses, all NSAIDs elicit similar analgesic and anti-inflammatory responses. Selection is based on patient preference, previous response, dosing frequency, tolerability, and cost.
- 7 Patients who do not respond adequately to one NSAID may respond to a different NSAID.
- 8 NSAIDs are associated with adverse GI, renal, hepatic, cardiovascular, and CNS effects and may increase blood pressure.
- 9 NSAIDs that are selective for the cyclooxygenase-2 (COX-2) enzyme are less likely to cause GI complications but may increase the risk of cardiovascular events. COX-2 inhibitors are no more effective than nonselective NSAIDs and should be reserved for patients at high risk of GI complications and low risk for cardiovascular events.
- 10 Glucosamine, tramadol, opioids, topical capsaicin, topical NSAIDs, intraarticular corticosteroids, hyaluronic acid, and surgery may be beneficial in certain situations.

INTRODUCTION

- 1 *Osteoarthritis (OA) is the most common form of arthritis.*
- Weight-bearing joints (e.g., hips and knees) are most susceptible, but non-weight-bearing joints, especially the hands, may also be involved. Because of its high prevalence and involvement of joints critical for daily functioning, the disease

causes tremendous morbidity and financial burden.¹ OA is the leading cause of chronic mobility disability and the most common reason for total-hip and total-knee replacement.²

① *OA is strongly related to age; thus its incidence and the cost of care will increase dramatically in the coming years due to a burgeoning senior citizenry.*

EPIDEMIOLOGY AND ETIOLOGY

The National Arthritis Data Workgroup estimates that 27 million Americans have signs and symptoms of OA.³ The true extent of the disease is much larger; nearly everyone has radiographic evidence of OA by the eighth decade of life, but individuals without symptoms often go undiagnosed. Approximately 7% of U.S. adults have daily symptomatic hand OA, whereas 6% and 3% report daily symptoms affecting the knees and hips, respectively.³ After age 60, 10% to 17% of persons report such symptoms.³

The prevalence of OA is higher in women, and they have more generalized disease. Women are also more likely to have inflammation of the proximal and distal interphalangeal joints of the hands, which manifest as **Bouchard's nodes** and **Heberden's nodes**, respectively. OA of the hip occurs more frequently in men.

The prevalence of OA in whites is similar to that in African Americans, but the latter may experience more severe and disabling disease. Persons of Chinese descent rarely have hip OA; they are also less likely to develop hand OA but more likely to develop knee OA.

PATHOPHYSIOLOGY

OA is characterized by damage to **diarthrodial** joints and joint structures (**Fig. 58-1**). OA is a multifactorial disease typified by progressive destruction of joint cartilage, erratic new bone formation, thickening of **subchondral** bone and the joint capsule, bony remodeling, development of **osteophytes**, variable degrees of mild **synovitis**, and other changes.⁴

The earliest stages of OA are characterized by increasing water content and softening of cartilage in weight-bearing joints. As the disease progresses, **proteoglycan** content of cartilage declines, and eventually, cartilage becomes hypocellular.

Increasing levels of protease enzymes, such as **matrix metalloproteinases** (MMPs), occur before changes in cartilage, suggesting that these catabolic proteinases play an important role in the initiation and progression of OA.

Subchondral bone undergoes metabolic changes, including increased bone turnover, that appear to be precursors to tissue destruction. The normally contiguous bony surface becomes fissured. Persistent use of the joint eventually results in loss of cartilage, permitting bone-to-bone contact that ultimately promotes thickening and **eburnation** of exposed bone. Microfractures may appear in subchondral bone, and **osteonecrosis** may develop beneath the surface.

New bone is formed haphazardly, leading to the formation of osteophytes that extend into the joint capsule and ligament attachments and may encroach on the joint space. Progressive loss of joint cartilage, subchondral damage, narrowing of joint spaces, and changes in the underlying bone and soft tissues may culminate in deformed, painful joints.

Classification

OA is often divided into primary (idiopathic) and secondary disease (**Table 58-1**). **Primary OA** is the predominant form and occurs in the absence of a precipitating event. It may assume a localized, generalized, or erosive pattern. Localized OA is distinguished from generalized disease by the number of sites involved, whereas erosive disease is characterized by an erosive pattern of bone destruction and marked proliferation of interphalangeal joints of the hands. **Secondary OA** results from congenital or developmental disorders or inflammatory, metabolic, or endocrine diseases.

Risk Factors

OA develops when systemic factors and biomechanical vulnerabilities combine. Systemic factors include age, gender, genetic predisposition, and nutritional status. Age is the strongest predictor of OA, although advanced age alone is insufficient to cause OA.

Joints exposed to biomechanical factors are at increased risk. Occupational and recreational activities involving repetitive motion or injury can provoke OA, although most daily activities do not produce enough joint trauma to cause

FIGURE 58-1. Characteristics of osteoarthritis in the diarthrodial joint. (From DiPiro JT, Talbert RL, Yee GC, et al (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 8th ed. New York: McGraw-Hill; 2011:1601, Fig. 101-2; With permission.)

Table 58-1

Classification of Osteoarthritis**Primary Osteoarthritis**

Localized (involving one or two sites)
 Generalized (involving three or more sites)
 Erosive

Secondary Osteoarthritis

Mechanical incongruity of joint
 Congenital or developmental defect
 Posttraumatic
 Prior inflammatory disease (rheumatoid arthritis, chronic gouty arthritis, pseudogout, infectious arthritis)
 Metabolic disorder (hemochromatosis, ochronosis, Wilson's disease, chondrocalcinosis, Paget's disease)
 Endocrinopathies (diabetes mellitus, obesity, acromegaly, iatrogenic hyperadrenocorticism, sex hormone abnormalities)
 Neuropathic disorders
 Intraarticular corticosteroid overuse
 Avascular necrosis
 Bone dysplasia

OA, even after decades of repeated use. However, daily activities may lead to OA if a joint is susceptible because of previous injury, joint deformity, muscle weakness, or systemic factors. Heavy physical activity is a stronger predictor of subsequent OA than light to moderate activities.⁵ This is especially true for older individuals, in whom the joint

structure is less capable of coping with highly stressful activities. Obesity increases load-bearing stresses on hip and knee joints. The risk of OA increases by 10% for each kilogram of body weight above ideal body weight.⁶

CLINICAL PRESENTATION AND DIAGNOSIS

See the accompanying text box for the clinical presentation of OA. There are no laboratory tests that are specific for the diagnosis of OA. The erythrocyte sedimentation rate (ESR) and hematologic and chemistry panels are usually unremarkable. If synovial fluid is aspirated from an affected joint, it is sterile, without crystals, and has a WBC count less than $1.5 \times 10^3/\text{mm}^3$ ($1.5 \times 10^9/\text{L}$). Radiographic changes are often absent in early OA. As the disease progresses, joint-space narrowing, subchondral bone sclerosis, and osteophytes may be detected. Gross joint deformity and joint effusions may occur in late severe OA.

TREATMENT**Desired Outcomes**

- 3 Goals of therapy include: (a) educating the patient and caregivers, (b) relieving pain, (c) maintaining or restoring mobility, (d) minimizing functional impairment, (e) preserving joint integrity, and (f) improving quality of life.

Clinical Presentation of OA**General**

- Patients are generally over the age of 50.
- Presentations encompass a spectrum ranging from asymptomatic to severe joint pain and stiffness with functional limitations.
- Joint involvement has an asymmetric local distribution without systemic manifestations.
- In contrast to some other arthritic conditions (e.g., rheumatoid arthritis, gout), inflammation usually is absent or mild and localized when present.

Symptoms

- 2 The cardinal symptoms are use-related joint pain, typically described as deep and aching in character, and stiffness. In advanced cases, pain also may be present during rest.
- Weight-bearing joints may be unstable.
- 2 Joint stiffness ("gelling") abates with motion and recurs with rest.
- 2 Joint stiffness generally lasts less than 30 minutes after periods of inactivity, limits the range of joint motion, impairs daily activities, and may be related to weather.

Signs

- One or more joints may be involved, usually in an asymmetric pattern.
- The following sites are most often involved in primary OA:
 - Distal interphalangeal finger joints (Heberden's nodes)
 - Proximal interphalangeal finger joints (Bouchard's nodes)
 - First carpometacarpal joint
 - Knees, hips, and cervicolumbar spine
 - Metatarsophalangeal joint of the great toe
- The following sites are involved most often in secondary OA:
 - Metacarpophalangeal joints
 - Wrists
 - Elbows
 - Glenohumeral joints
 - Ankles
- Joint examination may reveal local tenderness, bony proliferation, soft tissue swelling, crepitus, muscle atrophy, limited motion with passive/active movement, and effusion.

Patient Encounter, Part 1

OC is a 67-year-old obese Chinese man who presents to his primary care physician with right knee pain that has significantly worsened over the past several years. He describes the pain as dull and achy, and it is most severe in the morning after awakening until he “loosens up” 10 to 15 minutes later. He believes the morning stiffness is related to a previous knee injury for which he had surgery to repair a torn ACL. OC also reports feeling “down” because he is no longer able to be on his bowling team due to his knee pain and is now forced to stay home most nights of the week. OC is retired from a factory worker position that required him to be on his feet for long hours while he assembled electronics.

What information is suggestive of osteoarthritis (OA)?

What risk factors for OA does this patient have?

What cultural or ethnic factors may contribute to his OA?

What other information will you need to differentiate OA from rheumatoid arthritis (RA)?

What potential comorbidities should be considered in this patient?

What other information will be required before formulating a treatment plan?

General Approach to Treatment

Treatment is individualized and should consider medical history, physical examination, radiographic findings, distribution and severity of joint involvement, and response to previous treatment. Comorbid diseases, concomitant medications, and allergies are integrated into a holistic treatment approach.

A comprehensive treatment algorithm for OA is given in [Figure 58-2](#). Nonpharmacologic treatment is integral to achieving optimal outcomes in patients with OA. Pharmacologic therapy is used as an adjunctive measure to relieve pain; most treatments do not modify the disease course. Surgical intervention generally is reserved for patients with advanced disease complicated by unremitting pain or severely compromised function.

Nonpharmacologic Therapy

- Nondrug therapy consists of a three-pronged approach of education, lifestyle modification, and physical therapy.
 - ④ *Educational programs include a set of systematic educational activities designed to improve health behaviors and health status, thereby slowing OA progression.* The goal is to increase patient knowledge and self-confidence in adjusting daily activities in the face of evolving symptoms. Effective programs produce positive behavioral changes, decreased pain and disability, and improved functioning. In addition to physical outcomes, psychological outcomes such as

depression, self-efficacy, and life satisfaction are positively influenced. Patients can be referred to the Arthritis Foundation (www.arthritis.org) for educational materials and information on support groups.

- ④ *Lifestyle modification should be employed in all patients at risk for OA and in those with established disease.* In general, it is advisable to recommend low-impact exercise routinely.
- Aerobic exercise and strength-training programs improve functional capacity in older adults with OA. Stretching and strengthening exercises should target affected and vulnerable joints. Isometric exercises performed three to four times weekly improve physical functioning and decrease disability, pain, and analgesic use.
 - Obesity’s association with both the onset and progression of OA make weight loss a pivotal treatment strategy in overweight and obese patients. Women who reduce body weight by 5 kg (11 lb) can cut their risk of developing OA in half. Moreover, symptomatic relief and improved quality of life occur in people with knee OA who reduce their body weight. Weight loss should be pursued through a combination of dietary modification and increased physical activity (see Chap. 102). The patient’s physical capabilities should be considered when implementing an exercise program.
 - ④ *Application of heat or cold treatments to involved joints improves range of motion, reduces pain, and decreases muscle spasms. Practical applications of heat therapy include warm baths or warm water soaks.* Heating pads should be used with caution, especially in the elderly, and patients must be warned of the potential for burns if used inappropriately.
 - Referral to a physical or occupational therapist may be helpful, particularly in patients with functional disabilities. Physical therapy is tailored to the patient and may include assessment of muscle strength, joint stability, and mobility; use of heat (especially prior to episodes of increased physical activity); structured exercise regimens; and implementation of assistive devices, such as canes, crutches, and walkers. The occupational therapist ensures optimal joint protection and function, energy conservation, and use of splints and other assistive devices.

Pharmacologic Therapy

Simple analgesics such as acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) are first-line agents for treating OA ([Table 58-2](#)).

► Acetaminophen

- Acetaminophen is a centrally acting analgesic that inhibits prostaglandin production in the brain and spinal cord.
- ⑤ *Acetaminophen is an effective and inexpensive analgesic with a favorable risk-benefit profile. For treatment of mild-to-moderate pain, acetaminophen should be tried initially at an adequate dose and duration before considering an NSAID.*⁷⁻¹⁰ Acetaminophen is generally considered to be as effective as NSAIDs for mild-to-moderate joint pain with a superior safety profile.¹⁰

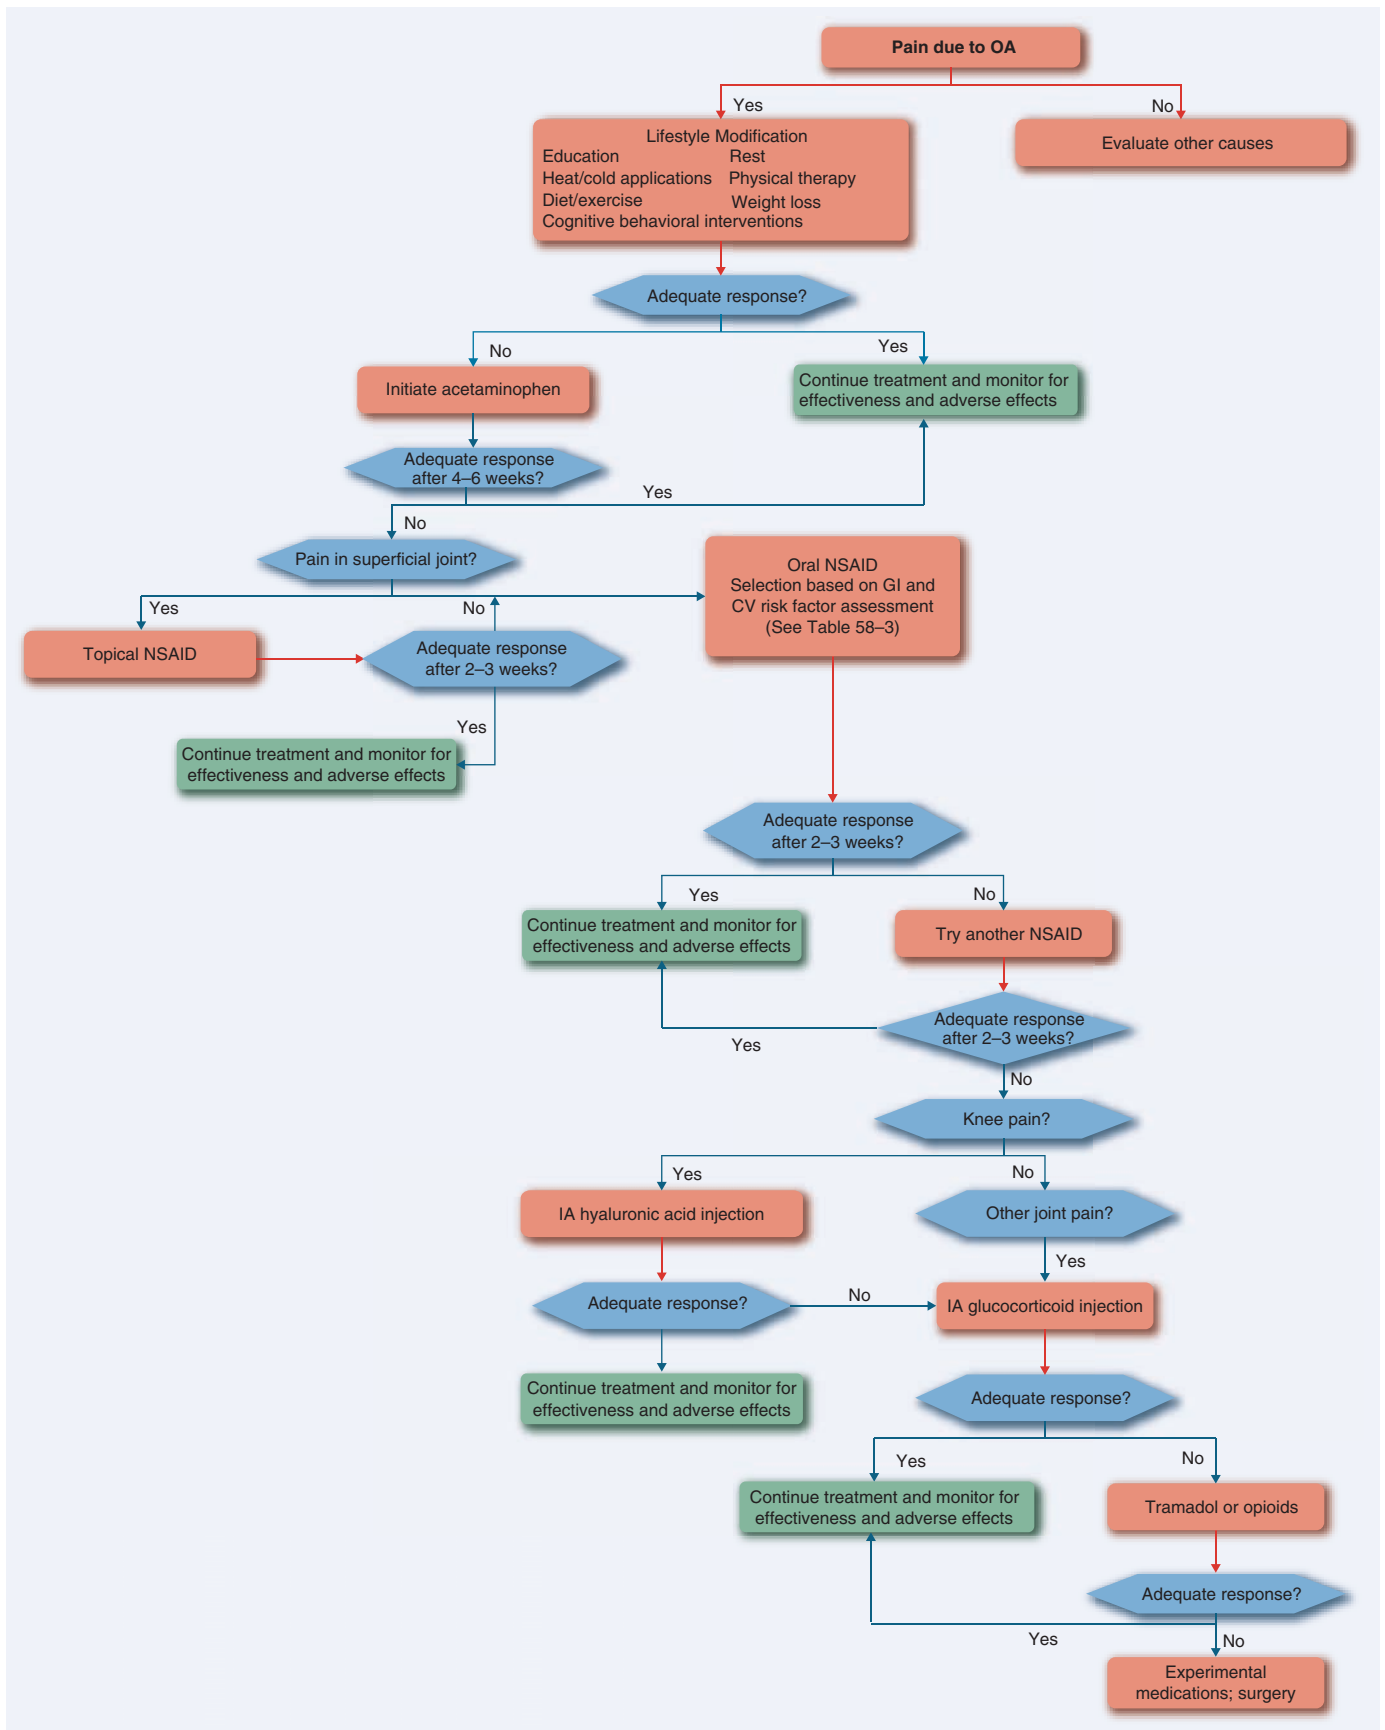

FIGURE 58-2. Treatment of osteoarthritis. (OA, osteoarthritis; COX-2, cyclooxygenase-2; CV, cardiovascular; IA, intraarticular; NSAID, nonsteroidal anti-inflammatory drug.)

Table 58-2

Dosing Parameters of Agents Commonly Used to Treat OA

Medication	Dosage and Frequency	Maximum Dosage (mg/day)
Oral Analgesics		
Acetaminophen	325 mg every 4–6 hours or 1 g every 6–8 hours	4,000
Tramadol	50–100 mg every 4–6 hours CrCl less than 30 mL/min (0.50 mL/s): 50–100 mg every 12 hours	400 (300 in elderly) 200
Oral Nonselective NSAIDs by Chemical Class		
<i>Carboxylic acid (salicylates)</i>		
Aspirin	325–650 mg every 4–6 hours	3,600 ^a
Salsalate	500–1,000 mg 2–3 times daily	3,000 ^a
<i>Acetic acid</i>		
Etodolac	300–600 mg twice daily 400–1,000 mg once daily (extended-release)	1,200
Diclofenac	50 mg 2–3 times daily 75 mg twice daily (delayed-release) 100 mg once daily (extended-release)	150
Indomethacin	25 mg 2–3 times daily 75 mg 1–2 times daily (sustained-release)	200
Nabumetone	500–1,000 mg 1–2 times daily	2,000
<i>Propionic acid</i>		
Ibuprofen	400–800 mg 3–4 times daily	3,200
Naproxen	250–500 mg 2 times daily 750–1,000 mg once daily (controlled-release) 275–550 mg 2 times daily (naproxen sodium)	1,500 1,650
<i>Enolic acid</i>		
Meloxicam	7.5–15 mg once daily	15
Piroxicam	20 mg once daily	20
COX-2-Selective Agents		
Celecoxib	100 mg twice daily or 200 mg once daily	200
Topical Analgesics		
Capsaicin cream 0.025% or 0.075%	Apply to affected joint every 6–8 hours	
Diclofenac 1% gel		
Lower extremity joints	4 g 4 times daily	16 g ^b
Upper extremity joints	2 g 4 times daily	8 g ^b
Nutritional Supplements		
Glucosamine sulfate	500 mg 3 times daily or 1,500 mg once daily	
Chondroitin	400–800 mg 3 times daily with glucosamine	

CrCl, creatinine clearance.

^aSerum salicylate levels should be monitored for doses greater than 3 g/day.

^bTotal daily dose of diclofenac 1% gel should not exceed 32 g for all affected joints.

Acetaminophen should be administered initially on an as-needed basis in daily doses up to 4 g. Single doses should not exceed 1 g. Some patients may require scheduled dosing to achieve adequate pain relief. Periodic assessment of pain control should be performed to maintain the lowest effective dose. A common reason for an inadequate response to acetaminophen is failure to use a sufficient dose for an adequate duration. A sufficient trial is defined as up to 4 g daily in divided doses for 4 to 6 weeks.

Despite being one of the safest analgesics, acetaminophen can cause significant adverse effects, including hepatic and renal toxicity.¹¹ Acetaminophen overdose, both intentional and unintentional, is the leading cause of acute liver injury in the United States.¹² Doses greater than 4 g are associated with an increased risk of hepatotoxicity. Total daily doses

of 4 g have been associated with significant liver enzyme elevations, but such elevations do not necessarily portend hepatotoxicity.¹³ Concomitant use of alcohol may increase the risk of hepatic injury; a maximum acetaminophen dose of 2.5 g daily is recommended in patients who consume more than two to three alcoholic beverages per day. Acetaminophen does not appear to exacerbate stable, chronic liver disease; it can be used with caution and vigilant monitoring of liver function in this population.¹¹ Prior to developing an acetaminophen regimen, a careful inventory should be taken of all concomitant medications to minimize the risk of inadvertent acetaminophen overdose from other sources.

Acetaminophen may worsen kidney function and increase blood pressure.^{14,15} Nevertheless, acetaminophen remains the preferred analgesic for mild to moderate pain in patients with

hypertension or kidney disease because of the greater risks associated with NSAID use.¹⁶ Monitoring specifically for these adverse effects generally is unnecessary.

► Nonsteroidal Anti-inflammatory Drugs

Prostaglandins play an important role in the function of several organ systems. These compounds are synthesized via the interaction of two isoforms of the **cyclooxygenase** enzyme (COX-1 and COX-2) with their substrate, arachidonic acid (Fig. 58–3).

The COX-1 enzyme is produced normally in various body tissues (e.g., gastric mucosa, kidney, and platelets). Prostaglandins produced by the actions of the COX-1 enzyme in the GI tract preserve the integrity of the GI mucosa by increasing mucus and bicarbonate secretion, maintaining mucosal blood flow, and decreasing gastric acid secretion. COX-1–associated prostaglandins also promote normal platelet activity and function. In the kidney, COX-1–mediated prostaglandins dilate the afferent arteriole, thereby maintaining intraglomerular pressure and glomerular filtration rate when renal blood flow is reduced.

In contrast, the COX-2 enzyme is not produced normally in most tissues, but its production is increased rapidly in the presence of inflammation and local tissue injury. This change leads to the synthesis of prostaglandins involved in pain and inflammation. Consequently, blocking the COX-2 enzyme results in analgesic and anti-inflammatory effects. The beneficial effects of NSAIDs in reducing pain, decreasing joint stiffness, and improving function in patients with OA are thought to be due to inhibition of the COX-2 enzyme.

All NSAIDs inhibit both COX-1 and COX-2 isoforms to varying degrees, but most (e.g., ibuprofen, naproxen) are not particularly selective for one isoform over the other. That is, they are nonselective inhibitors of the COX enzyme system. Inhibition of COX-2 is responsible for analgesic effects, whereas inhibition of COX-1 is responsible for the most common adverse effects of NSAIDs. COX-2–selective inhibitors were developed to preserve the beneficial effects of COX-2 inhibition while avoiding the deleterious effects associated with inhibition of the COX-1 enzyme. This approach has not been entirely successful, as discussed later.

- 6 NSAIDs are a reasonable adjunctive or alternative therapy when acetaminophen fails to provide an acceptable analgesic response. Some patients may respond well to topical NSAIDs combined with oral acetaminophen (see Topical Analgesics section later). This strategy minimizes systemic exposure to NSAIDs but is only appropriate for patients with OA of superficial joints. For patients with OA that affects other joints or those receiving no analgesic relief from acetaminophen, an oral NSAID should be considered. Some clinicians recommend NSAIDs over acetaminophen for the initial treatment of severe pain or signs and symptoms of inflammation. The rationale for this recommendation is that acetaminophen's central mechanism of action renders it ineffective against peripheral joint inflammation, and therefore less effective. Results from comparative trials of acetaminophen and NSAIDs have been equivocal, but consensus guidelines support the use of NSAIDs as an alternative to acetaminophen if clinical features of peripheral inflammation or severe pain are present.^{7–9} Unfortunately, no validated

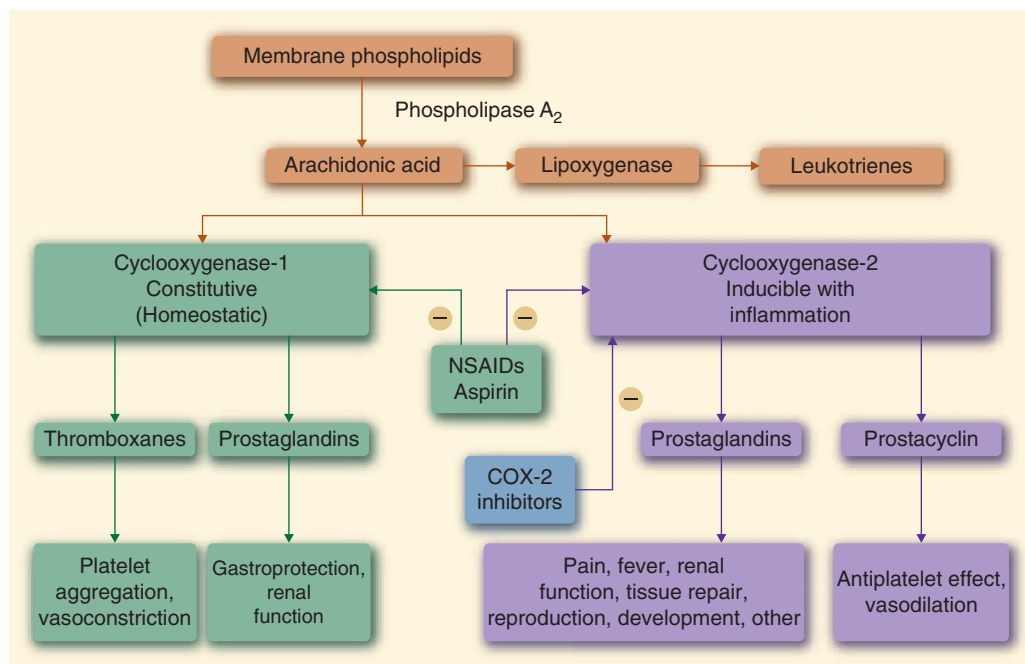

FIGURE 58–3. Synthesis pathway for prostaglandins and leukotrienes. COX-2, cyclooxygenase enzyme 2; NSAIDs, nonsteroidal anti-inflammatory drugs. (Modified from DiPiro JT, Talbert RL, Yee GC, et al (eds.) *Pharmacotherapy: A Pathophysiologic Approach*. 8th ed. New York: McGraw-Hill; 2011:1609, Fig. 101–5; With permission.)

mechanism exists to identify patients who are more likely to respond to NSAIDs than acetaminophen.

6 At equipotent doses, the analgesic and anti-inflammatory activity of all oral NSAIDs are similar. The selection of a specific NSAID should be based on patient preference, previous response, tolerability, dosing frequency, and cost. 7 Some patients respond to one NSAID better than to another. If an insufficient response is achieved with one NSAID, another agent should be tried. There is no convincing evidence that changing to an NSAID from a different chemical class is more likely to be effective than selecting another drug from the same chemical class. Pain relief occurs rapidly (within hours), but anti-inflammatory benefits are not realized until after 2 to 3 weeks of continuous therapy. This period is the minimal duration that should be considered an adequate NSAID trial.

Inhibition of the COX-1 enzyme is thought to be responsible primarily for the adverse effects of NSAIDs on the gastric mucosa, kidney, and platelets. Direct irritant effects also may contribute to adverse GI events. 8 Minor GI complaints, including nausea, dyspepsia, anorexia, abdominal pain, flatulence, and diarrhea, are reported by 10% to 60% of patients treated with NSAIDs. Asymptomatic gastric and duodenal mucosal ulceration can be detected in 15% to 45% of patients.¹⁷ Perforation, gastric outlet obstruction, and GI bleeding are the most severe complications and occur in 1.5% to 4% of patients annually.¹⁷

Several risk factors predict a greater likelihood of GI complications in NSAID-treated patients (see Chap. 18). Detecting high-risk patients based on symptoms alone is not possible because the presence of symptoms and actual gastroduodenal damage are poorly correlated. Patients at high risk for GI complications should be evaluated for the use of a COX-2-selective agent or concomitant treatment with a prophylactic gastroprotective agent such as a proton pump inhibitor or misoprostol. However, these strategies do not completely mitigate the risk of GI complications.

8 NSAIDs can cause renal insufficiency when administered to patients whose renal function depends on prostaglandins. Patients with chronic renal insufficiency or left ventricular dysfunction, the elderly, and those receiving diuretics or drugs that interfere with the renin-angiotensin system are particularly susceptible. Decreased glomerular filtration also may cause hyperkalemia. NSAIDs rarely cause tubulointerstitial nephropathy and renal papillary necrosis.

Caution is warranted in pregnant women and women of childbearing age because the risk of bleeding may be increased if the fetus is subjected to the antiplatelet activity of NSAIDs. Ibuprofen and naproxen are rated FDA Pregnancy Category B in the first and second trimesters. Indomethacin and sulindac have not been rated, whereas celecoxib and etodolac are Category C. NSAIDs are contraindicated during the third trimester because they may promote premature closure of the ductus arteriosus in the fetus.

NSAIDs are prone to drug interactions due to high protein binding, detrimental renal effects, and antiplatelet activity. Interactions are encountered frequently with aspirin, warfarin, oral hypoglycemics, antihypertensives, angiotensin-converting

enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), β -blockers, diuretics, and lithium. When an interaction with an NSAID is present, vigilant monitoring is warranted for therapeutic efficacy (e.g., NSAIDs blunt the antihypertensive efficacy of diuretics) and adverse effects (e.g., NSAIDs increase the risk of bleeding in anticoagulated patients).

► Selective COX-2 Inhibitors

Elucidation of the activities of individual COX isoforms led to the development of drugs that selectively inhibit the inducible form of the enzyme, COX-2. Thus COX-2 inhibitors were expected to minimize NSAID GI toxicity and antiplatelet effects (see Fig. 58-3). 9 COX-2 inhibitors are no more effective than nonselective NSAIDs in relieving pain and inflammation. In clinical trials, patients experienced similar levels of pain relief with COX-2 inhibitors and nonselective NSAIDs. This is to be expected because both drug classes inhibit the COX-2 enzyme, which is responsible for producing prostaglandins that result in pain and inflammation.

Celecoxib is the only agent currently marketed in the United States that is classified as a true COX-2-selective inhibitor. However, meloxicam, sulindac, and diclofenac also display preferential affinity for the COX-2 enzyme. Celecoxib reduces endoscopically detected GI lesions. However, the clinical importance of this observation has been challenged because many of these lesions are asymptomatic and resolve spontaneously. Celecoxib did not reduce the incidence of significant upper GI toxicity compared with NSAIDs in a large clinical trial.¹⁸ However, this study allowed patients to take concomitant low-dose aspirin. A post hoc analysis in patients who did not take aspirin revealed celecoxib to be effective in reducing significant upper GI toxicity.

The selective agents rofecoxib (removed from the U.S. market in 2004), etoricoxib, and lumiracoxib (neither currently FDA approved) decrease clinically important events such as perforations, ulcers, and bleeding.¹⁹⁻²¹

9 By selectively inhibiting the COX-2 isoform, COX-2-selective NSAIDs reduce GI events but may increase the risk of cardiovascular events in certain patients.²²⁻²⁴ The pharmacologic basis for this finding is not fully understood. One theory is that COX-2 is responsible for the production of prostacyclin, a vasodilatory and antiplatelet prostaglandin. In contrast, COX-1 controls the production of thromboxane A₂, a vasoconstrictor and platelet aggregator. Selective inhibition of COX-2 results in decreased prostacyclin levels relative to thromboxane A₂ levels. An imbalance in the thromboxane A₂:prostacyclin ratio ensues, which creates an environment that favors thrombosis. Additional factors are likely involved, including the degree of COX-2 selectivity, dosage and dosing schedule, and potency of agents.²² Other mechanisms for increasing cardiovascular risk have been proposed for individual agents.²⁵

Concomitant use of low-dose aspirin mitigates some of the increased cardiovascular risk but also obliterates the GI safety of COX-2 selectivity.¹⁸⁻²⁰ Patients treated with a COX-2-selective agent plus aspirin experience GI complications at a rate

Table 58-3

Treatment Options Based on Cardiovascular and Gastrointestinal Risk.

	High CV Risk	Low CV Risk
High GI risk	NS-NSAID ^a plus gastroprotection ^b	COX-2 ^c or NS-NSAID + gastroprotection ^b
Low GI risk	NS-NSAID ^a	NS-NSAID

COX-2, selective cyclooxygenase-2 inhibitor; CV, cardiovascular; NS-NSAID, non-selective nonsteroidal anti-inflammatory drug.

^aNaproxen may be considered initially due to potentially lower CV risk compared with other NS-NSAIDs.

^bGastroprotection with either a proton pump inhibitor (preferred) or misoprostol.

^cA COX-2 inhibitor + gastroprotection can be recommended for patients at very high GI risk (e.g., previous upper GI bleed attributable to NS-NSAID therapy).

commensurate with that of patients given traditional nonselective NSAIDs. Use of less selective agents (e.g., meloxicam) to avoid cardiovascular concerns with COX-2 inhibitors may not be justified because neither GI nor cardiovascular safety is optimized.

9 *COX-2 inhibitors should be reserved for patients at high risk for GI complications and low risk for cardiovascular events (Table 58-3).* For patients at particularly high GI risk (e.g., previous history of NSAID-induced GI bleed), a COX-2 inhibitor may be combined with a proton pump inhibitor.^{26,27} In patients at risk for GI events and cardiovascular disease, a nonselective NSAID plus a proton pump inhibitor is a reasonable option. Naproxen appears to have the least cardiovascular risk of the nonselective NSAIDs and should generally be considered first in such patients.²⁸

The COX-2 enzyme is also produced normally in the kidney; thus COX-2 inhibitors exert renal effects similar to those of conventional NSAIDs. Both drug classes may increase sodium reabsorption and fluid retention and can provoke renal insufficiency and hyperkalemia. COX-2 inhibitors should be used with caution in patients with heart failure or hypertension.

COX-2 inhibitors are susceptible to the same drug interactions as nonselective agents. However, the interaction with warfarin is less pronounced because platelet function is affected to a lesser degree.

► Glucosamine and Chondroitin

Glucosamine is believed to function as a “chondroprotective” agent, stimulating the cartilage matrix and protecting against oxidative chemical damage. Chondroitin, often administered in conjunction with glucosamine, is thought to inhibit degradative enzymes and serve as a substrate for the production of proteoglycans. Numerous clinical trials have evaluated the efficacy of these substances for the treatment

of OA. However, results vary widely, and the quality of many of these studies has been questioned.

In the landmark GAIT trial sponsored by the U.S. National Institutes of Health, glucosamine, chondroitin, and their combination were no more effective than placebo in decreasing pain symptoms in patients with knee OA after 24 weeks.²⁹ In the subgroup of patients with moderate to severe OA pain, the combination of glucosamine and chondroitin appeared to have a moderate effect, although this subgroup analysis must be interpreted with caution. Analysis of radiologic changes after 2 years of treatment showed no significant benefit of glucosamine, chondroitin sulfate, or the combination over placebo in preventing joint space narrowing.³⁰ In contrast, most industry-funded studies, many of which are limited by suboptimal study designs, have observed a significantly greater benefit with glucosamine, chondroitin, or the combination.³¹ Interpretation of these results is all the more challenging given the inconsistencies in study design, differences in end points applied, quality of glucosamine preparations, and the comparator agents (celecoxib versus acetaminophen).

10 *In the context of study limitations, glucosamine and chondroitin appear to modestly reduce pain and improve mobility.³¹⁻³³ They also may slow disease progression by decreasing the rate of cartilage destruction, although the clinical impact of this effect is not clear.³⁴* Glucosamine is not effective for treating acute pain since beneficial effects often mature over a period of weeks. Despite some studies suggesting the contrary, either glucosamine salt (hydrochloride or sulfate) can be recommended; both dissociate in stomach acid to the same amino sugar, glucosamine. Because these agents are loosely regulated in the United States as dietary supplements, product standards are inconsistent, and the constituents are not validated by any regulatory agency.

The use of glucosamine (derived from crab, lobster, or shrimp shells) and/or chondroitin (derived from cattle or shark cartilage) may warrant caution in patients with shellfish allergies, but preliminary evidence suggests little drug-allergy interaction.³⁵ Additionally, glucosamine may alter cellular glucose uptake, thus elevating blood glucose levels in diabetic patients.³⁶ A randomized, placebo-controlled trial of 38 diabetic participants failed to detect any significant alteration in A1C levels after 3 months of glucosamine/chondroitin therapy; however, a relatively short study period and low number of participants may account for these negative findings.³⁷ Blood glucose levels in diabetic patients should be monitored closely after glucosamine initiation or dosage adjustments. Given the favorable safety profile of glucosamine and chondroitin, it is reasonable to present these agents as a treatment option to patients with symptomatic knee OA in the absence of contraindicating factors.

► Intraarticular Therapy

10 *Intraarticular injection of corticosteroids or hyaluronan represents an alternative to oral agents for the treatment of joint pain.* These modalities usually are reserved for patients unresponsive to other treatments because of the relative

invasiveness of intraarticular injections compared with oral drugs, the small risk of infection, and the cost of the procedure.

Hyaluronan (Hyaluronic Acid) The mechanism of action of hyaluronan is not fully understood. Healthy cartilage and synovial fluid are replete with hyaluronic acid, a viscous substance believed to facilitate lubrication and shock absorbercy under varying conditions of load bearing. Patients with OA demonstrate an absolute and functional decline in hyaluronic acid; thus exogenous administration is referred to as viscosupplementation. In responders, the benefit of hyaluronan administration persists for periods that exceed its residence time in the synovium, suggesting that benefits beyond viscoelasticity are involved. Inhibition of inflammatory mediators and cartilage degradation, stimulation of the cartilage matrix, neuroprotective actions, and the ability of hyaluronan to induce its own synthesis may account in part for the benefit.

Pain and joint function have been evaluated frequently in clinical trials administering hyaluronan to patients with OA. Results are conflicting, with some suggesting dramatic improvements and others indicating no effect. A meta-analysis found that hyaluronan injections achieved a moderate reduction in pain at 7 to 10 weeks post-injection, compared with placebo.³⁸ This effect was generally similar to previously published effect sizes for acetaminophen, oral NSAIDs, and COX-2 inhibitors. Hyaluronan provides greater pain relief for a longer time than intraarticular corticosteroids, but corticosteroids work more rapidly.³⁹

Several formulations of hyaluronan are available for the treatment of knee pain in patients with OA who are unresponsive to other measures. Administration typically consists of weekly injections for 3 to 5 weeks, depending on the specific product. Most injections are well tolerated, although some patients may report local reactions. Rarely, postinjection flares and anaphylaxis have been reported. Intra-articular injection is associated with a low risk of infection (approximately 1 joint in 50,000 injections). Patients should be counseled to minimize activity and stress on the joint for several days after each injection.

Corticosteroids Use of systemic corticosteroids is discouraged in patients with OA. **10** *However, in a subset of patients with an inflammatory component or knee effusion, intraarticular corticosteroids can be useful as monotherapy or as an adjunct to analgesics.*³⁹ The affected joint can be aspirated and subsequently injected with a corticosteroid. The aspirate should be examined for the presence of crystalline formation and infection. Pain relief begins within days after the injection but may not persist beyond 4 weeks. A single joint should not be injected more than three to five times per year.

The crystalline nature of corticosteroid suspensions can provoke a postinjection flare in some patients. The ensuing flare mimics the flare of arthritis and inflammation that accompanies infection. Cold compresses and analgesics are recommended to treat symptoms in affected patients.

► Tramadol

Use of opioid analgesics may be warranted when pain is unresponsive to other pharmacologic agents or when such agents are contraindicated. Tramadol is an oral, centrally acting synthetic opioid analgesic that also weakly inhibits the reuptake of serotonin and norepinephrine. It is effective for treatment of moderate pain but is devoid of anti-inflammatory activity. Compared with conventional opioid analgesics, tramadol has a low abuse potential and is not scheduled as a controlled substance in the United States.

Tramadol is a reasonable option for patients with contraindications to NSAIDs or failure to respond to other oral therapies. **10** *For the treatment of hip or knee OA, tramadol can be effective in carefully selected patients.*⁴⁰ *The addition of tramadol to NSAIDs or acetaminophen may augment the analgesic effects of a failing regimen, thereby securing sufficient pain relief in some patients.* Moreover, concomitant tramadol may permit the use of lower NSAID doses. However, the increased risk for side effects associated with tramadol may offset the benefits.⁴⁰

Dizziness, vertigo, nausea, vomiting, constipation, and lethargy are all relatively common adverse events. These effects are more pronounced for several days after initiation and following upward dose titration. Seizures have been reported rarely; the risk is dose-related and appears to increase with concomitant use of antidepressants, such as tricyclic antidepressants or selective serotonin reuptake inhibitors. Tramadol should be avoided in patients receiving monoamine oxidase (MAO) inhibitors because tramadol inhibits the uptake of norepinephrine and serotonin.

► Other Opioid Analgesics

Opioids decrease pain, improve sleep patterns, and increase functioning in patients with OA who are unresponsive to nonpharmacologic therapy and nonopioid analgesics. Use of opioid analgesics for nonmalignant pain is increasing. Evidence suggests that patients can achieve satisfactory analgesia by using nonescalating doses of opioids with minimal risk of addiction.⁴¹ However, clinically significant improvement in pain that is nonresponsive to NSAIDs has only been demonstrated with stronger opioids. Oxycodone is the most extensively studied of the opioids recommended for OA. However, other agents such as morphine, hydromorphone, methadone, and transdermal fentanyl are also effective.⁴² The American Pain Society (APS) recommends against using codeine for OA because of the high incidence of adverse effects and limited analgesic effectiveness.⁴³

10 *Opioid analgesics should be reserved for patients who experience moderate to severe pain and do not respond to or are not candidates for other pharmacologic and nonpharmacologic strategies. Opioids also may be useful in patients with conditions that preclude the use of NSAIDs, such as renal failure, heart failure, or anticoagulation.*

These agents should be initiated at low doses in combination with acetaminophen or an NSAID when possible. Combining opioids with other analgesics reduces the opioid requirement, thereby minimizing adverse events. However,

use of combination opioid products containing acetaminophen should be accompanied by clear instructions to limit additional over-the-counter acetaminophen use. Conservative initial doses of opioids are warranted, with the dose titrated to adequate response with minimal side effects. Even with these conservative strategies, adverse effects are common. In clinical trials, more than 80% of opioid-treated patients experienced at least one adverse event, compared with approximately 50% of placebo-treated patients.⁴²

If opioid therapy is considered, there should be an initial comprehensive medical history and physical examination, firm documentation that nonopioid therapy has failed, clearly defined treatment goals, an understanding between the provider and the patient of the true benefits and risks of long-term opioids, use of a single provider and pharmacy whenever possible, and comprehensive follow-up.

► Topical Analgesics

Topical analgesics sometimes are used for mild pain or as an adjunct to systemic therapy. There are limited data to support the use of salicylate-containing **rubefaciants** (e.g., methyl salicylate and trolamine salicylate) or other **counter-irritants** (e.g., menthol, camphor, and methyl nicotinate) in OA.⁴⁴ See Chap. 60 for more information on these products when used for musculoskeletal disorders.

Capsaicin achieves pain relief by depleting substance P from sensory neurons in the spine, thereby decreasing pain transmission. Capsaicin is not effective for acute pain; pain relief may take up to 2 weeks with daily administration. Capsaicin may provide the greatest benefit to painful superficial joints (e.g., hand OA). Most patients experience a local burning sensation at the site of application. The discomfort usually does not result in discontinuation and often abates within the first week. Patients should be cautioned not to allow capsaicin to come into contact with eyes or mucous membranes and to wash their hands after each application.

10 *Topical NSAID preparations are effective for treating OA involving the superficial joints of the hands, wrists, elbows, knees, ankles, or feet.* Administration via a topical vehicle targets the joints involved and decreases systemic exposure while providing pain relief comparable to that of oral NSAIDs. This may be an attractive option for patients at risk of developing adverse events from oral NSAIDs.

Diclofenac sodium gel 1% is the only commercially available topical NSAID in the United States; it decreases pain and improves joint function in patients with hand or knee OA.^{45,46} Systemic absorption of topical diclofenac is approximately 17 times lower than that seen with oral diclofenac. Thus GI, cardiovascular, and renal adverse effects would not be expected with proper administration. The most common adverse effects include application site dermatitis, pruritus, and phototoxicity.

Surgery

10 *Surgery generally is reserved for patients who fail to respond to medical therapy and have progressive limitations*

in activities of daily living (ADL). In joint replacement surgery (arthroplasty), the damaged joint surfaces are replaced with metal or plastic prosthetic devices. Hip and knee joints are most commonly replaced, but arthroplasty may also be performed on shoulders, elbows, fingers, and ankles. Most patients achieve significant pain relief and functional restoration after arthroplasty, and it is a reasonable option in carefully selected refractory patients.

Surgical debridement may be performed arthroscopically. With this procedure, a tiny video camera is inserted into the affected joint through a small incision, and the surgeon removes torn cartilage or other debris from the joint. The long-term benefits of arthroscopic surgery for OA are unclear, and it may be no better than optimized physical and medical therapy.⁴⁷

Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH: Obesity (BMI 30 kg/m²), HTN × 24 years, dyslipidemia, MI 19 years ago, COPD

PSH: Torn ACL repair on right knee 15 years ago

FH: Father had OA of the hip and knee; mother died of MI at age 68

SH: Retired factory worker. Drinks 1 to 2 beers/night; denies illicit drug use; smoked two packs of cigarettes per day for 35 years but quit 3 years ago

Allergies: NKDA; shellfish allergy

Meds: Chlorthalidone 25 mg once daily, metoprolol succinate 100 mg once daily, atorvastatin 80 mg once daily, enteric-coated aspirin 81 mg once daily, tiotropium 18 mcg once daily, albuterol 90 mcg as needed for wheezing/shortness of breath, acetaminophen 500 mg, 1 to 2 tablets 2 to 4 times/day as needed for pain.

Vital signs: BP 135/82 mm Hg, pulse 71 beats/min, RR 16 breaths/min, temperature 98.6°F (37.0°C).

Labs: Not obtained.

Radiology: Radiography of the affected knee shows joint space narrowing, minor osteophyte formation, and subchondral bone sclerosis.

What clinical parameters are consistent with a diagnosis of OA?

What are the treatment goals for this patient?

What nonpharmacologic options are available to treat this patient?

What pharmacologic options are available to treat this patient?

What factors are important to consider when selecting medications for this patient?

Patient Encounter, Part 3: Creating a Care Plan

Based on the available information, create a care plan for this patient's OA. The plan should include:

- (a) A statement of the drug-related needs and/or problems
- (b) An individualized, detailed therapeutic plan
- (c) A plan for follow-up monitoring to document the patient's response and identify adverse reactions

Patient Care and Monitoring

1. Determine whether the patient's symptoms are consistent with OA. Review the medical history to determine whether other rheumatologic diseases may be involved.
2. Assess symptoms to determine whether pain warrants additional attention. Does the pain affect quality of life or interfere with activities of daily living?
3. Evaluate symptoms to determine what nonpharmacologic interventions can be recommended and whether pharmacologic treatment is warranted.
4. Obtain a thorough history of previous drug use, including prescription drugs, over-the-counter drugs, and dietary supplements. Determine whether and to what extent any of these treatments have been effective. Ask the patient about the dose and frequency of previous pharmacologic agents to determine whether an adequate trial was given.
5. Educate the patient about appropriate use of nonpharmacologic treatments for OA.
6. Formulate a drug therapy plan, taking into consideration the patient's medical history, concomitant medications, and previous use of medications.
7. Develop a plan to monitor the patient's response to therapy.
8. Evaluate for the presence of adverse drug reactions, drug hypersensitivity, and drug interactions.
9. Document whether the patient has had improvements in quality-of-life measures, such as improved functioning, increased ability to perform activities of daily living, and improved well-being.
10. Emphasize the value of adherence to medication regimens and lifestyle modifications. Facilitate adherence by implementing medication regimens and lifestyle plans that are simple and consistent with the patient's lifestyle.
11. Educate the patient about OA, lifestyle modifications, and medications.

OUTCOME EVALUATION

- At baseline, quantify the patient's pain using a visual analogue scale, assess range of motion of affected joints, and identify activities of daily living that are impaired.
- In patients treated with acetaminophen or oral NSAIDs, assess pain control after 2 to 3 weeks. It may take longer for the full anti-inflammatory effect of NSAIDs to occur.
- Incorporate other measures to track disease progress. Use radiography to assess severity of joint destruction, determine 50-ft walking time and grip strength, and administer the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) and the Stanford Health Assessment Questionnaire, where appropriate, to assess activities of daily living.
- Ask patients if they are experiencing side effects or other problems with their medications and follow-up with more specific questions.
- In patients taking oral NSAIDs, monitor for increases in blood pressure, weight gain, edema, skin rash, and CNS adverse effects such as headaches and drowsiness.
- Evaluate serum creatinine, complete blood count, and serum transaminases at baseline and at every 6 to 12 months in patients treated with oral NSAIDs or acetaminophen.
- Perform stool guaiac in patients taking oral NSAIDs when clinically indicated.
- Monitor for drug interactions, including alcohol, at every visit.

Abbreviations Introduced in This Chapter

ACR	American College of Rheumatology
APS	American Pain Society
COX	Cyclooxygenase
DJD	Degenerative joint disease
MMP	Matrix metalloproteinases
NSAID	Nonsteroidal anti-inflammatory drug
OA	Osteoarthritis
WOMAC	Western Ontario and McMaster Universities Osteoarthritis Index

Gout and Hyperuricemia

Geoffrey C. Wall

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Recognize major risk factors for developing gout in a given person.
2. Develop a pharmacotherapeutic plan for a patient with acute gouty arthritis or uric acid nephropathy that includes individualized drug selection and monitoring for efficacy and safety.
3. Identify patients for whom maintenance therapy for gout and hyperuricemia is warranted.
4. Select an appropriate drug to reduce serum uric acid (SUA) levels in patients with gout, and outline a plan for monitoring efficacy and toxicity.
5. Educate patients on appropriate lifestyle modifications to help prevent gouty arthritis attacks.
6. Identify patients at risk for tumor lysis syndrome and develop a rational plan to prevent this syndrome.

KEY CONCEPTS

- 1 Gout results from deposition of uric acid crystals in joint spaces, leading to an inflammatory reaction that causes intense pain, erythema, and joint swelling.
- 2 Some drugs can cause hyperuricemia and gout, such as thiazide diuretics, niacin, pyrazinamide, cyclosporine, and, occasionally, low-dose aspirin.
- 3 Long-term consequences of gout and hyperuricemia include joint destruction, tophi, and nephrolithiasis.
- 4 Treatment of gout involves: (a) acute relief of a gouty arthritis attack, and (b) in some patients, long-term maintenance treatment to prevent future attacks.
- 5 Nonsteroidal anti-inflammatory drugs, colchicine, or corticosteroids are used for acute attacks. Selection depends on several patient factors, especially renal function.
- 6 Asymptomatic hyperuricemia usually does not require treatment.
- 7 Patients with recurrent attacks, evidence of tophi or joint destruction, or uric acid nephrolithiasis are candidates for maintenance therapy with allopurinol, febuxostat, probenecid, or pegloticase to lower SUA levels.
- 8 Tumor lysis syndrome (TLS) is a metabolic disorder caused by rapid cell destruction (usually during chemotherapy treatment for cancer) and is associated with several electrolyte disturbances, notably hyperuricemia.

EPIDEMIOLOGY AND ETIOLOGY

Gout is the most common inflammatory arthritis in the United States and western Europe.¹ The annual incidence is approximately 62 cases per 100,000 persons in the United States.² The incidence increases with age and appears to be rising, probably because of a larger number of patients with risk factors for gout.³

PATHOPHYSIOLOGY

Gout is caused by an abnormality in uric acid metabolism. Uric acid is a waste product of the breakdown of purines contained in the DNA of degraded body cells and dietary protein. Uric acid is water soluble and excreted primarily by the kidneys, although some is broken down by colonic bacteria and excreted via the GI tract.^{4,5}

The solubility of uric acid depends on concentration and temperature. At high serum concentrations, lower body temperature causes the precipitation of **monosodium urate** (MSU) crystals. Collections of these crystals (called **microtophi**) can form in joint spaces in the distal extremities.

- 1 *Gout results from deposition of uric acid crystals in joint spaces, leading to an inflammatory reaction that causes intense pain, erythema, and joint swelling.*
- Free urate crystals can activate several proinflammatory mediators, including tumor necrosis factor α (TNF- α), interleukin 1 (IL-1), and IL-8. Activation of these mediators signals chemotactic movement of neutrophils into the joint space that “ingest” MSU crystals via phagocytosis. These neutrophils then are

lysed and release proteolytic enzymes that trigger the clinical manifestations of an acute gout attack, such as pain and swelling. These inflammatory mechanisms in gout, especially in untreated disease, can lead to cartilage and joint destruction.

The increased serum uric acid (SUA) involves either the underexcretion of uric acid (80% of patients) or its overproduction. The cause of overproduction or underexcretion of uric acid in most gout patients is unknown; this is referred to as *primary gout*.²

The reference range for SUA is 3.6 to 8.3 mg/dL (214 to 494 $\mu\text{mol/L}$). The risk of gout increases as the SUA concentration increases. Approximately 30% of patients with levels greater than 10 mg/dL (595 $\mu\text{mol/L}$) develop symptoms of gout within 5 years.³ However, most patients with hyperuricemia are asymptomatic. Other risk factors for gout include male gender, obesity, ethanol use (particularly beer and spirits), hypertension, and dyslipidemia.⁴⁻⁷ Gout occurs frequently in patients with type 2 diabetes mellitus and coronary artery disease, but a causal relationship has not been established. Preliminary investigations have suggested a possible role of hyperuricemia in the progression of chronic kidney disease.⁸

Uric acid excretion is reduced in patients with chronic kidney disease, putting them at risk for hyperuricemia. In patients with persistently acidic urine and hyperuricemia, uric acid **nephrolithiasis** can occur in up to 25% of patients; in severe cases, uric acid stones can cause nephropathy and renal failure.⁹ Extreme hyperuricemia can occur because of rapid tumor cell destruction in patients undergoing chemotherapy for certain types of cancer. This phenomenon is known as **tumor lysis syndrome** (TLS).

② Some drugs can cause hyperuricemia and gout, such as thiazide diuretics, niacin, pyrazinamide, cyclosporine, and, occasionally, low-dose aspirin. In most cases, these drugs block uric acid secretion in the kidney. ③ Long-term consequences of gout and hyperuricemia include joint destruction, tophi, and nephrolithiasis.

CLINICAL PRESENTATION AND DIAGNOSIS

Aspiration of affected joint fluid is essential for a definitive diagnosis. Joint fluid containing negatively birefringent MSU crystals confirms the diagnosis. Joint fluid has an elevated white blood cell (WBC) count with neutrophils predominating (Fig. 59-1).¹⁰

Although rarely performed, a 24-hour urine collection can be obtained to determine whether the patient is an overproducer or an underexcretor of uric acid. Individuals who excrete more than 800 mg of uric acid in this collection are considered overproducers. Patients with hyperuricemia who excrete less than 600 mg/day (3.57 mmol/day) are classified as underexcretors of uric acid.

Radiographs of affected joints may have characteristic appearances of gout, including cystic changes, punched-out lytic lesions with overhanging bony edges, and soft-tissue calcified masses. These signs may appear in other arthropathies as well.¹¹

FIGURE 59-1. Synovial fluid containing extracellular and intracellular monosodium urate crystals. (From Schumacher HR, Chen LX. Gout and other crystal arthropathies. Clinical Presentation and Diagnosis of Acute Gouty Arthritis

General

- Patients are usually in acute distress.

Symptoms

- There is severe pain, swelling, and warmth in the affected joint(s).
- The attack is usually monoarticular; the most common sites are the metatarsophalangeal and knee joints.
- In elderly patients, gouty attacks may be atypical with insidious and polyarticular onset, often involving hand or wrist joints.

Signs

- Affected joint(s) are warm, erythematous, and swollen.
- Mild fever may be present.
- Tophi (usually on hands, wrists, elbows, or knees) may be present in chronic, severe disease.

Laboratory Tests

- The peripheral WBC count may be only mildly elevated.
- The serum uric acid level often is elevated but may be normal during an acute attack.
- Other laboratory markers of inflammation (e.g., increased erythrocyte sedimentation rate) are often present.

TREATMENT

4 Treatment of gout involves: (a) acute relief of a gouty arthritis attack, and (b) in some patients, long-term maintenance treatment to prevent future attacks.

Desired Outcomes

The goals of therapy of an acute attack are: (a) achieving rapid and effective pain relief, (b) maintaining joint function, (c) preventing disease complications, (d) avoiding treatment-related adverse effects, (e) providing cost-effective therapy, and (f) improving quality of life.¹² Infrequent gouty arthritis is a self-limited disease, and treatment usually focuses on symptom relief.

Nonpharmacologic Therapy

Nondrug modalities play an adjunctive role and usually are not effective when used alone. Immobilization of the affected extremity speeds resolution of the attack. Applying ice packs to the joint also decreases pain and swelling, but heat application may be detrimental.¹³

Pharmacologic Therapy

5 Nonsteroidal anti-inflammatory drugs (NSAIDs), colchicine, and corticosteroids are used for acute attacks. Selection depends on several patient factors, especially renal function (Fig. 59–2). Each drug class has a unique safety and efficacy profile in gout that should be considered carefully before choosing a specific agent (Table 59–1). Generally, the earlier in the course of the arthritic attack these agents are employed, the better the outcome. Other analgesics such as opioids have little to no role in the treatment of acute gout, which results from overwhelming inflammation.¹⁴

► Nonsteroidal Anti-inflammatory Drugs

The NSAIDs largely have supplanted colchicine as the treatment of choice, and many NSAIDs have been used successfully. These agents are most effective when given within the first 24 hours of the onset of pain. Most studies have shown similar results among agents, and all NSAIDs are considered to be effective. Doses at the higher end of the therapeutic range are often needed.¹⁵ NSAIDs are usually continued until 24 hours after symptoms subside.

Indomethacin was used traditionally, but its relative cyclooxygenase-1 (COX-1) selectivity theoretically increases its gastropathy risk. Thus other generic NSAIDs may be preferred. Adverse effects of NSAIDs include gastropathy (primarily peptic ulcers), renal dysfunction, and fluid retention.¹⁶ NSAIDs generally should be avoided in patients at risk for peptic ulcers, those taking warfarin, and those with renal insufficiency or uncontrolled hypertension or heart failure. Theoretically, gastroprotective agents such as proton-pump inhibitors may protect against the development of ulcers in patients receiving NSAIDs for an acute gouty flare, but no studies to date have investigated this concept.

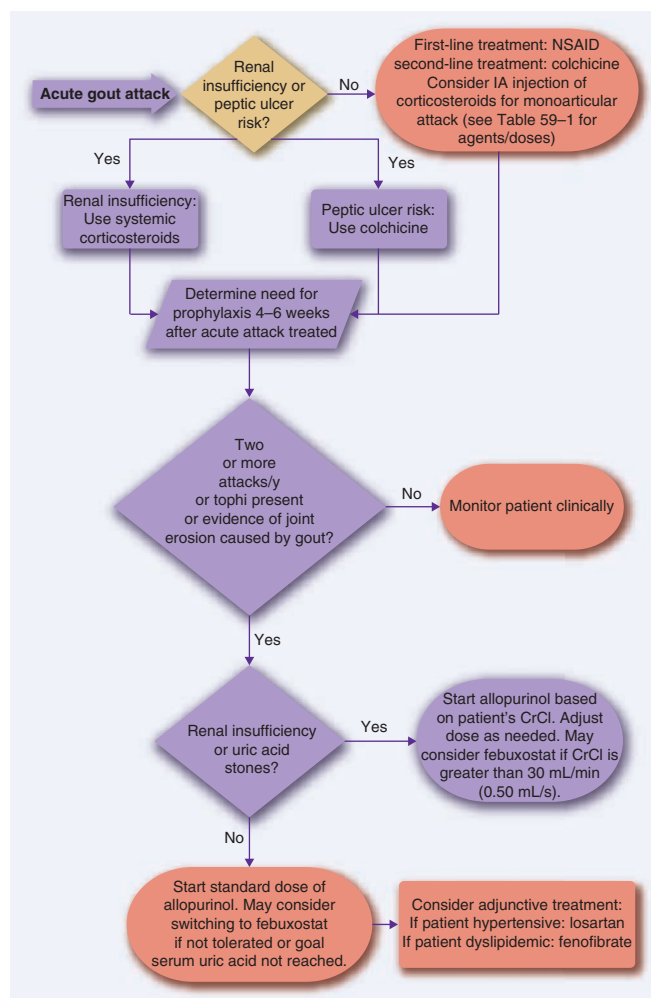

FIGURE 59–2. Treatment algorithm for gout and hyperuricemia. Renal insufficiency is defined as an estimated creatinine clearance (CrCl) of less than 30 mL/min (0.50 mL/s). (IA, intraarticular; NSAID, nonsteroidal anti-inflammatory drug.)

Cyclooxygenase-2 (COX-2)–selective inhibitors produce results comparable with those of traditional NSAIDs. However, cardiovascular safety concerns and the high cost of COX-2 inhibitors argue against their use for this disorder.

► Colchicine

Colchicine has a long history of successful use and was the treatment of choice for many years. It is used infrequently today because of its low therapeutic index. Colchicine is thought to exert its anti-inflammatory effects by interfering with the function of mitotic spindles in neutrophils by binding of tubulin dimers; this inhibits phagocytic activity.¹⁷

About two-thirds of patients with acute gout respond favorably if it is given within the first 24 hours of symptom onset. Because NSAIDs have not been directly compared with colchicine in rigorous trials, it is unknown which modality has a faster onset. GI effects (e.g., nausea, vomiting, diarrhea, and abdominal pain) are most common and are

Table 59-1

Dosage Regimens for Acute Gout and Antihyperuricemic Treatment

Drug	Dosage Regimen
Drugs for Treatment of Acute Gout	
NSAIDs ^a	
Fenoprofen	800 mg po every 6 hours
Flurbiprofen	100 mg po four times a day for 1 day, then 50 mg po four times a day
Ibuprofen	600–800 mg po four times a day
Indomethacin*	150–200 mg po daily (in 3 divided doses) for 3 days, then 100 mg po daily (in 2 divided doses) for 4–7 days
Indomethacin*	50 mg po three times a day
Ketoprofen	50 mg po four times a day or 75 mg po three times a day
Meclofenamate	100 mg po three to four times a day
Naproxen*	1,000 mg daily × 3 days, then 500 mg daily × 7 days or 750 mg po initially, then 250 mg po every 8 hours
Piroxicam	40 mg po once daily
Sulindac*	200 mg two times a day × 7–10 days
Tolmetin	400 mg po three to four times a day
Celecoxib	200 mg po two times a day
Meloxicam	7.5–15 mg po once daily
Colchicine (Colcris)	1.2 mg po at the onset of attack, then 0.6 mg 1 hour later
Local corticosteroids:	10–40 mg × 1 dose by intraarticular injection
Methylprednisolone (example)	
Systemic corticosteroids:	40–60 mg po once daily × 3 days, then decrease by 10 mg every 3 days
Prednisone (example)	
Triamcinolone acetonide	60 mg × 1 dose by IM injection
Antihyperuricemic Treatment	
Allopurinol	Starting dose: CrCl greater than 90 mL/min (1.50 mL/s) = 300 mg po daily CrCl 60–90 mL/min (1.00–1.50 mL/s) = 200 mg po daily CrCl 30–60 mL/min (0.50–1.00 mL/s) = 100 mg po daily CrCl less than 30 mL/min (0.50 mL/s) = 50 mg po daily Adjust dosage based on follow-up uric acid levels; maximum 800 mg po daily
Febuxostat	Starting dose 40 mg orally once daily; increase to 80 mg once daily if serum uric acid does not decline to 6.0 mg/dL (357 μmol/L) or lower after 2 weeks of treatment
Probenecid	Starting dose 250 mg po two times a day; may increase to 1,000 mg po two times a day
Pegloticase	8 mg given as an IV infusion once every 2 weeks
Rasburicase	0.2 mg/kg given as an IV infusion over 30 minutes once daily for up to 5 days

CrCl, creatinine clearance; IM, intramuscular; NSAIDs, nonsteroidal anti-inflammatory drugs; po, by mouth.

^aNSAIDs that are FDA approved for treatment of gout are indicated with an asterisk.

Drug regimens derived from various sources.

considered a forerunner of more serious systemic toxicity, including myopathy and bone marrow suppression (usually neutropenia). However, systemic toxicity can occur with oral colchicine without prior GI effects, especially in patients with renal insufficiency.^{18,19} In the presence of renal impairment, dosing should be repeated no more than once every 2 weeks. Colchicine should not be coadministered with p-glycoprotein or strong CYP3A4 inhibitors (e.g., clarithromycin). Because of these problems, oral colchicine should be reserved for patients who are at risk for NSAID-induced gastropathy or who have failed NSAID therapy.²⁰

In July 2009, the FDA approved Colcris, a single-ingredient colchicine product for treatment of acute gout attacks. As part of the approval process, a dosing study showed that one dose initially and a single additional dose after 1 hour was just as effective and less toxic than continued hourly colchicine dosing. As a result, the approved dosage regimen is 1.2 mg (two 0.6-mg tablets) at the onset of an acute flare, followed by 0.6 mg 1 hour later. This proprietary agent is much more costly than the generic compounds it replaced.

► Corticosteroids

- When only one or two joints are affected, **intraarticular** corticosteroid injection can provide rapid relief with a relatively low incidence of side effects. Joint fluid obtained by **arthrocentesis** should be examined for evidence of joint space infection and crystal identification. If uric acid crystals are present and there is no infection, intraarticular injection can proceed.

Systemic corticosteroids are a useful option in patients with contraindications to NSAIDs or colchicine (primarily renal impairment) or polyarticular attacks, especially in elderly patients. A single intramuscular injection of a long-acting corticosteroid such as triamcinolone hexacetonide may be used. Oral agents may be needed, especially for severe attacks. Prednisone 40 to 60 mg (or an equivalent dose of another agent) is given daily, with a gradual taper over 2 weeks.²¹ Oral methylprednisolone and naproxen have been shown to be equivalent in treating acute gout attacks.²²

Short-term adverse effects from corticosteroids include fluid retention, hyperglycemia, CNS stimulation, weight gain, and increased risk of infection. Patients with diabetes should have blood glucose levels monitored carefully during the corticosteroid course.

ANTHYPERURICEMIC GOUT PROPHYLAXIS

- Gout is an episodic disease, and the number of attacks varies widely from patient to patient. Thus the benefit of long-term prophylaxis against acute gout flares must be weighed against the cost and potential toxicity of therapy that may not be necessary in all patients. **6** *Asymptomatic hyperuricemia usually does not require treatment.*

Nonpharmacologic Therapy

- Lifestyle modifications alone usually are insufficient for lowering SUA levels in gout patients. Patients should be advised

Patient Encounter, Part 1

A 58-year-old woman with a history of hypertension, gastroesophageal reflux disease, gout (with two gouty arthritis flares in the last year), and morbid obesity presents to the emergency department complaining of excruciating pain in her left big toe. This is similar to a painful episode she had with her left toe previously. On examination, her left great toe is red, swollen, and warm to the touch. She describes the pain as throbbing and rates it as a 10/10 (where 10 is the worst pain she has ever experienced). She weighs 120 kg (264 lb) and is 5 ft, 3 in (160 cm) tall. Medications include cimetidine 300 mg at bedtime, lisinopril 10 mg daily, and allopurinol 300 mg once daily. She has no prescription insurance and is currently unemployed. Serum creatinine is 1.0 mg/dL (88 $\mu\text{mol/L}$) and serum uric acid is 7.1 mg/dL (422 $\mu\text{mol/L}$). The emergency department resident would like to increase the patient's allopurinol to treat the acute gouty flare.

What information suggests gout as the cause of her symptoms?

What treatment for acute gout would you recommend for this patient?

What is the value of a serum uric acid level during an acute gout flare?

What role does allopurinol play in the treatment of acute gout?

to lose weight if obese and to discontinue ethanol consumption. Low-purine diets are not well tolerated; instead, dietary recommendations should focus on general nutrition principles. Drugs that may cause or aggravate hyperuricemia should be discontinued if possible. Few patients adhere to lifestyle modifications long term, and pharmacologic therapy usually is needed to treat hyperuricemia adequately.²³

Pharmacologic Therapy

- 7 Patients with recurrent attacks, evidence of tophi or joint destruction, or uric acid nephrolithiasis are candidates for maintenance therapy with allopurinol, febuxostat, probenecid, or pegloticase to lower SUA levels. Because hyperuricemia is the strongest modifiable risk factor for acute gout, prophylactic therapy involves either decreasing uric acid production or increasing its excretion (Table 59–1). The goal of therapy is to decrease SUA levels significantly, leaving less uric acid available for conversion to MSU crystals.¹²

Ideally, the selection of long-term prophylactic therapy involves determining the cause of hyperuricemia (primarily by analyzing a 24-hour urine collection for uric acid) and tailoring therapy appropriately. If less than 600 mg of uric acid is found in the 24-hour sample, the patient is considered an underexcretor. However, this approach is not used commonly for several reasons. The urine collection is inconvenient for

patients and clinicians and does not identify patients who may be both overproducers and underexcretors of uric acid. Also, drugs used to increase uric acid excretion (**uricosurics**) generally are not as well tolerated as drugs that decrease production, and uricosurics increase the risk of uric acid nephrolithiasis.²⁴

- Because allopurinol (which reduces uric acid production) is effective in both overproducers and underexcretors and is generally well tolerated, many clinicians forego the 24-hour urine collection and treat patients empirically with it.

▶ Allopurinol

Most patients in the United States are treated with allopurinol, which usually is effective if the dosage is titrated appropriately. The drug and its primary active metabolite, oxypurinol, reduce SUA concentrations by inhibiting the enzyme xanthine oxidase, thereby blocking the oxidation of hypoxanthine and xanthine to uric acid.¹²

Allopurinol is well absorbed, with a short half-life of 2 to 3 hours. The half-life of oxypurinol approaches 24 hours, allowing allopurinol to be dosed once daily. Oxypurinol is cleared primarily renally and can accumulate in patients with reduced kidney function. Allopurinol should not be started during an acute gout attack because sudden shifts in SUA levels may precipitate or exacerbate gouty arthritis. Rapid shifts in SUA can change the concentration of MSU crystals in synovial fluid, causing more crystals to precipitate. Thus most clinicians advocate a prophylactic dose of colchicine (0.6 mg/day) during initiation of antihyperuricemic therapy. Patients receiving colchicine for this reason should be screened for drug–drug interactions (via the cytochrome p-450 system) that may increase the risk of colchicine adverse effects. NSAIDs can be used at a low dose if colchicine is contraindicated. Combined treatment is continued until uric acid levels return to normal or a maximum of 3 to 6 months. Acute episodes should be treated appropriately before maintenance treatment is started.

- The initial dose of allopurinol is based on the patient's renal function. Patients with a creatinine clearance (CrCl) of 50 mL/min (0.83 mL/s) or less should receive a starting dose of less than 300 mg/day, although the product literature and other sources list alternative dosing regimens for those with renal insufficiency. The relationship between dose of allopurinol and its most severe side effects is controversial.²⁵ However, the dose can be adjusted upward as needed and tolerated, even in patients with mild to moderate renal insufficiency provided that patients are monitored appropriately.²⁶ It is reasonable to reduce the dose temporarily in patients who develop reversible acute renal failure.

SUA levels must be monitored periodically, with the first follow-up level obtained 6 months (or sooner) after starting therapy. The target SUA level is less than 6.0 mg/dL (357 $\mu\text{mol/L}$). The dose should be titrated upward (to a maximum of 800 mg/day) or downward as these levels dictate.

Allopurinol generally is well tolerated; nausea and diarrhea occur in a small percentage of patients. A generalized, maculopapular rash occurs in about 2% of patients.²⁷ Although usually mild, this can progress to severe skin

reactions such as Stevens-Johnson syndrome. Perhaps the most feared side effect is the allopurinol hypersensitivity syndrome, which may involve severe desquamating skin lesions, high fever (usually greater than 39.0°C [102.2°F]), hepatic dysfunction, leukocytosis with predominant eosinophilia, and renal failure. Although rare, this severe reaction has a 20% mortality rate.²⁸ Patients with a history of the syndrome should never again receive allopurinol (including desensitization) or oxypurinol (which is available outside the United States). Patients with a mild skin rash who require allopurinol can be desensitized to it using published protocols or be switched to febuxostat.^{29,30}

There are several important drug–drug interactions with allopurinol. The effects of both theophylline and warfarin may be potentiated by allopurinol. Azathioprine and 6-mercaptopurine are purines whose metabolism is inhibited by concomitant allopurinol therapy; the dose of these drugs must be reduced by 75% with allopurinol cotherapy. Patients taking allopurinol who receive ampicillin are at increased risk of skin rashes.

► Febuxostat

Febuxostat is a nonpurine xanthine oxidase inhibitor structurally distinct from allopurinol that is FDA approved for chronic hyperuricemia associated with gout. The initial dose is 40 mg orally once daily. The dose may be increased to 80 mg orally once daily if the SUA does not decrease to 6.0 mg/dL (357 μmol/L) or less after 2 weeks of treatment. No dosage adjustment is necessary in patients with mild or moderate renal impairment. Because of its potency and rapid reduction of SUA levels, prophylactic low-dose colchicine or an NSAID is recommended for 3 to 6 months during initiation of therapy.

Data from phase III trials suggested that febuxostat is more effective than allopurinol (at currently prescribed doses) in achieving target SUA levels of 6.0 mg/dL (357 μmol/L) or less and may be more effective in reducing the number of acute gouty flares.³¹ However, fixed allopurinol doses were used rather than titrating the allopurinol dose to reach the target SUA level, which may confound these findings.

Adverse effects of febuxostat include nausea, arthralgias, rash, and transient elevation of hepatic transaminases. Periodic liver function tests are recommended (e.g., at baseline, 2 and 4 months after starting therapy, and then periodically thereafter). Due to differences in chemical structure, febuxostat would not be expected to crossreact in patients with a history of allopurinol hypersensitivity syndrome. It also appears to be safe and effective in patients with mild-to-moderate renal insufficiency.

Because of cost concerns, febuxostat should be reserved for patients who do not tolerate allopurinol or those who cannot achieve SUA levels of 6.0 mg/dL (357 μmol/L) or less despite allopurinol therapy.²

► Probenecid

Probenecid is a uricosuric agent that blocks the tubular reabsorption of uric acid, increasing its excretion. Because

Patient Encounter, Part 2

The patient is successfully treated for her symptoms and returns for a follow-up visit at your clinic 8 weeks later. She reports no pain or swelling in the joints affected previously. She is currently taking allopurinol 300 mg daily, cimetidine 300 mg at bedtime, and lisinopril 10 mg daily.

PE:

VS: BP 131/80, P 72, RR 15, T 36.1°C (96.9°F)

Ext: Trace edema in both ankles

Labs: Serum uric acid 8.1 mg/dL (482 μmol/L); serum creatinine 0.9 mg/dL (80 μmol/L).

What are the gout treatment goals for this patient?

What is your therapeutic plan to achieve these goals?

of its mechanism of action, probenecid is contraindicated in patients with a history of uric acid stones or nephropathy. Probenecid loses its effectiveness as renal function declines and should be avoided when the CrCl is 50 mL/min (0.83 mL/s) or less. Its uricosuric effect is counteracted by low aspirin doses, which many patients receive for prophylaxis of coronary heart disease.^{2,12}

Although generally well tolerated, probenecid can cause GI side effects such as nausea and other adverse reactions including fever, rash, and rarely, hepatic toxicity. Patients should be instructed to maintain adequate fluid intake and urine output to decrease the risk of uric acid stone formation. Some experts advocate alkalinizing the urine to decrease this risk.

► Pegloticase

Gout does not occur in most nonprimate mammals because these species produce the enzyme uricase, which metabolizes uric acid into the more soluble compound allantoin, which is readily excreted. Humans lack this enzyme, which allows uric acid to accumulate, leading to gout in some individuals.

Pegloticase is a recombinant form of uricase bound to polyethylene glycol that is approved for the treatment of chronic gout refractory to other therapy. At the approved dose of 8 mg IV every 2 weeks, the drug rapidly (within 6 hours) decreased SUA in subjects in published trials.³² However, pegloticase should be limited to patients with severe gout with tophi or nephropathy that has not responded to other agents because of significant adverse effects, including gout flares, anaphylaxis (in up to 5% of patients) that mandates pretreatment with antihistamines and corticosteroids, the inconvenience of IV therapy, and its high cost.

► Other Uricosuric Agents

Several other medications have mild uricosuric effects and may be appropriate adjunctive therapy in some patients.

Losartan increases both uric acid excretion and urine pH and may be an option in hypertensive patients with gout.³³ Feno-fibrate is also a uricosuric and may be appropriate in selected dyslipidemic patients with gout.

TUMOR LYSIS SYNDROME

8 *Tumor lysis syndrome (TLS) is a metabolic disorder caused by rapid cell destruction (usually during chemotherapy treatment for cancer) and associated with several electrolyte disturbances, notably hyperuricemia.*

TLS is most commonly associated with the chemotherapeutic treatment of cancers, such as leukemias and lymphomas. These types of cancers have a large tumor burden and are highly sensitive to destruction by chemotherapy. Massive lysis of intracellular contents occurs, including the breakdown of nucleotides into hypoxanthine, xanthine and, eventually, uric acid. These large amounts of uric acid overwhelm normal urinary excretion capacities and can undergo crystalline precipitation. This can lead to acute renal failure and a host of electrolyte disturbances, including hyperkalemia and hyperphosphatemia.³⁴ If not prevented or treated early, TLS can lead to acute kidney damage and perhaps death; thus TLS is considered an oncologic emergency. The incidence of TLS varies according to definition, tumor type, and patient characteristics, but is thought to be approximately 5% in high-risk cancers.

Due to the potential severity of TLS, strategies to prevent this disorder are mandatory in susceptible patients. Aggressive hydration (usually with isotonic fluids such as 0.9% saline) and diuresis are the cornerstones of TLS prevention. This strategy promotes the excretion of uric acid before crystallization occurs. Alkalinization of the urine to increase uric acid solubility has not been shown to be beneficial.³⁵

Allopurinol has a crucial role in the prevention of TLS. Due to its low cost and ease of administration, oral allopurinol is commonly used in doses up to 400 mg/m²/day for the prevention of TLS. The drug is usually started several days before the initiation of chemotherapy. In patients who cannot tolerate oral allopurinol, the IV formulation can prevent hyperuricemia in up to 90% of patients treated.³⁶ Allopurinol does not reduce levels of uric acid formed before treatment is initiated.

Rasburicase is a recombinant form of urate oxidase indicated for the prevention and treatment of TLS. This enzyme, similar to uricase (pegloticase), also converts uric acid to allantoin. Rasburicase can dramatically reduce uric acid levels in patients with TLS and appears to be more effective than allopurinol.³⁷ Rasburicase is indicated for patients who have developed TLS or in patients at high risk for developing this syndrome.³⁸ In these patients, the drug is approved at a dose of 0.2 mg/kg as an IV infusion over 30 minutes daily for up to 5 days. Rasburicase has a much higher acquisition cost than IV allopurinol, and some investigators have studied lower doses of the drug or use it preferentially in patients with existing renal insufficiency or uric acid levels greater than 10.0 mg/dL (595 μmol/L).³⁸

Rasburicase is well tolerated; mild cutaneous hypersensitivity reactions are the most common adverse effect. It can also cause hemolysis, especially in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency.

OUTCOME EVALUATION

Acute Gout

- Monitor the patient for pain relief and decreased swelling of the affected joints. Both parameters should be improved significantly within 48 hours of starting acute gout therapy.
- Assess the patient's subjective complaints and objective information for adverse effects. For NSAID therapy, be alert for new-onset epigastric pain, dark or tarry stools, blood in vomitus, dizziness or lightheadedness, development of edema, decreased urine output by more than 50% over a 24-hour period, or shortness of breath. For colchicine, monitor for nausea or vomiting, diarrhea, easy bruising, cold or flulike symptoms, lightheadedness, muscle weakness, or pain. Counsel the patient to inform you of any new medications started or stopped while taking colchicine.
- Monitor patients receiving intraarticular corticosteroid injections for increased swelling or pain at the injection site.
- Assess patients receiving systemic corticosteroids for mental status changes, fluid retention, increased blood glucose, muscle weakness, or development of new infections.

Antihyperuricemic Therapy

- Assess for new gouty arthritis attacks or the development of tophi. If neither one develops, continue antihyperuricemic therapy as prescribed.
- Obtain the first follow-up SUA level within 6 months of starting therapy. Then monitor levels at least every 6 to 12 months, and adjust the dose to achieve a target SUA level of less than 6.0 mg/dL (357 μmol/L).
- Evaluate patients taking allopurinol for development of rash, nausea, or new fever. These symptoms usually appear within the first 3 months of therapy but can occur anytime.
- Assess patients receiving probenecid for fever, nausea, or skin rash. Reevaluate therapy if a significant decrease in urine output occurs (greater than 50% in a 24-hour period).
- Reserve pegloticase for chronic gout refractory to other antihyperuricemic therapies or when other agents are not tolerated. Monitor SUA levels before each 2-week IV infusion.
- Evaluate patients on pegloticase for development of gouty flares and infusion reactions, which may include anaphylaxis. The manufacturer recommends giving an antihistamine and perhaps low-dose methylprednisolone before the infusion to minimize reactions.

Patient Care and Monitoring

1. Assess the patient's symptoms to determine the time of attack onset, which joints are affected, the level of pain, and other symptoms.
2. Review the patient history for contributing lifestyle factors and other disease states that may help guide therapy.
3. Obtain a thorough medication history for prescription drug, nonprescription drug, and dietary supplement use. Determine whether any of these products may be contributing to hyperuricemia.
4. Educate the patient on lifestyle modifications that will improve symptoms, including weight loss, if appropriate, and avoidance of ethanol.
5. If the diagnosis of gout has not been confirmed previously, consider aspiration of an affected joint to identify uric acid crystals.
6. Initiate therapy to treat the acute gout attack without delay. Develop a plan to assess this therapy after 24 and 48 hours.
7. Select therapy based on comorbidities and potential for adverse effects. In patients with no other disease states, NSAIDs are the preferred drug class.
8. Assess the need for continuous antihyperuricemic therapy. Use patient factors such as comorbidities to select an agent. Allopurinol is the standard prophylactic agent used in the United States.
9. Most patients need adjunctive therapy with low-dose colchicine or an NSAID during initiation or titration of antihyperuricemic therapy to prevent a rebound flare.
10. Do not start antihyperuricemic therapy within 4 weeks of an acute attack.
11. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
12. Stress the importance of adherence with the therapeutic regimen, including lifestyle modifications, to prevent future gout attacks and long-term complications.
13. Provide patient education about the disease state, lifestyle modifications, and drug therapy.

Abbreviations Introduced in This Chapter

ACTH	Adrenocorticotrophic hormone
COX	Cyclooxygenase
G6PD	Glucose-6-phosphate dehydrogenase
MSU	Monosodium urate
SUA	Serum uric acid
TLS	Tumor lysis syndrome

Musculoskeletal Disorders

Jill S. Borchert

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiologic principles associated with tissue injury and inflammation.
2. Identify the desired therapeutic goals and outcomes for a patient with musculoskeletal injury or pain.
3. Identify the factors that guide selection of an analgesic or counterirritant for a particular patient.
4. Recommend appropriate nonpharmacologic and pharmacologic therapy for a patient with musculoskeletal injury or pain.
5. Design a patient education plan including nonpharmacologic therapy and preventative strategies.
6. Develop a monitoring plan to assess treatment of a patient with musculoskeletal disorders.

KEY CONCEPTS

- 1 The two primary goals of treating musculoskeletal disorders are to: (a) relieve pain and (b) maintain functionality.
- 2 The cornerstone of nonpharmacologic therapy for acute injury in the first 48 to 72 hours is known by the acronym *RICE*: rest, ice, compression, and elevation.
- 3 Heat should not be applied during the acute injury phase (the first 48 hours) because it promotes swelling and inflammation.
- 4 There are two main approaches to pharmacologic intervention for pain relief: oral (systemic) and topical agents.
- 5 Localized pain may be treated effectively with local topical therapy, whereas generalized pain is best treated with systemic agents.
- 6 Acetaminophen is the drug of choice for mild-to-moderate regional musculoskeletal pain without inflammation.
- 7 Aspirin is not more effective than acetaminophen, and it is not recommended for treatment of acute musculoskeletal pain because its adverse effects may be more common and severe.
- 8 Nonsteroidal anti-inflammatory drugs (NSAIDs) are preferred over acetaminophen in musculoskeletal disorders in which inflammation is the primary problem.

- 9 Patient education on proper use of counterirritants is essential to therapeutic success.
- 10 Patients using capsaicin should be advised to apply it regularly and consistently three to four times daily and that full effect may take 2 to 3 weeks or longer.

INTRODUCTION

The musculoskeletal system consists of the muscles, bones, joints, tendons, and ligaments. Disorders related to the musculoskeletal system often are classified by etiology. Acute soft-tissue injuries include strains and sprains of muscles and ligaments. Repeated movements in sports, exercise, work, or activities of daily living can lead to repetitive strain injury, where cumulative damage occurs to the muscles, ligaments, or tendons.^{1,2} Although tendonitis and bursitis can arise from acute injury, more commonly these conditions occur as a result of chronic stress.² Other forms of chronic musculoskeletal pain, such as pain from rheumatoid arthritis (see Chap. 57) or osteoarthritis (see Chap. 58), are discussed elsewhere in this textbook.

EPIDEMIOLOGY

Musculoskeletal disorders are commonly self-treated, so true estimates of the incidence of both acute and chronic injury are difficult to obtain. Musculoskeletal disorders are among the top 10 reasons for ambulatory care visits in the United States for all age groups.³ These disorders account for a large

portion of medical care expenditures and are a leading cause of work absenteeism and disability, resulting in a substantial economic burden from lost productivity and lost wages.⁴

In addition to chronic conditions such as arthritis and low back pain, some musculoskeletal disorders are induced by trauma at the workplace either via repetition and cumulative trauma or a one-time overexertion.⁵ These are more likely to occur in the setting of a rapid work pace, heavy lifting, or poor posture. For each reported incident, it is likely that there are at least 10 unreported work-related musculoskeletal events related to repetitive stress to the bones and joints.⁶ In the elderly, these injuries may not be related to work but to daily life. Instability combined with activities of daily living such as stair climbing and lifting objects may lead to strains and sprains. In children and adolescents, fractures are more common than muscle and tendon injuries since growth spurts cause bones to weaken while the muscle–tendon unit tightens.^{7,8}

Muscle injuries comprise the majority of sports-related injuries, and roughly half are related to overuse.^{2,9} The shoulder and the knee are common sites of sports injuries.⁸ Soccer, football, basketball, track and field, and other sports that require rapid acceleration or higher speeds pose a greater risk of muscle strain.^{8,10} *Overuse musculoskeletal injury* is the phrase used to describe disorders arising from repetitive motion. This injury is common in activities such as running, particularly during periods of increased intensity or duration of training.² It also can occur in the workplace with repeated, unvaried motion.⁵

PATHOPHYSIOLOGY

Skeletal muscle consists of muscle fibers linked together by connective tissue. Tendons and ligaments are composed of collagenous fibers that have a restricted capability to stretch. Tendons connect the muscle to the bone, whereas ligaments connect bone to bone (Fig. 60–1).

Muscle Strains and Sprains

- A **sprain** is an overstretching of supporting ligaments that results in a partial or complete tear of the ligament.^{8,10} Although a **strain** also arises from an overstretching of the muscle–tendon unit, it is marked by damage to the muscle fibers or tendon without tearing of the ligament.¹¹ The key difference between a sprain and a strain is that a sprain involves damage to ligaments, whereas a strain involves damage primarily to muscle. One common example of muscle strain and sprain is low back pain.¹²

Overloading the muscle and connective tissue results in complete or partial tears of the skeletal muscle, tendons, or ligaments.⁸ This usually occurs when the muscle is activated in an *eccentric contraction*, defined as a contraction in which the muscle is being lengthened.⁸ Examples of this type of contraction include putting down a large, heavy laundry basket or lowering oneself from a chin-up bar. Small tears can occur in the muscle because it is lengthening while also trying to contract to support the load. This leads to

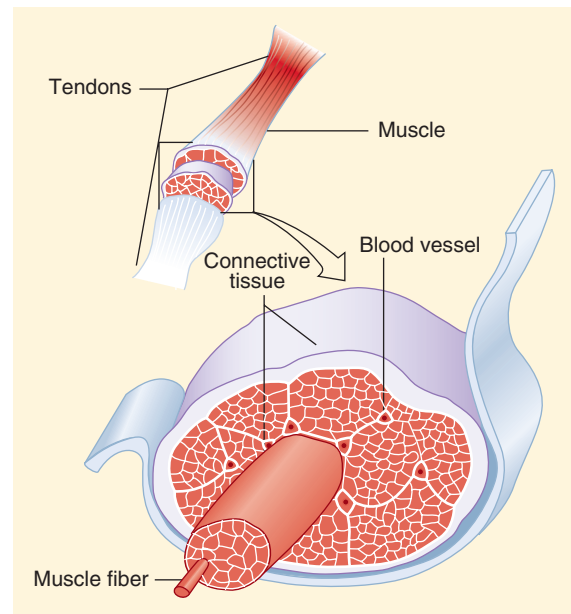

FIGURE 60–1. Skeletal muscle fiber organization. Tendons attach muscle to bone. (From Widmaier EP, Raff H, Strang KT, et al., eds. Vander, Sherman, & Luciano's Human Physiology: The Mechanisms of Body Function. 9th ed. New York: McGraw-Hill; 2004: Fig. 9–1.)

rupture of blood vessels at the site of the injury, resulting in the formation of a hematoma. Within 24 to 48 hours, an inflammatory response develops. In the inflammatory stage, macrophages remove necrotic fibers.^{9,11,13} The activated neutrophils release growth factors that will activate myocytes for regeneration. Finally, capillaries grow into the area, and muscle fibers regenerate during the repair and remodeling phases of healing.

Bursitis and Tendonitis

- **Bursitis** is an inflammation of the bursa, the fluid-filled sac near the joint where the tendons and muscles pass over the bone. The bursa assists with movement by reducing friction between joints. Overuse of a joint can result in an inflamed bursa. Bursitis causes stiffness and pain because the bursa serves to reduce friction within the joint space.

Tendonitis (or *tendinitis*) is an inflammation of the tendon or, more specifically, the fibrous sheath that attaches muscle to bone.² **Tenosynovitis** is an inflammation of the tendon sheath. Repetitive overuse of a tendon can cause cellular changes in the tissues. Specifically, collagenous tendon tissue is replaced with tissue that lacks the organized collagen arrangement of a normal tendon.¹⁴ In fact, many patients diagnosed with chronic tendonitis may not have inflammation but instead have tendinosis, a condition marked by these collagen changes. As a result of the cellular changes, the tendon progressively loses elasticity and its ability to handle stress or weight. This makes the tendon vulnerable to rupture or inflammation (tendonitis and tenosynovitis).

Inflammation and Peripheral Pain Sensation

Inflammation is a common pathway in soft-tissue injury of musculoskeletal disorders. Inflammatory processes lead to two outcomes: swelling and pain. Inflammatory processes traditionally are considered to be a necessary part of the remodeling process because inflammatory cells remove damaged tissue.^{15,16} However, inflammation also contributes to continued pain and swelling that limits range of motion.¹⁷

The initial injury exposes membrane phospholipids to phospholipase A₂, leading to the formation of arachidonic acid (Fig. 60-2).^{15,16} Next, arachidonic acid is transformed by cyclooxygenase (COX) to thromboxanes and prostaglandins (PGs), including prostaglandin E₂ (PGE₂). PGE₂ is the most potent inflammatory mediator; it increases vascular permeability, leading to redness, warmth, and swelling of the affected area. The increased permeability also increases **proteolysis**, or the breakdown of proteins in the damaged tissue.

Neutrophils, lymphocytes, and monocytes are attracted to the area, and monocytes are converted to macrophages.¹⁵ The macrophages then stimulate additional PG production. Phagocytic cells and other players in the immune system release cytokines, including interleukins, interferon, and tumor necrosis factor.

In addition to increasing vascular permeability, PGs also induce pain by sensitizing pain receptors to other substances such as bradykinin. Bradykinin, PGs, leukotrienes, and other inflammatory mediators lower the pain threshold through peripheral pain sensitization. These substances make nerve endings more excitable, and the nerve fibers are more reactive to serotonin, heat, and mechanical stimuli.^{16,18} The increased sensitization in the damaged tissue causes tenderness, soreness, and **hyperalgesia** or an exaggerated intensity of pain sensation.¹⁸ The process also facilitates production of additional PGs. In a cyclic fashion, the PGs then sensitize the nerves to bradykinin action.

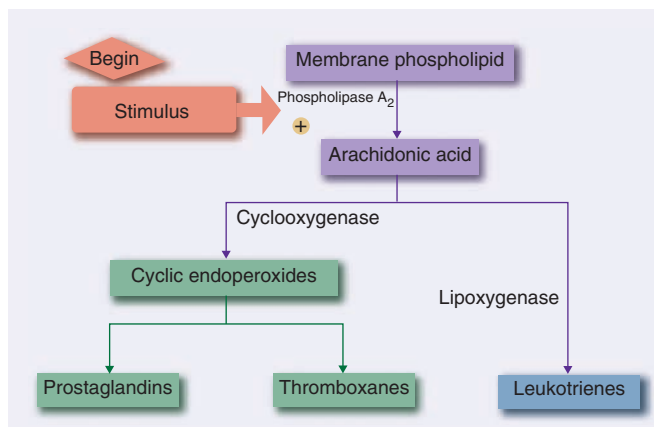

FIGURE 60-2. Eicosanoid synthesis pathway. Cyclooxygenase is inhibited by nonsteroidal anti-inflammatory drugs and aspirin. (Adapted with permission from Widmaier EP, Raff H, Strang KT. *Vander's Human Physiology: The Mechanisms of Body Function*. 12th ed. New York: McGraw Hill; 2011: Fig. 5-12.)

Without interruption, the neurochemicals ultimately lead to a firing of the unmyelinated or thinly myelinated afferent neurons. This sends messages along the pain pathway in the periphery and communicates the pain message to the CNS. Interruption of this cycle occurs via anti-inflammatory agents such as aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs).

Nerve receptors, or **nociceptors**, release substance P and other peptides when they are activated.¹⁸ Substance P mediates the production and release of inflammatory mediators and acts as a potent vasodilator. This receptor activation also increases the sensitivity of nociceptors to painful stimuli. Capsaicin relieves pain by stimulating the release of substance P from sensory nerve fibers, which ultimately depletes stores of substance P.¹⁹

CLINICAL PRESENTATION AND DIAGNOSIS

See next page for information on the clinical presentation and diagnosis of musculoskeletal disorders.

TREATMENT

Desired Outcomes

- 1 The two primary goals of treating musculoskeletal disorders are to: (a) relieve pain and (b) maintain functionality.
- This is accomplished by decreasing the severity and duration of pain, shortening the recovery period, and preventing acute injury pain from becoming chronic pain. If these goals are achieved, functional limitations are decreased. Ideally, a patient should be able to continue to perform activities of daily living (e.g., eating, dressing, cooking, doing laundry) and maintain normal functions in the workplace. Children ideally should be able to maintain usual play activities and sports schedules.

Patient Encounter 1, Part 1

A 58-year-old woman presents with left ankle pain. She was playing tennis earlier today and twisted her ankle. The pain occurs at rest and is worsened with weight-bearing on the ankle and rotation or movement. There is moderate swelling and bruising of the left ankle. She tries to avoid taking pain pills because she is on a medicine that her healthcare provider told her has lots of drug interactions. She asks for a recommendation for a topical medication.

What information is suggestive of a musculoskeletal disorder?

What is your assessment of the patient's ankle pain?

What additional information do you need to formulate a treatment plan?

Clinical Presentation and Diagnosis of Musculoskeletal Disorders

General^{2,8,14,17}

- Clinical presentation varies based on the etiology of the disorder.
- Repetitive strain or overuse injuries may have a gradual onset.
- Musculoskeletal disorders due to acute injury may be associated with other signs of the injury such as abrasion.
- Low back pain is often chronic.

Signs and Symptoms of Acute Soft-Tissue Injury (Strains, Sprains)^{2,8,11,17}

- Discomfort ranging from tenderness to pain; it may occur at rest or with motion
- Swelling and inflammation of the affected area
- Bruising
- Loss of motion
- Mechanical instability

Signs and Symptoms of Repetitive Strain or Overuse Injury (Tendonitis, Bursitis)^{2,14}

- Pain and stiffness that occurs either at rest or with motion
- Localized tenderness on palpation

- Mild swelling of the affected area
- Decreased range of motion
- Muscle atrophy

Other Diagnostic Tests and Assessments⁸

- *Radiograph (x-ray)*: Evaluate bony structures to rule out fracture, malalignment, or joint erosion as the primary cause of pain.
- *MRI*: Soft-tissue imaging to evaluate for tendon or ligament tears.
- *Ultrasound*: Superficial soft-tissue imaging to evaluate for tears in tendons or ligaments. Ultrasound does not penetrate bone, so it is of limited usefulness for assessing tendons or ligaments deep within joints.
- *Pain scale*: Patient self-rating of pain on a scale of zero (no pain) to 10 (worst possible pain). Used to assess pain both at rest and with movement. Determined at baseline and to assess response to therapy.

- Further goals include a return to usual activity and prevention of future injury. It is also important to minimize the potential for adverse drug events during treatment.

General Approach to Treatment

- Treatment of musculoskeletal disorders involves three phases: (a) therapy of an acute injury using the rest, ice, compression, and elevation (RICE) principle; (b) pain relief using oral or topical agents; and (c) lifestyle and behavioral modifications for rehabilitation and to prevent recurrent injury or chronic pain (**Fig. 60-3**).

- In many cases, musculoskeletal disorders are self-treated with over-the-counter (OTC) oral or topical agents. However, further evaluation may be warranted if acute pain persists longer than 7 to 10 days, symptoms worsen or subside and then return, or there are signs of a more serious condition.^{14,20,21} Warning signs of more serious conditions include joint deformity, dislocation, or lack of movement in a joint. Low back pain accompanied by burning, radiating pain, or difficulty urinating requires further evaluation.

- In children and adolescents, treatment practices are similar to the approach in adults with a focus on nonpharmacologic therapy and oral analgesics. Children younger than 2 years of age, elderly persons, and pregnant women also may need special care. Elderly patients may be more prone to systemic effects because of thinning of the skin and increased absorption of topical agents and drug interactions from polypharmacy.

Nonpharmacologic Therapy: RICE

- 2 *The cornerstone of nonpharmacologic therapy for acute injury in the first 48 to 72 hours is known by the acronym RICE: rest, ice, compression, and elevation^{9,17} (Table 60-1):* These four methods initially minimize bleeding from broken blood vessels. Rest eases pressure on the affected area and promotes pain control during the acute inflammatory phase (the first 1 to 5 days after injury). Cold causes vasoconstriction, assisting in prevention of a large hematoma and providing analgesia by slowing nerve impulses. Immediately after injury, ice also helps to reduce metabolism and tissue damage at the site.²² Compression, achieved by wrapping the area with an elastic bandage, also reduces the size of the developing hematoma.⁹ Preventing hematoma formation is important because a large hematoma can limit mobility and range of motion. Both cold and compression also decrease interstitial edema and swelling that accompany the injury. Elevation decreases blood flow and increases venous return from the affected area.

In addition to minimizing the acute inflammatory response, rest prevents additional injury to the affected area.⁹ The properties of the muscle-tendon unit are altered during the acute injury, with limitations on the ability of the muscles and tendons to stretch. Movement in the injured tissue can cause further retraction of the ruptured muscle and increase the size of the gap in the muscle to be healed. Therefore, early activity predisposes a patient to further injury, but prolonged inactivity can lengthen recovery times.

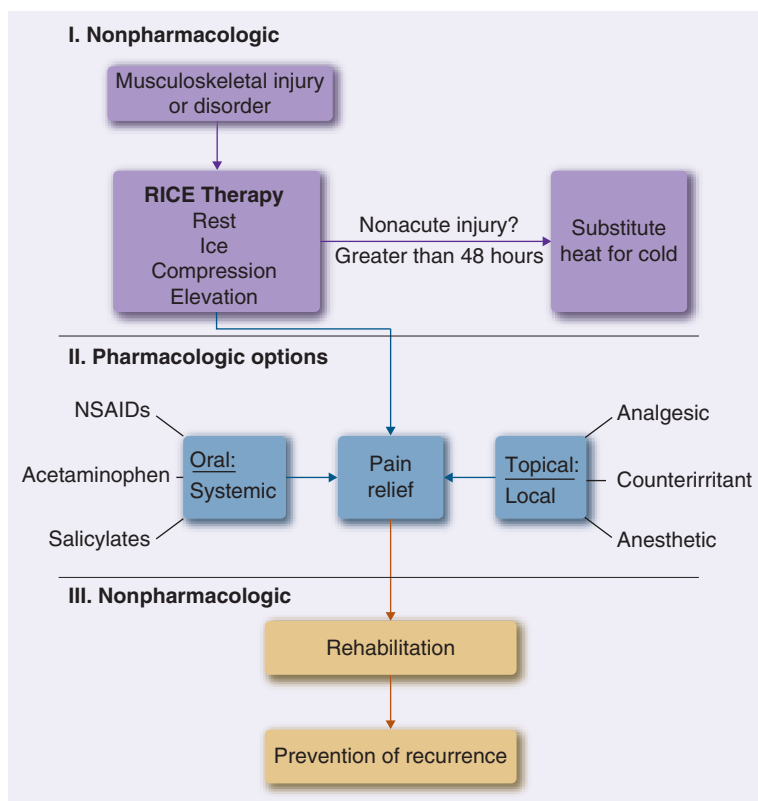

FIGURE 60-3. Treatment plan for musculoskeletal injury or disorder.

There are few studies comparing types of ice application, and recommendations vary widely.^{17,22} Clinicians should instruct patients to use crushed ice or ice chips because the area will cool more evenly than with large pieces of ice. Patients should not apply ice directly to the affected area or leave it on for longer than the recommended 20 minutes, because extreme cold can cause tissue damage.¹⁷ Similarly, patients should be instructed to wait at least 1 hour before reapplication of ice to allow the tissue to rewarm. A thin sheet or napkin will protect the skin and also allow for better cold transfer than thicker material such as a towel. Alternatively,

soaking the area for 20 minutes in a cool bath (13°C [55°F]) provides effective cooling.

For small areas, an ice massage for 5 to 10 minutes can cool the area and add relief.²³ This is accomplished by freezing water in a paper cup and removing the top part of the cup to expose the ice. The exposed ice is rubbed on the affected area. Any ice application should be stopped if the area becomes white or blue.

3 Heat should not be applied during the acute injury phase (the first 48 hours) because it promotes swelling and inflammation.⁸ After the first 48 hours, many patients find

Table 60-1

RICE Therapy

Therapy	General Guidelines	Therapeutic Benefit
Rest	Rest the affected area Use supports such as slings and crutches as necessary Employ during the acute inflammatory phase, 1–5 days after injury	Analgesia Anti-inflammatory Prevent further injury
Ice	Cool the affected area by submersion in cool water (13°C [55°F]) or by application of crushed ice in a plastic bag covered with a thin cloth Cool the affected area for 15–20 minutes; repeat every 2 hours for the first 48 hours	Analgesia Anti-inflammatory
Compression	Compress the affected area with an elastic bandage or support Begin wrapping the bandage at the point most distal to the injury (e.g., at the toes for an ankle injury); bind firmly but not tightly If the area distal to the injury (e.g., fingers, toes) throbs or turns cold or blue, the bandage is too tight and should be loosened	Anti-inflammatory Adjunctive analgesia
Elevation	Elevate the area (especially the extremities) above heart level	Anti-inflammatory

that heat decreases pain and eases muscle stiffness associated with immobility. A heating pad, heat wrap, or warm bath can be used on day three or later as long as no swelling develops after heat is applied. Heat should be discontinued if increased swelling occurs. Clinicians should educate patients to avoid sleeping with or sitting or lying on heating pads because this can result in burns. Low-level heat, such as that supplied by therapeutic heat wraps (e.g., ThermaCare), may provide a safer means of heat application.²⁴ However, elderly persons should still be cautioned about the risk of burns and be advised to wear the wrap over thin clothing.

Pharmacologic Therapy

- 4 There are two main approaches to pharmacologic intervention for pain relief: oral (systemic) and topical agents. The choice between systemic or topical options is often guided by patient preference. For example, many topical products have a medicinal odor and require frequent applications. The extent of musculoskeletal pain also guides treatment choice.
- 5 Localized pain may be treated effectively with local topical therapy, whereas generalized pain is best treated with systemic agents. Factors such as alcohol use, liver function, renal function, allergies, age, and comorbid conditions should be considered when choosing among therapeutic options.

► Oral Analgesics

Nonopioid analgesics, including acetaminophen, aspirin, and NSAIDs, are used commonly for musculoskeletal disorders. All these agents provide analgesia, but aspirin and NSAIDs also work peripherally to decrease production of the principal mediator of acute inflammation, PGE₂.^{8,18} NSAIDs and aspirin inhibit the enzyme COX. Although the mechanism of action of acetaminophen is less clear, it appears that acetaminophen acts as a weak inhibitor of PG production. In contrast to aspirin and NSAIDs that inhibit PG production peripherally, acetaminophen exerts its effect centrally with little or no anti-inflammatory effect.²⁵

Acetaminophen 6 *Acetaminophen is the drug of choice for mild-to-moderate regional musculoskeletal pain without inflammation.*^{26,27} Comparative trials between acetaminophen and oral NSAIDs demonstrate equivalent analgesia in some situations, but NSAIDs may be preferred in others.²⁷ Therefore, if adequate analgesia is not achieved with acetaminophen, switching to an NSAID is a reasonable approach. Acetaminophen offers the advantage of less GI toxicity than NSAIDs. Although tolerability of acetaminophen is high at therapeutic doses, hepatotoxicity has been reported after overdose and at therapeutic doses, especially in combination with other factors.²⁶ Acetaminophen should be used with caution in patients who have liver disease or consume alcohol because of the risk of hepatotoxicity. Clinicians should advise patients not to exceed 4 grams per day of acetaminophen to minimize the risk of liver injury. Due to concern over liver injury, many over-the-counter products are now labeled with a maximum of 3 grams per day; clinicians should encourage patients to follow these labeled directions.

Salicylates 7 *Aspirin is not more effective than acetaminophen, and it is not recommended for treatment of acute musculoskeletal pain because its adverse effects may be more common and severe.*²⁷ Gastric irritation is more common with aspirin, and bleeding risk is increased because aspirin irreversibly inhibits platelet aggregation.²⁷ Patients with aspirin-induced asthma should avoid aspirin and other salicylates.²⁸ Due to the risk of Reye's syndrome, aspirin should be avoided in children younger than age 19 during episodes of fever-causing illnesses.

Some salicylates are specifically marketed for musculoskeletal back pain, such as magnesium salicylate. However, no studies specifically support use of these salicylates over other systemic analgesics. Magnesium salicylate should be used with caution in patients with renal impairment because hypermagnesemia can occur.²⁹

NSAIDs Oral NSAIDs are used commonly for musculoskeletal pain because of their availability without a prescription and anti-inflammatory effects.^{18,29}

8 *NSAIDs are a preferred choice over acetaminophen in musculoskeletal disorders in which inflammation is the primary problem.*^{26,30} Most experts recommend the early use of NSAIDs after acute injury in cases in which soft tissue inflammation causes nerve impingement or when the predominate problem is inflammation, such as in bursitis.³⁰

NSAIDs are particularly beneficial for chronic overuse injury, in which inflammation is central to the pain and loss of motion. Although NSAIDs may be helpful in relieving pain and inflammation in tendonitis, many tendonopathies are not associated with inflammation. Therefore, use of a simple analgesic such as acetaminophen may relieve pain adequately.^{14,29}

The analgesic effects of NSAIDs are attributed to inhibition of the COX-2 enzyme, whereas the negative GI effects are due to inhibition of COX-1.²⁷ Patients taking oral anti-coagulants, those with a history of peptic ulcer disease, or others at high risk for GI complications may be considered candidates for a COX-2 inhibitor (e.g., celecoxib) or a combination of a nonselective NSAID with a gastroprotective agent such as a proton pump inhibitor (see Chap. 58).

COX-2 inhibitors are associated with adverse effects such as nephrotoxicity and a potential increased risk of myocardial infarction (see Chap. 58). Combination of COX-2 inhibitors with alcohol can increase GI adverse effects. All NSAIDs should be used with caution in patients with aspirin-induced asthma.²⁹

9 **Opioids** Opioid analgesics can be used for patients not responding adequately to nonopioid analgesics or for moderate-to-severe pain.²⁷ These agents generally are given alone or in combination with simple analgesics such as acetaminophen. Tolerance and physical dependence are considerations but less of a concern when treating acute pain. When used in equivalent doses, opioids produce similar pain relief and adverse effects such as sedation, nausea, constipation, and respiratory depression (see Chap. 33).

Topical (External) Analgesics Topically (or externally) applied drugs that exert a local analgesic, anesthetic, or

antipruritic effect by either suppressing cutaneous sensory receptors or by stimulating these receptors in a counterirritant fashion are termed *external analgesics*.²¹ These medications are applied directly to the affected area to create high local concentrations of the drug.^{19,31} Formulations include gel, cream, lotion, patch, liquid, liniment, or aerosol spray. Negligible systemic concentrations are achieved with intact skin, minimizing systemic adverse effects. Topical application should not be confused with transdermal delivery, in which drug absorption into the bloodstream produces a systemic effect. Musculoskeletal disorders often are treated with topical (but not transdermal) medications.

After application, the topical medication penetrates the skin to the soft tissue and peripheral nerves.²¹ At the site, topical analgesics suppress the sensitization of pain receptors, thereby reducing pain and burning. Examples include topical NSAIDs and local anesthetics, such as lidocaine. In contrast, *counterirritant* products are external analgesics that stimulate cutaneous sensory receptors, producing a burning, warming, or cooling sensation that masks the underlying pain. In effect, the irritation or inflammation caused by the counterirritant distracts from the underlying pain. Menthol and capsaicin are examples of counterirritants.

Some patients prefer external analgesics to systemic analgesics because the rubbing during application can be comforting.^{32,33} External analgesics are useful adjuvants to nonpharmacologic therapy and systemic analgesic therapy to provide additional relief. These agents also offer a therapeutic option in patients who cannot tolerate systemic analgesics. Because these agents are not in pill form and many are available without a prescription, they may be overused or misused. This prompted the FDA to caution consumers that the agents are medicines that may also cause harm.³⁴ Clinicians should advise patients to always read and follow directions on the labels of OTC products.

Topical NSAIDs. In acute soft-tissue injury such as strains and sprains, topical NSAIDs have efficacy that is superior to that of placebo and similar to that of oral NSAIDs.^{31,37} Tissue concentrations of topical NSAIDs are high enough to produce

anti-inflammatory effects, but systemic concentrations after application remain low.

Diclofenac is the only topical NSAID commercially available in the United States.^{35–38} Diclofenac patch (Flector Patch) is indicated specifically for the topical treatment of acute pain from minor sprains and strains.³⁵ The patch is applied to the most painful area twice daily. Diclofenac gel (Voltaren Gel) is indicated for joint pain in the knees and hands secondary to osteoarthritis; it is applied up to four times daily.³⁶ Diclofenac solution (Pennsaid) is indicated for osteoarthritis of the knee; it is applied via a dropper to the knee four times daily.³⁷ Patient education for topical NSAIDs is outlined in **Table 60–2**.^{35–37}

Theoretically, the risk of serious GI adverse events should be less than with oral NSAIDs, but long-term studies evaluating these events are lacking.^{31,38} Like oral NSAIDs, topical NSAIDs should be used with caution in patients with a history of GI bleeding or ulcer.^{35–37} Studies comparing topical NSAIDs with other topical products, including counterirritants, are also needed. Local cutaneous adverse reactions (e.g., erythema, rash, pruritus, and irritation) are reported and may be due in part to the vehicle used.^{35–38}

Local Anesthetics. Nonprescription topical anesthetics such as lidocaine and benzocaine are available in many types of products. Local anesthetics decrease discharges in superficial somatic nerves and cause numbness on the skin surface but do not penetrate deeper structures such as muscle where the pain often lies.¹⁹

However, local anesthetics are helpful when abrasion accompanies the injury. Application of an OTC antibiotic ointment containing an anesthetic provides soothing relief, promotes healing of abrasions, and prevents soft-tissue infection. Minor abrasions should be cleansed thoroughly with mild soap and water before application. More severe abrasions may require removal of debris or foreign bodies by a clinician followed by irrigation with normal saline.

• **Counterirritants.** Counterirritants are categorized by the FDA into four groups (groups A through D) based on their

Table 60–2

Patient Education for Topical NSAIDs

All Topical NSAIDs	Gel-Specific	Patch-Specific	Solution-Specific
Do not apply to damaged or nonintact skin Wash hands after application and/or removal Discontinue use if rash or irritation develops Do not use with oral NSAIDs	Use enclosed dosing card to determine amount for application Avoid bathing or showering for 1 hour after application Avoid sun exposure or tanning beds Do not use with other topical agents (e.g., sunscreens, lotions, moisturizers, and insect repellants)	Apply to skin at the most painful area Do not wear during bathing or showering Tape patch in place if it begins to peel off Discard used patches away from children and pets	Recommended dose is 40 drops to the each affected knee four times daily Apply 10 drops at a time directly to the knee or on the hand, then the knee Rub evenly around front, back, and sides of the knee Do not cover with clothing or apply other topical products onto knee until completely dry

From Refs. 35–37.

Table 60-3

Nonprescription Counterirritant External Analgesics

Group and Effect	Agents and Concentration	Example Products (If Applicable)	Comments
Group A Rubefacients: Produce redness	Allyl isothiocyanate 0.5–5% Ammonia water 1–2.5% Methyl salicylate 10–60%	BenGay Ultra Strength ^a Flexall Plus ^a Icy Hot Stick ^a	Mustard derivative; pungent odor; avoid inhalation More concentrated solutions are highly caustic; avoid inhalation Caution in aspirin sensitivity May produce systemic concentrations May increase INR with warfarin
Group B Produce cooling	Camphor 3–11% Menthol 1.25–16%	JointFlex BenGay Patch Icy Hot Patch Mineral Ice	Medicinal odor Sensation of heat follows cooling Mild anesthetic effects at low concentrations
Group C Produce vasodilation	Methyl nicotinate 0.25–1%		May produce systemic vasodilation
Group D Irritate without redness	Capsaicin 0.025–0.25% Capsicum oleoresin 0.025–0.25%	Capzasin-HP, Zostrix	Must use regularly Burning effect subsides with regular use

INR, International Normalized Ratio.

^aCombination products that also contain menthol and/or camphor.

primary actions (Table 60-3). They produce a feeling of warmth, cooling, or irritation that diverts sensation from the primary source of pain. Because these irritant effects are central to the beneficial actions, counterirritants should not be combined with topical anesthetics or topical analgesics.

Counterirritants are indicated for the temporary relief of minor aches and pains related to muscles and joints.²¹ These symptoms may be associated with simple backache, arthritis, strains, sprains, or bruises. Many are available commercially as combination products with ingredients from different counterirritant groups. Active ingredients in marketed products sometimes change; clinicians should be aware of the current ingredients before providing a product recommendation. **9** *Patient education on proper use of counterirritants is essential to therapeutic success (Table 60-4).*²¹

Rubefacients (group A) are counterirritants that produce redness on application. Topical rubefacients containing salicylates (e.g., methyl salicylate) are used most commonly. Turpentine oil is no longer judged as either safe or effective but remains in a few products.²¹ Clinical trial data evaluating the effect of rubefacients on acute pain from strains, sprains, sports injuries, and chronic musculoskeletal pain are lacking.³⁹ A systematic review of available evidence noted that topical salicylates are effective for pain from acute musculoskeletal conditions, but the low quality of the evidence led authors to conclude that there are no good data supporting the efficacy of rubefacients.³⁹

Methyl salicylate and trolamine salicylate are topical salicylates. Methyl salicylate is considered a counterirritant, but trolamine salicylate is not considered a counterirritant because it does not produce localized irritation after application.

Table 60-4

Patient Education for Counterirritants

Apply up to 3–5 times daily to affected area.
Only for external use on the skin; do not ingest.
Do not apply to broken or damaged skin or cover large areas.
Wash hands immediately after application.
Avoid contact with the eyes and mouth.
Do not use with heating pads or other methods of heat application, because burning or blistering can occur.
Do not wrap or bandage the area tightly after application.
Consult a physician if:

- Symptoms worsen
- Symptoms persist for more than 7 days^a
- Symptoms resolve but then recur

^aCapsaicin may be used for chronic pain and must be applied consistently for efficacy.

From External analgesics drug products for over-the-counter human use: Tentative final monograph. Fed Regist 1983;48: 5851–5869.

Application of both topical salicylates can lead to systemic effects, especially if the product is applied liberally.⁴⁰ Repeated application and occlusion with a wrap or bandage also can increase systemic concentrations. Salicylate-containing products should be used with caution in patients in whom systemic salicylates are contraindicated, such as patients with severe asthma or aspirin allergy.⁴⁰ Topical salicylates have been reported to increase prothrombin time in patients on warfarin and should be used with caution in

patients on oral anticoagulants. Methyl salicylate, including oil of wintergreen, is one of the most common sources of pediatric poisonings.⁴¹ Clinicians should advise patients to keep products out of the reach of children.

The FDA advises that there is insufficient evidence to support the effectiveness of trolamine salicylate contained in products such as Aspercreme.²¹ However, many patients choose trolamine products because of the lack of medicinal odor.

The group B counterirritants menthol and camphor exert a sensation of cooling through direct action on sensory nerve endings.^{40,42} A sensation of warmth follows the cooling effect. The agents also have mild anesthetic activity at low concentrations.⁴² In higher concentrations, they act as counterirritants and cause a burning sensation by stimulating cutaneous nociceptors. Menthol and camphor are used often in combination with rubefaciants.

Menthol, also known as peppermint oil, is used widely in toothpastes, mouthwashes, gum, sore-throat lozenges, lip balms, and nasal decongestants. For topical analgesic use, it is available in creams, lotions, ointment, and patches. The patches can be trimmed to fit the affected area.

Menthol and camphor have caused respiratory distress in infants and should not be used in children under 2 years of age. Despite limits on the concentration of available products, camphor can be toxic to children even in small amounts.⁴³ Patients should be advised to keep the products out of the reach of children.

The group C counterirritants methyl nicotinate and histamine dihydrochloride produce vasodilation.²¹ Methyl nicotinate is a nicotinic acid derivative that produces PG-mediated vasodilation.⁴⁴ NSAIDs and aspirin block the production of PGs and decrease methyl nicotinate-induced vasodilation. Application over a large area has been reported to cause systemic symptoms and syncope, possibly due to vasodilation and a decrease in blood pressure.⁴⁵ Patients should be educated to apply only scant amounts to the affected area to avoid this effect.

The primary counterirritant in group D is capsaicin, a natural substance found in red chili peppers and responsible for the hot, spicy characteristic when used in foods.^{19,32,33} Capsaicin stimulates the release of substance P from local sensory nerve fibers, depleting substance P stores over time. A period of reduced sensitivity to painful stimuli follows, and transmission of pain impulses to the CNS is reduced.

As with other counterirritants, capsaicin and its derivatives (i.e., capsicum and capsicum oleoresin) exert a warming or burning sensation. With repeated application, desensitization occurs, and the burning sensation subsides. This typically occurs within the first 1 to 2 weeks. After discontinuation, resensitization occurs gradually and returns completely within a few weeks.⁴⁶

Because of the lag time between initiation and effect, capsaicin is not used for treatment of acute pain from injury. Instead, topical capsaicin is used for chronic pain from musculoskeletal and neuropathic disorders. Capsaicin preparations have been studied in the treatment of pain from diabetic neuropathy, osteoarthritis, rheumatoid arthritis,

postherpetic neuralgia, and other disorders.⁴⁷ It is often used as an adjuvant to systemic analgesics in these chronic pain conditions.

Although systemic adverse effects to capsaicin are rare, local adverse effects are expected and common.^{19,32} Patient education regarding consistent use of capsaicin products is essential to achieving desired outcomes. Product should be applied in a thin layer and rubbed into the skin thoroughly until little remains on the surface.⁴⁰ **10** *Patients using capsaicin should be advised to apply it regularly and consistently three to four times daily and that full effect may take 1 to 2 weeks or longer.* Patients should be assured that the burning effects will diminish with repeated application. Adherence to therapy is essential because the burning sensation persists if applications are less frequent than recommended. Because the burning sensation is enhanced with heat, patients should avoid hot showers or baths immediately before or after application. Wearing gloves during application can decrease the potential for unintended contact with eyes or mucous membranes. Dried product residue has been reported to cause respiratory effects on inhalation,⁴⁷ and caution should be used in patients with asthma or other respiratory illnesses.

► Muscle Relaxants

Where pain is worsened by muscle spasm, oral muscle relaxants serve as a useful adjunct to therapy.⁴⁸ These agents include baclofen, metaxalone, methocarbamol, carisoprodol, and cyclobenzaprine. Muscle relaxants decrease spasm and stiffness associated with either acute or chronic musculoskeletal disorders. These agents should be used with caution because they all may cause sedation, especially in combination with alcohol or narcotic analgesics.

Lifestyle and Behavioral Modifications

After treatment of the acute injury with RICE and pharmacologic therapy, the final phase of therapy is rehabilitation and prevention of future injury. For most injuries, prolonged immobilization can lengthen the recovery time by causing wasting of the healthy muscle fibers.¹⁴ Rehabilitation starts with the development of range of motion via stretching exercises. Patient should warm the muscle first with light activity or moderate heat.⁹ Warmth produces relaxation and increases elasticity. Next, the patient should start general strengthening exercises.⁴⁹ Resistance exercises using resistance bands available at sporting goods stores are an effective method of strengthening. Strengthening and stretching exercises should be continued beyond the healing phase to prevent future injury.

After rehabilitation, the patient should be educated about behavior changes to prevent reinjury or the development of chronic pain.^{14,49} The warm-up and strengthening routines learned in the rehabilitation phase should be continued. For overuse injury, correction of biomechanical abnormalities with proper footwear and changes in technique may correct misalignments and imbalances. Repetitive trauma can

Patient Encounter 1, Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH: Atrial fibrillation

SH: Denies smoking; drinks wine with dinner on Saturdays

Meds: Warfarin 5 mg once daily, as directed to goal INR 2.0–3.0

Allergies: NKDA

Diagnostic Tests: Radiographs of left ankle show no evidence of fracture

What are your treatment goals and desired outcomes?

What nonpharmacologic and pharmacologic treatment options are available? Are there treatment options that should be avoided? If so, which options and why?

Patient Encounter 2

A 60-year-old woman presents with right elbow pain. On questioning, you determine that she works in the kitchen in a family restaurant and has the responsibility for chopping all of the ingredients every day. She is right-handed and reports a gradual onset of pain over the last few months. When she wakes in the morning, she has minimal pain after resting overnight, but the pain intensifies after a few hours in the kitchen. She tends to have less pain on weekends when she only does cooking for her own family and she has help from her granddaughter. She reports decreased range of motion compared with the left side. She is a nonsmoker and does not drink. She has a past medical history of asthma, which is well controlled on a beclomethasone inhaler; she reports an allergy to aspirin, which causes wheezing.

Given this information, what is your assessment of the patient's elbow pain? What is the likely etiology of the pain?

What nonpharmacologic and pharmacologic treatment options should be considered?

Based on the information presented, create a care plan for this patient's elbow injury. Your plan should include:

(a) The goals of therapy and desired outcomes

(b) A patient-specific therapeutic plan, including nonpharmacologic therapy

(c) A monitoring plan to determine whether goals of therapy have been met and adverse effects avoided

be decreased with proper training (e.g., by implementing a gradual increase in mileage in a running plan).

Patients with low back pain should be advised to stay active, as inactive muscles may become more sensitive to pain.⁵⁰ In the workplace, repetitive motion can be decreased through proper ergonomic design and diversification of job tasks.⁵¹ In pain of the lower extremity, weight loss in overweight or obese patients can assist in reduction of further inflammation and help to prevent reinjury or repetitive strain injuries. Non-weight-bearing activities, such as swimming or bicycling, can be recommended for initial return to activity.⁵²

OUTCOME EVALUATION

- Use a pain scale to monitor treatment interventions to ensure that pain relief is achieved. Ask the patient to rate pain on a scale of zero (no pain) to 10 (worst possible pain) both at rest and with movement. Compare the results with baseline pain assessment to monitor the response to therapy. In pediatric patients, use a visual

pain scale with facial expressions depicting various degrees of pain.

- Assess range of motion at baseline and after treatment by comparing movement with the unaffected limb and functionality before the injury. Assess functionality by asking patients if they are able to perform activities of daily living or participate in exercise as desired.
- If pain from acute injury does not decrease greatly within 7 to 10 days, further diagnostic evaluation is warranted.
- For patients using capsaicin products, assess adherence to regular application for therapeutic benefit. Assess chronic pain control in 2 weeks.
- Assess medication adverse effects on a regular basis. When NSAIDs and aspirin are used, ask about GI tolerability, bruising, and bleeding. Inquire about local adverse effects, such as burning, when topical counterirritants are used for treatment.
- Evaluate adherence to preventative rehabilitation measures such as proper footwear, warm-up before activity, strength training, and proper lifting technique.

Patient Encounter 1, Part 3: Creating a Care Plan

Based on the information presented, create a care plan to treat this patient's ankle injury. Your plan should include the following:

(a) The goals of therapy and desired outcomes

(b) A patient-specific therapeutic plan, including nonpharmacologic therapy

(c) A plan to monitor the outcome of therapy to determine whether goals of therapy have been met and adverse effects avoided

Patient Care and Monitoring

1. Assess the patient's symptoms to determine whether empirical care is appropriate or whether diagnostic evaluation is warranted. Determine the timing of injury (if applicable), duration of pain, type and degree of pain, and exacerbating factors. Determine whether the musculoskeletal disorder interferes with usual activities or range of motion.
2. Assess exacerbating or alleviating factors. Ask if the patient has tried any nonpharmacologic or pharmacologic treatments.
3. Obtain a complete medication history, including history of prescription drug, nonprescription drug, and dietary supplement use. Determine whether the patient has used any successful or unsuccessful treatments for this condition in the past.
4. Gather patient history. Assess factors involved in drug selection. Inquire about social history and alcohol use. Ask the patient about drug allergies and chronic health problems such as asthma.
5. Educate the patient on nonpharmacologic therapy, including each of the steps in RICE. If injury is the source of the pain and it occurred more than 48 hours ago, consider heat instead of ice.
6. Assess patient preference for systemic (oral) or local (topical) therapy. Would frequent application of topical medications be possible? Would the patient accept topical medications with a medicinal odor?
7. Recommend appropriate pharmacologic therapy and educate on proper use. If a counterirritant is recommended, counsel patients on the irritant effect of the product and recommend washing hands immediately after use and to avoid heating pads. For patients using a capsaicin product, emphasize that adherence to regular application is required for effectiveness.
8. Develop a plan to assess effectiveness of pharmacologic therapy. If pain is from an acute injury, assess effectiveness within 7 to 10 days. For chronic pain treated with capsaicin, begin to assess pain control in 2 weeks.
9. Evaluate for adverse effects and drug interactions. For patients on topical therapy, evaluate for local adverse effects. For patients on oral acetaminophen or NSAIDs, inquire about alcohol use.
10. Stress lifestyle modifications for rehabilitation and prevention. Recommend strength training, range-of-motion exercises, and a warm-up period before exercise. In repetitive-motion injury, recommend methods to correct biomechanical abnormalities and vary work tasks as applicable. Refer to a physical therapist or sports trainer as needed.

Abbreviations Introduced in This Chapter

COX	Cyclooxygenase
NSAIDs	Nonsteroidal anti-inflammatory drugs
PG	Prostaglandin

Glaucoma

Mikael D. Jones

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Identify risk factors for the development of primary open-angle glaucoma (POAG) and acute angle-closure glaucoma.
2. Recommend a frequency for glaucoma screening based on patient-specific risk factors.
3. Compare and contrast the pathophysiologic mechanisms responsible for open-angle glaucoma and acute angle-closure glaucoma.
4. Compare and contrast the clinical presentation of chronic open-angle glaucoma and acute angle-closure glaucoma.
5. List the goals of treatment for patients with POAG suspect, POAG, and acute angle-closure glaucoma.
6. Choose the most appropriate therapy based on patient-specific data for open-angle glaucoma, glaucoma suspect, and acute angle-closure glaucoma.
7. Develop a monitoring plan for patients on specific pharmacologic regimens.
8. Counsel patients about glaucoma, drug therapy options, ophthalmic administration techniques, and the importance of adherence to the prescribed regimen.

KEY CONCEPTS

- 1 Practitioners can play an important role in eye care by assessing patients for risk factors and referring to an ophthalmologist for appropriate screening and evaluation.
- 2 Acute angle-closure crisis is a medical emergency and requires laser or surgical intervention.
- 3 Patients with POAG typically have a slow, insidious loss of vision. This is contrasted by the course of acute angle-closure crisis, which can lead to rapid vision loss that develops over hours to days. There are exceptions in the rate of progression for both disease subtypes, and there can be mixed subtypes whereby patients exhibit features of both diseases, so-called “combined mechanism glaucoma.”
- 4 The goals of therapy are to prevent further loss of visual function; minimize adverse effects of therapy and impact on the patient’s vision, general health, and quality of life; maintain IOP at or below a pressure at which further optic nerve damage is unlikely to occur; and educate and involve the patient in the management of their disease.
- 5 Current therapy is directed at altering the flow and production of aqueous humor, which is the major determinant of IOP.
- 6 Because POAG is a chronic, often asymptomatic condition, the decision of when and how to treat patients is difficult because the treatment modalities are often expensive and have potential adverse effects or complications. Therefore, the clinician should evaluate the potential effectiveness, toxicity, and the likelihood of patient adherence for each therapeutic modality.
- 7 An initial target IOP should be set at least 25% lower than the patient’s baseline IOP. The target IOP can be set lower (30% to 50% of baseline IOP) for patients who already have severe disease, risk factors for disease progression, or normal-tension glaucoma (NTG).
- 8 Target IOP should be revised based on the course of the disease and rate of progression.

INTRODUCTION

Glaucoma refers to a spectrum of ophthalmic disorders characterized by neuropathy of the optic nerve and loss of retinal ganglion cells, which leads to permanent deterioration of the

visual field and potentially total vision loss. It is often, but not always, eye pressure related. Glaucoma can be classified as primary and secondary. *Primary glaucoma* refers to glaucoma that cannot be attributed to a preexisting ocular or systemic disease, whereas *secondary glaucoma* refers to glaucoma that can be attributed to preexisting ocular or systemic disease. Examples of primary glaucoma include open-angle, closed angle, and congenital. Examples of secondary glaucoma include pigmentary glaucoma, neovascular glaucoma, traumatic glaucoma, uveitic glaucoma, steroid-responsive glaucoma, aphakic glaucoma, and pseudoexfoliative glaucoma.

Primary open-angle glaucoma (POAG) is characterized by normal anterior-chamber angles, glaucomatous changes of the optic disc, and often peripheral visual field loss (initial stages of glaucoma sometimes result in no visual field loss). Patients with ocular hypertension (elevated IOP) that have normal-appearing anterior-chamber angles anatomy and/or an eye exam suspicious of early glaucomatous damage are classified as POAG suspects. Patients with a normal eye pressure, with measurements obtained from more than one visit, and one or both optic nerves with anatomic features consistent with nerve fiber loss are also classified as glaucoma suspects. Primary angle-closure glaucoma (PACG) is characterized by the obstruction of the anterior chamber angle resulting in either intermittent or progressive (often times acutely) elevated IOP with subsequent damage to the optic nerve. PACG is associated with moderate to high elevations in IOP.¹⁻⁴ PACG can progress to acute angle-closure crisis when a large percentage of the chamber angle is obstructed, resulting in a rapid increase in IOP. POAG and PACG represent the most common types of glaucoma and therefore are the focus of this chapter.

EPIDEMIOLOGY AND ETIOLOGY

It is estimated that 60.5 million people have open-angle or angle-closure glaucoma in 2010, making it the second leading cause of blindness after cataracts. By 2020 this number may increase to almost 80 million people worldwide.⁵ In the United States it is estimated that 2.22 million people are affected by POAG, and by 2020 this number will increase to 3.36 million. The prevalence varies with race and ethnicity, and it is three to five times more prevalent in African Americans than white Americans.⁶ The prevalence of POAG increases with age and is rarely seen in patients younger than 40 years.^{5,6} The prevalence of POAG suspects is difficult to estimate at this time, but it is estimated that 3.5% to 4.5% of white and Hispanic patients older than 40 years have ocular hypertension.³ Other estimates indicate that 3 to 6 million of the U.S. population has ocular hypertension; however, less than 10% will have progression to POAG within 5 years, with an increase to 22% after 13 years.^{7,8}

Almost 16 million people were estimated to have angle-closure glaucoma in 2010, and this is projected to increase to 21 million people by 2020.⁵ The prevalence of angle-closure glaucoma is lower than POAG and varies significantly by race and ethnicity. The prevalence is lower in patients of European descent (0.09% to 0.16%) but higher in patients

Table 61-1

Recommended Frequency of Comprehensive Adult Medical Eye Evaluation

Age (Years)	With Risk Factors for Glaucoma	No Known Risk Factors for Ocular Disease
65 or above	6–12 months	1–2 years
55–65	1–2 years	1–3 years
40–54	1–3 years	2–4 years

From American Academy of Ophthalmology. Preferred Practice Pattern Guidelines Comprehensive Adult Medical Eye Evaluation. San Francisco, CA: American Academy of Ophthalmology, 2010 [cited 2011 Oct 3]. <http://www.aao.org/ppp>.

Table 61-2

Risk Factors for Glaucoma

POAG	PACG
Elevated IOP	Advancing age
African or Hispanic descent	Asian or Eskimo ethnicity
Family history of glaucoma	Female sex
Older age	Hyperopia
Thinner CCT	Shallow anterior chamber
Type 2 diabetes	Family history of angle-closure glaucoma
Low ocular perfusion pressures	
Myopia	

CCT, central corneal thickness; IOP, intraocular pressure; POAG, primary open-angle glaucoma; PACG, primary angle-closure glaucoma.

From Refs. 2, 4.

of Chinese (1.3%), Eskimo (2.9% to 5%), and Asian Indian (4.33%) descent. PACG is also more prevalent with increasing age and among females.^{1,9}

POAG is a “silent disease,” with patient’s not experiencing vision loss until late in the disease process. **1** *Practitioners can play an important role in eye care by assessing patients for risk factors and referring to an eye care specialist for appropriate screening and evaluation.* Risk factor evaluation is essential in determining the frequency of comprehensive eye exams for patients (**Table 61-1**). It is also useful in deciding when to start therapy and determining the sequence of pharmacotherapeutic or surgical treatment modalities.¹ **Table 61-2** lists the major risk factors associated with POAG and PACG.

PATHOPHYSIOLOGY

The pathophysiologic alterations seen with POAG optic neuropathy are not fully understood. Elevated IOP is clearly associated with damage and eventual death of optic nerves;

Patient Encounter, Part 1

SJ, a 75-year-old Hispanic female with a history of congestive heart failure and hypertension, presents to your clinic for her yearly checkup. She states that she is concerned about losing her eyesight because her sister has started losing her vision from glaucoma. She denies any changes in her vision.

Meds: lisinopril 10 mg orally daily, carvedilol 6.25 mg orally twice daily, furosemide 20 mg PO once daily

Based on the patient's medical and family history, what risk factors does this patient have for glaucoma?

What objective assessments should be gathered in order to fully evaluate her risk factors for glaucoma?

How often would you recommend that this patient receive a comprehensive eye evaluation?

however, optic neuropathy still occurs in patients with a normal IOP. Optic nerve degeneration without elevated IOP indicates the presence of independent factors that contribute to ganglion cell death.^{10,11} The key to understanding the pathophysiology and treatment of POAG relies on an understanding of aqueous humor dynamics, IOP, and optic nerve anatomy and physiology.

Aqueous Humor

The eye is separated into two segments by the lens: the anterior segment and the posterior segment (Figs. 61-1 and 61-2). The anterior segment of the eye is separated by the iris

into the posterior and anterior chambers. The ciliary body, a ring-like structure that surrounds and supports the lens, produces and secretes an optically neutral fluid called aqueous humor through the diffusion and ultrafiltration of plasma. The nonpigmented epithelium of the ciliary body secretes the aqueous humor into the posterior chamber. Aqueous humor formation can be modified pharmacologically

FIGURE 61-1. Anatomy of the eye. (From Lesar TS, Fiscella RG, Edward D. Glaucoma. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York: McGraw-Hill, 2011:1634.)

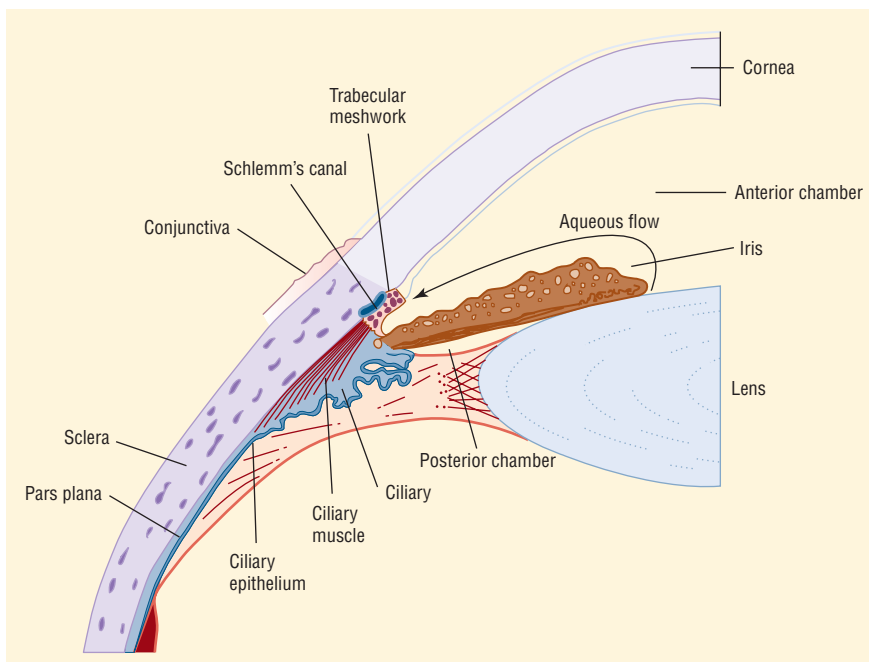

FIGURE 61-2. Anterior chamber of the eye and aqueous humor flow. (From Lesar TS, Fiscella RG, Edward D. Glaucoma. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York: McGraw-Hill, 2011:1634.)

through the α - and β -adrenoceptors, carbonic anhydrase, and sodium and potassium adenosine triphosphatase of the nonpigmented ciliary epithelium.^{12,13}

After the transport of aqueous humor into the posterior chamber, it flows through the pupil into the anterior chamber, where it provides oxygen and nutrition to the avascular lens and cornea. Aqueous humor then exits the anterior chamber through the trabecular meshwork and drains into the Schlemm's canal, which drains aqueous humor into the episcleral venous system.¹²⁻¹⁴

Eighty percent of aqueous humor drains through the trabecular meshwork, which is a lattice of connective tissue that surrounds the anterior chamber. The size of the trabecular meshwork can be altered by the contraction or the relaxation of the ciliary muscle. Stimulation of muscarinic receptors on the ciliary muscle causes contraction, which in turn causes the pores of the trabecular meshwork to open, increasing aqueous humor outflow.^{12,13}

A second pathway, uveoscleral outflow, comprises the other 20% of aqueous humor drainage. In the uveoscleral pathway, aqueous humor exits the anterior chamber through the iris root and through spaces in the ciliary muscles, which then drains into the suprachoroidal space. Uveoscleral outflow can be pharmacologically modulated by adrenoceptors, prostanoid receptors, and prostamide receptors.¹²⁻¹⁴

Intraocular Pressure

IOP is dependent on the balance between aqueous humor production and outflow and is important because the refractive properties of the eye depend on IOP to maintain the curvature of the cornea.¹⁵ The distribution of IOP in the general population is 10 to 21 mm Hg and is slightly skewed toward higher values; however, caution should be used in assigning this range as being “normal” for IOP because optic neuropathy may be present in the normal range and may be absent at higher IOPs. Elevated IOP is generally considered greater than 21 mm Hg. Optic nerve damage generally is slow and takes several years for noticeable progression between 20 and 30 mm Hg, whereas IOP of 40 to 50 mm Hg may lead to rapid optic nerve damage.¹⁶ IOP varies in a cyclic fashion over the 24-hour day. Patients with and without glaucoma may exhibit a circadian rhythm that consists of a peak in IOP right after falling asleep. Nighttime peaks in IOP are detrimental to patients with glaucoma, because systemic blood pressure decreases during the night, resulting in a low ocular perfusion pressure. Decreased ocular perfusion pressure can lead to further optic nerve damage, therefore highlighting the importance of IOP control throughout a 24-hour period.^{17,18}

IOP is clinically measured by **tonometry** and can be performed via applanation, indentation, and indirect tonometry. Central corneal thickness (CCT) affects the accuracy of IOP measurements. Thin corneas (less than 540 microns) can produce falsely low IOP readings, whereas thick corneas (greater than 555 microns) may produce falsely high readings. The potential consequences of this error in measurement may lead to overtreatment of patients with falsely high

IOP and undertreatment of patients with falsely low IOP. The Ocular Hypertension Treatment Study (OHTS) demonstrated that CCT is a predictive factor for the development of POAG. Patients with corneas less than 555 microns and IOP greater than 25.75 mm Hg had a 36% risk of progressing from ocular hypertension to glaucoma. The CCT of patient should be considered when evaluating a patient's IOP.¹⁹ IOP is no longer used as a diagnostic criterion for glaucoma, because the presence of glaucomatous changes can be absent at high IOPs and can be present at lower IOPs.

Optic Nerve

The posterior segment of the eye contains vitreous humor (a clear “jellylike” substance), the retina, retinal vasculature, and the optic nerve head. The retina converts light energy into neural signals, which are transmitted out of the eye by the retinal ganglion cells. The axons of the retinal ganglion cells converge and exit the eye as a bundle through the **lamina cribrosa**. The converged axons form the optic nerve (**Fig. 61-3**). The optic nerve contains 1 million nerve fibers and synapses at the lateral **geniculate nucleus** in the brain. The optic nerve head is the portion of the optic nerve that is susceptible to elevations in IOP and is visible on fundoscopic examination. The optic nerve head is vertically oval and pale yellow with a depression in the center of the optic nerve, called a physiologic cup, which is formed by convergence of the axons. The area surrounding the optic nerve head is the nerve fiber layer, which consists of converging retinal ganglion cell axons. The retinal artery and vein are contained within the optic nerve head. Additionally, glial cells aid in the maintenance of homeostasis, protection, and nutrition of retinal ganglion cells.^{10,11,14}

Glaucomatous changes to the optic nerve head precede visual field loss, making optic nerve head evaluation a

FIGURE 61-3. Normal fundus of the eye and optic disk and cup. (Reprinted with permission from Lesar TS, Fiscella RG, Edward D. Glaucoma. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York: McGraw-Hill, 2011:1635.)

useful screening and prognostic tool. The optic nerve head should be assessed for cupping, nerve fiber layer changes, and presence of splinter hemorrhages using a **slit-lamp biomicroscope**. Cupping refers to an increase in the size of the physiologic cup. The cup increases with the loss of retinal ganglion cell axons and the collapse of lamina cribrosa. The cup size is expressed as the ratio of the size of the cup to the size of the optic nerve head. A cup-to-disc ratio greater than 0.55 is associated with an increased risk of developing visual field loss. Other findings include atrophy and notching of the nerve fiber layer.^{11,14}

Pathophysiology of Open-Angle Glaucoma

The pathophysiology of glaucomatous neurodegeneration has not been completely elucidated but appears to be caused by both IOP-dependent and IOP-independent factors. In patients with POAG, the cause of elevated IOP is not obvious, as obstruction in aqueous humor outflow is not clinically discernible. Possible causes of this increased IOP may be related to an increase in outflow resistance in the trabecular meshwork. Some forms of POAG have been associated with a mutation in the *MYOC* gene that codes a protein called myocilin. Myocilin is a protein that is produced by the ciliary body and trabecular meshwork, but its function is not known. The mutated form of myocilin may accumulate intracellularly in trabecular meshwork tissue, subsequently damaging the cells and altering aqueous humor outflow. However, this does not explain the increase in IOP in all patients with POAG.¹⁰

Regardless of the underlying cause, elevated IOP initiates several detrimental changes to glial cells, the lamina cribrosa, and retinal ganglion cells. The increase in IOP can lead to alterations in retinal blood flow and axonal transport of neurotrophic factors, resulting in cellular stress of the retinal ganglion cells. This stress activates the glial cells in a manner that leads to inappropriate remodeling of the extracellular matrix. Elevated IOP deforms the lamina cribrosa, which places further strain on the retinal ganglion cells. Chronic elevation of IOP ultimately causes the retinal ganglion cells to undergo apoptosis.^{10,11,14,20}

Glaucomatous optic neuropathy may also occur independent of increased IOP. Pressure independent causes of optic neuropathy include abnormal blood flow, systemic hypotension, and abnormal blood coagulability.^{14,16,18} Current glaucoma therapies fail to target IOP-independent glaucoma pathophysiologic factors. However, IOP reduction may still be beneficial, as the rate of visual field progression is decreased in some patients who receive IOP reduction via medical or surgical modalities.²¹

Pathophysiology of Angle-Closure Glaucoma

PACG involves a mechanical obstruction of aqueous humor outflow through the trabecular meshwork by the peripheral iris. Two major mechanisms of trabecular meshwork obstruction by the peripheral iris include pupillary block and an abnormality of the iris called *iris plateau*. Pupillary block

Clinical Presentation and Diagnosis of POAG

General

- Adult onset (usually greater than 40 years of age)
- Patients may be unaware that they have glaucoma and may be diagnosed during routine eye evaluation
- POAG is usually bilateral with asymmetric disease progression

Symptoms

- Patients with severe disease progression may report loss of peripheral vision and may describe the presence of scotomata (blind spots) in their field of vision

Signs

Ophthalmoscopic examination may reveal:

- Optic nerve head (optic disc) cupping
- Large cup-to-disc ratio
- Diffuse thinning, focal narrowing, or notching of the optic nerve head rim
- Splinter hemorrhages
- Optic nerve head/nerve fiber layer changes occur before visual field changes can be detected

Diagnostic Tests

- Gonioscopy—anterior-chamber angles are to be open
- Applanation tonometry—elevated IOP (greater than 21 mm Hg) may be present. However, patient can have signs of optic neuropathy without elevated IOP
- Pachymetry—measures central corneal thickness. Thin corneas (less than 540 μm) are considered a glaucoma risk factor.
- Automated static threshold perimetry—evaluates visual fields. Useful in diagnosis and determining whether there is progression
- Other diagnostic tests—scanning laser polarimetry, confocal scanning laser ophthalmoscopy, and optical coherence tomography

is the more common mechanism of obstruction and results from a complete or functional apposition of the central iris to the anterior lens and is associated with mid-dilation. The trapped aqueous humor in the posterior chamber increases pressure behind the iris, causing the peripheral iris to bow forward and obstruct the trabecular meshwork. Plateau iris refers to an anterior displacement of the peripheral iris caused by anteriorly positioned ciliary processes. In this configuration the peripheral iris bunches as the eye dilates. Both of these mechanisms result in the occlusion of aqueous humor outflow, causing IOP elevation at extreme levels that can lead to vision loss in hours to days.^{2,11,22} The degree of iridotrabecular contact (angle closure) can be determined by **gonioscopy**.

The development of PACG is associated with several anatomical risk factors that lead to shallow anterior chambers. PACG patients may have a thick, anteriorly displaced lens that results from myopia or cataractous change. The anterior chamber depth may be shallower in some individuals with PACG, which predisposes those eyes to anatomically narrower iridocorneal inlets that are a set-up for developing critically narrow angles more susceptible to closure (from an enlarging cataractous lens or other insults).^{2,22}

Medications with anticholinergic properties induce mydriasis, which can lead to angle closure in pupillary block and plateau iris. Pupillary block may also be induced by drugs that cause miosis.²³

Patients with PACG are characterized by at least 180 degrees of iridotrabecular contact, elevated IOP, and ophthalmic exam characteristic of glaucomatous changes. Acute angle-closure crisis is the sudden obstruction of the trabecular meshwork, which leads to rapid increases in IOP resulting in pressure-induced optic neuropathy if left untreated.

2 *Acute angle-closure crisis is a medical emergency and requires urgent laser or surgical intervention.* Recurrent attacks or a prolonged acute attack can lead to the development of peripheral anterior **synechia**, which partially obstructs the flow of aqueous humor through the trabecular meshwork. Patients with peripheral anterior synechia and glaucomatous changes can be classified as PACG.^{2,22}

► Clinical Course

3 *Patients with POAG typically have a slow, insidious loss of vision. This is contrasted by the course of acute angle-closure crisis, which can lead to rapid vision loss that develops over hours to days.* For POAG, only 4% to 8% of patients may progress to legal blindness. It may take 13 to 16 years for a patient to go blind from glaucoma. A patient's quality of life

may not be affected until significant visual field loss is present and the patient can no longer perform the activities of daily living.²⁴ Vision loss does not occur until there has been significant loss of the retinal ganglion cells. Peripheral vision is the most susceptible to glaucomatous damage, with central vision being preserved until advanced disease progression has occurred. Visual field abnormalities include **paracentral scotoma**, **nasal scotoma**, and **arcuate scotoma**. Patients may also have problems with depth perception and contrast sensitivity. Peripheral vision may worsen until the patient has tunnel vision and ultimately total field loss.^{11,14} Visual fields can be measured by **perimetry** and can detect defects in the visual field before a patient may notice.²⁵

TREATMENT

Primary Open-Angle Glaucoma

► Desired Outcomes and Goals

4 *The goals of therapy are to prevent further loss of visual function; minimize adverse effects of therapy and impact on the patient's vision, general health, and quality of life; maintain IOP at or below a pressure at which further optic nerve damage is unlikely to occur; and educate and involve the patient in the management of their disease.* 5 *Current therapy is directed at altering the flow and production of aqueous humor, which is the major determinant of IOP.*

► General Approach

6 *Because POAG is a chronic, often asymptomatic condition, the decision of when and how to treat patients is difficult, as the treatment modalities are often expensive and have potential adverse effects or complications. The clinician should*

Clinical Presentation and Diagnosis of Acute Angle-Closure Crisis

General

- Medical emergency due to high risk of vision loss
- Unilateral in presentation, but fellow eye is at risk

Symptoms

- Ocular pain
- Red eye
- Blurry vision
- Halos around lights
- Systemic symptoms may develop
 - Nausea/vomiting
 - Abdominal pain
 - Headache
 - Diaphoresis

Signs

- Cloudy cornea caused by corneal edema
- Conjunctival hyperemia
- Pupil semidilated and fixed to light
- Eye will be harder on palpation through closed eye

Diagnostic Tests

- Gonioscopy—anterior-chamber angles will be closed. Peripheral anterior synechiae may be present.
- Applanation tonometry—elevated IOP (greater than 21 mm Hg, but when symptoms are present, IOP may be greater than 30 mm Hg)
- Slit-lamp biomicroscopy—reveals shallow anterior-chamber depth. Signs of previous attacks include peripheral anterior synechiae, iris atrophy, and pupillary dysfunction

evaluate the potential effectiveness, toxicity, and the likelihood of patient adherence for each therapeutic modality. The ideal therapeutic regimen should have maximal effectiveness and patient tolerance to achieve the desired therapeutic response. The American Academy of Ophthalmology (AAO) publishes Preferred Practice Patterns for POAG and POAG Suspect.^{3,4}

Before the selection of a therapeutic modality, the target IOP should be determined for each patient. The target IOP ideally represents an IOP range that will slow the progression of optic neuropathy and not simply obtain an IOP in the range of 10 to 21 mm Hg. Currently, the initial target IOP is an estimate, but it should be modified based on the progression of the disease at each follow-up visit. **7** The AAO recommends an initial target IOP to be set at least 25% lower than the patient's baseline IOP. The target IOP can be set lower (30% to 50% of baseline IOP) for patients who already have severe disease, risk factors for disease progression, or have normal-tension glaucoma (NTG).^{4,21} Risk factors for progression include high IOP, older age, hemorrhage of the optic disc, large cup-to-disc ratio, thinner CCT, and established glaucomatous progression.

Initial IOP control can be achieved by medical, laser, surgical, or combination of these therapies. The AAO guidelines do not provide a specific recommendation on which therapeutic modality should be selected first, but patients in the early stages of glaucoma should receive treatment. In general, medical and laser trabeculoplasty are preferred as early treatment options over surgical trabeculectomy. The ophthalmologist will individualize therapy based on the risk and benefits for a specific patient. **Table 61-3** describes non-pharmacologic treatment modalities for POAG.⁴

Medical treatment is the most commonly selected therapeutic modality. A well-tolerated ocular antihypertensive, at the lowest concentration, should be selected as the initial

mediation (**Table 61-4**). Bimatoprost, travoprost, latanoprost, and timolol are the most effective at lowering at IOP of both peak and trough measurements by at least 25% of baseline IOP.²⁶⁻²⁹ If monotherapy alone lowers IOP but does not reach target pressure or there is evidence of progression, then combination therapy or switching to another agent is appropriate. The addition of a second agent from another class generally has an additive effect on IOP reduction. The ocular hypotensive lipids, timolol, carbonic anhydrase inhibitors, or brimonidine are reasonable choices for addition as a second agent.³⁰ Increasing the concentration or dose frequency can also be tried when possible. Minimizing the fluctuation of IOP between visits has also been suggested as potential target for therapy.³¹

A uniocular trial can be used to assess the safety and effectiveness of a topical medication before initiation in both eyes; however, uniocular drug trials do not always predict the IOP response of the second eye. The lack of correlation between IOP of fellow eyes may be explained by asymmetric IOP in each eye or the potential for contralateral IOP lowering of a uniocular applied medication. Uniocular trials may be more predictive of fellow eye response to a medication in POAG suspects than POAG patients. Ideally, the effect of a medication should be assessed independently using baseline IOP measurements.^{32,33}

► Treatment Considerations for POAG Suspects

POAG suspects should be considered for topical medication therapy if they are at high risk for developing POAG or have a high IOP in which glaucomatous nerve damage is likely to occur. POAG suspects that develop evidence of glaucomatous damage or visual field defect have developed POAG and should be treated accordingly.³ The Ocular Hypertension Treatment Study (OHTS) demonstrated that a 20% decrease in IOP can reduce the progression from ocular hypertension to POAG over a 5-year period. The incidence of progression to POAG in the treatment (4.4%) and control (9.5%) groups was small, which underscores the importance of selecting patients at high risk of progressing to POAG.⁷ The rate of progression was similar 13 years later. POAG suspects with the highest baseline risk benefited the most from early treatment, as 40% of the observation group versus 28% of the treatment group progressed to POAG.⁸ When medical therapy is indicated, a well-tolerated agent should be selected and optimized following the POAG treatment algorithm (**Fig. 61-4**). The benefit of therapy should be reassessed in patients who may require third- or fourth-line agents to control IOP. Surgical or laser intervention are rarely indicated in the treatment of glaucoma suspects.³

Primary Angle-Closure Glaucoma

► Desired Outcomes and Goals

- Therapeutic modalities for PACG are targeted at decreasing IOP. The goals of therapy are to preserve visual function by controlling the elevation in IOP, prevent damage to the optic nerve, and manage or prevent an acute attack of angle closure.²

Table 61-3

Select Nonpharmacologic Treatment Options for POAG

Treatment Option	Description
Laser trabeculoplasty	Laser energy aimed at trabecular meshwork Improves aqueous humor outflow
Trabeculectomy	Surgical removal of a portion of the trabecular meshwork Improves aqueous humor outflow Mitomycin C and fluorouracil are used to decrease scarring
Cyclodestructive surgery	Trans-scleral laser reduce rate of aqueous humor production Reserved for patients who have failed other options
Aqueous shunts	Drainage device that redirects the outflow of aqueous humor through a small tube into an outlet chamber placed underneath the conjunctiva

From Refs. 2, 4, 14.

Table 61-4

Topical Drugs Used in the Treatment of Glaucoma

Drug	Pharmacologic Properties	Common Brand Names	Dose Form	Strength (%)	Usual Dose ^a	Mechanism of Action
β-Adrenergic Blocking Agents						
Betaxolol	Relative β_1 -selective	Generic Betoptic-S	Solution Suspension	0.5 0.25	1 drop twice a day 1 drop twice a day	All reduce aqueous production of ciliary body
Carteolol	Nonselective, intrinsic sympathomimetic activity	Generic	Solution	1	1 drop twice a day	
Levobunolol	Nonselective	Betagan	Solution	0.25, 0.5	1 drop twice a day	
Metipranolol	Nonselective	OptiPranolol	Solution	0.3	1 drop twice a day	
Timolol	Nonselective	Timoptic, Betimol, Istalol Timoptic-XE	Solution Gelling solution	0.25, 0.5 0.25, 0.5	1 drop every day— 1–2 times a day 1 drop every day ^a	
Nonspecific Adrenergic Agonists						
Dipivefrin	Prodrug	Propine	Solution	0.1	1 drop twice a day	Increased aqueous humor outflow
α_2-Adrenergic Agonists						
Apraclonidine	Specific α_2 -agonists	Iopidine	Solution	0.5, 1	1 drop 2–3 times a day	Both reduce aqueous humor production; brimonidine known to also increase uveoscleral outflow
Brimonidine		Alphagan P	Solution	0.15, 0.1	1 drop 2–3 times a day	
Cholinergic Agonists Direct Acting						
Carbachol	Irreversible	Carboptic, Isopto Carbachol	Solution	1.5, 3	1 drop 2–3 times a day	All increase aqueous humor outflow through trabecular meshwork
Pilocarpine	Irreversible	Isopto Carpine Pilocar	Solution	0.25, 0.5, 1, 2, 4, 6, 8, 10	1 drop 2–3 times a day 1 drop 4 times a day	
		Pilopine HS	Gel	4	Every 24 hours at bedtime	
Cholinesterase Inhibitors						
Echothiophate		Phospholine iodide	Solution	0.125	Once or twice a day	
Carbonic Anhydrase Inhibitors						
Topical	Carbonic anhydrase type II inhibition	Brinzolamide	Suspension	1	2–3 times a day	All reduce aqueous humor production of ciliary body
		Dorzolamide	Solution	2	2–3 times a day	
Systemic		Acetazolamide	Tablet	125 mg, 250 mg	125–250 mg 2–4 times a day	
			Injection	500 mg/vial	250–500 mg	
		Methazolamide	Capsule	500 mg	500 mg twice a day 25–50 mg 2–3 times a day	
			Tablet	25 mg, 50 mg		
Prostaglandin Analogs						
Latanoprost	Prostaglandin F _{2a} analog	Xalatan	Solution	0.005	1 drop every night	Increases aqueous uveoscleral outflow and, to a lesser extent, trabecular outflow
Travoprost		Travatan, Travatan Z	Solution	0.004	1 drop every night	
Bimatoprost	Prostamide analog	Lumigan	Solution	0.03	1 drop every night	
Combinations						
Timolol-dorzolamide		Cosopt	Solution		Timolol 0.5% dorzolamide 2%	1 drop twice daily
Timolol-brimonidine		Combigan	Solution		Timolol 0.5% brimonide 0.2%	1 drop twice daily

^aUse of nasolacrimal occlusion will increase the number of patients successfully treated with longer dosing intervals.

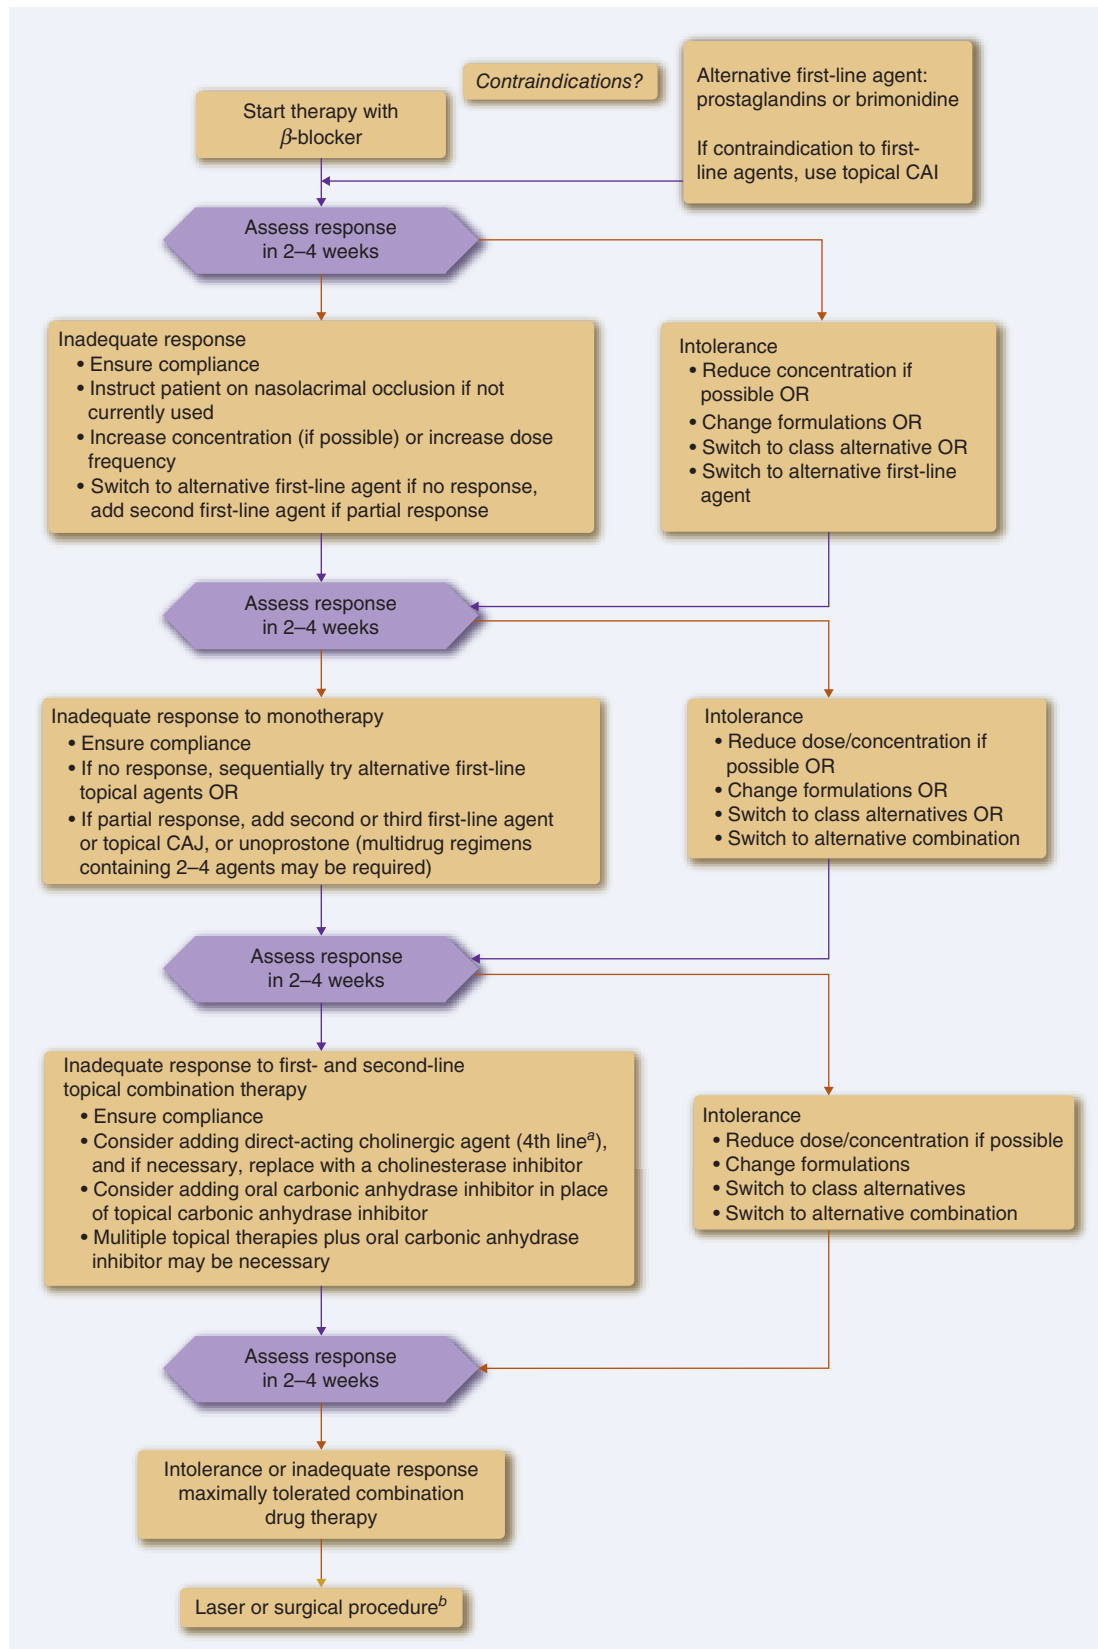

FIGURE 61-4. Algorithm for the pharmacotherapy of open-angle glaucoma. ^aFourth-line agents not commonly used any longer. ^bMost clinicians believe laser procedures should be performed earlier (e.g., after three-drug maximum, poorly adherent patient). CAI, carbonic anhydrase inhibitor. (From Lesar TS, Fiscella RG, Edward D. Glaucoma. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 8th ed. New York: McGraw-Hill, 2011:1640.)

Patient Encounter, Part 2

SJ was referred to an ophthalmologist for a comprehensive eye evaluation. The ophthalmology report reveals the patient has an IOP (as assessed by applanation tonometry) of 17 mm Hg in the right eye and 18 mm Hg in the left eye. Gonioscopic examination reveals open anterior angles in both eyes. Corneal pachymetry reveals a central corneal thickness (CCT) of 520 microns. Ophthalmoscopy reveals cupping of the optic discs in both eyes. Visual field examination reveals a nerve fiber bundle defect consistent with glaucoma in the left eye.

Given this additional information, what additional risk factors does this patient have for glaucoma?

What is your assessment this patient's glaucoma type?

What pharmacologic and nonpharmacologic treatment modalities are available for this patient?

► General Approach

The treatment of choice for PACG is laser iridotomy. Laser iridotomy uses laser energy to cut a hole into the iris to alleviate the aqueous humor buildup behind the iris, resulting in reversal of appositional angle closure. Patients currently experiencing an acute angle-closure crisis should receive medical therapy to lower IOP, reduce pain, and reverse corneal edema before the iridotomy. IOP should first be lowered with topical β -blockers, topical α -agonist, prostaglandin F_{2a} analog, systemic carbonic anhydrase inhibitors, or hyperosmotic agents. Once the IOP has been controlled, miotics (i.e., pilocarpine) can be used to break the pupillary block. A topical IOP-lowering agent should be continued to control IOP until laser iridotomy can be performed. Corneal indentation with a cotton-tipped applicator or gonioscopic lens may break pupillary block. If laser iridotomy cannot be performed, then surgical incisional iridectomy is used. Incisional iridectomy is the surgical removal of a small portion of the iris to allow flow of aqueous humor trapped in the posterior chamber to migrate to the anterior chamber (bypassing the normal flow pattern through the pupil). Topical corticosteroid may be employed to decrease inflammation postoperatively. The fellow eye is at high risk to develop an acute attack and should receive prophylactic iridotomy within a reasonable interval of time. PACG patients may require chronic medical therapy if the patient has PACG superimposed on preexisting POAG or if synechia formation causes reduced outflow with a continued increase in IOP.^{2,11,34}

Pharmacologic Therapy**► β -Adrenergic Antagonists**

Topical β -adrenergic antagonists (β -blockers) are generally considered one of the first-line agents for the treatment of POAG unless contraindications are present.¹² Topical

β -blockers decrease IOP by reducing the formation of aqueous humor made by the ciliary body, which results in a 20% to 35% reduction in IOP.^{12,29} Timolol, levobunolol, metipranolol, and carteolol are nonselective for β_1 - and β_2 -adrenergic receptors, whereas betaxolol has β_1 -selective properties. All of the topical β -blockers have similar efficacy and adverse effect profiles.^{12,35} Betaxolol reduces IOP to a lesser extent than the nonselective β -blockers, but part of its efficacy may be related to a neuroprotective mechanism independent of IOP reduction.³⁶

Topical β -blockers are typically administered twice daily. A gel-forming solution of timolol (Timoptic-XE) can be administered once daily. Tachyphylaxis may occur in 20% to 50% of patients on monotherapy with a β -blocker, resulting in the need for a different agent or combination therapy. Patients on concurrent systemic β -blockers may experience less IOP reduction than patients on only topical β -blockers.^{12,35}

Ocular medication requires the use of concentrated drug solutions to penetrate the eye. Excess drug drains into the nose via the nasolacrimal duct, where it is absorbed into the systemic circulation. β -Blockers can cause significant systemic adverse effects through this pathway, because first-pass hepatic metabolism is bypassed, resulting in pharmacologically significant serum drug concentrations.³⁷ Bronchospasm is the most common pulmonary effect of topical β -blockers. Pulmonary edema, status asthmaticus, and respiratory arrest have been reported with β -blockers as well. Cardiovascular effects include bradycardia, hypotension, and congestive heart failure exacerbation. As with systemic β -blockers, topical β -blockers have also been reported to cause depression and hyperlipidemia and mask symptoms of hypoglycemia. The β_1 -selective properties of betaxolol may cause less exacerbation of pulmonary disease. Despite the intrinsic sympathomimetic activity demonstrated by carteolol, this does not translate to a clinically significant decrease in pulmonary or cardiovascular adverse effects. Topical β -blockers are generally contraindicated in patients with asthma, chronic obstructive pulmonary disease (COPD), sinus bradycardia, second- or third-degree heart block, cardiac failure, and hypersensitivity to the product.^{12,37}

Local side effects are usually tolerable and may be caused by preservatives, therefore switching from one product to another may alleviate the local side effects. Stinging of the eyes upon instillation is the most common adverse effect. Other local adverse effects include conjunctivitis, keratitis, dry eyes, and **uveitis**.¹²

Patients prescribed topical β -blockers should be counseled on the nasolacrimal occlusion technique to decrease systemic absorption.

► Ocular Hypotensive Lipids

The ocular hypotensive lipids in typical ophthalmology practice are considered first-line agents along with β -blockers because of their superior efficacy and safety profiles. Many clinicians may choose to use the ocular hypotensive lipids as first line, especially in patients who have an initial requirement to lower IOP by greater than 25% or in patients

who have relative or absolute contraindications to topical β -blockers.^{12,35} All three of the available agents currently have an FDA indication for both POAG and ocular hypertension. Latanoprost and travoprost have dosing aids that help patients administer each medication. Travoprost is available as benzalkonium chloride–free solution.

Latanoprost and travoprost are analogs of prostaglandin $F_{2\alpha}$ and are agonists of the prostanoid FP receptor, which appears to lower IOP by increasing aqueous humor outflow through the uveoscleral pathway. Bimatoprost is a prostamide analog and appears to lower IOP by activating prostamide receptors in the uveoscleral pathway and possibly through increasing outflow through the trabecular meshwork. The exact mechanism of how uveoscleral outflow is increased is still unclear, but stimulation of prostanoid FP receptors and prostamide receptors in the ciliary body cause remodeling of the extracellular matrix, making it more permeable to aqueous humor, thus increasing aqueous humor outflow through the ciliary muscles.^{13,38,39}

Latanoprost, travoprost, and bimatoprost are administered once daily at bedtime and should not be increased to twice daily, as this may decrease effectiveness. The ocular hypotensive lipids can provide a consistent reduction in IOP over a 24-hour period. Peak and trough IOP reduction is approximately 28% to 30%. The prostaglandin analogs can be used as mono- or combination therapy.^{28–30} For patients nonresponsive to latanoprost, switching to bimatoprost may allow some patients to reach their IOP goal, presumably because of the proposed difference in the site of action of each drug.^{40,41}

The ocular hypotensive lipids are well tolerated and rarely cause systemic side effects (headache has been reported). Local effects include conjunctival hyperemia, stinging on instillation, increase in iris pigmentation, hypertrichosis, and darkening of the eyelashes. Increases in iris pigmentation occur most commonly in patients with multicolored irides on long-term prostaglandin analog therapy. The mechanism of this effect is by its action on melanocytes of the iris, in which the irides become darker because of increased production of melanin in the iris.⁴² The incidence of iris pigmentation varies among the agents, with latanoprost associated with highest incidence (3% to 10%) and bimatoprost with the least (1.5%).^{43–45} The increase in pigmentation may be irreversible or may reverse at a very slow rate. Increased iris pigmentation appears to be only a cosmetic effect but may affect your product selection, especially when choosing monocular therapy. Conjunctival hyperemia or engorgement of conjunctival blood vessels is a common adverse effect caused by a vasodilatory effect on scleral blood vessels. It is most prominent early in therapy and usually subsides over time. Although generally a benign adverse effect, patients may have a concern if it affects their cosmetic appearance.^{43–45} The ocular hypotensive lipids should be used with caution in patients, since they may worsen anterior uveitis and herpetic keratitis. Cystoid macular edema has been reported during treatment with the ocular hypotensive lipids; therefore, use caution in patients with intraocular inflammation, **aphakic** patients, **pseudophakic** patients with a history of intraoperative

complications (e.g., torn posterior lens capsule), or in patients with risk factors for macular edema.^{12,35}

Patients prescribed ocular hypotensive lipids should be counseled on potential adverse effects and appropriate administration. Patients receiving latanoprost therapy should be instructed to refrigerate the dropper bottle until opened. After the bottle has been opened it can be stored at room temperature for 6 weeks.

► α_2 -Adrenergic Agonists

Brimonidine and apraclonidine are α_2 -adrenergic agonists that decrease IOP by reducing aqueous humor production. Brimonidine has a higher selectivity to the α_2 -receptor than apraclonidine and has a dual mechanism of action by increasing uveoscleral outflow.^{12,13} Apraclonidine is often used for the prevention and treatment of postsurgical IOP elevations and is no longer commonly used for long-term treatment of POAG because of tachyphylaxis and high rate of blepharoconjunctivitis. Brimonidine lowers IOP by 14% to 25%. Peak IOP-lowering effect is similar to that of timolol, but the trough IOP-lowering effect is less than that of timolol.^{27,29} Brimonidine may exhibit a neuroprotective effect on retinal ganglion cells and has been shown to delay visual field progression compared with timolol.^{36,46}

Brimonidine is usually administered every 8 hours. A 12-hour dosing schedule may be employed when used in combination therapy. Brimonidine-purite 0.1% and 0.15% solution (Alphagan-P) has similar efficacy compared with the brimonidine 0.2% solution, because the purite solution's higher pH allows for more drug to penetrate the cornea.^{12,13}

Apraclonidine and brimonidine cause both local and systemic effects. Local effects of apraclonidine include blepharoconjunctivitis, foreign body sensation, pupillary mydriasis, and eyelid retraction. Brimonidine does not cause the α_1 -mediated mydriasis and eyelid retraction but does cause blepharoconjunctivitis, although at a lesser rate than apraclonidine. The brimonidine-purite solution has a lower incidence of ocular allergy. Systemic effects of both agents include headache, dry mouth, and fatigue.

Brimonidine is typically used as an adjunctive agent in combination with other agents but could be used as a first-line agent as well. The frequency of dosing and local adverse effects may lead to nonadherence in some patients. Patients prescribed brimonidine should be counseled on the nasolacrimal occlusion technique to reduce systemic adverse effects and to improve efficacy.¹² A combination product of brimonidine (0.2%) and timolol (0.5%) (Combigan) is available and can be administered twice daily.

► Carbonic Anhydrase Inhibitors

Carbonic anhydrase inhibitors decrease aqueous humor production by inhibition of the carbonic anhydrase isoenzyme II located in the ciliary body. In the eye, carbonic anhydrase catalyzes the conversion of H_2O and CO_2 to HCO_3^- and H^+ , which is a significant step in aqueous humor production. Carbonic anhydrase inhibitors are available in systemic and topical preparations.^{12,13}

Topical Carbonic Anhydrase Inhibitors Dorzolamide and brinzolamide are the only topical carbonic anhydrase inhibitors available on the market. Both medications are administered every 8 hours and are used as adjunctive therapy or as monotherapy for patients who cannot tolerate first-line therapies. Nasolacrimal occlusion may allow for an every-12-hour dosing interval. They lower peak and trough IOP by 17% to 20%.^{28,29}

Local side effects include burning, stinging, itching, foreign body sensation, dry eyes, and conjunctivitis. Brinzolamide may have fewer incidences of these side effects since the drug is in a neutral pH solution. Dorzolamide has been reported to cause irreversible corneal decompensation. Taste abnormalities have been reported with each agent. Both topical carbonic anhydrase inhibitors are sulfonamides and are contraindicated in patients with history of sulfonamide hypersensitivity.¹²

A combination product of timolol (0.5%) and dorzolamide (2%) (Cosopt) is available, can be administered twice daily, and provides an additive reduction in IOP.

Systemic Carbonic Anhydrase Inhibitors There are three systemic carbonic anhydrase inhibitors: acetazolamide, dichlorphenamide, and methazolamide. These agents effectively lower IOP by 20% to 30% but are reserved as third-line to fourth-line agents because of their significant adverse effects. They are typically used as bridge therapy from maximal medical therapy to laser or surgical intervention or to control IOP in the perioperative period following a laser or surgical ocular procedure. The systemic carbonic anhydrase inhibitors can also be used to lower IOP in acute angle-closure glaucoma. Acetazolamide has an IV formulation that can be used in patients who are experiencing nausea due to the angle-closure attack. Acetazolamide and methazolamide are the best tolerated of the three agents.

The systemic carbonic anhydrase inhibitors are associated with significant adverse effects that include paresthesias of the hands and feet, nausea, vomiting, and weight loss. Patients can develop systemic acidosis, hypokalemia, hyponatremia, and nephrolithiasis due to the inhibition of renal carbonic anhydrase. Sulfonamide allergy, renal failure, hepatic insufficiency, COPD, and decreased serum potassium and sodium levels are all contraindications of systemic carbonic anhydrase inhibitor therapy. Blood dyscrasias from bone marrow suppression have been reported and include agranulocytosis, aplastic anemia, neutropenia, and thrombocytopenia.¹²

► Cholinergic Agents

Cholinergic agents (also called parasympathomimetics or miotics) were the first class of agents to treat glaucoma. The class can be divided into direct-acting cholinergic agents and indirect-acting cholinergic agents.

Direct-Acting Cholinergic Agents Pilocarpine directly stimulates the muscarinic (M_3) receptors of the ciliary body, which causes contraction of the ciliary muscle. This results in the widening of spaces in the trabecular meshwork, which

causes an increase in aqueous humor outflow and reduces IOP by 20% to 30%.

Pilocarpine requires administration four times daily, since the IOP-lowering effect lasts only 6 hours. Pilocarpine is available in 1%, 2%, and 4% concentrations. Higher concentrations may be needed for patients with dark irides to obtain adequate IOP reduction. A pilocarpine 4% gel is available and allows for once-daily dosing at bedtime.¹² Pilocarpine is considered a third-line agent for glaucoma. In the treatment of PACG, it is important to delay use until IOP has been controlled, because pilocarpine could worsen angle closure by causing anterior displacement of the lens. Once IOP is controlled, pilocarpine can be given to break pupillary block by instilling one drop applied twice in an hour.

The adverse effects of pilocarpine are caused by the induction of miosis. The contraction of the ciliary muscle causes the lens to displace forward, which can lead to accommodation spasm and myopia, and can lead to brow ache. Pupillary constriction can also affect night vision. Pilocarpine should be avoided in patients with severe myopia as it increases the risk of developing retinal detachment. Systemic effects may occur at higher concentrations and include nausea, vomiting and diarrhea, and bradycardia.

Carbachol stimulates the same muscarinic receptor as pilocarpine and also inhibits acetylcholinesterase, the enzyme that metabolizes acetylcholine. Carbachol is more potent than pilocarpine, but it causes more accommodation spasm and brow ache and may also cause anterior uveitis. Other reported side effects include corneal clouding, persistent bullous keratopathy, and retinal detachment. Carbachol is rarely used today because of the side effect profile.

Indirect-Acting Cholinergic Agents Echothiophate iodide and demecarium bromide inhibit acetylcholinesterase. Inhibition of this enzyme increases the availability of acetylcholine at the nerve junction, thus increasing the stimulation of the muscarinic (M_3) receptors of the ciliary body. These products are given twice daily and have similar efficacy to pilocarpine in the degree of IOP reduction. The side effect profile is similar to that of pilocarpine; however, they can deplete systemic cholinesterases and pseudocholinesterases and may cause the formation of cataracts. These agents should be discontinued at least 1 week before general surgical procedures. Succinylcholine and some local anesthetics are metabolized by pseudocholinesterases; therefore, depletion of this enzyme by echothiophate or demecarium may lead to toxic effects. These agents are typically used when other topical agents have failed and are limited to patients who have had their lenses removed or who have artificial lenses.¹²

► Hyperosmotics

Glycerin, isosorbide, and mannitol are hyperosmotic agents that increase the osmolality of blood. These agents create an osmotic gradient that draws water from the vitreous humor, thus decreasing IOP. The resulting dehydration of the vitreous humor may cause posterior movement of the lens, which then causes the anterior chamber to deepen, thus opening the anterior angle. If the patient is not vomiting, glycerin (1 to

1.5 g/kg of a 50%) solution and isosorbide (1.5 to 2 g/kg) can be given orally. Isosorbide is preferred in patients with diabetes because it is not metabolized into glucose. If the patient has nausea or vomiting, mannitol (20%) can be given IV at a dose of 1 to 2 g/kg over 45 minutes. The hyperosmotic agents are rapid acting, reaching peak effect in 30 to 60 minutes. Headache and thirst are common complaints. Patients who are already dehydrated are at risk of developing CNS dehydration, which can lead to coma. These agents should be used with caution in patients with renal or cardiovascular disease, as extracellular water is increased.³⁴

► **Nonselective Adrenergic Agonists**

Epinephrine and its prodrug, dipivefrin, are rarely used for the treatment of glaucoma and are considered last-line agents because of their systemic side effect profile. Dipivefrin increases the corneal penetration. Once it is absorbed through the cornea, it is enzymatically cleaved to epinephrine. Epinephrine has α - and β -agonist activity and is thought to increase the outflow of aqueous humor through the trabecular meshwork and the uveoscleral pathway. Both products are instilled twice daily and reduce IOP by 15% to 25%. Local adverse effects include mydriasis, conjunctival hyperemia, and ocular irritation. Aphakic patients should not use these medications because they cause a reversible cystoid macular edema. Epinephrine and dipivefrin should not be used in patients with narrow angles since these agents can cause acute angle closure. Systemic side effects include palpitations, increased blood pressure, and arrhythmia, and therefore, these drugs should be used with caution in patients with cardiovascular disease, cerebrovascular disease, and hyperthyroidism. Using the nasolacrimal technique may decrease systemic effects.¹²

SPECIAL CONSIDERATIONS: DRUG-INDUCED GLAUCOMAS

Medications have the potential to cause or exacerbate both POAG and PACG; however, PACG is more likely to be exacerbated by medications than POAG. The use of medications with anticholinergic or sympathomimetic properties can precipitate angle closure. Medications with anticholinergic properties include first-generation antihistamines, tricyclic antidepressants, and antipsychotics. Medications with sympathomimetic properties include phenylephrine and pseudoephedrine. PACG patients who have been treated with laser iridotomy can usually use these agents without causing an exacerbation. Sulfa-based drugs, such as topiramate, acetazolamide, and hydrochlorothiazide, cause swelling of the ciliary body, which causes an anterior displacement of the lens, resulting in a decrease in anterior-chamber depth. Patients with open or closed anterior angles can experience elevated IOP from these drugs. Controlled POAG is rarely exacerbated by anticholinergics and sympathomimetics unless the patient is concomitantly at risk for angle closure. For uncontrolled or untreated POAG, the risk–benefit ratio should be considered before employing these agents. POAG can be exacerbated by any administered form of corticosteroids. Corticosteroids increase IOP by causing

obstruction of the trabecular meshwork with extracellular material. The increase in IOP appears to increase with potency and intraocular penetration. Ophthalmic corticosteroid preparations carry the highest risk of increasing IOP. However, all administered routes have been shown to raise IOP in some patients. The onset and extent of IOP elevation is dependent on the specific corticosteroid, dose, route, and frequency. Generally corticosteroid-induced IOP elevation typically occurs within a few weeks of beginning steroid therapy. In most cases, the IOP lowers spontaneously to the baseline within a few weeks to months upon stopping the steroid. In rare instances, the IOP remains elevated. Some patients exhibit clinically significant and dangerously high IOP as a result of steroid use.²³

OUTCOME EVALUATION

Primary Open-Angle Glaucoma

Evaluate patients 2 to 4 weeks after the initiation or alteration of medical therapy. The clinician should elicit the status of ocular health since the last visit, systemic medical history, medication history, and presence of local and ocular adverse effects of medications. IOP measurement, visual acuity assessment, and slit-lamp biomicroscopy at every POAG follow-up visit is necessary. The frequency of visual fields and optic nerve evaluation depends on whether IOP is controlled, the length of time IOP has been controlled, and whether there is progression of the disease. Patients who are at target IOP and have no disease progression should have optic nerve head evaluation and visual field testing every 6 to 12 months. Patients with disease progression and/or who are not at target IOP should receive follow-up evaluation every 1 to 6 months. Assess the patient's ability to use topical eye drops.⁴ (See Application of Ophthalmic Solutions or Suspensions textbox.) Finally, evaluate the patient's adherence to their medical regimen. Nonadherence among patients on topical medical therapy ranges from 5% to 80%. Suspect nonadherence in patients who have visual field and optic nerve progression despite a low IOP measurement, as patients may be more adherent to their medical regimen before their visit. Pharmacy refill histories may be useful in assessing adherence but do not confirm that the patient is actually taking the regimen as prescribed.⁴⁷ Specific patient factors related to the risk of nonadherence may include health literacy, medication cost, complicated medication regimens, adverse effects, and ethnicity.⁴⁸ Using adherence aids, prescribing the least complex regimen, and educating patients about their glaucoma are ways to reduce nonadherence.⁴⁹

8 *Target IOP should be revised based on the course of the disease and rate of progression.* Adjust therapy if the patient fails to reach his or her target IOP. Patients who have achieved target IOP yet have progressive damage of the optic nerve or who have worsening of their visual fields should have further adjustment of their therapy. Evaluate these patients further for possible reasons of continued disease progression. Consider determining the diurnal pattern of IOP and looking for signs of poor ocular perfusion pressure. Establish a lower target IOP. Adjust therapy in patients who are intolerant, are

nonadherent, or develop contraindications to their drug therapy regimen. Consider increasing the target IOP and reducing drug therapy for patients who have stable disease and who have maintained a low IOP; closely follow these patients to assess their response.⁴

Patient Care and Monitoring

1. In undiagnosed patients, assess their risk factors for glaucoma and their recommended interval of glaucoma screening.
2. Obtain a thorough history of the patient's prescription, nonprescription, and natural product use. Review for potential drug–drug and drug–glaucoma interactions.
3. Evaluate diagnostic tests (IOP, visual fields, optic nerve evaluations, etc.) to determine whether the patient's current glaucoma therapy is effective.
4. Assess the patient's ability to use ophthalmic preparations.
5. Determine the patient's adherence level to prescribed medication regimen and factors contributing to poor adherence.
6. Evaluate the patient for systemic and ocular adverse drug reactions and drug allergy.
7. Provide patient education in regard to disease state, drug therapy, and surgical/laser therapy:
 - What causes glaucoma or puts people at risk for glaucoma
 - Possible complications of glaucoma
 - How to use ophthalmic preparations appropriately
 - When to take medications
 - Potential adverse drug reactions of medical therapy
 - Potential benefits and complications of laser or surgical procedures

Patient Encounter, Part 3

The practitioner and SJ agree to start medication therapy. Develop a patient-specific care plan.

Address the patient's (a) drug-related needs, (b) goals of therapy, (c) potential pharmacologic therapies, and (d) plan for follow-up of therapy.

List the monitoring parameters for effectiveness and safety for the chosen therapy.

Explain how you would counsel the patient on the chosen therapy, including the administration of an ophthalmic preparation.

Primary Angle-Closure Glaucoma

Follow-up of acute angle-closure crisis occurs in the postoperative period. Evaluate the patency of the iridotomy and IOP in the postoperative period. Perform gonioscopy and optic nerve head evaluation if not already performed. Stable patients with PACG should be evaluated at least annually, specifically for the presence of peripheral anterior synechia and optic neuropathy. Treat patients according to POAG guidelines if they have underlying POAG or areas of peripheral anterior synechia with the presence of optic neuropathy.²

Application of Ophthalmic Solutions or Suspension

1. Clean hands with soap and water.
2. Avoid touching the dropper tip with your fingers or against your eye to maintain sterility of product; shake dropper bottle if product is a suspension.
3. Tilt head back; pull down the lower eye lid with index finger.
4. Hold the dropper bottle with other hand as close as possible without touching the eye. The dropper should be pointing toward the eye with remaining fingers bracing against the face.
5. Gently squeeze the bottle so that one drop is placed into the pocket.
6. Close your eye for 2 to 3 minutes to allow for the maximum corneal penetration of drug.
7. Use a tissue to wipe away any excess liquid.
8. Replace and retighten the cap to the dropper bottle.
9. Wait at least 5 minutes before instilling another ophthalmic drug preparation.
10. Application of some ophthalmic preparations (suspension and gels) may cause blurring of vision.

Abbreviations Introduced in This Chapter

POAG	Primary open-angle glaucoma
PACG	Primary angle-closure glaucoma
IOP	Intraocular pressure
CCT	Central corneal thickness
NTG	Normal tension glaucoma
AAO	American Academy of Ophthalmology

Self-assessment questions and answers are available at <http://mhpharmacotherapy.com/pp.html>.

Ophthalmic Disorders

Melissa L. Hunter and Michelle L. Hilaire

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Differentiate between the various ophthalmic disorders based on patient-specific information.
2. Choose an appropriate treatment regimen for an ophthalmic disorder.
3. Discuss the product differences that direct the selection of ophthalmic medications.
4. Assess when further treatment is required based on patient-specific information.
5. Recommend an ophthalmic monitoring plan given patient-specific information, a diagnosis, and a treatment regimen.
6. Educate patients about ophthalmic disease states and appropriate drug and nondrug therapies.

KEY CONCEPTS

- 1 The clinician must be able to distinguish ophthalmic conditions that lead to significant morbidity, including blindness.
- 2 In contact lens wearers, choose an antibiotic that covers *Pseudomonas aeruginosa*.
- 3 Both acute and chronic bacterial conjunctivitis are self-limiting, except if caused by *Staphylococci*.
- 4 Viral conjunctivitis is usually self-limiting, resolving within 2 weeks.
- 5 Nonpharmacologic measures are critical to prevent the spread of viral conjunctivitis.
- 6 Use a step-care approach for treatment of allergic conjunctivitis.
- 7 Untreated bacterial keratitis is associated with corneal scarring and potential loss of vision. Corneal perforation may cause the loss of the eye.
- 8 There is no cure for age-related macular degeneration, and the efficacy of most treatments is low.
- 9 Dry eye is a chronic condition in which symptoms can be improved with treatment, but it is not usually curable.

This chapter provides an overview of common ophthalmic disorders and their treatments. 1 Many ophthalmic disorders are benign or self-limited, but the clinician must be able to distinguish conditions that lead to serious morbidity, including blindness. Preserving both visual

function and cosmetic appearance should be done whenever possible.¹ The clinician must understand when referral is appropriate and the proper time frame for follow-up. These vary greatly by condition.

OCULAR EMERGENCIES

ETIOLOGY AND EPIDEMIOLOGY

Ophthalmic problems encompass 3% of all emergency department visits.² Falls are a frequent cause of traumatic eye injury in the elderly.³ Corneal abrasions are the most common eye injury in children and are often due to fingernail scratches or objects swung near the eye. Even aggressive eye rubbing may damage the cornea.⁴ Healthcare practitioners must know the proper treatment for ocular emergencies and the time frame for follow-up in order to prevent further morbidity (Table 62-1).

CORNEAL ABRASIONS

Treatment

► **Desired Outcomes**

- Complete healing of the corneal abrasion with no scarring or vision impairment
- Prevent infection and pain
- Prevent corneal loss or corneal transplant

Clinical Presentation and Diagnosis of Corneal Abrasions⁴

Symptoms

- Photophobia
- Pain with extraocular muscle movement
- Foreign body sensation
- Recent ocular trauma
- Gritty feeling
- Headache

Signs

- Excessive tearing
- Blepharospasm
- Blurred vision

Diagnostic Test

Use sterile fluorescein dye strips and visualize the cornea under a cobalt-blue filtered light; abrasions appear green; ensure that no foreign body remains in the eye.

Table 62–1

Ophthalmic Emergencies: Time to Follow-Up by Ophthalmologist

Immediate Consult Required	Within 24 Hours
Foreign body in eye	Acute angle-closure glaucoma
Acute, painless loss of vision	Orbital cellulitis
Acute chemical burn	Blood in the eye (hyphema)
Blunt trauma to eye	Macular edema
	Retinal detachment
	Sudden congestive proptosis (bulging of eye forward)
	Corneal ulcer
	Corneal abrasion

From Handler JA, Ghezzi KT. General ophthalmologic examination. *Emerg Med Clin North Am* 1995;13:521–538.

► General Approach to Treatment

The five layers of the cornea contain no blood vessels but are nourished by tears, oxygen, and aqueous humor. Minor corneal abrasions heal quickly. Moderate abrasions take 24 to 72 hours to heal. Deep scratches may scar the cornea and require corneal transplant if vision is impaired. Do not use eye patches to treat corneal abrasion, as they decrease oxygen delivery, increase pain, and increase the chance of infection.⁴

Corneal Abrasion Prevention⁴

- Wear eye protection during sports
- Wear industrial safety lenses
- Carefully fit and place contact lenses

- Clip fingernails of infants and children
- Remove low-hanging branches and objects
- Tape the eyelids closed or use gels or soft contacts during general anesthesia to prevent **lagophthalmos**.

Pharmacologic Therapy

► Topical NSAIDs

- Topical nonsteroidal anti-inflammatory drugs (NSAIDs) decrease pain from corneal abrasion. Available ocular NSAIDs are bromfenac 0.09%, diclofenac 0.1%, ketorolac 0.5%, and nepafenac 0.1%. The usual dose for diclofenac and ketorolac is one drop four times daily; nepafenac is dosed three times daily, and bromfenac is dosed twice daily. Use topical NSAIDs with caution in patients with clotting disorders or those who are on systemic NSAIDs or warfarin therapy. Topical administration of NSAIDs may delay wound healing, especially with concurrent topical corticosteroid use.^{4,5} Oral analgesics are not well studied for use in corneal abrasion; however, they are less expensive than topical NSAIDs and may be an option for some patients.⁴

► Topical Antibiotics

- Because an infection slows the healing of a corneal abrasion, prophylactic antibiotics are often used. Studies on the efficacy of this are mixed. Discontinue the use of contact lenses until the abrasion is healed and the antibiotic course complete. 2 In contact lens wearers, choose an antibiotic that covers *Pseudomonas aeruginosa*, like *gentamicin ointment* or *solution* or a *fluoroquinolone*.⁴ Antibiotic resistance is an increasing problem. Resistance occurs primarily with older antibiotics, but has been reported for fluoroquinolones as well. Two newer fluoroquinolones, gatifloxacin and moxifloxacin, have low reports of resistance (2%).⁶ These agents are more expensive.

Outcome Evaluation

- 1. Reevaluate patients in 24 hours.
- 2. If symptoms worsen, recheck for foreign bodies.
- 3. If not fully healed, evaluate again in 3 to 4 days.
- 4. Refer to ophthalmologist if:⁴
 - No improvement in 3 days
 - Worsening symptoms
 - Symptoms do not improve daily
 - Symptoms do not improve within a few hours of contact lens removal

OTHER OCULAR EMERGENCIES: TREATMENT

Traumatic Injuries

Attempt to remove loose foreign bodies by gentle irrigation with artificial tears or sterile saline. If removal is successful,

a topical broad-spectrum antibiotic, such as erythromycin, will prevent infection. Some patients may need a short-acting cycloplegic mydriatic like cyclopentolate or tropicamide to help with pain.² Cycloplegic mydriatics should be used with extreme caution in children.⁵ If irrigation is unsuccessful, mechanical removal of foreign objects should be completed only by ophthalmologists using a slitlamp. Protect the eye from further injury with a metal eye shield or a paper cup taped over the eye while awaiting the ophthalmologist.²

Splash Injuries and Chemical Exposure

- Instruct patients by phone to irrigate the eye immediately with water or saline continuously for at least 15 minutes before seeking a clinician. Irrigation dilutes and removes the chemical agent and is the best way to decrease ocular tissue damage. Patients should then seek immediate care from an ophthalmologist or emergency facility.⁷

Loss of Vision

A variety of disorders may lead to rapid, painless, monocular or binocular vision loss. These include central retinal artery occlusion, acute narrow-angle glaucoma, trauma, and others.⁸

- The differential diagnosis is complex and needs to be undertaken by an emergency department or ophthalmologist.

conjunctiva is the most common cause of red eye.⁹ The vast majority of conjunctivitis cases are viral in nature. Use the differential diagnosis algorithm shown in **Figure 62-1** to determine the proper treatment or need for referral.

BACTERIAL CONJUNCTIVITIS

Etiology and Pathophysiology

The primary cause of acute bacterial conjunctivitis is gram-positive organisms, including *Streptococcus pneumoniae* and *Staphylococcus aureus*, and gram-negative *Haemophilus influenzae*.⁹

Staphylococcus and *Moraxella* are common bacterial causes of chronic conjunctivitis.¹⁰ *Moraxella* infections may cluster in groups of women who share makeup.¹⁰ **3** Both acute and chronic bacterial conjunctivitis are self-limiting except if caused by Staphylococci.¹¹ Because of this, the pathogens are rarely cultured unless the case is unresponsive to treatment. Although infection typically begins in one eye, it will often spread to both within 48 hours.¹²

Hyperacute bacterial conjunctivitis is associated with gonococcal infections in sexually active patients. The causative agents are *Neisseria gonorrhoeae* or *N. meningitidis*. Prompt workup and treatment is required, as corneal perforation occurs in 10% of cases within 48 hours.¹²

Treatment

► Desired Outcomes

- Complete resolution of the bacterial conjunctivitis
- Prevent adverse consequences of the infection
- Preserve functionality of the eye

CONJUNCTIVITIS

Although no exact numbers are available, **conjunctivitis**, also known as red eye, is one of the most common ophthalmic complaints seen by general clinicians. An inflamed

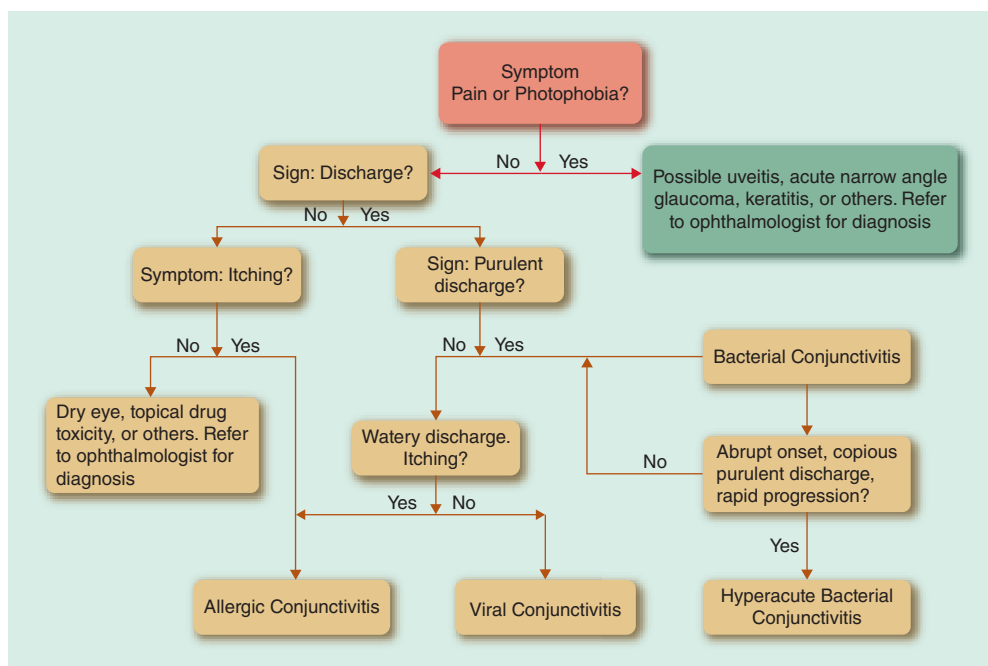

FIGURE 62-1. Differential diagnosis for red eye.

► General Approach to Treatment

- Treat acute bacterial conjunctivitis with broad-spectrum antibiotics. Although the condition is usually self-limiting, antibiotic treatment decreases the spread of disease to other people and prevents extraocular infection. Additionally, treatment may help decrease the risk of corneal ulceration or other complications that affect sight. Finally, treatment speeds recovery.⁹

► Pharmacologic Therapy

- The choice of an antibiotic agent for acute bacterial conjunctivitis is largely empiric. The initial treatment needs to include *Staphylococcus* coverage, but also may be chosen on the basis of cost and side-effect profile.⁹ In general, ointments are a good dosage form for children. Adults may prefer drops because they do not interfere with vision.¹³

- Many broad-spectrum topical antibiotics are approved to treat acute bacterial conjunctivitis (Tables 62-2 and 62-3). Polymyxin B/trimethoprim solution, polymyxin B with bacitracin ointment, or erythromycin ointment are cost-effective, first-line treatments. The aminoglycosides (tobramycin, neomycin, and gentamicin) are alternatives but have incomplete gram-positive coverage.¹³ The aminoglycosides can cause corneal epithelial toxicity. Neomycin often causes allergic reactions. Tobramycin is the best tolerated of the class, but is also the most expensive. Sulfacetamide 10% has significant resistance. If infection recurs, use a topical fluoroquinolone like ofloxacin, ciprofloxacin, gatifloxacin, moxifloxacin, or levofloxacin.¹⁰ Fluoroquinolones are not used first-line for conjunctivitis because they have poor *Streptococcus* coverage and are expensive. Development of resistance is also a concern with fluoroquinolones.¹³

Treat hyperacute bacterial conjunctivitis with a single dose of 1 g of intramuscular ceftriaxone in combination with topical antibiotics and refer the patient to an ophthalmologist.¹²

Patients with chronic bacterial conjunctivitis often have a concurrent case of blepharitis. Add a lid hygiene regimen to topical antibiotic treatment.^{9,10}

Outcome Evaluation

- Significant improvement of acute bacterial conjunctivitis should be seen within 1 week.^{9,12} Terminate treatment with topical antibiotics when the inflammation is resolved.¹⁰

VIRAL CONJUNCTIVITIS

Etiology

The most common cause of viral conjunctivitis is adenovirus. It is often called “pink-eye.”⁹ Viral conjunctivitis infections are easily spread through swimming pools, camps, and contaminated fingers and medical instruments.^{9,13} Patients often present with an upper respiratory tract infection or recent exposure to viral conjunctivitis. Although the infection begins in one eye, it often spreads to the other.

- 4 Viral conjunctivitis is usually self-limiting, resolving within

Table 62-2

Adult Bacterial Conjunctivitis Dosing Guidelines for Topical Ophthalmic Antibiotics

Azithromycin 1% solution	Days 1 and 2: 1 drop twice daily, 8–12 hours apart Days 3–7: 1 drop once daily
Ciprofloxacin 3.5 mg/mL solution	Days 1 and 2: 1–2 drops every 2 hours while awake Days 3–7: 1–2 drops every 4 hours while awake
Ciprofloxacin 0.3% ointment	Apply a ½ in. ribbon of ointment 3 times daily for 2 days, then twice daily for next 5 days
Erythromycin 0.5% ointment	Apply a ½ in. ribbon of ointment up to 6 times daily
Gatifloxacin 0.3% solution	Days 1 and 2: 1 drop every 2 hours while awake up to 8 times daily Days 3–7: 1 drop every 4 hours while awake
Gatifloxacin 0.5% solution	Days 1: 1 drop every 2 hours while awake up to 8 times daily Days 2–7: 1 drop 2–4 times per day while awake
Gentamicin 0.3% solution	1–2 drops every 4 hours. In severe infections, may use up to 2 drops every hour
Gentamicin 0.3% ointment	Apply a ½ in. ribbon of ointment 2–3 times daily; up to every 3–4 hours
Levofloxacin 0.5% solution	Days 1 and 2: 1–2 drops every 2 hours while awake, up to 8 times per day Days 3–7: 1–2 drops every 4 hours while awake, up to 4 times daily
Moxifloxacin 0.5% solution	1 drop 2 times a day for 7 days (Moxeza) 1 drop 3 times a day for 7 days (Vigamox)
Ofloxacin 0.3% solution	Days 1 and 2: 1–2 drops every 2–4 hours while awake Days 3–7: 1–2 drops 4 times daily
Polymyxin B with bacitracin ointment	Apply a ½ in. ribbon of ointment every 3–4 hours, or 2–3 times per day for 7–10 days
Polymyxin B/trimethoprim solution	1 drop every 3 hours for 7–10 days
Sulfacetamide 10% ointment	Apply a ½ in. ribbon of ointment every 3–4 hours and at bedtime
Sulfacetamide 10% solution	1–2 drops every 2–3 hours for 7–10 days
Tobramycin 0.3% ointment	Mild-to-moderate infections: Apply a ½ in. ribbon of ointment 2–3 times daily; Severe infections: Apply every 3–4 hours
Tobramycin 0.3% solution	Mild-to-moderate infections: 1–2 drops every 2–4 hours Severe infections: initially, 2 drops every hour

Table 62-3

Pediatric Dosing Guidelines for Bacterial Conjunctivitis for Topical Ophthalmic Antibiotics

Azithromycin 1% solution	Children 1 year of age or older: Days 1 and 2: 1 drop twice daily, 8–12 hours apart Days 3–7: 1 drop once daily
Ciprofloxacin 3.5 mg/mL solution	Children 1 year of age or older, days 1 and 2: 1–2 drops every 2 hours while awake Days 3–7: 1–2 drops every 4 hours while awake
Ciprofloxacin 0.3% ointment	Children 2 years of age or older: Apply a ½ in. ribbon of ointment 3 times daily for 2 days, then twice daily for next 5 days
Erythromycin 0.5% ointment	Apply a ½ in. ribbon of ointment up to 6 times daily
Gatifloxacin 0.3% solution	Children 1 year of age or older, days 1 and 2: 1 drop every 2 hours while awake up to 8 times daily Days 3–7: 1 drop every 4 hours while awake
Gentamicin 0.3% solution	1–2 drops every 4 hours. In severe infections, may use up to 2 drops every hour
Gentamicin 0.3% ointment	Apply a ½ in. ribbon of ointment 2–3 times daily; up to every 3–4 hours
Levofloxacin 0.5% solution	Children 1 year of age or older, days 1 and 2: 1–2 drops every 2 hours while awake, up to 8 times daily Days 3–7: 1–2 drops every 4 hours while awake, up to 4 times daily
Moxifloxacin 0.5% solution	Children 4 months of age or older: 1 drop 2 times per day for 7 days (Moxeza)
Ofloxacin 0.3% solution	Children 1 year of age or older, days 1 and 2: 1–2 drops every 2–4 hours while awake Days 3–7: 1–2 drops 4 times daily
Polymyxin B with bacitracin ointment	Apply a ½ in. ribbon of ointment every 3–4 hours for 7–10 days
Polymyxin B/trimethoprim solution	Infants and children 2 months of age or older: 1 drop every 3 hours for 7–10 days
Sulfacetamide 10% ointment	Apply a ½ in. ribbon of ointment every 3–4 hours and at bedtime
Sulfacetamide 10% solution	1–2 drops every 2–3 hours for 7–10 days
Tobramycin 0.3% ointment	Infants and children 2 months of age or older: Mild-to-moderate infections: Apply an approximately ½ in. ribbon 2–3 times daily Severe infections: Apply every 3–4 hours
Tobramycin 0.3% solution	Infants and children 2 months of age or older: Mild-to-moderate infections: 1–2 drops every 4 hours Severe infections: initially, 2 drops every hour

Patient Encounter 1

This morning, a mother brings in her 7-year-old daughter who has been complaining of irritation, redness, and “goop” coming out of her left eye for the past 13 hours. She woke up terrified this morning because her left eye seemed glued shut. A warm washcloth was used to ease the eye open, and upon examination, the left eye was red and revealed a whitish discharge, whereas the right eye was just red.

What is the probable diagnosis?

Please differentiate between bacterial, hyperacute bacterial, viral, and allergic causes based on physical assessment.

What organisms should be suspected, and what are reasonable treatment regimens?

If the child would have been diagnosed with viral conjunctivitis, what nonpharmacologic measures should be employed to prevent spreading?

2 weeks.⁹ Five percent of patients remain contagious 16 days after the appearance of symptoms.¹²

Treatment**► Desired Outcomes**

- Complete resolution of the viral conjunctivitis
- Prevent adverse consequences of the infection
- Avoid spreading infection to other patients

► Nonpharmacologic Therapy

5 *Nonpharmacologic measures are critical to prevent the spread of viral conjunctivitis.* Cold compresses may relieve symptoms.⁹ Patients should not share towels or other contaminated objects, should avoid close contact with other people, and avoid swimming for 2 weeks.¹² The virus remains viable on dry surfaces for more than 2 weeks.¹¹ Take care in the medical setting to thoroughly decontaminate instruments and wash hands.¹²

► Pharmacologic Therapy

Patients may obtain further symptomatic relief by using artificial tears and topical decongestants.⁹ If artificial tear solutions sting, recommend a preservative-free formula.

- Topical antivirals are not used to treat adenovirus conjunctivitis. Topical antibiotics are often prescribed for viral conjunctivitis, presumably to prevent bacterial superinfection. In reality, this is a case of the patient insisting on a medication to speed healing.¹² Avoid the use of antibiotics for a viral infection.¹⁰ Eliminating superfluous antibiotic use also helps prevent the development of antibiotic resistance.
- If patients have a severe subepithelial infiltration, a topical steroid may be required. However, topical steroids may

cause serious ocular complications and may worsen herpetic conjunctivitis, which has similar symptoms as viral conjunctivitis. Only ophthalmologists should prescribe topical steroids.⁹ Additionally, the period of virus shedding may be significantly prolonged by topical prednisolone.¹⁴

► Outcome Evaluation

- Refer patients who do not see improvement within 7 to 10 days to an ophthalmologist to rule out herpetic and other infectious processes.¹² If pain or photophobia occurs, suspect corneal involvement and refer the patient. This typically occurs 10 to 14 days after the onset of conjunctivitis.¹¹

ALLERGIC CONJUNCTIVITIS

Etiology and Clinical Presentation

- Ocular allergy is a broad term that includes several diseases with the hallmark symptom of itching, often accompanied by tearing, conjunctival swelling, photophobia, and stringy or sticky mucoid discharge.¹⁵ Seasonal ocular allergy is the most common type of allergic conjunctivitis. This is an IgE-mediated hypersensitivity to pollen or other airborne allergens.¹² Often, the patient's history is positive for atopic conditions such as allergic rhinitis, asthma, or eczema.¹⁵ Perennial allergic conjunctivitis has similar but less severe symptoms and may not be tied to a specific time of year. Finally, **conjunctivitis medicamentosa** is a drug-induced form of allergic conjunctivitis caused by overuse of topical vasoconstricting agents.¹⁵

Pathophysiology

The conjunctiva of the eye is often the initial site of contact with an environmental allergen. Mast cell degranulation

occurs, resulting in the release of mediators. The earliest mediator is histamine, which causes itching, redness, and swelling. Leukotrienes and prostaglandins cause cellular infiltration and increased mucus secretion along with chemosis, resulting in conjunctival vasodilation. Mast cells release cytokines, chemokines, and growth factors, which trigger inflammatory processes.¹⁷

Treatment of ocular allergy is aimed at slowing or stopping these processes. Antihistamines block the histamine receptors, and some prevent histamine production and/or inhibit mediator release from the mast cells.¹⁷ Mast cell stabilizers inhibit the degranulation of mast cells, preventing mediator release. Some topical agents have multiple mechanisms of action, combining antihistaminic, mast cell stabilization, and anti-inflammatory properties (Tables 62-4, 62-5, and 62-6).¹⁸

Treatment

► Desired Outcomes

- Relief of current allergic symptoms
- Prevention of future allergic symptoms
- No adverse effects from treatment

► Nonpharmacologic Therapy

- The primary treatment for ocular allergy is removal and avoidance of the allergen.¹⁹ For conjunctivitis medicamentosa, discontinue the offending medication.¹⁵ Apply cold compresses several times daily to reduce redness and itching and to provide symptomatic relief.

► Pharmacologic Therapy

- 6 Use a step-care approach for the treatment of allergic conjunctivitis. The first step is a nonmedicated, artificial

Table 62-4

Mechanisms of Action of Ocular Allergy Drugs

Drug	Mechanisms	Notes
Azelastine	H ₁ -receptor antagonist, mast cell stabilizer	May inhibit cytokine release
Cromolyn sodium	Mast cell stabilizer	
Emedastine	H ₁ -receptor antagonist; inhibits eosinophil chemotaxis	Superior H ₁ -receptor binding ability
Epinastine	H ₁ - and H ₂ -receptor antagonist, mast cell stabilizer, anti-inflammatory	
Ketorolac	Prostaglandin inhibitor	
Ketotifen	H ₁ -receptor antagonist, mast cell stabilizer, eosinophil inhibitor, platelet-activating factor inhibitor	May inhibit eosinophil chemotaxis
Levocabastine	H ₁ -receptor antagonist	Downregulates intracellular adhesion molecules, decreasing the inflammatory response; may be used for up to 2 weeks
Lodoxamide	Mast cell stabilizer	May be used for up to 3 months
Loteprednol	Corticosteroid	Only 0.2% approved for seasonal allergic conjunctivitis
Nedocromil	Mast cell stabilizer, H ₁ -receptor antagonist	May inhibit eosinophils
Olopatadine	Antihistaminic, mast cell stabilizer	
Pemirolast	Mast cell stabilizer	
Pheniramine	H ₁ -receptor antagonist	Available only in combination with naphazoline

From Refs. 17-19.

Table 62-5

Adult Dosing and Common Side Effects of Ocular Allergy Drugs

Drug	Dosing ^a	Common Side Effects ^b
Azelastine 0.05%	1 drop in affected eye(s) twice daily	Ocular stinging, headache, bitter taste
Cromolyn sodium 4%	1–2 drops in each eye 4–6 times daily	Ocular stinging
Emedastine 0.05%	1 drop in affected eye up to 4 times daily	Headache
Epinastine 0.05%	1 drop in each eye twice daily	Ocular stinging, cold symptoms
Ketorolac 0.5%	1 drop 4 times a day	Ocular stinging, irritation
Ketotifen 0.025%	1 drop in affected eye(s) twice daily	Red eyes (conjunctival injection), headache
Levocabastine 0.05%	1 drop in affected eye(s) 4 times daily	Ocular stinging, headache
Lodoxamide 0.1%	1–2 drops in affected eye(s) 4 times daily	Ocular stinging, foreign body sensation
Loteprednol 0.2%	1 drop in affected eye(s) 4 times daily	Elevated intraocular pressure, cataracts, decreased wound healing, secondary ocular infections, systemic side effects possible
Nedocromil 2%	1–2 drops in each eye twice daily	Ocular stinging, bitter taste
Olopatadine 0.1%; 0.2%	0.1%: 1 drop in affected eye(s) 2 times daily with minimum 6- to 8-hour interval between doses 0.2%: 1 drop in affected eye(s) once daily	Headache
Pemirolast 0.1%	1–2 drops in affected eye(s) 4 times daily	Headache, cold symptoms
Pheniramine	Varies by manufacturer and product	Ocular stinging

^aFrom Refs. 5, 16.^bFrom Ref. 19.

Table 62-6

Pediatric Dosing of Ocular Allergy Drugs

Drug	Dosing
Azelastine 0.05%	Children 3 years of age or older: 1 drop in affected eye(s) twice daily
Cromolyn sodium 4%	Children 4 years of age or older: 1–2 drops in each eye 4–6 times daily
Emedastine 0.05%	Children 3 years of age or older: 1 drop in affected eye up to 4 times daily
Epinastine 0.05%	Children 2 years of age or older: 1 drop in each eye twice daily
Ketorolac 0.5%	Children 3 years of age or older: 1 drop in affected eye(s) 4 times a day
Ketotifen 0.025%	Children 3 years of age or older: 1 drop in affected eye(s) twice daily
Levocabastine 0.05%	Children 12 years of age or older: 1 drop in affected eye(s) 4 times daily
Lodoxamide 0.1%	Children 2 years of age or older: 1–2 drops in affected eye(s) 4 times daily
Nedocromil 2%	Children 3 years of age or older: 1–2 drops in each eye twice daily
Olopatadine 0.1%; 0.2%	Children 3 years of age or older: 1 drop in affected eye(s) 2 times daily with minimum 6- to 8-hour interval between doses 0.2%: 1 drop in affected eye(s) once daily
Pemirolast 0.1%	Children 3 years of age or older: 1–2 drops in affected eye(s) 4 times daily
Pheniramine	Varies by manufacturer and product

From McEvoy GK, ed. AHFS Drug Information 2011. Bethesda, MD: American Society of Health-System Pharmacists, 2011.

tears solution. The solution dilutes or removes the allergen, providing relief while lubricating the eye. Solutions are applied two to four times daily as needed. Ointments may be used in the evenings to further moisturize the surface of the eye.¹⁹ There are many products on the market. Try a preservative-free formulation if other products sting or burn. Unit-dose preservative-free products are more expensive. Some newer multidose products, such as sodium perborate (Purite), have rapidly dissociating preservatives and are more cost-effective.

If artificial tears are insufficient, the second treatment step is a topical antihistamine or antihistamine/decongestant combination. The antihistamine/decongestant combination is more

effective than either agent alone. Decongestants are vasoconstrictors that reduce redness and seem to have a small synergistic effect with the antihistamine. The only topical decongestant used in combination products is naphazoline. Topical decongestants burn and sting on instillation and commonly cause **mydriasis**, especially in patients with lighter-colored eyes. Long-term use leads to rebound congestion. Topical decongestant use should be limited to less than 10 days.¹⁹

There is still debate whether oral antihistamines control ocular allergy as well as topical antihistamines. Topical antihistamines are recommended before oral agents in step therapy because of the increased risk of systemic side effects with oral drugs. Additionally, topical antihistamines provide

Patient Encounter 2

DJ is a 37-year-old female presenting with swollen, teary eyes, and complains of itching. Her symptoms seem to be worse in the spring and summer months. Her past medical history is positive for asthma and eczema. She has been using over-the-counter naphazoline for the past 2 weeks.

What information is suggestive of allergic conjunctivitis?

What nonpharmacologic therapies should be recommended for this patient?

What pharmacologic therapies should be recommended for this patient?

How should the patient be monitored?

faster relief of ocular symptoms. Consider oral antihistamines when systemic symptoms are present.¹⁷

If insufficient relief is obtained from these products, either a mast cell stabilizer or a multiple-action agent is appropriate.¹⁹ Use mast cell stabilizers prophylactically throughout the allergy season. Full response may take 4 to 6 weeks.

If mast cell stabilizers or multiple-action agents are not successful, a trial of a topical NSAID is appropriate. Ketorolac is the only approved topical agent for ocular itching. NSAIDs do not mask ocular infections, affect wound healing, increase intraocular pressure, or contribute to cataract formation like the topical corticosteroids. However, in clinical trials, for allergic conjunctivitis, topical ketorolac was not as effective as olopatadine or emedastine.¹⁷ Full efficacy of ketorolac may take up to 2 weeks.¹⁹

If all these avenues are ineffective, short-term topical corticosteroids and immunotherapy are the third-line treatments for ocular allergy.^{15,19}

Outcome Evaluation

Monitor patients for relief of symptoms. Ensure an adequate trial of the agent. If no improvement is seen, follow a stepped-care approach to treatment. Refer severe cases that do not respond to an ophthalmologist for short-term topical corticosteroids.

BACTERIAL KERATITIS

EPIDEMIOLOGY

Thirty thousand cases of microbial keratitis occur annually in the United States.²⁰ Microbial keratitis encompasses bacterial, fungal, and *Acanthamoeba* keratitis.²⁰ Only bacterial keratitis, the most common form, is discussed here.

PATHOPHYSIOLOGY

Bacterial keratitis is a broad term for a bacterial infection of the cornea. This includes corneal ulcers and corneal abscesses.

Clinical Presentation and Diagnosis of Bacterial Keratitis^{9,20}

General

The rate of progression of signs and symptoms varies depending on the infecting organism. A differential diagnosis for keratitis must include viral, fungal, and nematodal infections in addition to bacterial causes.

Symptoms

- Photophobia
- Rapid onset of ocular pain

Signs

- Red eye
- Conjunctival discharge
- Decreased vision

Laboratory Tests

Culture if keratitis is severe or sight-threatening. Otherwise, culture or smear only if the corneal infiltrate is chronic or unresponsive to broad-spectrum antimicrobial therapy.

The cornea in a healthy eye has natural resistance to infection, making bacterial keratitis rare. However, many factors may predispose a patient to bacterial infection by compromising the defense mechanisms of the eye (Table 62-7).²⁰

The most common pathogens in bacterial keratitis are *Pseudomonas* (including *Pseudomonas aeruginosa*) and other gram-negative rods, *Staphylococci*, and *Streptococci*.²⁰ If the keratitis is related to the use of contacts, *Pseudomonas* and *Serratia marcescens* are the most common pathogens.²⁰ For hospitalized infants and adults on respirators, *Pseudomonas* is the most common.²⁰

7 Untreated bacterial keratitis is associated with corneal scarring and potential loss of vision.²⁰ Corneal perforation may occur, and the patient may lose the eye.²⁰ In virulent organisms, this destruction may occur within 24 hours.²⁰ Central corneal scarring may result in vision loss even after successful eradication of the organism.²⁰

TREATMENT

Desired Outcomes²⁰

- Resolution of infection
- Resolution of corneal inflammation
- Reduced corneal pain
- Restored corneal integrity with minimal scarring
- Restored visual function

General Approach to Treatment

- All cases of suspected bacterial keratitis require prompt ophthalmology consultation to prevent permanent vision loss.⁹

Table 62-7

Risk Factors for Bacterial Keratitis**Exogenous Factors**

Contact lenses
Loose sutures from ocular surgeries
Previous corneal surgery
Previous ocular or eyelid surgery
Trauma, including foreign bodies, chemical and thermal injuries and local irradiation

Ocular Surface Disease

Abnormal lid anatomy or function
Misdirection of eyelashes
Ocular infection (e.g., conjunctivitis, blepharitis)
Tear film deficiencies

Systemic Conditions

Atopic dermatitis
Connective tissue disease
Debilitating illness (e.g., malnourishment or respirator dependence)
Diabetes mellitus
Factitious disease (including anesthetic abuse)
Gonococcal infection
Immunocompromised
Stevens-Johnson syndrome
Substance abuse
Vitamin A deficiency

Ocular Medications

Anesthetics
Antimicrobials
Contaminated ocular medications
Glaucoma medications
Preservatives
Steroids
Topical NSAIDs

Corneal Epithelial Abnormalities

Corneal epithelial edema
Predisposition to recurrent erosion of the cornea
Viral keratitis (e.g., herpes simplex or zoster keratitis)

From Feder RS, Dunn SP, Jones MR, et al. Bacterial keratitis, Preferred Practice Pattern – limited revision [Internet]. San Francisco: American Academy of Ophthalmology, 2011 [cited 2012 Feb 3]. Available from: <http://one.aaopt.org/CE/PracticeGuidelines/PPP.aspx>.

Pharmacologic Therapy**► Dosage Considerations**

- Topical antibiotic drops are preferred. Consider subconjunctival antibiotics if compliance is a concern. Systemic therapy is useful in cases of systemic infection (e.g., gonorrhea) or if the sclera is infected. Reserve ointments for minor cases or adjunctive nighttime therapy.²⁰

► Drug Choice

- Start topical broad-spectrum antibiotics empirically. Use a loading dose for severe keratitis (Table 62-8). Single-drug therapy with a fluoroquinolone is as effective as combination therapy. Resistance is seen with some fluoroquinolones. Because of this, choose a newer fluoroquinolone such as moxifloxacin or gatifloxacin in severe keratitis cases.^{6,20} Fortified antibiotic therapy is an option for severe or unresponsive infections, but may increase toxicity to the cornea and

Table 62-8

Pharmacologic Therapies for Bacterial Keratitis

Organism	Drug
Unknown or multiple types of organisms	Cefazolin 50 mg/mL and tobramycin/gentamicin 9–14 mg/mL or Fluoroquinolones various strengths
Gram-positive cocci	Cefazolin 50 mg/mL or Vancomycin ^a 15–50 mg/mL or Bacitracin ^a 10,000 international unit or Moxifloxacin or gatifloxacin various strengths
Gram-negative rods	Tobramycin 9–14 mg/mL or Gentamicin 9–14 mg/mL or Ceftazidime 50 mg/mL or Fluoroquinolones various strengths
Gram-negative cocci	Ceftriaxone 50 mg/mL or Ceftazidime 50 mg/mL or Fluoroquinolones various strengths
Nontuberculous mycobacteria	Amikacin 20–40 mg/mL or Oral clarithromycin, adults: 500 mg every 12 hours
<i>Nocardia</i>	Fluoroquinolones various strengths Amikacin 20–40 mg/mL or Trimethoprim 16 mg/mL and sulfamethoxazole 80 mg/mL
Adult Topical Dosing	
Severe keratitis: loading dose every 5–15 minutes for the first hour, then every 15 minutes to 1 hour around the clock. Less severe keratitis may use less frequent dosing	

^aUse for resistant *Enterococcus* and *Staphylococcus* species and penicillin allergy. Due to the absence of gram-negative activity, do not use vancomycin or bacitracin for single-agent empiric therapy in bacterial keratitis.

From Feder RS, Dunn SP, Jones MR, et al. Bacterial keratitis, Preferred Practice Pattern – limited revision [Internet]. San Francisco: American Academy of Ophthalmology, 2011 [cited 2012 Feb 3]. <http://one.aaopt.org/CE/PracticeGuidelines/PPP.aspx>.

surrounding tissues. Fortified antibiotics are compounded products that are a higher concentration than the commercially available formulation.²⁰ All compounded formulations must comply with governmental 797 regulations concerning compounding of drug preparations.

- Topical corticosteroids are employed in some cases of bacterial keratitis. The suppression of inflammation may reduce corneal scarring. However, local immunosuppression, increased ocular pressure, and reappearance of the infection are disadvantages to their use. There is no conclusive evidence that they alter clinical outcomes. If the patient is already on topical corticosteroids when the keratitis occurs, discontinue use until the infection is eliminated.²⁰

Outcome Evaluation²⁰

- Monitor patient symptoms for improvement to determine therapeutic efficacy.
- Modify treatment regimen based on results of culture and sensitivity testing, if necessary.

- Modify the treatment regimen if the patient does not show improvement within 48 hours.
- Gram-negative keratitis will have increased inflammation in the first 24 to 48 hours, even on appropriate therapy.
- Taper therapy based on clinical response.
- Reculture or biopsy if negative clinical response; to improve culture results, discontinue antibiotics for 12 to 24 hours before culturing.
- Contact lenses wears should be educated about the increased risk of infection overnight and continuous wear and the importance of adherence to contact lens hygiene.

MACULAR DEGENERATION

EPIDEMIOLOGY AND ETIOLOGY

Age-related macular degeneration (AMD) is the primary cause of severe, irreversible vision impairment in developed countries (Figs. 62–2 and 62–3). The prevalence increases with age.²¹ In the United States, 1.75 million people age 40 or older have advanced AMD, and another 7 million people may have intermediate AMD.²¹ Because of the rapid aging of the U.S. population, it is projected that almost 3 million people will develop AMD by 2020.²² The causes of AMD are not completely known (Table 62–9).²¹

PATHOPHYSIOLOGY

AMD is a deterioration of the **macula**, the central portion of the retina. The macula facilitates central vision and high-resolution visual acuity because it has the highest concentration of photoreceptors in the retina. The loss of central vision leads to irreversible loss of the ability to drive, read, and perform other

FIGURE 62–2. Normal vision. (From the National Eye Institute, National Institutes of Health Ref. No. EDS01. <http://www.nei.nih.gov/photo/>)

FIGURE 62–3. The scene in Figure 62–2 as it might be viewed by a person with age-related macular degeneration. (From the National Eye Institute, National Institutes of Health Ref. No. EDS05. <http://www.nei.nih.gov/photo/>)

Table 62–9

Risk Factors for AMD

Definite Risk Factors	Potential Risk Factors
Advancing age	Cardiovascular disease
Light pigmentation (white ethnicity)	Hypertension
Cigarette smoking	Low dietary intake of antioxidant vitamins or zinc
Family history	Increased body mass index
	Higher dietary fat intake

From Chew EY, Benson WE, Blodi BA, et al. Age-related macular degeneration, Preferred Practice Pattern [Internet]. San Francisco: American Academy of Ophthalmology, 2008 [cited 2011 Oct 1]. <http://one.aao.org/CE/PracticeGuidelines/PPP.aspx>.

fine visual tasks like recognize faces.²³ Peripheral vision is preserved, allowing mobility.²¹ AMD is characterized by one or more of the following: **drusen** formation, retinal pigment abnormalities (e.g., hypo- or hyperpigmentation), geographic atrophy, and **neovascular maculopathy**.²¹

Based on clinical presentation, AMD is classified as early, intermediate, or advanced.²¹ Early AMD is characterized by small or intermediate drusen and minimal macular pigment abnormalities.²¹ These patients generally have normal central vision.²¹ Intermediate AMD patients have medium or large drusen in one or both eyes.²¹ Approximately 18% of these patients will progress to advanced AMD within 5 years.²¹

Advanced AMD is classified as non-neovascular (also called the atrophic, nonexudative, or dry form) or neovascular (the exudative or wet form).^{21,23} In the non-neovascular form, the retina and other layers atrophy.²³ In the neovascular form, new blood vessels appear.^{21,23} Generally, vision is already affected when patients progress to advanced AMD; vision loss is seen in both forms.²¹ Ten to twenty percent of patients with the non-neovascular form will progress to the neovascular form.²⁴ Once one eye develops advanced AMD, 43% of patients will develop neovascular changes or atrophy in the other eye within 5 years.²¹

Clinical Presentation and Diagnosis of AMD^{22,24}

Symptoms

- Mild blurry central vision
- Difficulty reading
- Trouble with color and contrast
- Painless, progressive, moderate to severe blurring of central vision
- Sudden loss or distortion of vision possible

Signs

- Drusen
- Retinal pigment epithelial mottling

Other Diagnostic Tests

- Amsler's grid abnormalities indicate fluid in subretinal space (Figs. 62–4 and 62–5)
- Dilated fundus examination shows drusen and pigmentary abnormalities in the macula
- Rapid sequence fluorescein angiography shows leakage in the neovascular form

TREATMENT

Desired Outcomes

The primary goal of treatment for AMD is to slow the disease progression. This includes slowing the loss of visual acuity and the progression to legal blindness, along with maintaining contrast sensitivity and slowing the rate of progression to late AMD. The secondary goals are maintaining quality of life for the patient and minimizing the adverse effects of treatment.²³

General Approach to Treatment

8 *There is no cure for AMD, and the efficacy of most treatments is low. Newer drug developments show promise, but no treatment can reverse damage that has already occurred.²⁴ Early diagnosis is critical. High-risk patients need periodic eye examinations because some patients do not notice any changes, even when neovascularization has occurred.²¹*

Nonpharmacologic Therapy

► Non-neovascular AMD

- Advise patients to stop smoking, as observational data supports a causal relationship between smoking and AMD.²¹ Drusen ablation by laser has been used in non-neovascular AMD. However, it is not clear whether the treatment reduces progression to neovascular AMD.²⁴ There is a possibility that the treatments may induce neovascularization and retinal atrophy.²³ Other nonpharmacologic therapies are in trials,

Patient Encounter 3, Part 1

KS, a 72-year-old white female, presents with difficulty seeing license plates on cars while she is driving. She can still distinguish street signs and other cars, but notices that smaller details seem hazy. She notes that this is only occurring in her left eye, so sometimes she closes that eye and everything is fine. Her son is concerned that she shouldn't be driving.

PMH: Hypertension, osteoporosis, hyperlipidemia

SH: Denies smoking, drinking, or illicit drugs

Widowed, two adult children

FH: Mother died at 70 from "old age"

Father died at 75 from cancer

PE:

BP 136/78

P 72

R 16

Ht 5'4" (163 cm)

Wt 142 lbs (65 kg)

Medications:

Lisinopril 10 mg daily

Fosamax 70 mg q week (on Fridays)

Lipitor 20 mg daily

Aspirin 81 mg daily

Multivitamin daily

Does KS have any definitive or potential risk factors for age-related macular degeneration?

but there is insufficient evidence for experts to recommend these procedures at this time.²¹

► Neovascular AMD

- Thermal laser photocoagulation reduces severe visual loss 2 to 5 years after the procedure, but leads to an immediate and permanent reduction in central vision. There is a 50% chance that leakage will recur in the next 2 years after the procedure.²³ Use of photodynamic therapy in combination with the medication verteporfin has shown success in clinical trials.²⁵ Verteporfin is reconstituted to achieve the desired dose of 6 mg/m² body surface area and diluted with 5% dextrose for injection to a total infusion volume of 30 ml. The drug is given intravenously, and laser light delivery is performed on the patient 15 minutes after the start of the 10-minute infusion with verteporfin. Photodynamic therapy uses non-thermal red light to activate verteporfin, which produces reactive oxygen species that locally damage the neovascular endothelium.²⁵ Verteporfin treatment reduces the risk of loss of visual acuity and legal blindness over 1 to 2 years. Long-term results are not yet available. Severe photosensitivity for

3 to 5 days after the procedure is common, and some patients experience a severe loss of vision. Eventually, most patients have some visual recovery. This procedure requires multiple treatments over time.²³ Other nonpharmacologic therapies are in trials, but there is insufficient evidence for experts to recommend these procedures at this time.²¹

Pharmacologic Therapy

- There are no approved pharmacologic treatments for non-neovascular AMD.²⁶ The Age-Related Eye Disease Study showed that a supplement containing ascorbic acid 500 mg, vitamin E 400 IU, β -carotene 15 mg, zinc oxide 80 mg, and cupric oxide 2 mg reduced the rate of clinical progression of all types of AMD by 28% in patients with at least intermediate macular degeneration.²⁶ No benefit was seen in patients with earlier stages of AMD; however, the duration of the study may have been insufficient to detect this benefit.²⁶ Currently, experts recommend antioxidant supplementation for intermediate AMD or advanced AMD in one eye.²¹ Supplementation is not without risk.²⁴ For example, β -carotene supplementation in smokers may increase the risk of developing lung cancer.^{21,24} At this time, it is not clear from the evidence whether a patient at a high risk but without symptoms of AMD would benefit from supplementation.²⁷

Vascular endothelial growth factor induces **angiogenesis**, increases vascular permeability, and increases inflammation, all of which are thought to contribute to neovascular AMD.²⁸ Pegaptanib, a vascular endothelial growth factor antagonist, binds to these growth factors in an attempt to suppress neovascularization.^{21,28} In clinical studies, patients treated with pegaptanib experienced a slower rate of visual decline than patients treated with a placebo injection.²⁹ Vision loss continued to occur in patients, and the drug was less effective in

the second year of treatment.²⁸ Long-term efficacy studies are not available yet.²⁸

- Another drug, ranibizumab, binds to and inhibits the activity of vascular endothelial growth factor (VEGF) A, a critical protein in angiogenesis.²¹ In one clinical study, 95% of patients treated with ranibizumab maintained visual acuity after 12 months compared with 62% of control patients.²¹ Both pegaptanib and ranibizumab are administered by intravitreal injection.^{21,28}

A new VEGF-A inhibitor, aflibercept, was approved in late 2011 for wet age-related macular degeneration. The dosing of 2 mg every 4 weeks for the first 3 months, followed by 2 mg every 8 weeks thereafter, results in seven injections during the first year of treatment compared with 12 injections with other products.³⁰ Patients treated with aflibercept or other VEGF-A inhibitors are at risk for arterial thrombotic events. Specifically, stroke, nonfatal heart attack, or vascular death were observed in 1.8% of 1,824 patients in aflibercept clinical trials.³⁰

Outcome Evaluation

- Monitor patients for acute and chronic vision changes or loss. The Amsler's grid (Figs. 62-4 and 62-5) and frequent eye examinations may detect changes more quickly. The long-term prognosis for AMD is poor. Monitor patients for inability to drive and remove driving privileges as appropriate. Work with patients and family members to plan for lifestyle changes as vision decreases.²¹

FIGURE 62-4. Amsler's grid distortions in the lines of the grid may be caused by subtle changes in central vision due to fluid in the subretinal space. This is the Amsler's grid as it appears to someone with normal vision. (From the National Eye Institute, National Institutes of Health Ref. No. EC03. <http://www.nei.nih.gov/photo/>)

Patient Encounter 3, Part 2

After meeting with a retinologist, KS has been diagnosed with early non-neovascular age-related macular degeneration. She has been advised to use a magnifying glass for her left eye instead of closing it while reading. She has been advised to not drive at night, but is still able to drive during the day.

What pharmacologic and nonpharmacologic treatment options are available for KS?

KS's daughter is very FRUSTRATED that her mother is not on a "medication," as a family friend is being treated for macular degeneration. What information is necessary to relay to KS's daughter?

What monitoring is appropriate for KS?

KS's daughter is concerned that she will develop macular degeneration because she read that it runs in families. What symptoms should KS's daughter watch for as she gets older?

FIGURE 62-5. Amsler's grid as it might appear to someone with AMD. (From the National Eye Institute, National Institutes of Health Ref. No. EC04. <http://www.nei.nih.gov/photo/>)

DRY EYE

EPIDEMIOLOGY AND ETIOLOGY

Dry eye is a frequent cause of eye irritation. The lack of a single diagnostic test for the condition limits the available epidemiologic data. Reports of the prevalence of dry eye range from 5% to 30%, being more frequent in elderly patients.³¹ The risk factors for dry eye are listed in [Table 62-10](#). Of interest, the use of caffeine is associated with a decreased risk of dry eye. Dry eye that is left untreated can cause loss of vision, structural damage, an increased risk for infection, and compromised efficacy of ocular surgery.³²

CLINICAL PRESENTATION

- Symptoms of dry eye are similar to those of other diseases and may include blurred vision, burning, irritation, itching, soreness, and/or the sensation of a foreign body in the eye.³²

Table 62-10

Risk Factors for Dry Eye

Older age
 Female gender
 Connective tissue disease
 Vitamin A deficiency
 Androgen deficiency
 Estrogen replacement therapy

From Jackson WB. Management of dysfunctional tear syndrome: a Canadian consensus. *Can J Ophthalmol* 2009;44:385-394.

Clinical Presentation and Diagnosis of Dry Eye³¹

General

Many other ocular diseases have similar symptoms. Patients with suggestive symptoms without signs should be placed on a treatment trial. Repeated observations over time may be required for a clinical diagnosis.

Symptoms

- Dry or foreign body sensation
- Mild itching
- Burning
- Stinging
- Photophobia
- Ocular irritation or soreness
- Blurry vision
- Contact lens intolerance
- Diurnal fluctuation or symptoms worsening later in the day

Signs

- Redness
- Mucus discharge
- Increased blink frequency
- Tearing

Other Diagnostic Tests

- The tear break-up time test assesses the stability of precorneal tear film. Break-up times of less than 10 seconds are considered abnormal.
- Ocular surface dye staining assesses the ocular surface and will show blotchy or exposure-zone punctate areas in the dry eye.
- Schirmer's test evaluates aqueous tear production but is not diagnostic for dry eye. Results of 5 mm or less are considered abnormal.
- Assess corneal sensation if trigeminal nerve dysfunction is suspected.
- Evaluate for an autoimmune disorder if significant dry eyes or other signs and symptoms or family history are present.

PATHOPHYSIOLOGY

The surface of the eye and the tear-secreting glands work together as an integrated unit that refreshes the tear supply and clears away used tears. Dry eye may be caused by impaired tear secretion and/or increased tear evaporation.³² It has been suggested that dry eye be called "dysfunctional tear syndrome," as all of the predisposing factors cause some disruption of the tear.³¹

Table 62–11

Associated Conditions That Cause or Worsen Dry Eye

Ocular Conditions	Environmental Factors
Blepharitis	Wind
Meibomian gland dysfunction	Reduced humidity
	Air conditioning or heating
Systemic Diseases	Exogenous irritants or allergens
Sjögren's syndrome	Prolonged use of computer or reading
Rosacea	Contact lenses
Lymphoma	Air travel
Sarcoidosis	Smoke exposure
Hemochromatosis	Local Trauma
Amyloidosis	Orbital surgery
HIV	Radiation
Hepatitis C	Injury
Epstein-Barr virus	Chemical exposure
Graft-versus-host disease	Systemic Medications
Rheumatoid arthritis	Diuretics
Systemic lupus erythematosus	Antihistamines
Scleroderma	Anticholinergics
Neuromuscular diseases	Antidepressants
Bell's palsy	Systemic retinoids
Parkinson's disease	Hormone antagonists
	Hormone therapy
	Cardiac antiarrhythmics
	Diphenoxylate/atropine
	β-Blockers
	Chemotherapy agents

From Refs. 31 and 32.

Dysfunction may be caused by aging, systemic inflammatory diseases, a decrease in androgen hormones, surgery, ocular surface diseases (including herpes simplex), systemic diseases, or medications that affect the efferent cholinergic nerves. Dysfunctional tear film may result in an inflammatory response on the ocular surface called **keratoconjunctivitis sicca**.³²

Conditions that increase the evaporative loss of tears also worsen dry eye. In addition to environmental causes (Table 62–11), an abnormal blink reflex is a common cause of increased evaporative loss.³²

TREATMENT

Desired Outcomes³²

- Relief of the symptoms of dry eye
- Maintain or improve visual acuity
- Prevention of long-term adverse effects from dry eye

General Approach to Treatment

9 Dry eye is a chronic condition. Symptoms can be improved with treatment, but unless dry eye is secondary to a disease, it is not usually curable. Because of this, patient education is critical, and a periodic reassessment of the efficacy of the treatment is appropriate. If the patient is unresponsive to treatment, refer to an ophthalmologist for additional options. If the dry eye is secondary to a systemic disease, the disease should be managed by the appropriate medical specialist.³²

Nonpharmacologic Therapy

- Behavioral and environmental modifications may significantly improve dry eye, especially in mild cases. Patients should be counseled to increase their frequency of blinking, use eyelid hygiene and warm compresses, and stop smoking. Evaluate the patient's environment for air drafts. Consider adding a humidifier in low-humidity areas. Schedule regular breaks from computer work or reading. Lower the computer screen to below eye level to decrease lid aperture. Evaluate medication profile and therapeutically substitute medications that do not exacerbate dry eye. Spectacle side shields or goggles may reduce tear evaporation.^{31,32}

If pharmacologic and other therapies are not sufficient, punctal occlusion or lateral tarsorrhaphy may be an option.^{31,32} Punctal occlusion is the plugging of the punctal drainage sites with collagen or silicone plugs. Lateral tarsorrhaphy sutures portions of the lid margins together to decrease evaporative tear loss.

Pharmacologic Therapy

- Regardless of the cause, the mainstay of treatment for dry eye is artificial tears. Artificial tears augment the tear film topically and provide symptom relief. If a patient uses artificial tears more than four times daily, recommend a preservative-free formulation. Preservative-free formulations are also appropriate if the patient develops an allergy to ophthalmic preservatives. Artificial tears are available in gel, ointment, and emulsion forms that provide a longer duration of relief and may allow for less frequent instillation. Ointment use is appropriate at bedtime.³¹

Preliminary data suggest dietary or supplemental intake of omega-3 fatty acids may be beneficial.^{9,31,32} Omega-3 fatty acids may block the production of inflammatory cytokines and proinflammatory mediators.³¹

Anti-inflammatory agents may be used in conjunction with artificial tears. The only approved agent is cyclosporine emulsion. Administered topically, the exact mechanism is unknown, but it is believed to act as a partial immunomodulator suppressing ocular inflammation. Cyclosporine emulsion increases tear production in some patients. Fifteen minutes should elapse after instillation of cyclosporine before artificial tears are instilled.³³ Use of topical corticosteroids for short periods (2 weeks) may suppress inflammation and ocular irritation symptoms.³²

The oral cholinergic agonists pilocarpine and cevimeline are used for patients with Sjögren's syndrome (combined dry eye and dry mouth) or severe dry eye. By binding to muscarinic receptors, the cholinergic agonists may increase tear production. Excessive sweating is a common side effect with pilocarpine and may limit its use (Table 62–12).³²

Outcome Evaluation³²

- Monitor patient for relief of symptoms and ocular damage.

Table 62–12

Pharmacologic Therapies for Dry Eye

Drug (Brand Name)	Dosing
Pilocarpine 5 mg tablet (Salagen)	5 mg orally 4 times daily
Cevimeline 30 mg capsule (Evoxac)	30 mg orally 3 times daily
Cyclosporine ophthalmic emulsion 0.05% (Restasis)	One drop in each eye twice daily

From Lacy CF, Armstrong LL, Goldman MP, Lance LL. Drug Information Handbook 2011. Hudson, OH: American Pharmaceutical Association, 2011.

Patient Care and Monitoring: Patient Counseling

Wash hands before and after instilling medication(s) into the eye

Contact lenses should be removed prior to instilling eye medication, and the patient should wait 10 minutes after instilling ocular medications into the eye before inserting contact lenses

Do not touch the tip of the eye medication container with hands or surfaces, including the eye

Use of **nasolacrimal occlusion** decreases systemic absorption up to 60% and may increase ocular bioavailability of the drug. After instilling the eye drop, the patient should close the eye and press a finger gently against the nasolacrimal duct (tear duct) for 2 to 3 minutes.³⁴

- Periodically reassess the patient's compliance with therapy and understanding of the disease.
- It may take 6 to 12 weeks before improvement is seen with pilocarpine therapy.³¹
- Cyclosporine therapy may take up to 3 months for full improvement.
- If a patient presents with vision loss, moderate or severe pain, corneal ulceration, or a lack of response to therapy, refer the patient to an ophthalmologist for prompt evaluation.

DRUG-INDUCED OCULAR DISORDERS

Many systemic medications can cause ocular adverse effects. Patients presenting with ocular complaints should have their medication profile evaluated for potential causative agents. **Table 62–13** shows some ocular changes due to the use of certain drugs.

Table 62–13

Selected Drug-Induced Ocular Changes

Miosis Alcohol Narcotics Barbiturates Phenothiazines	Mydriasis Anticholinergics Corticosteroids Tricyclic antidepressants Sympathomimetics
Decreased Tear Volume Anticholinergics Diuretics β -Blockers Tricyclic antidepressants	Corneal Deposits Amiodarone Hydroxychloroquine Tamoxifen Gold Indomethacin Phenothiazines (ocular pigment deposits)
Nystagmus Phenytoin Barbiturates	Cause or Worsen Cataracts Corticosteroids Phenothiazines
Increased Tear Volume Cholinergic agents Benzodiazepines Phenothiazines	Decreased Blink Rate Botulinum toxin type A Ethanol
Induce Uveitis Bisphosphonates Sulfonamides Cidofovir Topical metipranolol Topical corticosteroids Latanoprost	Lid or Corneal Edema Chlorthalidone Oral contraceptives Ibuprofen Digoxin Phenothiazines

From Refs. 16, 35, and 36.

Abbreviations Introduced in This Chapter

AMD Age-related macular degeneration
NSAID Nonsteroidal anti-inflammatory drug

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Allergic Rhinitis

David A. Apgar

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Describe two different systems for categorizing allergic rhinitis (AR).
2. Describe the basic pathophysiology of AR.
3. List the four most typical symptoms of AR and identify the usual single most troublesome one.
4. List at least three of the reasons for referral to an allergy specialist.
5. Discuss the categories of pharmacotherapy choices for treatment of AR.
6. Rank the pharmacotherapy choices for efficacy in treating the usual single most troublesome symptom of AR.
7. Describe an approach for treatment of mild AR with over-the-counter (OTC) drugs.
8. Create a therapy plan for treatment of moderate–severe AR.
9. Describe how to monitor patients treated for AR.
10. Identify the differences in approach to the treatment of AR for children, pregnant women, and the elderly compared with the routine approach in adults.

KEY CONCEPTS

- 1 Allergic rhinitis (AR) is an allergen-induced and immunoglobulin E (IgE)-mediated inflammatory condition of the lining of the nose and upper respiratory tract.
- 2 AR can be categorized in different ways.
- 3 AR is a common disorder that can negatively impact quality of life to a significant degree, yet it has been trivialized in the past.
- 4 The goals of treatment of AR are to reduce or minimize the frequency and severity of symptoms, prevent comorbid disorders and complications, improve the patient's quality of life, improve work attendance and productivity and/or school attendance and performance, and minimize adverse effects of therapy.
- 5 The general approach for treatment of AR is fourfold: avoidance of allergen triggers, pharmacotherapy, immunotherapy, and patient/family education.
- 6 Routine first-line agents for the treatment of AR are intranasal corticosteroids and oral and/or intranasal antihistamines. Adjunctive or secondary choice agents, each of which may have a first-line role in selected patients, include decongestants, cromolyn, montelukast, ipratropium, and intranasal saline irrigation.
- 7 Intranasal corticosteroids are the most effective therapy for AR, especially for nasal congestion. They are first-line agents for severe manifestations and are also used for those with moderate disease not controlled with oral and/or intranasal antihistamines. Their anti-inflammatory mechanism of action probably contributes to this superiority.
- 8 Second-generation antihistamines are first-line agents, especially for mild or intermittent AR. They are preferred over first-generation antihistamines because of their improved side-effect profile. Although effective for most symptoms of AR, they are less effective than intranasal corticosteroids for nasal congestion. Intranasal administration of an antihistamine is more effective than oral administration for nasal congestion.
- 9 The best applications of decongestants in AR are in short-term use to overcome severe nasal congestion and to facilitate improved efficacy of intranasal agents. The intranasal administration of decongestants should usually not exceed 3 consecutive days.
- 10 Generally speaking, the treatment of AR in children is the same as it is for adults, except for limitations in terms of FDA-approved products for some age groups and route of administration issues with some products.

INTRODUCTION¹⁻³

Rhinitis is inflammation of the lining of the nose and other parts of the upper respiratory tract. Allergy is only one cause of rhinitis. Although there are several other types of rhinitis (see [Table 63-1](#)), and some patients can manifest a mixed form (both allergic and nonallergic rhinitis), allergic rhinitis (AR) is the focus of this chapter. Because ocular symptoms frequently occur in association with AR, another term used is allergic rhinoconjunctivitis. This acknowledges involvement of the bulbar and palpebral conjunctivae in the allergic process. **1** *AR is an allergen-induced and immunoglobulin E (IgE)-mediated inflammatory condition of the lining of the nose and upper respiratory tract.*

2 *AR has traditionally been categorized as either seasonal or perennial.* Seasonal allergic rhinitis (SAR) is attributed to inhaled allergens (**aeroallergens**) that have a seasonal variation. These allergens are usually encountered outdoors and are most often plant pollens and substances from molds and fungi. Perennial allergic rhinitis (PAR) is attributed to aeroallergens that are present in the patient's environment almost continuously throughout the year and are usually

encountered indoors. Common perennial allergens are the house dust mite, indoor molds and fungi, insects (especially cockroaches), and companion animals (pets). Some patients are affected year round, but have seasonal exacerbations. These people are probably allergic to both seasonal and perennial aeroallergens. Other patients have only episodic manifestations. These people are probably allergic to aeroallergens that are only occasionally (episodically) encountered. The Joint Task Force on Practice Parameters (representing the American Academy of Allergy, Asthma and Immunology [AAAAI], the American College of Allergy, Asthma and Immunology [ACAAI], and the Joint Council of Allergy, Asthma and Immunology) published practice parameters for the diagnosis and management of AR in August 2008.¹ This document also introduces the term “episodic” AR, as a category in addition to SAR and PAR.

Recognizing that the traditional categories of seasonal and perennial AR are imperfect, another system for categorizing AR has been suggested by the international group Allergic Rhinitis and its Impact on Asthma (ARIA).² **2** *This alternative system categorizes the manifestations by a combination of frequency and severity.* There are two divisions of frequency: intermittent and persistent. Intermittent frequency is defined as AR manifestations occurring less often than 4 days per week or for fewer than 4 consecutive weeks. Persistent frequency is defined as AR manifestations occurring for 4 or more days per week *and* for 4 or more consecutive weeks. Severity is categorized either as mild or as moderate–severe. Mild manifestations are those that do *not* cause interference with sleep, daily activities, or work or school performance and that are not “troublesome.” Moderate–severe manifestations were combined because distinction between moderate and severe was not clinically practical. This category includes those patients with manifestations of AR that do cause interference with sleep, impairment of daily activities, problems at work or school, or are “troublesome.” The ARIA document uses IAR (for intermittent) and PER (for persistent) for the two frequency categories. It is important to realize that IAR and PER are not synonymous with the classical categories of SAR and PAR, respectively. The ARIA system results in four categories: mild intermittent, mild persistent, moderate–severe intermittent, or moderate–severe persistent. The ARIA approach was updated in early 2008.² See [Table 63-2](#) for a summary of these categories of AR.

Table 63-1

Types of Rhinitis

Allergic (see [Table 63-2](#) for details)

Nonallergic

Vasomotor (also known as perennial nonallergic rhinitis) (triggered by irritants, cold air, exercise/running, or unidentified factors)

Food/meal related (gustatory)

Infectious

NARES (nonallergic rhinitis with eosinophilia syndrome)

Occupational

Caused by protein allergens (IgE-mediated) or by irritants/sensitizers (probably non-IgE-mediated)

Other rhinitis syndromes

Hormonally related (pregnancy and menstrual cycle related)

Drug-related

Rhinitis medicamentosa (rebound from overuse of intranasal decongestants)

Drug-induced

Angiotensin-converting enzyme inhibitors (ACEI)

α -Antagonists (used for treatment of BPH and HT)

Phosphodiesterase-5 inhibitors (used for treatment of ED)

Aspirin and other NSAIDs (as an isolated side effect of AERD)

Oral contraceptives (controversial)

Atrophic rhinitis

Rhinitis associated with inflammatory or immunologic diseases (e.g., granulomatous infections, RA, SLE, Wegener's granulomatosis, sarcoidosis, Churg–Strauss syndrome, and others)

ACEI, angiotensin-converting enzyme inhibitor; AERD, aspirin-exacerbated respiratory disease; BPH, benign prostatic hyperplasia/hypertrophy; ED, erectile dysfunction; HT, hypertension; NARES, nonallergic rhinitis with eosinophilia [on nasal smear] syndrome; NSAIDs, nonsteroidal anti-inflammatory drugs; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

From Refs. 1–3.

Table 63-2

Categories of Allergic Rhinitis**Based on AAAAI/ACAAI Practice Parameter**

Seasonal—symptoms present only during specific portions of the year

Perennial—symptoms present throughout the year

Episodic—symptoms present only during intermittent exposure to allergen trigger

Based on ARIA 2008 Update

Mild versus moderate–severe

Mild means no interference with sleep, daily activities, work or school function and attendance, and no troublesome symptoms

Moderate–severe means the presence of any one of the following: abnormal sleep, impairment of daily activities, impairment of work or school function, troublesome symptoms

Intermittent versus persistent

Intermittent means that symptoms are present for less than 4 days/week, or for less than 4 consecutive weeks

Persistent means that symptoms are present for more than 4 days/week and for more than 4 consecutive weeks

Any one of the four possibilities of these variables can occur: mild intermittent, mild persistent, moderate–severe intermittent, and moderate–severe persistent

From Refs. 1–3.

The major risk factors for AR are: a family history of allergic disorder; elevated serum IgE levels, especially before the age of 6 years; higher socioeconomic class; positive skin test results; and emigration into a Western industrialized environment.^{1,2}

Certain disorders occur commonly with AR. The most important example is asthma. Some sources consider AR and asthma as two manifestations on a spectrum within the same disease. As many as 78% of patients with asthma have AR, and up to 38% of patients with AR have asthma.^{4,8,10} There is evidence that AR can predispose to the development of asthma.^{1,4,8,10} Other conditions that can occur with AR include sinusitis, obstructive sleep apnea, otitis media with effusion, and nasal polyposis.¹

Pathophysiology^{1–3,5,10–12}

AR is an IgE-mediated disorder of people who are allergy prone. Initial contact is required to sensitize the patient to subsequent exposures. Patients with an inherited tendency to allergic disorders produce T-helper lymphocyte type 2 (Th-2)-directed responses, including production of specific IgE antibodies, to one or more allergens. The details of the process are complex and still being defined. Many types of cells, mediators, and intermediate substances (including cytokines) are involved. In response to subsequent exposures to the trigger antigen(s), there is an early-phase and often a late-phase allergic response. This distinction has therapeutic implications.

During the early phase, the trigger allergen becomes bound to IgE that is fixed to mast cells in the nasal mucosa.

This occurs within minutes of subsequent exposure to the antigen and causes the mast cells to degranulate. Degranulation results in release of preformed mediators, the most important of which is histamine. This step stimulates more mast cells, as well as macrophages, eosinophils, and basophils to produce more substances, including cysteine leukotrienes and prostaglandin D₂. These newly produced mediators bind to receptors in the nose and facilitate many of the manifestations of AR. The resultant vasodilation, mucosal edema, and hypertrophy all contribute to nasal congestion. Clear, watery, and often profuse rhinorrhea is also characteristic in this early phase, a combined result of mucous secretion and increased vascular permeability. Sneezing and nasal itch are other prominent features of the early phase. Many patients also have ocular symptoms.

The late phase occurs in up to 50% of AR sufferers. It can begin as soon as 2 hours after the early phase and usually peaks within 12 hours. The late phase involves a second release of many of the mediators of the early phase. In addition, the late phase is characterized by an inflammatory component caused by infiltration of several cell types (e.g., mast cells, eosinophils, basophils, neutrophils, and T lymphocytes) into the nasal mucosa. The most significant manifestation during the late phase is nasal congestion that is often severe and long lasting.

A phenomenon known as the priming response is also of importance. This simply means that prolonged and/or repeated allergen exposure makes it easier to stimulate the process resulting in mediator release with symptoms. The inflammatory component that characterizes the late phase probably contributes to this effect. A vicious cycle results in which smaller doses of allergen can create symptoms (i.e., the threshold is lowered). Thus, even when pollen exposure is decreased, symptoms may continue. In some patients, the threshold is lowered to the degree that even irritant substances (e.g., formaldehyde, tobacco smoke, perfumes, automobile exhaust, and other environmental pollutants) may cause symptoms, on a nonallergic basis.

TREATMENT**Desired Outcomes**

4 The goals of treatment of AR are to reduce or minimize the frequency and severity of symptoms, prevent comorbid disorders and complications, improve the patient's quality of life, improve work attendance and productivity and/or school attendance and performance, and minimize adverse effects of therapy. Until a cure is established, these are the only realistic goals.

Nonpharmacologic Therapy

5 The general approach for treatment of AR is fourfold: avoidance of allergen triggers, pharmacotherapy, immunotherapy, and patient/family education. Immunotherapy will be considered nonpharmacologic, for this discussion, because it is not self-administered by the patient and its implementation requires referral to a specialist.

Clinical Presentation and Diagnosis of Allergic Rhinitis^{1-4,8}

Typical Symptoms

- Rhinorrhea (usually clear and bilateral; primarily anterior but may have posterior [postnasal drip])
- Sneezing
- Itching (affecting mostly the nose, but also the palate, throat, eyes, and ears)
- Nasal congestion (usually the most troublesome symptom)

Other Symptoms

- Sleep disturbances
- Headache, mild facial or ear pain or fullness
- Cough (especially in those with concurrent asthma)
- Fatigue, asthenia, malaise, and irritability
- Ocular manifestations (itch, redness, tearing, **chemosis**, periorbital edema)
- Presenteeism (impaired performance at work or school)
- Absenteeism from work or school
- Quality of life impairment (including social function)
- Children (especially): rubbing the nose, snorting, sniffing, clearing the throat, learning or attention problems, poor appetite

Signs (especially common in children)

- Rubbing the nose (especially with the back of the hand or the palm; so-called allergic salute, which may create a horizontal crease just above the tip of the nose)
- Rubbing/scratching at the eyes
- Mouth breathing
- Dark circles under the eyes
- **Dennie-Morgan** lines or folds

Diagnosis

- Typical symptoms, especially in association with exposure to allergen triggers
- Other diagnostic testing usually optional, but may be necessary to rule out nonallergic causes of rhinitis or if immunotherapy is a consideration (physical exam, especially of the upper respiratory tract with emphasis on the nose, specific IgE antibody testing by either skin testing or in vitro serum testing, other specialized testing).

Avoidance of allergen triggers, to the extent they have been identified and to the extent such avoidance is possible, underlies the treatment for all patients with AR (see **Table 63-3**).^{1,2}

Immunotherapy must be administered by a physician. The initial evaluation includes identification of specific allergens to determine individualized therapy. The role of a pharmacist in immunotherapy is appropriate referral of patients to an allergist or immunologist. See **Clinical Presentation and Diagnosis** for considerations for referral. At the time of this writing, in the United States, subcutaneous injection immunotherapy is the only option.^{1-3,13,14} In other parts of the world, sublingual immunotherapy is an alternative.^{9,13,15-17} The major advantage is ease of administration. Questions remain about comparative efficacy and the details of optimal dosage, frequency of administration, and duration of therapy.

Education of the patient as well as the patient's support system is essential.¹ They all need to understand the potential seriousness of AR (including complications such as asthma) and the chronic and/or recurrent nature of the disorder. The patient and significant others should be told about the various treatment options, including their relative advantages and disadvantages. Proper understanding and use of current medication in the patient's regimen should be assured. A better educated patient and support system will result in a better relationship with healthcare providers and hopefully will optimize patient outcomes.

Patient Encounter 1, Part 1

LF is a 30-year-old woman who presents to your place of work. She moved to this part of the country about 3 months ago. She complains of sneezing and runny nose, which began about 1 month ago. Her symptoms are worse when she is outdoors, especially if the weather is windy. Also, her symptoms interfere with her sleep so that often she awakens tired. This tiredness causes her to "doze off" several times a day while sitting at her computer at work. She asks your recommendation for OTC treatment.

Which of the typical symptoms consistent with AR does this patient have?

Which of the other (less typical) symptoms consistent with AR does she demonstrate?

What additional information is needed to accurately assess her current condition?

Pharmacologic Therapy

There are three guideline documents, all published in 2008, that are the basis for the summary that follows.¹⁻³ Although guideline documents are highly regarded by many, the patients enrolled in the randomized clinical trials that are a major basis for their conclusions and recommendations

Table 63-3

Allergen Avoidance Measures**Allergen avoidance underlies all other treatments of AR**

There are several limitations to implementing allergen avoidance:

- Identification of allergens is necessary to successfully employ avoidance strategies.
- Literature support for a clinically significant impact on symptoms from allergen avoidance, especially any single measure, is meager.
- Quality of life may be negatively impacted by forced removal of a pet from the household.

Outdoor plant pollen and mold/fungi parts:

- Limit outdoor exposure, especially during high pollen conditions (warm sunny days with wind and low humidity) and during mold/fungi spore release (shortly after rains).
- Wear a face mask during activities that disturb the earth and decaying vegetation.
- Keep windows and doors closed.
- Use air conditioning when possible, but maintain clean equipment.

Indoor allergens (house dust mite, mold/fungi, cockroaches, and pets):

- Use air-conditioning, as above.
- Maintain humidity below 50% if possible, and maintain clean equipment.
- Clean frequently and thoroughly to prevent mold growth (dilute bleach with detergent).
- Avoid exposed food and garbage, especially in the kitchen, to deter insects.
- Clean kitchen frequently and thoroughly.
- Use roach traps that facilitate removal of allergen-containing bodies.
- Vacuum frequently, and consider use of a high-efficiency particulate air (HEPA) filter.
- Minimize carpeting, fabric covered furniture, and fabric wall/window coverings.
- Cover bedding (pillows, mattresses, box springs) with allergen-proof, zippered cases.
- Launder bedding frequently, in hot water (greater than 130°F or 54°C) if possible, to kill mite ova.
- Consider **acaricide** (e.g., benzyl benzoate) treatment of carpets to kill mites and ova.
- Put items that cannot be laundered (e.g., soft toys) in a plastic bag and freeze.
- Keep pets out of bedroom and bathe cats weekly, if possible.

Irritants:

- Avoid, to the degree possible, all exposure to smoke, chlorine fumes, formaldehyde fumes, and other substances identified as irritant triggers in the patient (e.g., perfumes, newspaper ink).

From Refs. 1 and 2.

are not always representative of patients in a primary practice population.¹⁸ Other sources provide additional information for the treatment of AR.^{8-10,19-29} The recommended approaches begin with allergen avoidance, emphasize patient/family education, and include immunotherapy as an option in selected patients.

The most reasonable plan may include considerations from several of these documents. **6** Routine first-line agents are intranasal corticosteroids and oral and/or intranasal antihistamines. Adjunctive or secondary choice agents, each of which may have a first-line role in selected patients, include decongestants, the mast cell stabilizer/cromone (cromolyn),

Table 63-4

Intranasal and Oral Medications for AR**Corticosteroids**

Intranasal^a (budesonide, beclomethasone, ciclesonide, flunisolide, fluticasone [propionate and furoate], mometasone, triamcinolone)

Oral (rarely used)

Parenteral (not recommended)

Antihistamines

Intranasal^a (azelastine, olopatadine)

Oral^b

- First generation/sedating (cautious use in selected patients) (most OTC depending on strength: diphenhydramine, chlorpheniramine, clemastine, and others)
- Second generation/low- or nonsedating^a (desloratadine, levocetirizine; OTC: loratadine, cetirizine, fexofenadine)

Mast cell stabilizer/cromone

Intranasal (OTC: cromolyn)

Decongestant

Intranasal (short-term use) (tetrahydrozoline; OTC: phenylephrine, naphazoline, oxymetazoline)

Oral^b (OTC: phenylephrine; BTC: pseudoephedrine)

LTRA

Oral (montelukast)

Antimuscarinic

Intranasal (ipratropium)

Note: All products are prescription unless indicated as OTC.

^aFirst-line choices.

^bSome products combine an antihistamine with a decongestant, sometimes with other ingredients.

^cBehind the counter (OTC plus other requirements necessary; see the Decongestants section of text).

From Refs. 1-3 and 25-29.

the leukotriene receptor antagonist (LTRA) (montelukast), the antimuscarinic/anticholinergic (ipratropium), and intranasal saline. In all cases, therapy must be individualized, in cooperation with the patient. Considerations include frequency and severity of specific symptoms, realistic avoidance measures, patient age, patient preferences for route of administration, tolerance of side effects, adherence issues, comorbid disorders, and concurrent therapy. See **Table 63-4** for intranasal and oral medications for the treatment of AR.

The guideline document on AR published in August 2008 by the Joint Task Force (for AAAAI and ACAAI) includes an action plan (similar to what is used for asthma). The entire article, with a sample Rhinitis Action Plan, is available on the AAAAI website (<http://www.aaaai.org/Aaaai/media/MediaLibrary/PDF%20Documents/Practice%20and%20Parameters/rhinitis2008-diagnosis-management.pdf>) in the public domain, for universal access.¹ The application of the differently colored zones on the Rhinitis Action Plan is explained at the bottom of the form, which is on page S25 of the document. Many patients will benefit from having an action plan.

► First-Line Agents

Corticosteroids Corticosteroids are usually administered by the intranasal route for the treatment of AR. Occasionally, a short course of oral therapy (burst and taper) is

Patient Encounter 1, Part 2

Further questioning of LF reveals that she had “allergies” as a child, but apparently “outgrew” them. She does not know any other details about her childhood allergies. She has not had any previous episodes as an adult. This episode started 6 weeks after her arrival to her new home. You also establish that she has had these symptoms steadily for at least the last 6 weeks and that they occur most days during the week. She also admits to almost daily nasal congestion. In fact, it is the congestion that is most bothersome to her and is the thing that interferes with her sleep. She also admits to itching of the roof of her mouth and a tickling sensation in her throat. She also has some itching and watering of both eyes. She does have some symptoms indoors, especially in the kitchen. However, the symptoms are definitely worse when she is outside, especially when doing yard work (mowing the lawn or trimming bushes and flowers). Her sleep is so disturbed that she feels tired most of the rest of the day, especially during the weekdays, while at work. The tiredness even interferes with activities during the weekend. The only things she notices that make her worse are spending a lot of time in the kitchen and especially being outdoors when the weather is windy. So far, she has tried nothing for these symptoms, because she does not know what to use. She thinks all this is due to allergies to local plants that are new to her because of her recent move.

What additional symptoms that are consistent with AR does she now demonstrate?

Presuming the patient has AR, how would you categorize her condition?

What additional information is needed to accurately assess possible causes for her symptoms other than plant allergies?

necessary. This oral use of corticosteroids is best applied to overcome severe nasal congestion, particularly that due to rhinitis medicamentosa from intranasal decongestants (see the section on Decongestants later in this chapter). Parenteral administration of corticosteroids in the management of AR is discouraged.¹

7 *Intranasal corticosteroids are considered the most effective therapy for AR. They are recommended as the drugs of choice for severe manifestations and for those with moderate disease not controlled with oral and/or intranasal antihistamines. They provide very good relief for sneezing, itching, and rhinorrhea, as well as nasal congestion and even ocular symptoms. Nasal congestion is often the most bothersome symptom of AR, and the most difficult to control. This is probably because it results from inflammation that predominates in the late phase of the allergic response in AR.*

7 *Intranasal corticosteroids are the best agents for nasal congestion, probably because of their anti-inflammatory mechanism of action.^{1,19,22} Systemic corticosteroids (i.e., orally*

administered) are also effective, but they are used only as a last resort due to systemic side effects.

Several meta-analyses have evaluated the relative efficacy of intranasal corticosteroids in comparison with other types of pharmacologic therapy of AR. The majority (but not all) of the literature suggests that intranasal corticosteroids are superior to intranasal antihistamines, to oral antihistamines, even when combined with a leukotriene antagonist, and to a leukotriene antagonist alone.^{1,19}

There are currently eight intranasal corticosteroid products available in the United States, including two different salt forms of fluticasone. Most (e.g., budesonide, ciclesonide, fluticasone furoate, mometasone, and triamcinolone) are usually given in a single daily dose. However, fluticasone propionate may be given either once or twice daily; beclomethasone is usually given twice daily, and flunisolide is given two or three times daily. Despite some differences in formulation, potency, chemistry, and pharmacokinetic and pharmacodynamic properties among the products, there is no good evidence that any single product is superior in efficacy. Intranasal corticosteroids are best given regularly, as the onset of action usually takes up to 12 hours and the maximum effects may be delayed up to 7 to 14 days.^{1,8,10} However, there is evidence that in some people the onset is within 3 to 4 hours, so these agents may even be used on an as needed basis.^{1,30} When nasal congestion is severe, intranasal administration may not be effective due to limited exposure to the nasal mucosa. In that situation, short-term intranasal decongestants may facilitate better exposure. See [Table 63–5](#) for intranasal corticosteroid products.

The correct technique for administration of intranasal medication is important for optimum efficacy. Consult the individual product labeling for specific instructions. However, also see [Table 63–6](#) for general instructions for the optimal administration of intranasal medications. The technique described maximizes exposure of the drug to the nasal mucosa to optimize efficacy and minimizes both exposure to the nasal septum and loss of medication down the esophagus. See later for instructions about preparation and use of intranasal saline irrigations.

Most patients tolerate intranasal corticosteroids very well. Local side effects include nasal burning, irritation, and dryness, which may occur in up to 12% of patients.^{1,8,10,19,23} Also, up to 10% to 12% of patients may experience mild **epistaxis**.^{19,24} This may be partly due to the administration technique. Sore throat and headache may be noted by some patients.²⁴ Perforation of the nasal septum is a very rare side effect. This can be minimized by proper administration technique (see [Table 63–6](#)), specifically, directing the spray laterally and away from the (medial) nasal septum.^{1,10}

The older intranasal corticosteroids (beclomethasone, flunisolide, and budesonide) have significant absorption, whereas, among the newer products, fluticasone and mometasone, have bioavailability of no more than 1% to 2%.¹⁹ The decreased absorption minimizes systemic side effects. However, there is still some concern for growth suppression, other manifestations of hypothalamic–pituitary–adrenal (HPA) axis suppression, and bone and ocular effects.¹⁹

Table 63-5

Intranasal Corticosteroids

Generic (Brand) Name	mcg/spray	Usual Adult Dosage (each nostril)	Usual Pediatric Dosage (each nostril)
Beclomethasone dipropionate (Beconase AQ)	42	1–2 sprays twice daily	6 yo or more: 1–2 sprays twice daily
Budesonide (Rhinocort Aqua)	32	1–4 sprays once daily	6–11 yo or more: 1–2 sprays once daily
Ciclesonide (Omnaris)	50	2 sprays once daily	6 yo or more: 2 sprays once daily (seasonal AR) 12 yo or more: 2 sprays once daily (perennial AR)
Flunisolide	25	2 sprays two or three times daily	6–14 yo or more: 1 spray three times daily or 2 sprays twice daily
Fluticasone furoate (Veramyst)	27.5	1–2 sprays once daily	2–11 yo or more: 1–2 sprays once daily
Fluticasone propionate (Flonase)	50	1–2 sprays once daily or 1 spray twice daily	4–11 yo or more: 1–2 sprays once daily
Mometasone (Nasonex)	50	2 sprays once daily	2–11 yo or more: 1 spray once daily
Triamcinolone acetonide (Nasacort AQ)	55	2 sprays once daily	2–5 yo: 1 spray once daily 6–11 yo: 1–2 sprays once daily

mcg, micrograms; yo, years old.

Note: All products are FDA Pregnancy category C except budesonide, which is B.

From Refs. 1, 10, 25–27, and 29.

Table 63-6

Administration Instructions for Intranasal Medications

1. Clear the nose of mucus and debris to the extent possible.
2. Consult product labeling for preadministration instructions (e.g., shaking the container, priming the spray pump).
3. If seated or standing, do not just tilt head backward. This increases the amount of the dosage lost down the esophagus. This decreases efficacy and increases the potential for systemic absorption and thus systemic side effects.
4. If standing, bend the head forward (flex the chin onto the chest) so that the nose is the lowest portion of the head. This is best for nasal sprays.
If possible, lie in the prone position with the stomach (ventral side) on a flat surface or kneel down. Then, flex chin onto neck, so that the open nostrils are pointing as far upward, toward the ceiling as possible. This position may be best for nose drops (more volume than sprays).
An alternate position is to lie supine (on the back) on a flat surface, then bend the head backward (extend the head), again, so that the open nostrils point upward toward the ceiling.
5. Use the contralateral hand to insert the spray nozzle or dropper into one nostril (i.e., the left hand for right nostril).
6. Use the other hand to occlude the opposite nostril (the one not being medicated).
7. Aim the spray or drops toward the outer (lateral) internal surface of each nostril and away from the nasal septum (which is the inner or medial surface).
8. Breathe in slowly but deeply through the medicated nostril.
9. Repeat this procedure to apply medication to the other nostril.
10. Consult the product labeling for instructions on cleaning the device.
11. See the text for information about preparation and use of saline irrigation.

From Refs. 3 and 8.

Several studies have evaluated the effects of intranasal and inhaled corticosteroids on HPA axis suppression and growth.^{1,19} Most have shown little or no clinically significant effects. The product most implicated with growth suppression is beclomethasone. According to one of the guideline documents, one study demonstrated suppression in children using the drug for 1 year, but at twice the usual recommended dose.¹ There is no confirmation of a causal effect of intranasal corticosteroids on posterior subcapsular cataracts, increased intraocular pressure, or decreased bone density; however, those with risk factors for any of these conditions should be monitored carefully for their development. Ultimately, patient preference for a specific intranasal corticosteroid may be determined more by cost and by formulation differences that affect odor and aftertaste.

Antihistamines Antihistamines used for the treatment of AR are administered by either the oral or the intranasal route. These agents interact with the H₁ (histamine type 1) receptor. Histamine is involved with both the early and the late phases of AR. Activation of H₁ receptors in the nose, upper airway mucosa, and the eye produces the common manifestations of AR (sneezing, itching, rhinorrhea, nasal congestion, and ocular symptoms). The antihistamines are very effective for the sneezing, itching, and rhinorrhea of AR. There is some effect to improve nasal congestion, but less so than for the other symptoms. There is also benefit for the ocular symptoms (e.g., itch, redness, tearing). Intranasal administration is more effective than oral administration for the nasal congestion, but less effective for the ocular symptoms. The onset of action by oral administration is usually within 1 to 2 hours, and that for intranasal administration within 30 minutes.^{1,8,19} All antihistamines probably provide better relief if used continuously during symptomatic periods, but they are also effective used only when needed.

Antihistamine drugs used for AR are technically inverse agonists, not competitive antagonists; however, there may be little clinical significance to the difference.^{10,19,22} These drugs bind to the H₁ receptor, changing its three-dimensional conformation such that it is kept in the inactive state. This results in downregulation of H₁ receptor activity and a decrease in end organ effects. These agents do not prevent release of histamine. Research continues relative to the clinical importance of blockade of other types of histamine receptors (H₂, H₃, H₄) in the treatment of AR.³¹

The oral agents are divided into first- and second-generation drugs. The first-generation agents are distributed among six chemical classes, including the more sedating ethanamine class (e.g., diphenhydramine) and the least sedating alkylamine class (e.g., chlorpheniramine). **8** *Most sources now discourage the routine use of the first-generation agents for AR. This is due to their CNS and anticholinergic side effects.* The CNS effects are primarily sedation, as well as impairment of cognitive function and performance of tasks. Studies have shown that decision making and driving or work performance are impaired even when the patient is unaware of any overt effects.¹ There is also evidence of decreased performance at school and impaired learning, among pediatric patients.¹ Some controversy remains, however, about how common these problems truly are.²⁴ The major anticholinergic (perhaps more accurately stated as antimuscarinic) effects include blurred vision, dry mouth, urinary retention, and constipation. The only possible advantage of the antimuscarinic properties is an additional effect to decrease rhinorrhea. However, some patients complain about the increased thickness of the secretions.²² Another disadvantage of the first-generation antihistamines is that most must be administered three to four times daily. If first-generation antihistamines are recommended by a healthcare practitioner, care must be taken to educate the patient about these CNS and anticholinergic side effects. Patients who take other sedative substances are prone to an additive effect from the antihistamine. Those taking any other medications with anticholinergic or antimuscarinic properties may experience additive effects from the antihistamine. The elderly are, in general, more sensitive to both types of adverse effects.

Currently available oral second-generation H₁ antihistamines are cetirizine, levocetirizine, loratadine, desloratadine, fexofenadine, and acrivastine. All except acrivastine are available alone, and some are marketed in combination with the decongestant pseudoephedrine. At the time of this writing, cetirizine, loratadine, and fexofenadine are available OTC. The second-generation antihistamines do not have the anticholinergic effects of the first-generation agents. Based on current literature, no single H₁ antihistamine (first or second generation) is clearly superior in efficacy; however, very few head-to-head comparative studies have been conducted. Individual variation is likely, and patients may need to try more than one product to realize optimal benefit. The oral second-generation antihistamines are effective for the sneezing, itching, and rhinorrhea of AR, but less effective for the nasal congestion. They also improve ocular symptoms. Intranasal antihistamines are better for nasal congestion.

Fexofenadine has virtually no sedative effects, even at doses higher than usually recommended. Loratadine and desloratadine are not sedative at recommended doses, but can be at higher doses. Cetirizine, levocetirizine, and acrivastine have some sedative effects, even at recommended doses.¹ All the oral second-generation agents require some dosage reduction with impaired renal function, although the specific recommendations vary with creatinine clearance.^{29,32} To date, none of the currently available oral second-generation antihistamines have been reported to cause QT prolongation or torsade de pointes, as were associated with the two agents that have been removed from the U.S. market (terfenadine and astemizole).¹⁹ Most of the oral second-generation antihistamines can be administered once daily (except for the lower dosage forms of fexofenadine). This probably improves adherence.

There are only two intranasal antihistamine products available in the U.S. market at the time of this writing. Both azelastine and olopatadine are considered second-generation agents, although they also have some mast cell stabilizing effects.²⁵ Both are available only by prescription. The most common side effect of these products is a bitter taste. This occurs in up to 20% of patients on azelastine and probably somewhat fewer on olopatadine.¹ Also, there is enough systemic absorption to cause sedation in some patients using azelastine (about 10%) and perhaps somewhat fewer on olopatadine.¹ There are no direct comparisons of the two agents, so definitive statements regarding their relative efficacy and side-effect incidence cannot be made. A recent manufacturer-sponsored supplement issue of an allergy journal had several articles that were favorable to the increased use of intranasal antihistamines.³³⁻³⁵ However, until these changes are supported more universally, they are considered preliminary. See [Table 63-7](#) for the single-agent second-generation antihistamine products.

- **8** *Many patients with mild-to-moderate AR are adequately treated with an oral OTC first- or (preferably) second-generation antihistamine alone.* Others may prefer the intranasal administration of an antihistamine, but they require a prescription. Some patients will need or prefer combination therapy.
- If nasal congestion is not relieved by the above regimens, addition of a decongestant is reasonable, either alone or as a combination product (see Decongestant section that follows). Perhaps even the combination of an oral with an intranasal antihistamine is reasonable for some patients, depending on their preferences. Other pharmacologic agents can be combined with oral and/or intranasal antihistamines, as necessary for optimal control of symptoms (see later).

► **Adjunctive or Secondary Choice Agents**

Decongestants Decongestant drugs are useful to relieve the nasal congestion component of AR.^{1-3,10,19} This is due to their α_1 adrenergic agonist activity, which results in constriction of the vasculature in the nasal mucosa. They do not prevent release of any of the mediators involved in AR. Thus they do not provide any benefit for the sneezing, itching, rhinorrhea, or the ocular manifestations. Decongestants

Table 63–7

Single-Agent Second-Generation Antihistamine Products (Oral and Intranasal)

Oral

Generic (Brand) Name	Formulation	Usual Adult Dosage	Usual Pediatric Dosage
Cetirizine ^{ab} (Zyrtec, generic)	5, 10 mg tabs/chew tabs; 5 mg/mL syrup	5–10 mg once daily	6–11 mo; 2.5 mg once daily 12–23 mo; 2.5 mg once or twice daily 2–5 yo; 2.5–5 mg once daily or 2.5 mg twice daily
Desloratadine ^b (Clarinex)	5 mg tabs; 0.5 mg/mL syrup 2.5, 5 mg orally disintegrating tabs	5 mg once daily	6–11 mo; 1 mg once daily 1–5 yo; 1.25 mg once daily 6–11 yo; 2.5 mg once daily 2–11 yo; 30 mg twice daily
Fexofenadine ^{ab} (Allegra, generic)	30, 60, 180 mg tabs, 6 mg/mL suspension 30 mg orally disintegrating tabs	60 mg twice daily or 180 mg once daily	2–11 yo; 30 mg twice daily
Levocetirizine (Xyzal)	5 mg tabs 0.5 mg/mL solution	5 mg once daily	6 mo–5 yo; 1.25 mg once daily 6–11 yo; 2.5 mg once daily
Loratadine ^{ab} (Claritin; Alavert, generic)	10 mg tabs; 10 mg gel cap; 1 mg/mL syrup/susp; 10 mg disintegrating tabs; 5 mg chewable tab	10 mg once daily	2–5 yo; 5 mg once daily

Intranasal Spray

Generic (Brand) Name	mcg/spray	Usual Adult Dosage (each nostril)	Usual Pediatric Dosage (each nostril)
Azelastine (Astelin, Astepro)	137	1–2 sprays twice daily	5–11 yo; 1 spray twice daily
Olopatadine (Patanase)	665	2 sprays twice daily	6–11 yo; 1 spray twice daily

Note: acrivastine is available only with pseudoephedrine and so is not included in this table.

mo, months old; yo, years old.

^aAvailable OTC.

^bAvailable in combination with pseudoephedrine (consult labeling for pediatric dosage).

From Refs. 1, 25–27, and 29.

Patient Encounter 1, Part 3

LF definitely denies all use of medications in an attempt to treat this episode, including OTC meds, alternative measures like herbals, and specifically any type of nose drops or spray. She notices no association of these current symptoms with fever, meals, or menstruation. She has had a diagnosis of essential hypertension for the last 6 years. Her previous PCP (where she lived before her recent move) told her that her blood pressure was “well controlled” on her current medication regimen. She does not remember the numbers of her BP readings. Her current medication is a single combination tablet that she takes regularly once daily. She says it contains a water pill and an “ace” drug. You confirm this from the prescription bottle she has in her purse, which indicates Prinzide 20/12.5 (lisinopril/hydrochlorothiazide). She admits that she is not the best housekeeper and that she has seen a few cockroaches in her kitchen.

What additional information is needed before a recommendation could be made?

can be given alone, either by the oral or by the intranasal route. Also, numerous combination products, consisting of a decongestant with an antihistamine (and sometimes other ingredients), are available as oral medications. There are some special considerations for use of decongestants in pediatric and pregnant patients (see the Special Populations section later).

Oral decongestant products are currently limited to pseudoephedrine and phenylephrine (phenylpropanolamine was removed from the market in 2000).¹⁰ Pseudoephedrine has been changed from truly OTC to a more controlled status because it is an ingredient in the illicit manufacture of methamphetamine. The new, so-called behind-the-counter (BTC) status, established by the federal Combat Methamphetamine Act of 2005, requires: special storage; photo identification of purchasers; a log book of sales, which must be signed by purchasers; and specific limitations on daily and monthly quantities.^{36,37} Subsequent to this change in status of pseudoephedrine, some manufacturers changed the ingredients of their products by replacing pseudoephedrine with phenylephrine. This was probably to maintain shelf presence in the OTC sales area. However, much controversy surrounds the efficacy of oral phenylephrine. At the time of this writing, the

clinical literature suggests that the currently recommended adult dose is minimally effective as a nasal decongestant.^{38–40}

The side effects of orally administered decongestants most often affect cardiovascular function or the CNS. The side effects are primarily due to sympathetic stimulation and are usually dose-related. Some elevation of blood pressure may occur, but in normotensive and well-controlled hypertensive patients, the elevation is usually small. It is not of clinical significance in most situations, especially considering that these drugs are most appropriately used only briefly or intermittently. Insomnia, nervousness, irritability, and anxiety are relatively common CNS side effects. Some patients may have decreased appetite, tremors, headache, and even hallucinations. Men with benign prostatic hyperplasia (BPH) and other patients with disorders causing bladder outlet obstruction may have increased urinary retention due to α_1 stimulation of the urethral sphincter. Theoretically, there may be some differences in the overall side effects between pseudoephedrine and phenylephrine. Pseudoephedrine stimulates both α and β receptors, whereas the effects of recommended oral doses of phenylephrine are essentially limited to stimulation of α receptors. Comparative studies are not available to confirm meaningful differences in the clinical setting.

The intranasal agents currently available include the OTC products phenylephrine, oxymetazoline, and naphazoline, and the prescription product tetrahydrozoline. Product labeling should be followed for dosage, but it is noteworthy that oxymetazoline is the longest acting of these agents and is usually given only twice daily. Intranasal application of decongestants provides rapid and effective relief of nasal congestion. This therapy may provide relief for nasal congestion, even for those patients already on intranasal corticosteroids.⁴¹ However, the continuous use of intranasal decongestants often causes a paradoxical rebound phenomenon of persistent nasal congestion, called *rhinitis medicamentosa*.^{1–3,10,42} **9** *Although some patients do not develop rhinitis medicamentosa even after several weeks of continuous use of intranasal decongestants, the usual recommendation is to use them for no more than 3 consecutive days.*¹ Intranasal decongestants can cause local side effects, including stinging, burning, dryness, and even sneezing. These are usually mild and well tolerated. Due to very limited absorption, the intranasal route rarely causes systemic side effects.^{1,8,10} Administration technique should be optimized as described in Table 63–6. Should rhinitis medicamentosa occur, the best management is first to discontinue the decongestant, possibly with a taper to minimize worsening the situation. However, the response to withdrawal is often delayed for days. Therefore, it may be necessary to start intranasal corticosteroids and/or (especially if intranasal corticosteroids are already part of the patient's regimen) begin a short course of oral corticosteroid.⁴²

Despite the usual good tolerance of recommended doses of oral decongestants, caution is warranted when they are used in patients with cardiac disease (dysrhythmias, angina pectoris, heart failure), hypertension, cerebrovascular disease, bladder outlet obstruction (including BPH), glaucoma (especially closed angle), hyperthyroidism, and possibly diabetes.^{1,10,19} **9** *The best application of decongestants*

in AR is short-term to overcome severe nasal congestion, especially to facilitate improved efficacy of (other) intranasal agents (e.g., corticosteroids and antihistamines). The choice between the two routes of administration is based on several considerations, including cost, convenience, patient preference, speed of onset (within 30 minutes orally, within 5 to 10 minutes intranasally), and side effects.^{1,8,43}

Mast Cell Stabilizer/Cromone^{1,10,22,23,43} Cromolyn is the only agent in the cromone class that is approved in the United States for treatment of AR. It is available as an OTC intranasal product. The mechanism of action in AR is mast cell stabilization. The drug binds to mast cells and prevents release of the mediators of AR that would otherwise result from allergen exposure. The drug is moderately effective, but less so than both intranasal corticosteroids and oral or intranasal antihistamines. It does have effects on both early and late phases of AR. Its effects begin within 4 to 7 days of use, but may not be maximal for up to 2 weeks.¹ However, it can be used effectively on an as needed basis for episodic exposures to allergen.¹ As with all intranasal products, if there is severe nasal congestion, contact with the nasal mucosa will be limited. Short-term use of a decongestant or an intranasal antihistamine may solve this problem. Cromolyn is very well-tolerated. The most common side effects are mild local stinging and/or burning, sneezing, unpleasant taste, and possibly nose bleed. A disadvantage is the frequency of administration. At least initially, it should be used four times daily. Some patients may need only two or three daily doses when used continuously after the first few weeks at four times daily. It is most useful for patients with mild or intermittent symptoms, especially in the pediatric population and in pregnant women.

Leukotriene Receptor Antagonist Leukotrienes are involved in the pathophysiology of AR and in particular contribute to the nasal congestion in the late phase.¹ They contribute little if anything to nasal itch and sneezing.⁴³ Leukotriene antagonists have been shown to be effective for some of the manifestations of AR. Montelukast is the only agent in this class with FDA approval for treatment of AR. It is marketed as oral granules and as both chewable and swallow tablets. The majority of clinical studies published to date indicate that montelukast is inferior to intranasal corticosteroids.^{1,10,19,43} Montelukast is either equivalent or slightly inferior to oral H_1 antihistamines.^{1,10,25,43} The combination of montelukast with an oral antihistamine shows improved efficacy over either agent alone.¹⁹ However, even the combination is probably not better than intranasal corticosteroids.¹ The onset of action of montelukast is delayed for a day or more.¹ The drug is usually considered to be very well-tolerated with minimal side effects. However, the FDA updated their preliminary report concerning case reports of neuropsychiatric events, including suicidal ideation in association with the drug.⁴⁴ It is administered once daily, considered safe (FDA Pregnancy Category B and indicated for children as young as 6 months of age), and particularly well-suited to those patients who have concurrent asthma and AR.

Antimuscarinic (Anticholinergic) Agent¹ Ipratropium is currently the only antimuscarinic (or anticholinergic) agent indicated for treatment of AR. It is a quaternary ammonium structure, so systemic absorption is minimal. The product is available by prescription as an intranasal spray. Its use is limited to those patients whose rhinorrhea has not been controlled by other therapy (antihistamines and/or intranasal corticosteroids). There are two strengths available. The 0.03% product is approved for AR in children as young as 6 years of age. The 0.06% product is indicated for rhinorrhea associated with the common cold in children as young as 5 years old. Local side effects are essentially limited to mild epistaxis and nasal dryness.

● **Saline^{1,45,46}** Nasal administration of saline is an alternative for treatment of AR. This therapy may benefit any patient with AR. Saline may be administered as drops or a spray, but the irrigation mode of administration is popularly known by several terms, including neti pot, nasal wash, nasal douche, nose bidet, and as nasal irrigation. Although less effective than intranasal corticosteroids, it has been shown to improve sneezing and nasal congestion. It can be used either alone or as add-on therapy. It is best to use canning or pickling salt, which has no iodine, preservatives, or other additives, all of which can be irritating. It appears that isotonic saline is as effective as hypertonic solutions.

An approximate isotonic concentration can be made by dissolution of one teaspoonful of noniodized salt (sodium chloride) in one pint of water. The AAAAI has another recipe.⁴¹ Their instructions start with preparation of the dry powder component. This is done by combining three heaping teaspoonfuls of pickling salt with one rounded teaspoonful of baking soda, and mixing thoroughly. Then, one teaspoonful of the dry powder mixture is dissolved in one cup (8 oz; 237 mL) of lukewarm water. It is best if the water is distilled or has been boiled. About 4 oz (118 mL) of this solution will be used to irrigate each side of the nose. Application can be accomplished while the patient is in the shower or leaning over a sink. The head is bent forward and downward, then tilted to the side opposite the treated nostril. That is, the head is tilted to the left if the right nostril will be irrigated. Then, with a bulb syringe or similar device, slowly introduce about 4 oz (118 mL) of the warm saline solution into one side. Soon, the solution will run out of the opposite nostril. The position of the head should be adjusted as necessary to avoid the solution running into the ears or down the throat.

Nasal irrigation is one delivery method, although the optimal method (spray, drops, nebulizer, or irrigation) is not known. Optimal frequency of administration is also not known. Nasal irrigation is usually given twice daily, but use of smaller volumes as spray products may be given up to four times daily. Local side effects are usually limited to minor nasal irritation. Nausea has been reported.

Omalizumab^{1,23,43} Omalizumab is a monoclonal antibody that binds to IgE. The product is approved for asthma, but not for AR. It is administered by subcutaneous injection. Dosage is determined by the patient's circulating IgE levels. The cost is high compared with that of other commonly used

Patient Encounter 1, Part 4

Even more questioning reveals that LF has no recent fever, facial pain, purulent nasal discharge, ear pain, or nose bleeds. She has never noticed a whistling sound to her breathing (wheezing), persistent or recurring nighttime cough, tightness in her chest, or shortness of breath. She has never been told she has polyps in her nose. She has heard about "allergy shots" but has no interest in getting them at this time. She has never been told that she has any specific allergies. She never took any medicine that caused skin rash, trouble breathing, or other bothersome symptoms. No foods have caused these types of reactions. No healthcare provider has ever told her to specifically avoid any medication. However, she does presume that she is allergic to some sort of pollen, based on her symptoms. She claims that her menstrual periods are regular and, in fact, her most recent period ended only 3 days ago.

Based on all the accumulated information, develop a comprehensive pharmaceutical care plan for this patient, including specific OTC medication recommendations.

modes of therapy for both asthma and AR. Investigational use has demonstrated efficacy in AR, although relative efficacy compared with other modes of therapy for AR is unknown. Its use is best limited to those with concurrent asthma and AR, pending specific approval for AR.

Complementary and Alternative Medicine Therapy

Although some would consider saline in the category of complementary and alternative agents, this monograph considers it as an adjunctive mode. Complementary and alternative therapy for AR has been reviewed.⁴⁷ Consistent evidence for efficacy has not been established, and there are some safety concerns.

► Special Populations

● **Children ¹⁰** *Generally speaking, the treatment of AR in children is the same as it is for adults. There are, however, limitations in terms of FDA-approved products for different age groups. Also, depending on the age of the patient, there may be administration issues with some products.* Most children affected by AR are more than 2 years old, although the disease may begin in children as young as 6 months of age.¹

There has been concern about use of combination cough and cold products (many contain an antihistamine and a decongestant) in children. In October 2007, the Nonprescription Drug Advisory Committee of the FDA recommended that OTC combination cough and cold products be limited to children 6 years of age and older. This was based on reports of more than 100 deaths in association with these combination products.¹ Most of these bad outcomes seem to have resulted from inadvertent overdosage, often by giving doses of the same medication from different combination products.

In October 2008, the FDA notified consumers and health-care providers that the Consumer Health Protection Agency (CHPA) decided to voluntarily modify the labeling of combination cough and cold products to indicate that they should not be used in children less than 4 years old. This recommendation has been published online as a reminder to consumers, including a link to a question and answer page.⁴⁸

First-generation H₁ antihistamines are discouraged for children as they are for adults, due to the possible detrimental effects on school performance and learning. Second-generation (less sedating) H₁ antihistamines (primarily for mild or intermittent symptoms) or intranasal corticosteroids (for moderate–severe or persistent manifestations) are first-line modes of therapy. Antihistamines may need to be used even for more severe and/or persistent symptoms in those children who have difficulty with use of intranasal products. If necessary, these two classes can be combined.

See Table 63–7 for dosages of second-generation antihistamines by age groups for which they are indicated. If first-generation antihistamines are used, the healthcare practitioner should guarantee that the family members or caregivers are carefully and thoroughly educated to read and use the dosage recommendations appropriate for age or weight of the patient, as indicated on the product labeling. They should also be warned about the possibility of a paradoxical CNS stimulant side effect. Special care should be given to avoid administration of the same medication from different (especially combination) products. The most common side effects of second-generation antihistamines in children are similar to those for adults.

See Table 63–5 for dosages of intranasal corticosteroids by age groups for which they are indicated. The consensus of opinion about intranasal corticosteroids and systemic side effects, especially delay in growth, is that most products are safe. The greatest potential for problems may exist with beclomethasone.¹ Several products have been studied in children and have not been shown to delay growth. However, not every product has been studied carefully in all age groups. Some of the conclusions about safety are extrapolated from data with inhaled corticosteroids, used for asthma. The local side effects of intranasal corticosteroids are the same in children as for adults.

Other therapy options may be worth consideration for some pediatric patients. Montelukast provides an oral alternative, especially for those who are too young to cooperate with intranasal administration of corticosteroids. It may be used in combination with an oral antihistamine in hopes of providing some additional efficacy. Another advantage of montelukast is that it is indicated for children as young as 6 months. Another option for mild or intermittent symptoms is intranasal cromolyn, primarily due to its excellent safety. This OTC product is labeled for use in children 2 years of age and older. Intranasal ipratropium is indicated for patients 6 years of age or older and may benefit unresponsive rhinorrhea.

Pregnant Women^{1,49} Women who have AR may suffer an exacerbation of symptoms during pregnancy. However, only minor changes in the routine approach to therapy are necessary as a result of the pregnancy. Second-generation

antihistamines are generally considered safe, based on an increasing number of studies and experience.¹ The same generalization applies to intranasal corticosteroids. However, the products with the best documented safety record are beclomethasone, budesonide, and fluticasone propionate.¹ If an intranasal product is started during pregnancy, the wisest choice might be to use budesonide, based on the fact that it is FDA Pregnancy Category of B. Cromolyn is also FDA Pregnancy Category B and is considered safe. The disadvantages, however, are frequent administration and lesser efficacy than antihistamines and intranasal corticosteroids. Montelukast is also FDA Pregnancy Category B, but some recommend it be used primarily in those with concurrent asthma or in those who have demonstrated a good response prior to pregnancy.¹ Ipratropium is FDA Pregnancy Category B, despite limited data.⁴⁴ The decongestants are not considered safe, especially in the first trimester. The theoretical concern is the possibility of vasoconstriction of very small caliber fetal vasculature. If nasal congestion is severe enough to warrant consideration for a decongestant, the intranasal route of administration is preferable, due to decreased systemic exposure and the short-term duration of therapy.¹

Elderly^{1,8} Elderly patients can be treated for AR according to the approach for (younger) adults.^{1,8} However, the elderly may be more sensitive to the sedative and antimuscarinic effects of antihistamines and to the cardiovascular and CNS stimulant effects of decongestants. Also, the aging process can affect the manifestations of AR. Generalized atrophy of nasal tissues can result in more nasal congestion. An increase in cholinergic activity may result in more rhinorrhea.

Athletes¹ The use of certain medications is prohibited during national and international athletic competition. The list of prohibited drugs changes each year and may not always be consistent among organizations. The most up-to-date information is available from the World Anti-Doping Agency (WADA).⁵⁰ Additional information may be obtained from the United States Anti-Doping Agency (USADA) (<http://www.usantidoping.org/>). This site has a link to the prohibited drugs in the form of the Global Drug Reference Online (DRO).

► Ocular Symptoms^{1,25,29}

Several products are available for instillation directly into the eyes for those patients with predominant or unresponsive ocular manifestations. They may be appropriate for occasional moderate–severe flares or episodic AR when other modes of therapy are not optimally effective. The combination (antihistamine and mast cell stabilizing) agents may be the most effective, and they have the advantages of rapid onset of action and (usually) only twice daily administration. See Table 63–8 for these products.

Summary of Treatment

Once an agent appropriate for initial therapy is chosen, ongoing management requires repeated checks to ascertain

Table 63–8

Intraocular Medications

Category	Generic (Brand) Name	Formulation	Frequency	Age
Decongestant/vasoconstrictor	Naphazoline ^a (Naphcon, Privine, others)	0.012% + 0.025%	Four times daily	Adult
Decongestant/vasoconstrictor + antihistamine	Naphazoline + pheniramine ^a (Visine A)	0.025%/0.3%	Four times daily	6 yo or more
Antihistamine	Emedastine (Emadine)	0.05%	Four times daily	3 yo or more
Mast cell stabilizer	Alcaftadine (Lastacaft)	0.25%	Once daily	2 yo or more
	Cromolyn (generic)	4%	Every 4–6 hours	4 yo or more
	Lodoxamide (Alomide)	0.1%	Four times daily	2 yo or more
	Nedocromil (Alocril)	2%	Twice daily	3 yo or more
	Pemirolast (Alamast)	0.1%	Four times daily	3 yo or more
Antihistamine + mast cell stabilizer	Azelastine (Optivar)	0.05%	Twice daily	3 yo or more
	Epinastine (Elestat)	0.05%	Twice daily	3 yo or more
	Ketotifen ^a (Zaditor, Alaway, Claritin, Zyrtec, generic)	0.025%	Every 8–12 hours	3 yo or more
	Olopatadine (Patanol/Pataday)	0.1%/0.2%	Twice daily/once daily	3 yo or more
	Bepotastine (Bepreve)	1.5%	Twice daily	2 yo or more
NSAIDs	Ketorolac (Acular)	0.5%	Four times daily	3 yo or more
Corticosteroid	Loteprednol (Alrex)	0.2%	Four times daily	Adult

NSAID, nonsteroidal anti-inflammatory drug; yo, years old.

^aAvailable OTC.

From Refs. 1, 25, 26, and 29.

Patient Encounter 2, Part 1

LW is a 60-year-old male who comes to your place of work to ask for your help. His main questions concern how to use the medications he has been given for what he calls “bad nose allergies.” He says he has three different nose sprays, three different oral meds, and one bottle of eye drops. You recognize him as a regular customer. His computerized pharmacy record indicates the following information. His chronic problems are Parkinson’s disease, hypertension, BPH, and moderately severe, persistent allergic rhinitis. His current medications are ropinirole (Requip) 4 mg three times a day; amantadine 100 mg three times a day; trihexyphenidyl 5 mg three times a day; Lotensin HCT 20/25 (benazepril/hydrochlorothiazide) one tablet once daily; tamsulosin 0.4 mg two tablets once daily; flunisolide nasal spray given as 2 sprays in each nostril twice daily; olopatadine nasal spray given as two sprays in each nostril twice daily; tetrahydrozoline 0.1% nasal spray given as 1 spray into each nostril, up to 3 times a day as needed for congestion, but not to exceed 3 consecutive days use; levocetirizine 5 mg once a day; diphenhydramine 25 mg tablets (OTC), pseudoephedrine 30 mg tablets (OTC), and ketotifen eye drops (OTC).

What medication-related problems does this patient’s regimen present?

Explain how you would deal with his primary question about how to use his AR medications?

response and freedom from intolerable or adherence limiting side effects. Either “step-up” or “step-down” therapy may be appropriate, depending on the individual patient’s response.

- See **Table 63–9** for a summary of the approach to treatment of AR. **Table 63–10** attempts to rank the relative effectiveness of the classes of agents for treatment of AR by specific symptoms.

OUTCOME EVALUATION

- Confirm the understanding of the disorder on the part of the patient and their family (see Clinical Presentation and Diagnosis).
- Confirm the understanding about allergen avoidance measures on the part of the patient and their family (see Table 63–3).
- Assess the patient’s symptom response, tolerance, and adherence at each visit.
- Assess the patient’s administration technique with intranasal products, especially when symptom response or tolerance is not optimal.
- Use or recommend second-generation oral antihistamine therapy for most patients with mild or intermittent (especially seasonal) symptoms (see Clinical Presentation and Diagnosis and Table 63–9).
- Recommend intranasal corticosteroid therapy for moderate–severe or persistent (especially perennial) symptoms. Advise additional adjunctive therapy for those

Table 63–9

Routine Approach to Therapy of AR

All patients should practice avoidance of identified allergens to the extent possible

Mild intermittent (including many patients with what some would call seasonal AR)

First line:

Oral antihistamine (OTC, initially; preferably second generation)

Adjunctive/secondary (may use more than one):

Add OTC oral decongestant for nasal congestion

Add short-term OTC intranasal decongestant for refractory nasal congestion

Add nasal saline (e.g., as irrigation)

Consider intraocular medications, as needed (See Table 63–8)

Consider prescription therapy for inadequate response (see below)

Possibly consider referral for immunotherapy

Persistent or moderate–severe

First line:

Intranasal corticosteroid

Add oral antihistamine for possible additional benefit if necessary

Adjunctive/secondary (may use more than one):

Add short-term intranasal decongestant for refractory nasal congestion

Add nasal saline (e.g., as irrigation)

Add ipratropium for inadequately controlled rhinorrhea

Consider replacement of one first-line agent, if poorly tolerated, with montelukast

Consider intraocular medications, as needed (See Table 63–8)

Consider referral for immunotherapy

Episodic (no order of preference intended)

Intranasal cromolyn (OTC)

Intranasal antihistamine

Intranasal corticosteroid

Special situations (children, pregnant women, elderly, athletes, ocular symptoms)

See Special Populations section of text

From Refs. 1–3, 8, 10, 20–22, 24, 25, and 43.

Table 63–10

Relative Efficacy (Semiquantitative) by Classes of Agents for Specific Symptoms of Allergic Rhinitis

Drug Class	Nasal Congestion	Sneezing	Rhinorrhea	Nasal Itch	Ocular Symptoms
Nasal corticosteroids	3	3	3	3	2
Oral antihistamines ^a	1	2	2	3	2
Nasal antihistamines	2	2	2	3	0
Oral decongestants ^a	1½	0	0	0	0
Nasal decongestants ^{a,b}	3	0	0	0	0
Oral leukotriene antagonist	2	½	2	½	2
Nasal mast cell stabilizer ^a	1½	1½	1½	1½	1½
Nasal antimuscarinic	0	0	2	0	0

Note: The information in this table is a composite from numerous sources. There are different opinions about some of the rankings, partly due to inadequate study. Individual variation may create different relative efficacy in some patients. Higher number equals greater activity.

^aSome products in these classes are available OTC.

^bNasal decongestants are best used for severe, unresponsive nasal congestion, or to facilitate mucosal contact of other intranasal medications, but in either case, should usually be limited to no more than 3 days.

From Refs. 1, 8, 10, and 21–23.

- with less than optimal control (see Clinical Presentation and Diagnosis and Table 63–9).
- Consider step-up therapy for exacerbations or less than optimal response.
- Consider step-down therapy if symptoms have been minimal or stable for several months (especially if the disorder is primarily seasonal).
- Consider referral to rule out nonallergic causes of rhinitis in nonresponding patients or those with an atypical presentation (see Clinical Presentation and Diagnosis).
- Consider referral for patients who request immunotherapy.
- Consider referral for patients with comorbid conditions, especially asthma.

Patient Encounter 3, Part 1

You are at your place of work at a community pharmacy, and you receive a phone call from a medical student who is doing a rotation with a pediatrician in the neighborhood. The pediatrician advised the medical student to phone your pharmacy to ask about the use of OTC “cold medicines” in children. The student indicates that this question involves a real patient situation. The mother of a 4-year-old girl brought the child in for evaluation and advice. The child has been having sneezing, runny nose, poor appetite, and fussiness. The symptoms are present most days of every week and have been present for at least 2 months. The child is particularly fussy and “not herself” today. The student describes the child as having dark circles under her eyes and a horizontal crease about half-way up from the tip of her nose. She snuffles and rubs her nose frequently. She is a bit irritable and not always cooperative with the interview and exam. The child weighs 35 pounds (15.9 kg).

The student emphasizes that the pediatrician’s evaluation has ruled out infectious causes and serious chronic disease. He thinks the child has allergic rhinitis. The mother has been giving two medications for the last week. One is called Allerfrim syrup (pseudoephedrine 30mg/5 mL and triprolidine 1.25 mg/5 mL). The other is Bromfed DM syrup (brompheniramine 2 mg/5 mL, pseudoephedrine 30 mg/5 mL, and dextromethorphan 10 mg/5 mL). She has been using ½ teaspoonful of both medicines 3–4 times daily for the last 4 days. At first, they seemed to help the girl’s symptoms, but in the last day, she seems worse in some ways.

What can you tell this person about use of “cold” medicines in children?

What advice can you provide about medications that are appropriate for use to treat AR in a child of this age?

Patient Care and Monitoring

- Determine the patient’s manifestations. This is best done as a chief complaint would be evaluated: location (including referral or location of other symptoms); onset (current and past episodes); quality (the exact nature of the symptom); quantity (the severity of the symptom); setting/context (circumstances in which symptom occurs); associated symptoms (other abnormalities during primary symptom); modifying factors (what makes the symptom worse or better). This can be followed by selected questions about past medical history, allergies or intolerances (to anything, not just medicines), and current medication (OTC, prescription and herbal). Some of the most important specific questions follow.
 - What is the most troublesome symptom?
 - What is the frequency and severity of symptoms?
 - How do symptoms affect quality of life, work/school performance, and sleep?
 - What allergen or irritant triggers have been identified?
- Attempt to rule out complications or comorbid conditions that preclude self-care (asthma, sinusitis, otitis media with effusion, and possibly nasal polyposis) and/or warrant referral to a physician, as follows:
 - Unilateral rhinitis, nasal obstruction without other typical symptoms of AR
 - Purulent rhinitis, fever, marked facial or ear pain, or recurrent nose bleeds
 - Ocular symptoms without typical symptoms of AR
 - Unilateral ocular symptoms, or photophobia, or vision changes
 - Severe symptoms
 - Failure of therapy (nonresponse or adherence limiting side effects or intolerance)
 - Desire to have specific allergen triggers identified (e.g., by skin testing)
 - Candidates for immunotherapy
 - Concurrent asthma, nasal polyposis, sinusitis, or otitis media with effusion
- Determine past attempts at therapy. There is some overlap in this section, with 1., above (modifying factors).
 - What has the patient tried previously for these symptoms (including prescription and all nonprescription [OTC, herbal, other complementary] forms)?
 - What was the response to all previous treatments (efficacy and side effects)?
- Determine other current disorders and treatments:
 - What conditions are present for which medications are taken regularly?
 - What medications are currently being taken regularly?
- Assess patient’s understanding of AR and its management:
 - What does the patient currently do to avoid triggers?
 - How does/did the patient administer and adhere to current or past treatments?

(Continued)

Patient Care and Monitoring (Continued)

6. Fill in gaps in patient's knowledge:
 - Manifestations of AR and its complications
 - Principles of management (allergen/trigger avoidance, pharmacologic modes, immunotherapy)
 - Choices for pharmacologic therapy (OTC and prescription) and determinates (previous experience, ease of use, tolerability, cost, patient preference, and age)
 - Discuss realistic goals, which may not be complete elimination of all symptoms
7. Establish a plan appropriate for and with input from the patient:
 - Recommend initial OTC regimen or refer for evaluation and possible prescription therapy
 - Fill in gaps in patient's knowledge about allergen avoidance and optimal adherence and administration technique (where applicable)
8. Reevaluate the patient at appropriate intervals, that will vary with the individual, but will usually be every 1 to 3 months:
 - Evaluate for efficacy of therapy, including improvement in symptoms, quality of life, work/school performance and sleep pattern
 - Evaluate for tolerance of side effects
 - Modify the plan as needed (to increase efficacy or modify side effects), including recommendations for a change in medication and/or referral to a physician

Psoriasis

Rebecca M.T. Law

LEARNING OBJECTIVES

● Upon completion of this chapter, the reader will be able to:

1. Discuss the etiology of psoriasis, including genetic and immune changes.
2. Describe the pathophysiology of psoriasis, including the types of psoriasis and clinical presentations.
3. Describe the comorbidities and risks in patients with psoriasis.
4. Compare and contrast the pharmacologic treatment modalities for psoriasis, that is, topical therapies, systemic therapies including biologics, and phototherapies.
5. Recommend an appropriate treatment plan for a patient with psoriasis, including nonpharmacologic and pharmacologic therapies
6. Recommend appropriate monitoring parameters for a patient with psoriasis.
7. Provide appropriate counseling information to a patient with psoriasis.

KEY CONCEPTS

- 1 Patients with psoriasis have a lifelong illness that may be very visible and emotionally distressing. There is a strong need for empathy and a caring attitude in interactions with these patients.
- 2 Psoriasis is a T-lymphocyte-mediated inflammatory disease that results from a complex interplay between multiple genetic factors and environmental influences. Genetic predisposition coupled with some precipitating factor triggers an abnormal immune response, resulting in the initial psoriatic skin lesions. Keratinocyte proliferation is central to the clinical presentation of psoriasis.
- 3 Diagnosis of psoriasis is usually based on recognition of the characteristic plaque lesion and is not based on lab tests.
- 4 Treatment goals for patients with psoriasis are to minimize signs such as plaques and scales; alleviate symptoms such as pruritus; reduce the frequency of flare-ups; ensure appropriate management of any associated comorbidities such as psoriatic arthritis, cardiovascular disorders, Crohn's disease, or clinical depression; and minimize treatment-related morbidity.
- 5 Management of patients with psoriasis generally involves both nonpharmacologic and pharmacologic therapies.
- 6 Nonpharmacologic alternatives such as stress reduction and the liberal use of moisturizers may be extremely beneficial and should always be considered and initiated when appropriate.
- 7 Pharmacologic alternatives for psoriasis include topical agents, phototherapy, and systemic agents, including the use of biologic response modifiers (BRMs).
- 8 In initiating pharmacologic treatment, the choice of therapy is generally guided by the severity of disease: topical agents would be appropriate for mild to moderate disease, whereas a systemic agent would be a more appropriate choice for moderate to severe disease. Phototherapy or photochemotherapy is used for patients with moderate to severe psoriasis, generally when topical therapies alone are inadequate. Patient-specific concerns such as existing comorbid conditions (e.g., hypertension, hyperlipidemia, diabetes mellitus, renal impairment or hepatic disease) must also be taken into consideration in the choice of therapy. Once the disease is under control, it would be important to step down to the least potent, least toxic agent(s) that maintain control.
- 9 Rotational therapy (i.e., rotating systemic drug interventions in a sequential manner) is a means to minimize drug-associated toxicities since systemic agents for psoriasis often have differing toxicities. However, continuous treatment has largely replaced rotational therapies and is now the standard of care.
- 10 Some BRMs have proven efficacy for psoriasis; however, there are differences among these agents,

including mechanism of action, duration of remission, and adverse-effect profile. In general, due to their immunosuppressive effects, there is an increased risk of infection with most of these agents. The use of live or live-attenuated vaccines during therapy is generally not recommended. Currently, BRMs are often considered for patients with moderate to severe psoriasis when other systemic agents are inadequate or relatively contraindicated. It has also been recommended that BRMs be considered as first-line therapy, alongside conventional systemic agents, for patients with moderate to severe psoriasis; however, in practice, drug access due to cost considerations may be a limiting factor. They may be appropriate if comorbidities exist.

INTRODUCTION

Psoriasis is a chronic illness that is never cured; however, the signs and symptoms of psoriasis may subside totally and then return. Remission may last years in some patients, whereas in others exacerbations may occur every few months. Triggers include stress, seasonal changes, and some drugs. Disease flare-ups may also occur at times of life crises. Disease severity may vary from mild to disabling. In addition, there may be associated chronic comorbid conditions that also need appropriate treatments. Thus management of patients with psoriasis is necessarily long term, and management modalities may change according to the severity of illness at the time and should be individualized to meet patient needs.

1 *Patients with psoriasis have a lifelong illness that may be very visible and emotionally distressing. There is a strong need for empathy and a caring attitude in interactions with these patients.*

EPIDEMIOLOGY AND ETIOLOGY

Psoriasis is a common inflammatory skin disorder estimated to affect 1.5% to 3% of the white population.^{1,2} Ethnic factors influence disease prevalence. In the United States, prevalence among people of African or Asian descent (0.45% to 0.7%) is lower (versus 1.4% to 4.6% in general).^{1,3} It may present at any age.⁴ Up to 42% of patients with psoriasis have been reported to also have psoriatic arthritis (PsA).⁵ PsA generally appears much later (up to decades later) than psoriasis. However, in about 10% to 15% of psoriatic patients with arthritis, joint symptoms may appear prior to skin involvement. Furthermore, although PsA more commonly occurs in psoriatics with more extensive disease, some patients may have deforming PsA with little to no cutaneous involvement.⁵

Besides PsA, other comorbidities associated with psoriasis may have significant morbidity and mortality risks. Well-known psychiatric/psychological comorbidities include depression, anxiety, and poor self-esteem. More recently,

related conditions (hypertension, obesity, type 2 diabetes, the metabolic syndrome), inflammatory bowel disease, multiple sclerosis, and lymphoma.^{6,7}

Clinical depression may present in up to 60% of patients with psoriasis⁶ and may be severe enough that patients contemplate suicide. Other psychopathologies include poor self-esteem, anxiety, and sexual dysfunction. The emotional and psychological impact of psoriasis may not correlate with the severity of the skin presentation, and it is important to always evaluate the psychosocial effects of psoriasis on the patient.⁶

The incidence of inflammatory bowel diseases (e.g., Crohn's and ulcerative colitis) may be 3.8 to 7.5 times higher in psoriatic patients than in the general population.⁶ This has been attributed to shared or closely linked genetic susceptibility traits, with individual susceptibility localized to a similar region of chromosome 16, among others.⁶ There may also be a genetic link to multiple sclerosis.⁶

Recent research has shown that psoriatic patients have an increased risk of cardiovascular diseases.^{5,7,8} There is a higher than normal incidence of myocardial infarction. The risk is increased in patients with both mild and severe psoriasis, with the highest risk in younger patients with severe disease.⁸ These findings persist even when corrected for the cardiovascular risk factors.^{6,8} The corrections are especially relevant since psoriatic patients also have increased incidences of type 2 diabetes, obesity, hypertension, smoking, alcohol consumption, metabolic syndrome, body mass index (BMI), and an atherogenic lipid profile.⁵⁻⁸ In a recent study in hospitalized patients, the metabolic syndrome is significantly more prevalent in patients with psoriasis than those without.^{6,7}

With regard to increased cancer risk, although there is controversy, some studies show an increased risk of lymphoma, with one study demonstrating a significantly increased risk of cutaneous T-cell lymphoma (relative risk of 10.75) or Hodgkin's lymphoma (relative risk of 3.18) in patients with severe disease.⁶ However, the risk of melanoma and nonmelanoma skin cancer appears equal to that of the general population,⁶ although risks are associated with some psoriatic treatments. Some psoriatic treatments with a known lymphoma risk may be confounding factors. Increased cancer risk may be limited to subpopulations: Caucasians with more than 250 PUVA (psoralens + UVA) treatments have a 14-fold greater risk of cutaneous squamous cell carcinoma than those with fewer treatments.⁶

2 *Psoriasis is a T-lymphocyte-mediated inflammatory disease that results from a complex interplay between multiple genetic factors and environmental influences.^{1,5} Genetic predisposition coupled with some precipitating factor triggers an abnormal immune response, resulting in the initial psoriatic skin lesions. Other risk factors may exacerbate preexisting psoriasis and cause disease flare-ups. Precipitating factors include skin trauma such as a horse-fly bite (known as the **Koebner phenomenon**),⁶ environmental changes such as cold weather, stress, a viral or streptococcal infection, or use of a β -adrenergic blocker.² Factors exacerbating*

psoriasis include drugs (e.g., lithium, NSAIDs, antimalarials, β -adrenergic blockers, and withdrawal of corticosteroids), and psoriatic patients commonly have exacerbations during times of stress.²

There is a clear genetic component to psoriasis. Studies conducted in twins show a risk of psoriasis that is two to three times as high in monozygotic twins versus fraternal twins.⁹ As many as 71% of patients with psoriasis during childhood have some positive family history.^{1,10} Similarly, psoriatic arthritis is heritable, with a prevalence 19 times higher in first-degree relatives of patients with psoriatic arthritis than in the general population.¹⁰

The inheritance pattern for psoriasis is complex and polygenic. Genome-wide linkage studies have identified at least nine genetic loci with statistically significant linkage to psoriasis: these are named psoriasis susceptibility 1 through 9 (PSORS1 through PSORS9).⁹ PSORS1 has been considered the major gene locus for psoriasis^{1,4,6,9,10}; it appears to be associated with 35% to 50% of cases of psoriasis.⁹ There are three genes within this gene locus that appear to have polymorphic coding-sequence variations strongly associated with psoriasis: HLA-C with the associated HLA-Cw6 variant, CCHCRI with the associated variant WWCC, and corneodesmosin with the associated variant allele 5.⁹ Current data suggest that HLA-Cw6 is the susceptibility allele within PSORS1.⁹ CCHCRI and corneodesmosin encode different proteins that are overexpressed in psoriatic epidermis.⁹

Different clinical types of psoriasis appear to be associated with different genetic loci. Guttate psoriasis is strongly associated with PSORS1, but late-onset psoriasis (onset at age over 50) and palmoplantar psoriasis do not appear to be.⁹ Other genetic loci of importance and under study include genes involved in IL-23 signaling (IL-23R, IL-23A, IL-12B) and susceptibility genes within the LCE gene locus on 1q21.⁹ In addition, several genetic loci for psoriasis are also associated with other diseases, including Crohn's disease, rheumatoid arthritis, and diabetes.⁹ There are possibly other genetic loci.

PATHOPHYSIOLOGY

2 *Keratinocyte proliferation is central to the clinical presentation of psoriasis. Keratinocytes* are skin cells producing keratin, which acts as a skin barrier. Increased keratinocyte cell turnover (hyperkeratosis) with immature maturation of keratinocytes and incomplete cornification with retention of nuclei in the stratum corneum (parakeratosis)⁹ result in the characteristic thick, scaly skin lesions seen in patients with psoriasis. Hyperkeratosis results from immune derangements.

The abnormal immune response seen in psoriasis is mediated primarily by T lymphocytes (T cells).^{1,9} In psoriatic patients, certain types of T cells are overactive, migrating to the skin in large numbers by binding to activated endothelial cells via intracellular cell adhesion molecules (ICAM-1).^{1,11} These naïve T cells then encounter antigens in the skin, presented to them by antigen-presenting cells (APCs),

and become activated T cells. There is an LFA-3–CD2 signal that plays an important part in T-cell activation: LFA-3 is the leukocyte function–associated antigen type 3 found on APCs; CD2 is a cell-surface glycoprotein expressed on T-cell subtypes.¹ When LFA-3 interacts with CD2, there is an increased proliferation of T cells.¹²

Activated T cells begin releasing cytokines including interleukin-2 (IL-2), interferon- γ (IFN- γ), tumor necrosis factor- α (TNF- α), and others.^{4,12} Cytokine activity leads to a rapid proliferation and turnover of skin cells, triggering the inflammatory process and the development of psoriatic skin lesions.^{4,12,13} TNF- α may have a role in disease severity; it upregulates endothelial and keratinocyte expression of ICAM-1, activates T cells, enhances T-cell infiltration, and augments keratinocyte proliferation.¹¹

Dendritic cells are key sentinel cells of the immune system that bridge the gap between innate and adaptive immunity. Myeloid dermal dendritic cells are seen in increased numbers in psoriatic lesions, and they induce the auto-proliferation of T cells and production of type-1 helper T-cell cytokines. Specialized dendritic cells produce TNF- α , as well as other substances.⁹

Treatment of psoriasis is based on an understanding of the underlying pathophysiology. Agents that modulate the abnormal immune response, such as corticosteroids and biologic response modifiers (BRMs), are important treatment strategies for psoriasis. Targeted immunotherapy and phototherapy (i.e., PUVA) reduce the numbers of dendritic cells in patients with psoriasis.⁹ In addition, topical therapies that affect cell turnover are effective for psoriasis. Clinically, a treatment regimen should always be individualized, taking into consideration severity of disease, patient responses, and tolerability of various interventions.

CLINICAL PRESENTATION

3 *Diagnosis of psoriasis is usually based on recognition of the characteristic plaque lesion and is not based on lab tests.*

Patient Encounter, Part 1

A 45-year-old man with a 12-year history of plaque psoriasis presents with well-demarcated reddish-violet raised lesions on his legs, abdomen, back, elbows, and knees. The lesions are covered with loose silvery scales, which when removed show pinpoint points of bleeding. When questioned, the patient says his skin was relatively clear until about a week ago; since then, the lesions have been spreading and are extremely itchy. There are signs of excoriation on the patient's legs.

What information is consistent with a flare-up of psoriasis in this patient?

Clinical Presentation and Diagnosis of Plaque Psoriasis

General

Patients have small, discrete lesions to generalized confluent lesions over a large body surface area (BSA).

Symptoms

Patients may complain of severe itching.

Signs

- Lesions are raised and are red to violet in color (commonly known as plaques).
- Lesions have sharply demarcated borders, except where confluent.
- Lesions are loosely covered with silvery-white scales, which if lifted off, show small pinpoint of bleeding (Auspitz's sign).
- Plaques appear most commonly on the elbows, knees, scalp, umbilicus, and lumbar areas, and often extend to involve the trunk, arms, legs, face, ears, palms, soles, and nails.
- Nail involvement presents as pitting, discoloration ("oil spots"), crumbling, splinter hemorrhages, growth arrest lines, or tissue buildup around the nails.

Clinical Presentation and Diagnosis of Other Types of Psoriasis

Inverse psoriasis spares the areas commonly involved in plaque psoriasis and instead appears in intertriginous areas, where scaling is minimal.

Guttate psoriasis presents as a sudden eruption of small, disseminated erythematous papules and plaques, often preceded by a streptococcal infection 2 to 3 weeks prior.

Pustular psoriasis may be localized or generalized and may be an acute emergency requiring systemic therapy.

Generalized pustular psoriasis is characterized by disseminated deep-red erythematous areas and pustules, which may merge to become "lakes of pus."

Erythrodermic psoriasis is a generalized, life-threatening condition that presents with erythema, desquamation, and edema and may require life support measures as well as systemic therapy.

Psoriatic diaper rash is the most common type of psoriasis in children younger than 2 years. This usually affects inguinal folds, and greater than 90% of psoriatic diaper rash cases may have involvement outside the diaper area.

Disease severity is generally classified as mild/limited disease, moderate disease, or severe disease based on body surface area (BSA) involvement or various measurements of symptom and involvement such as the Psoriasis Area and Severity Index (PASI) and the Dermatology Life Quality Index (DLQI).^{14,15}

Disease Severity Classification^{14,15}

Mild or limited disease	Less than or equal to 5% BSA involvement
Moderate disease	PASI greater than or equal to 8 (higher in trials of biologics)
Severe disease	The Rule of Tens: PASI greater than or equal to 10 or DLQI greater than or equal to 10 or BSA greater than or equal to 10% (in some phototherapy trials, BSA greater than or equal to 20% is used as the lower limit)

TREATMENT

Desired Outcomes and Goals

4 Since psoriasis is a chronic illness, goals of treatment focus on controlling the signs and symptoms, ensuring appropriate management of comorbidities, and minimizing treatment-related morbidity. Goals include the following:

- Minimizing or eliminating the signs of psoriasis, such as plaques and scales
- Alleviating pruritus and minimizing excoriations
- Reducing flare-up frequency
- Ensuring appropriate management of associated comorbidities such as psoriatic arthritis, cardiovascular disorders, Crohn's disease, clinical depression, or itching
- Avoiding or minimizing adverse effects from treatments used
- Providing cost-effective therapy
- Providing guidance or counseling as needed (e.g., stress-reduction techniques)
- Maintaining or improving the patient's quality of life

General Approach to Treatment

5 Management of patients with psoriasis generally involves both nonpharmacologic and pharmacologic therapies.

- Pharmacologic alternatives for plaque psoriasis include topical treatments, **phototherapy**, **photochemotherapy**, and systemic therapies alone (orally or by injection). Systemic therapies are generally further sorted into traditional systemic therapies and biologic response modifiers (BRMs). The choice of treatment is usually dictated by the severity

Patient Encounter, Part 2

Additional relevant information was obtained from the patient, including the following history.

FH: One of his brothers has psoriasis and his sister has atopic dermatitis. His father died of a massive heart attack at age 51.

SH: He works as an assistant copywriter in a busy publishing house and is constantly struggling with multiple deadlines; he is an occasional social drinker and nonsmoker; he is a single father to an 8-year-old boy with asthma.

PE:

He appears anxious about the lesions.

VS: BP 125/70 mm Hg, P 72 beats/min, RR 16 breaths/min, T 37°C (98.6°F)

Height & Weight: Ht 5 ft 8 in (173 cm), Wt 175 lb (80 kg)

Abd: Soft, nontender; bowel sounds present; lesions on abdomen

Exts: Within normal limits; no joint pains; lesions on legs, elbows, and knees; “oil spots” on finger nails

Skin: Well-demarcated raised reddish-violet lesions on legs, abdomen, back, elbows, and knees; evidence of excoriation on legs

Labs: All within normal limits, including lipids, renal function tests, and LFTs

What risk factors does he have for psoriasis and/or its associated comorbidities?

Identify your treatment goals for the patient.

of disease; however, the presence or absence of comorbidities, such as psoriatic arthritis, is playing a greater role in drug therapy selection. In some cases, a combination of treatment options may optimize therapy. Topical therapies can be used in patients with mild/limited to moderately severe disease. Phototherapy and photochemotherapy are generally used in moderate to severe disease. Systemic therapies are used for patients with extensive or moderate to severe disease. To minimize drug toxicities or increase efficacy, systemic therapies are sometimes used in conjunction with topical or phototherapy.^{14,15} BRMs are currently recommended for consideration as first-line therapies alongside traditional systemic agents for moderate to severe disease.¹⁴ Their safety profile in comparison with other systemic agents and relatively good acceptability by patients are all positive factors.¹⁴ However, due to a significant cost difference, biologic agents are often reserved for cases in which traditional systemic agents provide inadequate control or for patients with comorbidities (e.g., in a patient with PsA or for whom traditional systemic agents may be inappropriate due to potential adverse effects). In addition, it is important to ensure appropriate screening and treatment of any comorbid illnesses such as depression or diabetes⁷ and

to ensure appropriate management of symptoms such as itching.

There are several recently published treatment guidelines and consensus guidelines.^{5,6,14,16–23}

Efficacy Assessment

Quantitative tools to evaluate the efficacy of psoriasis treatments are generally used in clinical trials and rarely in practice. These include the Psoriasis Area and Severity Index (PASI), the Physician’s Global Assessment (PGA), and the National Psoriasis Foundation—Psoriasis Score (NPF-PS). PASI is the most well known and measures overall extent and severity of psoriasis, assessing areas of coverage, erythema, induration, and scaling. Clinical efficacy is reported as a decrease in the PASI score, or an improvement (e.g., 75% improvement or PASI-75).⁶

In clinical practice, subjective qualitative assessment of disease severity is generally used to determine treatment efficacy. In addition, an assessment of the patient’s quality of life (QOL) is important. The impact of psoriasis on a patient’s psychological well-being may differ substantially from the severity of disease. Various QOL instruments validated for dermatologic diseases include the Dermatology Quality of Life Scales, Dermatology Life Quality Index (DLQI), Dermatology Specific Quality of Life Instrument, and Skindex-29.

Nonpharmacologic Treatment

6 *Nonpharmacologic alternatives may be extremely beneficial in the patient with psoriasis and complement pharmacologic therapies and thus should always be considered and initiated when appropriate.* These include the following²⁴:

- **Stress reduction techniques.** Psychotherapy including stress management, guided imagery, and relaxation techniques are being used more frequently as adjunctive therapies for patients with psoriasis. Stress reduction has been shown to improve both the extent and severity of psoriasis.
- **Oatmeal baths.** Regular use of oatmeal baths in tepid water may help soothe the itching associated with psoriasis and reduce the need for systemic antipruritic agents.
- **Nonmedicated moisturizers.** Maintaining adequate skin moisture helps to control the scaling associated with psoriasis. Emollients restore skin pliability, reduce skin shedding, reduce pruritus, and help prevent painful cracking and bleeding.² Nonmedicated moisturizers may be liberally applied several times daily to help prevent skin dryness. Fragrance-free products should be selected when available.
- **Avoid irritant chemicals on the skin.** Harsh soaps or detergents should not be used. Cleansing should be done with tepid water, preferably using lipid-free and fragrance-free cleansers.

- *Avoid skin trauma.* Sunburns can induce a flare-up of psoriasis. Sunscreens with a sun protection factor of at least 15 should be routinely used when outdoors; often a sun protection factor of 30 is recommended. Avoid scratching the skin, which could lead to excoriations and exacerbate psoriasis. Loose-fitting cotton garments should be worn to minimize skin irritation.

Pharmacologic Treatment

7 *Pharmacologic alternatives for psoriasis include topical agents, phototherapy, and systemic agents including the use of BRMs.* See [Figures 64-1](#) and [64-2](#) for treatment algorithms.

FIGURE 64-1. Treatment algorithm for mild to moderate psoriasis.

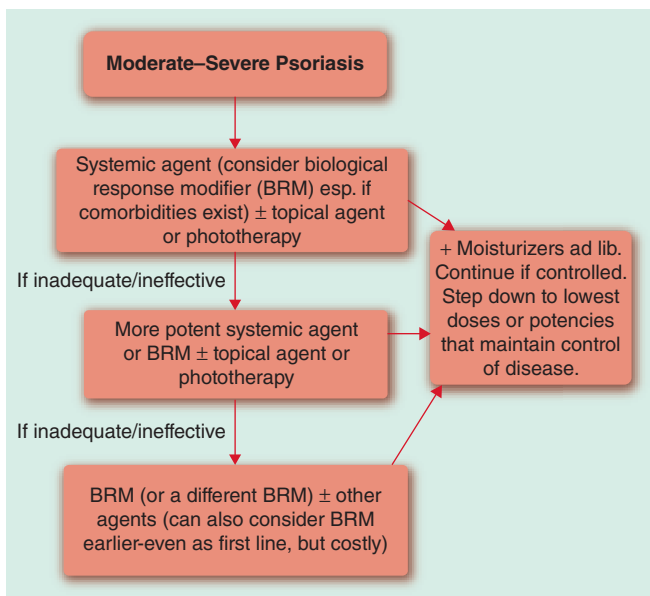

FIGURE 64-2. Treatment algorithm for moderate to severe psoriasis.

Patient Encounter, Part 3

The diagnosis is that the patient has a moderate flare-up of his plaque psoriasis.

Current meds: Nonmedicated moisturizer being applied to entire body once daily after bathing. Hydrocortisone 0.5% cream being applied to lesions twice daily (patient obtained this as an OTC product).

Identify the drug-related problems in this patient.

What nonpharmacologic alternatives are appropriate for this patient?

What pharmacologic treatments are appropriate for this patient?

► Topical Therapy for Psoriasis

8 *Topical therapy is the initial drug treatment strategy for patients with mild to moderate psoriasis.* Approximately 70% to 80% of psoriasis patients may be adequately managed with topical drug therapy.¹ These include corticosteroids, coal tar products, anthralin, vitamin D₃ analogues (e.g. calcipotriol), retinoids (e.g. tazarotene), and topical immunomodulators (e.g. tacrolimus, pimecrolimus).¹⁷ Topical corticosteroids remain the mainstay of topical therapy for most psoriatic patients.^{14,17} Vitamin D₃ analogues and topical retinoids all affect keratinocyte functions and the immune response and are sometimes the initial choice of therapy. Currently, these are in wider use than either anthralin or coal tar preparations.

- Topical agents may be incorporated into various vehicles, including ointments, creams, gels, lotions, foams, sprays, tapes, pastes, and shampoos. Vehicle selection is an important consideration and may vary from one body part to another. Ointments and tapes provide occlusion, enhancing drug penetration to improve efficacy. Creams and lotions are easier to spread, especially in hairy areas. Gels may have drying and cooling effects in addition to easy spreadability. Foams may have enhanced drug delivery and/or efficacy versus lotions or creams and can become a cosmetically elegant liquid upon skin contact, providing good patient acceptance. Shampoos incorporating tar distillates or salicylic acid are useful for scalp psoriasis. Pastes such as Lassar's paste have an inherent stiffness, minimizing the spread of medication, and are useful for incorporating drugs such as anthralin, which, especially in higher concentrations used in short-contact methods, may cause skin irritation and burning if in contact with normal skin. It is important to remember that changing to a different vehicle may significantly alter drug potency. For example, a tape formulation (highly occlusive) is much more potent than a cream formulation. However, ultimately the optimal vehicle may be the vehicle that the patient is willing to use—occlusive ointments may be too greasy and cosmetically unappealing, resulting in poor compliance. Sometimes using a cream formulation during the day and an ointment at night may be the best option.¹⁷

For mild to moderate psoriasis, mid-potency corticosteroids such as betamethasone valerate (0.05% to 1%) are most frequently selected first, with escalation to higher potency corticosteroids, if needed, and stepping down to lower potency corticosteroids when the psoriasis improves. High-potency corticosteroids may be used initially in thicker plaque areas such as palms and soles, but should be considered for short-term use only. These include fluocinonide, clobetasol, halobetasol, and betamethasone dipropionate in optimized base. Low-potency corticosteroids such as hydrocortisone (0.5% to 2%) are appropriate choices if treatment of the face or flexures is necessary. Topical corticosteroids are available as ointments, creams, lotions including scalp lotions, and a few foam products and should be applied in a thin layer on the skin. Intralesional triamcinolone may be useful for specific lesions, such as nail matrix psoriasis.

Tachyphylaxis, defined as the loss of effectiveness with continued use¹⁷ or a progressive decrease in their biological action with repeated use¹⁴ can occur. However, this is not always seen in studies, and it remains somewhat controversial whether tachyphylaxis results from a true loss of effectiveness or reflects a loss of patient adherence.^{5,17} Regardless, pulse-dosing (using a potent topical corticosteroid for only 1 to 2 days per week) has been shown to lengthen the duration of effectiveness and reduce the incidence of adverse effects.¹⁴ Another possible concern is rebound, defined as the disease recurring worse than the pretreatment baseline after the topical corticosteroid is discontinued.¹⁷ Rebound most typically occurs when topical corticosteroids are abruptly discontinued; however, its frequency and severity are poorly characterized.¹⁷

It is important to remember that adverse effects of *topical* corticosteroids may be *systemic* in nature, and hypothalamic–pituitary–adrenal axis suppression can occur, especially when high-potency corticosteroids are used. Infants and small children may be more susceptible due to their increased skin surface:body mass ratio. Much less common systemic side effects of topical corticosteroids include osteonecrosis of the femoral head, cataracts, and glaucoma.¹⁷ Topical corticosteroids may also cause **striae**, skin atrophy, acne, **telangiectasias**, folliculitis, contact dermatitis, hypertrichosis, perioral dermatitis, traumatic purpura, and rosacea.^{14,17} Atrophy can result in thin, fragile, easily lacerated skin. Striae are caused by tearing of dermal connective tissue and are irreversible. Due to their significant adverse-effect profile, it has been recommended that no topical corticosteroid be used regularly for more than 4 weeks without review and reassessment.² Continuous use of high-potency (class I) topical corticosteroids should normally be limited to no more than twice daily for up to 2 to 4 weeks and no more than 50 g/week¹⁷ (based on evidence from clinical trials); however, in practice, longer durations are frequently used with judicious patient monitoring.¹⁷ All topical corticosteroids are Pregnancy Category C and of unknown safety in nursing women.¹⁷

Vitamin D analogues (calcipotriol, calcitriol, tacalcitol) may also be initial pharmacotherapy for mild to moderate

psoriasis.^{2,5} These inhibit keratinocyte proliferation and enhance keratinocyte differentiation.⁵ They are less effective than high-potency topical corticosteroids (class I)⁵ and are often used in various combination regimens with topical corticosteroids to enhance efficacy and reduce steroid atrophy, as discussed later. Unlike corticosteroids, tachyphylaxis does not occur with prolonged use. Clearance of lesions should occur after 4 to 6 weeks of treatment.² Lack of response by 8 weeks indicates treatment failure.² These analogues may cause skin irritation leading to erythema, dryness, stinging, or burning. They may also cause hypercalcemia secondary to excessive absorption or use.^{2,14,17} This is rare unless patients are applying more than the recommended weekly dosage or have underlying renal disease or impaired calcium metabolism.¹⁷ Recommended dosage is 5 mg calcipotriol (i.e., 100 g of calcipotriol cream or ointment) per week.^{14,17} Calcipotriol (50 mcg/g) is also available as a combination ointment product with betamethasone propionate.¹⁷ Topical calcitriol (the active metabolite of vitamin D) has been studied for treatment of psoriasis and appears almost as effective as betamethasone dipropionate in clearance of lesions, with a longer remission period.² It is less irritating than calcipotriol and can be used for the face and flexures.^{2,5} Calcipotriol is inactivated by UVA; thus it would be important to apply calcipotriol after and not before UVA exposure if used together.¹⁷

Tazarotene is a topical retinoid effective for mild to moderate psoriasis and also for acne. It normalizes keratinocyte differentiation and has antiproliferative and anti-inflammatory effects.^{14,17} Tazarotene is available commercially as a 0.05% or 0.1% gel. Similar to vitamin D analogues, it is also steroid-sparing⁵ and often used in combination, as discussed later. It may cause significant skin irritation, including erythema, pruritus, and burning, especially upon initial use.^{14,17} Skin irritation can be minimized by using the cream formulation, the lower concentration product, moisturizers, application on alternate days, or short-contact (30 to 60 minutes) treatment.¹⁷ Avoid use in women of child-bearing age (Pregnancy Category X), unless effective contraception is being used; there is a potential risk of systemic drug absorption, and systemic retinoids are known teratogens. Concomitant use of other topical preparations or cosmetics with a strong drying effect should be avoided.¹⁵

Keratolytic agents, such as salicylic acid, are often added to bath oil or shampoos (typically 3% to 4%) for scalp psoriasis.²⁴ Salicylic acid can also be added to topical corticosteroid preparations to enhance steroid penetration (salicylic acid breaks down keratin).^{14,17} Systemic absorption of topical salicylate is rare but can occur, especially if applied to more than 20% of BSA.¹⁷ Topical salicylate reduces the efficacy of ultraviolet B (UVB) phototherapy due to a filtering effect and should be applied after a UVB treatment if used together.¹⁷

Coal tar is keratolytic and may have antiproliferative and anti-inflammatory effects.² Coal tar products include crude coal tar and tar distillates (liquor carbonis detergens) available as ointments, creams, and shampoos in various strengths. Coal tar may cause acne, folliculitis, local irritation,

and phototoxicity; it will stain clothing and has an unpleasant odor.^{14,17,24} It is photosensitizing and can be combined with UVB phototherapy (Goekermann's regimen) to increase treatment response.¹⁷

Anthralin (dithranol) has a direct antiproliferative effect on epidermal keratinocytes² and is generally used only on thick plaque areas. It can be used continuously or as short-contact anthralin therapy (SCAT): exposure to anthralin for 2 hours or less.¹⁷ SCAT is most commonly administered as 20- to 30-minute outpatient treatments, starting at 1% anthralin concentration with increasing concentration over time as tolerated.¹⁷ Anthralin may be highly irritating, especially if SCAT treatments are misused or mistakenly applied continuously.²⁴ It is important to remember when compounding anthralin preparations that prescribed concentrations range from 0.1% (meant for continuous use) to 1% to 4% (meant for SCAT).¹⁵ Normal skin surrounding the psoriasis plaques should be protected with nonmedicated paste or zinc oxide.^{17,24} Persons handling the dry anthralin powder should avoid skin contact (e.g., by wearing gloves while compounding).¹⁵

Tacrolimus and pimecrolimus are topical calcineurin inhibitors approved for treatment of atopic dermatitis in children 2 years or older. Although currently not approved for treatment of psoriasis, they have been successfully used in treating facial and intertriginous psoriasis in several RCTs, where concerns about corticosteroid toxicity including skin atrophy is higher.¹⁷ In fact, AAD's Work Group states that topical tacrolimus also be considered first line of therapy for intertriginous psoriasis.⁵

Combination therapy may be more efficacious and can result in reduced side effects. Topical corticosteroids used with either vitamin D analogues or retinoids are successful combinations whether used concomitantly or sequentially.^{5,14} Combining tazarotene use with a topical corticosteroid (e.g., an alternate-day regimen or morning corticosteroid–evening tazarotene regimen) may minimize skin irritation and steroid-induced skin atrophy and enhance efficacy.¹⁷ Tazarotene plus topical corticosteroid are synergistic, lengthening the duration of treatment benefit/remission.⁵ Similarly, morning calcipotriol and evening halobetasol ointment resulted in reduced overall severity of psoriasis versus monotherapy.¹⁴ Also, 2 weeks of calcipotriol followed by pulse therapy with halobetasol ointment twice daily on weekends and calcipotriol ointment twice daily on weekdays was superior to either of the two agents when pulsed with placebo.¹⁴ Fixed-dose combination products are also more efficacious than monotherapy; however, the adverse effects of continuous corticosteroid use are not reduced. Corticosteroid/topical retinoid combination products may reduce topical irritation related to the retinoid. As mentioned earlier, salicylic acid can enhance steroid efficacy by increasing penetration, and there are combination products with corticosteroids such as betamethasone dipropionate or diflucortolone valerate.¹⁴

► Phototherapy for Psoriasis

8 Phototherapy or photochemotherapy is used for patients with moderate to severe psoriasis, generally when topical therapies

alone are inadequate. Phototherapy involves the use of either ultraviolet A (UVA) or B (UVB). Photochemotherapy is the concurrent use of phototherapy together with topical^{14,17,19} or systemic agents.^{14,19} UVA is a longer wavelength, and therapy with UVA is always combined with psoralens (e.g., methoxsalen or trioxsalen), which are used as photosensitizers to increase efficacy. There is an increased risk of skin cancers after prolonged use of phototherapy, and risks are greater with PUVA than UVB.^{14,15,19} Narrowband UVB (NB-UVB) is generally well tolerated.

Bath PUVA, topical PUVA, and oral PUVA regimens are available.^{14,19} Bath PUVA involves soaking in a bath of psoralens liquid for 15 minutes prior to UVA treatment and is commonly used in Scandinavian countries for generalized psoriasis to reduce systemic toxicities from psoralens.¹⁹ Topical PUVA involves painting the compound on affected skin prior to UVA treatment¹⁴ and is commonly used for psoriasis localized to palms and soles.¹⁹ When using any form of topical PUVA, the UVA treatment should be done within 30 minutes of the psoralens skin treatment.¹⁹ Oral PUVA involves ingesting a psoralens capsule the day prior to a UVA treatment. Oral psoralens (e.g., 5- or 8-methoxsalen) often causes nausea.^{6,14} Other adverse effects of PUVA include photosensitivity (necessitating the use of eye protection and UVA-blocking sunscreen for 24 hours after a PUVA treatment), macular **melanosis** at exposed sites (PUVA **lentiginos**),¹⁹ photoaging; increased risk of cataract formation¹⁹; and increased risk of nonmelanoma skin cancers (especially squamous cell carcinoma; less commonly basal cell carcinomas).^{14,19} One large prospective trial found an additional risk of melanoma with increasing cumulative UVA doses,¹⁴ although other studies differ, and this is an area of controversy.¹⁹ Regardless, it is recommended that the lifetime cumulative exposure be capped at 200 PUVA treatments.^{14,19}

PUVA has been used in conjunction with other topical agents to increase treatment efficacy. Calcipotriol added to a PUVA regimen may reduce both the number of PUVA treatments and the total UVA dosage needed to clear lesions.^{25,26} The rate ratio for marked improvement in patients receiving PUVA plus calcipotriol versus PUVA alone was 1.2 in a recent meta-analysis of 11 controlled studies.²⁷ To use calcipotriol and PUVA together, calcipotriol must be applied *after* PUVA, since UVA irradiation will inactivate calcipotriol.²⁸ Use with other topical agents has been limited. Tazarotene plus PUVA was studied in 12 patients with extensive plaque psoriasis, and results showed significant improvements after 3 weeks²⁹; however, UVA doses should be reduced by at least one-third, since tazarotene increases the risk for immediate pigment darkening caused by UVA.³⁰

PUVA can be effectively used with other systemic agents, including oral retinoids (RePUVA) and methotrexate. This will be discussed later in greater detail.

UVB treatments are often used alone.⁶ Narrowband UVB (NB-UVB) is more effective than broadband UVB (BB-UVB)¹⁹ and avoids some adverse effects of PUVA, but is slightly less effective than PUVA.⁶ NB-UVB can be safely used in patients with demyelinating diseases where

TNF- α -inhibiting BRMs are contraindicated.⁵ Efficacy in part depends on frequency of treatments.¹⁴ Thrice weekly NB-UVB has been found equally effective as twice weekly PUVA, but twice weekly NB-UVB is less efficacious.¹⁴ UVB is dosed based on either skin type or the minimal erythema dose (MED) with subsequent doses adjusted accordingly.¹⁹ Adverse effects of BB-UVB include erythema, itching, burning, stinging, cataract formation, reactivation of herpes simplex virus infection, photoaging, and increased risk of genital tumors in men treated without genital shielding.¹⁹ Eye goggles and genital shielding are standard practices to minimize risks, as is covering the face when there are no facial psoriasis lesions or minimizing the UVB dose to the face.¹⁹ Lesional blistering, although uncommon, can occur with NB-UVB.¹⁹ NB-UVB may be two to three times more carcinogenic per MED than BB-UVB; however, due to significantly greater efficacy, the total MED needed with NB-UVB is far less than BB-UVB, and a recent review found no significant association with basal cell carcinoma, squamous cell carcinoma, or melanoma in patients followed for about 5.5 years.¹⁹

UVB treatments have been used with topical or systemic agents to increase treatment efficacy. Topical regimens have included UVB with tazarotene, with crude coal tar (Goekermann's regimen), with anthralin (Ingram's regimen), with calcipotriol, and with topical corticosteroids.¹⁹ UVB with tazarotene may be synergistic: The effect of each agent seems to be enhanced; efficacy is increased, whereas the number of treatment sessions and the cumulative UVB dose needed are reduced.^{14,19} UVB with crude coal tar is a highly effective regimen developed early in the twentieth century; however, many patients consider it messy and time-consuming and it is less commonly used today.^{14,19} UVB with SCAT has shown little additional benefit,¹⁹ and UVB with calcipotriol has shown conflicting results.¹⁹ UVB with topical steroids may actually shorten the remission period³¹ or lead to a higher relapse rate.¹⁹

Several UVB and systemic therapy combinations have shown efficacy. These include UVB with acitretin (ReUVB) and UVB with methotrexate and will be discussed later.

► Systemic Therapy for Psoriasis

8 Systemic therapies are seldom used for mild to moderate psoriasis and are generally reserved for patients with moderate to severe psoriasis.^{5,14,15,18} Oral agents include sulfasalazine, acitretin, methotrexate, cyclosporine, mycophenolate mofetil, azathioprine, tacrolimus, and hydroxyurea. Parenteral agents include the BRMs alefacept, etanercept, adalimumab, infliximab, ustekinumab, and many others, currently at various stages of research or approval for psoriasis.

8 Patient-specific concerns such as existing comorbid conditions (e.g., hypertension, hyperlipidemia, diabetes mellitus, renal impairment, or hepatic disease) must also be taken into consideration in the choice of therapy.

8 Once the disease is under control, it would be important to step down to the least potent, least toxic agent(s) that maintain control.

Patient Encounter, Part 4

The patient's psoriatic condition remains well controlled with topical treatments for about 11 years, then flare-ups become a frequent occurrence. Phototherapy with NB-UVB was initiated. The patient did not respond well to NB-UVB therapy used alone. He is currently presenting with fairly extensive plaque psoriasis, affecting about two-thirds of his body surface area. There are signs of excoriation as well.

Current weight: 70 kg.

Current meds: Nonmedicated moisturizer after bathing and ad lib. Betamethasone valerate 0.1% ointment bid to lesions.

Relevant social history: Patient has remarried and his son is doing well in college.

What are the drug-related problems in this patient at this time?

What pharmacologic treatments would be appropriate for this patient at this time?

Rotational therapy (i.e., rotating systemic drug interventions in a sequential manner) is a means to minimize drug-associated toxicities, since systemic agents for psoriasis often have differing toxicities. However, continuous treatment has largely replaced rotational therapies and is now the standard of care.

Sulfasalazine has variable efficacy and is of limited potency for psoriasis, although it is effective for inflammatory bowel disease. There is no FDA- or Health Canada-approved use for psoriasis.¹⁸ However, its side-effect profile is better than that of other systemic therapies for psoriasis, and it is sometimes tried as an initial systemic agent for moderate to severe psoriasis. Usual doses are 2 to 4 g/day in divided doses,²⁴ starting with an initial dose of 500 mg twice daily and titrating up as tolerated.¹⁸ Side effects include nausea/vomiting, anorexia, headache, arthralgias, and reversible oligospermia.¹⁸

Acitretin is an oral retinoid, likely safer than methotrexate or cyclosporine since potentially serious adverse effects can usually be minimized by appropriate patient selection, careful dosing, and monitoring.¹⁸ It has the advantage of not being immunosuppressive.⁶ The usual dose range is 10 to 50 mg once daily, with lower doses (10 to 25 mg) used more often to minimize side effects^{14,18}; higher doses (70 mg/day) have been used in clinical trials.¹⁸ Acitretin given concurrently with phototherapy (ReUVB or RePUVA) has a synergistic treatment effect: The number and duration of phototherapy sessions needed to achieve clearance is reduced.^{18,19} Acitretin monotherapy is usually given for 14 days before instituting UVB or PUVA.¹⁸ The ultraviolet light dose should be reduced by 30% to 50%.¹⁸ ReUVB and RePUVA are well-established treatment regimens for psoriasis.^{1,5,6,14,18,19}

However, acitretin is teratogenic (Pregnancy Category X) and relatively contraindicated in women of childbearing

potential. It must not be used in pregnant women, those with unreliable contraception, or those who intend to become pregnant at any time during or for 3 years after discontinuation of therapy.^{6,15,18} Acitretin can transform spontaneously or be converted by ethanol (transesterification) into etretinate, which may take up to 3 years for clearance.¹⁸ Alcohol should be avoided during therapy and for at least 2 months after acitretin discontinuation—it is unknown what the minimum amount of alcohol consumption is for transesterification to occur.^{15,18} Common side effects include mucocutaneous dryness and hyperlipidemia.^{14,18} Long-term continuous use has caused **diffuse idiopathic skeletal hyperostosis (DISH)**¹⁴ and periungual pyogenic granulomas.¹⁸ Drug interactions include vitamin A (use of vitamin A should be avoided due to the increased risk of hypervitaminosis A), and caution should be used with drugs that interfere with cytochrome P450 metabolism or have significant plasma albumin binding.¹⁸

Methotrexate used in low doses is one of the mainstays of systemic therapy in the treatment of psoriasis.²⁰ Compared with cyclosporine, methotrexate has a more modest effect but can be used continuously for years, with durable benefits.¹⁴ An initial test dose of 2.5 to 5 mg/week (single dose given once) is recommended.^{15,18} If lab values are normal after 1 week, the dose can be increased to a range of 7.5 to 25 mg once weekly.¹⁸ This can be given as a single dose or split into two or three doses given 12 hours apart to minimize GI side effects.^{15,20} It may take up to 4 weeks to see a clinical response after a dose increase.¹⁸ Always titrate to the lowest effective dosage for maintenance. Methotrexate is contraindicated in pregnancy, renal impairment, hepatitis, cirrhosis, alcoholics, unreliable patients, and patients with leukemia or thrombocytopenia.⁶

Serious side effects of methotrexate include hepatotoxicity, bone marrow suppression, and pulmonary fibrosis. Cumulative liver toxicity was shown in a Canadian study to be severe in nearly one-fourth of psoriatics receiving methotrexate over 1 to 11 years.¹⁴ Psoriatic patients with comorbid diabetes are at particularly high risk of severe liver fibrosis and cirrhosis.¹⁴ Psoriatic patients have a greater risk of hepatotoxicity than rheumatoid arthritis patients given similar cumulative doses of methotrexate; thus guidelines have traditionally recommended routine pretreatment liver biopsies for psoriatics¹⁴ but not patients with rheumatoid arthritis. Currently, for psoriatics with no hepatic risk factors, a liver biopsy is suggested every time the cumulative dose of methotrexate reaches 1.5 g,^{6,14} with a suggestion that 3.5 to 4 g of cumulative methotrexate may be a more appropriate time frame for the first liver biopsy.¹⁸ However, if a history of significant liver disease exists, a liver biopsy should be considered at baseline,²⁰ or else delayed for 2 to 6 months (until drug efficacy and tolerability has been established),¹⁸ with a repeated liver biopsy at a cumulative dose of 1 to 1.5 g, then repeated with every additional 1 to 1.5 g of methotrexate.¹⁸ For lab monitoring of hepatotoxicity, patients without hepatic risk factors require liver chemistry evaluation every 1 to 3 months.^{18,20} In patients with hepatic risk factors (history of or current alcohol intake greater than moderate, persistent abnormal liver chemistries, history of liver disease including chronic hepatitis B or C, family history

of inheritable liver disease, obesity, renal insufficiency, advanced age, hypoalbuminemia, on other hepatotoxic medications, etc.),^{18,20} liver chemistries should be monitored more frequently.²⁰ Besides hepatotoxicity, methotrexate, even in low doses used in psoriasis, may cause leukopenia, megaloblastic anemia, pneumonitis, and pulmonary fibrosis. Complete blood cell counts (CBC; 7 to 14 days after starting or increasing the dose, every 2 to 4 weeks for the first few months, then every 1 to 3 months),²⁰ renal function tests (every 2 to 3 months),²⁰ and pulmonary toxicity testing should also be routinely conducted.^{15,18,20,24} A pregnancy test is indicated in women of child-bearing potential, as methotrexate is an abortifacient and teratogen (Pregnancy Class X).¹⁸ Drug interactions are numerous and include protein binding interactions (salicylates, sulfonamides, etc.), renal excretion interactions (salicylates, probenecid, acidic drugs including high-dose ascorbic acid, etc.), and concomitant hepatotoxic drug interactions (alcohol, statins, retinoids, azathioprine, etc.).¹⁸

Methotrexate and UVB appear synergistic; responses may occur at lower cumulative doses of both methotrexate and UVB.³¹ However, stopping methotrexate may cause rebound,³¹ and there is concern about photosensitivity.^{14,18,20} Methotrexate and PUVA have been used in patients refractory to other treatments; however, there is increased risk of squamous cell cancer and phototoxicity.

Methotrexate has been used successfully with cyclosporine, either concurrently³² or in rotation. Rotational therapy effectively minimizes the serious adverse effects of both agents: Hepatotoxicity from methotrexate and nephrotoxicity and hypertension from cyclosporine. However, rotational therapy is less commonly used today.

Cyclosporine is efficacious in both inducing remission and in maintenance therapy for patients with moderate to severe plaque psoriasis and is also effective in treating pustular, erythrodermic, and nail psoriasis.^{14,15,21,22} Cyclosporine is used in low doses whether alone or in combination with other agents. The usual dose range is 2 to 2.5 mg/kg/day, given orally in two divided doses, for patients with stable generalized psoriasis or for moderate to severe disease.^{21,22} Failing an adequate response with low-dose cyclosporine after 4 weeks of treatment, the dose can be increased in 0.5 to 1 mg/kg/day increments every 2 to 4 weeks to a maximum of 5 mg/kg/day.^{18,22} For patients with severe inflammatory flares of psoriasis, or recalcitrant cases who fail to respond to numerous other therapies, or for a highly distressed patient in a crisis situation, the starting dose is higher at 4 to 5 mg/kg/day^{21,22} in two divided doses. Doses can be adjusted by 0.5 to 1 mg/kg/day every 2 weeks to the lowest effective dose.^{21,22} Cyclosporine should normally be used intermittently for short term (12 weeks)¹⁴ to minimize drug toxicity. If relapse occurs, cyclosporine can be reinstated at the previously established effective dose.²² It has been proposed that continuous cyclosporine (for up to 2 years) may be appropriate for a subset of patients.^{14,21} In the United States, cyclosporine is approved for only up to 1 year of continuous therapy at a time.⁵ Cyclosporine is contraindicated in psoriatic patients with abnormal renal function, uncontrolled hypertension,

malignancy (except for nonmelanoma skin cancer), prior treatment with PUVA, uncontrolled infection, and primary or secondary immunodeficiency excluding autoimmune disease.¹⁸

- Blood pressure and serum creatinine (SCr) should be assessed prior to beginning cyclosporine therapy to obtain accurate baselines and should be reassessed biweekly once therapy is started for at least the first 12 weeks of therapy (until values stabilize), and then closely monitored during therapy (e.g., monthly). If SCr increases to greater than 25% above the patient's baseline on two occasions 2 weeks apart, the cyclosporine dosage needs to be decreased by 25% to 50% and SCr rechecked every other week for a month.^{18,21} If the SCr does not return to within 10% of the patient's baseline, another dose decrease of 25% to 50% should be considered.²¹ If the SCr still does not return to 10% of the patient's baseline, cyclosporine should be discontinued and only resumed when the SCr returns to within 10% of the patient's baseline.^{21,23} Besides impaired renal function and hypertension, cyclosporine may cause hypertriglyceridemia, hypomagnesemia, hyperuricemia, and hypertrichosis and increase the risk of lymphomas and cutaneous malignancies after long-term treatment.^{6,14,18,21} Patients should have a careful physical exam (for malignancy) and appropriate blood work prior to initiation of therapy. Testing for TB should be considered.¹⁸ There are clinically significant drug and food interactions (e.g., grapefruit juice) since cyclosporine is metabolized by cytochrome P450 3A4.^{5,18,21} Patients taking greater than 3 mg/kg/day, on drugs with potential interaction, or who have liver disease may require monitoring of cyclosporine blood levels.¹⁸
 - The combination of cyclosporine with calcipotriol, SCAT, or topical corticosteroids may all be effective.^{18,21} Cyclosporine and calcipotriol may be more efficacious than either agent used alone.³³ However, cyclosporine *should not* be used concurrently with PUVA: a well-documented increased risk of squamous cell cancer exists, and the combination may have a negative effect on lesion clearance.¹⁸ Cyclosporine alternating with methotrexate is extremely effective and minimizes toxicity from either agent. Cyclosporine has also been used successfully with mycophenolate mofetil³⁴ and fumaric acid esters.²²
 - Mycophenolate mofetil was found useful in patients with cyclosporine-induced nephrotoxicity as a switch-over agent: although PASI increased, patients' renal function improved.³⁵ As adjunctive or monotherapy, there are a few studies in relatively small groups of patients with moderate to severe psoriasis that showed some benefit (at least a 50% reduction in PASI).^{18,35}
- Fumaric acid esters (fumarates) are commonly used in Europe for the treatment of moderate to severe psoriasis but is not approved in the United States.¹⁸ Hydroxyurea is an older agent still used occasionally today for patients with psoriasis, although there is no FDA-approved use for psoriasis,¹⁸ and there have been precautions about its use in the elderly and cutaneous vasculitic toxicities in patients with myeloproliferative disorders. Toxicity associated with systemic tacrolimus has limited its use in psoriasis.

- Azathioprine has a slow onset and significant toxicity. Oral corticosteroids are reserved for severe or life-threatening conditions such as severe psoriatic arthritis or exfoliative psoriasis; prolonged oral steroid use should be avoided.

► **Biologic Response Modifiers (BRMs)**

Based on recent advances in our understanding of the pathogenesis and pathophysiology of psoriasis, there was accompanying research into the development and use of

- BRMs for psoriasis and psoriatic arthritis. *Some BRMs have proven efficacy for psoriasis; however, there are differences among these agents, including mechanism of action, duration of remission, and adverse-effect profile. Currently, BRMs are often considered for patients with moderate to severe psoriasis when other systemic agents are inadequate or relatively contraindicated. It has also been recommended that BRMs be considered as first-line therapy, alongside conventional systemic agents, for patients with moderate to severe psoriasis; however, in practice, drug access due to cost considerations may be a limiting factor. They may be appropriate if comorbidities exist.* 10 BRMs with proven efficacy for psoriasis include alefacept, etanercept, adalimumab, infliximab, and ustekinumab. These agents employ the following targeted immunosuppressive strategies: alefacept inhibits T-cell activation by targeting LFA-3–CD2 and inducing apoptosis in memory T cells¹; etanercept, adalimumab, and infliximab are all TNF- α inhibitors^{1,6,14}; ustekinumab targets IL-12 and IL-23. There are other biologic agents in clinical trials
- for psoriasis. 10 *In general, due to their immunosuppressive effects, there is an increased risk of infection (including life-threatening severe infections) with most of these agents. In particular, efalizumab was withdrawn in the United States by the company (in consultation with the FDA) due to serious*
- *adverse CNS effects from viral causes. 10 The use of live or live-attenuated vaccines during therapy is generally not recommended.*

The most promising types of BRMs are monoclonal antibodies, cytokines, and fusion proteins.¹ Monoclonal antibodies may be chimeric (fused mouse and human segments; designated “-ximab”), humanized with intermittent murine sequences (designated “-zumab”), human backbone with monkey sequences, or fully human.³⁵

Alefacept is a recombinant dimeric fusion protein composed of the extracellular CD2-binding portion of lymphocyte function–associated antigen (LFA)-3 linked to the constant portion of human IgG.^{6,14,35} Alefacept inhibits T-cell activation by binding to their CD2 sites and also interacts with natural killer cells to destroy already activated T cells.^{1,6} It is approved for moderate to severe chronic plaque psoriasis patients who are candidates for systemic agents or phototherapy.⁶ Alefacept is intended for intermittent rather than continuous use. About one-third of alefacept-treated patients enter prolonged remissions ranging from 6 to 18 months. Alefacept appears to spare helper T-cell function and does not significantly impair primary or secondary antibody responses (e.g., the ability to combat infections or respond to vaccinations). A significant risk of malignancy

exists. Common side effects include lymphopenia, myalgias/chills, pharyngitis, cough, nausea, and for intramuscular (IM) injections, pain and inflammation at the injection site.^{15,36} The dosage recommended is 15 mg IM once weekly for 12 weeks provided the CD4⁺ T-cell count is normal (defined as greater than or equal to 250 cells/mm³ [250 10⁶ cells/L]). Biweekly monitoring of CD4 counts is required during treatment.⁶ Dosing should be held for counts less than 250 cells/mm³ (250 10⁶ cells/L) and discontinued if the CD4⁺ count remains below 250 cells/mm³ (250 10⁶ cells/L) for four consecutive weeks.⁶ Maximal response generally occurs 6 to 8 weeks after the last IM injection of the 12-week course.^{6,37} The regimen may be repeated when the loss of control becomes unacceptable up to twice per year¹⁴ and if CD4 counts are normal. Although predictive markers for which patients will respond are currently unknown, those who achieve a PASI-75 or greater tend to maintain a 50% or greater reduction in PASI for a median duration of 10 months.⁶ Alefacept is contraindicated in human immunodeficiency virus–positive patients due to the potential for accelerating disease progression from CD4 count reduction.⁶ Alefacept in combination with NB-UVB reduces the number of UVB treatments that would otherwise be needed.¹⁴

The three TNF- α inhibitors etanercept, infliximab, and adalimumab discussed next share common safety concerns, including serious infections (sepsis, new-onset or reactivation tuberculosis [TB], and opportunistic infections such as histoplasmosis, cryptococcosis, aspergillosis, candidiasis, and *Pneumocystis*), autoimmune conditions (lupus and demyelinating disorders), and malignancies such as lymphoma.^{14,15} Although the above are safety concerns common to etanercept, adalimumab, and infliximab, their safety profiles are not identical (e.g., the risk for TB is lowest with etanercept and highest with infliximab).¹⁵

Etanercept is a fully human dimeric fusion protein composed of human TNF- α p75 receptor fused to the Fc portion of human IgG1.⁶ It acts as a TNF- α inhibitor by binding to and inactivating soluble and membrane-bound TNF- α , thus preventing interactions with its cell surface receptors.⁶ Etanercept is approved for chronic moderate to severe plaque psoriasis and for psoriatic arthritis. Dosing in psoriasis is different from its other indications (rheumatoid arthritis, juvenile rheumatoid arthritis, and ankylosing spondylitis).⁶ The approved psoriasis regimen is 50 mg subcutaneously twice weekly for the first 12 weeks followed by 50 mg weekly thereafter, dosing being continuous.⁶ In clinical trials, 49% of patients given 50 mg subcutaneously twice weekly achieved a 75% improvement in PASI by 12 weeks.³⁸ Clinical responses continue to improve with longer treatment,^{6,38} but some patients show a loss of response after 12 weeks when the dose is reduced to once weekly.⁶ Etanercept seems well tolerated; common side effects include mild injection site reactions, headache, increased respiratory tract infections (colds and sinusitis), and GI symptoms.^{6,38} There are increased risks of tuberculosis⁶ and hepatitis B reactivation. Serious infections including fatalities have been reported, and there were reports of worsening congestive heart failure (CHF) and new-onset

CHF.¹⁵ Due to rare reports of blood disorders (anemia, aplastic anemia, leukopenia, neutropenia, pancytopenia, and thrombocytopenia), patients are advised to contact their doctor if they experience persistent fever, bruising, bleeding, or paleness.¹⁵ Baseline and yearly purified protein derivative (PPD) and periodic CBC and liver function tests (LFTs) are recommended while on treatment.⁶ Etanercept is effective in children and adolescents (aged 4 to 17) with plaque psoriasis. Fifty-seven percent of patients receiving etanercept 0.8 mg/kg once weekly (to a maximum of 50 mg) achieved PASI-75.^{6,39}

Infliximab is a chimeric human/murine monoclonal antibody against TNF- α that binds to both soluble and transmembrane TNF- α molecules. It is approved for both psoriasis and psoriatic arthritis. Dosing for these patients is 5 mg/kg IV over 2 to 3 hours at weeks 0, 2, and 6 and continuously every 8 weeks thereafter.⁶ Approximately 80% of patients achieved PASI-75 by 10 weeks (after 3 doses of infliximab); however, by week 50, only about 60% of patients maintained PASI-75.^{40,41} Significant adverse effects from postmarketing experience and clinical trials have included hematologic abnormalities (leukopenia, neutropenia, thrombocytopenia, and pancytopenia), hepatotoxicity (rarely: acute liver failure, jaundice, hepatitis, and cholestasis), hypersensitivity reactions (anaphylaxis, urticaria, and serum sickness), ocular toxicity (optic neuritis and optic neuropathy), CHF exacerbation and new-onset CHF, and increased infections (tuberculosis, hepatitis B reactivation, *Listeria monocytogenes* infections, fungal infections, and sepsis). There is an increased risk of infection by live vaccines, and vaccination with live vaccines while receiving infliximab therapy is not recommended. Recommended baseline and ongoing monitoring include yearly PPD, LFTs, and CBC.⁶

Adalimumab is a fully human TNF- α inhibitor approved for treatment of psoriasis and psoriatic arthritis. The dosage in psoriasis is 80 mg subcutaneously in the first week, followed by 40 mg the following week, and 40 mg subcutaneously every 2 weeks thereafter continuously.⁶ With this regimen, 71% of patients achieved PASI-75 by 16 weeks of treatment.⁴² These clinical benefits were maintained for at least 1 year with continuous therapy, although about 10% of patients who were initially considered responsive became inadequately responsive with further therapy.^{14,42} Exclude patients with active or latent TB infection (tuberculin PPD skin test) prior to therapy. There is an increased risk of serious infections (especially respiratory infections including pneumonia and tuberculosis, and hepatitis B reactivation), of exacerbation in heart failure patients, and of lymphoma. Hematologic abnormalities (pancytopenia, thrombocytopenia, and leukopenia) have occurred rarely. Positive antinuclear antibody titers and a lupus syndrome have been reported. Anti-ds DNA antibody determinations are recommended in patients presenting with lupus-like symptoms during adalimumab therapy. A pruritic urticarial eruption that lessens in severity with each subsequent injection has been reported. Rebound does not usually occur.⁶

Ustekinumab is an IL-12/23 monoclonal antibody recently approved for treatment of moderate to severe psoriasis

in the United States and Canada. Approximately 70% of patients achieved 75% skin clearance, and the response was maintained for 1 year with continued treatment.⁴³ A longer-term follow-up study indicated that clinical responses were durable, and improvements in PASI scores can be maintained through 148 weeks with continued every-12-weeks maintenance therapy.⁴⁴ Interestingly, ustekinumab was found to significantly improve symptoms of anxiety and depression, in addition to skin-related quality of life, for patients with moderate to severe psoriasis,⁴⁵ which was maintained through 3 years among responders.⁴⁶ Dosing is 45 mg for patients weighing 220 lb (100 kg) or less, and 90 mg for those over 220 lb (100 kg),⁵ given subcutaneously at weeks 0, 4, then every 12 weeks thereafter. Common side effects include upper respiratory infections, headache, and tiredness. Serous side effects include those seen with other BRMs such as serious infections (e.g., tuberculosis, fungal, viral) and cancer risk; in addition, a reversible posterior leukoencephalopathy syndrome (RPLS) has been reported.¹⁵

► Natural Health Products and Treatments

Several natural health products are considered possibly effective for psoriasis. The most promising is *Mahonia aquifolium* (Oregon grape). This is not a grape, but a plant with blue-violet berries, native to southern British Columbia, western Oregon, and northern Idaho, and is the state flower of Oregon. An extract from the medicinal part of the plant, the rhizome and root, has been formulated into a 10% topical cream/lotion (Relieva, Apollo Pharmaceuticals) and is marketed in Canada for the treatment of psoriasis. This product was shown in several recent clinical trials to modestly decrease the severity of psoriasis and improve the quality of life for patients with mild to moderate psoriasis.⁴⁷ Preliminary research suggests similar efficacy as calcipotriene cream.⁴⁷ Adverse effects include a burning sensation, irritation, redness, itching, and possible allergic reactions. Heliotherapy is the exposure to natural ultraviolet radiation from sunlight, and there are limited randomized controlled trials of supervised heliotherapy versus no intervention that show efficacy. There are risks of photoaging and skin cancers, including basal cell and squamous cell carcinoma.

Other natural health products possibly effective include an aloe vera extract 0.5% cream and an omega-3 fatty acid-based lipid IV infusion (with docosahexaenoic acid [DHA] and eicosapentaenoic acid [EPA]). Oral supplementation with dietary fish oils containing DHA and EPA may possibly be effective. More research into these natural health products is required before they can be recommended for psoriasis.

OUTCOME EVALUATION

- Monitor for clearance of skin lesions. Depending on the agent(s) used and site of lesions, it may take 2 to 6 weeks or longer to see a response. Complete clearance may not be achieved for all patients.

Patient Encounter, Part 5

It was decided by the treating dermatologist to begin systemic therapy but not biologic therapy at this time. The choices were to treat with either methotrexate or cyclosporine to control the flare-ups. Both alternatives with their respective pros and cons were presented to the patient and discussed with the patient, with the choice being ultimately up to the patient.

What lab tests or other measurements would be important to perform prior to starting therapy with methotrexate? With cyclosporine?

What dosing regimen would be appropriate for methotrexate? For cyclosporine?

What monitoring plan would be appropriate during therapy with methotrexate? With cyclosporine?

- Monitor for specific adverse effects and drug interactions, depending on agent(s) used. Some agents are noted below, others (e.g., BRMs) were individually discussed earlier.
- Methotrexate: Monitor CBC and liver function tests at baseline and regularly, and consider liver biopsy prior to treatment and at a cumulative dose of 1.5 g for high-risk patients, as discussed earlier in the chapter. Monitor pulmonary function.
- Cyclosporine: Monitor SCr, blood urea nitrogen, serum lipids, magnesium, and blood pressure at baseline and reassess biweekly for at least 12 weeks (or longer until values stabilize), then regularly. Adjust doses when needed in response to SCr changes as discussed earlier.
- Acitretin: Monitor serum lipids and liver function tests. Pregnancy testing.
- Topical corticosteroids: Monitor for skin thinning, telangiectasias, and possible hypothalamic–pituitary–adrenal axis suppression.

SUMMARY

It is important to remember that psoriasis is a lifelong illness with no known cure and often has a significant psychosocial component. This disease may be very visible and emotionally distressing and can cause significant disability both physically and psychologically, affecting psychosocial functioning and quality of life. Empathy and a caring attitude can go a long way in the care of these patients.⁴⁸

Acknowledgments

In the first edition, portions of this chapter had been adapted from the following article: Law RM. Psoriasis: An update. *Pharm Pract* 2005;21:CE 1–7. With permission from the publisher.

Patient Care and Monitoring

With respect to pharmacologic therapies, it is important to:

1. Provide patients with an approximate time frame for improvement based on the patient's areas of involvement and type of drug therapy. For example, a statement such as: "There should be less scaling and redness of your scalp lesions and a reduction in the thickly crusted areas within 1 to 2 weeks. You should notice a general improvement in your condition by 6 to 12 weeks. Your palms, soles, elbows, and knees may take longer to clear."
2. Provide appropriate advice about drug regimens, including how to apply a specific topical agent, how to use a specific systemic agent, and precautions and possible toxicities of any drug therapy, remembering that topical therapies can have significant systemic adverse effects.
3. Check the patient profile and talk with the patient to ensure that there are no significant drug interactions with other concurrent medications and therapies.
4. Reinforce the importance of adherence to therapies and specific drug regimens.
5. Reinforce the importance of regular follow-up with the patient's healthcare providers, including all appointments for follow-up care and lab work (if any).
6. Interact with the patient's other healthcare providers as needed to discuss patient concerns or issues detected, including drug interactions, nonadherence, other comorbidities, and adverse effects.

Abbreviations Introduced in This Chapter

AAD	American Academy of Dermatology
APC	Antigen-presenting cells
BB-UVB	Broadband ultraviolet B
BAD	British Academy of Dermatology
BMI	Body mass index
BRM	Biologic response modifier
BS	Bowel sounds
BSA	Body surface area
CHF	Congestive heart failure
DHA	Docosahexaenoic acid
DISH	Diffuse idiopathic skeletal hyperostosis
EPA	Eicosapentaenoic acid
ICAM-1	Intracellular cell adhesion molecules
IF- γ	Interferon- <i>gamma</i>
IL-2	Interleukin-2
IL-12/23	Interleukin-12 and interleukin-23
LFA-3	Leukocyte function-associated antigen type 3
LFT	Liver function test
MED	Minimal erythema dose
MI	Myocardial infarction
NB-UVB	Narrowband ultraviolet B
PASI	Psoriasis Area and Severity Index
PIIINP	The aminoterminal propeptide of type III procollagen
PML	Progressive multifocal leukoencephalopathy
PPD	Purified protein derivative
PsA	Psoriatic arthritis
PSORS1	Psoriasis susceptibility 1
PSORS9	Psoriasis susceptibility 9
PUVA	Psoralens + ultraviolet A
RePUVA	Oral retinoid + PUVA

ReUVB	Acitretin + ultraviolet B
RRR	Regular rate and rhythm
SCAT	Short-contact anthralin therapy
TNF	Tumor necrosis factor
UVB	Ultraviolet B

Common Skin Disorders

Angie L. Goeser-Iske

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of common skin disorders.
2. Assess the signs and symptoms of common skin disorders in a presenting patient.
3. List the goals of treatment for patients with common skin disorders.
4. Select appropriate nonpharmacologic and pharmacologic treatment regimens for patients presenting with common skin disorders.
5. Identify adverse effects that may result from pharmacologic agents used in the treatment of common skin disorders.
6. Develop a monitoring plan that will assess the safety and efficacy of the overall disease state management of common skin disorders.
7. Create educational information for patients about common skin disorders, including appropriate self-management, available drug treatment options, and anticipated therapeutic responses.

KEY CONCEPTS

- 1 The development of acne lesions results from four pathogenic factors, which include excess sebum production, keratinization, bacterial growth, and inflammation.
- 2 Although eliminating existing lesions and preventing the development of new lesions are primary goals of acne therapy, secondary goals include relieving pain or discomfort and preventing permanent scarring.
- 3 Acne is categorized as mild, moderate, or severe based on the lesion type and lesion severity. Successful treatment approaches are developed based on these categories, as well as any previous treatment information presented by the patient.
- 4 Irritant contact dermatitis results from first-time exposures to irritating substances such as soaps, plants, cleaning solutions, or solvents. Allergic contact dermatitis occurs after an initial sensitivity and further exposure to allergenic substances, including poison ivy, latex, and certain types of metals.
- 5 The initial treatment goal of contact dermatitis is identifying the causative substance and eliminating its exposure. The second treatment goal is symptom relief.
- 6 Although many factors contribute to the etiology of diaper rash, it is most likely the result of prolonged contact of the skin with urine and feces in the diaper.

- 7 The primary goal in the treatment of diaper rash is prevention and is most often accomplished through frequent diaper changes.
- 8 When a diaper rash is already present, repairing the damaged skin, relieving discomfort, and preventing infection are important factors to consider when developing an effective treatment regimen.

INTRODUCTION

The skin is the largest organ of the human body. One of its most important functions is to assist the immune system by serving as a barrier that protects underlying structures from trauma, infection, and exposure to harmful environmental elements. The skin also holds in place essential organs and fluids necessary for life. Any significant injury to this outer protective layer may potentially compromise an individual's overall health.

Several thousand skin disorders are currently documented, and many patients will seek the assistance of a healthcare provider when a complication with their skin develops. Others will utilize methods of self-care to effectively treat their symptoms. Some skin problems, such as mild acne or diaper rash, may be successfully treated with over-the-counter medications and lifestyle modifications. However, if left untreated or treated inadequately, these seemingly simple disorders can worsen and require more advanced care.

As healthcare providers, it is important to be familiar with the diagnosis and treatment of skin disorders. This chapter discusses acne vulgaris, contact dermatitis (irritant and allergic), and diaper dermatitis; other common skin and soft tissue infections and superficial fungal infections are discussed in Chaps. 73 and 83, respectively. Providing patients with appropriate therapy options, as well as patient education on methods of treatment and prevention, will assist the successful resolution of many common skin disorders.

ACNE VULGARIS

Acne vulgaris, an inflammatory skin disorder of the pilosebaceous units of the skin, is the most common dermatologic reason for physician visits in the United States.¹ Although most commonly seen on the face, acne can also present on the chest, back, neck, and shoulders (Fig. 65-1).² Although generally a self-limiting condition, long-term physical complications of acne may include extensive scarring and psychological distress.^{1,3}

FIGURE 65-1. Twenty-year-old male. In this case of papulopustular acne, some inflammatory papules become nodular and thus represent early stages of nodulocystic acne. (From Wolff K, Johnson RA. Disorders of sebaceous and apocrine glands. Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology, 6th ed. New York: McGraw-Hill; 2009: 3.)

EPIDEMIOLOGY AND ETIOLOGY

With an estimated 40 to 50 million people affected, acne vulgaris is the number one skin disease in the United States.^{3,4} Although acne affects approximately 85% of adolescents and adults aged 12 to 25 years, the disease can develop or recur

in adults aged 30 to 50 years.⁵ The prevalence of acne among whites, African Americans, Hispanics, and Asians is similar, with acne occurring more often in males during adolescence and females during adulthood.^{6,7}

PATHOPHYSIOLOGY

- 1 The development of acne lesions results from four pathogenic factors: excess sebum production, **keratinization**, bacterial growth, and inflammation.^{3,7}

The **pilosebaceous unit** of the skin consists of a hair follicle and the surrounding sebaceous glands. An initial acne lesion called a comedo forms when there is a blockage in the pilosebaceous unit.⁸

Sebum is released by the sebaceous glands and naturally maintains hair and skin hydration. An increase in androgen levels, especially during puberty, can cause an increase in the size of the sebaceous gland and the production of abnormally high levels of sebum within those glands. This excess sebum can result in plugged follicles and acne formation.

- 2 Keratinization, the sloughing of epithelial cells in the hair follicle, is also a natural process. In acne, however, **hyperkeratinization** occurs and causes increased adhesiveness of the sloughed cells. Accumulation of these cells clogs the hair follicle, blocks the flow of sebum, and forms an acne lesion called an **open comedo** or “blackhead.”

Propionibacterium acnes (*P. acnes*), an anaerobic organism, is also found in the normal flora of the skin. This bacteria proliferates in the mixture of sebum and keratinocytes and can result in an inflammatory response producing a **closed comedo** or “whitehead.” More severe acne lesions such as pustules, papules, and nodules also form with inflammatory acne and result in significant scarring if treated inadequately (see Fig. 65-2 for various stages of acne development).

TREATMENT

Desired Outcomes and Goals

- 2 Although eliminating existing lesions and preventing the development of new lesions are primary goals of acne therapy, secondary goals include relieving pain or discomfort and preventing permanent scarring.⁸ In addition, acne can cause patients a significant amount of stress, anxiety, frustration, embarrassment, and even depression.^{6,10} Because of these psychological symptoms, treatment compliance and patient education on both physical and psychological aspects of this skin disorder are also imperative.

General Approach to Treatment

- 3 Acne is categorized as mild, moderate, or severe based on the lesion type and lesion severity (Table 65-1). Successful treatment approaches are developed based on these categories, as well as any previous treatment information presented by the patient. Improvement of symptoms following treatment

FIGURE 65-2. Stages of acne. A. Normal follicle; B. open comedo (blackhead); C. closed comedo (whitehead); D. papule; E. pustule. (From Hartsock M. Medical illustrations. Cincinnati, OH: The Medical Art Company.)

occurs gradually, sometimes taking 6 to 8 weeks for results to be physically apparent.⁸ Patients need to be educated on continual treatment compliance during this time and not get discouraged if acne lesions appear to worsen before getting better during the initial 2 to 3 weeks of therapy.¹¹

Nonpharmacologic Therapy

There is significant variance in the clinical benefit of many nonpharmacologic interventions for acne vulgaris. Among nondrug treatment alternatives, mild, noncomedogenic facial

Clinical Presentation and Diagnosis of Acne

Acne lesions are most often seen on the face, but can also present on the chest, back, neck, and shoulders and are described as either noninflammatory or inflammatory. In addition, severe inflammatory lesions can lead to scarring and hyperpigmentation.

Noninflammatory Lesions

Open comedo or “blackhead”: A plugged follicle of sebum, keratinocytes, and bacteria that protrudes from the surface of the skin and appears black or brown in color. Although dark in color, blackheads do not indicate the presence of dirt, but rather, an accumulation of melanin.

Closed comedo or “whitehead”: A plugged follicle of sebum, keratinocytes, and bacteria that remains beneath the surface of the skin. Closed comedos usually appear as small white bumps about 1 to 2 mm in diameter.

Inflammatory Lesions

Papules: Solid, elevated lesion less than 0.5 cm in diameter

Pustules: Vesicles filled with purulent fluid less than 0.5 cm in diameter

Nodules: Lesions greater than 0.5 cm in both width and depth

Cysts: Nodules filled with a fluid or semisolid that can be expressed

Scars

Inflammatory acne can result in permanent scarring that ranges from small depressed pits to large elevated blemishes.

Hyperpigmentation

Inflammatory acne may result in hyperpigmentation of the skin that can last for weeks to months.

Diagnosis

The diagnosis of acne vulgaris is clinical. Lesion cultures may be warranted when treatment regimens fail to rule out other skin infections.

Table 65-1

Predominance of Acne Lesion Type by Acne Severity

Acne Severity	Predominant Lesions	Typical Frequency of Lesion Type					
		Closed Comedones	Open Comedones	Papules	Pustules	Nodules	Scarring
Mild	Noninflammatory lesions (open and closed comedones)	Few to numerous	Few to numerous	Possible	Possible	None	None
Moderate	Inflammatory papules and pustules with some noninflammatory lesions	Few to numerous	Few to numerous	Numerous	Numerous	Few	Possible
Severe	Inflammatory lesions and scarring with some noninflammatory lesions	Few to numerous	Few to numerous	Extensive	Extensive	Extensive	Extensive

From West DP, Loyd A, Bauer KA, West LE, Scuderi L, Micali G. Acne vulgaris. In: Dipiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiological Approach*. 7th ed. New York: McGraw-Hill; 2008:1591–1602.

soap used twice daily, as well as the avoidance of oily skin products and the avoidance of manipulating or squeezing lesions, are helpful self-treatment recommendations.

Pharmacologic Therapy

► Topical Agents

- **Benzoyl Peroxide** Benzoyl peroxide is easy to use and is recommended as first-line therapy in the treatment of mild to moderate noninflammatory acne. Benzoyl peroxide has a **comedolytic** effect that increases the rate of epithelial cell turnover and helps to unclog blocked pores. It also has antibacterial activity against *P. acnes*, which appears to be the main reason for its effectiveness.¹³

Benzoyl peroxide is available with or without a prescription and remains the most commonly purchased over-the-counter topical treatment for acne.¹² It is available in concentrations ranging from 1% to 10% in various formulations, including creams, lotions, gels, and facial washes.

- Adverse effects commonly reported with benzoyl peroxide are dryness, irritation, redness, and stinging of the skin. Reducing the incidence of these effects can be achieved by beginning a treatment regimen with the lowest strength and titrating up to higher effective strengths over several weeks if needed. In addition, newer formulations of benzoyl peroxide are combined with moisturizers to help decrease skin redness and irritation.¹³ A disadvantage of the agent is that it can bleach and discolor hair and fabrics that come into contact.¹²

A typical regimen for benzoyl peroxide is to apply the product to clean, dry skin no more than two times a day. The strength and dosage form selected may vary from patient to patient depending on acne severity and the sensitivity of the patient's skin. Since gel preparations are the most potent dosage form, patients with dry or overly sensitive skin should be recommended a milder cream, lotion, or facial wash.³ If severe irritation or allergic reaction develops, benzoyl peroxide use should be discontinued.

● **Retinoids** Retinoids, which are highly effective in the treatment of acne, stimulate epithelial cell turnover and aid in unclogging blocked pores. Retinoids also exhibit anti-inflammatory properties through the inhibition of neutrophil and monocyte chemotaxis.⁸ Because of these comedolytic and anti-inflammatory effects, topical retinoids are recommended as first-line treatment for mild to moderate comedonal and inflammatory acne.³ Although success is seen with monotherapy, using a retinoid in combination with benzoyl peroxide or topical antibacterials is also an appropriate and effective therapeutic treatment option.³ Tretinoin, adapalene, and tazarotene are topical retinoids available for use in the treatment of acne. **Table 65-2** describes the strengths and formulations of these agents.

● Transient erythema, irritation, dryness, and peeling at the site of application are all common adverse effects. Newer retinoids formulated in either a microsphere gel (Retin-A Micro) or an aqueous-based gel (Atralin) appear to cause less initial skin discomfort than older agents in this class.¹³ Photosensitivity can also occur with retinoid use, causing increased skin irritation and redness.¹⁴

The topical retinoid selected should be applied once daily at bedtime, beginning with a low-potency formulation. Increased strengths are then initiated according to treatment results and tolerance. Patients should be advised that a worsening of acne symptoms generally occurs in the first few weeks of therapy, with lesion improvement occurring in 3 to

4 months.¹⁶ The use of topical retinoids should be avoided in children younger than 12 years and in pregnant women.¹⁴

● **Antibacterials** Topical antibacterials directly suppress *P. acnes* and are also first-line agents used in the treatment of mild to moderate inflammatory acne.^{3,16}

Clindamycin 1% and erythromycin 2% preparations, applied once or twice daily, have similar effects and are the most commonly prescribed topical antibacterial agents.¹⁷ These agents, as well as sodium sulfacetamide, are available in various formulations for the treatment of acne.

● Adverse effects are generally mild and include dryness, erythema, and itching.¹⁸ Although rare and seen most often with oral therapy, pseudomembranous colitis can occur with the prolonged use of topical clindamycin.¹⁹ As with any antibacterial agent, the possibility of resistance exists with the use of topical antibiotics. However, coadministration of clindamycin or erythromycin and benzoyl peroxide has shown to decrease the incidence of resistance, as well as to improve symptoms of mild to moderate inflammatory acne.^{7,20}

● **Azelaic Acid** With antibacterial and anti-inflammatory properties, and the ability to stabilize keratinization, azelaic acid is an effective alternative in the treatment of mild to moderate acne in patients who cannot tolerate benzoyl peroxide or topical retinoids.^{3,21} It can also even out skin tone and may prove effective in patients who are prone to postinflammatory hyperpigmentation resulting from acne.²²

● Adverse effects are minimal and transient, with erythema and skin irritation most common.²¹

Azelaic acid 20% cream should be applied twice daily, with improvement of symptoms seen in 1 to 2 months.²¹

● **Dapsone** A sulfone drug, dapsone gel has antimicrobial and anti-inflammatory properties and is approved for patients with mild to moderate acne.^{23,24} The development of topical dapsone marks the first new chemically based agent used in the treatment of acne vulgaris in 10 years.

Table 65-2

Topical Retinoids Available for the Treatment of Acne

Agent	Brand Name	Dosage Form	Dosage	Side Effects
Tretinoin	Retin-A	0.025%, 0.05%, and 0.1% cream	Apply small amount once daily before bedtime	Skin irritation, dryness, photosensitivity, initially may worsen acne
	Retin-A Micro	0.01%, 0.025% gel	Apply small amount once daily before bedtime	
	Atralin	0.05% gel	Apply small amount once daily before bedtime	
	Ziana	0.025% with 1.2% clindamycin gel	Apply small amount once daily before bedtime	
Adapalene	Differin	0.1% cream 0.1% and 0.3% gel 0.1% lotion	Apply small amount once daily before bedtime	Same as tretinoin but may be <i>less</i> severe
	Epiduo	0.1% with 2.5% benzoyl peroxide gel	Apply small amount once daily before bedtime	
	Tazarotene	Tazorac	0.05% and 0.1% cream 0.05% and 0.1% gel	

From Wickersham RM, ed. Drug Facts and Comparisons. St. Louis, MO: Drug Facts and Comparisons; 2011.

The topical gel form appears to be safer, free from the hemolysis, hemolytic anemia, and peripheral neuropathy that can result from orally administered dapsone.²³ Adverse effects are similar to what is seen with other topical acne products and include dryness, erythema, oiliness, and peeling of the skin.²⁴

Dapsone 5% (Aczone) is a gritty gel that should be applied in a thin layer to the affected areas twice daily. If after 12 weeks there is no improvement, treatment with topical dapsone should be reevaluated.²⁴

Keratolytics Sulfur, resorcinol, and salicylic acid are not as effective as other topical agents, but can be used as second-line therapies in the treatment of mild to moderate acne.¹²

Although these agents may cause less skin irritation than benzoyl peroxide or the topical retinoids, several disadvantages exist. Sulfur preparations produce an unpleasant odor when applied to the skin, whereas resorcinol may cause brown scaling. And although rare, the possibility of salicylism exists with continual salicylic acid use.^{3,12}

► Oral Agents

Antibacterials Moderate to severe acne can be effectively treated with oral antibiotics, especially when treatment with topical therapy has failed. Because of their ability to decrease *P. acnes* colonization, oral antibiotics can prevent acne lesions from developing.⁸ Improvement of symptoms is generally evident at 6 to 10 weeks, with maximum benefits occurring after 6 months of therapy.²⁵

Tetracycline, doxycycline, and minocycline are the most commonly prescribed oral antibiotics for acne. Erythromycin and clindamycin are appropriate second-line agents for use when patients cannot tolerate or have developed resistance to tetracycline or its derivatives.³ Other antibiotics, including trimethoprim (± sulfamethoxazole) and azithromycin, are also effective agents to use when patients fail or are unable

to tolerate conventional treatment.⁷ (See [Table 65-3](#) for antibiotic dosing guidelines.)

Adverse effects with the tetracyclines include GI upset; drug interactions with dairy products, antacids, and iron; and phototoxicity. Minocycline can also cause vestibular complications (headache, dizziness) and skin discoloration that is not typical with tetracycline and doxycycline.¹⁶

Although their effectiveness is similar to the tetracyclines, erythromycin and clindamycin use is often limited due to their potential adverse outcomes. Erythromycin has increased resistance to *P. acnes* and a high incidence of GI intolerance, whereas clindamycin causes diarrhea and the risk of developing pseudomembranous colitis with long-term use.^{3,8}

Isotretinoin Isotretinoin is effective in up to 80% of patients with severe nodulocystic acne who are unresponsive to other topical and oral treatment regimens.^{8,25,26} Isotretinoin works on the four pathogenic factors that contribute to acne development and can produce acne remission rates of up to several years.

Adverse effects with the use of isotretinoin are frequent and generally dose-related. About 90% of patients experience drying of the mucosa of the mouth, eyes, and nose.³ Drying, peeling, and pruritus of the facial skin is also likely. Increases in cholesterol and triglyceride levels have been reported with isotretinoin use; therefore, it is recommended to monitor liver function and serum lipids at baseline and at 4 and 8 weeks of therapy to identify any complications. Other serious adverse effects from this medication include increased creatine phosphokinase, increased blood glucose, teratogenicity, photosensitivity, muscle pain, suicidality, and depression.³ [Table 65-4](#) lists the common adverse effects from isotretinoin therapy and management strategies for those symptoms.

Because it is teratogenic and classified as Pregnancy Category X, the FDA mandates an online registry program called iPLEDGE to ensure that females do not become pregnant while taking isotretinoin. Wholesalers, pharmacies,

Table 65-3

Oral Agents Used in the Treatment of Moderate to Severe Acne

Drug	Dosage Form	Strength (mg)	Regimen	Side Effects
Tetracycline	Tablets, capsules	250	500 mg twice daily before meals.	GI upset, phototoxicity, tooth discoloration, drug and food interactions
		500	Maintenance dose: 500 mg daily	
Doxycycline	Tablets, capsules	50	100–200 mg daily before meals.	GI upset, phototoxicity, drug and food interactions
		100	Maintenance dose: 50 mg daily	
Minocycline	Tablets, capsules	50	50 mg twice daily or 100 mg once daily	GI upset, phototoxicity, drug and food interactions, vestibular toxicity, skin discoloration
		75	Maintenance dose: 50 mg daily	
		100		
Erythromycin	Tablets	250	500 mg twice daily with food	GI intolerance, drug interactions
		500	Maintenance dose: 500 mg daily	
Clindamycin	Capsules	75	150–300 mg daily	Diarrhea, pseudomembranous colitis
		150	Maintenance dose: 150 mg daily	
		300		
Isotretinoin	Capsules	10	0.5–1 mg/kg/day in two divided doses	Dry skin and mucous membranes, muscle and joint pain, elevated liver enzymes and triglycerides, depression, teratogenicity
		20	Maximum dose: 2 mg/kg/day	
		40	Cumulative dose: 120–150 mg/day	

From Wickersham RM, ed. Drug Facts and Comparisons. St. Louis, MO: Drug Facts and Comparisons; 2011

Table 65–4

Principle Adverse Effects of Oral Isotretinoin

Adverse Effect	Response
Teratogenicity	Contraindicated during pregnancy
Depression	Patient monitoring and counseling; antidepressants
Dryness	
Mouth	Hard candy
Eyes	Eyedrops; avoid contact lenses if possible during treatment course
Nose	Lubricant
Skin	Nondrying gentle skin cleansers; noncomedolytic moisturizers
Lips	Lip moisturizer with sunscreen
Muscle and joint pain	Nonsteroidal anti-inflammatory drugs
Alopecia	Reversible when drug discontinued or dose decreased
Hypertriglyceridemia	Reversible when drug discontinued or dose decreased
Acne flare at start of therapy	Continue therapy
Photosensitivity	Use sunscreens (moisturizing), protective clothing, and sun avoidance

From West DP, Loyd A, Bauer KA, West LE, Scuderi L, Micali G. Acne vulgaris. In: Dipiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiological Approach*. 7th ed. New York: McGraw-Hill; 2008:1591–1602.

doctors, and patients must be registered in the iPLEDGE computer-based system in order to control the distribution, prescribing, and dispensing of isotretinoin. Two negative pregnancy tests prior to initiating therapy and one negative pregnancy test each month thereafter must be obtained and confirmed in the system before a prescription can be dispensed to female patients of child-bearing potential. These patients must also commit to effective measures of birth control during the course of isotretinoin therapy. Contact the program at their website: <https://www.ipledgeprogram.com/> for further details.

Initial dose ranges for treatment are 0.5 to 1 mg/kg daily in two divided doses, with beneficial results generally reported at total daily doses of 120 to 150 mg/day.³

Oral Contraceptives Oral contraceptives are a valuable second-line treatment option for moderate to severe acne in female patients. Although many contraceptives are effective, three agents (*Yaz*, *Estrostep*, and *Ortho Tri-Cyclen*) have been FDA approved for the treatment of acne.²⁷ Oral contraceptives decrease the production of androgens by the ovaries, which in turn leads to a decrease in sebum production.^{3,16}

Adverse effects include nausea, weight gain, breast tenderness, and breakthrough bleeding. Oral contraceptives have also been associated with an increased incidence of thromboembolic disease, particularly in women who use tobacco products or have other risk factors for thromboembolism. The development of these complications is significantly reduced when low-dose estrogen formulations of oral contraceptives are used.³

Other Agents Although use is infrequent, several other agents are available as second- or third-line treatment options for acne when first-line therapies fail and include the following^{3,7}:

- Corticosteroids
- Chemical peels
- Surgical extraction
- Phototherapy/photodynamic therapy
- Laser treatments

Figure 65–3 shows useful algorithms for the effective treatment of the various stages of acne.

OUTCOME EVALUATION

Depending on severity, complete resolution of acne may take weeks to months. Monitor patients after 6 weeks of pharmacologic therapy for any improvement of signs and symptoms¹²:

- Decreased number of lesions
- Decreased severity of lesions
- Relief of pain/irritation

If no improvement is reported or symptoms have worsened, patients should be reevaluated and a change in the current treatment regimen may be necessary.

Educate patients on the possibility of adverse effects. Consider a change in therapy if a patient experiences effects that are not tolerated or are considered a compromise to their health.

Patient Care and Monitoring: Acne

1. Assess patient symptoms and the presence of acne lesions. Determine severity of acne: mild, moderate, or severe.
2. Review patient history to determine treatment regimens that have been used in the past, including nonprescription, prescription, and herbal medications.
3. Obtain patient's allergy status.
4. Develop a treatment plan appropriate for improvement of acne.
5. Discuss any monitoring parameters that may be necessary throughout the course of therapy.
6. Provide patient education on acne and its treatment:
 - a. What is acne and how does it develop?
 - b. Physical and psychological complications that can result from acne.
 - c. What drug and nondrug therapies are available for treatment?
 - d. Describe the possible side effects of drug therapy.
 - e. Emphasize the importance of treatment regimen compliance to ensure positive results.

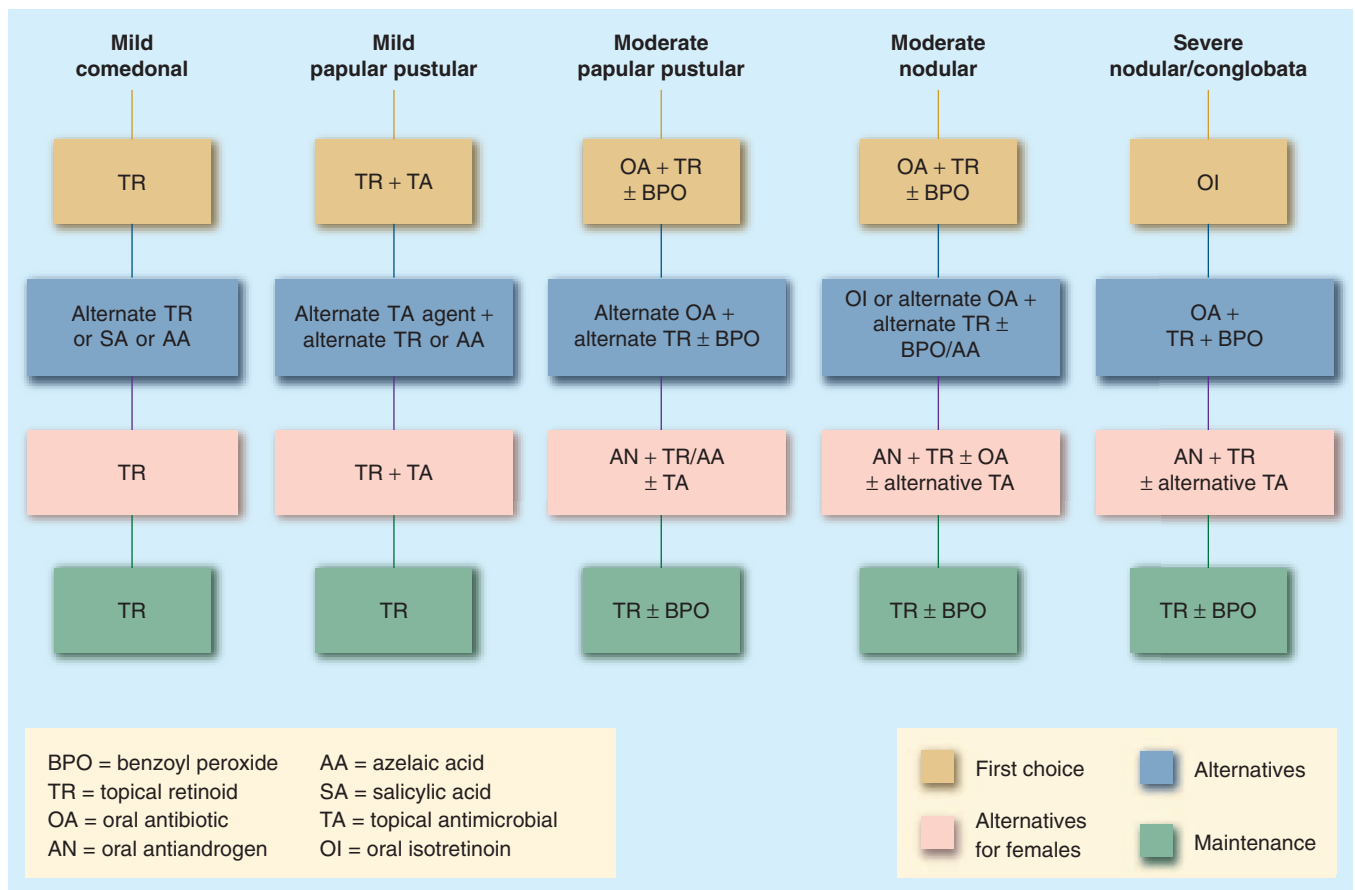

FIGURE 65-3. Algorithms for acne treatment. (From West DP, Loyd A, Bauer KA, West LE, Scuderi L, Micali G. Acne vulgaris. In: Dippiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiological Approach. 7th ed. New York: McGraw-Hill; 2008:1591–1602.)

Patient Encounter 1

A 16-year-old adolescent boy presents to your pharmacy with complaints of worsening acne. Upon visual examination, numerous papules, pustules, and nodules are noted on his forehead, cheeks, and chin. It is also apparent that previous breakouts have caused some scarring on his cheeks. After interviewing the patient, you conclude that his acne lesions are extremely painful. He states that he uses various over-the-counter acne washes and topical creams multiple times a day but has seen minimal improvement. He also states that he recalls being prescribed an oral antibiotic for about 3 months when he was 14 years old, but has not seen a physician since. The patient has no other medical complaints and appears to be in good physical health.

What reported symptoms support the diagnosis of acne?

What other information would you obtain from this patient before creating a treatment plan for him?

What professional recommendation would you give to this patient in regard to the current severity of his acne?

Describe your treatment goals for this patient.

What pharmacologic treatment options are available for this patient?

Given the information presented, develop a treatment regimen for this patient that includes the following:

- A statement of the problem*
- A patient-specific therapeutic plan*
- Monitoring parameters to assess efficacy and safety*

CONTACT DERMATITIS

- Contact dermatitis is a condition in which exposure to an offending substance produces inflammation, erythema, and pruritus of the skin.²⁸ More specifically, contact dermatitis can be divided into either irritant or allergic forms.^{28,29} **4**
- *Irritant contact dermatitis results from first-time exposure to irritating substances such as soaps, plants, cleaning solutions, or solvents. Allergic contact dermatitis occurs after an initial sensitivity and further exposure to allergenic substances, including poison ivy, latex, and certain types of metal.*³⁰ (Figs. 65-4 and 65-5.) **Table 65-5** lists agents commonly responsible for irritant and allergic contact dermatitis. Although generally occurring on the exposed skin, such as the hands and face, contact dermatitis can appear anywhere on the body.²⁸ Although most cases are easily treated, contact dermatitis remains an uncomfortable and sometimes embarrassing skin condition.

EPIDEMIOLOGY AND ETIOLOGY

Contact dermatitis is a common reason for dermatology referrals and constitutes up to 90% of all workers' compensation claims for dermatologic conditions. Although most often seen in adults, contact dermatitis can affect all age groups, with females at slightly greater risk than males.³¹

FIGURE 65-4. Acute irritant contact dermatitis on the hand due to an industrial solvent. There is massive blistering on the palm. (From Wolff K, Johnson RA. Eczema/dermatitis. Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology. 6th ed. New York: McGraw-Hill; 2009: 23.)

FIGURE 65-5. Allergic contact dermatitis of the hand: chromates. Confluent papules, vesicles, erosions, and crusts on the dorsum of the left hand in a construction worker who was allergic to chromates. (From Wolff K, Johnson RA. Eczema/dermatitis. Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology. 6th ed. New York: McGraw-Hill; 2009: 27.)

Table 65-5

Common Agents Causing Contact Dermatitis

Irritant Contact Dermatitis

Soaps
Detergents
Cosmetics
Solvents
Acid, mild or strong
Alkali, mild or strong

Allergic Contact Dermatitis

Plant resins, poison ivy, poison oak, sumac
Metals (nickel or gold in jewelry)
Latex and rubber
Cigarette smoke
Local anesthetics (lidocaine, benzocaine)

PATHOPHYSIOLOGY

- *Irritant* contact dermatitis is not the result of an immunologic process, but rather occurs from direct injury to the skin. An irritating agent comes into contact with the skin, damages the protective layers of the epidermis, and can cause erythema, the formation of vesicles and pruritus.^{28,32,33} Symptoms occur within minutes to hours of exposure and begin to heal soon after removal of the offending substance.³⁰

Clinical Presentation and Diagnosis of Contact Dermatitis

Contact dermatitis is generally confined to the area of contact, but in a highly sensitive person, a widespread or even generalized eruption may occur. Contact dermatitis is divided into two forms—irritant and allergic. Both forms may include, but are not limited to:

- Erythema
- Pruritus
- Vesicles
- Papules
- Crusts
- Burning

Irritant Form

The irritant form usually presents within hours of exposure and the rash is often localized. Irritant contact dermatitis may also result in fissuring and scaling.

Allergic Form

The allergic form can take several days to present and the condition may extend beyond the borders of the region exposed. Allergic contact dermatitis may also include oozing pustules and skin erosion.

Diagnosis

When the causative agent is known, the diagnosis of contact dermatitis is clinical. Patch testing is done if the allergens are unknown and is usually performed several weeks after the resolution of the original dermatitis.

• *Allergic contact dermatitis is a delayed hypersensitivity reaction.³¹ Upon initial exposure, a substance penetrates the skin, binds to a protein, and develops into sensitizing antigens. Subsequent exposures to that substance will then elicit an allergic reaction.^{28,32,33} Symptoms of allergic contact dermatitis are similar to those of the irritant type, but may take several hours to several days to develop following reexposure.^{28,29}*

TREATMENT

Desired Outcomes and Goals

• **5** *Identifying the causative substance and eliminating its exposure is the initial treatment goal for contact dermatitis. Although physical symptoms can develop almost immediately after contact, removal of the offending agent will improve existing symptoms and prevent the occurrence of further complications.* **5** *The second treatment goal is symptom relief. Since inflammation and pruritus, as well as lesion formation, are likely to result from contact dermatitis, appropriate selection of nonpharmacologic and pharmacologic agents for these symptoms is necessary.*

Nonpharmacologic Therapy

In many cases, contact dermatitis may not require medical treatment at all. Nondrug therapy for contact dermatitis is aimed at relieving pruritus and maintaining skin hydration.³⁰

- Effective agents used for this include the following^{28,30}:
 - Colloidal oatmeal baths
 - Cool or tepid soapless showers
 - Cool, moist compresses applied to the area for 30 minutes three times a day
 - Emollients or lubricants applied to the area after bathing (mineral oil, petrolatum)

Pharmacologic Therapy

► Astringents

The drying effect of **astringents** will decrease oozing from lesions and relieve itching.^{28,29} Due to their ability to cause blood vessel constriction, astringents can also decrease inflammation.

- Aluminum acetate (Burow's solution), calamine, and witch hazel are safe and effective.²⁸ Patients apply solutions as a compress for 15 to 30 minutes two to four times a day.
- Adverse effects reported with these agents are minimal and include drying and tightening of the skin. Because of this, their use should be limited to no more than 7 days.^{28,29,31}

► Topical Steroids

- Erythema, inflammation, pain, and itching caused by contact dermatitis can be effectively treated with topically applied corticosteroids. With such a wide range of products and potencies, an appropriate steroid selection is based on severity and location of lesions (see **Table 65–6** for a list of topical steroids and potencies.) Higher potency preparations are used in areas where penetration is poor, such as the elbows and knees. Lower potency products should be reserved for areas of higher penetration, such as the face, axillae, and groin. Low-potency steroids are also recommended for the treatment of infants and children.^{35,36}

Adverse effects from topical steroids are usually related to the potency of the steroid, frequency of application, duration of therapy, and the site of application. Skin atrophy, hypopigmentation, striae, and steroid-induced acne are all possible side effects associated with long-term use.³⁵

Topical steroids are typically applied two to four times daily. As improvement begins, maintenance therapy should be limited to the lowest strength steroid that continues to control the condition. Once symptoms are completely resolved, use should be discontinued.

► Antihistamines

- Whether due to their antihistaminic activity or their sedative side effects, pruritus caused by contact dermatitis can be relieved with the use of sedating oral antihistamines such as diphenhydramine or hydroxyzine. Topical antihistamines are available, but use is limited due to their high-sensitizing potential.^{28,35}

Table 65-6

Topical Steroids to Treat Contact Dermatitis

Corticosteroids	Dosage Forms	Strength (%)	USP Potency Ratings ^a	Vasoconstrictive Potency Rating ^b
Alclometasone dipropionate	Cream	0.05	Low	VI
	Ointment	0.05	Low	V
Amcinonide	Lotion, ointment	0.1	High	II
	Cream	0.1	High	III
Beclomethasone dipropionate	Cream, lotion, ointment	0.025	Medium	—
Betamethasone benzoate	Cream, gel	0.025	Medium	III
	Ointment	0.025	Medium	IV
Betamethasone dipropionate	Cream AF (optimized vehicle)	0.05	Very high	I
	Cream	0.05	High	III
	Gel, lotion, ointment (optimized vehicle)	0.05	Very high	I
	Lotion	0.05	High	V
	Ointment	0.05	High	II
	Topical aerosol	0.1	High	—
	Cream	0.01, 0.05, 0.1	Medium	V
Betamethasone valerate	Lotion, ointment	0.05, 0.1	Medium	III
	Foam	0.12	Medium	IV
	Cream, ointment, solution, foam	0.05	Very high	I
Clobetasol propionate	Cream, ointment	0.05	Medium	—
Clobetasol butyrate	Cream, ointment	0.05	Medium	—
Clocortolone pivalate	Cream	0.1	Low	—
Desonide	Cream, lotion, ointment	0.05	Low	VI
Desoximetasone	Cream	0.05	Medium	II
	Cream, ointment	0.25	High	II
	Gel	0.05	High	II
	Gel	0.1	Low	VII
Dexamethasone	Topical aerosol	0.01, 0.04	Low	VII
	Cream	0.1	Low	VII
Dexamethasone sodium phosphate	Cream	0.1	Low	VII
Diflorasone diacetate	Cream	0.05	High	III
	Ointment	0.05	High	II
	Ointment (optimized vehicle)	0.05	Very high	II
Diflucortolone valerate	Cream, ointment	0.1	Medium	—
Flumethasone pivalate	Cream, ointment	0.03	Low	—
Fluocinolone acetonide	Cream	0.01	Medium	VI
	Cream	0.025	Medium	V
	Cream	0.2	High	—
	Ointment	0.025	Medium	IV
	Solution	0.01	Medium	VI
	Gel, cream, ointment	0.05	High	II
Fluocinonide	Solution	0.05	High	II
	Solution	0.05	High	II
Flurandrenolide	Cream, ointment	0.0125	Low	—
	Ointment	0.05	Medium	IV
	Cream, lotion	0.05	Medium	V
	Tape	4 mcg/cm ²	Medium	I
Fluticasone propionate	Cream	0.05	Medium	IV
	Ointment	0.05	Medium	III
Halcinonide	Cream	0.025, 0.1	High	II
	Ointment	0.1	High	III
	Solution	0.1	High	—
Halobetasol propionate	Cream, ointment	0.05	Very high	I
Hydrocortisone	Cream, lotion, ointment	All strengths	Low	VII
Hydrocortisone acetate	Cream, lotion, ointment	All strengths	Low	VII
Hydrocortisone butyrate	Cream	0.1	Medium	V
	Ointment	0.1	Medium	—
Hydrocortisone valerate	Cream	0.2	Medium	V
	Ointment	0.2	Medium	IV
Methylprednisolone acetate	Cream, ointment	0.25	Low	VII
	Ointment	1	Low	VII
Mometasone furoate	Cream	0.1	Medium	IV
	Lotion, ointment	0.1	Medium	II

(Continued)

Table 65-6

Topical Steroids to Treat Contact Dermatitis (Continued)

Corticosteroids	Dosage Forms	Strength (%)	USP Potency Ratings ^a	Vasoconstrictive Potency Rating ^b
Triamcinolone acetonide	Cream, ointment	0.1	Medium	IV
	Cream, lotion, ointment	0.025	Medium	—
	Cream (Aristocort)	0.1	Medium	VI
	Cream (Kenalog)	0.1	High	IV
	Lotion	0.1	Medium	V
	Ointment (Aristocort, Kenalog)	0.1	High	III
	Cream, ointment	0.5	High	III
	Topical aerosol	0.015	Medium	—

^aUSP ratings are low, medium, high, and very high.

^bVasoconstriction potency scale is I (highest) to VII (lowest)—denotes unknown vasoconstrictive properties.

From West DP, Loyd A, West LE, Bauer KA, Musumeci ML, Micali G. Psoriasis. In: Dipiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiological Approach. 7th ed. New York: McGraw-Hill; 2008:1603–1617.

In addition to sedation, many oral antihistamines can cause hypotension, dizziness, blurred vision, and confusion.³¹

Diphenhydramine and hydroxyzine can be safely administered to children older than 2 years and adults. Table 65-7 outlines the recommended doses for these medications.

OUTCOME EVALUATION

With adequate treatment, most cases of contact dermatitis should improve within 7 days. Complete resolution of

symptoms may take up to 3 weeks.²⁸ If a patient experiences severe symptoms associated with fever or difficulty breathing, they should be instructed to seek medical attention immediately. Furthermore, patients should return to their healthcare provider if any of the following occur:

- Rash has not improved or has worsened after several days of treatment
- Rash has increased in size or has spread to other locations
- Patient is experiencing adverse effects from the treatment regimen

Table 65-7

Oral Antihistamines Used for Pruritus

Drug	Pediatric Dosage	Adult Dosage
Diphenhydramine (Benadryl)	Not recommended for use in infants or neonates Less than 6 years old: 6.25–12.5 mg every 4–6 hours as needed 6–12 years old: 12.5–25 mg every 4–6 hours as needed	25–50 mg every 6–8 hours as needed
Hydroxyzine (Atarax)	0.6 mg/kg/dose every 6 hours as needed	25 mg every 6–8 hours as needed

From Wickersham RM, ed. Drug Facts and Comparisons. St. Louis, MO: Drug Facts and Comparisons; 2011.

Patient Care and Monitoring of Contact Dermatitis

1. Assess the patient's symptoms. Determine which form of contact dermatitis is present—irritant or allergic?
2. Obtain a thorough patient history. Has there been prior exposure to this agent? If so, what treatment regimens were used in the past to alleviate symptoms?
3. Obtain patient's allergy status.
4. Develop a treatment plan appropriate for contact dermatitis.
5. Discuss testing that may need to be performed to suggest or confirm the etiologic agent (patch testing).
6. Provide patient education on contact dermatitis and treatment:
 - a. What is contact dermatitis and how does it develop?
 - b. List various types of contact dermatitis.
 - c. What drug therapies are available for treatment?
 - d. What are the possible adverse effects of drug therapy?
 - e. What are the symptoms that warrant physician referral?
 - f. Explain the importance of treatment compliance.
 - g. Educate on the recognition of agents that may cause contact dermatitis.

Patient Encounter 2

A 38-year-old woman presents to your clinic with complaints of a new-onset rash on the inside of both arms and wrists that is red, itching, and stinging. Upon visual examination you see that she has localized erythematous areas on the inner sides of both arms. You also note that there are small vesicles located within the affected area. After further questioning, you learn that she noticed the rash earlier that day at a medical office building where she works in the housekeeping department. She states that she uses various chemicals and cleaners at her work and thinks she may have come in to contact with bleach or “something” while she was cleaning today. The rash appeared approximately 6 hours ago, and the patient says that it has not spread since it first developed. From the information she has presented, you conclude that she came in contact with an agent at work that caused an irritant contact dermatitis to develop.

What information supports the possibility of exposure to an irritating agent?

Describe the symptoms that support this diagnosis.

Determine what the patient has tried to relieve her symptoms.

Describe the differences between allergic and irritant contact dermatitis.

What are your treatment goals for this patient?

What nonpharmacologic and pharmacologic treatment options are available for this diagnosis?

Given the information presented, develop a treatment regimen for this patient that includes the following:

(a) A statement of the problem

(b) A patient-specific therapeutic plan

(c) Monitoring parameters to assess efficacy and safety

DIAPER DERMATITIS

EPIDEMIOLOGY AND ETIOLOGY

Diaper dermatitis, more commonly known as diaper rash, is a form of irritant contact dermatitis that affects the buttocks, upper thighs, lower abdomen, and genitalia of an estimated 7% to 35% of all infants.^{37,38} Onset of occurrence is usually between 3 weeks and 2 years of age, with the most cases reported between 9 and 12 months of age.³⁹ The rise in the number of adults who use diapers for incontinence also increases the risk of developing diaper dermatitis.³⁷

PATHOPHYSIOLOGY

- **6** Although many factors contribute to the etiology of diaper rash, it is most likely the result of prolonged contact of the skin with urine and feces in the diaper. If a diaper is not changed soon after urination or defecation, the protective layer of the skin can break down and make the area more susceptible to irritation and infection from the contents of the diaper.⁴⁰
- Although most mild cases of diaper rash present as erythema, moderate to severe cases can result in the formation of papules, vesicles, and even ulceration. If these cases are not effectively treated, the likelihood of secondary fungal or bacterial infections developing is greatly increased.³⁷

Clinical Presentation and Diagnosis of Diaper Dermatitis

Typical Symptoms

- Erythema is the most common symptom presented with a diaper rash. The rash may begin as light to medium pink with poorly defined edges, but when further developed may become dark red and raised lesions with distinct edges.
- Rashes generally appear in the folds of the skin around the diaper area, thighs, genitals, and buttocks.
- Other typical symptoms include irritation and pruritus.

Atypical Symptoms

Patients presenting with the following symptoms may indicate the need for more aggressive antibiotic or antifungal therapy and should be referred to a primary care physician for further evaluation:

- Rashes not responding to typical creams and concurrent nonpharmacologic treatment

- Rashes extending beyond the diaper region (upper abdomen, back)
- Formation of papules, bullae, ulceration
- Excessive oozing
- Presence of genital discharge
- Concurrent fever
- Rashes appearing when diapers have not been used or rashes that fail to improve upon discontinuing diaper usage for extended periods of time (several days or more)
- Bleeding or open skin

Diagnosis

The diagnosis of diaper dermatitis is clinical. The presence of *Candida albicans* can be determined by KOH testing or culture, but is generally not necessary.

TREATMENT

Desired Outcomes and Goals

- 7 The primary goal in the treatment of diaper rash is prevention and is most often accomplished through frequent diaper changes. 8 When a diaper rash is already present, repairing the damaged skin, relieving discomfort, and preventing secondary infections from occurring are important factors to consider when developing an effective treatment regimen.⁴⁰

Nonpharmacologic Therapy

- Most mild cases of diaper rash can be resolved with the use of nonpharmacologic therapies. Keeping the diaper area clean and dry by changing diapers as soon as practically possible is highly effective for treatment and prevention.^{37,38} Other nondrug options include^{29,37}:

- Washing the area with lukewarm water and mild soap and allowing to completely dry before applying a new diaper
- Keeping diapers loose and well ventilated
- Avoiding plastic pants over diapers
- Allowing infants to take naps on an open diaper or absorbent pad to promote drying and healing

Pharmacologic Therapy

► Protectants

- Protectants form an occlusive barrier between the skin and moisture from the diaper. Cream and ointment preparations are effective in providing a sufficient barrier in mild, irritant, and noninfected diaper rashes. For more severe cases, a paste is the topical agent of choice. Pastes are thicker and often contain additional ingredients (petrolatum, moisturizers) to help decrease discomfort and promote healing.³⁹ Zinc oxide is one of the most commonly used topical protectants. In addition to forming an effective barrier against moisture, it has astringent and antiseptic properties that provide added symptom relief.³⁷

- Protectants are generally applied to the affected area after every diaper change and can be discontinued when the rash resolves. Other available protectants that can be used alone or in combination for the safe and effective treatment of diaper rash include white petrolatum, Vitamins A and D, lanolin, and topical cornstarch. Many agents contain a combination of occlusive and protective agents such as Triple Paste and Calmoseptine.

► Topical Steroids

- Because of the increased permeability of their skin, infants are at risk for excessive absorption and toxicity from the use of topical steroids. Although these agents are effective in decreasing inflammation and relieving pruritus, steroid use in infants for the treatment of diaper dermatitis should be limited to only the low-potency preparations.⁴¹
- A thin layer of hydrocortisone cream (0.25% to 1%) applied twice a day for no more than 2 weeks is an appropriate treatment regimen. The use of higher potency steroids or use

extending beyond 2 weeks should be at the discretion of a physician only.

► Antifungals

- Diaper rashes lasting longer than 48 to 72 hours are at increased risk for the development of fungal infections. These complications are most frequently caused by *Candida albicans* and will require treatment with a topical antifungal.^{38,39} (Fig. 65–6.)

FIGURE 65–6. Candidiasis: diaper dermatitis. Confluent erosions, marginal scaling, and “satellite pustules” in the area covered by a diaper in an infant. (From Wolff K, Johnson RA. Cutaneous fungal infections. Fitzpatrick’s Color Atlas & Synopsis of Clinical Dermatology. 5th ed. New York: McGraw-Hill; 2009: 723.)

- Adverse events with the use of topical antifungals are generally limited to local irritation at the site of application. Nystatin, clotrimazole, and miconazole creams or ointments applied two to four times daily with diaper changes have all shown to be effective in the treatment of candidal diaper rash. Although some of these products are available over the counter, parents and caregivers should be advised to initiate treatment with antifungal agents only after physician recommendation.

► Antibacterials

- If conventional treatment fails, unresolved diaper rash can also lead to secondary bacterial infections. *Staphylococcus aureus* and *Streptococcus* are the most likely pathogens responsible for these infections and require treatment with systemic antibiotics.^{39,40} While topical protectants may be used as an adjunct in treatment, suspected bacterial infections should always be referred to a physician for accurate diagnosis and the selection of an appropriate antibacterial regimen.³⁷ Figure 65–7 shows a useful algorithm for the effective treatment of diaper dermatitis.

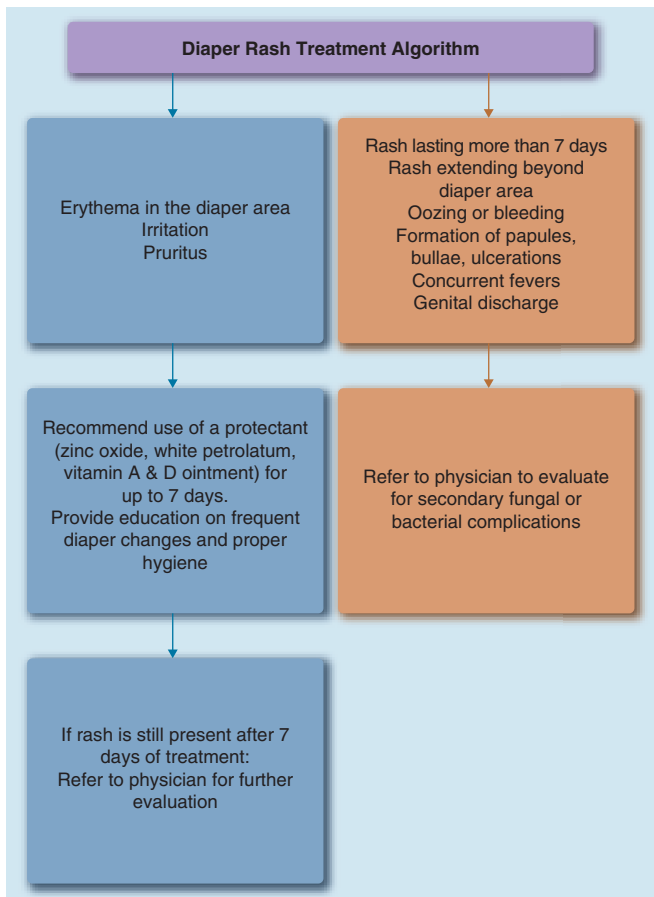

FIGURE 65-7. Diaper dermatitis treatment algorithm.

OUTCOME EVALUATION

- Most diaper rashes can be effectively treated in less than 1 week. If symptoms do not resolve or begin to worsen, advise caregivers to seek medical attention to determine the presence

Patient Encounter 3

A woman presents to a community pharmacy inquiring about a product to purchase for her 3-month-old son who recently developed a rash in his diaper area. She says the rash is bright red and seems to fluctuate in severity from diaper change to diaper change. After further questioning, it is determined that the rash has lasted about 4 to 5 days and seems to be painful for her son when she cleans him with diaper wipes during changing. She has tried using white petrolatum a few times and is now concerned about the rash becoming infected.

What reported symptoms support the diagnosis of diaper rash?

Elicit additional information to aid in your assessment of this patient.

What are your treatment goals for this patient?

What nonpharmacologic and pharmacologic treatment options are available for this diagnosis?

Given the information presented, develop a treatment regimen for this patient that includes the following:

- A statement of the problem*
- A patient-specific therapeutic plan*
- Monitoring parameters to assess efficacy and safety*

of secondary fungal or bacterial infections. In addition, provide educational information on proper diaper hygiene techniques in order to prevent the development of future diaper rashes.

Patient Care and Monitoring: Diaper Dermatitis

- Assess rash symptoms. Determine the level of severity—is there a possibility of a secondary fungal or bacterial infection?
- Identify signs and symptoms that require immediate physician referral.
- Inquire about the patient's history, including any similar rashes in the past.
- Educate the caregiver on the importance of frequent diaper changes and proper hygiene.
- Obtain patient allergy status.
- Discuss labs that may be necessary if a secondary infection is suspected (cultures, biopsies).
- Develop a treatment regimen for the patient, including a plan for assessing improvement of the condition.
- Provide patient education about diaper rash etiology, treatment, and prevention:
 - What is diaper rash and how does it develop? What exacerbates diaper rash?
 - Symptoms to report to a physician (blistering, oozing, bleeding, changes in rash, or no improvement in symptoms within 2 to 3 days)
 - Available treatment options, including proper usage instructions and potential side effects
 - Importance of treatment compliance
 - Prevention measures

Anemia

Robert K. Sylvester

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Identify common causes of anemia.
2. Describe common signs and symptoms of anemia.
3. Describe diagnostic evaluation required to determine the etiology of anemia.
4. Recommend a treatment regimen for anemia considering the underlying cause and patient-specific variables.
5. Compare and contrast commonly prescribed oral and parenteral iron preparations.
6. Explain the optimal use of folic acid and vitamin B₁₂ in patients with macrocytic anemia.
7. Evaluate the proper use of epoetin and darbepoetin in anemia patients with cancer chemotherapy associated or chronic kidney disease.
8. Develop a plan to monitor the outcomes of anemia pharmacotherapy.

KEY CONCEPTS

- 1 Anemia is a below-normal concentration of hemoglobin (Hgb) that results in a reduction of the oxygen-carrying capacity of the blood.
- 2 Common signs and symptoms of anemia include fatigue, lethargy, dizziness, shortness of breath, headache, edema, and tachycardia.
- 3 A complete blood count (CBC) is the laboratory evaluation that provides objective characteristics of red blood cells (RBCs) useful in determining etiology and appropriate treatment.
- 4 The goal of anemia therapy is to increase Hgb concentrations to levels that improve RBC oxygen-carrying capacity, alleviate symptoms, and prevent anemia complications.
- 5 The underlying cause of anemia (e.g., iron, folic acid, or B₁₂ deficiency; blood loss; or chronic disease) must be determined and used to guide therapy.
- 6 In patients with iron-deficiency anemia (IDA), appropriate oral iron therapy should be attempted before giving parenteral iron.
- 7 Anemia from vitamin B₁₂ or folic acid deficiency is effectively treated by administration of the deficient nutrient.

- 8 In patients with anemia related to cancer chemotherapy or chronic kidney disease (CKD), administration of erythropoietin-stimulating agents (ESAs) can increase Hgb and decrease transfusion requirements.
- 9 ESAs have significant safety risks that require careful monitoring. Use the lowest dose of epoetin alfa and darbepoetin alfa to avoid RBC transfusions.
- 10 At appropriate intervals, patients should be monitored for Hgb response, symptom resolution, and adverse effects and treatment regimens adjusted accordingly.

INTRODUCTION

- 1 **Anemia** is a reduction in the concentration of hemoglobin (Hgb) that results in reduced oxygen-carrying capacity of the blood. Some patients with anemia may be asymptomatic initially, but eventually, the lack of oxygen to tissues results in fatigue, lethargy, shortness of breath, headache, edema, and tachycardia. Common causes of anemia include blood loss, decreased red blood cell (RBC) production, increased RBC destruction, or a combination of these events. Determination of the underlying cause of anemia is essential for successful management. Appropriate treatment of anemia will result in an increase in Hgb, with a corresponding increase in oxygen-carrying capacity and reduction in symptoms.

Table 66-1

Prevalence of Anemia^{1,2}

Children (1–16 years)	6–9%
Males (16–69 years)	2%
Males (85+ years)	26%
Females (16–19 years)	16%
Females (20–49 years, nonpregnant)	12%
White, non-Hispanic	10%
Black, non-Hispanic	19%
Mexican American	22%
Females (85+ years)	20.1%

EPIDEMIOLOGY AND ETIOLOGY

Anemia is a common diagnosis with a prevalence that varies widely based on age, gender, and race/ethnicity (see [Table 66-1](#)).^{1,2} Patients with specific comorbidities such as cancer and chronic kidney disease (CKD) have significantly higher rates of anemia. The incidence of anemia in cancer patients ranges from 30% to 90%.³ Contributing factors include the underlying malignancy and myelosuppressive antineoplastic therapy.⁴ The prevalence of anemia in patients with CKD ranges from 15% to 20% in patients with CKD stages 1 through 3 and up to 70% in patients with stage 5.⁵

Causes of anemia can be divided into three main categories: decreased production, increased destruction, and blood loss. Drug therapy is the mainstay of treatment for anemias caused by reduced production of erythrocytes and is the focus of this chapter; anemia due to destruction of erythrocytes will not be discussed.

A decrease in erythrocyte production can be multifactorial. Nutritional deficiencies (iron, vitamin B₁₂, and folic acid) are common causes and often easily treatable. Patients with cancer or CKD are at risk for developing anemia caused by dysregulation of iron and erythropoietin (EPO) hemostasis. Patients with chronic immune-related diseases such as rheumatoid arthritis and systemic lupus erythematosus are also at increased risk to develop anemia as a complication of their disease. Anemia related to these chronic inflammatory conditions is termed *anemia of chronic disease* (ACD).⁶

PATHOPHYSIOLOGY

Erythropoiesis

Erythropoiesis is a process that begins with a pluripotent stem cell in the bone marrow undergoing differentiation and ends with the appearance of erythrocytes (RBCs) in peripheral blood. The production of RBCs is stimulated by EPO, a hormone that is secreted by the kidney in response to detection of decreased oxygen-carrying capacity of blood. EPO stimulates RBC production by stimulating differentiation of RBC precursors in the bone marrow to become **reticulocytes** ([Fig. 66-1](#)). Reticulocytes become erythrocytes after 1 to 2 days in the bloodstream.⁷

FIGURE 66-1. The process of erythropoiesis.

Decreased-Production Anemias

▶ Nutritional Deficiencies

- Deficiencies in nutrients such as folic acid and vitamin B₁₂ may hinder the process of erythrocyte maturation. Folic acid and vitamin B₁₂ are required for the formation of DNA. Significant decreases in the amount of these nutrients inhibits DNA synthesis and consequently RBC production.^{7,8} Poor diet can contribute to folic acid and vitamin B₁₂ deficiencies. Patients with pernicious anemia are unable to absorb B₁₂ due to inadequate production of intrinsic factor, a glycoprotein produced by gastric parietal cells that binds to vitamin B₁₂ and facilitates its absorption in the ileum. This condition results in B₁₂ deficiency despite adequate dietary B₁₂ intake.⁹
- Iron is another nutrient essential for production of RBCs. It is required for formation of Hgb. Lack of iron leads to a decrease in Hgb synthesis and decreased RBC production. Normal homeostasis of iron transport and metabolism is depicted in [Figure 66-2](#).¹⁰ Approximately 1 to 2 mg of iron is absorbed through the duodenum each day, and the same amount is lost via blood loss, desquamation of mucosal cells, or menstruation.

Iron-deficiency anemia (IDA) typically occurs because of inadequate absorption of iron or excessive blood loss. Inadequate absorption may occur in patients who have congenital or acquired intestinal conditions, such

FIGURE 66-2. The distribution of iron use in adults. (From Andrews NC. Disorders of iron metabolism. *N Engl J Med* 1999;341:1986–1995.)

as inflammatory bowel disease, celiac disease, or bowel resection. **Achlorhydria** and diets poor in iron also may contribute to iron deficiency states. Iron deficiency also may occur in patients following excessive rates of iron loss from the body. Common etiologies include excessive menstruation, ulcers or neoplastic lesions in the gastrointestinal tract, and excessive bleeding following surgery or trauma.¹⁰

► **Dysregulation of Iron Homeostasis and Impaired Marrow Production**

Chronic diseases associated with ACD include infection, autoimmune disease, CKD, and cancer. A major contributing factor for development of ACD is disturbance of iron homeostasis related to activation of the immune system. Hepcidin is an acute-phase protein expressed in response to upregulation of interleukin-6 and exposure to lipopolysaccharide. Increased expression of hepcidin causes decreased iron absorption from the gastrointestinal tract and inhibition of iron release from macrophages. In addition, immune activation can cause upregulation of cytokines (interferons, interleukin-1, tumor necrosis factor- α) known to impair the proliferation and differentiation of erythroid precursors. Decreased production and blunted responsiveness to EPO can also contribute to ACD; this is best documented in patients with CKD. Finally, disruption of erythropoiesis secondary to infiltration of the bone marrow by cancer can significantly contribute to anemia in patients with cancer.^{4–6}

Clinical Presentation and Diagnosis of Anemia

Signs and Symptoms

2 Generally, the signs and symptoms of anemia are nonspecific and *may include* the following:

- Fatigue, lethargy, dizziness
- Shortness of breath
- Headache
- Edema
- Tachycardia

Other findings that may be present in some patients include:

- Dry skin, chapped lips
- Nail brittleness
- Hunger for ice, starch, or clay (termed pica)

Past Medical History

Inquire about the following conditions:

- History of blood loss, such as hemorrhoids, melena, or menorrhagia (IDA)
- Malnourished or recent weight loss (vitamin B₁₂ or folate deficiency)
- Alcoholism (folate deficiency)
- Cancer or chronic kidney disease (CKD)
- Chronic autoimmune disorders or infections, such as HIV infection or rheumatoid arthritis (anemia of chronic disease)

Physical Examination

These findings aid the clinician in determining the severity of the anemia:

- Orthostatic hypotension and tachycardia secondary to volume depletion
- Cutaneous changes such as pallor, jaundice, and nail brittleness

Laboratory Evaluation

Table 66-2 describes common tests used to determine the etiology of anemia. A diagnostic and treatment algorithm for anemia is outlined in **Figure 66-3**.

1. 3 A CBC is a necessary first step in evaluating a patient with anemia. If the Hgb and Hct are less than the normal range, the patient is anemic. *Subsequent evaluations of RBC indices and the peripheral smear often are necessary to determine the etiology (and ultimately, the treatment) of the anemia.*
2. Evaluating the mean corpuscular volume (MCV) is the next step in an anemia workup. It is classified as microcytic, normocytic, or macrocytic if the MCV is below, within, or above the normal range of 80 to 96 fL/cell, respectively.

(Continued)

Clinical Presentation and Diagnosis of Anemia (Continued)

Microcytic Anemia and Iron Evaluation

Iron studies (see Table 66–2) should be evaluated in the setting of a low MCV. These include:

- Serum iron
- **Serum ferritin**—the best indirect determinant of body iron stores. It is commonly decreased in patients with IDA
- Total iron-binding capacity (TIBC)—quantifies the iron-binding capacity of transferrin and is increased in IDA
- **Transferrin saturation** (serum iron/TIBC)—indicates the amount of transferrin that is bound with iron; it is lower in IDA

Macrocytic Anemia

- Evaluate folic acid and vitamin B₁₂ levels in the setting of an elevated MCV
- Further investigation by administering radiolabeled B₁₂ (i.e., Schilling test) to determine if lack of intrinsic factor
- Consider obtaining homocysteine and methylmalonic acid levels

Normocytic Anemia

- Evaluate reticulocytes and CBC
- High reticulocyte counts may indicate RBCs loss via acute blood loss, hemolysis, or splenic sequestration
- Low reticulocyte counts may indicate a diseased bone marrow (e.g., aplastic anemia, myelodysplasia, or leukemia)

Patient Encounter 1, Part 1

A 24-year-old Mexican mother returns for an appointment with her primary healthcare provider for a 1-week postpartum visit. She has two healthy children (aged 2 years and 4 years); past medical history is negative. She has experienced several episodes of dizziness and shortness of breath after walking up stairs. She states her postpartum bleeding seemed to last a few days longer than previous deliveries.

What aspects of this patient's history suggest she may be anemic?

What laboratory assessments are required to make an appropriate diagnosis and therapeutic plan?

How would the requested laboratory parameter(s) aid your decision making?

TREATMENT

Desired Outcomes

- **4** *The goal of anemia therapy is to increase Hgb to levels that improve red cell oxygen-carrying capacity, alleviate symptoms, and prevent complication from anemia.* Normal Hgb values are 14.0 to 17.5 g/dL (140 to 175 g/L or 8.69 to 10.9 mmol/L) for males and 12.3 to 15.3 g/dL (123 to 153 g/L or 7.63 to 9.50 mmol/L) for females. It is important to note that continuation of a patient's therapy should be assessed primarily by resolution of clinical signs and symptoms. Patients who experience a resolution in their symptoms (e.g., shortness of breath, tachycardia, fatigue, dizziness, and edema) may not require aggressive therapy to maintain their Hgb values within normal limits. Prevention of complications owing to anemia such as hypoxia and cardiovascular sequelae can be avoided if Hgb levels are greater than 7.0 g/dL (70 g/L or 4.34 mmol/L).¹¹

General Approach to the Anemic Patient

- **5** *The underlying cause of anemia must be determined and used to guide therapy. The mean corpuscular volume (included in a CBC) and determination of iron, ferritin, folate, and vitamin B₁₂ levels are required to correctly determine the etiology of a patient's anemia.* Figure 66–3 and Table 66–2 illustrate how laboratory test results determine the correct diagnosis.

Nonpharmacologic Therapy

The most important nonpharmacologic treatment of anemia is transfusion of RBCs. Safety concerns, cost, and the limited availability of this therapy support efforts to establish the “optimum” threshold for administering RBC transfusions. A Cochrane review of 17 controlled studies concluded that it is appropriate to use “restrictive transfusion triggers in patients who are free of serious cardiac disease.” The authors concluded a reasonable “trigger for transfusion” for patients without significant cardiovascular disease is 7.0 g/dL (70 g/L or 4.34 mmol/L).¹² The Transfusion Requirements In Critical Care trial reported no significant differences in in-hospital mortality between patients randomly assigned to maintain Hgb levels of 7.0 to 9.0 g/dL (70 g/L to 90 g/L or 4.34 mmol/L to 5.59 mmol/L) and 10.0 to 12.0 g/dL (100 g/L to 120 g/L or 6.21 mmol/L to 7.45 mmol/L).¹³ Typically, only patients with acute symptoms (i.e., dyspnea, chest pain) and Hgb concentrations in the range of 7.0 to 9.0 g/dL (70 g/L to 90 g/L or 4.34 mmol/L to 5.59 mmol/L) require blood transfusions.

Certainly, anemia can be attributed to diets poor in iron, folic acid, or vitamin B₁₂. However, in the United States, nutrient-poor diets are rarely the sole cause of anemia. Therefore, ingesting a diet that is rich in iron, folic acid, or vitamin B₁₂ should be encouraged, but is rarely the sole modality of treatment. Food sources of iron, folic acid, and vitamin B₁₂ are listed in Table 66–3.⁸

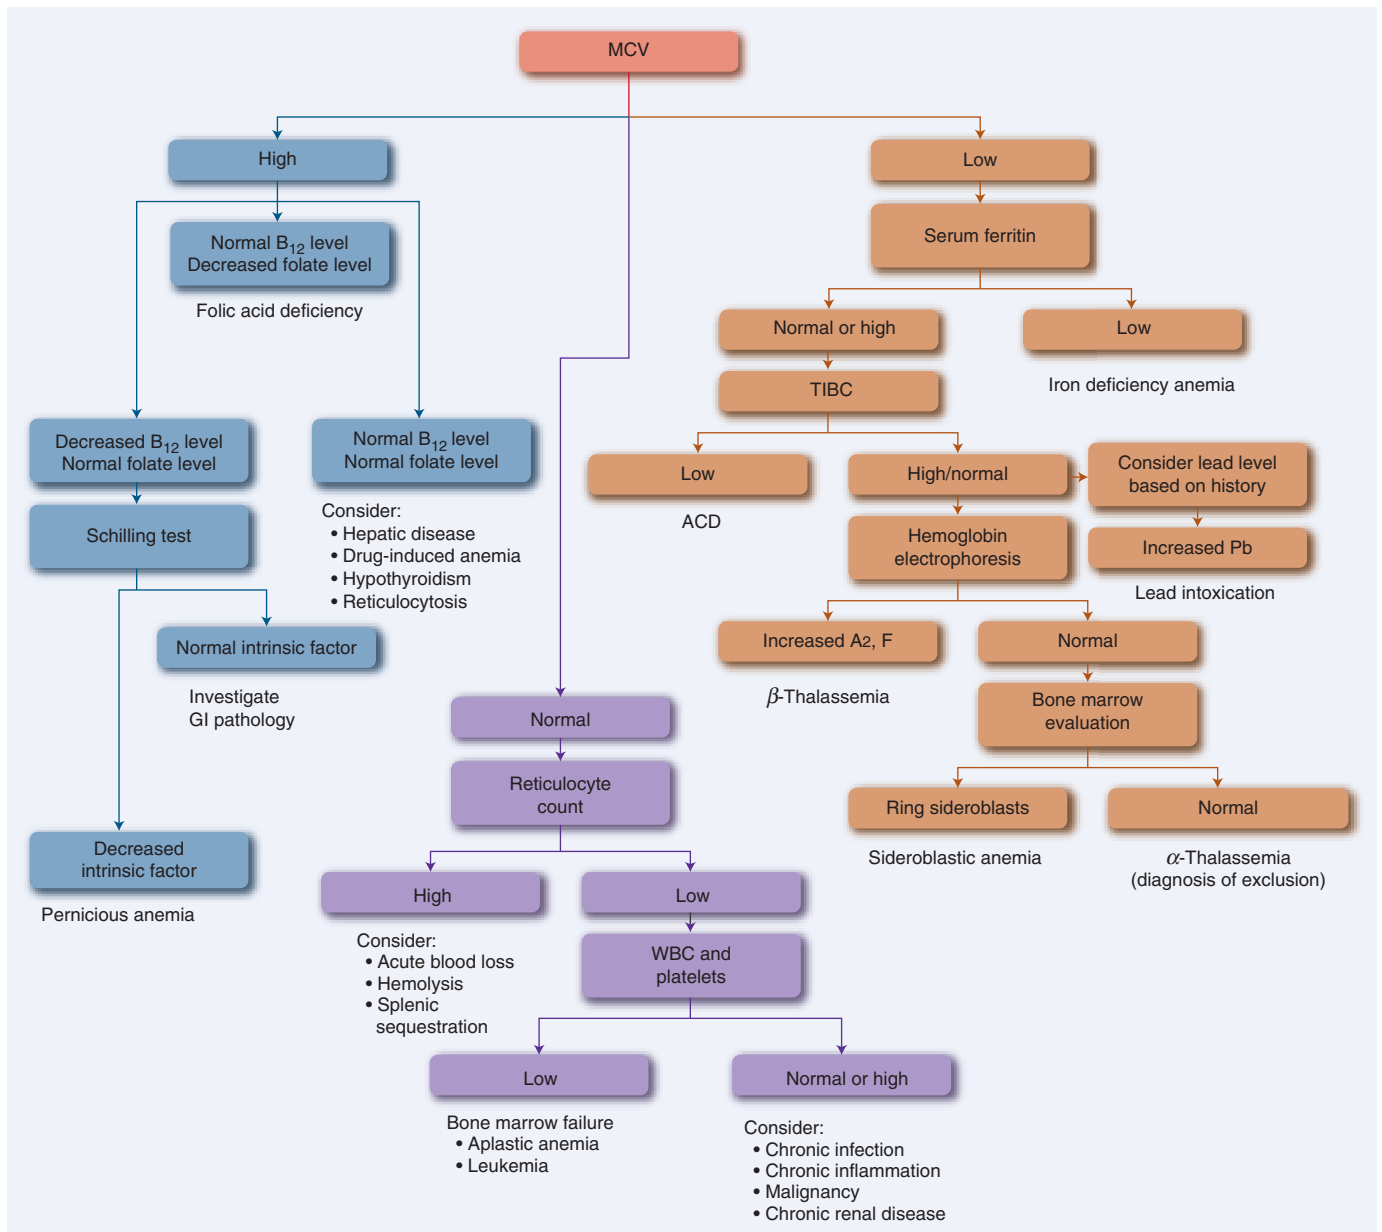

FIGURE 66-3. The anemia evaluation process. ACD, anemia of chronic disease; MCV, mean corpuscular volume; Pb, lead; TIBC, total iron-binding capacity.

Pharmacologic Therapy

► Iron-Deficiency Anemia

6 The initial treatment of IDA is oral iron therapy that provides 150 to 200 mg of elemental iron daily. Many different iron products and salt forms are available. **Table 66-4** lists commonly prescribed oral iron products and the amount of elemental iron provided by each.

Iron supplementation resolves anemia by replenishing iron stores to levels necessary for RBC production and maturation. If treated properly, reticulocytosis should be seen in 7 to 10 days, and Hgb values should rise by about 1.0 g/dL (10 g/L or 0.62 mmol/L) per week. Patients should be

reassessed if Hgb does not increase by 2.0 g/dL (20 g/L or 1.24 mmol/L) in 3 weeks.¹⁴

- The preferred dosing regimen for oral iron is to administer 50 to 65 mg of elemental iron two to three doses daily on an empty stomach. Administration on an empty stomach (1 hour before or 2 hours after a meal) is preferred for maximal absorption. However, if patients develop intolerable GI side effects (i.e., heartburn, nausea, bloating) after taking iron on an empty stomach, they should be advised to take it with meals. After absorption, iron binds to transferrin in the plasma and is transported to the muscles (for myoglobin), liver (for storage), or bone marrow (for red cell production). Common toxicities associated with oral iron products include

Table 66-2

Pertinent Laboratory Tests in the Evaluation of Anemia

Test Name	Normal Range	Description/Significance
CBC		
Hgb	Males: 14.0–17.5 g/dL (140–175 g/L or 8.69–10.9 mmol/L) Females: 12.35–15.3 g/dL (123–153 g/L or 7.63–9.50 mmol/L)	Amount of Hgb in the blood; signifies oxygen-carrying capacity of the blood and determines whether a patient is anemic
Hct	Males: 40.7–50.3% (0.407–0.503) Females: 36.1–44.3% (0.361–0.443)	The percent of blood that the erythrocytes encompass; also indicates anemia; the Hgb is measured, and the Hct is calculated
RBC	Males: 4.5–5.9 10^6 cells/ μ L (4.5–5.9 10^{12} cells/L) Females: 4.1–5.1 10^6 cells/ μ L (4.1–5.1 10^{12} cells/L)	The number of erythrocytes in a volume of blood; also indicates anemia, but seldom used
RBC Indices		
MCV	80–97.6 μ m ³ /cell (80–97.6 fL/cell)	A widely used laboratory value to measure RBC “size”; higher values indicate macrocytosis and lower values indicate microcytosis
MCH	27–33 pg/cell	Amount of Hgb per RBC; may be decreased in IDA
MCHC	32–36 g/dL (320–360 g/L)	Hgb divided by the Hct; also low in IDA
Iron Studies		
Serum iron		
Males	45–160 mcg/dL (8.1–28.6 μ mol/L)	Measures amount of iron bound to transferrin; low in IDA
Females	30–160 mcg/dL (5.4–28.6 μ mol/L)	
Serum ferritin		
Males	20–250 ng/mL (20–250 mcg/L)	Ferritin is the protein–iron complex found in macrophages used for iron storage; low in IDA
Females	10–150 ng/mL (10–150 mcg/L)	
TIBC	220–420 mcg/dL (39.4–75.2 μ mol/L)	Measures the capacity of transferrin to bind iron; high in IDA
TSAT	15–50% (0.15–0.50)	TSAT(%) = (serum iron/TIBC) \times 100; a saturation of less than 15% (0.15) is common in IDA
Other Tests		
RBC distribution width (RDW)	11.5–14.5% (0.115–0.145)	A higher value means the presence of many different sizes of RBCs; the MCV is therefore less reliable
Reticulocyte count		
Males	0.5–1.5% of RBCs (0.005–0.015)	Should be elevated in patients who are responding to treatment
Females	0.5–2.5% of RBCs (0.005–0.025)	
Folic acid (plasma)	3.1–12.4 ng/mL or mcg/L (7.0–28.1 nmol/L)	Used to determine folic acid deficiency
Folic acid (RBC)	125–600 ng/mL (283–1,360 nmol/L)	Used to determine folic acid deficiency
Vitamin B ₁₂	180–1,000 pg/mL (133–738 pmol/L)	Used to determine vitamin B ₁₂ deficiency
EPO level	2–25 mIU/mL (2–25 IU/L)	Patients may benefit from EPO therapy if they are anemic and EPO levels are normal or mildly elevated

EPO, erythropoietin; Hct, hematocrit; Hgb, hemoglobin; IDA, iron-deficiency anemia; MCH, mean cell hemoglobin; MCHC, mean cell hemoglobin concentration; MCV, mean cell volume; RDW, RBC distribution width; TIBC, total iron-binding capacity; TSAT, transferrin saturation.

abdominal pain, nausea, heartburn, constipation, and dark stools.¹⁴ Potentially clinically significant drug interactions involving iron products include fluoroquinolones, tetracyclines, and mycophenolate mofetil. Iron decreases the absorption of these drugs. To minimize this effect, oral iron should be administered not less than 3 hours before or 2 hours after the affected drug.¹⁵

Parenteral iron therapy is indicated when patients cannot tolerate oral formulations, are noncompliant, or fail to respond to oral iron because of malabsorption syndromes. Five parenteral iron formulations are available in the United States.^{16–20} Use and availability of parenteral iron formulations have changed significantly since introduced over 30 years ago. The initial iron dextran formulation approved for use in the United States was a high-molecular-weight product

(HMW ID). The relatively infrequent occurrence of severe acute hypersensitivity reactions associated with this product resulted in a “black box warning” and recommendation for administration of a test dose. In 1991, this product was withdrawn from market. The same year, a low-molecular-weight iron dextran (LMW ID) was approved for use and became an established component in combination with ESAs for treating anemia in patients with CKD.¹⁶ Although total dose infusion (TDI) is not an approved method of administration in the United States, LMW ID is approved for TDI in Europe. TDI administration has been shown to achieve similar patient outcomes (equal efficacy and safety) while lowering cost. In 1996, a new HMW ID received FDA labeling for the treatment of IDA. Sodium ferric gluconate complex, iron sucrose, and ferumoxytol received

Patient Encounter 1, Part 2

Laboratory parameters are ordered, and the following is observed:

CBC

- *WBC*: 6.50 $10^3/\mu\text{L}$ (6.50 $10^9/\text{L}$)
- *Hgb*: 8.3 g/dL (83 g/L or 5.15 mmol/L)
- *Hct*: 24.8% (0.248)
- *Plt*: 210 $10^3/\mu\text{L}$ (210 $10^9/\text{L}$)

Red blood Cell Indices

- *MCV*: 75 $\mu\text{m}^3/\text{cell}$ (75 fL/cell)
- *MCH*: 26 pg/cell
- *MCHC*: 30.3 g/dL (303 g/L)

Others

- *RBC count*: $3 \times 10^6/\mu\text{L}$ ($3 \times 10^{12}/\text{L}$)
- *RDW*: 15% (0.15)
- *Retic%*: 3% (0.03)

Iron Studies

- *Serum iron*: 28 mcg/dL (5.3 $\mu\text{mol}/\text{L}$)
- *Serum ferritin*: 7 mcg/L (15.7 pmol/L)
- *TIBC*: 462 mcg/dL (82.7 $\mu\text{mol}/\text{L}$)
- *Transferrin saturation*: 10% (0.10)

B₁₂ and Folate

- *Serum folate*: 10 mcg/dL (22.7 nmol/L)
- *Serum B₁₂*: 496 pg/mL (366 pmol/L)

Is this a macrocytic or microcytic anemia?

Specifically, what is the etiology of the anemia?

Recommend the most appropriate drug regimen (drug, dosage form, and schedule).

FDA labeling for the treatment of patients with anemia and CKD in the last decade.^{17–20} Although the occurrence of life-threatening adverse events caused by parenteral iron is extremely low, the absolute rate of life-threatening events is substantially higher for HMW ID.^{21,22} **Table 66–5** provides details pertinent to the use of these products.

The dose of iron dextran can be calculated by the following equation: dose (mL) = 0.0442 (desired Hgb – observed Hgb) body weight + (0.26 body weight). The body weight that should be used is lean body weight for adults and children weighing more than 15 kg and actual body weight for children weighing 5 to 15 kg. The dose in milligrams can be calculated based on a standard concentration of 50 mg of elemental iron per milliliter.¹⁶ Prescribing information recommends administering iron dextran in 100-mg aliquots daily until the total dose is achieved. However, anecdotal evidence reports that the total calculated dose can be administered safely over 4 to 6 hours in 1 day. Because of the risk of anaphylaxis, a test dose of iron dextran (0.5 mL over at least 30 seconds) must be administered to patients before their first dose of iron dextran. Patients should be monitored for signs of anaphylaxis for at least 1 hour before administering the total dose. Other adverse effects include arthralgias, arrhythmias, hypotension, flushing, and pruritus.²¹

Table 66–3

Food Sources of Iron, Folic Acid, or Vitamin B₁₂

Nutrient	Food Sources
Iron	Red meat, organ meats, wheat germ, egg yolks, oysters
Folic acid	Green vegetables, liver, yeast, fruits
Vitamin B ₁₂	Animal by-products, legumes

► Vitamin B₁₂ and Folic Acid Anemia

- 7 *Anemia from vitamin B₁₂ or folic acid deficiency is treated effectively by replacing the missing nutrient.* Both folic acid and vitamin B₁₂ are essential for erythrocyte production and maturation. Replacing these nutrients allows for normal DNA synthesis and, consequently, normal erythropoiesis.

Oral and parenteral Vitamin B₁₂ (cyanocobalamin) replacement therapies are equally effective. Vitamin B₁₂ is absorbed completely following parenteral administration, whereas oral vitamin B₁₂ is absorbed poorly via the GI tract. Furthermore, parenteral vitamin B₁₂ may circumvent the need to perform a Shilling test used to diagnose a deficiency of intrinsic factor. Consequently, cyanocobalamin is commonly administered as an intramuscular injection. A typical cyanocobalamin dosing regimen is 1,000 mcg/day for 1 week, followed by 1,000 mcg/week for a month or until the Hgb normalizes. Life-long maintenance therapy (1,000 mcg/month)

Table 66–4

Oral Iron Products and Elemental Iron Content

Salt Form	Brand Name(s)	Elemental Iron Content per Dose Form
Ferrous sulfate	Feosol	65 mg/325-mg tablet
Ferrous sulfate, anhydrous	N/A	60 mg/300-mg tablet
Ferrous gluconate	Fergon	65 mg/200-mg tablet
Ferrous fumarate	Feostat	39 mg/325-mg tablet
Polysaccharide–iron complex	Niferex, Ferrex	37 mg/300-mg tablet
		33 mg/100-mg tablet
		150 mg/150-mg capsule
		50 mg/ 50-mg tablet

Mol. Wt. (Da), molecular weight (Daltons); Max., maximum; TDI, total dose infusion; NR, not reported.

^aHMW DI marketed in the United States in 1996, different manufacturer than HMW DI withdrawn in 1991.

From Auerbach M, Ballard H. Clinical use of intravenous iron: Administration, efficacy and safety. Hematology Am Soc Hematol Educ Program 2010:338–347.

is required for patients with pernicious anemia or surgical resection of the terminal ileum. If the etiology was a dietary deficiency or reversible malabsorption syndrome, treatment can be discontinued after the underlying cause is corrected and vitamin B₁₂ stores normalized. A common oral dosing regimen is from 1,000 to 2,000 mcg/day. If parenteral cyanocobalamin is used initially, oral vitamin B₁₂ can be useful as maintenance therapy. Typically, resolution of neurologic symptoms, disappearance of megaloblastic RBCs, and increased Hgb levels occur within a week of therapy.

Vitamin B₁₂ is well tolerated. Reported adverse effects include injection-site pain, pruritus, and rash. Clinical significance of decreases in protein-bound cyanocobalamin related to proton pump inhibitor therapy has not been established.¹⁵

The effective dose of folic acid is 1 mg/day by mouth. Absorption of folic acid generally is rapid and complete. However, patients with malabsorption syndromes may

require doses up to 5 mg/day. Resolution of symptoms and reticulocytosis occurs within days of commencing therapy. Typically a patient's Hgb will start to rise after 2 weeks of therapy and normalize after 2 to 4 months of therapy.

Folic acid is well tolerated. Nonspecific adverse effects include allergic reactions, flushing, malaise, and rash. A small study evaluating the effect of folic acid doses of 10 mg/day on phenytoin levels reported decreased phenytoin levels in 3 of 4 subjects. However, the occurrence of this interaction at folic acid doses of 1 mg/day has not been reported.¹⁵

► Anemia of Chronic Disease

- 8 *Decreased RBC transfusion requirements is an outcome achieved in patients with ACD treated with the ESAs. However, in 2007, the FDA product labeling for epoetin and darbepoetin were revised to include new data documenting safety concerns. Subsequently, the Centers for Medicare and Medicaid Services (CMS) implemented more restrictive ESA coverage determination guidelines. In 2010, the FDA implemented a risk evaluation and mitigation strategy (REMS) for ESAs administered to treat patients with cancer who are undergoing chemotherapy. Table 66-6 summarizes the FDA-labeled dosing regimens for patients whose anemia is related to cancer chemotherapy, CKD, or zidovudine treatment.*

Anemia Due to Chemotherapy in Patients with Cancer Epoetin, a recombinant human EPO, and darbepoetin, a synthetic EPO analog, bind to the EPO receptors on RBC precursor cells in the bone marrow and result in increased RBC production. Darbepoetin differs from epoetin in that it is a glycosylated protein and exhibits a longer half-life, allowing for a longer dosing interval. Clinical practice guidelines consider epoetin and darbepoetin to be therapeutic equivalents.^{4,23} 9 *ESAs should only be used to prevent a transfusion and should not be initiated unless the hemoglobin is less than or equal to 10.0 g/dL (100 g/L,*

Patient Encounter 1, Part 3

The patient is diagnosed with iron-deficiency anemia and is started on ferrous sulfate 325 mg orally three times daily to be taken on an empty stomach. Follow-up CBC 1 month later reveals an Hgb of 10 g/dL (100 g/L or 6.21 mmol/L), previously 8.3 g/dL (83 g/L or 5.15 mmol/L). The patient reports improvement in shortness of breath and less frequent episodes of dizziness. She also states she occasionally misses doses due to her hectic days and remembering to take it on an empty stomach.

What hemoglobin level would constitute a therapeutic response in this patient?

How can compliance be improved in this patient?

Table 66-6

ESA Products and Usual Doses for Anemia from Cancer/Chemotherapy, CKD, and Zidovudine/HIV Infection^a

	Epoetin-alfa (Epogen, Procrit)	Darbepoetin-alfa (Aranesp)
Cancer/chemotherapy dosing regimens	150 units/kg SC or IV 3 per week. 40,000 units SC or IV once every week	2.25 mcg/kg SC or IV once every week 500 mcg SC or IV fixed dose every 3 weeks
CKD dosing regimens	50–100 units/kg SC or IV 3 per week	0.45 mcg/kg SC or IV once every week ^b 0.75 mcg/kg SC or IV once every 2 weeks ^b 0.45 mcg/kg SC or IV once every 4 weeks ^c
Zidovudine/HIV dosing regimen ^d	100 units/kg IV or SC 3 per week	

^aIndications and dosage regimens per FDA product labeling.³²⁻³⁴

^bfor patients on dialysis

^cfor patients not on dialysis

^dFDA labeled indication for Procrit (epoetin alfa), not Epogen (epoetin alfa) or darbepoetin

6.21 mmol/L). ESA-labeled dosing regimens for treatment of patients receiving chemotherapy are summarized in Table 66-6.

A number of clinical trials and a recent meta-analysis revealed that patients administered ESAs experienced increased thrombotic events and shorter progression-free and overall survival.²³ In the meta-analysis, a total of 13,933 cancer patients from 53 trials were analyzed. ESAs increased on study mortality (combined hazard ratio [cHR] 1.17; 95% CI 1.06 to 1.30) and worsened overall survival (cHR 1.06; 95% CI 1.00 to 1.12). This corresponds to a 17% increased risk of mortality for patients treated with ESAs while on study and a 6% increase overall. Based on these data, the FDA revised ESA product labeling, restricting their administration to patients with chemotherapy-induced anemia without a curative intent. The 2010 update of the American Society of Clinical Oncology/American Society of Hematology clinical practice guideline on the use of ESAs in patients with cancer adopted FDA recommendations calling for more restrictive use of ESA in patients with cancer.²⁴

CMS published more restrictive national coverage criteria for ESA treatment of anemia associated with cancer chemotherapy in 2008. Patients should be monitored every 4 weeks. If Hgb has not increased by 1.0 g/dL (10 g/L, 0.62 mmol/L) after 4 weeks and remains less than 10.0 g/dL (100 g/L, 6.21 mmol/L), a one-time dose escalation of 25% is appropriate. If Hgb increases by more than 1.0 g/dL (10 g/L, 0.62 mmol/L), or is more than 10.0 g/dL (100 g/L, 6.21 mmol/L), the ESA should be discontinued. At 8 weeks if Hgb has increased by 1 g/dL (10 g/L, 0.62 mmol/L) but remains less than 10.0 g/dL (100 g/L, 6.21 mmol/L), continued ESA administration is covered. However, if after 8 weeks Hgb fails to increase by 1 g/dL (10 g/L, 0.62 mmol/L), CMS payment of therapy is not covered. CMS covers ESA therapy for up to 8 weeks after completion of chemotherapy for patients achieving responses.²⁵

“Functional” iron deficiency has been described in patients with ACD. Therefore, it is imperative that patients starting ESA therapy have laboratory studies performed to assess

Patient Encounter 2, Part 1

A 65-year-old woman with a diagnosis of metastatic, hormone-refractory breast cancer returns to the infusion center for her fifth paclitaxel infusion. She states her level of energy seems to be dropping. Her CBC reveals the following:

CBC

- WBC: 3.50 $10^3/\mu\text{L}$ (3.50 $10^9/\text{L}$)
- Hgb: 9.3 g/dL (93 g/L or 5.77 mmol/L)
- Hct: 24.8% (0.248)
- Plt: 210 $10^3/\mu\text{L}$ (210 $10^9/\text{L}$)

Red Blood Cell Indices

- MCV: 85 $\mu\text{M}^3/\text{cell}$ (85 fL/cell)
- MCH: 30 pg/cell
- MCHC: 35.3 g/dL (303 g/L)

Others

- RBC count: $3.8 \times 10^6/\mu\text{L}$ ($3.8 \times 10^{12}/\text{L}$)
- RDW: 12% (0.15)

Iron studies

- Serum iron: 38 mcg/dL (5.8 $\mu\text{mol/L}$)
- Serum ferritin: 100 ng/mL (100 mcg/L)
- TIBC: 462 mcg/dL (82.7 $\mu\text{mol/L}$)
- Transferrin saturation: 10% (0.10)

 B_{12} and folate

- Serum folate: 20 mcg/dL (45 nmol/L)
- Serum B_{12} : 707 pg/mL (498 pmol/L)

In addition to the order for paclitaxel, you receive the following orders:

Epoetin 40,000 units SC weekly, ferrous sulfate 325 mg tablet three times daily.

What is your assessment of the orders for epoetin and ferrous sulfate?

What discussion must be presented to the patient before ESA therapy can be initiated?

Patient Encounter 2, Part 2

A month later, the patient returns for another cycle of chemotherapy and epoetin. Her Hgb is 9.7 g/dL.

What if any changes should be recommended?

When should ESA therapy be stopped?

iron stores. If results document a patient has suboptimal iron stores, iron replacement therapy is indicated.

Anemia Due to CKD Patients with CKD progress through five stages of disease based on glomerular filtration rate (GFR).²⁷ As discussed previously, anemia is common in patients with CKD. Early treatment of anemia in patients with CKD on dialysis has been associated with slower disease progression and lower risk of death. Therefore, it is essential to evaluate and treat anemia in patients before they progress to stage 5 CKD (GFR of less than 15 mL/min/1.73 m² [0.14 mL/s/m²]).^{25,26}

Patients with CKD typically develop normocytic, normochromic anemia as a result of EPO deficiency. However, a thorough workup of anemia should be performed to rule out other etiologies.^{25–28} Regardless, ESA therapy is effective in treating CKD anemia. The National Kidney Foundation Clinical Practice Recommendations 2007 update recommend a Hgb target range of 11.0 to 12.0 g/dL (110 g/L to 120 g/L or 6.83 mmol/L to 7.45 mmol/L) in dialysis and nondialysis patients.²⁹ However, in June 2011, the FDA notified healthcare providers that the target Hgb range in patients with CKD was lowered to 11.0 g/dL (110 g/L or 6.83 mmol/L) in patients on hemodialysis and to 10.0 g/dL (100 g/L or 6.21 mmol/L) in CKD patients not on hemodialysis.³⁰ This revision was adopted because data documented that the use of ESAs to achieve an Hgb greater than 11.0 g/dL (110 g/L or 6.83 mmol/L) resulted in increased risk of serious adverse cardiovascular events. The product labels previously recommended administration of ESAs to reach a Hgb target range of 10.0 to 12.0 g/dL (100 g/L to 120 g/L or 6.21 mmol/L to 7.45 mmol/L) for these patients. This target range was deleted from the revised product package inserts.^{31–33} ESA-labeled dosing regimens for patients with CKD are summarized in Table 66–6.

Although EPO deficiency is the primary cause of CKD anemia, iron deficiency may also exist. Iron stores in patients with CKD should be maintained so that transferrin saturation is greater than 20% (0.20) and serum ferritin is greater than 100 ng/mL (100 mcg/L or 225 pmol/L). If iron stores are not maintained appropriately, epoetin or darbepoetin will not be effective. Most CKD patients will require iron supplementation.²⁸

Anemia Due to Zidovudine in HIV-Infected Patients Early clinical trials evaluating the efficacy of zidovudine in HIV-infected patients documented that nearly 50% of patients treated with zidovudine develop anemia requiring RBC transfusions. Subsequently, results from four double-blind, placebo-controlled, multicenter studies reported that epoetin resulted in statistically significant decreases in transfusion requirements for patients with serum erythropoietin levels less than 500 mUnits/mL (500

U/L). Currently, epoetin has a labeled indication for the treatment of anemia in patients with EPO levels less than 500 mUnits/mL (500 U/L) and administered zidovudine doses less than 4,200 mg/week.³⁵

Other Chronic Diseases Patients with infections and autoimmune disorders such as rheumatoid arthritis and systemic lupus erythematosus can also develop ACD. The appropriate treatment of the underlying disease is the primary therapeutic intervention in these patients. However, because functional iron deficiency and blunted EPO responsiveness are frequent complications in these patients, parenteral iron and EPO are effective adjunctive therapies for correcting anemia.

OUTCOME EVALUATION

10 *Patients should be monitored for Hgb response, symptom resolution, and adverse effects at appropriate intervals, and treatment regimens adjusted accordingly.* The goal of anemia therapy is to correct the underlying etiology of the anemia, normalize the Hgb, and alleviate associated symptoms.

- To ensure response for patients with IDA, monitor CBC with special attention to occurrence of reticulocytosis and iron studies.
- A 1.0-g/dL (10 g/L or 0.62 mmol/L) per week increase in Hgb is desirable in patients with IDA. Reevaluate patients with increases less than 2.0 g/dL (20 g/L or 1.24 mmol/L) in 3 weeks.
- For patients with folic acid deficiency, monitor Hgb periodically and reevaluate patients who fail to normalize Hgb levels after 2 months of therapy.
- For patients with vitamin B₁₂ deficiency, monitor for resolution of neurologic symptoms (i.e., confusion and paresthesias), if applicable, and Hgb levels weekly until the levels normalize.
- For patients treated with chemotherapy, initiate ESA treatment when Hgb levels are less than 10.0 g/dL (100 g/L or 6.21 mmol/L) and monitor Hgb levels weekly. If Hgb increases exceed 1.0 g/dL (10 g/L or 0.62 mmol/L) or exceed 10.0 g/dL (100 g/L or 6.21 mmol/L), hold therapy until the level drops below 10.0 g/dL (100 g/L or 6.21 mmol/L). Restart the ESA at the lowest dose sufficient to reduce transfusions
- For patients with CKD on dialysis, initiate ESA treatment when Hgb levels are less than 10.0 g/dL (100 g/L or 6.21 mmol/L) and monitor Hgb levels weekly. If Hgb levels approach or exceed 11.0 g/dL, reduce or hold further doses until the level drops below 10.0 g/dL (100 g/L or 6.21 mmol/L). Restart the ESA at the lowest dose sufficient to reduce transfusions.
- For patients with CKD not on dialysis, initiate ESA treatment when Hgb levels are less than 10.0 g/dL (100 g/L or 6.21 mmol/L) and monitor Hgb levels weekly. If Hgb levels exceed 10.0 g/dL (100 g/L or 6.21 mmol/L), reduce or hold further doses until the level drops below 10.0 g/dL (100 g/L or 6.21 mmol/L). Restart the ESA at the lowest dose sufficient to reduce transfusions.

Patient Care and Monitoring

1. Identify and treat the underlying cause of anemia.
2. Determine whether immediate correction of anemia is required with a transfusion or if chronic therapy can be initiated.
3. Monitor symptoms such as fatigue, shortness of breath, lethargy, headache, edema, and tachycardia for resolution.
4. Monitor the CBC monthly.
5. When initiating ESAs, assess the patient's iron status.
6. Monitor side effects of therapy, such as
 - *Oral iron*: nausea, vomiting, abdominal pain, heartburn, constipation, and dark stools
 - *Parenteral iron*: anaphylaxis (test dose required for iron dextran and observe for 1 hour after), injection-site pain/irritation, arthralgias, myalgias, flushing, malaise, and fever
 - *Folic acid*: bad taste and nausea, rash, and allergic reactions
 - *Vitamin B₁₂*: pain and erythema at injection site
 - *ESAs*: hypertension (monitor blood pressure), thrombosis (e.g., deep vein thrombosis/pulmonary embolism, myocardial infarction, cerebrovascular accident, and transient ischemic attack), arthralgias, and headache

Abbreviations Introduced in This Chapter

CFU-E	Erythroid colony-forming unit
CKD	Chronic kidney disease
EPO	Erythropoietin
ESA	Erythropoietin stimulating agent
GFR	Glomerular filtration rate
GM-CSF	Granulocyte-monocyte colony-stimulating factor
Hct	Hematocrit
Hgb	Hemoglobin
IDA	Iron-deficiency anemia
IL-3	Interleukin 3
MCV	Mean corpuscular volume
MCH	Mean corpuscular hemoglobin
NCCN	National Comprehensive Cancer Network
NKF-K/DOQI	National Kidney Foundation Kidney Disease Outcomes Quality Initiative
TIBC	Total iron-binding capacity

Self-assessment questions and answers are available at <http://mhpharmacotherapy.com/pp.html>.

Coagulation and Platelet Disorders

Anastasia Rivkin

LEARNING OBJECTIVES

● Upon completion of this chapter, the reader will be able to:

1. Describe the basics of the regulation of hemostasis and thrombosis.
2. Determine which factor replacement preparation is appropriate in a given clinical situation.
3. Calculate an appropriate factor-concentrate dose for a product, given the percentage correction desired based on clinical situation.
4. List the complications from hemophilia bleeding episodes.
5. Choose appropriate treatment strategy for patients with factor VIII or IX inhibitors.
6. Devise a treatment plan for a patient with a specific variant of von Willebrand's disease (vWD).
7. Describe various recessively inherited coagulation disorders (RICDs) and role of specific factor replacement in RICD management.
8. Formulate an appropriate treatment plan based on presentation of disseminated intravascular coagulation (DIC).
9. Recommend first-line and a second-line treatment approaches for immune thrombocytopenic purpura (ITP).
10. Identify basic clinical features, causes, and management of thrombotic thrombocytopenic purpura (TTP).

KEY CONCEPTS

- 1 IV replacement with recombinant or plasma-derived products to treat or prevent bleeding is the primary treatment of hemophilia.
- 2 Patients with type 1 von Willebrand's disease (vWD) unresponsive to desmopressin, patients with types 2 and 3 vWD, and major surgery patients require replacement therapy with plasma-derived intermediate- and high-purity factor VIII, virus-inactivated factor VIII concentrate containing von Willebrand's factor (vWF).
- 3 The primary treatment of recessively inherited coagulation disorders (RICDs) is single-donor fresh-frozen plasma (FFP) that contains all coagulation factors.
- 4 The cornerstone of the management of disseminated intravascular coagulation (DIC) is aggressive treatment of the underlying primary illness. Supportive measures may be used as necessary; however, owing to the heterogeneity of the DIC etiology, treatment should be guided by predominant symptoms (bleeding or clotting).

- 5 The treatment of immune thrombocytopenic purpura (ITP) is determined by the symptom severity. In some cases, no therapy is needed.
- 6 The present standard of treatment for thrombotic thrombocytopenic purpura (TTP) is urgent plasma exchange (PEX). If PEX is unavailable, treatment with plasma infusion and glucocorticoids is indicated until PEX is available.

INTRODUCTION

Components of the Hemostatic System

- Following endothelial injury, vessel-wall response involves vasoconstriction, platelet plug formation, coagulation, and **fibrinolysis** regulation. In normal circumstances, platelets circulate in the blood in an inactive form. After injury, platelets undergo activation, which consists of (a) adhesion to the subendothelium, (b) secretion of granules containing chemical mediators (e.g., adenosine diphosphate, thromboxane A₂, thrombin, etc.), and (c) aggregation. Chemical factors released from the injured tissue and platelets

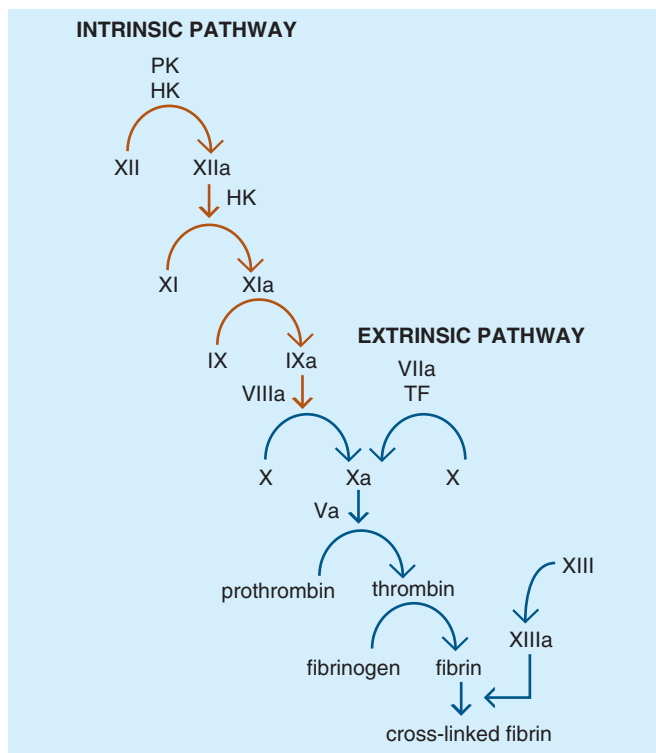

FIGURE 67-1. Cascade model of coagulation demonstrates activation via the intrinsic or extrinsic pathway. This model shows successive activation of coagulation factors proceeding from the top to the bottom where thrombin and fibrin are generated. (PK, prekallikrein; HK, high-molecular weight kininogen; TF, tissue factor.) (From Roberts HR et al. Molecular biology and biochemistry of the coagulation factors and pathways of hemostasis. In: Lichtman MA, Beutler E, Coller BS et al, eds. Williams Hematology, 7th ed. New York: McGraw-Hill, 2006:1665–1694.)

stimulate the coagulation cascade and thrombin formation. In turn, thrombin catalyzes the conversion of fibrinogen to fibrin and its subsequent incorporation into plug.

The coagulation system consists of intrinsic and extrinsic pathways. Both pathways are composed of a series of enzymatic reactions that ultimately produce thrombin, fibrin, and a stable clot. In parallel with the coagulation, the fibrinolytic system is activated locally. Plasminogen is converted to plasmin, which dissolves the fibrin mesh (Fig. 67-1).¹

INHERITED COAGULATION DISORDERS

HEMOPHILIA

Etiology and Epidemiology

Hemophilia A and B are coagulation disorders that result from defects in the genes encoding for plasma coagulation proteins. Hemophilia A (classic hemophilia) is caused by the deficiency of factor VIII, and hemophilia B (Christmas disease) is caused

by the deficiency of factor IX. The incidences of hemophilia A and B are estimated at 1 in 5,000 and 1 in 30,000 male births, respectively. Both types of hemophilia are evenly distributed across all ethnic and racial groups.¹

Pathophysiology

The pathophysiology of hemophilia is based on the deficiency of factor VIII or IX resulting in inadequate thrombin generation and an impaired intrinsic-pathway coagulation cascade (see Fig. 67-1). Factor VIII and IX genes are located on the X chromosome. Hemophilias are recessive X-linked diseases. Generally, affected males carrying either defective allele on their X chromosome do not transmit the gene to their sons. However, their daughters are obligate carriers. Over 2,100 mutations, deletions, and inversions have been identified throughout the factor VIII and IX genes.²

Consequently, hemophilia is not a result of a single genetic mutation. However, inversion at intron 22 of the factor VIII gene accounts for 45% of severe hemophilia A cases. Owing to the high incidence, this mutation is used for carrier and prenatal testing.³

Complications of Hemophilia

- The severity of bleeding associated with hemophilia correlates with the degree of factor VIII or factor IX deficiency as measured against the normal plasma standard. **Table 67-1** summarizes the age at onset and laboratory and clinical manifestations of hemophilia A and B.⁴

Treatment

► Desired Outcomes

Currently, there is no cure for hemophilia A or B. The life expectancy of hemophiliacs was only 8 to 11 years in the 1920s and 1930s. With the development of effective treatment strategies, life expectancy is currently about 63 to 75 years, or nearly that of the normal population.⁵

The short-term goals of hemophilia treatment are to:

- Decrease the number of bleeding episodes per year or bleeding frequency
- Normalize or improve clotting factor concentrate levels

The long-term goals of hemophilia treatment are to:

- Maintain clinical joint function
- Normalize orthopedic joint score
- Normalize radiologic joint score
- Maintain quality-of-life measurements

► General Approach to Treatment

① IV factor replacement with recombinant or plasma-derived products to treat or prevent bleeding is the primary treatment of hemophilia. Primary prophylaxis is defined as the regular administration of factor concentrates with the intention of preventing joint bleeds.⁶ The rationale for primary

Table 67-1

Laboratory and Clinical Manifestations of Hemophilia

	Severe (Less Than 0.01 IU/mL [10 IU/L]) ^a	Moderate (0.01–0.05 IU/mL [10–50 IU/L]) ^a	Mild (More Than 0.05 IU/mL [50 IU/L]) ^a
Age at onset	1 year or less	1–2 years	2 years–adult
Neonatal symptoms			
PCB	Usual	Usual	Rare
ICH	Occasional	Uncommon	Rare
Muscle/joint hemorrhage	Spontaneous	Minor trauma	Minor trauma
CNS hemorrhage	High risk	Moderate risk	Rare
Postsurgical hemorrhage (without prophylaxis)	Frank bleeding, severe	Wound bleeding, common	Wound bleeding
Oral hemorrhage following trauma, tooth extraction	Usual	Common	Common

CNS, central nervous system; ICH, intracranial hemorrhage; PCB, postcircumcisional bleeding.

Normal range of factor VIII/IX activity level is 0.5–1.5 IU/mL (50–150 IU/L). 1 IU/mL (1,000 IU/L) corresponds to 100% of the factor found in 1 mL of normal plasma.

^a0.01 IU/mL = 10 IU/L; 0.05 IU/mL = 50 IU/L; 0.5 IU/mL = 500 IU/L; 1 unit/mL = 1 IU/mL = 1,000 IU/L; 1.5 IU/mL = 1,500 IU/L.

prophylaxis is that individuals with factor levels of greater than 0.02 IU/mL (20 IU/L) rarely suffer from spontaneous bleeds and arthropathy. Therefore, to maintain a trough level above this might convert “severe” hemophilia to “moderate” disease, with the abolition of joint bleeds and the associated arthropathy.⁷

Although primary prophylaxis is expensive, historical cohorts show progressively better outcomes (joint function and radiologic appearances) with its use. The Medical and Scientific Advisory Council of the National Hemophilia Foundation of the United States recommends primary prophylaxis in patients with severe hemophilia A and B (factor VIII or factor IX less than 1%). The optimal duration of prophylactic therapy is unknown.^{8,9} Vaccination against hepatitis A and B is recommended in all hemophiliacs.

► Nonpharmacologic Therapy

Supportive Care Rest, ice, compression, elevation (RICE) can be used during the bleeding episode, following with casts, splints, and crutches after the bleeding has been controlled.

Surgery Surgical arthroscopic synovectomy reduces replacement therapy-resistant disease and repetitive hemiarthrosis of a single joint. This procedure removes inflamed joint tissue. Patients may have decreased range of motion after the surgery.

Orthotics Joint prostheses do not deal with the deformities directly. Orthotics in hemophilia serve as an important supportive measure before or after surgery.

Clinical Presentation and Diagnosis of Hemophilias A and B

Hemophilias A and B are clinically indistinguishable.

Symptoms

- Ecchymoses
- **Hemarthrosis**—bleeding into joint spaces^a (especially knee, elbow, and ankle)
 - Joint pain, swelling, and erythema
 - Cutaneous warmth
 - Decreased range of motion
- Muscle hemorrhage
 - Swelling
 - Pain with motion of affected muscle
 - Signs of nerve compression

- Potential life-threatening blood loss, especially with thigh bleeding
- Mouth bleeding with dental extractions or trauma
- Genitourinary bleeding
- GI bleeding
- Hematuria
- Intracranial hemorrhage (spontaneous or following trauma), with headache, vomiting, change in mental status, and focal neurologic signs
- Excessive bleeding with surgery

^aHallmark of hemophilia; recurrent inadequately managed hemarthrosis leads to deformity and chronic pain (hemophilic arthropathy).

► **Pharmacologic Therapy****Hemophilia A**

DDAVP. Primary therapy is based on disease severity and type of hemorrhage.¹⁰ Most patients with mild to moderate disease and a minor bleeding episode can be treated with 1-desamino-8-D-arginine vasopressin (desmopressin acetate [DDAVP]), a synthetic analog of the antidiuretic hormone, vasopressin. DDAVP causes release of von Willebrand's factor (vWF) and factor VIII from endothelial storage sites. DDAVP increases plasma factor VIII levels by three- to five-fold within 30 minutes. The recommended dose is 0.3 mcg/kg IV (in 50 mL of normal saline infused over 15 to 30 minutes) or subcutaneously (in less than 1.5 mL) or 150 to 300 mcg intranasally via concentrated nasal spray every 12 hours. Peak effect with intranasal administration occurs 60 to 90 minutes after administration, which is somewhat later than with IV administration. Desmopressin infusion may be administered daily for up to 2 to 3 days. Facial flushing, hypertension or hypotension, GI upset, and headache are common side effects of desmopressin. Water retention and hyponatremia may occur; patients should be instructed to limit water intake while taking desmopressin. Serious side effects include seizures related

to hyponatremia, most frequently seen in children younger than 2 years of age, and myocardial infarction in the elderly. Tachyphylaxis, an attenuated response with repeated administration, may occur after several doses.¹¹

According to the manufacturer, use of DDAVP is contraindicated in patients with creatinine clearance less than 50 mL/min (0.83 mL/s); however, it has been used off label in patients with impaired renal function.

Antifibrinolytic Therapy. Aminocaproic acid and tranexamic acid are antifibrinolytic agents that reduce plasminogen activity leading to inhibition of clot lysis and clot stabilization. These agents are usually used as adjuncts in dental procedures or in difficult-to-control **epistaxis** and menorrhagia episodes.

Factor VIII Replacement. Patients with severe hemophilia may receive primary (before the first major bleed) or secondary (after the first major bleed) prophylaxis. All hemophiliacs with a major bleed require factor VIII replacement.¹² The therapy may include recombinant (produced via transfection of mammalian cells with the human factor VIII gene) or plasma-derived (concentrate from pooled plasma) factor VIII (Table 67-2). The choice of product and dose are based on the overall clinical scenario because the efficacy of various

Table 67-2**Factor Concentrates**

Brand Name	Product Type	Viral Inactivation or Exclusion Method	Other Contents
Factor VIII Concentrates			
Alphanate	Plasma	Solvent detergent, dry heat	Albumin, heparin, vWF

Bebulin VH	Plasma	Vapor heat	Heparin, II, IX, X
Profilnine SD	Plasma	Solvent detergent	II, VII, IX, X
Proplex T	Plasma	Dry heat	Heparin, II, VII, IX, X
Other			
NovoSeven RT	Recombinant VII	None	Sucrose
Wilate	Plasma vWF/VIII complex	Solvent detergent and dry heat	Sucrose

APCC, activated prothrombin complex concentrate; PCC, prothrombin complex concentrate; vWF, von Willebrand's factor.

Table 67-3

Guidelines for Replacement Dosing with Factor VIII and Factor IX

Type of Hemorrhage	Desired Plasma Factor VIII	Desired Plasma Factor IX	Duration of Therapy (days)
	Level (% of Normal)	Level (% of Normal)	
CNS, intracranial, retropharyngeal, retroperitoneal, surgical prophylaxis	80–100	80–100	Factor VIII: every 8–12 hours over 10–14 days Factor IX: every 12 hours over 10–14 days
Mild hemarthrosis, mucosal (e.g., epistaxis), superficial hematoma	30	20–30	Factor VIII: every 8–12 hours over 1–2 days Factor IX: every 12–24 hours over 1–2 days

preparations does not differ. Newer generation plasma-derived coagulation factor concentrates are considerably safer owing to advancements in viral testing and inactivation technology. Although original recombinant factor VIII concentrates were stabilized with human serum albumin, potentially creating a source for viral contamination, new-generation recombinant factor VIII concentrates are stabilized with sucrose, eliminating the concern for viral transmission.

The severity of hemorrhage and its location are major determinants of percentage correction to target, as well as duration of therapy (Table 67-3). The normal range of factor VIII activity level is 1 IU/mL (1000 IU/L), which corresponds to 100% of the factor found in 1 mL of normal plasma. Minor bleeding may be treated with a goal of 25% to 30% (0.25 to 0.30 IU/mL [250 to 300 IU/L]) of normal activity, whereas serious or life-threatening bleeding requires greater than 75% of normal activity. Factor VIII is a large molecule that remains in the intravascular space, and its estimated volume of distribution is approximately 50 mL/kg. Generally, factor VIII levels increase by 2% (0.02 IU/mL [20 IU/L]) for every 1 unit/kg of factor VIII concentrate infused. To calculate factor VIII replacement dose, the following equation can be used:

$$\begin{aligned} \text{Dose of factor VIII (units)} \\ = \text{weight (kg)} \times (\text{desired percentage increase}) \times 0.5 \end{aligned}$$

Thus, to increase factor VIII levels by 50% (e.g., from 0 to 50%) in a 70-kg (154-lb) patient, an IV dose of 1,750 units is required. The half-life of factor VIII ranges from 8 to 15 hours. Half the initial dose is given every half-life (every 8 to 12 hours) to maintain the desired factor VIII level.¹³ Although intermittent bolus infusions of factor VIII concentrates have been used successfully, continuous-infusion protocols are being instituted successfully in patients requiring prolonged treatment of acute hemorrhage to avoid dangerously low trough levels and decrease the overall cost of therapy. Factor VIII can be administered as a continuous infusion at 2 to 4 units/kg/h with daily factor level monitoring to ensure appropriate rate of infusion.^{14,15}

► Hemophilia B

Factor IX Replacement Hemophilia B therapy may include recombinant (produced via transfection of mammalian cells with the human factor IX gene) or plasma-derived (concentrate from pooled plasma) factor IX (see Table 67-2). Guidelines for choosing the factor-concentrate formulation

for hemophilia B are similar to the guidelines for hemophilia A. However, older generation factor IX concentrates containing other vitamin K-dependent proteins (e.g., factors II, VII, and IX), called prothrombin complex concentrates (PCCs), have been associated with thrombogenic side effects. Consequently, these products are not first-line treatment for hemophilia B. Because it is a small protein, the factor IX molecule passes into both the intravascular and the extravascular spaces. Therefore, the volume of distribution of recombinant factor IX is twice that of factor VIII. Consequently, 1 unit of factor IX administered per kilogram of body weight yields a 1% rise in the plasma factor IX level (0.01 IU/mL [10IU/L]). To calculate the factor IX replacement dose, the following equation can be used:

$$\begin{aligned} \text{Dose of factor IX (units)} \\ = \text{weight (kg)} \times (\text{desired percentage increase}) \times F \end{aligned}$$

Where F = 1 for human plasma-derived products and 1.2 for recombinant factor IX.

Thus, to increase factor IX levels by 50% (e.g., from 0 to 50%) in a 70-kg (154-lb) patient, the required dose of factor IX is 4,200 units IV (using the recombinant factor IX product). The half-life of factor IX ranges from 18 to 22 hours; therefore, doses are given every 12 to 24 hours.

► Treatment of Patients with Factor VIII or IX Inhibitors

Factor VIII and IX inhibitors are antibodies that develop in 20% and 5% of hemophilia A and hemophilia B patients, respectively, in response to replacement therapy. These antibodies bind to and neutralize the activity of infused factor concentrates. Although the inhibitors do not increase hemorrhage frequency, their existence challenges the treatment of bleeding episodes. Titers of inhibitors are measured and reported in Bethesda units (BU), and this measurement is used to guide therapy (Fig. 67-2). Management options for acute bleeding in patients with factor inhibitors include the administration of factor VIII concentrates, PCCs, recombinant factor VIIa (rFVIIa), and porcine factor VIII (currently, recombinant porcine factor VIII is in phase II/III clinical trials in the United States). Immune tolerance induction can be attempted to prevent future bleeding episodes.

Factor VIII concentrates can be used in patients with low inhibitor levels to control acute bleeding episodes. The dose

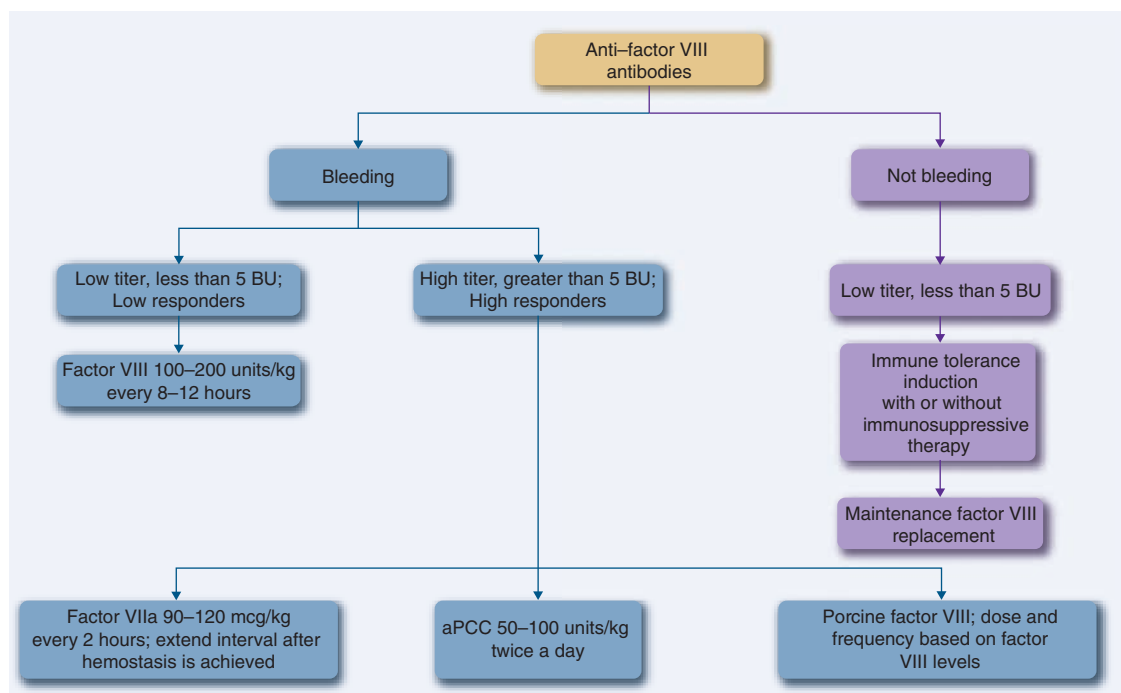

FIGURE 67-2. Treatment algorithm for the management of patients with hemophilia A and factor VIII antibodies. Porcine factor VIII is not available in the United States; recombinant porcine factor VIII is currently in phase II/III clinical trials. (BU, Bethesda unit; aPCC, activated prothrombin complex concentrate.) (Modified from DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*. 8th ed. New York: McGraw-Hill; 2011:1751, Figure 110–3.)

of factor VIII is determined based on clinical response (see Fig. 67–2).

PCCs contain the vitamin K–dependent factors II, VII, IX, and X. These agents bypass factor VIII at which the antibody is directed (see Fig. 67–2). However, PCCs carry the risk of serious thrombotic complications.

Factor VIIa (rFVIIa) is a bypassing agent designed to generate thrombin only at tissue injury sites, where it binds tissue factor. Due to its local action, rFVIIa is associated with fewer systemic thrombotic events than PCC. rFVIIa is used effectively in surgeries and spontaneous bleeds.¹⁶

Plasma-derived porcine factor VIII participates in the coagulation cascade in place of human factor VIII. However, due to contamination with parvovirus, it is no longer available. Recombinant porcine factor VIII is currently under review and could serve as a third-line agent (only after factor VIIa and a PCC have failed) owing to the relatively high incidence of cross-reactivity with factor VIII inhibitors.

Induction of immune tolerance is often performed with the goal of eliminating the inhibitor. Immune tolerance induction is accomplished by the administration of repetitive doses of factor VIII or IX with or without immunosuppressive therapy. It is effective in 70% of patients with hemophilia A and 30% of patients with hemophilia B.

Pain Associated with Hemophilia

Pain commonly occurs in patients with hemophilia. Acute bleeding episodes and long-term joint destruction

are common sources of pain. Acetaminophen and opioid analgesics are recommended to control mild to moderate and severe pain, respectively. Nonsteroidal anti-inflammatory drugs and aspirin should be avoided if possible, because these drugs bind to platelets and increase the risk of bleeding episodes. Cyclooxygenase-2 (COX-2) inhibitors can be used with caution.¹⁷

Outcome Evaluation

The main goal of hemophilia treatment is to prevent bleeding episodes and their long-term complications. Clinicians should evaluate patients for the following:

- Musculoskeletal status, including joint range of motion and radiologic assessment, as indicated.
- Number and type of bleeding episodes to assess adequacy of prophylactic treatment and home therapy.
- Use of clotting-factor concentrates to check for the development of inhibitors, especially in patients with severe disease and poor treatment responders.

VON WILLEBRAND'S DISEASE

Epidemiology and Etiology

von Willebrand's disease (vWD) is the most common inherited bleeding disorder caused by a deficiency or dysfunction of vWF. It is classified based on the quantitative deficiency of vWF or qualitative abnormalities of vWF.

Table 67-4

Classification of vWD

Phenotype	Mechanism of Disease	Percentage of Cases	Genetic Transmission
Type 1 vWD	Partial (mild to moderate) quantitative deficiency of vWF and factor VIII	70–80	Autosomal dominant
Type 2 vWD	Qualitative abnormalities of vWF	10–30	
2A	Decreased platelet-dependent vWF function owing to lack of larger multimers	10–15	Autosomal dominant (or recessive)
2B	Increased platelet-dependent vWF function owing to lack of larger multimers	Uncommon	Autosomal dominant
2M	Defective platelet-dependent vWF functions not associated with multimer defects	Uncommon	Autosomal dominant (or recessive)
2N	Defective vWF binding to factor VIII	Uncommon	Autosomal recessive
Type 3 vWD	Severe quantitative deficiency of vWF	Rare	Autosomal recessive

The disease prevalence is estimated at 30 to 100 cases per million. In contrast to hemophilia, the majority of vWD cases are inherited as an autosomal dominant disorder, ensuing equal frequency in males and females.¹⁸

Pathophysiology

vWF is a large multimeric glycoprotein with two main functions in **hemostasis**: to aid platelet adhesion to injured blood vessel walls and to carry and stabilize factor VIII in plasma. **Table 67-4** represents three main vWD phenotypes, their frequency, and genetic transmission.¹⁹

Treatment

► *Desired Outcomes*

Unlike hemophilia, the bleeding tendency in vWD is less frequent and generally less severe. Consequently, chronic

prophylaxis is usually unwarranted. The goal of two mainstay therapeutic options in vWD is:

- To stop spontaneous bleeding as necessary
- To prevent surgical and postpartum bleeding

► *Nonpharmacologic Therapy*

Local measures, including pressure and ice, may be used to control superficial bleeding.

► *Pharmacologic Therapy*

Systemic therapy is used to prevent bleeding associated with surgery, childbirth, and dental extractions and to treat bleeding that cannot be controlled with local measures. The two systemic approaches involve using desmopressin, which stimulates the release of endogenous vWF, or administering products that contain vWF. The general approach to the

Clinical Presentation and Diagnosis of vWD

Clinical manifestations vary depending on the subtype. Patients with mild disease may be asymptomatic into adulthood.

Symptoms

- Bruising
- Mucocutaneous bleeding
 - Epistaxis
 - Oral cavity bleeding
 - Menorrhagia
 - GI bleeding
- Joint and deep tissue bleeding
- Postoperative bleeding

Laboratory Testing

- Low or normal von Willebrand's factor antigen concentration in plasma (vWF:Ag)
- Low or normal factor VIII coagulation assay (FVIII:C)^a
- Low ristocetin cofactor activity (vWF:RCO)^b

^aFactor VIII coagulation assay measures the ability of vWF to bind and maintain adequate levels of factor VIII.

^bRistocetin cofactor activity (vWF:RCO) assay measures the ability of vWF to interact with intact platelets (normal 50–200 IU/dL).

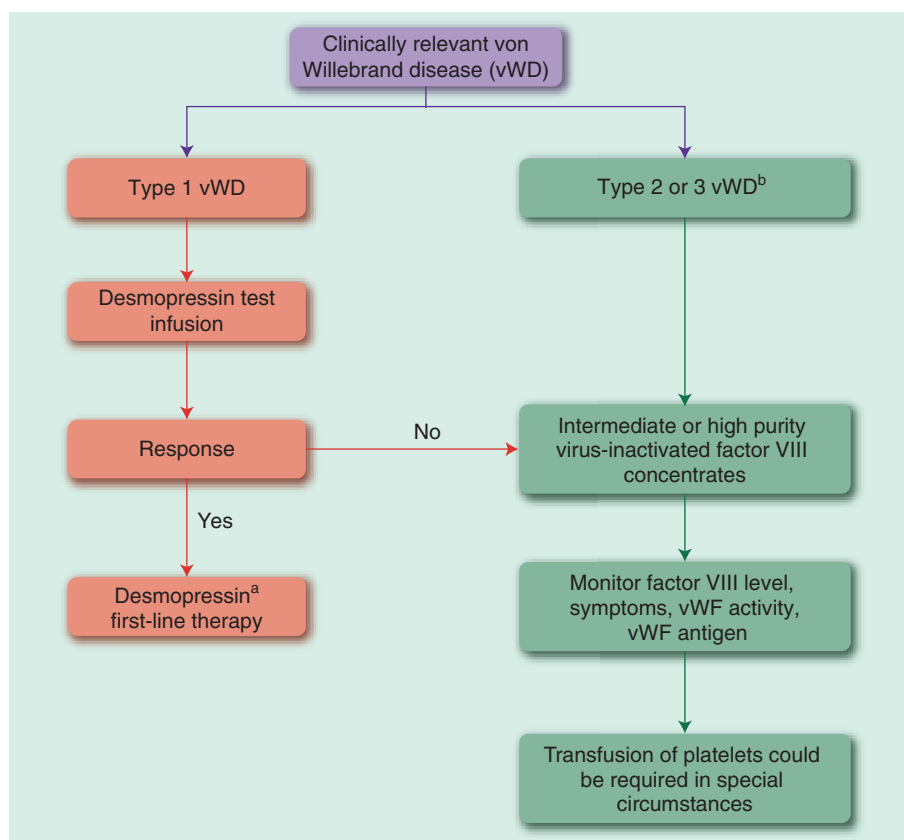

FIGURE 67-3. Guidelines for the treatment of vWD. ^aUse factor VIII concentrate for life-threatening bleeding. ^bSome patients with type 2 or 3 vWD may respond to desmopressin. (From DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*. 8th ed. New York: McGraw-Hill; 2011:1754, Figure 110–4.)

treatment of vWD is depicted in [Figure 67-3](#). In 2008, The National Heart, Lung, and Blood Institute issued comprehensive evidence-based guidelines for the diagnosis and management of vWD.²⁰

- **DDAVP** Most patients with type 1 vWD (functionally normal vWF) and a minor bleeding episode can be treated successfully with desmopressin, which induces release of factor VIII and vWF from endothelial cells through interaction with vasopressin V2 receptors. The recommended dose is the same as that used to treat mild factor VIII deficiency (0.3 mcg/kg IV in 50 mL of normal saline infused over 15 to 30 min or 150 to 300 mcg intranasally via concentrated nasal spray every 12 hours). This therapy is generally ineffective in type 2A patients, who secrete abnormal vWF, and is controversial in type 2B patients because it may increase the risk of postinfusion thrombocytopenia. Type 3 vWD patients who lack releasable stores of vWF do not respond to DDAVP therapy.²¹

The individual responsiveness to desmopressin is consistent, and a test dose administered at the time of diagnosis or prior to therapy is the best predictor of response. Generally, DDAVP is more effective in vWD than in hemophilia patients, with an average two- to five-fold increase in vWF and factor VIII levels over baseline. In patients with an adequate response, desmopressin is first-line therapy because

it allows for once-daily administration (elevates plasma levels for 8 to 10 hours), does not pose a threat in terms of viral transmission, and costs substantially less than that of the plasma-derived products.

- **Antifibrinolytic Therapy** Fibrinolysis inhibitors and oral contraceptives are used successfully in the management of epistaxis and menorrhagia or as adjuvant treatments. Fibrinolysis inhibitors include aminocaproic acid (25 to 60 mg/kg orally or IV (or 4 to 5 g) every 4 to 6 hours, to a maximum dose of 24 g/day) and tranexamic acid (10 mg/kg IV every 8 hours). Oral tranexamic acid recently received FDA approval for the treatment of cyclic heavy menstrual bleeding; its use is currently not approved for vWD patients. The IV form of tranexamic acid given as swish and swallow or spit every 6 to 8 hours has been used as bleeding prophylaxis in dental surgery. Both aminocaproic acid and tranexamic acid are dose adjusted for patients with renal insufficiency.
- **Replacement Therapy** ② *Type 1 patients unresponsive to desmopressin, patients with types 2 and 3 vWD, and major surgery patients require replacement therapy with plasma-derived, intermediate- and high-purity factor VIII virus-inactivated factor VIII concentrates containing vWF.*
Table 67-5 provides typical dosing guidelines and target levels of replacement therapy—concentrates to control various

Table 67-5

Replacement Therapy in vWD

Condition	Therapy	Recommended Dosage
Major surgery	Maintain vWF:RCo and factor VIII levels at least 100 IU/dL (1000 IU/L) followed by 50 IU/dL (500 IU/L) for 7–14 days To minimize risk of thrombosis: vWF:RCo levels should not exceed 200 IU/dL (2000 IU/L), and factor VIII levels should not exceed 250 IU/dL (2500 IU/L)	40–60 units/kg ^a loading dose, followed by 20–40 units/kg every 8–24 hours DDAVP may be added after a few days
Minor surgery	Prophylaxis: maintain vWF:RCo and factor VIII levels at least 30 IU/dL (300 IU/L) (preferably greater than 50 IU/dL [greater than 500 IU/L]) Minor surgery: maintain vWF:RCo and factor VIII levels at least 30 IU/dL (300 IU/L) (preferably greater than 50 IU/dL [greater than 500 IU/L]) for 3–5 days	30–60 units/kg loading dose, followed by 20–40 units/kg every 12–48 hours DDAVP may be added after a few days

^avWF concentrates are dosed based on vWF:RCo units concentration in the preparation to achieve the desired vWF:RCo levels.

types of hemorrhage. Ultra-high-purity (monoclonal) plasma-derived and recombinant factor VIII concentrates do not contain vWF and should not be used in the treatment of vWD.

Outcome Evaluation

The main goal of vWF treatment is to prevent bleeding with surgery or dental procedures. Clinicians should evaluate patients every 6 to 12 months for the following:

- Number and type of bleeding episodes to assess the need for prophylactic treatment.
- Ensure adequate levels of vWF and factor VIII prior to minor and major surgical procedures and for the treatment of bleeding.

- Vaccination against hepatitis A and B is recommended in all patients with vWF deficiency.

OTHER CLOTTING FACTOR DEFICIENCIES

Etiology and Epidemiology

Recessively inherited coagulation disorders (RICDs) refer to relatively rare deficiencies in factor II, V, VII, and X to XIII resulting in either decreased clotting factor production or production of a dysfunctional molecule with reduced activity.²² The clinical severity of bleeding varies and generally is poorly correlated with the factor blood levels. [Table 67-6](#) illustrates these clotting factor deficiencies and some of their characteristics.

Table 67-6

Clotting Factor Deficiency Characteristics

Factor Deficient	Inheritance Pattern	Estimated Incidence	Laboratory Abnormalities	Severity and Site of Bleeding
II	Autosomal dominant or recessive	Extremely rare	Prolonged PT and aPTT	Mild to moderate umbilical cord, joint, and mucosal tract
V	Autosomal recessive	1:1,000,000	Prolonged PT and aPTT	Mild to moderate mucosal tract
VII	Autosomal recessive	1:500,000	Prolonged PT	Mild to severe mucosal tract and joint
X	Autosomal recessive	1:1,000,000	Prolonged PT and aPTT	Mild to severe umbilical cord, joint, and muscle
XI	Autosomal recessive	4% of Ashkenazi Jews; otherwise rare	Prolonged aPTT	Mild to moderate posttraumatic bleeding
XII	Unknown	Unknown	Prolonged aPTT	No bleeding
XIII	Autosomal recessive	Less than 1:2,000,000	Normal PT and aPTT	Moderate to severe umbilical cord, intracranial, and joint bleeding; recurrent miscarriages, impaired wound healing

aPTT, activated partial thromboplastin time; PT, prothrombin time.

Pathophysiology

The RICDs are rare genetic disorders. Mutations in the genes responsible for the respective clotting factors result in impaired functionality or production of the factor.

Treatment

► Desired Outcomes

Therapeutic options for RICDs improve hemostasis via replacement of deficient blood coagulation factors while minimizing the development of immune tolerance.²³

Hemostatic levels should be maintained for the following conditions:

- Spontaneous bleeding—until bleeding stops
- Minor surgery—for 2 to 3 days
- Major surgery—until incision site has healed

► Nonpharmacologic Therapy

Transfusional Therapies **3** *The primary treatment of RICDs is single-donor fresh-frozen plasma (FFP) that contains all coagulation factors.* Disadvantages of FFP treatment include the risk of the patient becoming volume overloaded, especially when repeated infusions are administered to improve and maintain hemostasis; risk of infections; and risk of inhibitor development. PCCs licensed for the treatment of hemophilia B also contain significant levels of vitamin K-dependent factors and may be used off label for treatment of RICD. **Table 67-7** lists the recommended RICD treatment schedules in different clinical scenarios.

► Pharmacologic Therapy

Less severe hemorrhages may be treated successfully with antifibrinolytic amino acids alone or in combination with factor replacement therapy. Tranexamic acid and aminocaproic acid may be administered IV or orally (for doses, see von Willebrand's Disease, Pharmacologic Therapy above).

ACQUIRED COAGULATION DISORDERS

DISSEMINATED INTRAVASCULAR COAGULATION

Etiology and Epidemiology

Disseminated intravascular coagulation (DIC) is a systemic thrombohemorrhagic disorder characterized by an increased propensity for clot formation secondary to a wide variety of clinical conditions (**Table 67-8**). Central to the etiology of DIC is excessive and unregulated generation of thrombin, leading to an aggressive compensatory **fibrinolysis**. Therefore, clinical manifestations of DIC result from a loss of balance between the clot-promoting (leading to thrombosis) and the clot-lysing (leading to hemorrhage) systems. Although this balance may tip in either direction, presenting as bleeding or clotting, bleeding is most common. Incidence of bleeding, end-organ dysfunction, and other manifestations depend on the etiology of DIC.²⁴

Pathophysiology

Once injured or activated by a toxic substance (e.g., bacterial toxins, placenta chemicals, snake venom, etc.), endothelial cells and monocytes respond by generating tissue factor on the cell surface. Generation of tissue factor-factor VIIa complexes leads to extrinsic pathway activation, excessive generation of thrombin and fibrin, generation of systemic microthrombi, and consumption of coagulation factors and platelets. In addition, inhibition of naturally occurring endothelium-linked anticoagulant pathways (e.g., antithrombin, protein C, and tissue factor pathway inhibitor) and fibrinolytic system (due to a rise in plasminogen activator inhibitor, PAI-1 concentrations) leads to a vast procoagulant state. Although bleeding into the subcutaneous tissues, skin, and mucous membranes takes place, microvascular thrombosis exacerbates tissue ischemia and organ damage.²⁵

Table 67-7

Treatment of Factor Deficiencies

Factor Deficient	Major Surgery	Spontaneous Bleeding
II	1. PCC: 20–30 units/kg 2. FFP: 15–20 mL/kg	1. FFP: 15–20 mL/kg
V	1. FFP: 15–20 mL/kg	1. FFP: 15–20 mL/kg

Treatment► **Desired Outcomes**

4 The cornerstone of the management of DIC is aggressive treatment of the underlying primary illness. Supportive measures may be used as necessary, but owing to the

heterogeneity of DIC etiology, treatment should be guided by predominant symptoms (bleeding or clotting).²⁶

Goals of DIC treatment include:

- Replace missing blood components
- Interrupt coagulation
- Treat underlying disease

Clinical Presentation of DIC

Clinical manifestations generally are associated with underlying primary illness, as described in Table 67-8.

Signs and Symptoms

- Thrombosis, hemorrhage, or both
- Hemorrhagic bullae
- Peripheral cyanosis
- Petechiae and purpura

Thrombus and End-Organ Dysfunction

- Skin
- Lungs
- Kidneys

- Liver
- Adrenal glands
- Heart
- Evidence of end-organ dysfunction or failure

Laboratory Testing

- Increased D-dimer
- Thrombocytopenia
- Decreased fibrinogen
- Increased fibrin degradation products (FDP)
- Increased prothrombin time (PT)

Patient Encounter 1, Part 1: DIC

A 74-year-old man with a history of chronic obstructive pulmonary disease (COPD) and coronary artery disease (CAD) was admitted to the intensive care unit with severe COPD exacerbation that required mechanical ventilation. Upon admission, his arterial blood gas analysis showed acute on chronic respiratory acidosis. His other laboratory parameters were within normal limits. After 4 days of invasive mechanical ventilation, he started having episodes of fever and hypotension and had to be started on vasopressor support. Peripheral blood cultures show gram-positive cocci in clusters.

What are this patient's risk factors for disseminated intravascular coagulation (DIC)?

What additional information do you need to create a treatment plan for this patient?

What is the most important intervention at this time?

Antithrombin concentrate has been evaluated in clinical trials and has not been associated with reduced mortality in septic patients. rFVIIa can be used in DIC after all other options fail; however, its efficacy and toxicity is not supported by sufficient clinical data.

Platelets and FFP Treatment with platelet concentrates and plasma is indicated in patients who are bleeding or who require an invasive procedure. In a bleeding patient, the platelet count should be maintained above $50 \times 10^3/\text{mm}^3$ ($50 \times 10^9/\text{L}$), and platelet concentrates should be given at a dose of 1 unit/10 kg of body weight. For patients who are not bleeding, a lower threshold of less than 10 to $20 \times 10^3/\text{mm}^3$ or less than 10 to $20 \times 10^9/\text{L}$ is used. FFP contains all the coagulant factors as well as fibrinogen. Adding fibrinogen to the blood system in a situation where the level of antithrombin is already low may predispose patients to widespread microvascular thrombosis and may aggravate end-organ damage. Therefore, FFP use is reserved for actively bleeding patients who have significantly elevated prothrombin time and a fibrinogen concentration less than 50 mg/dL (0.5 g/L). The recommended FFP dose is 10 to 15 mL/kg.

► Pharmacologic Therapy

Anticoagulants Although bleeding is the most frequently observed symptom of DIC, thrombotic events cause most of the mortality. Heparin is an effective anticoagulant that activates the antithrombin system and inhibits factors II (thrombin), IXa, and Xa; however, its use is limited by the potential for bleeding. Clinical trials of heparin in DIC have not shown a consistent improvement in organ function or mortality benefit; thus treatment-dose heparin is used infrequently in DIC management. DIC patients most likely to benefit from heparin are those with chronic symptomatic thromboemboli, extensive fibrin deposition, and solid tumors. Heparin is contraindicated in DIC patients with serious or life-threatening bleeding, such as intracranial bleeding.²⁷

Heparin may be given IV or subcutaneously; there is no universally accepted dose. Heparin administered subcutaneously for venous thromboembolism prophylaxis (5,000 units every 8 to 12 hours) can be beneficial in DIC patients without serious or life-threatening bleeding. Full-dose heparin therapy in adults is a bolus of 5,000 units, followed by a continuous infusion of 1,000 units/h. In general, full-dose heparin should be avoided in patients with DIC due to increased risk of bleeding, and a lower dose of 500 units/h can be used. Since the activated partial thromboplastin time (aPTT) is already elevated in many patients with DIC, monitoring heparin therapy may be difficult. Low-molecular-weight heparins can also be used in place of heparin. Venous thromboembolism prophylaxis is recommended in nonbleeding critically ill patients with DIC.²⁸

Patient Encounter 1, Part 2: DIC**Medications**

- Albuterol/ipratropium via nebulizer
- Methylprednisolone 40 mg IV every 6 hours
- Levofloxacin 750 mg IV every 24 hours
- Insulin via sliding scale SC
- Fentanyl 50 mcg/h continuous infusion
- Norepinephrine 10 mcg/min continuous infusion
- Heparin 5,000 U SQ every 8 hours
- Aspirin 325 mg po daily
- Clopidogrel 75 mg po daily
- Pantoprazole 40 mg IV every 24 hours

Laboratory findings

- Platelet count: $45 \times 10^3/\text{mm}^3$ ($45 \times 10^9/\text{L}$) (normal 140 – $440 \times 10^3/\text{mm}^3$ [140 – $440 \times 10^9/\text{L}$])
- aPTT: 50 seconds (normal 25–40 seconds)
- INR 4 (normal 0.8–1.2)
- D-dimer: 1 mcg/mL (1 mg/L; 5.5 nmol/L) (normal 0.250 mcg/mL [0.25 mg/L; 1.4 nmol/L])
- Fibrinogen: 0.7 g/L (normal 2–4 g/L)

Given this additional information, is this patient's presentation consistent with DIC?

Identify your treatment goals for this patient.

Patient Encounter 1, Part 3: DIC: Creating a Care Plan

Based on the information presented, create a care plan for this patient's DIC.

- **Cryoprecipitate** If FFP cannot maintain fibrinogen concentration above 100 mg/dL (1 g/L) in a symptomatic patient, cryoprecipitate may be administered. One bag of cryoprecipitate contains 200 mg of fibrinogen and will raise plasma fibrinogen level by about 0.07 g/L.²⁸

Outcome Evaluation

- With each therapeutic option, postinfusion monitoring parameters (platelets, prothrombin time [PT], aPTT, and fibrinogen) should be checked within 30 to 60 minutes and every 6 hours thereafter, and the dose should be adjusted accordingly.
- Monitor the patient for relief of symptoms and signs of hemorrhage.

PLATELET DISORDERS

IMMUNE THROMBOCYTOPENIC PURPURA

Etiology and Epidemiology

Immune (or idiopathic) thrombocytopenic purpura (ITP) is one of the most common causes of acquired thrombocytopenia. The estimated incidence is 100 cases per 1 million persons per year, about half of whom are children. ITP is an autoimmune disorder caused by the binding of antibodies (usually immunoglobulin G [IgG]) to platelet surface antigens, resulting in shortened platelet life span. ITP can occur as an isolated condition or secondary to an underlying disorder. Childhood-onset and adult-onset ITP present very differently. Adult-onset ITP is generally chronic (greater than 6 months) and affects women two to three times more often than men. By contrast, childhood-onset ITP is acute in onset and usually follows an infectious illness, and both sexes are equally affected. Childhood ITP typically resolves on its own within 4 to 6 weeks without major sequelae. In adults presenting with ITP, testing for human immunodeficiency virus (HIV) and hepatitis C virus (HCV) is recommended, because treating these infections may improve ITP course. ITP occurs in 1 to 2 of every 1,000 pregnancies. In pregnant women with preexisting ITP, both maternal and fetal complications may occur, requiring separate management.²⁹

Pathophysiology

In ITP, IgG autoantibodies bind to platelet-antigen complex and are cleared from the blood via binding to mononuclear

Clinical Presentation and Diagnosis of ITP

General

The typical patient is well with the exception of bleeding.

Symptoms

- **Petechiae**
- **Purpura**
- **Ecchymoses**
- Cutaneous bleeding
- Mucosal site bleeding
- Epistaxis
- Gingival bleeding
- Hematuria
- Intracranial hemorrhage (rare)

Laboratory Testing

- Normal or slightly elevated thrombopoietin
- Decreased hemoglobin, hematocrit, platelets
- Prolonged bleeding time
- Peripheral blood smear for abnormal platelets
- *Helicobacter pylori* testing
- HIV, HCV testing

phagocytes by macrophage Fc γ receptor, leading to thrombocytopenia. Platelet survival time is significantly shorter in patients with ITP (from minutes to 2 to 3 days compared with normal 7 to 10 days). Sequestration in spleen, liver, and bone marrow is partially responsible for decreased platelet survival. Megakaryopoiesis may be reduced due to antibody binding to megakaryocyte precursors in the bone marrow.

Patient Encounter 2, Part 1: ITP

TR is a 25-year-old woman with no known past medical history. She presents with complaints of increased menstrual blood loss and a recent oral mucosal bleeding that was slow to respond to placing ice cubes and swishing cold water in the mouth. A laboratory analysis reveals platelet count of $15 \times 10^3/\text{mm}^3$ ($15 \times 10^9/\text{L}$).

What information is suggestive of immune thrombocytopenic purpura (ITP)?

What additional information do you need to create a treatment plan for this patient?

Patient Encounter 2, Part 2: ITP**Meds at Home:** None**PMH:** None**PE:** Weight 60 kg**Labs**

- Platelet count: $15 \times 10^3/\text{mm}^3$ ($15 \times 10^9/\text{L}$) (normal $140\text{--}440 \times 10^3/\text{mm}^3$ [$140\text{--}440 \times 10^9/\text{L}$])
- aPTT: 30 seconds (normal 25–40 seconds)
- PT: 10 seconds (normal 10–12 seconds)
- Hemoglobin 10.8 g/dL (108 g/L or 6.70 mmol/L) (normal 13.8–17.2 g/dL or 138–172 g/L or 8.57–10.68 mmol/L)
- HCV antibody negative
- HIV negative

Given this additional information, is this patient's presentation consistent with ITP?

Identify your treatment goals for this patient.

Treatment**► Desired Outcomes**

In children, the main goal of ITP treatment is to maintain the platelet count associated with sufficient hemostasis, while awaiting spontaneous or treatment-induced remission. In adults, the main goal is to maintain platelet count greater than $30 \times 10^3/\text{mm}^3$ ($30 \times 10^9/\text{L}$), because below this count, the incidence of bleeding is increased.³⁰

► General Approach to Treatment

5 *The treatment of ITP is determined by the symptom severity. In some cases, no therapy is needed (Table 67–9). The initial treatment of children with ITP is controversial because greater than 75% to 80% of cases resolve spontaneously*

irrespective of pharmacologic intervention. Therapy may be given in children with severe hemorrhage or platelet counts less than $10 \times 10^3/\text{mm}^3$ ($10 \times 10^9/\text{L}$) and mucocutaneous bleeding. In adults, treatment is indicated when platelet counts are less than $30 \times 10^3/\text{mm}^3$ ($30 \times 10^9/\text{L}$).³⁰

► Nonpharmacologic Therapy

- In adults, splenectomy is generally considered after 3 to 6 months if the patient continues to require 10 to 20 mg/day of prednisone to maintain the platelet count greater than $30 \times 10^3/\text{mm}^3$ ($30 \times 10^9/\text{L}$). Splenectomy may also be considered for urgent treatment of neurologic symptoms or for managing relapse despite an adequate trial of corticosteroids, IV immunoglobulin (IVIg), or anti-Rh(D). Even though individual patient response cannot be predicted, approximately two-thirds of refractory adult patients have a favorable response to splenectomy within several days; however, 30% to 40% will have no response or will experience a relapse some time after splenectomy. In children, splenectomy is usually reserved due to the self-limited nature of ITP and
- fear of infectious complications of splenectomy. Splenectomy is recommended in children with ITP duration greater than 1 year with significant bleeding symptoms and unresponsive or intolerant of pharmacological therapies. Between 70% and 80% of children attain complete remission following splenectomy. Laparoscopic splenectomy is preferable to open splenectomy because it speeds the recovery and shortens the duration of hospitalization. The major drawback of splenectomy is bacterial sepsis, occurring at incidence rates of approximately 1%. Immunization with *Haemophilus influenzae* type b, pneumococcal, and meningococcal vaccines is indicated in all patients 2 weeks prior to splenectomy.³¹

► Pharmacologic Therapy

- The general approach to management of ITP in adults is summarized in Table 67–9.

Glucocorticoids Glucocorticoids may decrease splenic sequestration of antibody-coated platelets, diminish antibody

Table 67–9**Guidelines for the Management of Adult ITP**

Greater than 30×10^3 platelets/ mm^3 ($30 \times 10^9/\text{L}$), no bleeding	No treatment
First line	Prednisone (1–1.5 mg/kg/day)
Less than 30×10^3 platelets/ mm^3 ($30 \times 10^9/\text{L}$), bleeding symptoms	Anti-D immune globulin (75 mcg/kg/day, $\times 1$ dose) if corticosteroids contraindicated
Second line	IVIg (1 g/kg/day $\times 1$ dose, repeat as necessary) if corticosteroids contraindicated
Reserved for patients with bleeding symptoms and platelets less than 30×10^3 platelets/ mm^3 ($30 \times 10^9/\text{L}$) after an adequate trial of first-line agents	Splenectomy
	Rituximab (375 mg/ m^2 once weekly for 4 doses)
	Eltrombopag (25–75 mg daily)
	Romiplostim (1–10 mcg/kg)
	Immunosuppressants
Hemorrhage	Platelet transfusion
	IVIg (1 g/kg/day $\times 1$ dose, repeat as necessary)
	Methylprednisolone (1 g/day for 3 days)

generation by the spleen and the bone marrow, and increase platelet output by the bone marrow. In adults, the response rate to oral prednisone (1 to 1.5 mg/kg/day) is 50% to 75%, with patients usually responding within the first 2 to 3 weeks. In children, oral or parenteral corticosteroids (prednisone, dexamethasone, methylprednisolone) can be used; various dosage regimens have been studied with no specific dose or dosage regimen showing superiority.³²

IV Immunoglobulin (IVIg) IVIg impairs the clearance of platelets coated with IgG by activating inhibitory receptor FcγRIIb. Roughly 80% of adults will respond to IVIg, but remission usually is not sustained. In adults, use of IVIg (1 g/kg/day) is reserved for situations in which rapid increase in platelet count is necessary, for example, for severe life-threatening bleeding and platelet counts less than $5 \times 10^3/\text{mm}^3$ ($5 \times 10^9/\text{L}$), with extensive purpura. If treatment is indicated in children, a single dose of IVIg (0.8 to 1 g/kg) is usually effective. IVIg use is complicated by many serious adverse effects and high cost.

Anti-Rh(D) Anti-Rh(D) can be used only in Rh(D)-positive patients who have not had splenectomy. It is as efficacious as IVIg and is generally less expensive. The indications for use of anti-Rh(D) are identical to those for IVIg. Anti-Rh(D) is a desirable form of treatment in chronic ITP when the goal is to circumvent long-term exposure to corticosteroids. At doses of 50 to 75 mcg/kg/day, anti-Rh(D) may increase the platelet count in about 70% to 80% of children with ITP. Dosage adjustment is recommended based on hemoglobin levels. Response to anti-Rh(D) lasts about 3 to 5 weeks, and substantial numbers of patients treated repetitively with Rh(D) can postpone or avoid splenectomy. Rare fatal intravascular hemolysis has been reported with use of anti-Rh(D); special monitoring for this side effect is recommended.

Immunosuppressants Immunosuppressant therapy is generally utilized for patients who are refractory to or intolerant of all other ITP treatments. Rituximab (375 mg/m² once weekly for 4 doses) can induce long-term response in 18% to 35% of patients.³³ Progressive multifocal leukoencephalopathy has been rarely reported with rituximab use. Rituximab can be considered as a second- or third-line therapy in patients who have experienced treatment failure with corticosteroids, IVIg, or splenectomy. Azathioprine and cyclophosphamide produce response rates of 20% to 40% in adult patients who are treated for 2 to 6 months. Other medications used in ITP include vincristine, vinblastine, cyclosporine, danazol, and mycophenolate mofetil; due to major toxicities and lack of adequate evidence-based recommendations, their use is reserved for refractory ITP.

Thrombopoietic Growth Factors New treatment options for ITP include a thrombopoiesis-stimulating protein and a small-molecule thrombopoietin (TPO) receptor agonist. These agents stimulate the bone marrow to make enough platelets to overcome the body's premature destruction of platelets. Romiplostim and eltrombopag are two TPO mimetics that have been approved by the FDA for the treatment of thrombocytopenia in patients with chronic ITP who

have had an insufficient response to corticosteroids, immunoglobulins, or splenectomy. Use of TPO-mimetic agents is reserved for refractory ITP due to cost considerations, lack of durability of response after discontinuation, and limited knowledge of long-term side effects. Currently, these agents are not FDA approved for use in children.

Romiplostim is a TPO peptide mimetic that binds to and activates the human TPO receptor. As a once weekly subcutaneous injection, romiplostim stimulates megakaryopoiesis, resulting in enhanced platelet production. Initial dose of romiplostim is based on the actual body weight, adjusted weekly by increments of 1 mcg/kg until a maximum of 10 mcg/kg and the patient achieves a platelet count greater than or equal to $50 \times 10^3/\text{mm}^3$ ($50 \times 10^9/\text{L}$) as necessary to reduce the risk for bleeding. In clinical studies, most patients who responded to romiplostim achieved and maintained platelet counts greater than or equal to $50 \times 10^3/\text{mm}^3$ ($50 \times 10^9/\text{L}$), with a median dose of 2 mcg/kg. Both agents need to be discontinued if platelet counts do not increase after 4 weeks at a maximum dose.

Eltrombopag is a once-daily oral nonpeptide thrombopoietin receptor agonist with a low immunogenic potential that stimulates megakaryocyte proliferation and differentiation.

For most patients, the initial dose of eltrombopag is 50 mg once daily. The daily dose is subsequently adjusted to a maximum dose of 75 mg daily in order to achieve and maintain a platelet count greater than or equal to $50 \times 10^3/\text{mm}^3$ ($50 \times 10^9/\text{L}$) in order to reduce the risk for bleeding.

Romiplostim and eltrombopag are effective in increasing platelet counts in patients with ITP and can be used in combination with therapies that inhibit platelet destruction. Although usually well tolerated, a number of rare but serious risks have been reported, including changes in the bone marrow, worsened thrombocytopenia and the risk of bleeding after cessation of the medication, thrombotic/thromboembolic complications (including portal vein thrombosis with eltrombopag), and worsening of blood cancers. Eltrombopag carries a “black box warning” regarding hepatic toxicity. It is also associated with development of cataracts and has drug–drug interactions with antacids and several minerals (calcium, iron, aluminium, magnesium, selenium, zinc).

To enhance patient safety, both romiplostim and eltrombopag are available only through restricted access programs. For both programs, each institution must enroll in the program to receive drug and training kits, and only prescribers, pharmacists, and patients registered with the

Patient Encounter 2, Part 3: ITP: Creating a Care Plan

Based on the information presented, create a care plan for this patient. Please include whether pharmacologic therapy is indicated, and if so, please list first-line and alternative therapies.

program are able to prescribe, dispense, and receive the product, respectively.

Outcome Evaluation

- Monitor platelet counts as indicated clinically.
- In adults, the goal of therapy is to maintain platelet count greater than or equal to $30 \times 10^3/\text{mm}^3$ ($30 \times 10^9/\text{L}$).
- Monitor for signs and symptoms of bleeding.

THROMBOTIC THROMBOCYTOPENIC PURPURA

Etiology and Epidemiology

Thrombotic thrombocytopenic purpura (TTP) is a severe systemic disorder characterized by thrombi formation within the circulation that results in the platelet consumption and subsequent thrombocytopenia. Acute idiopathic TTP is more common in women and African Americans and most frequently occurs in people between 30 and 40 years of age. The estimated annual incidence of TTP is 3.8 cases per million.³⁴ Common conditions associated with TTP are summarized in [Table 67–10](#).

Pathophysiology

Endothelial cells normally synthesize vWF in the form of a high-molecular-weight multimer composed of smaller identical monomers. Each monomer is able to bind platelets, and the number of monomers on the vWF multimer is directly proportional to its platelet-binding capacity. Consequently, particularly adherent ultra-large molecules of the vWF (ULvWF) are broken down to smaller size by vWF-cleaving proteases such as ADAMTS13 (a disintegrin and metalloprotease with thrombospondin type 1 repeats) to avoid undesired clot formation. TTP results from genetic or acquired deficiency in the vWF-cleaving protease ADAMTS13 activity. This, in turn, elevates circulating levels of ULvWF, leading to inappropriate platelet agglutination. Thrombocytopenia develops because the rate of aggregated platelet consumption is faster than megakaryocyte bone marrow production. Microangiopathic hemolytic anemia

Clinical Presentation and Diagnosis of TTP

Typical Pentad of Symptoms (Rare That All Five Are Present)^a

1. Thrombocytopenia
 - Thrombocytopenic purpura
 - Bleeding
2. Fever
3. Microangiopathic hemolytic anemia
4. Neurologic symptoms
 - Headache, confusion, difficulty speaking, transient paralysis, numbness
5. Renal abnormalities
 - Proteinuria, hematuria, mild renal insufficiency

Laboratory Testing

- Decreased hemoglobin, hematocrit, and platelets
- Peripheral blood smear showing schistocytes
- Decreased serum haptoglobin
- Elevated lactate dehydrogenase (LDH)
- Elevated indirect bilirubin level
- Elevated reticulocyte count
- Normal PT and aPTT
- Elevated urine protein, red blood cells, and/or serum creatinine

^aTTP diagnosis can be based on the presence of thrombocytopenia and microangiopathic hemolytic anemia in the absence of other possible causes.

generally follows as a consequence of red blood cell damage by platelet clumps occluding the microcirculation. Occlusive ischemia of the brain or GI tract is common, and renal dysfunction may occur.

Table 67–10

Conditions Associated with TTP

- Infections
 - Bacterial, fungal, viral, atypical
- Transplantation
 - Solid organ or bone marrow
- Malignancy
- Pregnancy
- Collagen vascular diseases
- Medications
 - Antineoplastic agents, ticlopidine, clopidogrel, antibiotics, immunosuppressants, others

Patient Encounter 3, Part 1: TTP

A 35-year-old Hispanic woman is brought by her husband to the emergency department. He states that she had been complaining of headache, weakness, fever, and bloody nasal discharge over the past few days. He also noticed increased confusion and slurred speech today. She had undergone a liver transplantation 2 years ago, and her medication regimen had recently been adjusted to include tacrolimus.

What information could be suggestive of thrombotic thrombocytopenic purpura (TTP)?

What additional information do you need to create a treatment plan for this patient?

Patient Encounter 3, Part 2: TTP

Meds at Home: Tacrolimus 5 mg po twice daily; mycophenolate mofetil 1,500 mg po twice daily; dapsone 100 mg po daily; fluconazole 100 mg po daily.

PE: Wt 55 kg

Labs

- Platelet count: $11 \times 10^3/\text{mm}^3$ ($11 \times 10^9/\text{L}$) (normal $140\text{--}440 \times 10^3/\text{mm}^3$ [$140\text{--}440 \times 10^9/\text{L}$])
- aPTT: 30 seconds (normal 25–40 seconds)
- PT: 10 seconds (normal 10–12 seconds)
- Haptoglobin 10 mg/dL (100 mg/L) (normal 30–200 mg/dL or 300–2,000 mg/L)
- LDH 2,550 U/L (42.5 $\mu\text{kat}/\text{L}$) (normal 100–250 U/L, or 1.67–4.17 $\mu\text{kat}/\text{L}$)
- Hemoglobin 10.5 g/dL (105 g/L or 6.52 mmol/L) (normal 12.1–15.1 g/dL or 121–151 g/L or 7.51–9.37 mmol/L)
- Blood peripheral smear: numerous schistocytes (11–12 per high power field)
- Serum creatinine 2mg/dL (177 $\mu\text{mol}/\text{L}$) (increased from 0.8 mg/dL [71 $\mu\text{mol}/\text{L}$] on record 2 month prior) (normal 0.6–1.2 mg/dL [53–106 $\mu\text{mol}/\text{L}$])

Given this additional information, is this patient's presentation consistent with TTP?

What is the likely etiology of this patient's TTP?

Identify your treatment goals for this patient.

Patient Encounter 3, Part 3: TTP: Creating a Care Plan

Based on the information presented, create a care plan for this patient's TTP.

Treatment**► Desired Outcomes**

The main goal of TTP treatment is to prevent end-organ damage.

► Nonpharmacologic Therapy

- 6 The present standard of treatment for TTP is urgent plasma exchange (PEX). If PEX is unavailable, treatment with plasma infusion and glucocorticoids is indicated until PEX is available.³⁰

Plasma Exchange The procedure involves removal of the patient's plasma and its substitution with donor plasma. In this manner, circulating antibody inhibitor of ADAMTS13 is removed and enzyme is replenished. PEX involves placement of two IV lines (cannulae) into two separate veins. Blood removed through one cannula is centrifuged to separate the blood cells from the plasma. The blood cells are mixed subsequently with donor plasma and returned to the patient via the second cannula. The goal is to exchange 1 to 1.5 plasma volumes (40 to 60 mL/kg). The procedure generally

Patient Care and Monitoring

1. Obtain a complete history.
2. In a patient presenting with a bleeding or clotting disorder, an initial evaluation should include bleeding time, prothrombin time (PT), activated partial thromboplastin time (aPTT), thrombin time, and platelet count.
 - Activated partial thromboplastin time: aPTT is performed by adding calcium phospholipids and kaolin to citrated blood and measuring the time required for a fibrin clot to form. In this manner, aPTT measures the activity of intrinsic and common pathways. Prolongation of aPTT may be due to a deficiency or inhibitor for factors II, V, VIII, IX, X, XI, and XII. It also may be due to heparin, direct thrombin inhibitors, vitamin K deficiency, liver disease, or lupus anticoagulant.
 - Prothrombin time: PT is performed by adding thromboplastin (tissue) factor and calcium to citrate-anticoagulated plasma, recalcifying the plasma, and measuring the clotting time. The major utility of PT is to measure the activity of the vitamin K–dependent factors II, VII, and X. The PT is used in evaluation of liver disease, to monitor warfarin anticoagulant effect, and to assess vitamin K deficiency.
 - Thrombin time is an assessment of the time required for the appearance of the fibrin clot after thrombin is added to plasma. It may be affected by thrombin inhibitors or fibrinogen abnormalities. Most commonly, thrombin time is used to monitor fibrinolytic therapy.
 - Bleeding time indicates how well platelets interact with blood vessel walls to form blood clots by assessing the length of time to arrest the bleeding after a standardized skin cut. The bleeding time is prolonged in thrombocytopenia, fibrinogen disorders, and collagen defects.
3. After a diagnosis is made, institute specific therapy.
4. Monitor resolution of laboratory and clinical symptoms with treatment.

is repeated daily until neurologic symptoms resolve and normal lactate dehydrogenase (LDH) and platelet counts are maintained for several days. After complete remission is achieved, PEX frequency can be reduced to every other day for an additional few days, with subsequent PEX discontinuation and close patient follow-up. When PEX is started immediately upon diagnosis, remission and survival rates at 6 months are approximately 80%. Although generally considered safe, complications from catheter insertion or catheter infection may occur and include hemorrhage, pneumothorax, sepsis, and thrombosis. Allergic reactions to plasma can cause severe hypotension and hypoxia.³⁵

• **Splenectomy** Splenectomy is reserved for patients with frequently relapsing disease who are refractory to PEX or immunosuppressive therapy.

► Pharmacologic Therapy

• **Corticosteroids** Corticosteroids can be used for their immunosuppressive effect in combination with PEX; however, they are not as efficacious as monotherapy in TTP. The most commonly used agents are methylprednisolone 250 mg/day to 1 g/day IV for 3 days or prednisone 1 to 2 mg/kg/day orally for the duration of PEX therapy.

• **Immunosuppressants** TTP that fails to respond adequately to PEX can be treated with immunosuppressive agents. Cytotoxic immunosuppressive therapies with the most potential benefit in refractory TTP include cyclosporine and rituximab. Other agents that had been used include vincristine, cyclophosphamide, azathioprine, and IVIg.³⁰

Outcome Evaluation

Monitor platelet counts, hemoglobin, and LDH.

Abbreviations Introduced in This Chapter

ADAMTS13	A disintegrin and metalloprotease with thrombospondin type 1 repeats (vWF-cleaving metalloprotease)
BU	Bethesda units
DDAVP	1-Desamino-8-D-arginine vasopressin (desmopressin acetate)
DIC	Disseminated intravascular coagulation
FFP	Fresh-frozen plasma
HCV	Hepatitis C virus
ICH	Intracranial hemorrhage
ITP	Immune thrombocytopenic purpura
IVIg	IV immunoglobulin
PCC	Prothrombin complex concentrate
PEX	Plasma exchange
rFVIIa	Recombinant factor VIIa
RICD	Recessively inherited coagulation disorder
TTP	Thrombotic thrombocytopenic purpura
ULvWF	Ultra-large molecules of vWF
vWD	von Willebrand's disease
vWF	von Willebrand's factor

Sickle Cell Anemia

Tracy M. Hagemann and Teresa V. Lewis

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Explain the underlying causes of sickle cell disease (SCD) and their relationship to patient signs and symptoms.
2. Identify the typical characteristics of SCD as well as symptoms that indicate complicated disease.
3. Identify the desired therapeutic outcomes for patients with SCD.
4. Recommend appropriate pharmacotherapy and nonpharmacotherapy interventions for patients with SCD.
5. Recognize when chronic maintenance therapy is indicated for a patient with SCD.
6. Describe the components of a monitoring plan to assess effectiveness and adverse effects of pharmacotherapy for SCD.
7. Educate patients about the disease state, appropriate therapy, and drug therapy required for effective treatment and prevention of complications.

KEY CONCEPTS

- 1 Sickle cell disease (SCD) is an inherited disorder caused by a defect in the gene for hemoglobin. Patients may have one defective gene (sickle cell trait [SCT]) or two defective genes (SCD).
- 2 Although most often seen in persons of African ancestry, other ethnic groups can be affected.
- 3 SCD involves multiple organ systems.
- 4 Prophylaxis against pneumococcal infection reduces death during childhood.
- 5 Hydroxyurea has been shown to decrease the incidence of painful crises. However, the patient population that receives hydroxyurea should be carefully monitored.
- 6 Chronic transfusion therapy programs have been shown to be beneficial in decreasing the occurrence of stroke in children with SCD.
- 7 Patients with fever greater than 38.5°C (101.3°F) should be evaluated, and appropriate antibiotics should include coverage for encapsulated organisms, especially pneumococcal.
- 8 Pain episodes can usually be managed at home. Hospitalized patients usually require parenteral analgesics. Analgesic options include opioids, nonsteroidal anti-inflammatory agents, and

acetaminophen. The patient characteristics and the severity of the crisis should determine the choice of agent and regimen.

INTRODUCTION

1 “Sickle cell syndrome” refers to a collection of autosomal recessive genetic disorders that are characterized by the presence of at least one sickle hemoglobin gene (HbS).^{1,2}

Sickle cell disease (SCD) is a chronic illness that is associated with frequent crisis episodes. Acute complications are unpredictable and potentially fatal. Common symptoms include excruciating musculoskeletal pain, life-threatening pneumonia-like illness, cerebrovascular accidents, and splenic and renal dysfunction.² As the disease progresses, patients may develop organ damage from the combination of hemolysis and infarction. Because of the complexity and severity of SCD, it is imperative that patients have access to comprehensive care with providers who have a good understanding of the countless clinical presentations and the management options of this disorder.

EPIDEMIOLOGY AND ETIOLOGY

- Sickle cell trait (SCT) is the heterozygous form (HbAS) of SCD in which a person inherits one normal adult

hemoglobin (HbA) gene and one sickle hemoglobin (HbS) gene. These individuals are carriers of the SCT and are usually asymptomatic.² Symptomatic disease is seen in homozygous and compound heterozygous genotypes of SCD. Sickle cell anemia (SCA) is the homozygous (HbSS) state of SCD.² It is the most common and severe form of SCD. Compound heterozygosity is seen when individuals inherit one copy of the mutation that causes HbS and one copy of another abnormal hemoglobin gene. Compound heterozygosity may also include the coinheritance of HbS and one of the many different mutations of β -thalassemia (HbS β^0 -thalassemia and HbS β^+ -thalassemia).¹⁻³ SCA affects both males and females equally because it is not a sex-linked disease.

2 *Nine percent of African Americans possess the SCT and 1 in 600 has HbSS.*⁴ Two thousand infants are identified with SCD annually in the United States.⁵ For every infant diagnosed with SCD, 50 are identified as carriers.⁵ HbSS (approximately 45%) is the most common genotype, followed by HbSC (approximately 25%), HbS β^+ -thalassemia (approximately 8%), and HbS β^0 -thalassemia (approximately 2%). Other variants account for fewer than 1% of patients.^{2,5}

Having the sickle hemoglobin gene protects heterozygous carriers from succumbing to *Plasmodium falciparum* (malaria) infection.¹ The microorganism cannot parasitize abnormal red blood cells (RBCs) as easily as normal RBCs. Consequently, persons with heterozygous sickle gene (SCT) have a selective advantage in tropical regions where malaria is endemic.

The highest incidence of SCD is seen in those with African heritage, but SCD also affects persons of Indian, Saudi Arabian, Mediterranean, South and Central American, and Caribbean ancestry.^{5,6}

Normal adult hemoglobin (HbA) is composed of two α -chains and two β -chains ($\alpha_2\beta_2$).³ A single substitution of the amino acid valine for glutamic acid at position 6 of the β -polypeptide chain is responsible for the production of a defective form of hemoglobin called sickle hemoglobin (HbS).¹ Different genetic mutations encode for other hemoglobin variants such as hemoglobin C (HbC). HbC is produced by the substitution of lysine for glutamic acid at the sixth amino acid position in the β -globulin chain.³ The α -chains of HbS, HbA, and HbC are structurally identical. The chemical differences in the β -chain are responsible for RBC sickling and its associated sequelae.

SCA is the homozygous (HbSS) state of SCD in which individuals inherit the mutant hemoglobin gene (HbS) from both parents. The progeny of two carriers will have a 25% probability of having SCD and a 50% risk of being a carrier (Fig. 68-1). β -Thalassemia can be found in conjunction with HbS. Patients with HbSS and HbS β^0 -thalassemia do not have normal β -globulin production and usually have a more severe course than those with HbSC and HbS β^+ -thalassemia.

Impaired circulation, destruction of RBCs, and vascular stasis are three known problems that are primarily responsible for the clinical manifestations of SCD (Fig. 68-2).

FIGURE 68-1. Sickle gene inheritance scheme for both parents with sickle cell trait (SCT). Possibilities with each pregnancy: 25% normal (AA); 50% SCT (AS); 25% sickle cell anemia (SS). (A, normal hemoglobin; S, sickle hemoglobin.) (From Chan CYJ, Moore R. Sickle cell disease. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*. 8th ed. New York: McGraw-Hill; 2011.)

PATHOPHYSIOLOGY

Erythrocyte Physiology

A review of RBC physiology is important to understand the pathophysiology of SCD. Pediatric RBCs possess normal hemoglobin concentrations between 9.0 and 18.5 g/dL (90 and 185 g/L or 5.59 and 11.5 mmol/L), depending on the age of the child.⁷ Adult RBCs contain 12.0 to 15.5 g/dL (120 to 155 g/L or 7.45 to 9.62 mmol/L) hemoglobin.⁷ The predominant form of hemoglobin is adult hemoglobin or HbA (96%). Other forms of hemoglobin include HbA2 and fetal hemoglobin (HbF). HbA2 makes up less than 1% of hemoglobin in newborns. In adults, HbA2 constitutes approximately 1.6% to 3.5%.⁷ Fetal hemoglobin (HbF) is present primarily in fetal RBCs (60% to 90%), whereas adult RBCs contain less than 1% HbF.⁷ HbF is the primary oxygen transport protein in the fetus. After birth, only a small proportion of red cell clones remain to produce HbF. The elasticity of young erythroid cells enables them to deform and squeeze through capillaries. As RBCs age, mean corpuscular hemoglobin concentration (MCHC) increases, deformability decreases, and the cells are removed by the reticuloendothelial system.

3 *SCD involves multiple organ systems, and its clinical manifestations vary greatly between and among genotypes.*

Sickle Hemoglobin Polymerization

The primary event in the molecular pathogenesis of SCD involves polymerization of deoxygenated HbS. Since RBCs are packaged with such a high concentration of hemoglobin (32.0 to 34.0 g/dL, 320 to 340 g/L, or 19.9 to 21.1 mmol/L), it is important that the proteins be extremely soluble.¹ HbS carries oxygen normally, and when oxygenated, the solubility of HbS and HbA are the same. Once the oxygen

FIGURE 68-2. Pathophysiology of SCD. (Arg, arginine; ET-1, endothelin-1; Hb, hemoglobin; NO, nitric oxide; NOS, nitric oxide synthase; VCAM-1, vascular cell adhesion molecule 1; XO, xanthine oxidase.) (From Kato GJ, Gladwin MT. Sickle cell disease. In: Hall JB, Schmidt GA, Wood LDH, eds. Principles of Critical Care. 3rd ed. New York: McGraw-Hill; 2005:1658.)

is unloaded to the tissues, HbS solubility decreases. This promotes hydrophobic interactions between the hemoglobin molecules and polymerization, which leads to the distortion of the RBC into the characteristic crescent or sickle shape.¹ Polymerization of deoxy-HbS is influenced by the degree of red cell deoxygenation, MCHC, temperature, intracellular pH, intraerythrocytic HbS concentration, and intracellular HbF concentration.¹

Viscosity of Erythrocytes and Sickle Cell Adhesion

When HbS becomes reoxygenated, the polymers within the RBCs disappear, and the cells eventually return to normal shape. Vasoocclusion is caused by a combination of factors. Repeated assaults on RBCs from sickling and unsickling can lead to cell membrane damage, loss of membrane flexibility, and rearrangement of surface phospholipids. Damage to cell membranes can interfere with ion transport, leading to loss of potassium and water. This creates dehydrated, dense sickle cells and irreversible sickle cells (ISCs). ISCs are the densest cells, and they tend to remain sickled even when oxygenated. Rigid ISCs can become trapped in microvasculature, leading to cell fragmentation and chronic hemolysis, thus contributing to short survival of RBCs. The life span of sickled RBCs is markedly shorter (10 to 20 days) than that of normal RBCs (100 to 120 days). As intracellular membrane viscosity of HbS-containing RBCs increases, blood viscosity increases, which further contributes to vasoocclusion.⁸ There is also increasing evidence that suggest sickle cells adhere to vascular endothelium.^{1,8} The combined effects

of decreased RBC deformability, slow transit through microcirculation, and adhesion to vascular endothelium contribute to obstruction of small and sometimes large blood vessels. The resulting local tissue hypoxia can accentuate the pathologic process of SCD.

Protective Hemoglobin Types

Fetal hemoglobin binds oxygen more tightly than HbA, and it has a decreased propensity to sickling. HbA2 also possesses this characteristic but to a lesser extent. RBCs that contain HbF sickle less readily than cells without. ISCs are found to have low HbF concentrations. In some patients, higher HbF may ameliorate the disease.

Other Pathophysiologic Effects

Other factors may be responsible for the pathogenesis of some of the clinical features of SCD. Sick cells can obstruct blood flow to the spleen leading to functional asplenia. Impaired splenic function can increase the propensity to infection by encapsulated organisms, particularly *Streptococcus pneumoniae*.¹ Additionally, coagulation abnormalities are not uncommon since almost every component of hemostasis is altered in SCD.

TREATMENT

Desired Outcomes

- Multidisciplinary, regularly scheduled care is required over the lifetime of the SCD patient, with the goal of reduction

Clinical Presentation and Diagnosis of SCT

General

- Generally asymptomatic

Symptoms

- Females may have frequent urinary tract infections

Signs

- Microscopic hematuria occurs rarely
- Gross hematuria may occur spontaneously or with heavy-intensity exercise

Laboratory Tests

- Normal Hgb values

Clinical Presentation and Diagnosis of SCD

General

- Identified by neonatal screening before 2 months of age

Symptoms

- Painful vasoocclusive crises are the hallmark of SCD
- Dactylitis (hand–foot syndrome) before age 1 year
- May develop infarction of the spleen, liver, bone marrow, kidney, brain, and lungs
- Gallstones
- Priapism in males
- Slow-healing lower extremity ulcers after trauma or infection
- Weakness, fatigue

Signs

- Chronic hemolytic anemia is common
- Enlargement of spleen and heart
- Scleral icterus

Laboratory Tests

- Hgb 7.0 to 10.0 g/dL (70 to 100 g/L or 4.34 to 6.21 mmol/L)
- Low HgF and increased reticulocytes, platelets, and WBCs
- Presence of sickled cells on blood smear (see Fig. 68–2)
- Neonatal screening: hemoglobin electrophoresis, isoelectric focusing, or DNA analysis

of complications and hospitalizations. Comprehensive care should include medical, educational, and psychosocial aspects as well as genetic and medication counseling.

Therapeutic interventions for SCD should be targeted at preventing and/or minimizing the symptoms related to the disease and its complications. The goals of treatment are to reduce or eliminate the patient's symptoms; decrease the frequency of sickle crises, including vasoocclusive pain crises; prevent the development of complications; and maintain or improve the quality of life through decreased hospitalizations and decreased morbidity. Specific therapeutic options may:

- Maintain or increase the hemoglobin level to the patient's baseline
- Increase the HbF concentration
- Decrease the HbS concentration
- Prevent infectious complications
- Prevent or effectively manage pain
- Prevent CNS damage, including stroke

General Approach to Treatment

Patients should be educated to recognize the signs and symptoms of complications that would require urgent evaluation. Patients and parents of children with SCD should be educated to read a thermometer properly and to seek immediate medical care when a fever develops or signs of infection occur. With acute illnesses, prompt evaluation is important, as deterioration may occur rapidly. Fluid status should be monitored to avoid dehydration or overhydration, both of which may worsen complications of SCD. Patients in acute distress should maintain oxygen saturation at 92% (0.92) or at their baseline. Any supplemental oxygen requirements should be evaluated.⁵

Nonpharmacologic Therapy

Patients should avoid smoking and excessive alcohol intake. Patients with SCD should maintain adequate hydration in order to help decrease blood viscosity and should be educated to avoid extreme temperature changes and to dress properly in hot and cold weather. Physical exertion that leads to complications should be avoided.⁵ Regular exams, including ophthalmic, renal, pulmonary, and cardiac function, are required to monitor for organ damage. A treatment overview is shown in [Table 68–1](#).

Pharmacologic Therapy

► Health Maintenance

Immunizations Children with SCD should receive the required immunizations as recommended by the American Academy of Pediatrics and the Advisory Committee on Immunization Practices.⁹ Additionally, influenza vaccine should be administered yearly to SCD patients 6 months of age and older, including adult patients. Any SCD patient who

Table 68-1

Management of SCD	
	Options and Comments
Health maintenance	
Infection prophylaxis	<ul style="list-style-type: none"> • Pneumococcal vaccines (PCV 13 and PPV 23) • Penicillin prophylaxis for children less than 5 years of age • Annual influenza vaccine
Induction of fetal hemoglobin	<ul style="list-style-type: none"> • Hydroxyurea is the primary agent • Other agents are butyrates (arginine butyrate and sodium phenylbutyrate), decitabine, clotrimazole, and erythropoietin • Combination HbF inducers have been proposed
Chronic transfusion therapy	<ul style="list-style-type: none"> • Primary indication: stroke prevention in pediatric patients • May also reduce pain crisis and acute chest syndrome • Goal: maintain HbS less than 30% (0.30)
Future prospects	
Transplantation	<ul style="list-style-type: none"> • May potentially cure the disease • Most experience is with HLA-matched donors; umbilical cord blood transplantation is being evaluated
Crises and complications	
Fever and infection	<ul style="list-style-type: none"> • Broad-spectrum antibiotic: cefotaxime or ceftriaxone (clindamycin for cephalosporin allergy); vancomycin for staphylococcal and resistant pneumococcal organisms
Stroke	<ul style="list-style-type: none"> • Fluids • Acetaminophen or ibuprofen for fever • Exchange transfusion • Initiate chronic transfusion therapy to prevent recurrent strokes
Acute chest syndrome	<ul style="list-style-type: none"> • Broad-spectrum antibiotics (include Mycoplasma coverage) • Bronchodilator if wheezing or history of reactive airway disease • Fluids • Pain management
Pain crisis	<ul style="list-style-type: none"> • Transfusion • Hydration • Analgesics

is scheduled for splenectomy should receive the vaccine for meningococcal disease if over 2 years of age.⁹

Because patients with SCD have impaired splenic function, they are less adequately protected against encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Salmonella*.⁴ The use of pneumococcal vaccine in SCD patients has dramatically decreased the rates of morbidity and mortality; however, there are still groups of SCD children who continue to have high rates of invasive pneumococcal infections.¹⁰⁻¹² Infection is the leading cause of death in children younger than 3 years of age.^{4,12,13} Two pneumococcal vaccines are available. The 13-valent conjugate vaccine (PCV 13; Prevnar) is indicated for infants and children and provides good protection against the 13 most common isolates seen in this age range. Administer the first dose of PCV 13 between 6 weeks and 6 months of age, followed by two additional doses at 2-month intervals and a fourth dose at 12 to 15 months of age. The 23-valent polysaccharide vaccine (PPV 23; Pneumovax 23) is indicated for children over 2 years of age and adults. Because PPV 23 is a polysaccharide vaccine, children less than 2 years of age do not respond well. PPV 23 contains the 23 most common isolates of *S. pneumoniae* seen in older children and adults. Because of the different serotypes seen in the two vaccines, it is recommended that SCD children receive both vaccines, with a dose of PPV 23 administered after the child turns 2 years of age. The dose of PPV 23 should be separated from

the last dose of PCV 13 by at least 2 months. An additional dose of PPV 23 should be considered in children 3 to 5 years of age to ensure antibody response. All adults with SCD should be vaccinated once with PPV 23 also. Because some children fall behind on their childhood vaccinations, a catch-up schedule is presented in Table 68-2.⁹

Patient Encounter 1

A 3-year-old boy with SCD is currently taking penicillin V potassium 125 mg orally twice daily, folic acid 0.4 mg orally daily, and acetaminophen/codeine 120/12 mg per 5 mL orally every 6 hours as needed for pain. He fully completed all his routine childhood vaccinations at age 2 years. He was hospitalized 1 month ago for aplastic crisis.

What are the general pneumococcal prophylaxis recommendations for children with SCD?

What interventions do you want to make today to his medication/immunization regimens?

Design an infection prevention plan for this patient.

Table 68-2

Pneumococcal Immunization for Children with SCD¹⁰

Recommended Schedule

Previously unvaccinated

Age 2–6 months	PCV 13 (Prennar): three doses 8 weeks apart; then 1 dose at 12–15 months
Age 7–11 months	PCV 13 (Prennar): two doses 8 weeks apart; then 1 dose at 12–15 months
Age 12–23 months	PCV 13 (Prennar): two doses 8 weeks apart
Age 24–71 months	PCV 13 (Prennar): two doses 8 weeks apart
	PPV 23 (Pneumovax): two doses; first dose at least 8 weeks after last PCV 13 dose; second dose 5 years after the first PPV 23 dose
Age 5 years or older	PCV 13 (Prennar): one dose
	PPV 23 (Pneumovax): one dose at least 8 weeks after last PCV 13 dose; second dose 5 years after the first PPV 23 dose

Previously vaccinated

Age 12–23 months, incomplete PCV 13 series	PCV 13 (Prennar): two doses 8 weeks apart
Age 24–71 months, any incomplete schedule or completed less than 3 doses with PCV 13	PCV 13 (Prennar): two doses 8 weeks apart
	PPV 23 (Pneumovax): two doses; first dose at least 6–8 weeks after last PCV 13 dose; second dose 5 years after the first PPV 23
Age 24–71 months, any incomplete schedule of 3 doses or 4 doses of PCV 13	PCV 13 (Prennar): one dose at least 8 weeks after the most recent dose
	PPV 23 (Pneumovax): two doses; first dose at least 6–8 weeks after last PCV 13 dose; second dose 5 years after the first PPV23
Age 24–71 months, 1 dose PPV 23 given	PCV 13 (Prennar): one dose at least 8 weeks after PPV 23 dose
	PPV 23 (Pneumovax): second dose 5 years after first PPV 23
Age 5 to 18 years, received 1 dose PPV 23	PCV 13 (Prennar): one dose at least 8 weeks after PPV 23
	If only received one dose of PPV 23 (Pneumovax): second dose 5 years after the first PPV 23 dose

Penicillin 4 Children with SCD should receive prophylactic penicillin until at least the age of 5 years, even if they have been appropriately immunized with PCV 13 against pneumococcal infections. Penicillin V potassium is typically initiated at age 2 months, with a dose of 125 mg orally twice daily until age 3 years, then 250 mg orally twice daily until 5 years of age. The intramuscular use of benzathine penicillin 600,000 units every 4 weeks from age 6 months to 6 years is also an option for noncompliant patients. Penicillin-allergic patients may receive erythromycin 10 mg/kg twice daily. Penicillin prophylaxis usually is not continued in children over the age of 6 years, but may be considered in patients with a history of invasive pneumococcal infection or surgical splenectomy.^{5,14,15}

Folic Acid Folic acid supplementation with 1 mg daily is generally recommended in adult SCD patients, women considering pregnancy, and any SCD patient with chronic hemolysis.⁵ Because of accelerated erythropoiesis, these patients have an increased need for folic acid. There are conflicting studies in the SCD population, especially among infants and children, but if the child has chronic hemolysis, supplementation is recommended.¹⁶

Fetal Hemoglobin Inducers Fetal hemoglobin (HbF) induction in patients with SCD, especially those with frequent crises, has been shown to decrease RBC sickling and RBC adhesion. A direct relationship between HbF concentrations and the severity of disease has been demonstrated in studies.²

Hydroxyurea Hydroxyurea is a ribonucleotide reductase inhibitor that prevents DNA synthesis and traditionally has

been used in chemotherapy regimens. Studies in the 1990s also found that hydroxyurea increases HbF levels as well as increasing the number of HbF-containing reticulocytes and intracellular HbF. Other beneficial effects of hydroxyurea include antioxidant properties, reduction of neutrophils and monocytes, increased intracellular water content leading to increased red cell deformability, decreased red cell adhesion to endothelium, and increased levels of nitric oxide, which is a regulator involved in physiologic disturbances.¹⁷

5 Hydroxyurea reduced the frequency of hospitalizations and the incidences of pain, acute chest syndrome, and blood transfusions by almost 50% in a landmark trial in adult SCD patients with moderate to severe disease. Hemoglobin and HbF concentrations increased and hemolysis decreased.¹⁷ A follow-up study demonstrated a 40% reduction in mortality over a 9-year period in patients continuing to receive hydroxyurea.¹⁸ Not all patients responded equally; therefore, hydroxyurea may not be the best option for all patients.

The use of hydroxyurea in children and adolescents with SCD has been investigated, and similar results were reported as in adult trials, with no adverse effects on growth and development.^{5,19,20} Hydroxyurea is recommended as an option for children with moderate to severe SCD.²¹

The most common adverse effect of hydroxyurea in reported studies is myelosuppression. Long-term adverse effects are unknown, but myelodysplasia, acute leukemia, and chronic opportunistic infections have been reported.¹⁷ Hydroxyurea is teratogenic in high doses in animal studies and this is a concern, which should be addressed with patients. Normal pregnancies with no birth defects have been

reported in some women receiving hydroxyurea, but close monitoring and weighing risk versus benefit to the patient are vitally important. Hydroxyurea is excreted in breast milk and should be avoided in lactating mothers.¹⁷

Hydroxyurea should be considered in SCD with frequent vasoocclusive crises, severe symptomatic anemia, repeated history of acute chest syndrome (ACS), or other history of severe vasoocclusive crisis (VOC) complications.⁵ The prevention of organ damage or reversal of previous damage has not been shown to occur with chronic use of hydroxyurea.¹⁸ The goals of therapy with hydroxyurea are to decrease the acute complications of SCD, improve quality of life, and reduce the number and severity of pain crises.

Hydroxyurea is available in 200-, 300-, 400-, and 500-mg capsules. Extemporaneous liquid preparations can be prepared for children who cannot swallow capsules. Doses should start at 10 to 15 mg/kg daily in a single oral dose, which can be increased after 8 to 12 weeks if blood counts are stable and there are no side effects. Individualize the dosage based on the patient's response and the toxicity seen. With close monitoring, doses can be increased 5 mg/kg/day up to 35 mg/kg daily.¹⁷ In patients with renal failure, dosing of hydroxyurea will need to be adjusted according to the creatinine clearance, as shown in [Table 68-3](#).

Closely monitor patients for efficacy and toxicity while they are receiving hydroxyurea. Monitor mean corpuscular volume (MCV), since it increases as the level of HbF increases. If the MCV does not increase with hydroxyurea use, the

marrow may be unable to respond, the dose may not be adequate, or the patient may be noncompliant.¹⁷ HbF levels can also be monitored to assess response with a goal of increasing HbF to 15% to 20% (0.15 to 0.20). Assess blood counts every 2 weeks during dose titration and then every 4 to 6 weeks once the dose is stabilized. Temporary discontinuation of therapy is warranted if hemoglobin level is less than 5.0 g/dL (50 g/L or 3.10 mmol/L), absolute neutrophil count is less than $2 \times 10^3/\text{mm}^3$ ($2 \times 10^9/\text{L}$), platelets are less than $80 \times 10^3/\text{mm}^3$ ($80 \times 10^9/\text{L}$), or the reticulocytes are less than $80 \times 10^3/\text{mm}^3$ ($80 \times 10^9/\text{L}$). Monitor for increases in serum creatinine and transaminases. Once the patient's blood counts have returned to baseline, hydroxyurea may be restarted with a dose that is 2.5 to 5 mg/kg less than the dose associated with the patient's toxicity. Doses may then be increased by 2.5 to 5 mg/kg daily after 12 weeks with no toxicity.

Administer prophylactic folic acid supplementation to SCD patients receiving hydroxyurea, because folate deficiency may be masked by the use of hydroxyurea.

5-Aza-2'-Deoxycytine (Decitabine) For patients who do not respond to hydroxyurea, 5-azacytidine and 5-aza-2'-deoxycytidine (decitabine) may be useful. Both induce HbF by inhibiting methylation of DNA, preventing the switch from γ - to β -globin production. Decitabine appears to be safer and more potent than 5-azacytidine. In a small study in adults refractory to hydroxyurea, decitabine 0.2 mg/kg subcutaneously one to three times weekly was associated

Table 68-3

Dosage Adjustments for Renal and Hepatic Dysfunction

Medication	Renal Adjustment	Hepatic Adjustment
Decitabine (Decagon)	For Scr greater than or equal to 2 mg/dL (177 $\mu\text{mol/L}$): hold therapy until values return to baseline	For serum alanine transaminase (ALT), serum glutamic pyruvic transaminase (SGPT), or total bilirubin values greater than 2 times the upper limit of normal: hold therapy until values return to baseline
Deferoxamine (Desferal)	Cl_c less than 10 mL/min (0.17 mL/s): decrease the dose by 50%	
Deferasirox (Exjade) children	Greater than 33% increase in Scr (on two consecutive readings) and above the age-appropriate upper limits of normal: decrease daily dose by 10 mg/kg	Severe or persistent elevations in liver function tests: decrease the daily dose or discontinue therapy
Adults	Greater than 33% increase in Scr above pretreatment values on two consecutive readings: decrease daily dose by 10 mg/kg	Severe or persistent elevations in liver function tests: decrease the daily dose or discontinue therapy
Folic acid	No adjustment necessary	No adjustment necessary
Hydroxyurea	Cl_c less than 60 mL/min (1.00 mL/s): Initial dose of 7.5 mg/kg/day Cl_c 10–50 mL/min (0.17–0.83 mL/s): reduce the daily dose by 50% Cl_c less than 10 mL/min (0.17 mL/s): administer 20% of the usual dose Hemodialysis: 7.5 mg/kg/day given after dialysis	Monitor patient for bone marrow toxicity

From Refs. 22–27.

Patient Encounter 2

SC is a 22-year-old African American woman with SCD. She was admitted to the hospital for progressive neck, shoulder, back, and chest pain that began 2 days ago. The patient denies injury. She also has productive cough and subjective fever but denies chills.

PMH

- Sickle cell anemia (*HbSS*)
- Admitted for vasoocclusive crises 5 times over the past year
- Acute chest syndrome at age 14, 16, and 20
- Multiple blood transfusions

PSH

- Cholecystectomy
- Splenectomy
- Port placement × 3

FH: Father with SC trait. Mother with SCD.

Allergies: NKDA

SH: Occasional alcohol use. Is sexually active.

Home Meds

- Hydrocodone/acetaminophen 7.5/500 mg, one tablet every 6 hours prn for pain
- Folic acid 1 mg daily by mouth

PE

VS: T 39° C (102.2° F), BP 113/66, P 78, RR 22, O₂ Sat 99% on 2 L nasal cannula, Ht 162.56 cm, Wt 62.7 kg

Gen: awake, alert × 3, in no acute distress, but obviously in pain

HEENT: Normocephalic, atraumatic. PERRLA. No lymphadenopathy

Chest: Normal to inspection and palpation. No rhonchi, rales, or wheezes. Lower lobe crackles with left greater than right

CV: RRR, no m/g/r

Abd: Soft, NT/ND

Ext: No clubbing, cyanosis, or edema. Shoulder pain with palpation

Neuro: Cranial nerves II through XII are grossly intact. Nonfocal

Labs: Hgb 7.3 g/dL (73 g/L or 4.53 mmol/L), Hct 23.1% (0.231 fraction), WBC 19 × 10³/microliter (19 × 10⁶/L), BMP WNL

Chest x-ray showed a left lower lobe atelectasis and right hemidiaphragm consistent with possible left lower lobe pneumonia.

What is your assessment of this patient's condition?

Devise a detailed therapeutic plan for this patient's hospital management.

Is the patient a candidate for hydroxyurea? Why or why not?

with an increase in HbF in all patients. Additionally, RBC adhesion was reduced. Neutropenia was the only significant toxicity reported.²⁸

Combinations of HbF Inducers Very limited information is available on the use of combination therapy for potentiation of HbF production. Erythropoietin has shown inconsistent results in small numbers of patients. When used with hydroxyurea, erythropoietin has been shown to increase HbF to a greater extent than hydroxyurea alone, and although more studies are needed, this may provide an option for patients who do not respond to hydroxyurea alone.

Patient Encounter 3

Four months later, SC is seen on follow-up in the outpatient clinic for management of her SCD. She reports that she is 3 months pregnant.

Is the patient a candidate for hydroxyurea? Why or why not?

Chronic Transfusion Therapy Chronic transfusion therapy is warranted to prevent serious complications from SCD, including stroke prevention and recurrence. **6** *Especially in children, chronic transfusions have been shown to decrease stroke recurrence from approximately 50% to 10% over 3 years.* Without chronic transfusions, approximately 70% of ischemic stroke patients will have another stroke. Chronic transfusion therapy also may be used to prevent vasoocclusive pain and ACS, as well as prevent progression of organ damage. Patients receiving chronic transfusion therapy report increased energy levels, improved quality of life, and better exercise tolerance. Patients in whom chronic transfusion therapy should be considered include those with severe or recurrent ACS, debilitating pain, splenic sequestration, recurrent priapism, chronic organ failure, transient ischemic attacks, abnormal transcranial Doppler studies, intractable leg ulcers, severe chronic anemia in the presence of cardiac failure, and complicated pregnancies.⁵

Several methods of transfusion may be used, including simple transfusion, exchange transfusion, or erythrocytapheresis. The goal of chronic transfusion therapy is to maintain the HbS level at less than 30%

(0.30) of total hemoglobin concentration. Transfusions are usually administered every 3 to 4 weeks depending on the HbS concentration. For secondary stroke prevention, current studies have indicated that lifelong transfusion may be required, with increased incidence of recurrence once transfusions are stopped.⁵

The benefits of transfusion should be weighed with the risks. Risks associated with transfusions include alloimmunization (sensitization to the blood received), hyperviscosity, viral transmission, volume overload, iron overload, and transfusion reactions. Approximately 18% to 30% of SCD patients who receive transfusions will experience alloimmunization, which can be minimized by the use of leukocyte-reduced RBCs or HLA-matched units. Viral transmission is still a concern, despite increased screening of blood donors and units. Although the risk of contraction of AIDS has decreased dramatically, hepatitis C remains a concern. All SCD patients should be vaccinated for hepatitis A and B and should be serially monitored for hepatitis C and other infections. Parvovirus occurs in 1 of every 40,000 units of RBCs and can be associated with acute anemia and multiple sickle cell complications.⁵ Iron overload remains a concern among those patients maintained on chronic transfusions for greater than 1 year. Counsel patients to avoid excessive dietary iron, and monitor serum ferritin regularly. Chelation therapy with deferoxamine or deferasirox should be considered when the serum ferritin level is greater than 1,500 to 2,000 ng/mL (1,500 to 2,000 mcg/L). Deferoxamine should be initiated at 20 to 40 mg/kg daily (to a maximum of 1 to 2 g/day) over 8 to 12 hours subcutaneously and has been associated with growth failure.⁵ Monitor children receiving deferoxamine for adequate growth and development on a regular basis. Deferasirox should be initiated at 20 mg/kg daily and is available in a tablet that should be dispersed in water, orange juice, or apple juice and taken orally 30 minutes before food.^{29,30} Monitor all chelation patients for auditory and ocular changes on a yearly basis. Exchange transfusions may also be helpful in cases of iron overload.

Sickle cell hemolytic transfusion reaction syndrome is a unique problem in SCD patients. Due to alloimmunization, an acute or delayed transfusion reaction may occur. Delayed reactions typically occur 5 to 20 days posttransfusion. Alloantibodies and autoantibodies resulting from previous transfusions can trigger the reaction, in which patients develop symptoms suggestive of a pain crisis or worsening symptoms if they are already in crisis. A severe anemia after transfusion also may occur due to a rapid decrease in hemoglobin and hematocrit, along with a suppression of erythropoiesis. Further transfusions may worsen the clinical picture due to autoimmune antibodies. Recovery may occur only after ceasing all transfusions and is evidenced by a gradual increase in hemoglobin with reticulocytosis, which indicates the patient is now making their own RBCs.⁵

Allogeneic Hematopoietic Stem Cell Transplant
Allogeneic hematopoietic stem-cell transplantation (HSCT)

is the only potential cure for SCD. The best candidates are children with SCD who are younger than 16 years of age with severe complications, who have an identical HLA-matched donor, usually a sibling. The transplant-related mortality rate is between 5% and 10%, and graft rejection is approximately 10%. Other risks include secondary malignancies, development of seizures or intracranial bleeding, and infection in the immediate posttransplant period.^{5,31,32}

Experience with HSCT in adult patients with SCD is very limited. Umbilical cord blood and hematopoietic cells from nonmatched donors are potential alternatives in some patients, but use is limited.^{5,32}

► Acute Complications

● **Transfusions for Acute Complications** Red cell transfusion is indicated in patients with acute exacerbations of baseline anemia; in cases of severe vasoocclusive episodes, including ACS, stroke, and acute multiorgan failure; and in preparation for procedures that will require the use of general anesthesia or ionic contrast products. Transfusions also may be useful in patients with complicated obstetric problems, refractory leg ulcers, refractory and prolonged pain crises, or severe priapism. Hyperviscosity may occur if the hemoglobin level is increased to greater than 10.0 to 11.0 g/dL (100 to 110 g/L or 6.21 to 6.83 mmol/L). Volume overload leading to congestive heart failure is more likely to occur if the anemia is corrected too rapidly in patients with severe anemia and should be avoided.⁵

Infection and Fever 7 *Any fever greater than 38.5°C (101.3°F) in a SCD patient should be immediately evaluated, and the patient should have a blood culture drawn and be started on antibiotics that provide empirical coverage for encapsulated organisms.⁵*

Patients who should be hospitalized include the following:

- Infants younger than 1 year of age
- Patients with a previous sepsis or bacteremia episode
- Patients with temperatures in excess of 40°C (104°F)
- Patients with WBC counts greater than $30 \times 10^3/\text{mm}^3$ ($30 \times 10^9/\text{L}$) or less than $0.5 \times 10^3/\text{mm}^3$ ($0.5 \times 10^9/\text{L}$) and/or platelets less than $100 \times 10^3/\text{mm}^3$ ($100 \times 10^9/\text{L}$) with evidence of other acute complications
- Acutely ill-appearing individuals

Broad IV antibiotic coverage for the encapsulated organisms can include ceftriaxone or cefotaxime. For patients with true cephalosporin allergy, clindamycin may be used. If staphylococcal infection is suspected due to previous history or the patient appears acutely ill, vancomycin should be initiated. Macrolide antibiotics, such as erythromycin or azithromycin, may be initiated if mycoplasma pneumonia is suspected. While the patient is receiving broad-spectrum antibiotics, their regular use of penicillin for prophylaxis can be suspended. Fever should be controlled with acetaminophen or ibuprofen. Because of the risk of dehydration during infection with fever, increased fluid may be needed.^{1,5}

Clinical Presentation and Diagnosis of Infection in SCD

General

- Patients may become acutely distressed very rapidly
- A low threshold to begin empiric therapy is recommended

Symptoms

- Patients may complain of lethargy, nausea, cough, or a general “unwell” feeling

Signs

- Temperature greater than 38.5°C (101.3°F)

Laboratory Tests

- CBC with reticulocyte count
- Cultures (urine, blood, and throat)
- Lumbar puncture if toxic-looking or signs of meningitis
- Urinalysis
- Chest x-ray

Potential Pathogens

- *Streptococcus pneumoniae* (most common), *Haemophilus influenzae*, *Salmonella*, *Mycoplasma pneumoniae*, *Chlamydia*, and viruses (parvovirus B19)

Clinical Presentation and Diagnosis of Stroke in SCD

General

- Most common cause is cerebrovascular occlusion
- Initial episode most often occurs during first 10 years of life
- Silent infarcts seen on MRI have been reported in 22% of patients and may be associated with increased risk of stroke and decreased neurocognitive function

Symptoms

- Patients may present with headache, vomiting, stupor, hemiparesis, aphasia, visual disturbances, and seizure

Evaluation

- CT scan and MRI for acute event
- Magnetic resonance angiography for asymptomatic infarction
- Transcranial Doppler to detect abnormal velocity and identify high-risk patients
- Electroencephalography if there is history of seizure
- Chest x-ray

Bone infarcts or sickling in the periosteum usually is indicated by pain and swelling over an extremity. Osteomyelitis also should be considered. *Salmonella* species are the most common cause of osteomyelitis in SCD children, followed by *Staphylococcus aureus*.¹ Select an appropriate antibiotic to cover the suspected organisms empirically.

Cerebrovascular Accidents Acute neurologic events, such as stroke, will require hospitalization and close monitoring. Patients should have physical and neurologic examinations every 2 hours.⁵ Acute treatment may include exchange transfusion or simple transfusion to maintain hemoglobin at approximately 10.0 g/dL (100 g/L or 6.21 mmol/L) and HbS concentration at less than 30% (0.30). Patients with a history of seizure may need anticonvulsants, and interventions for increased intracranial pressure should be initiated if necessary. Children with history of stroke should be initiated on chronic transfusion therapy. Adults presenting with ischemic stroke should be considered for thrombolytic therapy if it has been less than 3 hours since the onset of symptoms.⁵

Early detection of ischemic stroke can be done with the use of transcranial Doppler ultrasonography. In the Stroke Prevention Trial in Sickle Cell Anemia (STOP) study, screening with this method followed by chronic transfusion therapy significantly reduced the incidence of stroke.^{33–35} Screening is recommended in all patients over the age of 2 years.

Acute Chest Syndrome ACS will require hospitalization for appropriate management of symptoms and to avoid complications. Patients should be encouraged to use incentive spirometry at least every 2 hours. Incentive spirometry helps the patient take long, slow breaths to increase lung expansion. Appropriate management of pain is important, but analgesic-induced hypoventilation should be avoided. Patients should maintain appropriate fluid balance because overhydration can lead to pulmonary edema and respiratory distress. Infection with gram-negative, gram-positive, or atypical bacteria is common in ACS, and early use of broad-spectrum antibiotics, including a macrolide, quinolone, or cephalosporin is recommended. Fat emboli, from infarction of the long bones, may lead to ACS. Oxygen therapy should be utilized in any patient presenting with respiratory distress or hypoxia. Oxygen saturations, measured by pulse oximeter, should be maintained at 92% (0.92) or above. Transfusions are often indicated, and patients who present with wheezing may require inhaled bronchodilators.^{5,36,37}

The use of corticosteroids is controversial. Although they may decrease the inflammation and endothelial cell adhesion seen with ACS, their use has also been associated with higher readmission rates for other complications. Tapered corticosteroids, nitric oxide therapy, and L-arginine are being evaluated for use in ACS in studies.^{36,37}

Priapism By age 18, approximately 90% of SCD males will have had at least one episode of priapism. Stuttering priapism, where erection episodes last anywhere from a few minutes to

Clinical Presentation and Diagnosis of ACS in SCD

General

- Occurs in 15% to 43% of patients and is responsible for 25% of deaths
- Risk factors include young age, low HbF level, high Hgb and WBCs, winter seasons, reactive airway disease
- Recurrences are up to 80% and can lead to chronic lung disease

Symptoms

- Patients may complain of cough, fever, dyspnea, chest pain

Signs

- Temperature greater than 38.5°C (101.3°F)
- Hypoxia
- New infiltrate on chest x-ray

Laboratory Tests

- CBC with reticulocyte count
- Blood gases
- Oxygen saturation
- Cultures (blood and sputum)

Other

- Closely monitor pulmonary status

Clinical Presentation and Diagnosis of Priapism in SCD

General

- Mean age of initial episode is 12 years of age
- Most males with SCD will have one episode by age 20
- Repeated episodes can lead to fibrosis and impotence

Symptoms

- Patients may complain of painful and unwanted erection lasting anywhere from less than 2 hours (stuttering type) to more than 2 hours (prolonged type)

Signs

- Urinary obstruction

Laboratory Tests

- CBC with reticulocyte count

Other

- Monitor for duration of episode
- Prolonged episodes should be considered medical emergencies

Clinical Presentation and Diagnosis of Acute Aplastic Crisis in SCD

General

- Transient suppression of RBC production in response to bacterial or viral infection
- Most commonly due to infection with parvovirus B19

Symptoms

- Patients may complain of headache, fatigue, dyspnea, pallor, or fever
- Patients may also complain of upper respiratory or GI infection symptoms

Signs

- Temperature greater than 38.5°C (101.3°F) may occur
- Hypoxia
- Tachycardia
- Acute decrease in Hgb with decreased reticulocyte count

Laboratory Tests

- CBC with reticulocyte count
- Chest x-ray
- Parvovirus titers
- Cultures (blood, urine, and throat)

less than 2 hours, resolves spontaneously. Erections lasting more than 2 hours should be evaluated promptly. Goals of therapy are to provide pain relief, reduce anxiety, provide detumescence, and preserve testicular function and fertility. Initial treatment should include aggressive hydration and analgesia. Transfusion may or may not be helpful, but should be considered in anemic patients. Avoid the use of ice packs due to the risk of tissue damage.⁵

Both vasoconstrictors and vasodilators have been used in the treatment of priapism. Vasoconstrictors are thought to work by forcing blood out of the cavernosum and into the venous return. Aspiration of the penile blood followed by intracavenous irrigation with epinephrine (1:1,000,000 solution) has been effective with minimal complications.³⁸ In severe cases, surgical intervention to place penile shunts has been used, but there is a high failure rate, and the risk of complications, from skin sloughing to fistulas, limits its use.

Pseudoephedrine dosed at 30 to 60 mg/day taken at bedtime has been used to prevent or decrease the number of episodes of priapism.⁵ Terbutaline 5 mg has been used orally to prevent priapism, with mixed results.^{38,39} Leuprolide, a gonadotropin-releasing hormone, also has been used for this indication. Hydroxyurea may be helpful in some patients.^{38,40} The use of antiandrogens is under investigation.⁵

Clinical Presentation and Diagnosis of Sequestration Crisis in SCD

General

- Acute exacerbation of anemia due to sequestration of large blood volume by the spleen
- More common in patients with functioning spleens
- Onset often associated with viral or bacterial infections
- Recurrence is common and can be fatal

Symptoms

- Sudden onset of fatigue, dyspnea, and distended abdomen
- Patients may present with vomiting and abdominal pain

Signs

- Rapid decrease in Hgb and Hct with elevated reticulocyte count
- Splenomegaly
- May exhibit hypotension and shock

Evaluation

- Vital signs
- Spleen size changes
- Oxygen saturations
- CBC with reticulocyte count
- Cultures (blood, urine, throat)

Clinical Presentation and Diagnosis of Vasoocclusive Crisis in SCD

General

- Most often involves the bones, liver, spleen, brain, lungs, and penis
- Precipitating factors include infection, extreme weather conditions, dehydration, and stresses
- Recurrent acute crises result in bone, joint, and organ damage and chronic pain

Symptoms

- Patients may complain of deep throbbing pain, local tenderness

Signs

- Erythema and swelling of painful area
- Dactylitis in young infants
- Temperature greater than 38.5°C (101.3°F)
- Leukocytosis

Laboratory tests

- CBC with reticulocyte count
- Urinalysis
- Abdominal studies (if symptoms exist)
- Cultures (blood and urine)
- Liver function tests and bilirubin
- Chest x-ray

► Treatment of Acute Complications

Aplastic Crisis Most patients in aplastic crisis will recover spontaneously and therefore treatment is supportive. If anemia is severe or symptomatic, transfusion may be indicated. Infection with human parvovirus B19 is the most common cause of aplastic crisis. Isolate infected patients because parvovirus is highly contagious. Pregnant individuals should avoid contact with infected patients because midtrimester infection with parvovirus may cause hydrops fetalis and still birth.^{1,5}

Sequestration Crisis RBC sequestration in the spleen in young children may lead to a rapid drop in hematocrit, resulting in hypovolemia, shock, and death. Treatment is RBC transfusion to correct the hypovolemia, as well as broad-spectrum antibiotics, because infections may precipitate the crisis.^{1,5}

Recurrent episodes are common and can be managed with chronic transfusion and splenectomy. Observation is used commonly in adults because their episodes are milder. Splenectomy is usually delayed until after 2 years of age to lessen the risk of postsplenectomy septicemia. Patients with chronic hypersplenism should be considered for splenectomy.^{5,41}

Vasoocclusive Pain Crisis The mainstay of treatment for vasoocclusive crisis includes hydration and analgesia (Table 68-4). Pain may involve the extremities, back, chest, and abdomen. **8** *Patients with mild pain crisis may be treated as outpatients with rest, warm compresses to the affected (painful) area, increased fluid intake, and oral analgesia.* Patients with moderate to severe crises should be hospitalized. Infection should be ruled out because it may trigger a pain crisis, and any patient presenting with fever or critical illness should be started on empirical broad-spectrum antibiotics. Patients who are anemic should be transfused to their baseline. IV or oral fluids at 1.5 times maintenance is recommended. Close monitoring of the patient's fluid status is important to avoid overhydration, which can lead to ACS, volume overload, or heart failure.⁵

Aggressive pain management is required in patients presenting in pain crisis. Assess pain on a regular basis (every 2 to 4 hours), and individualize management to the patient. The use of pain scales may help with quantifying the pain rating. Obtain a good medication history of what has worked well for the patient in the past. Use acetaminophen or a nonsteroidal anti-inflammatory drug (NSAID) for treatment of mild to moderate pain. Patients with bone or joint pain

Table 68-4

Management of Acute Pain of SCD**Principles**

- Treat underlying precipitating factors.
- Avoid delays in analgesia administration.
- Use pain scale to assess severity.
- Choice of initial analgesic should be based on previous pain crisis pattern, history of response, current status, and other medical conditions.
- Schedule pain medication; avoid as-needed dosing.
- Provide rescue dose for breakthrough pain.
- If adequate pain relief can be achieved with one or two doses of morphine, consider outpatient management with a weak opioid; otherwise hospitalization is needed for parenteral analgesics.
- Frequently assess to evaluate pain severity and side effects; titrate dose as needed.
- Treating adverse effects of opioids is part of pain management.
- Consider nonpharmacologic intervention.
- Transition to oral analgesics as the patient improves; choose an oral agent based on previous history, anticipated duration, and ability to swallow tablets; if sustained-release products are used, a fast-release product is also needed for breakthrough pain.

Analgesic Regimens

Mild to moderate pain:

Acetaminophen with codeine

- Dose based on codeine—children: 1 mg/kg per dose every 6 hours; adults: 30–60 mg/dose

Hydrocodone + acetaminophen:

- Dose based on hydrocodone—children: 0.2 mg/kg per dose every 6 hours; adults: 5–10 mg/dose

Anti-inflammatory agents

- Use with caution in patients with renal failure (dehydration) and bleeding
- Ibuprofen (oral): children: 10 mg/kg every 6–8 hours; adults: 200–400 mg/dose
- Naproxen: 5 mg/kg every 12 hours; adults: 250–500 mg/dose
- Ibuprofen + hydrocodone: Each tablet contains 200 mg ibuprofen and 7.5 mg hydrocodone per tablet; only for older children who can swallow tablets

Moderate to severe pain:

Morphine—children: 0.1–0.15 mg/kg per dose every 3–4 hours; adults: 5–10 mg/dose

- Continuous infusion: 0.04–0.05 mg/kg/h; titrate to effect

Hydromorphone—children: 0.015 mg/kg per dose every 3–4 hours; adults: 1.5–2 mg/dose

- Continuous infusion: 0.004 mg/kg/h; titrate to effect

IV anti-inflammatory agents:

- Ketorolac: 0.5 mg/kg up to 30 mg/dose every 6 hours

Patient-controlled analgesics:

- Morphine: 0.01–0.03 mg/kg/h basal; demand 0.01–0.03 mg/kg every 6–10 minutes; 4 hours lockout 0.04–0.06 mg/kg
- Hydromorphone: 0.003–0.005 mg/kg/h basal; demand 0.003–0.05 mg/kg every 6–10 minutes; 4 hours lock out 0.4–0.6 mg/kg

who require IV medications may be helped by the use of ketorolac, an injectable NSAID. Because of the concern for side effects, including GI bleeding, ketorolac should be used only for a maximum of 5 consecutive days. Monitor for the total amount of acetaminophen given daily, because many products contain acetaminophen. Maximum daily dose of acetaminophen for adults is 4 g/day, and for children, five doses over a 24-hour period.⁴² Add an opioid if pain persists or if pain is moderate to severe in nature. Combining an opioid with an NSAID can enhance the analgesic effects without increasing adverse effects.^{43–46}

Severe pain should be treated with an opioid such as morphine, hydromorphone, methadone, or fentanyl. Moderate pain can be effectively treated in most cases with a weak opioid such as codeine or hydrocodone, usually in combination with acetaminophen. Meperidine should be avoided because of its relatively short analgesic effect and its toxic metabolite, normeperidine. Normeperidine may

accumulate with repeated dosing and can lead to CNS side effects including seizures.

IV opioids are recommended for use in treatment of severe pain because of their rapid onset of action and ease in titration. Intramuscular injection should be avoided. Analgesia should be individualized and titrated to effect, either by scheduled doses or continuous infusion. The use of continuous infusion will avoid the fluctuations in blood levels between doses that is seen with bolus dosing. As-needed dosing of analgesia is only appropriate for breakthrough pain or uncontrolled pain. Patient-controlled analgesia (PCA) is commonly used and allows the patient to have control over his or her analgesic breakthrough dosing. As the pain crisis resolves, the pain medications can be tapered. Physical therapy and relaxation therapy can be helpful adjuvants to analgesia.^{43–46}

Tolerance to opioids is seen when patients have had continuous long-term use of the medications and can be managed during acute crises by using a different potent

opioid or using a larger dose of the same medication. Adverse effects associated with the use of opioids include respiratory depression, itching, nausea and vomiting, constipation, and drowsiness. Patients on continuous infusions of opioids should be on continuous pulse oximeter to assess oxygen saturations. Monitor the patient for oxygen saturations less than 92% (0.92). Oxygen should be administered as needed to keep the saturations above 92% (0.92). Itching can be managed with an antihistamine such as diphenhydramine. Nausea and vomiting can be treated and managed with the administration of antiemetics such as promethazine or the 5HT₃ antagonists, but the use of promethazine is contraindicated in children younger than 2 years of age. Assess stool frequency in all patients on a continuous opioid, and start stool softeners or laxatives as needed. Excessive sedation is difficult to control, and the concurrent use of an opioid with diphenhydramine or other sedative medications can exacerbate the drowsiness, leading to hypoxemia. A continuous very low dose of naloxone, an opioid antagonist, has been used successfully when the adverse effects such as itching are unbearable.⁴⁷

OUTCOME EVALUATION

SCD treatment and prevention are considered successful when complications are minimized. The major outcome parameters are a decrease in morbidity and mortality,

measured by the number of hospitalizations, and the extent of end-organ damage seen over time. Today, with longer survival for SCD, chronic manifestations of the disease contribute to the morbidity later in life (Table 68–5). Thirty years ago, complications from SCD contributed to high mortality. It was estimated that approximately 50% of patients with SCD did not survive to reach adulthood.⁴ Since that time, data suggest improvement in mortality rates for patients with SCD. The survival age for individuals with HbSS has increased to at least the fifth decade of life. Recent reports suggest 85% survival by 18 years of age.⁴ SCD is a chronic disease and cannot be cured, except in some patients with transplant.

Starting with birth, SCD patients should have regularly scheduled health assessments and interventions when necessary. Obtain a urine analysis, complete blood count, liver function tests, ferritin or serum iron level and total iron-binding capacity, blood urea nitrogen (BUN), and creatinine on at least a yearly basis and more often for children younger than 5 years of age to monitor for complications. All SCD patients should have regular screening of their hearing and vision.

All patients and parents of children with SCD should have a plan for what to do in the event of symptoms of infection or pain. Obtain a medication history when patients are admitted to the hospital. Assess compliance with prophylactic penicillin and childhood immunization schedules in all pediatric SCD patients.

Table 68–5

Chronic Complications of SCD

System	Complications
Auditory	Sensorineural hearing loss due to sickling in cochlear vasculature with hair cell damage
Cardiovascular	Cardiomegaly, myocardial ischemia, murmurs, and abnormal ECG; patients with SCD have lower BP than the normal population; normal BP values for SCD should be used for diagnosis of hypertension (“relative” hypertension); heart failure usually is related to fluid overload
Dermatologic	Painful leg ulcers; failure to heal occurs in 50% of patients; recurrences are common
Genitourinary	Renal papillary necrosis, hematuria, hyposthenuria, proteinuria, nephrotic syndrome, tubular dysfunction, chronic renal failure, impotence
Growth and development	Delay in growth (weight and height) and sexual development; decreased fertility; increased complications during pregnancy; depression may be more prevalent than in general population, especially in patients with unstable disease
Hepatic and biliary	Cholelithiasis, biliary sludge, acute and chronic cholecystitis, and cholestasis (can be progressive and life-threatening)
Neurologic	“Silent” brain lesions on MRI are associated with poor cognitive and fine motor functions; pseudotumor cerebri (rare)
Ocular	Retinal or vitreous hemorrhage, retinal detachment, transient or permanent visual loss; central retinal vein occlusion
Pulmonary	Pulmonary fibrosis, pulmonary hypertension, cor pulmonale
Renal	Hematuria, hyposthenuria (inability to concentrate urine maximally), tubular dysfunction, enuresis during early childhood, acute renal failure can also occur
Skeletal	Aseptic necrosis of ball-and-socket joints (shoulder and hip); prostheses may be needed due to permanent damage; bone marrow hyperplasia resulting in growth disturbances of maxilla and vertebrae
Spleen	Asplenia (autosplenectomy or surgical splenectomy)

Patient Care and Monitoring

1. Assess the patient's symptoms to determine whether the patient should be evaluated by a physician and/or receive immediate care. Determine the type of symptoms, onset of symptoms, frequency and exacerbating factors. Does the patient have evidence of SCD-related complications?
2. Review any available diagnostic data to determine the severity and status of the patient's SCD. When was the patient last hospitalized for SCD complications?
3. Obtain a thorough history of prescription, nonprescription, and natural drug product use. For pain control, determine which treatments have been helpful to the patient in the past. Is the patient currently taking any medications on a chronic basis?
4. Educate the patient on lifestyle modifications that may lessen complications. These include maintaining adequate hydration status, avoiding extreme temperature changes, dressing appropriately for hot or cold weather, and avoiding physical exertion, smoking, and excessive alcohol intake.
5. Is the patient up-to-date on immunizations? Have they received their annual influenza vaccine? If not, why?
6. Is the patient taking appropriate doses of their pain medication to achieve effect? If not, why?
7. Develop a plan to assess the effectiveness of pain medications.
8. Determine whether the patient is a candidate for hydroxyurea therapy.
9. Assess improvement in quality-of-life measures, such as physical, psychological, and social functioning and well-being.
10. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
11. Stress the importance of adherence with the therapeutic regimen, including lifestyle modifications. Recommend a therapeutic regimen that is easy for the patient/parent to accomplish.
12. Provide patient education on disease state, lifestyle modifications, and drug therapy:
 - Possible complications of SCD, both long and short term
 - When to take their medications
 - Adverse effects and how to manage them
 - Which drugs may interact with their medication therapy
 - Warning signs to report to the physician (increased or new pain, sudden headache, bleeding or bruising, fever, loss of energy, loss of appetite)

Abbreviations Introduced in This Chapter

ACS	Acute chest syndrome
HbA	Normal adult hemoglobin
HbAS	One normal and one sickle hemoglobin gene
HbC	Hemoglobin C
HbF	Fetal hemoglobin
HbS	Sickle hemoglobin
HbS β^0 -thalassemia	One sickle hemoglobin and one β^0 -thalassemia gene
HbS β^+ -thalassemia	One sickle hemoglobin and one β^+ -thalassemia gene
HbSC	One sickle hemoglobin and one hemoglobin C gene
HbSS	Homozygous sickle hemoglobin
Hgb	Hemoglobin
HSCT	Hematopoietic stem cell transplantation
ISC	Irreversibly sickled cell
MCHC	Mean corpuscular hemoglobin concentration
MCV	Mean corpuscular volume

NSAID

PCA

PCV 13

PPV 23

SCA

SCD

SCT

STOP

VOC

Nonsteroidal anti-inflammatory drug

Patient-controlled analgesia

13-Valent pneumococcal conjugate vaccine

23-Valent pneumococcal polysaccharide vaccine

Sickle cell anemia

Sickle cell disease

Sickle cell trait

Stroke Prevention Trial in Sickle Cell Anemia

Antimicrobial Regimen Selection

Catherine M. Oliphant and Karl Madaras-Kelly

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Recognize that antimicrobial resistance is an inevitable consequence of antimicrobial therapy.
2. Describe how antimicrobials differ from other drug classes in terms of their effects on individual patients as well as on society as a whole.
3. Identify two guiding principles to consider when treating patients with antimicrobials, and apply these principles in patient care.
4. Differentiate between microbial colonization and infection based on patient history, physical examination, and laboratory and culture results.
5. Evaluate and apply at least six major drug-specific considerations when selecting antimicrobial therapy.
6. Evaluate and apply at least seven major patient-specific considerations when selecting antimicrobial therapy.
7. Select empirical antimicrobial therapy based on spectrum-of-activity considerations that provide a measured response proportional to the severity of illness. Provide a rationale for why a measured response in antimicrobial selection is appropriate.
8. Identify and apply five major principles of patient education and monitoring response to antimicrobial therapy.
9. Identify two common causes of patients failing to improve while on antimicrobials, and recognize other less common but potential reasons for antimicrobial failure.

KEY CONCEPTS

- 1 An inevitable consequence of exposing microbes to antimicrobials is that some organisms will develop resistance to the antimicrobial.
- 2 Antimicrobials are different from other classes of pharmaceuticals because they exert their action on bacteria infecting the host as opposed to acting directly on the host.
- 3 Two guiding principles to consider when treating patients with antimicrobials are (a) make the diagnosis and (b) do no harm!
- 4 Only bacteria that cause disease should be targeted with antimicrobial therapy, and colonizing flora should be left intact whenever possible.
- 5 Bacterial cultures should be obtained prior to antimicrobial therapy in patients with a systemic inflammatory response, risk factors for antimicrobial resistance, or infections where diagnosis or antimicrobial susceptibility is uncertain.
- 6 Drug-specific considerations in antimicrobial selection include the spectrum of activity, effects on nontargeted microbial flora, appropriate dose, pharmacokinetic and pharmacodynamic properties, adverse-effect and drug-interaction profile, and cost.
- 7 Empirical therapy should be based on patient- and antimicrobial-specific factors such as the anatomic location of the infection, the likely pathogens associated with the presentation, the potential for adverse effects, and the antimicrobial spectrum of activity.
- 8 Key patient-specific considerations in antimicrobial selection include recent previous antimicrobial exposures, identification of the anatomic location of infection through physical examination and diagnostic imaging, history of drug allergies, organ dysfunction that may affect drug clearance, immunosuppression, pregnancy, and adherence.
- 9 Patient education, de-escalation of antimicrobial therapy based on culture results, monitoring for clinical

response and adverse effects, and appropriate duration of therapy are important treatment components.

- 10 Inadequate diagnosis resulting in poor initial antimicrobial selection, poor source control, or the development of a new infection with a resistant organism are relatively common causes of antimicrobial failure.

The discovery of antimicrobials is among the greatest medical achievements of the 20th century. Prior to the antimicrobial era, patients who contracted common infectious diseases developed significant morbidity or perished. The discovery of penicillin in 1927, followed by the subsequent discovery of other antimicrobials, contributed to a significant decline in infectious disease–related mortality during the next five decades. However, since 1980, infectious disease–related mortality in the United States has increased, in part owing to increases in antimicrobial resistance. The discovery of virtually every new class of antimicrobials has occurred in response to the development of bacterial resistance and loss of clinical effectiveness of existing antimicrobials. 1 *An inevitable consequence of exposing microbes to antimicrobials is that some organisms will develop resistance to the antimicrobial.* Today, there are dozens of antimicrobial classes and hundreds of antimicrobials available for clinical use. However, in many cases, differences in mechanisms of action between antimicrobials are minor, and the microbiologic properties of the agents are similar. 2 *Antimicrobials are different from other classes of pharmaceuticals because they exert their action on bacteria infecting the host as opposed to acting directly on the host.* Because use of an antimicrobial in one patient affects not only that patient but also other patients if they become infected with resistant bacteria, correct selection, use, and monitoring of clinical response are paramount.

3 *There are two guiding principles to consider when treating patients with antimicrobials: (a) make the correct diagnosis and (b) do no harm!* Patients with infections frequently present with signs and symptoms that are nonspecific for infection and may be confused with other noninfectious disease. Not only is it important to determine whether a disease process is of infectious origin, but it is also important to determine the specific causative pathogen of the infection. Antimicrobials vary in their **spectrum of activity**, the ability to inhibit or kill different species of bacteria. Antimicrobials that kill many different species of bacteria are called *broad-spectrum antimicrobials*, whereas antimicrobials that kill only a few species of bacteria are called *narrow-spectrum antimicrobials*. One might argue that treating everybody with broad antimicrobial antimicrobials will increase the likelihood that a patient will get better even without knowing the bacteria causing infection. However, counter to this argument is the principle of “Do no harm!” Broad antimicrobial coverage does increase the likelihood of empirically killing a causative pathogen; unfortunately, the development of

secondary infections can be caused by selection of antimicrobial-resistant nontargeted pathogens. In addition, adverse events are thought to complicate up to 10% of all antimicrobial therapy, and for select agents, the adverse-event rates are similar to high-risk medications such as warfarin, digoxin, or insulin.¹ Therefore, the overall goal of antimicrobial therapy should be to cure the patient’s infection; limit harm by minimizing patient risk for adverse effects, including secondary infections; and limit societal risk from antimicrobial-resistant bacteria.

EPIDEMIOLOGY AND ETIOLOGY

Infectious disease–related illnesses, particularly respiratory tract infections, are among the most common reasons patients seek medical care.² Antimicrobial prescribing in the past has been associated with inappropriate use of antimicrobial agents. During the late 1990s/early 2000s, many organizations initiated campaigns to promote appropriate antimicrobial use. Recent trends in prescribing suggest a modest reduction in antimicrobial use for these infections, suggesting an increased recognition of the negative consequences of antimicrobial use.⁴ Prescribing of antimicrobials in hospitalized patients is also common, as up to one-half of all patients receive at least one antimicrobial during hospitalization. In 2002, the estimated number of nosocomial infections was 1.8 million, with an estimated 99,000 deaths.⁵ In 2009, the CDC reported 25,000 fewer central line–associated bloodstream infections than in 2001, a 58% reduction.⁶ Nosocomial infections tend to be associated with antimicrobial-resistant strains of bacteria. However, there has been a shift in the etiology of some community-acquired infections. Increasingly, infections caused by antimicrobial-resistant pathogens, traditionally nosocomial in origin, are being identified in ambulatory care settings. Reasons for this change include an aging populace, improvement in the management of chronic comorbid conditions including immunosuppressive conditions, and increases in outpatient management of more debilitated patients. The majority of infections caused by antimicrobial-resistant pathogens in the ambulatory care setting occur in patients who have had recent exposure to some aspect of the healthcare system and are therefore defined as healthcare–associated infections. The converging bacterial etiologies and increasing resistance in all healthcare environments emphasize the need to “make the diagnosis.”

PATHOPHYSIOLOGY

Normal Flora and Endogenous Infection

Many areas of the human body are colonized with bacteria—this is known as *normal flora*. Infections often arise from one’s own normal flora (also called an *endogenous infection*). Endogenous infection may occur when there are alterations in the normal flora (e.g., recent antimicrobial use may allow for overgrowth of other normal flora) or disruption of host defenses (e.g., a break or entry in the skin). Knowing what organisms reside where can help to guide empirical

FIGURE 69-1. Normal flora and concentrations of bacteria (organisms per milliliter).

antimicrobial therapy (Fig. 69-1). In addition, it is beneficial to know what anatomic sites are normally sterile. These include the cerebrospinal fluid, blood, and urine.

Determining Colonization Versus Infection

- Infection refers to the presence of bacteria that are causing disease (e.g., the organisms are found in normally sterile anatomic sites or in nonsterile sites with signs/symptoms of infection). *Colonization* refers to the presence of bacteria that are not causing disease. **4** Only bacteria that cause disease should be targeted with antimicrobial therapy, and non-disease-producing colonizing flora should be left intact. It is important to differentiate infection from colonization because antimicrobial therapy targeting bacterial colonization is inappropriate and may lead to the development of resistant bacteria.

Exogenously Acquired Bacterial Infections

Infections acquired from an external source are referred to as *exogenous infections*. These infections may occur as a result of human-to-human transmission, contact with exogenous

bacterial populations in the environment, and animal contact. Resistant pathogens such as methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *Enterococcus* spp. (VRE) may colonize hospitalized patients or patients who access the healthcare system frequently. It is key to know which patients have acquired these organisms because patients generally become colonized prior to developing infection, and colonized patients should be placed in isolation (per infection-control policies) to minimize transmission to other patients.

Contrasting Bacterial Virulence and Resistance

Virulence refers to the pathogenicity or disease severity produced by an organism. Many bacteria may produce toxins or possess growth characteristics that contribute to their pathogenicity. Some virulence factors allow the organism to avoid the immune response of the host and cause significant disease. Virulence and resistance are different microbial characteristics. For example, *Streptococcus pyogenes*, a common cause of skin infections, produces toxins that can cause severe disease, yet it is very susceptible to penicillin. *Enterococcus faecium* is

a highly resistant organism but is frequently a colonizing flora that causes disease primarily in the immunocompromised.

CLINICAL PRESENTATION AND DIAGNOSIS

Physical Examination

Findings on physical examination, along with the clinical presentation, can help to provide the anatomic location of the infection. Once the anatomic site is identified, the most probable pathogens associated with disease can be determined based on likely endogenous or exogenous flora.

Fever often accompanies infection and is defined as a rise in body temperature above the normal 37°C (98.6°F). Oral and axillary temperatures may underestimate core temperature by at least 0.6°C (1°F), whereas rectal temperatures best approximate core temperatures. Fever is a host response to bacterial toxins. However, bacterial infections are not the sole cause of fever. Fever also may be caused by other infections (e.g., fungal or viral), medications (e.g., penicillins, cephalosporins, salicylates, and phenytoin), trauma, or other medical conditions (e.g., autoimmune disease, malignancy, pulmonary embolism, and hyperthyroidism). Some patients with infections may present with hypothermia (e.g., patients

with overwhelming infection). Elderly patients may be afebrile, as may those with localized infections (e.g., urinary tract infection).⁷ For others, fever may be the only indication of infection. For example, neutropenic patients may not have the ability to mount normal immune responses to infection (e.g., infiltrate on chest x-ray, pyuria on urinalysis, or erythema or induration around catheter site), and the only finding may be fever.

Imaging Studies

Imaging studies also may help to identify anatomic localization of the infection. These studies usually are performed in conjunction with other tests to establish or rule out the presence of an infection. Radiographs are performed commonly to establish the diagnosis of pneumonia, as well as to determine the severity of disease (single versus multilobe involvement). Computed tomography (CT) scans are a type of x-ray that produces a three-dimensional image of the combination of soft tissue, bone, and blood vessels. In contrast, magnetic resonance imaging (MRI) uses electromagnetic radio waves to produce two- or three-dimensional images of soft tissue and blood vessels with less detail of bony structures.

Clinical Presentation

- Review of symptoms consistent with an infectious etiology?
- Signs and symptoms may be nonspecific (e.g., fever) or specific.
- Specific signs and symptoms are beyond the scope of this chapter (see disease state–specific chapters for these findings).

Patient History

- History of present illness
- Comorbidities
- Current medications
- Allergies
- Previous antibiotic exposure (may provide clues regarding colonization or infection with new specific pathogens or pathogens that may be resistant to certain antimicrobials)
- Previous hospitalization or healthcare utilization (also a key determinant in selecting therapy because the patient may be at risk for specific pathogens and/or resistant pathogens)
- Travel history
- Social history
- Pet/animal exposure

- Occupational exposure
- Environmental exposure

Physical Findings

- Findings consistent with an infectious etiology?
- Vital signs
- Body system abnormalities (e.g., rales, altered mental status, localized inflammation, erythema, warmth, edema, pain, and pus)

Diagnostic Imaging

- Radiographs (x-rays)
- CT scans
- MRI
- Labeled leukocyte scans

Nonmicrobiologic Laboratory Studies

- White blood cell count (WBC) with differential
- Erythrocyte sedimentation rate (ESR)
- C-reactive protein
- Procalcitonin

Microbiologic Studies

- Gram stain
- Culture and susceptibility testing

Nonmicrobiologic Laboratory Studies

Common nonmicrobiological laboratory tests include the white blood cell count (WBC) and differential, erythrocyte sedimentation rate (ESR), and determination of biomarkers C-reactive protein (CRP) or procalcitonin levels. In most cases, the WBC count is elevated in response to infection, but it may be decreased owing to overwhelming or long-standing infection. The differential is the percentage of each type of WBC (Table 69–1). In response to physiologic stress, neutrophils leave the bloodstream and enter the tissue to “fight” against the offending pathogens (i.e., leukocytosis). It is important to recognize that leukocytosis is nonspecific for infection and may temporarily occur in response to non-infectious conditions such as acute myocardial infarction. During an infection, immature neutrophils (e.g., bands) are released at an increased rate to help fight infection, leading to what is known as a bandemia or left shift. Therefore, a WBC count differential is key to determining whether an infection is present. Some patients may present with a normal total WBC with a left shift (e.g., the elderly). ESR and CRP are

Patient Encounter 1

HPI: An 87-year-old woman with a history of hypertension, hyperlipidemia, atrial fibrillation, and recent cerebrovascular accident is transported from a nursing home facility to the emergency room. Nursing staff report a several day history of fatigue, anorexia, nausea, and increasing confusion. She awoke this morning with a fever of 38.1°C and shortness of breath. She received cephalexin 14 days ago for a lower extremity cellulitis.

PMH: Hypertension, hyperlipidemia, atrial fibrillation, cerebrovascular accident 2 months ago for which she was hospitalized for 10 days.

FH: Father died of pneumonia at age 68. Mother died of lung cancer at age 81.

SH: Lives in a nursing home. Has 3 daughters and 2 sons.

Allergies: Sulfa (rash).

Meds:

Lisinopril 10 mg daily

Simvastatin 20 mg daily

Metoprolol XL 50 mg daily

Warfarin 2.5 mg daily

Alendronate 70 mg weekly

Calcium carbonate 500 mg BID

Multivitamin 1 daily

What information in the history supports an infectious etiology?

Is this patient at risk for resistant pathogens? Why?

Table 69–1

WBC and Differential

Basophil	Less than 1 (0.01)		Hypersensitivity reactions

nonspecific markers of inflammation that increase as a result of the acute-phase reactant response, which is a response to inflammatory stimuli such as infection or tissue injury. These tests may be used as markers of infectious disease response because they are elevated when the disease is acutely active and usually fall in response to successful treatment. Clinicians may use these tests to monitor a patient’s response to therapy in osteomyelitis and infective endocarditis. These tests should not be used to diagnose infection because they may be elevated in noninfectious inflammatory conditions (e.g., rheumatoid arthritis, polymyalgia rheumatica, and temporal arteritis). In contrast, procalcitonin, a prohormone of calcitonin, is rapidly produced in response to bacterial infection. Procalcitonin serum levels in conjunction with clinical findings are increasingly being utilized to assess both the need to initiate antibiotic therapy as well as determine when antibiotic therapy may be safely discontinued.

A full discussion of the role of procalcitonin in diagnosing and treating disease is beyond the scope of this chapter.^{8,9}

Microbiologic Studies

Microbiologic studies that allow for direct examination of a specimen (e.g., sputum, blood, or urine) also may aid in a presumptive diagnosis and give an indication of the characteristics of the infecting organism. Generally, microbial cultures are obtained with a Gram stain of the cultured material.

A Gram stain of collected specimens can give rapid information that can be applied immediately to patient care. A Gram stain is performed to identify whether bacteria are present and to determine morphologic characteristics of bacteria (e.g., gram-positive or gram-negative or shape—cocci, bacilli). Certain specimens do not stain well or at all and must be identified by alternative staining techniques (*Mycoplasma* spp., *Legionella* spp., *Mycobacterium* spp.). **Figure 69-2** identifies bacterial pathogens as classified by

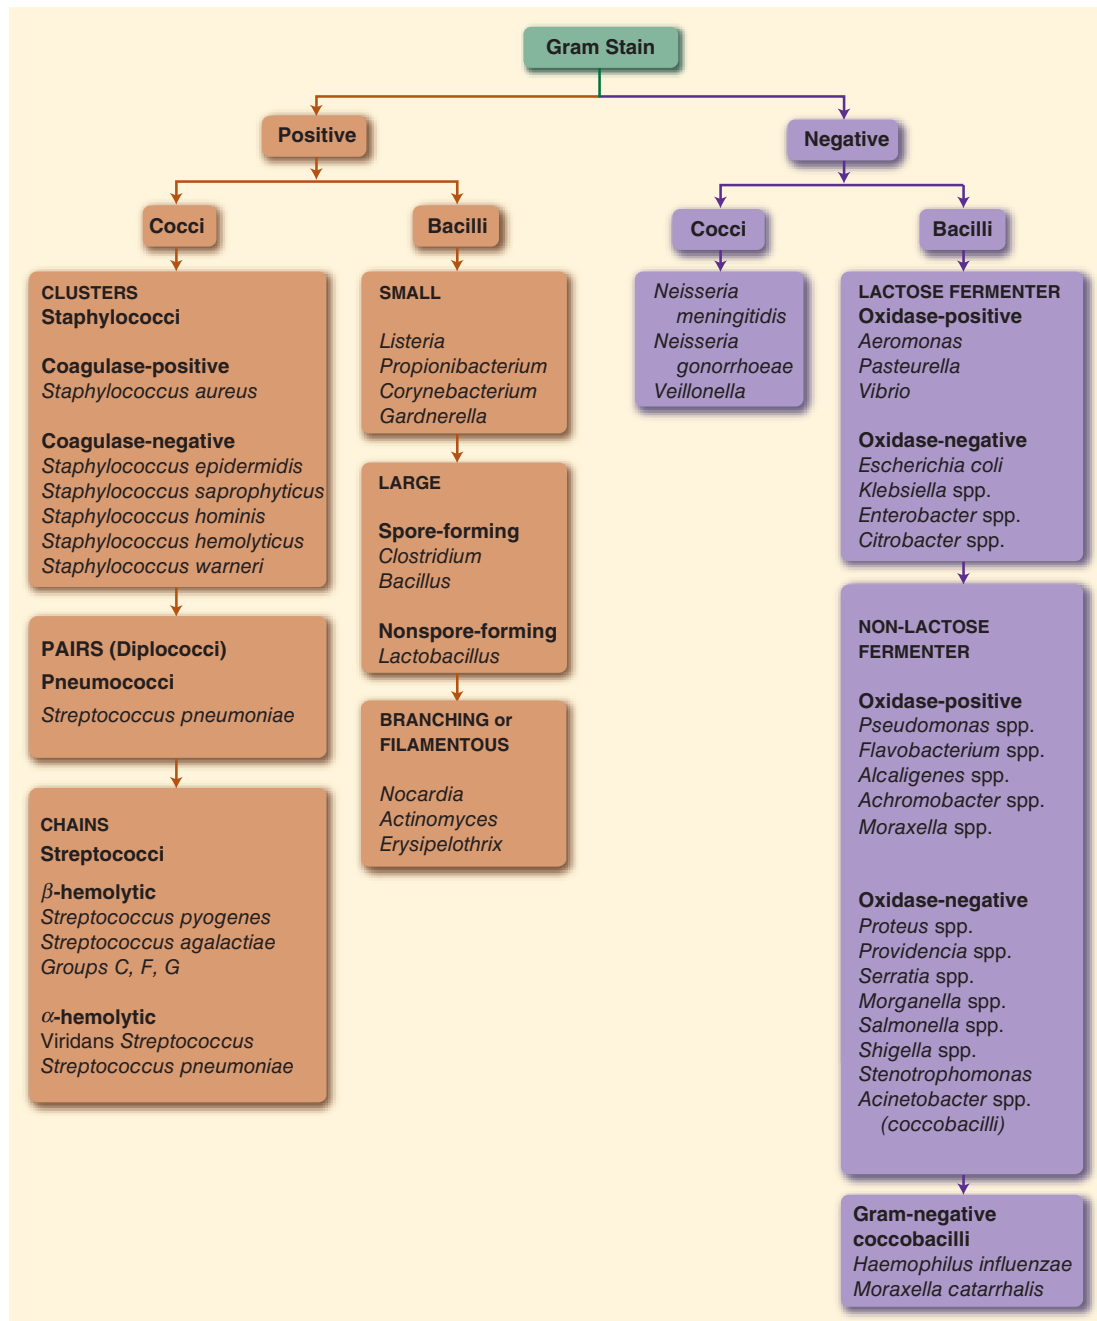

FIGURE 69-2. Important bacterial pathogens classified according to Gram stain and morphologic characteristics. (From Rybak MJ, Aeschlimann JR. Laboratory tests to direct antimicrobial pharmacotherapy. In: In DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach. 8th ed. New York: McGraw-Hill; 2011.)

Gram stain and morphologic characteristics. The presence of WBCs on a Gram stain indicates inflammation and suggests that the identified bacteria are pathogenic. The Gram stain may be useful in judging a sputum specimen's adequacy. For example, the presence of epithelial cells on sputum Gram stain suggests that the specimen is either poorly collected or contaminated. A poor specimen can give misleading information regarding the underlying pathogen and is a waste of laboratory personnel time and patient cost.

Culture and susceptibility testing provides additional information to the clinician to select appropriate therapy. Specimens are placed in or on culture media that provide the proper growth conditions. Once the bacteria grow on culture media, they can be identified through a variety of biochemical tests. Once a pathogen is identified, susceptibility tests can be performed to various antimicrobial agents. The *minimum inhibitory concentration* (MIC) is a standard susceptibility test. The MIC is the lowest concentration of antimicrobial that inhibits visible bacterial growth after approximately 24 hours (Fig. 69-3). Breakpoint and MIC values determine whether the organism is susceptible (S), intermediate (I), or resistant (R) to an antimicrobial. The *breakpoint* is the concentration of the antimicrobial that can be achieved in the serum after a normal or standard dose of that antimicrobial. If the MIC is below the breakpoint, the organism is considered to be susceptible to that agent. If the MIC is above the breakpoint, the organism is said to be resistant. Reported culture and susceptibility results may not provide MIC values but generally report the S, I, and R results.

5 In general, bacterial cultures should be obtained prior to initiating antimicrobial therapy in patients with a systemic inflammatory response, risk factors for antimicrobial resistance, or infections where diagnosis or antimicrobial susceptibility is uncertain. The decision to collect a speci-

FIGURE 69-3. Macrotube minimal inhibitory concentration (MIC) determination. The growth control (C), 0.5 mg/L, and 1 mg/L tubes are visibly turbid, indicating bacterial growth. The MIC is read as the first clear test tube (2 mg/L). (From Rybak MJ, Aeschlimann JR. Laboratory tests to direct antimicrobial pharmacotherapy. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*. 8th ed. New York: McGraw-Hill; 2011.)

men for culture depends on the sensitivity and specificity of the physical findings, diagnostic examination findings, and whether or not the pathogens are readily predictable. Culture and susceptibility testing usually is not warranted in a young, otherwise healthy woman who presents with signs and symptoms consistent with a urinary tract infection (UTI) because the primary pathogen, *Escherichia coli*, is readily predictable. Cultures and susceptibility testing are routine for sterile-site specimens (e.g., blood and spinal fluid), as well as for material presumed to be infected (e.g., material obtained from joints and abscesses). Cultures need to be interpreted with caution. Poor specimen collection technique and processing speed can result in misleading information and inappropriate use of antimicrobials.

Patient Encounter 2: Review of Symptoms, Physical Examination, and Laboratory Data

ROS: Elderly woman who is confused and unable to answer questions. No reports of emesis or diarrhea but with decreased appetite per nursing staff.

PE:

- **VS:** BP 100/58 P 84, RR 30, T 38.5°C, O₂ sat 84% (0.84) on room air, Ht 5 ft 1 in (155 cm), Wt 50 kg
- **HEENT:** Dry mucous membranes
- **Chest:** Diminished breath sounds, rales, and rhonchi LLL
- **CV:** Tachycardic with irregularly irregular rhythm

Labs:

- WBC $17.6 \times 10^3/\text{mm}^3$ ($17.6 \times 10^9/\text{L}$), segs 75% (0.75), bands 15% (0.15), lymphs 10% (0.10)
- SCr 2.1 mg/dL (186 $\mu\text{mol/L}$)
- Glucose 142 mg/dL (7.9 mmol/L)
- INR 3.5
- Procalcitonin 0.5 $\mu\text{g/L}$
- Sputum Gram stain: less than 10 epithelial cells/lpf, greater than 25 WBCs/lpf; gram-negative bacilli

Blood Cultures: Pending

What findings on physical examination are suggestive of an infectious process?

What laboratory findings and/or diagnostic studies have been performed to help establish the presence of an infection?

Are the findings of these laboratory and diagnostic studies suggestive of an infection?

What is your working diagnosis based on this patient encounter?

TREATMENT

General Approach to Treatment, Including Nonantimicrobial Treatment

While selection of antimicrobial therapy may be a major consideration in treating infectious diseases, it may not be the only therapeutic intervention. Other important therapies may include adequate hydration, ventilatory support, and other supportive medications. In addition, antimicrobials are unlikely to be effective if the process or source that leads to the infection is not controlled. *Source control* refers to this process and may involve removal of prosthetic materials such as catheters and infected tissue or drainage of an abscess. Source control considerations should be a fundamental component of any infectious diseases treatment. It is also important to recognize that there may be many different antimicrobial regimens that may cure the patient. While the following therapy sections provide factors to consider when selecting antimicrobial regimens, an excellent and more in-depth resource for selecting antimicrobial regimens for a variety of infectious diseases are the *Infectious Diseases Society of America Guidelines*.¹⁰

Antimicrobial Considerations in Selecting Therapy

6 *Drug-specific considerations in antimicrobial selection include spectrum of activity, effects on nontargeted microbial flora, appropriate dose, pharmacokinetic and pharmacodynamic properties, adverse-effect and drug-interaction profile, and cost (Table 69–2).*

► Spectrum of Activity and Effects on Nontargeted Flora

Most initial antimicrobial therapy is empirical because cultures usually have not had sufficient time to allow identification of a pathogen. **7** *Empirical therapy should be based on patient- and antimicrobial-specific factors such as the anatomic location of the infection, the likely pathogens associated with the presentation, the potential for adverse effects in a given patient, and the antimicrobial spectrum of activity.* Prompt initiation of appropriate therapy is paramount in hospitalized patients who are critically ill. Patients who receive initial antimicrobial therapy that provides coverage against the causative pathogen

survive at twice the rate of patients who do not receive adequate therapy initially.¹¹ Empirical selection of antimicrobial spectrum of activity should be related to the severity of the illness. Generally, acutely ill patients may require broader-spectrum antimicrobial coverage, whereas less ill patients may be managed initially with narrow-spectrum therapy. While a detailed description of antimicrobial pathogen-specific spectrum of activity is beyond the scope of this chapter, this information can be obtained readily from a number of sources.^{12,13}

Collateral damage is defined as the development of resistance occurring in a patient's nontargeted antimicrobial flora that can cause secondary infections. Clostridium difficile infection (CDI) is an example of a disease that occurs secondary to collateral damage from antimicrobial therapy. Antibiotics can increase the risk of CDI by suppressing normal intestinal flora, resulting in overgrowth of the non-susceptible *C. difficile* bacteria. In addition, CDI is associated with the prior use of broad-spectrum antibiotics, particularly fluoroquinolones.¹⁴ If several different antimicrobials possess activity against a targeted pathogen, the antimicrobial that is least likely to be associated with collateral damage may be preferred.

► Single Versus Combination Therapy

A common subject of debate involves the need to provide similar bacterial coverage with two antimicrobials for serious infections. Proponents state that double coverage may be synergistic, prevent the emergence of resistance, and improve outcome. However, there are few clinical examples in the literature to support these assertions. Examples where double coverage is considered superior are limited to infections associated with large bacterial inocula and in species that are known to readily develop resistance such as active tuberculosis or enterococcal endocarditis.^{15,16} A study of patients with *Pseudomonas aeruginosa* infections, an intrinsically resistant organism, demonstrated that empirical double coverage with two antipseudomonal antimicrobials improved survival.¹⁷ The analysis found that combination therapy increased the likelihood of appropriate empirical coverage; however, once organism susceptibilities were known, there was no difference in outcome between double coverage and monotherapy. Double antimicrobial coverage with similar spectra of activity may be beneficial for selected infections associated with high bacterial loads or for initial empirical coverage of critically ill patients in whom antimicrobial-resistant organisms are suspected. Monotherapy usually is satisfactory once antimicrobial susceptibilities are established.

► Antimicrobial Dose

Clinicians should be aware that dosage regimens with the same drug may be different depending on the infectious process. For example, ciprofloxacin, a fluoroquinolone, has various dosage regimens based on site of infection. The dosing for uncomplicated UTIs is 250 mg twice daily for 3 days. For complicated UTIs, the dose is 500 mg twice daily for 7 to 14 days. Severe complicated pneumonia requires a dosage regimen of

Table 69–2

Considerations for Selecting Antimicrobial Regimens

Drug Specific	Patient Specific
Spectrum of activity and effects on nontargeted flora	Anatomic location of infection
Dosing	Antimicrobial history
Pharmacokinetic properties	Drug allergy history
Pharmacodynamic properties	Renal and hepatic function
Adverse-effect potential	Concomitant medications
Drug-interaction potential	Pregnancy or lactation
Cost	Compliance potential

750 mg twice daily for 7 to 14 days. Clinicians are encouraged to use dosing regimens designed for treatment of the specific diagnosed infection because they have demonstrated proven efficacy and are most likely to minimize harm.

► Pharmacokinetic Properties

Pharmacokinetic properties of an antimicrobial may be important in antimicrobial regimens. *Pharmacokinetics* refers to a mathematical method of describing a patient's drug exposure in vivo in terms of absorption, distribution, metabolism, and elimination. *Bioavailability* refers to the amount of antimicrobial that is absorbed orally relative to an equivalent dose administered IV. Drug-related factors that may affect oral bioavailability include the salt formulation of the antimicrobial, the dosage form, and the stability of the drug in the gastrointestinal tract. Frequently, absorption may be affected by gastrointestinal tract blood flow. All patients that manifest systemic signs of infection such as hypotension or hypoperfusion should receive intravenous antimicrobials to ensure drug delivery. In almost all cases where patients have a functioning gastrointestinal tract and are not hypotensive, antimicrobials with almost complete bioavailability (greater than 80%) such as the fluoroquinolones, fluconazole, and linezolid may be given orally. With antimicrobials with modest bioavailability (e.g., many β -lactams), the decision to choose an oral product will depend more on the severity of the illness and the anatomic location of the infection. In sequestered infections, where higher systemic concentrations of antimicrobial may be necessary to reach the infected source (e.g., meningitis) or for antimicrobials with poor bioavailability, IV formulations should be used.

Several points regarding how the antimicrobial distributes into tissue are worth mentioning. First, only antimicrobials not bound to albumin are biologically active. Protein binding is likely clinically irrelevant in antimicrobials with low or intermediate protein binding. However, highly protein-bound antimicrobials (greater than 50%) also may not be able to penetrate sequestered compartments, such as cerebral spinal fluid, resulting in insufficient concentration to inhibit bacteria. Second, some drugs may not achieve sufficient concentrations in specific compartments based on distribution characteristics. For example, *Legionella pneumophila* is a nonenteric gram-negative organism that causes severe pneumonia. The organism is known to survive and reside inside pulmonary macrophages. Treatment with an antibiotic that works by inhibiting bacterial cell wall synthesis, such as a cephalosporin, will be ineffective because it only distributes into extracellular host tissues. However, macrolide or fluoroquinolone antimicrobials, which concentrate in human pulmonary macrophages, are highly effective against pneumonia caused by this organism.

Many antimicrobials undergo some degree of metabolism once ingested. Metabolism may occur via hepatic, renal, or non-organ-specific enzymatic processes. The route of elimination of the metabolic pathway may be exploited for infections associated with tissues related to the metabolic pathways. For example, many fluoroquinolone antimicrobials are metabolized only in part and undergo renal elimination.

Urinary concentrations of active drug are many times those achieved in the systemic circulation, making several of these agents good choices for complicated urinary tract infections.

► Pharmacodynamic Properties

Pharmacodynamics describes the relationship between drug exposure and pharmacologic effect of antibacterial activity or human toxicology. Antimicrobials generally are categorized based on their concentration-related effects on bacteria. Concentration-dependent pharmacodynamic activity occurs where higher drug concentrations are associated with greater rates and extents of bacterial killing. Concentration-dependent antimicrobial activity is maximized when peak antimicrobial concentrations are high. In contrast, *concentration-independent (or time-dependent) activity* refers to a minimal increase in the rate or extent of bacterial killing with an increase in antimicrobial dose. Concentration-independent antimicrobial activity is maximized when these antimicrobials are dosed to maintain blood and/or tissue concentrations above the MIC in a time-dependent manner. Fluoroquinolones, aminoglycosides, and metronidazole are examples of antimicrobials that exhibit concentration-dependent activity, whereas β -lactam and glycopeptide antimicrobials exhibit concentration-independent activity. Pharmacodynamic properties have been optimized to develop new dosing strategies for older antimicrobials. Examples include single-daily-dose aminoglycoside or β -lactam therapy administered by continuous or extended infusion. The product labeling for many new antimicrobials takes pharmacodynamic properties into account.

Antimicrobials also can be classified as possessing bactericidal or bacteriostatic activity in vitro. Bactericidal antibiotics generally kill at least 99.9% (3 log reduction) of a bacterial population, whereas bacteriostatic antibiotics possess antimicrobial activity but reduce bacterial load by less than 3 logs. Clinically, bactericidal antibiotics may be necessary to achieve success in infections such as endocarditis or meningitis. A full discussion of the application of antimicrobial pharmacodynamics is beyond the scope of this chapter, but excellent sources of information are available.¹⁸

► Adverse-Effect and Drug-Interaction Properties

A major concern when selecting antimicrobial regimens should be the propensity for the regimen to cause adverse effects and the potential for interaction with other drugs. Patients may possess characteristics or risk factors that increase their likelihood of developing an adverse event, emphasizing the need to obtain a good patient medical history. In general, if several different antimicrobial options are available, antimicrobials with a low propensity to cause specific adverse events should be selected, particularly for patients with risk factors for a particular complication. Risk factors for adverse events may include the coadministration of other drugs that are associated with a similar type of adverse event. For example, coadministration of the known nephrotoxin gentamicin with vancomycin increases the risk for nephrotoxicity compared

with administration of either drug alone.¹⁹ Other drug interactions may predispose the patient to dose-related toxicity through inhibition of drug metabolism. For example, erythromycin has the potential to prolong cardiac QT intervals in a dose-dependent manner, potentially increasing the risk for sudden cardiac death. A cohort study of patients taking oral erythromycin found that patients with concomitantly prescribed medications that inhibited the metabolism of erythromycin exhibited a fivefold increase in cardiac death versus controls.²⁰

► Antimicrobial Cost

A final consideration in selecting antimicrobial therapy relates to cost. It is important to remember that the most inexpensive antimicrobial is not necessarily the most cost-effective antimicrobial. Antimicrobial costs constitute a relatively small portion of the overall cost of care. Frequently, regulatory studies are not designed to identify differences in hospital length of stay, less common adverse events, monitoring costs, collateral damage, or antimicrobial-specific resistance issues, all of which may contribute to medical costs. Careful consideration of antimicrobial microbiologic, pharmacologic, and patient-related factors such as compliance and a variety of clinical outcomes is necessary to establish the cost versus benefit of an antimicrobial in a given patient. If there is no difference or a small difference in these factors, the least costly antimicrobial may be the best choice.

Patient Considerations in Antimicrobial Selection

8 Key patient-specific considerations in antimicrobial selection include recent previous antimicrobial exposures, identification of the anatomic location of infection through physical examination and diagnostic imaging, history of drug allergies, pregnancy or breast-feeding status, organ dysfunction that may affect drug clearance, immunosuppression, compliance, and the severity of illness (see Table 69–2).

► Host Factors

Host factors can help to ensure selection of the most appropriate antimicrobial agent. Age is an important factor in antimicrobial selection. With regard to dose and interval, renal and hepatic function varies with age. Populations with diminished renal function include neonates and the elderly. Hepatic function in the neonate is not fully developed, and drugs that are metabolized or eliminated by this route may produce adverse effects. For example, sulfonamides and ceftriaxone may compete with bilirubin for binding sites and may result in hyperbilirubinemia and kernicterus. Gastric acidity also depends on age; the elderly and children younger than 3 years of age tend to be achlorhydric. Drugs that need an acidic environment (e.g., ketoconazole) are not well absorbed, and those whose absorption is enhanced in an alkaline environment will have increased concentrations (e.g., penicillin G).

Disruption of host defenses due to IV or indwelling Foley catheters, burns, trauma, surgery, and increased gastric pH

Patient Encounter 3: Empirical Selection of Antibiotics

Based on the information presented, select an empirical antimicrobial regimen for this patient. Your plan should include:

- A tentative infectious diagnosis or source, including likely pathogens or resistant organisms
- A specific antimicrobial(s) regimen, including drug(s), dose, and route of administration
- Description of any ancillary treatments
- A rationale for your empirical antimicrobial selection based on drug- and patient-specific considerations

(secondary to antacids, H₂ blockers, and proton pump inhibitors) may place patients at higher risk for infection. Breaks in skin integrity provide a route for infection because the natural barrier of the skin is disrupted. Increased gastric pH can allow for bacterial overgrowth and has been associated with an increased risk of pneumonia.²¹

Recognizing the presumed site of infection and most common pathogens associated with the infectious source should guide antimicrobial choice, dose, and route of administration. For example, community-acquired pneumonia is caused most commonly by *S. pneumoniae*, *E. coli* is the primary cause of uncomplicated UTIs, and staphylococci and streptococci are implicated most frequently in skin and skin-structure infections (e.g., cellulitis).

Patients with a history of recent antimicrobial use may have altered normal flora or harbor resistant organisms. If a patient develops a new infection while on therapy, fails therapy, or has received antimicrobials recently, it is prudent to prescribe a different class of antimicrobial because resistance to the current treatment is likely. Previous hospitalization or healthcare utilization (e.g., residing in a nursing home, hemodialysis, and outpatient antimicrobial therapy) are risk factors for the acquisition of nosocomial pathogens, which are often resistant organisms.

Antimicrobial allergies are some of the most common drug-related allergies reported and have significant potential to cause adverse events. In particular, penicillin-related allergy is common and can be problematic because there is an approximately 4% cross-reactivity with cephalosporins as well as carbapenems.^{22,23} In general, a patient's medical history should be reviewed to determine the offending β -lactam and nature of the allergic reaction. In some cases, patients with mild or nonimmunologic reactions may receive a β -lactam antimicrobial with low cross-reactive potential. However, patients with a history of physical findings consistent with IgE-mediated reactions such as anaphylaxis, urticaria, or bronchospasm should not be administered any type of β -lactam antimicrobial, including cephalosporins, unless there are no other alternatives, and even then they should be administered with caution. Administration of potentially

cross-reactive agents in this situation should occur only under controlled conditions, and some patients may need to undergo desensitization. If the specific medical history relating to a reported allergy cannot be obtained, the patient should be assumed to have had an IgE-mediated reaction and should be managed in a similar manner. Monobactams (i.e., aztreonam) may be administered to patients with IgE-mediated allergic reactions to penicillin and are therefore an appropriate choice in these patients.

Renal and/or hepatic function should be considered in every patient prior to initiation of antimicrobial therapy. In general, most antimicrobials undergo renal elimination and exhibit decreased clearance with diminished renal function, and dosing adjustments are frequently necessary and recommendations for adjustment are available in the literature.²⁴ In contrast, dosing adjustments for antimicrobials that undergo nonrenal elimination are less well documented. Failure to adjust the antimicrobial dose or interval may result in drug accumulation and an increase in adverse effects.

Concomitant administration of other medications may influence the selection of the antimicrobial, dose, and monitoring. Medications that commonly interact with antibiotics include, but are not limited to, warfarin, rifampin, phenytoin, digoxin, theophylline, multivalent cations (e.g., calcium, magnesium, and zinc), and sucralfate. Drug interactions between antimicrobials and other medications may occur via the cytochrome P-450 system, protein-binding displacement, and alteration of vitamin K-producing bacteria. Interactions may result in increased concentrations of one or both agents, increasing the risk of adverse effects or additive toxicity. A key consideration in selecting antimicrobial regimens starts with obtaining a good patient medical and drug history, recognizing drug-specific adverse-event characteristics, and anticipating potential problems proactively. If it is necessary to use an antimicrobial with a relatively high frequency of adverse effects, informing patients of the risks and benefits of therapy, as well as what to do if an adverse effect occurs, may improve patient compliance and may facilitate patient safety.

Antimicrobial agents must be used with caution in pregnant and nursing women. Some agents pose potential threats to the fetus or infant (e.g., quinolones, tetracyclines, and sulfonamides). For some agents, avoidance during a specific trimester of pregnancy is warranted (e.g., the first trimester with trimethoprim/sulfamethoxazole). Pharmacokinetic variables also are altered during pregnancy. Both the clearance and volume of distribution are increased during pregnancy. As a result, increased dosages and/or more frequent administration of certain drugs may be required to achieve adequate concentrations. This information can be obtained from a number of sources.^{25,26}

Adherence is essential to ensure efficacy of a particular agent. Patients may stop taking their antibiotics once the symptoms subside and save them for a “future” infection. If the patient does not complete the course of therapy, the infection may not be eradicated, and resistance may emerge. Self-medication of saved antibiotics may be harmful, leading to overtreatment, which may further contribute to antibiotic resistance. Poor patient adherence may be due to adverse effects, tolerability, cost, and lack of patient education.

OUTCOME EVALUATION

Figure 69–4 provides an overview of patient- and antimicrobial agent-specific factors to consider when selecting an antimicrobial regimen. It further delineates monitoring of therapy and actions to take depending on the patient’s response to therapy. The duration of therapy depends on patient response and type of infection being treated.

Modifying Empirical Therapy Based on Cultures and Clinical Response

If a successful clinical response occurs and culture results are available, therapy should be de-escalated. Antibiotic *de-escalation* generally refers to the discontinuation of antibiotics that are providing a spectrum of activity greater than necessary to treat the infection, discontinuation of duplicative spectrum antibiotics, or switching to a narrower spectrum antibiotic once a patient is clinically stable. De-escalation of empirical therapy may also include discontinuing antibiotics based on clinical criteria and negative culture results, such as the absence of antibiotic-resistant pathogens.²⁷ The purpose of de-escalation therapy is to minimize the likelihood of secondary infections owing to antimicrobial-resistant organisms. In cases in which a specific organism is recovered that has a known preferred agent of choice, therapy might be changed to that specific agent. For example, antistaphylococcal penicillins are considered to be the agents of choice for methicillin-susceptible *S. aureus* owing to their bactericidal activity and narrow-spectrum activity and may be preferable to other antibiotic regimens. In other cases, empirical coverage might be discontinued if a specific suspected pathogen is excluded by culture or an alternative, noninfectious diagnosis is established. In addition, IV antimicrobials frequently are more expensive than oral therapy. Therefore, it is usually desirable to convert therapy to oral antimicrobials with a comparable antimicrobial spectrum or specific pathogen sensitivity as soon as the patient improves clinically.²⁸

Failure of Antimicrobial Therapy

While many infections respond readily to antimicrobials, some infections do not. A relatively common question when a patient’s condition fails to improve relates to whether the antimicrobial therapy has failed. Changing antimicrobials generally is one of the easiest interventions relative to other options. However, it is important to remember that antimicrobial therapy comprises only a portion of the overall disease treatment, and there may be many factors that contribute to a lack of improvement. **10** *In general, inadequate diagnosis resulting in poor initial antimicrobial or other nonantibiotic drug selection, poor source control, or the development of a new infection with a resistant organism are relatively common causes of antimicrobial failure.* An infection-related diagnosis may be difficult to establish and generally has two components: (a) differentiating infection from noninfection-related disease and (b) providing adequate empirical spectrum of activity if

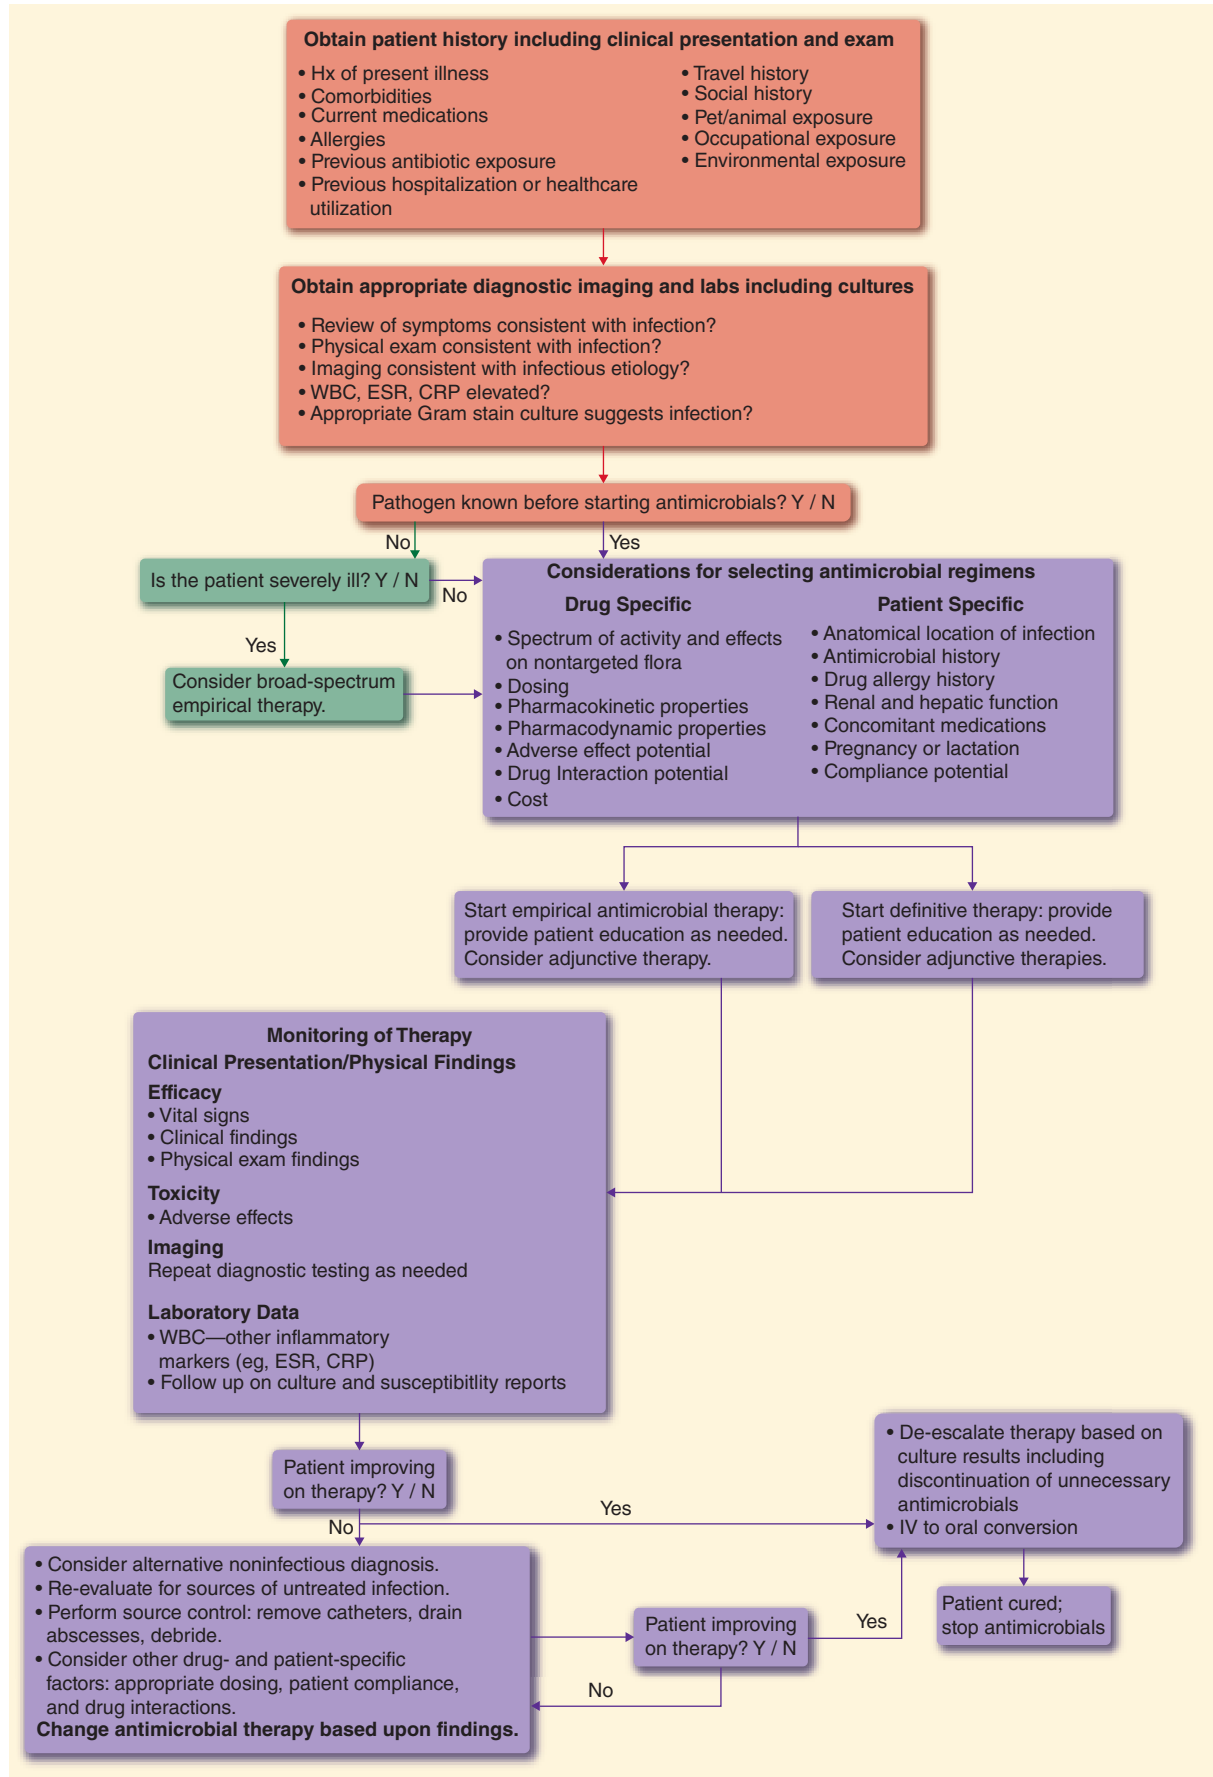

FIGURE 69-4. Approach to selection of antimicrobial therapy.

Patient Encounter 4: Patient Care and Monitoring

Update: The patient was admitted to the hospital with a presumptive diagnosis of healthcare-associated pneumonia. She received IV hydration with normal saline, 4 L oxygen, and empirical antibiotic therapy with cefepime, levofloxacin, and vancomycin.

After 48 hours of therapy, the following parameters are obtained:

PE:

- VS: BP 120/72, P 70, RR 22, T 37.9°C (100.2°F), O₂ sat 92% (0.92) on 2 L
- Repeat CXR: Infiltrate unchanged

Labs:

- WBC $11.2 \times 10^3/\text{mm}^3$ ($11.2 \times 10^9/\text{L}$)
- SCr 1.5 mg/dL (133 $\mu\text{mol}/\text{L}$)
- Glucose 116 mg/dL (6.4 mmol/L)
- Blood cultures $\times 2$: Negative
- Sputum culture: *Klebsiella pneumoniae*

Sensitivity Report:

Cefepime sensitive (MIC = 1 mg/L)
 Ceftazidime sensitive (MIC = 2 mg/L)
 Ceftriaxone sensitive (MIC = 1 mg/L)
 Piperacillin/taz sensitive (MIC = 8 mg/L)
 Meropenem resistant (MIC greater than 64 mg/L)
 Gentamicin sensitive (MIC = 0.5 mg/L)
 Amikacin sensitive (MIC = 0.5 mg/L)
 Ciprofloxacin resistant (MIC greater than 4 mg/L)

What information suggests improvement in the patient's condition?

Do any of the antimicrobial doses need to be adjusted for changes in organ function?

Should antimicrobial therapy be modified based on the culture results?

Can the antimicrobial therapy be converted from IV to oral therapy?

the cause is infectious. Failure of improvement in a patient's condition should warrant broadening the differential diagnosis to include noninfection-related causes, as well as considering other potential infectious sources and/or pathogenic organisms. Another common cause of failure is poor source control. A diagnostic search for unknown sources of infection and removal of indwelling devices in the infected environment or surgical drainage of abscesses should be undertaken if the patient's condition is not improving. Less common but still frequent causes of therapeutic failure include the development

of secondary infections. In this case, the patient generally improves, but then develops a new infection caused by an antimicrobial-resistant pathogen and relapses. The emergence of resistance to a targeted pathogen while on antimicrobial therapy can be associated with clinical failure but usually is limited to tuberculosis, pseudomonads, or other gram-negative enterics. Drug- and patient-specific factors such as appropriate dosing, patient compliance, and drug interactions can be associated with therapeutic failure and also should be

Patient Care and Monitoring

After selection and initiation of antimicrobial regimen, there are a number of additional patient care and monitoring considerations that should be addressed to improve the likelihood of a successful outcome. **9** *Patient education, de-escalation of antimicrobial therapy based on culture results, monitoring for clinical response and adverse effects, and appropriate duration of therapy are important.*

Patient Education

Provide patient education with regard to appropriate use of antimicrobials (e.g., dose, interval), adverse effects, and drug interactions (which may play a role in therapy failure and increased toxicity).

Therapeutic Monitoring

Monitor for therapeutic response by assessing efficacy and toxicity of the antimicrobial regimen.

- Clinical presentation/physical findings
- *Efficacy:* Assess vital signs (monitor for return to normal or lack of altered findings; e.g., fever), physical examination findings, patient's subjective impression
- *Toxicity:* Monitor and assess for adverse effects and evaluate antimicrobial serum concentrations when appropriate to minimize toxicity and improve outcomes
- *Diagnostic imaging:* Diagnostic testing is disease state-dependent
- Laboratory data
- Monitor and assess laboratory data: WBC with differential (goal is a reduction in WBC if elevated initially and resolution of left shift), renal and/or hepatic function (consider need for dosage adjustments), other labs as indicated (e.g., ESR, CRP)
- Follow up on culture and susceptibility reports with subsequent de-escalation of therapy, if possible
- Reculture of specimens is not performed routinely except in few cases (e.g., endocarditis) or where a secondary infection is suspected because data may be misleading and lead to the addition of broader or more powerful antimicrobials

considered. A common assumption is that the correct diagnosis was made, but the patient was not treated long enough with antimicrobials. There are certain types of infections (e.g., endocarditis or osteomyelitis) where the standard of care is to treat for prolonged periods of time (i.e., weeks or months). However, the optimal duration of therapy for many infectious diseases is somewhat subjective. Recently, studies of several infectious processes have suggested that shorter durations of therapy can result in similar clinical outcomes as longer durations of therapy, frequently with fewer complications or secondary infections.^{29–31} The general trend has been to treat these disease processes with shortened courses of antibiotic therapy. In this period of extensive antimicrobial resistance, clinicians should keep abreast of changing recommendations emphasizing shorter durations of therapy.

CONCLUSION

Antimicrobial regimen selection is a complex process involving the integration of a multitude of factors. The guiding principles to make the diagnosis and do no harm must be considered when choosing an antimicrobial for a given patient. In summary, when infection is suspected, rapid and accurate diagnosis should be followed by early intervention that includes administration of appropriately dosed antibiotics with appropriate empirical spectra. De-escalation to suitable narrow-spectrum antibiotics if susceptibilities are known should occur as soon as possible, and therapy should be stopped as soon as the patient is cured. These fundamental actions improve infectious disease outcomes and minimize collateral damage and adverse effects.

Abbreviations Introduced in This Chapter

CDC	Centers for Disease Control and Prevention
CRP	C-reactive protein
ESR	Erythrocyte sedimentation rate
HPI	History of present illness
MIC	Minimum inhibitory concentration
MRSA	Methicillin-resistant <i>Staphylococcus aureus</i>
PMH	Past medical history
UTI	Urinary tract infection
VRE	Vancomycin-resistant <i>Enterococcus</i>
WBC	White blood cell count

Central Nervous System Infections

P. Brandon Bookstaver and April D. Miller

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Discuss the pathophysiology of CNS infections and the impact on antimicrobial treatment regimens (e.g., antimicrobial dosing and CNS penetration).
2. Describe the signs, symptoms, and clinical presentation of CNS infections.
3. List the most common pathogens causing CNS infections and identify risk factors for infection with each pathogen.
4. State the goals of therapy for CNS infections.
5. Design appropriate empirical antimicrobial regimens for patients suspected of having CNS infections caused by each of the following pathogens (taking age, vaccine history, and other patient-specific information into account), and analyze the impact of antimicrobial resistance on both empirical and definitive therapy: *Neisseria meningitidis* meningitis, meningitis, *Haemophilus influenzae* meningitis, *Listeria monocytogenes* meningitis, group B *Streptococcus* meningitis, gram-negative bacillary meningitis, postneurosurgical infection, CNS shunt infection, herpes simplex encephalitis.
6. Modify empirical antimicrobial regimens based on laboratory data and other diagnostic criteria.
7. Discuss the management of close contacts of patients diagnosed with CNS infections.
8. Identify candidates for vaccines and other prophylactic therapies to prevent CNS infections.
9. Describe the role of adjunctive agents (e.g., dexamethasone) in the management of CNS infections.
10. Formulate a monitoring plan to assess efficacy and adverse effects of therapy for CNS infections.

KEY CONCEPTS

- 1 Meningitis is a neurologic emergency that requires prompt recognition, diagnosis, and management to prevent death and residual neurologic defects. Patients with fever, headache, and neck stiffness should be evaluated for meningitis.
- 2 Ideally, lumbar puncture (LP) to obtain cerebrospinal fluid (CSF) for direct examination and laboratory analysis, as well as blood cultures and other relevant cultures, should be obtained before initiation of antimicrobial therapy. However, initiation of antimicrobial therapy should not be delayed if a pretreatment LP cannot be performed.
- 3 The treatment goals for CNS infections are to prevent death and residual neurologic deficits, eradicate or control causative microorganisms, ameliorate clinical signs and symptoms, and identify measures (e.g., vaccination and suppressive therapy) to prevent future infections.
- 4 Prompt initiation of IV high-dose bactericidal antimicrobial therapy directed at the most likely pathogen(s) is essential due to the high morbidity and mortality associated with CNS infections.
- 5 IV antimicrobial therapy is administered for the full course of therapy for CNS infections to ensure adequate CSF penetration throughout the course of treatment.
- 6 Empirical antimicrobial therapy should be directed at the most likely pathogen(s) for a specific patient, taking into account age, risk factors for infection (including underlying disease and immune dysfunction, vaccine history, and recent exposures), CSF Gram stain results, CSF antibiotic penetration, and local antimicrobial resistance patterns.
- 7 Empirical antimicrobial therapy should be modified on the basis of laboratory data and clinical response.
- 8 Close contacts of patients with CNS infections should be evaluated for possible antimicrobial prophylaxis.

- 9 Components of a monitoring plan to assess the efficacy and safety of antimicrobial therapy of CNS infections include clinical signs and symptoms and laboratory data (e.g., CSF findings, culture, and sensitivity data).

The term *CNS infections* describes a variety of infections involving the brain and spinal cord and associated tissues, fluids, and membranes, including meningitis, encephalitis, brain abscess, shunt infections, and postoperative infections (see Glossary). 1 *CNS infections, such as meningitis, are considered neurologic emergencies that require prompt recognition, diagnosis, and management to prevent death and residual neurologic deficits.* Improperly treated, CNS infections are associated with high rates of morbidity and mortality. Despite advances in care, the overall mortality of bacterial meningitis in the United States remains at approximately 15%, and at least 10% to 30% of survivors are afflicted with neurologic impairment, including hearing loss, **hemiparesis**, and learning disabilities.¹⁻⁴ Antimicrobial therapy and preventive vaccines have revolutionized management and improved outcomes of bacterial meningitis and other CNS infections dramatically.

EPIDEMIOLOGY AND ETIOLOGY

CNS infections are uncommon, and rates of bacterial meningitis are declining, with an incidence of two cases per 100,000 in 1998 and 1999 down to 1.38 cases per 100,000 in 2006 and 2007.³ Increased rates of vaccination appear to prevent four to six cases of meningitis reported per 100,000 adults annually.⁵ However, the severity of these infections demands prompt medical intervention and treatment. CNS infections can be caused by bacteria, fungi, mycobacteria, viruses, parasites, and spirochetes.

Bacterial meningitis is the most common cause of CNS infections. *Streptococcus pneumoniae* (pneumococcus) was the most common pathogen for bacterial meningitis (0.8 to 1.09 cases/100,000), followed by *Neisseria meningitidis* (meningococcus, 0.19 to 0.44 cases/100,000), group B *Streptococcus* (0.21 to 0.3 cases/100,000), *Haemophilus influenzae* (0.08 to 0.12 cases/100,000), and *Listeria monocytogenes* (0.03 to 0.1 cases/100,000).^{3,5} Vaccines directed against bacteria causing meningitis and related infections (e.g., pneumonia and ear infections) have reduced the risk of infections due to *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* type b (Hib) dramatically. Prior to the availability of Hib conjugate vaccines, Hib meningitis or other invasive disease was documented in one in 200 children by the age of 5 years.⁶ Widespread use of the Hib vaccine has reduced the incidence of invasive Hib disease by 99% and has reduced the incidence of Hib meningitis in children by 35%.^{1,3,7} The routine use of the 7-valent conjugate pneumococcal vaccine (PCV7) in children has reduced the incidence of pneumococcal meningitis from PCV7 serotypes from 3.37 cases per 100,000 in 1998 and 1999 to 0.07 cases per 100,000 in 2006 and 2007 in children under the age of 5 years. In addition, cases of PCV7 serotype

pneumococcal meningitis in adults aged 65 years or more declined between the same time periods from 0.77 to 0.11 cases per 100,000.³ Despite use of the PCV7, *S. pneumoniae* remains the most common pathogen for pediatric bacterial meningitis, with nearly 50% of cases due to nonvaccine serotypes.^{3,9} From 2003 to 2007, PCV13 serotypes, reflecting a new 13-valent vaccine licensed for use in 2010, accounted for 57.2% and 41.6% of meningitis cases in children and adults, compared with only 15.5% and 16.0% accounted for by PCV7 serotypes, respectively.³ Introduction of the PCV13 vaccine may have a significant impact on the epidemiology of pneumococcal meningitis in the future.

- Encephalitis may result from viral, bacterial, parasitic, and other noninfectious causes. Herpes simplex virus (HSV) is the most common cause of encephalitis in the United States, accounting for 10% of all cases.¹⁰ The annual incidence of viral encephalitis is 3.5 to 7.4 infections per 100,000 persons.¹⁰ Other pathogens include common bacterial meningitis causes, *Rickettsia* species, enteroviruses, arboviruses, varicella-zoster virus, rotavirus, coronavirus, influenza viruses A and B, West Nile virus, and Epstein-Barr virus may be associated with a meningo-encephalopathic presentation.¹¹ Approximately 20,000 hospitalizations each year are secondary to encephalitis, accounting for \$650 million in healthcare costs.¹² Over the past 10 to 20 years, mortality secondary to encephalitis has remained constant, correlating well with the increased number of people living with human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS). HIV infection is concurrent in nearly 20% of patients dying from encephalitis.¹³

Neurosurgical procedures may place patients at risk for meningitis due to bacteria (e.g., *Staphylococcus aureus*, coagulase-negative staphylococci, and gram-negative bacilli) acquired at the time of surgery or in the postoperative period. In addition to bacteria, other pathogens may cause meningitis in at-risk patients. Immunocompromised patients, such as solid-organ transplant patients and patients living with HIV infection, are at risk for fungal meningitis with *Cryptococcus neoformans* and encephalitis secondary to *Toxoplasma gondii* and JC virus (see Chap. 84). Tuberculosis can spread from pulmonary sites to cause clinical disease in the CNS. Life-threatening viral encephalitis and meningitis can occur in otherwise healthy, young individuals, as well as in patients immunocompromised by age or other factors. Because the treatments for different types of CNS infections are often different, it is important to pay close attention to patients' risk factors when choosing empirical antimicrobial therapy. Patients at extremes of age, those living in close contact with others, and those with immune defects are most susceptible to meningitis. Risk factors for CNS infections can be classified as follows:

- *Environmental*—recent exposures (e.g., close contact with meningitis or respiratory tract infection, contaminated foods), active or passive exposure to cigarette smoke, close living conditions
- *Recent infection in the patient*—respiratory infection, otitis media, sinusitis, mastoiditis

Table 70-1

Most Likely Pathogens and Recommended Empirical Therapy, by Risk Factor, for Bacterial Meningitis

Predisposing Factor	Most Likely Pathogens	Recommended Empirical Antibiotic Therapy
Age		
Less than 3 months	Group B <i>Streptococcus</i> <i>Escherichia coli</i> <i>Klebsiella pneumoniae</i> <i>Listeria monocytogenes</i>	Ampicillin <i>plus</i> cefotaxime or aminoglycoside
3 months to less than 18 years	<i>Streptococcus pneumoniae</i> <i>Neisseria meningitidis</i> <i>Haemophilus influenzae</i>	Cefotaxime or ceftriaxone <i>plus</i> vancomycin
18 years to less than 60 years	<i>S. pneumoniae</i> <i>N. meningitidis</i>	Cefotaxime or ceftriaxone <i>plus</i> vancomycin
60 years or older	<i>S. pneumoniae</i> Gram-negative bacilli <i>L. monocytogenes</i>	Cefotaxime or ceftriaxone <i>plus</i> vancomycin <i>plus</i> ampicillin
Immunocompromised	<i>S. pneumoniae</i> <i>N. meningitidis</i> <i>L. monocytogenes</i> Gram-negative bacilli (including <i>Pseudomonas aeruginosa</i>)	Cefotaxime or ceftriaxone <i>plus</i> vancomycin <i>plus</i> ampicillin (consider double antibiotic coverage against <i>Pseudomonas</i> spp. if suspected)
Surgery, Trauma		
Postneurosurgical infection	<i>S. aureus</i> (including MRSA) Coagulase-negative <i>Staphylococcus</i> (including MRSE) Gram-negative bacilli (including <i>P. aeruginosa</i>)	Vancomycin or linezolid <i>plus</i> ceftazidime or cefepime or meropenem (consider double antibiotic coverage against <i>Pseudomonas</i> spp. if suspected)
Penetrating head trauma	<i>S. aureus</i> (including MRSA) coagulase-negative <i>Staphylococcus</i> Gram-negative bacilli (including <i>P. aeruginosa</i>)	Vancomycin or linezolid <i>plus</i> ceftazidime or cefepime or meropenem (consider double antibiotic coverage against <i>Pseudomonas</i> spp. if suspected)
CSF shunt	Coagulase-negative <i>Staphylococcus</i> (including MRSE) <i>S. aureus</i> (including MRSA) Gram-negative bacilli (including <i>P. aeruginosa</i>)	Vancomycin or linezolid <i>plus</i> ceftazidime or cefepime or meropenem (consider double antibiotic coverage against <i>Pseudomonas</i> spp. if suspected)

MRSA, methicillin-resistant *Staphylococcus aureus*; MRSE, methicillin-resistant *Staphylococcus epidermidis*.

From Refs. 15 and 25.

Patient Encounter 1, Part 1

NB is a 67-year-old woman resident of an elderly singles assisted living facility. She maintains her activities of daily living on her own. NB participates in group activities with co-residents on a weekly basis, with the most recent being a wine and cheese party about 1 week ago. She now presents to the emergency department with a 2-day history of headache, fever, and photophobia. Physical findings and laboratory values include temperature of 38.3°C (101°F) and WBC of $13.4 \times 10^3/\text{mm}^3$ ($13.4 \times 10^9/\text{L}$), with 70% (0.70) polymorphonuclear cells. Examination reveals nuchal rigidity; remainder is benign for additional findings. NB also reports occasional nausea. She has a significant history for osteoporosis for which she takes alendronate and calcium with vitamin D. She receives the influenza vaccine yearly.

What signs and symptoms consistent with meningitis are present in NB?

What causative pathogens should be suspected in NB?

What empiric antimicrobials should be started?

- **Immunosuppression**—anatomic or functional asplenia, sickle cell disease, alcoholism, cirrhosis, immunoglobulin or complement deficiency, cancer, HIV/AIDS, uncontrolled diabetes mellitus, debilitated state of health
- **Surgery, trauma**—neurosurgery, head trauma, CSF shunt, cochlear implant
- Noninfectious causes of meningitis include malignancy, medications (e.g., sulfonamides, nonsteroidal anti-inflammatory drugs [NSAIDs], IV immunoglobulin), autoimmune disease (e.g., lupus), and trauma.^{9,10}
- The most common pathogens causing bacterial meningitis, by age group and other risk factors, are found in [Table 70-1](#).

PATHOPHYSIOLOGY

Meningitis is an inflammation of the membranes of the brain and spinal cord (**meninges**) and the CSF in contact with these membranes, whereas encephalitis is an inflammation of the brain tissue. CSF flows through the subarachnoid space, insulating and protecting delicate CNS tissue. CSF is

produced within the ventricles of the brain and flows downward through the spinal cord, serving as a continuous flushing mechanism for the CNS.

The blood–brain barrier and blood–CSF barrier are made of specialized tissue capillaries that isolate the brain from substances circulating in the bloodstream or colonizing nearby tissues. To initiate a CNS infection, pathogens must gain entry into the CNS by **contiguous** spread, **hematogenous** seeding, direct inoculation, or reactivation of latent infection. **Contiguous** spread occurs when infections in adjacent structures (e.g., sinus cavities or the middle ear) invade directly through the blood–brain barrier (e.g., Hib). **Hematogenous** seeding occurs when a more remote infection causes bacteremia that seeds the CSF (e.g., pneumococcal pneumonia). Reactivation of latent infection results from dormant viral, fungal, or mycobacterial pathogens in the spine, brain, or nerve tracts. Direct inoculation of bacteria into the CNS is the result of trauma, congenital malformations, or complications of neurosurgery.

Once through the blood–brain barrier, pathogens thrive and replicate due to limited host defenses in the CNS. **Figure 70-1** depicts the pathophysiologic changes associated with meningitis. Neurologic tissue damage is the result of the host's immune reaction to bacterial cellular components (e.g., lipopolysaccharide, teichoic acid, and peptidoglycan), which triggers **cytokine** production, particularly tumor necrosis factor alpha (TNF- α) and interleukin 1 (IL-1), as well as other mediators of inflammation.¹⁵ Bacteriolysis resulting from antibiotic therapy further contributes to the inflammatory process. **Cytokines** increase permeability of the blood–brain barrier,

allowing influx of neutrophils and other host defense cells that contribute to the development of cerebral edema and increased intracranial pressure characteristic of meningitis.¹⁶ The increase in intracranial pressure is responsible for the hallmark clinical signs and symptoms of meningitis: headache, neck stiffness, altered mental status, photophobia, and seizures. Unaltered, these pathophysiologic changes may result in cerebral ischemia and death.

The CNS response to infection is evident by demonstrable changes in the CSF. **2** *Ideally, LP to obtain CSF for direct examination and laboratory analysis, as well as blood cultures and other relevant cultures, should be obtained before initiation of antimicrobial therapy. However, initiation of antimicrobial therapy should not be delayed if a pretreatment LP cannot be performed.*

Normal CSF has a characteristic composition in terms of protein and glucose content, as well as cell count. **Table 70-2** lists CSF findings observed in the absence of infection, as well as in patients with bacterial, viral, fungal, and tuberculous meningitis.

CLINICAL PRESENTATION AND DIAGNOSIS

A high index of suspicion should be maintained for patients at risk for CNS infections. Prompt recognition and diagnosis are essential so that antimicrobial therapy can be initiated as quickly as possible. A medical history (including risk factors for infection and history of possible recent exposures) and

From Refs. 5, 11, 20, and 33.

Clinical Presentation and Diagnosis of CNS Infections

General

- Evaluate patient risk factors and recent exposures
- Evaluate other possible causes: space-occupying lesion (which may or may not be malignant), drug-induced CNS pathology autoimmune disease, and trauma^{12,13}

Signs and Symptoms²

- 95% of patients with bacterial meningitis have two of the following: headache, fever, neck stiffness, and altered mental status
- Headache (87%)
- Nuchal rigidity (stiff neck) (83%)
- Fever (77%)
- Nausea (74%)
- Altered mental status (i.e., confusion, lethargy, and obtundation) (69%)
- Focal neurologic defects (including positive Brudzinski's sign and Kernig's sign) (33%)
- Seizures
- Malaise, restlessness
- Photophobia
- Skin lesions (diffuse petechial rash observed in 50% of patients with meningococcal meningitis)
- Signs and symptoms in neonates, infants, and young children: nonspecific findings, such as altered feeding and sleep patterns, vomiting, irritability, lethargy, bulging fontanel, seizures, respiratory distress, and petechial/purpuric rash¹⁷
- Predictors of an unfavorable outcome: seizures, focal neurologic findings, altered mental status, papilledema, hypotension, septic shock, and pneumococcal meningitis⁴

Laboratory Tests^{5,18,19}

- CSF examination via lumbar puncture (LP, spinal tap); contraindicated in patients with cardiorespiratory compromise, increased intracranial pressure and

papilledema, focal neurologic signs, seizures, bleeding disorders, abnormal level of consciousness, and possible brain herniation (a CT scan should be performed before LP if there is a question of a CNS mass to avoid potential for brain herniation) (see Table 70-2 for specific CSF findings)

- Elevated opening pressure (may be decreased in neonates, infants, and children)
- Cloudy CSF
- Decreased glucose
- Elevated protein
- Elevated WBC (differential provides clues to offending pathogen)
- Gram stain (adequate for diagnosis in 60% to 90% of patients with bacterial meningitis)
- Culture and sensitivity (positive in 70% to 85% without prior antibiotic therapy, positive in less than 20% who have had prior therapy)
- If CSF Gram stain and/or culture is negative, rapid diagnostic tests (such as latex agglutination) may be useful; these tests are positive even if bacteria are dead
- Polymerase chain reaction (PCR; DNA amplification of the most common bacterial meningitis pathogens) may be useful to help exclude bacterial meningitis
- Elevated CSF lactate and C-reactive protein
- Blood cultures (at least two cultures, one "set"; positive in 66%)
- Scraping of skin lesions (e.g., rash) for direct microscopic examination and culture
- Other cultures should be obtained as clinically indicated (e.g., sputum)
- WBC with differential
- Fungal meningitis: CSF culture, CSF and serum cryptococcal antigen titers, microscopic examination of CSF specimens
- Tuberculous meningitis: CSF culture, PCR evaluation (preferred), and acid-fast stain

Patient Encounter 1, Part 2

The 67-year-old patient with signs and symptoms of meningitis underwent lumbar puncture. Initial results from CSF studies are WBC $1.8 \times 10^3/\text{mm}^3$ ($1.8 \times 10^9/\text{L}$) with 47% (0.47) PMNs and 41% (0.41) monocytes, protein 176 mg/dL (1,760 mg/L), glucose 18 mg/dL (1.0 mmol/L). Gram stain shows gram-positive rods. Vital signs remain stable in the ED. First doses of antimicrobial therapy are initiated in the ED, and NB is admitted to a medicine ward for continued treatment and confirmation of final diagnosis. Culture results confirm *L. monocytogenes* infection. Antimicrobials are streamlined and continued for the full duration.

What clues in the CSF results are suggestive of bacterial meningitis?

Would adjunctive steroids offer additional benefit in this patient?

How can her antibiotic regimen be streamlined at this time?

Patient Encounter 1, Part 3

NB has clinically improved on hospital day 5 and would like to be discharged home to continue therapy, but would prefer oral therapy if available. Following discharge back to the group home and learning of her illness, coresident of NB are concerned about the possibility of getting sick and begin to follow up with the on-call physician at the group home. They wonder about medications and vaccinations to prevent the disease.

How long should therapy be continued in NB?

What oral options are viable options for continuation as an outpatient in this case?

*Who should receive antimicrobial prophylaxis for *L. monocytogenes*?*

and wound care (for surgical wounds), is an important adjunct to antimicrobial therapy, particularly early in the treatment course.

Treatment Principles

4 Prompt initiation of IV high-dose bactericidal antimicrobial therapy directed at the most likely pathogen(s) is essential due to the high morbidity and mortality associated with CNS infections. Although there are no prospective studies that relate timing of antibiotic administration to clinical outcome in bacterial meningitis, a longer duration of symptoms and more advanced disease before treatment initiation increase the risk of a poor outcome.^{4,18,21} Initiation of antibiotic therapy as soon as possible after bacterial meningitis is suspected or proven (even before hospitalization) reduces mortality and neurologic sequelae, as long as antibiotics were started before patients deteriorate to a score of 10 on the **Glasgow Coma Scale**.^{22,23} Rapid sterilization of CSF is important; delayed CSF sterilization after approximately 24 hours of antibiotic therapy increases the risk of neurologic sequelae, including moderate to profound hearing loss.^{24,25}

Meningitis occurs in a tissue with limited host defenses. Bacterial replication occurs rapidly in the absence of complement and specific antibodies directed toward common bacterial pathogens.²⁶ High-dose parenteral bactericidal antibiotic therapy is required to treat meningitis effectively. Data from animal studies and patients demonstrate better outcomes when bactericidal antibiotic therapy (versus bacteriostatic therapy) is used to sterilize the CSF.²⁷ However, successful treatment of meningitis has been reported with bacteriostatic agents. High doses of parenteral therapy are required to achieve CSF antibiotic concentrations adequate to rapidly sterilize the CSF and reduce the risk of complications. The presence of infection in the CSF reduces the activity of some classes of antibiotics. For example, the decreased pH of CSF associated with meningitis significantly reduces the activity of aminoglycoside antibiotics.²⁸

physical examination yield important information to help guide the diagnosis and treatment of meningitis. Common signs and symptoms include fever, headache, nuchal rigidity (stiff neck), and photophobia. As common meningeal signs are not typically present in infants, nonspecific signs and symptoms including excessive irritability or crying, vomiting or diarrhea, tachypnea, altered sleep pattern, and poor eating should be noted. Depending on involved pathogens and disease severity, patients may also present with altered mental status, stupor, and seizures.

TREATMENT**Goals of Therapy**

The introduction of antibiotic therapy and vaccines has reduced dramatically the mortality associated with bacterial meningitis.²⁰ Prior to these advances, bacterial meningitis was almost universally fatal, and those few patients who survived often suffered from debilitating residual neurologic deficits, such as permanent hearing loss. Although significant improvements have been made, the fatality rate of meningitis remains above 15% in adults, likely due to its occurrence in debilitated patient populations.

3 The treatment goals for CNS infections are to prevent death and residual neurologic deficits, eradicate or control causative micro-organisms, ameliorate clinical signs and symptoms, and identify measures to prevent future infections (e.g., vaccination and suppressive therapy). These goals should be accomplished with minimal adverse drug reactions and interactions. Surgical debridement should be employed, if appropriate (as in postneurosurgical infections and brain abscess). Supportive care, consisting of hydration, electrolyte replacement, antipyretics, antiemetics, analgesics, antiepileptic drugs,

Antimicrobial pharmacokinetics and pharmacodynamics must be considered when designing treatment regimens for CNS infections. Ability of antibiotics to reach and achieve effective concentrations at the infection site is the key to treatment success. In experimental models of meningitis, maximum bactericidal activity is achieved when CSF concentrations exceed the minimum bactericidal concentration (MBC) of the infecting pathogen by 10- to 30-fold.¹⁷ In general, low-molecular-weight lipophilic antibiotics that are unionized at physiologic pH and not highly protein bound penetrate best into CSF and other body tissues and fluids.^{26,28} In addition to drug characteristics, integrity of the blood-brain barrier determines antibiotic penetration into CSF. The CSF penetration of most, but not all, antibiotics is enhanced by the presence of infection and inflammation. Sulfonamides, trimethoprim, chloramphenicol, rifampin, and most antitubercular drugs achieve therapeutic CSF levels even without meningeal inflammation.¹⁰ Most β -lactams and related antibiotics (i.e., carbapenems and monobactams), vancomycin, quinolones, acyclovir, linezolid, daptomycin, and colistin achieve therapeutic CSF levels in the presence of meningeal inflammation.¹¹ Aminoglycosides, first-generation cephalosporins, second-generation cephalosporins (except cefuroxime), clindamycin, and amphotericin do not achieve therapeutic CSF levels, even with inflammation, but clindamycin does achieve therapeutic brain tissue levels.¹¹

An adequate duration of therapy is required to treat meningitis successfully (Table 70-3). **5** Parenteral (IV) therapy is administered for the full course of therapy for CNS infections to ensure adequate CSF penetration throughout the course of treatment. Antibiotic treatment (and dexamethasone, if used as a treatment adjunct) reduces the inflammation associated with meningitis, which, in turn, reduces the penetration of some antibiotics into the CSF. To ensure adequate antibiotic concentrations throughout the treatment course, parenteral administration is continued for the full treatment course. Carefully selected patients who have close medical monitoring and follow-up may be able to receive a portion of their parenteral meningitis treatment on an outpatient basis.^{18,29} A management algorithm for adults with suspected bacterial meningitis, as recommended by the Infectious Diseases Society of America (IDSA), is summarized in Figure 70-2.

Empirical Antimicrobial Therapy

After expeditious workup (i.e., evaluation of risk factors, clinical signs and symptoms, and laboratory data) and diagnosis, prompt and aggressive antimicrobial therapy is initiated. Appropriate empirical treatment is of the utmost importance in patients with suspected CNS infections. In most patients, a diagnostic LP will be performed before beginning antibiotics, but this never should delay initiation of antimicrobials. Antibiotic pretreatment may alter the CSF profile and complicate interpretation. **6** Empirical therapy should be directed at the most likely pathogen(s) for a specific patient, taking into account age, risk factors for infection (including underlying disease and immune dysfunction, vaccine history, and recent

exposures), CSF Gram stain results, CSF antibiotic penetration, and local antimicrobial resistance patterns. Results of the CSF Gram stain may be used to help narrow empirical therapy for bacterial meningitis. In the absence of a positive Gram stain, empirical therapy should be continued for at least 48 to 72 hours, when meningitis may, in most cases, be ruled out by CSF findings inconsistent with bacterial meningitis, negative CSF culture, and negative polymerase chain reaction (PCR) evaluations. A repeat LP may be useful in the absence of other findings. Table 70-1 outlines recommendations for empirical antibiotic therapy for bacterial meningitis by most likely pathogen(s) and patient risk factors.

Impact of Antimicrobial Resistance on Treatment Regimens for Meningitis

Development of resistance to β -lactam antibiotics, including penicillins and cephalosporins, has significantly impacted the management of bacterial meningitis. Approximately 17% of U.S. pneumococcal CSF isolates are resistant to penicillin, and 3.5% of CSF isolates are resistant to cephalosporins.³⁰ The Clinical and Laboratory Standards Institute (CLSI) has set a lower ceftriaxone susceptibility breakpoint for pneumococcal CSF isolates (1 mg/L) than for isolates from non-CNS sites (2 mg/L). Increasing pneumococcal resistance to penicillin G has changed empirical treatment regimens to the combination of a third-generation cephalosporin plus vancomycin. Recognition of relative and high-level resistance to *N. meningitidis* in the laboratory, as well as in clinical treatment failures, has led to greater use of third-generation cephalosporins for empirical therapy of meningococcal meningitis.²¹ Traditionally, ampicillin was the cornerstone of treatment for *H. influenzae* meningitis. Now, treatment of suspected or proven β -lactamase-mediated Hib meningitis requires a third-generation cephalosporin. Increasing rates of methicillin-resistant *S. aureus* (about one-third of staphylococcal CSF isolates) and coagulase-negative staphylococci require the use of vancomycin for empirical therapy when these pathogens are suspected.²⁹ As previously mentioned, hospitalized patients, especially those residing in an intensive care unit, are at risk for developing meningitis secondary to gram-negative pathogens. The emergence and continued rise of multidrug resistant strains of gram-negative organisms such as *Pseudomonas aeruginosa*, *Acinetobacter* species, AmpC, and extended spectrum β -lactamase (ESBL) producing strains of Enterobacteriaceae have become a recognized threat nationally. Global and local resistance patterns should be taken into account and combined with optimized pharmacodynamic dosing strategies when designing empirical treatment regimens for bacterial meningitis.

Pathogen-Directed Antimicrobial Therapy

7 Empirical antimicrobial therapy should be modified on the basis of laboratory data and clinical response. If cultures or other diagnostics, such as CSF Gram stain or bacterial antigen or antibody tests, indicate a specific pathogen, therapy should be adjusted quickly as needed to ensure adequate

Table 70–3

Pathogen-Based Definitive Treatment for CNS Infections

Pathogen	Recommended and Alternative Antimicrobial Therapy (Adult Doses)	Adverse Effects/Safety Monitoring	Renal and Hepatic Dose Adjustment	Duration (Days)
<i>Neisseria meningitidis</i> Penicillin MIC 0.1 mg/L	<i>Standard Therapy</i> Penicillin G 4 million units IV every 4 hours or	Hypersensitivity (rash, anaphylaxis), diarrhea	<i>Renal:</i> CrCl less than 50 mL/min (0.83 mL/s): 3 million units IV every 4 hours; CrCl less than 10 mL/min (0.17 mL/s): 2 million units IV every 4 hours <i>Hepatic:</i> No dose adjustment	7
	Ampicillin 2 g IV every 4 hours	Hypersensitivity (rash, anaphylaxis), diarrhea	<i>Renal:</i> CrCl less than 50 mL/min (0.83 mL/s): 2 g IV every 8 hours; CrCl less than 30 mL/min (0.50 mL/s): 2 g IV every 12 hours; CrCl less than 10 mL/min (0.17 mL/s): 2 g IV every 24 hours <i>Hepatic:</i> No dose adjustment	
	<i>Alternative Therapies</i> Ceftriaxone 2 g IV every 12 hours or	LFT elevation, cholecystitis	<i>Renal:</i> No dose adjustment <i>Hepatic:</i> Caution in severe hepatic impairment	
	Cefotaxime 2 g IV every 4 hours	Pseudocholelithiasis	<i>Renal:</i> CrCl less than 80 mL/min (1.34 mL/s): 2 g IV every 6–8 hours; CrCl less than 50 mL/min (0.83 mL/s): 2 g IV every 8–12 hours; CrCl less than 30 mL/min (0.50 mL/s): 2 g IV every 12 hours; CrCl less than 10 mL/min (0.17 mL/s): 2 g IV every 24 hours <i>Hepatic:</i> No dose adjustment	
	Penicillin MIC 0.1–1 mg/L	<i>Standard Therapy</i> Ceftriaxone or cefotaxime		
<i>Streptococcus pneumoniae</i> Penicillin MIC 0.1 mg/L	<i>Alternative Therapies</i> Moxifloxacin 400 mg IV every 24 hours or	Nausea/vomiting/diarrhea, dizziness, headache, QT prolongation	<i>Renal:</i> No dose adjustment <i>Hepatic:</i> Caution in severe hepatic impairment	10–14
	Meropenem 2 g IV every 8 hours or	Rash, hypersensitivity, diarrhea, decreased seizure threshold	<i>Renal:</i> CrCl less than 50 mL/min (0.87 mL/s): 2 g IV every 12 hours; CrCl less than 30 mL/min (0.50 mL/s): 500 mg to 1 g IV every 12 hours; CrCl less than 10 mL/min (0.17 mL/s): 500 mg to 1 g IV every 24 hours <i>Hepatic:</i> No dose adjustment	
	Chloramphenicol 1–1.5 g IV every 6 hours	Rash, diarrhea, seizures, anemia, gray baby syndrome, hypersensitivity, neurotoxicity (last choice due to toxicities)	<i>Renal:</i> No dose adjustment <i>Hepatic:</i> Reduce dose in moderate to severe impairment; consider serum drug monitoring	
	<i>Standard Therapy</i> Penicillin G or ampicillin			
	<i>Alternative Therapies</i> Ceftriaxone or cefotaxime or chloramphenicol

Table 70–4

Pediatric Doses of Selected Agents Used in Bacterial Meningitis Treatment

	Neonates, 0–7 Days	Neonates, 8–28 Days	Infants and Children
Ampicillin	150 mg/kg IV per day in divided doses every 8 hours	200 mg/kg IV per day in divided doses every 6–8 hours	300 mg/kg IV per day in divided doses every 8 hours
Cefepime	—	—	150 mg/kg per day in divided doses every 8 hours
Cefotaxime	100–150 mg/kg IV per day in divided doses every 8–12 hours	150–200 mg/kg IV per day in divided doses every 6–8 hours	225–300 mg/kg per day in divided doses every 6–8 hours
Ceftriaxone	—	—	80–100 mg/kg IV per day in divided doses every 12 hours
Gentamicin	5 mg/kg IV per day in divided doses every 12 hours (with dosing based on serum levels)	7.5 mg/kg IV per day in divided doses every 8 hours (with dosing based on serum levels)	7.5 mg/kg IV per day in divided doses every 8 hours based on serum levels)
Meropenem	—	—	120 mg/kg IV per day in divided doses every 8 hours
Nafcillin/oxacillin	75 mg/kg IV per day in divided doses every 8–12 hours	Nafcillin: 100–150 mg/kg IV per day in divided doses every 6–8 hours; Oxacillin: 150–200 mg/kg IV per day in divided doses every 6–8 hours	200 mg/kg IV per day in divided doses every 6 hours max, 2 g pediatrics greater than 3 months of age
Penicillin G	0.15 million units/kg IV per day in divided doses 8–12 hours	0.2 million units/kg IV per day in divided doses every 6–8 hours	0.3 million units/kg IV per day in divided doses every 4–6 hours
Vancomycin	20–30 mg/kg IV per day in divided doses every 8–12 hours	30–45 mg/kg IV per day in divided doses every 6–8 hours	60 mg/kg IV per day in divided doses every 6 hours

► *Neisseria meningitidis* Meningitis

N. meningitidis CNS infections most commonly occur in children and young adults. *N. meningitidis* accounts for 13.9% of all cases of bacterial meningitis annually. Its overall incidence has declined by 58% between 1998 and 2007, largely due to the use of vaccines. In 2006 and 2007, there were 0.19 cases per 100,000 of meningococcal meningitis.³ From 11% to 19% of survivors of meningococcal meningitis experience long-term sequelae, including hearing loss, limb loss, and neurologic deficits.³¹ Nearly all meningococcal disease is caused by five serogroups: A, B, C, Y, and W-135. In the United States, serotypes B, C, and Y each are responsible for approximately 30% of cases.

Meningococcal meningitis is observed most commonly in individuals living in close quarters (e.g., college students, military personnel). Infants younger than 1 year of age are at highest risk, possibly because pneumococcal vaccination reduces bactericidal antibodies.³³ However, nearly 60% of cases occur in patients over 11 years of age.^{31,34} *N. meningitidis* colonizes the nasopharynx and usually is transmitted via inhaled respiratory droplets from patients or asymptomatic carriers. A subclinical bacteremia typically ensues, seeding the **meninges**. Meningococcal disease is often (approximately 50%) associated with a diffuse petechial rash, and patients may experience behavioral changes. Patients may develop fulminant meningococcal sepsis, characterized by shock, disseminated intravascular coagulation, and multiorgan failure.^{31,32} Meningococcal

sepsis has a poor prognosis and carries a mortality rate of up to 80%, whereas the mortality rate with meningococcal meningitis alone is 13%.^{21,35} Patients with suspected meningococcal infection should be kept on respiratory isolation for the first 24 hours of treatment.⁵

Traditionally, high-dose penicillin G was the treatment standard for meningococcal disease. However, increasing penicillin resistance requires that third-generation cephalosporins now be used for empirical treatment until in vitro susceptibilities are known.²⁸ Patients with a history of type I penicillin allergy or cephalosporin allergy may be treated with vancomycin. Treatment should be continued for 7 days, after which no further treatment is necessary.

- Prevention of meningococcal disease by vaccination is a key to reducing the incidence of meningococcal meningitis. Adolescents should be routinely immunized with a 2-conjugate vaccine series beginning at age 11 or 12 years. In addition, individuals aged 2 through 54 years who are immunocompromised (including those with complement deficiencies, who have HIV, or who have asplenia) should receive a 2-polysaccharide vaccine series.³⁶ The quadrivalent conjugate meningococcal vaccine protects against four of the five serotypes causing invasive disease (A, C, Y, and W-135). Meningococcal vaccines do not protect against serotype B, which causes more than 50% of the cases of meningococcal meningitis in children younger than 2 years of age.³⁷ Meningococcal

vaccines can be used in outbreak situations, with protective antibodies measurable within 7 to 10 days. **8** *Close contacts of patients with meningococcal infections should be evaluated for antimicrobial prophylaxis.* Close contacts include members of the same household, individuals who share sleeping quarters, daycare contacts, and individuals exposed to oral secretions of meningitis patients. After consultation with the local health department, close contacts should receive prophylactic antibiotics to eradicate nasopharyngeal carriage of the organism. Household contacts of patients with meningococcal meningitis have a 400- to 800-fold increased risk of developing meningitis.³² Prophylactic antibiotics should be started as soon as possible, preferably within 24 hours of exposure (and within 14 days, after which the benefit is significantly reduced). Recommended regimens, all of which are 90% to 95% effective, for adults include rifampin 600 mg orally every 12 hours for 2 days, ciprofloxacin 500 mg orally for one dose, or ceftriaxone 250 mg intramuscularly for one dose. Regimens for children include rifampin 5 mg/kg orally every 12 hours for 2 days (less than 1 month of age), rifampin 10 mg/kg orally every 12 hours for 2 days (greater than 1 month of age), or ceftriaxone 125 mg intramuscularly for one dose (less than 12 years of age).^{31,32} It is not known whether close contacts who have been vaccinated will benefit from prophylaxis. Patients with meningococcal meningitis who are treated with antibiotics other than third-generation cephalosporins also should be considered for prophylaxis to eradicate the nasopharyngeal carrier state.³⁴

► *Streptococcus pneumoniae* Meningitis

S. pneumoniae is the most common cause of meningitis in adults and in children younger than 2 years of age. Pneumococcus is associated with the highest mortality observed with bacterial meningitis in adults (14–18%), and coma and seizures are more common in pneumococcal meningitis.^{1–4} Patients at high risk for pneumococcal meningitis include

the elderly, alcoholics, splenectomized patients, patients with sickle cell disease, and patients with cochlear implants. At least 50% of pneumococcal meningitis cases are due to a primary infection of the ears, sinuses, or lungs.

High-dose penicillin G traditionally has been the drug of choice for the treatment of pneumococcal meningitis. However, due to increases in pneumococcal resistance, the preferred empirical treatment now includes a third-generation cephalosporin in combination with vancomycin.¹⁸ All CSF isolates should be tested for penicillin and cephalosporin resistance by methods endorsed by the CLSI. Once in vitro sensitivity results are known, therapy may be tailored (Table 70–3). Patients with a history of type I penicillin allergy or cephalosporin allergy may be treated with vancomycin. Treatment should be continued for 10 to 14 days, after which no further maintenance therapy is required. Antimicrobial prophylaxis is not indicated for close contacts.

Administration of vaccines to high-risk individuals is a key strategy to reduce the risk of invasive pneumococcal disease. The 23-valent pneumococcal vaccine targets serotypes that account for more than 90% of invasive disease in high-risk patients. However, the 23-valent vaccine does not produce a reliable immunologic response in children younger than 2 years of age, nor does it reduce pneumococcal carriage. The 7-valent pneumococcal protein-polysaccharide conjugate vaccine used between 2000 and 2010 targeted the seven most common serotypes in children and provided protection (94% reduction) against invasive pneumococcal disease (such as sepsis and meningitis) in children younger than 5 years of age.³⁷ Widespread administration of the 7-valent conjugate vaccine to children has also contributed to a 28% reduction in invasive pneumococcal disease in adults.⁸ There are some concerns about an apparent increase in cases caused by nonvaccine serotypes including 19A, 22F, and 35B, including strains with increased antimicrobial resistance.³⁵ In 2010, a 13-valent vaccine, PCV13, was introduced that confers protection against 1,3,4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, and 23F. It is intended for use in children younger than 18 years in the same schedule as the 7-valent conjugate vaccine.³⁸ Immunization schedules provided by the U.S. Centers for Disease Control and Prevention (CDC) are updated at least annually and should be consulted for additional details. The impact of PCV13 on the incidence of pneumococcal disease is unknown at this time, but should be anticipated to further reduce disease burden in both children and adults.

► *Haemophilus influenzae* Meningitis

Prior to the introduction of the Hib conjugate vaccine, *H. influenzae* type b was the most common cause of bacterial meningitis in the United States.⁵ Routine inoculation of pediatric patients against Hib has reduced the incidence of Hib meningitis by 38% between 1998 and 2007.³ The Hib vaccine is also recommended for patients undergoing splenectomy. Hib meningitis is often associated with a parameningeal focus such as a sinus or middle ear infection. Increases in β -lactamase-mediated resistance have changed the empirical treatment of choice from ampicillin to

Patient Encounter 2, Part 1

BB is a 4-year-old boy who is brought to the ED with a 3-day history of fever and irritability. In the past 24 hours, he has become more lethargic, sleeping for 18 hours, and is difficult to arouse. Vital signs and laboratory values include a rectal temperature of 39.4°C (103°F), respirations 40 per minute, heart rate 145 beats per minute, and peripheral WBC of $15.9 \times 10^3/\text{mm}^3$ ($15.9 \times 10^9/\text{L}$), with 68% (0.68) PMNs. Physical examination reveals that the patient is more comfortable when lying flat and has some nuchal rigidity. BB also has a 9-year-old brother with autism and therefore he has not received any routine vaccinations.

What signs and symptoms consistent with meningitis are present in BB?

What clues to causative pathogen are present in BB?

What empiric antimicrobial regimen should be started?

Patient Encounter 2, Part 2

BB underwent lumbar puncture. Initial results from CSF studies are WBC $1.76 \times 10^3/\text{mm}^3$ ($1.76 \times 10^3/\text{L}$) with 79% (0.79) PMNs, protein 265 mg/dL (2,650 mg/L), glucose 30 mg/dL (1.7 mmol/L), with a concurrent serum glucose of 110 mg/dL (6.1 mmol/L). Gram stain shows gram-negative rods and culture results identify *H. influenzae* infection. The patient is admitted to an acute care unit and remains clinically stable.

What complications is BB at risk for acutely? What potential long-term complications may result?

How can his antibiotic regimen be streamlined at this time?

How long should the antibiotics be continued?

third-generation cephalosporins (e.g., ceftriaxone and cefotaxime). Treatment should be continued for 7 days, after which no further maintenance therapy is required.

8 *Close contacts of patients with H. influenzae type B meningitis should be evaluated for antimicrobial prophylaxis.* The risk of Hib meningitis in close contacts may be up to 200- to 1,000-fold higher than in the general population.¹¹ Invasive Hib disease, including meningitis, should be reported to the local health department and the CDC. Prophylaxis to eliminate nasal and oropharyngeal carriage of Hib in exposed individuals should be initiated after consultation with local health officials. Rifampin (600 mg/day for adults; 20 mg/kg/day for children, maximum of 600 mg/day) is administered for 4 days.¹⁷ Rifampin prophylaxis is not necessary for individuals who have received the full Hib vaccine series. Exposed, unvaccinated children between 12 and 48 months of age should receive one dose of vaccine, and unvaccinated children 2 to 11 months of age should receive three doses of vaccine, as well as rifampin prophylaxis.¹⁷ Because of prior vaccine shortages, it cannot be assumed that all children have been vaccinated. Further, some children have not received all childhood vaccines because of parental fears regarding vaccine safety.

► *Listeria monocytogenes* Meningitis

L. monocytogenes is an intracellular gram-positive bacillus that has been reported to contaminate certain foods, such as soft cheese, unpasteurized milk, raw meats and fish, processed meats, and raw vegetables. Bacteria from contaminated foods colonize the GI tract, pass into the bloodstream, and overcome natural cellular immune responses to cause infection. *L. monocytogenes* meningitis, usually observed in patients at extremes of age and in immunocompromised patients with depressed cellular immunity (including patients with leukemia, solid-organ transplants, and HIV/AIDS) has an overall mortality rate of up to 30%.^{39,40}

Only a limited number of antibiotics show bactericidal activity against *Listeria*. The combination of high-dose ampicillin or penicillin G and an aminoglycoside is synergistic

and bactericidal against *Listeria*. A total treatment course of at least 3 weeks is required. Because of concerns about the risk of nephrotoxicity with an extended treatment course of aminoglycosides, patients are treated with combination therapy for 10 days and may finish out the remainder of their treatment with ampicillin or penicillin alone.⁴⁰ In penicillin-allergic patients, trimethoprim-sulfamethoxazole is the agent of choice due to documented in vitro bactericidal activity against *Listeria*, as well as good CNS penetration. Vancomycin and cephalosporins are not effective treatments for *Listeria* meningitis. Prophylaxis is not needed for close contacts, nor is suppressive therapy indicated. Patients with severe depression of cell-mediated immunity should be advised to avoid foods that may be contaminated with *Listeria*.

► *Group B Streptococcus* Meningitis

Infection with group B *Streptococcus* (e.g., *S. agalactiae*) is the most common cause of neonatal sepsis and meningitis. Fifteen to 35% of pregnant women are a carrier of group B *Streptococcus* in the vagina or rectum. Group B streptococci can be acquired during childbirth after exposure to infected secretions from the mother's birth canal or rectum. Neonates born to women who are carriers are at very high risk (1 of every 100–200 babies) of developing invasive group B streptococcal disease, including sepsis and meningitis.⁴¹ Neonatal meningitis is associated with significant morbidity and mortality. Synergistic treatment with penicillin or ampicillin, plus gentamicin, for 14 to 21 days is recommended for the treatment of group B streptococcal meningitis.¹⁸

To reduce the risk of clinical group B streptococcal disease in neonates, pregnant women should be screened at 35 to 37 weeks' gestation to determine whether they are carriers of group B streptococci.⁴¹ Intrapartum antibiotics (e.g., penicillin or ampicillin) are recommended for pregnant women with the following characteristics: group B streptococcal carrier state detected at screening, history of group B streptococcal bacteriuria at any time during pregnancy, and history of delivery of infant with invasive group B streptococcal disease.⁴¹

► *Gram-Negative Bacillary* Meningitis

Meningitis caused by enteric gram-negative bacilli is an important cause of morbidity and mortality in populations at risk, including those with diabetes, malignancy, cirrhosis, immunosuppression, advanced age, parameningeal infection, and/or a defect allowing communication from skin to CNS (e.g., neurosurgery, congenital defects, cranial trauma).¹¹

The optimal treatment for gram-negative bacillary meningitis is not well defined. The introduction of extended-spectrum cephalosporins has improved patient outcomes significantly. Although the third-generation cephalosporins ceftriaxone and cefotaxime provide good coverage for most *Enterobacteriaceae*, these antibiotics are not active against *P. aeruginosa*. Ceftazidime, cefepime, and carbapenems are effective in pseudomonal meningitis.^{26,28} Addition of an aminoglycoside may improve treatment results; however, CNS penetration of aminoglycosides is extremely poor, even in the setting of inflamed meninges. Intrathecal or intraventricular

administration of aminoglycosides may be useful, but intraventricular antibiotics have been associated with increased mortality in neonates.^{26,42} Intrathecal therapy is accomplished by administering the antibiotic into the CSF via LP, whereas intraventricular therapy is usually administered into a reservoir implanted in the ventricles of the brain.

Initial therapy of suspected or documented pseudomonal meningitis should include an extended-spectrum β -lactam (e.g., ceftazidime, cefepime, meropenem) plus an aminoglycoside (preferably tobramycin or amikacin). Although the carbapenem imipenem-cilastatin has similar activity to these β -lactams, its use is not recommended in meningitis because of the risk of seizures. Aztreonam, high-dose ciprofloxacin, and colistin are alternative treatments for pseudomonal meningitis. Local therapy (i.e., intrathecal or intraventricular therapy) may be indicated in patients with gram-negative bacillary meningitis (especially infections caused by multidrug-resistant *P. aeruginosa*) or in patients who fail to improve on IV antibiotics alone. In cases of multidrug-resistant pathogens, alternative pharmacodynamic dosing strategies such as continuous or extended infusion of β -lactam antimicrobials may be considered to optimize target attainment (time greater than minimum inhibitory concentration). Given the differences in local hospital resistance patterns, administration of pathogen-directed treatment is very important after microbiology results become available. Therapy for gram-negative bacillary meningitis should be continued for at least 21 days.

► Postoperative Infections in the Neurosurgical Patient and Shunt Infections

Patients who undergo neurosurgical procedures or have invasive or implanted foreign devices (e.g., CSF shunts, intraspinal pumps or catheters, epidural catheters) are at risk for CNS infections. Key pathogens in postneurosurgical infections include coagulase-negative staphylococci, *S. aureus*, streptococci, propionibacteria, and gram-negative bacilli, including *P. aeruginosa*. Clinical signs and symptoms may be similar to those of other CNS infections, and there also may be evidence of malfunction of implanted hardware or visible signs of a postoperative wound infection.

Empirical therapy for postoperative infections in neurosurgical patients (including patients with CSF shunts) should include vancomycin in combination with either cefepime, ceftazidime, or meropenem. Linezolid reaches adequate CSF concentrations and resolves cases of meningitis refractory to vancomycin.^{40,43} However, data with linezolid are limited. The addition of rifampin should be considered for treatment of shunt infections. When culture and sensitivity data are available, pathogen-directed antibiotic therapy should be administered. Removal of infected devices is desirable; aggressive antibiotic therapy (including high-dose IV antibiotic therapy plus intraventricular vancomycin and/or tobramycin) may be effective for patients in whom hardware removal is not possible.⁴⁴ If methicillin-resistant *S. aureus* is identified as the causative organism, daptomycin may be considered an alternative therapy.⁴⁵

The use of prophylactic antibiotics against meningitis postcraniotomy remains controversial. A meta-analysis suggests that prophylaxis reduces rates of postoperative meningitis by nearly one-half.⁴⁷ Other studies have demonstrated no benefit, and there are limited data on organism-specific reductions in infection rate.^{48,49} Additionally, breakthrough meningitis that does occur may be a result of drug-resistant pathogens.⁴⁸

Brain abscesses are localized collections of pus within the cranium. These infections are difficult to treat due to the presence of walled-off infections in the brain tissue that are hard for some antibiotics to reach. In addition to appropriate antimicrobial therapy (a discussion of which is beyond the scope of this chapter), surgical debridement is often required as an adjunctive measure. Surgical debridement may also be required in the management of neurosurgical postoperative infections.

► Viral Encephalitis and Meningitis

Viral encephalitis and meningitis may mimic bacterial meningitis on clinical presentation but often can be differentiated by CSF findings (Table 70–2). The most common viral pathogens are enteroviruses, which cause approximately 85% of cases of viral CNS infections.¹¹ Other viruses that may cause CNS infections include arboviruses, HSV, cytomegalovirus, varicella-zoster virus, rotavirus, coronavirus, influenza viruses A and B, West Nile virus, and Epstein-Barr virus. Viral CNS infections are acquired through **hematogenous** or neuronal spread.¹¹ Most cases of enteroviral meningitis or encephalitis are self-limiting with supportive treatment.⁴⁶ However, arbovirus, West Nile virus, and Eastern equine virus infections are associated with a less favorable prognosis.

In contrast to other viral encephalitides, HSV type 1 and 2 encephalitis are treatable. Although rare (one case per 250,000 population per year in the United States), HSV encephalitis is a serious, life-threatening infection.⁵⁰ More than 90% of HSV encephalitis in adults is due to HSV type 1, whereas HSV type 2 predominates in neonatal HSV encephalitis (greater than 70%).⁵¹ HSV encephalitis is the result of reactivation of a latent infection (two-thirds of cases) or a severe case of primary infection (one-third). Without effective treatment, the mortality rate may be as high as 85%, and survivors often have significant residual neurologic deficits. In accordance with 2008 IDSA guidelines, high-dose IV acyclovir is the drug of choice, given for 2 to 3 weeks at a dose of 10 mg/kg IV every 8 hours in adults, based on ideal body weight, and for 3 weeks at a dose of 20 mg/kg IV every 8 hours in neonates.^{52,53} Patients receiving acyclovir should maintain adequate hydration (consider continuous IV hydration in those receiving high-dose acyclovir) to help prevent acute kidney injury secondary to crystal nephropathy.^{52,53} Foscarnet 120 to 200 mg/kg/day divided every 8 to 12 hours for 2 to 3 weeks is the treatment of choice for acyclovir-resistant HSV isolates.^{52,53}

► Opportunistic CNS Infections

Cerebral Toxoplasmosis Across the globe, cerebral toxoplasmosis represents the most common focal brain infection in HIV-infected patients. Infection rates in the United

States vary but are reported to be approximately 15% among patients with AIDS.⁵⁴ Nearly all cases occur in patients with CD4⁺ cell counts less than 200 cells/mm³ (less than 200 × 10⁶/L), and the greatest risk is in severely immunocompromised hosts with CD4⁺ cell counts less than 50 cells/mm³ (less than 50 × 10⁶/L). Potent antiretroviral therapy and primary prophylaxis in IgG-positive patients has greatly reduced the disease burden. First-line therapy in toxoplasmosis encephalitis is pyrimethamine plus sulfadiazine, given concomitantly with leucovorin to prevent severe hematologic adverse effects secondary to pyrimethamine (see tables for dosing). Clindamycin may be substituted for sulfadiazine in cases of contraindications to sulfa-based therapy. Sulfamethoxazole-trimethoprim may also be an option, specifically in patients unable to take oral therapy. Adjunctive corticosteroids and anticonvulsant therapy should be considered to reduce sequelae from the inflammatory process and control active seizures, respectively.⁵⁵

Cryptococcal Meningitis CNS disease secondary to *Cryptococcus neoformans* is primarily observed in severely immunocompromised hosts, such as those with HIV infection. Potent antiretroviral therapy has significantly reduced the disease burden from pre-antiretroviral therapy rates of 5% to 8% in developed countries. The majority of disease occurs in patients with CD4⁺ cell counts less than 50 cells/mm³ (less than 50 × 10⁶/L). First-line therapy is considered amphotericin B deoxycholate 0.7 mg/kg IV daily plus flucytosine 100mg/kg/day orally in four divided doses for a minimum of 2 weeks. Therapeutic drug monitoring may be considered for flucytosine to help reduce the risk of adverse effects. Development of renal dysfunction as a result of disease and/or drug toxicity should be closely monitored and may prompt dose reduction or possible switch to alternative lipid formulations of amphotericin, which may be less nephrotoxic. High-dose fluconazole is considered an alternative first-line therapy, especially in resource-limited areas. Secondary prophylaxis with fluconazole for an indefinite period is recommended following the completion of at least 2 weeks of induction therapy and 8 weeks of maintenance therapy with fluconazole.⁵⁵

► Adjunctive Dexamethasone Therapy

The adjunctive agent dexamethasone improves outcomes in selected patient populations with meningitis. Dexamethasone inhibits the release of proinflammatory **cytokines** and limits the CNS inflammatory response stimulated by infection and antibiotic therapy.

Clinical benefit in reducing neurologic deficits (primarily by reducing hearing loss) has been observed in infants and children with *H. influenzae* meningitis, as well as other pathogens causing meningitis, if dexamethasone is initiated prior to antibiotic therapy.^{1,14} The American Academy of Pediatrics recommends dexamethasone (0.15 mg/kg IV every 6 hours for 2 to 4 days) for infants and children at least 6 weeks of age with Hib meningitis and consideration of dexamethasone in pneumococcal meningitis.^{18,56} In contrast to this recommendation, a large multicenter cohort study failed to show any mortality benefit of adjunctive dexamethasone therapy

regardless of age or responsible pathogen (*S. pneumoniae* or *N. meningitidis*).⁵⁷ Dexamethasone should be initiated 10 to 20 minutes before or no later than the time of initiation of antibiotic therapy; it is not recommended for infants and children who have already received antibiotic therapy because it is unlikely to improve treatment outcome in these patients. There are insufficient data to make a recommendation regarding the use of adjunctive dexamethasone therapy in neonatal meningitis.

In adults, a significant benefit was observed with dexamethasone over placebo in reducing meningitis complications, including death, particularly in patients with pneumococcal meningitis.⁵⁸ The IDSA recommends dexamethasone 0.15 mg/kg IV every 6 hours for 2 to 4 days (with the first dose administered 10 to 20 minutes before or with the first dose of antibiotics) in adults with suspected or proven pneumococcal meningitis.¹⁸ Dexamethasone is not recommended for adults who have already received antibiotic therapy. Some clinicians would administer dexamethasone to all adults with meningitis pending results of laboratory tests. Benefit of dexamethasone in bacterial meningitis in a HIV-positive population has not been clearly established.⁵⁹

There is some controversy regarding the administration of dexamethasone to patients with pneumococcal meningitis caused by penicillin- or cephalosporin-resistant strains, for which vancomycin would be required. Animal models indicate that concurrent steroid use reduces vancomycin penetration into the CSF by 42% to 77% and delays CSF sterilization due to reduction in the inflammatory response.²⁸ A prospective evaluation in patients with pneumococcal meningitis receiving vancomycin and adjunctive dexamethasone demonstrated that adequate concentrations of vancomycin, nearly 30% of serum concentrations, were achievable in the CSF, provided appropriate vancomycin dosage was utilized.⁶⁰ Treatment failures have been reported in adults with resistant pneumococcal meningitis who were treated with dexamethasone, but the risk-benefit of using dexamethasone in these patients cannot be defined at this time. Animal models indicate a benefit of adding rifampin in patients with resistant pneumococcal meningitis whenever dexamethasone is used.^{26,28}

OUTCOME EVALUATION

- Monitor patients with CNS infections continuously throughout their treatment course to evaluate their progress toward achieving treatment goals, including relief of symptoms, eradication of infection, and reduction of inflammation to prevent death and the development of neurologic deficits. These treatment goals are best achieved by appropriate parenteral antimicrobial therapy, including empirical therapy to cover the most likely pathogens, followed by directed therapy after culture and sensitivity results are known. **9** *Components of a monitoring plan to assess efficacy and safety of antimicrobial therapy of CNS infections include clinical signs and symptoms and laboratory data (e.g., CSF findings, culture, sensitivity data).*

Patient Encounter 2, Part 3

As noted, BB had not received any vaccinations since birth. The parents are concerned and inquire about the need for antibiotic prophylaxis for the family and now are considering vaccination for BB.

*Who should receive antimicrobial prophylaxis for *H. influenzae*?*

Who should receive vaccination against Hib disease?

How is vaccination important in the prevention of Hib disease, especially for BB?

During the patient's treatment course, monitor clinical signs and symptoms at least three times daily. Trends are more important than one-time assessments. Expect fever, headache, nausea and vomiting, and malaise to begin to improve within 24 to 48 hours of initiation of antimicrobial therapy and

supportive care. Evaluate the patient for resolution of neurologic signs and symptoms, such as altered mental status and nuchal rigidity, as the infection is eradicated and inflammation is reduced within the CNS. Expect improvement and subsequent resolution of signs and symptoms as the treatment course continues. At the time of hospital discharge, arrange outpatient follow-up for several weeks to months depending on the causative pathogen, clinical treatment course, and patient's underlying comorbidities. Specifically evaluate patients for the presence of residual neurologic deficits.

Monitoring of laboratory tests is important in patients receiving treatment for CNS infections. Monitor CSF and blood cultures so that antimicrobial therapy can be tailored to the etiologic organisms. Follow-up cultures may be obtained to prove eradication of the organism(s) or treatment failure. Although repeat LP generally is not performed, consider repeat LP for patients who do not respond clinically after 48 hours of appropriate antimicrobial therapy, especially those with resistant pneumococcus who receive dexamethasone.¹⁴ Other candidates for repeat LP include those with infection

Patient Care and Monitoring

1. Assess the patient's signs, symptoms, and risk factors for meningitis. Do these offer any clues to the offending pathogen?
2. Determine whether the patient can undergo an immediate LP or if the LP should be delayed until a CNS mass lesion can be ruled out. If the LP is delayed, blood cultures should be drawn and appropriate empirical antimicrobial therapy initiated immediately.
3. Based on patient-specific data, local resistance patterns, and other relevant data, design an appropriate empirical antimicrobial regimen directed at the most likely pathogens; empirical regimens should consist of high-dose IV bactericidal therapy.
4. Determine whether adjunctive dexamethasone therapy is indicated; if so, start steroid therapy 15 to 20 minutes before the first dose of antimicrobial therapy.
5. Provide supportive care for patients with CNS infections, including hydration, electrolyte replacement, antipyretics, analgesics, and antiepileptic drugs.
6. Monitor culture and sensitivity data from the microbiology laboratory to determine whether any refinements are needed in the patient's treatment regimen. Design a therapeutic plan to finish out the patient's course of therapy for acute meningitis.
7. Monitor the patient's response to therapy (i.e., clinical signs/symptoms and laboratory data), as well as the development of complications, including seizures and hearing loss. Dexamethasone therapy may reduce antibiotic penetration, so antimicrobial drug dosing may have to be increased (especially vancomycin) to achieve adequate CSF levels. Serum levels of vancomycin should be measured and doses titrated to ensure adequate CNS concentrations. Evaluate whether intraventricular or intrathecal antibiotics are indicated.
8. Perform ongoing surveillance for adverse drug reactions, drug allergies, and drug interactions.
9. Determine whether prophylaxis is indicated for close contacts of patients with CNS infections. Close contacts should be located for patients with suspected meningococcal or Hib meningitis. After consultation with the local health department, antibiotic prophylaxis should be provided promptly to these individuals to avoid secondary disease.
10. Evaluate whether the patient is a candidate for finishing out his or her course of parenteral treatment on an outpatient basis. If so, the importance of close medical follow-up and medication compliance should be stressed to the patient and his or her family.
11. Consider how to minimize the patient's risk of contracting the current (and other) CNS infections in the future; administer appropriate vaccines after recovery from the acute infection.
12. Arrange for patient follow-up after discharge from the hospital. Continue to monitor for neurologic sequelae for several months after completion of treatment, and educate the patient and family in this regard. Serious complications that may occur include, among others, hearing loss, **hemiparesis**, quadriparesis, muscular hypertonia, ataxia, seizure disorders, mental retardation, learning disabilities, and obstructive hydrocephalus.

with gram-negative bacilli, prolonged fever, and recurrent meningitis. Repeat the LP in neonates to determine the duration of therapy. Repeat LP also may be performed to relieve elevated intracranial pressure. Expect repeat blood cultures to become negative quickly during therapy and the serum WBC count to improve and normalize with appropriate antimicrobial therapy.

Evaluate antimicrobial dosing regimens to ensure efficacy of the treatment regimen. Trough vancomycin concentrations of 15 to 20 mg/L (10 to 14 $\mu\text{mol/L}$) are recommended for the treatment of CNS infections.¹⁸ Monitor patients for drug adverse effects, drug allergies, and drug interactions. The specific safety monitoring plan will depend on the antibiotic(s) used (Table 70–3). Pay close attention to concomitant medications in patients on rifampin for treatment or prophylaxis. Rifampin is a potent inducer of hepatic metabolism and may reduce the efficacy of other drugs metabolized by the cytochrome P-450 3A enzyme pathway.

Abbreviations Introduced in This Chapter

CDC	Centers for Disease Control and Prevention
CLSI	Clinical and Laboratory Standards Institute
CNS	Central nervous system
CSF	Cerebrospinal fluid
DIC	Disseminated intravascular coagulation
ESBL	Extended spectrum beta-lactamase
GBS	Group B <i>Streptococcus</i>
Hib	<i>Haemophilus influenzae</i> type B
HSV	Herpes simplex virus
IDSA	Infectious Diseases Society of America
IL-1	Interleukin 1
LP	Lumbar puncture
MBC	Minimum bactericidal concentration
MIC	Minimum inhibitory concentration
MRSA	Methicillin-resistant <i>Staphylococcus aureus</i>
MRSE	Methicillin-resistant <i>Staphylococcus epidermidis</i>
NSAIDs	Nonsteroidal anti-inflammatory drugs
PCR	Polymerase chain reaction
PMN	Polymorphonuclear cell
SJS	Stevens-Johnson Syndrome
TNF- α	Tumor necrosis factor-alpha

Lower Respiratory Tract Infections

Diane M. Cappelletty

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. List the common pathogens that cause community-acquired pneumonia (CAP), aspiration pneumonia, ventilator-associated pneumonia (VAP; early versus late onset), and healthcare-associated pneumonia.
2. Explain the host defenses that protect against infection.
3. Explain the pathophysiology of pneumonia.
4. List the signs and symptoms associated with CAP and VAP.
5. Identify patient and organism factors required to guide the selection of a specific antimicrobial regimen for an individual patient.
6. Design an appropriate empirical antimicrobial regimen based on patient-specific data for an individual with CAP, aspiration pneumonia, and VAP or healthcare-associated pneumonia (early versus late onset).
7. Design an appropriate antimicrobial regimen based on both patient- and organism-specific data.
8. Develop a monitoring plan based on patient-specific information for a patient with CAP and healthcare-associated pneumonia or VAP.
9. Formulate appropriate educational information to be provided to a patient with pneumonia.

KEY CONCEPTS

- 1 There are five classifications of pneumonia: community-acquired, aspiration, hospital-acquired, ventilator-associated, and healthcare-associated.
- 2 The etiology of bacterial pneumonia varies in accordance with the type of pneumonia.
- 3 *Streptococcus pneumoniae* is the most common bacterial pathogen associated with community-acquired pneumonia (CAP).
- 4 The signs and symptoms and severity of pneumonia are needed not only to diagnose the infection but also to determine and assess response to therapy.
- 5 The goal of therapy is to eliminate the patient's symptoms, minimize or prevent complications, and decrease mortality.
- 6 Antimicrobial treatment of CAP is predominantly empirical.
- 7 Selection of antimicrobial therapy for ventilator-associated, health-care associated, and hospital-associated pneumonia is empirical and broad spectrum; however, once culture and susceptibility information are

available, the antimicrobial therapy should be narrowed (de-escalation) to cover the identified pathogen(s).

- 8 Duration of antimicrobial therapy should be kept to the shortest length possible.
- 9 Monitoring response to therapy is essential for determining efficacy, identifying adverse reactions, and determining the duration of therapy.
- 10 Prevention of both pneumococcal and influenza pneumonia by use of vaccination is a national goal.

Pneumonia is inflammation of the lung with consolidation. The cause of the inflammation is infection, which can be caused by a wide range of organisms.

1 There are five classifications of pneumonia: community-acquired, aspiration, hospital-acquired, ventilator-associated, and healthcare-associated. Patients who develop pneumonia in the outpatient setting and have not been in any health-care facilities, which include wound care and hemodialysis clinics, have community-acquired pneumonia (CAP). Pneumonia can be caused by aspiration of either oropharyngeal or gastrointestinal contents. Hospital-acquired pneumonia (HAP) is defined as pneumonia that occurs 48 hours or more

1243

after admission.^{1,2} Ventilator-associated pneumonia (VAP) requires endotracheal intubation for at least 48 to 72 hours before the onset of pneumonia.^{2,3} The newest category is healthcare-associated pneumonia (HCAP), which is defined as pneumonia occurring in any patient hospitalized for at least 2 days within 90 days of the onset of the infection; residing in a nursing home or long-term care facility; received IV antibiotic therapy, wound care, or chemotherapy within the last 30 days prior to the onset of the infection; or having attended a hemodialysis clinic.^{2,4}

EPIDEMIOLOGY AND ETIOLOGY

Etiology and Mortality Rates

2 The etiology of bacterial pneumonia varies in accordance with the type of pneumonia. Table 71-1 lists the more common pathogens associated with the various types or classifications of pneumonia. *Streptococcus pneumoniae* colonizes the nasopharyngeal flora in up to 50% of healthy adults and may colonize the lower airways in individuals with chronic bronchitis.^{5,6} It possesses many virulence factors, enhancing its ability to cause infection in the respiratory tract.

3 Therefore, it is not surprising that *S. pneumoniae* is the predominant bacterial pathogen associated with CAP. The second most common pathogen is one of the atypical organisms, *Mycoplasma pneumoniae*. Nontypeable *Haemophilus influenzae* intermittently colonizes about 80% of the population, and the incidence of permanent colonization increases in chronic obstructive pulmonary disease (COPD) patients and those with cystic fibrosis. Therefore, the likelihood of nontypeable *H. influenzae* causing pneumonia increases in COPD patients. *Moraxella catarrhalis* is a more common

cause of pneumonia in the very young and the very old. *Chlamydia pneumoniae* and *Legionella pneumophila* are less frequent causes than the other bacterial and atypical organisms. Community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) is associated with necrotizing and severe pneumonia in healthy children and young adults. Less than 2% of all CA-MRSA infections are pneumonia (most are skin and soft tissue); however, the number of reports of pneumonia are increasing.⁷

Viruses are a common cause of CAP in children (about 65%) and much less common in adults (about 15%).⁸ Viruses often associated with pneumonia in adults include influenza A and B and adenoviruses, whereas less common causes include rhinoviruses, enteroviruses, cytomegalovirus, varicella-zoster virus, herpes simplex virus, and others. In children, viral pneumonia is more commonly caused by respiratory syncytial virus, influenza A, and parainfluenza, and less commonly the viruses are similar to those listed previously for adults. Influenza is associated with seasonal local outbreaks (epidemics) and global outbreaks (pandemics). Influenza viruses are characterized and named for the hemagglutinin (H) and neuraminidase (N) proteins on the surface of the viruses. There are 16 hemagglutinin and nine neuraminidase subtypes of influenza A, and H1-3 and N1 and 2 are the principal antigenic types found in humans.⁹

Mortality associated with CAP is dependent on the severity of the illness and the age of the patient. In elderly patients admitted to the hospital with severe pneumonia, the mortality rate is up to 40%.¹⁰⁻¹³ In the outpatient setting (mild to moderate disease), the mortality rate is less than 5%.¹⁴ Mortality among case reports of CA-MRSA necrotizing pneumonia is 42%.⁷ Pneumonia owing to aspiration of oral contents is caused by a variety of anaerobes (*Bacteroides* spp., *Fusobacterium* spp., *Prevotella* spp., and anaerobic gram-positive cocci) as well as *Streptococcus* spp. *Moraxella catarrhalis* and *Eikenella corrodens* may be involved but much less frequently.^{15,16} When gastric contents are aspirated, enteric gram-negative bacilli and *Staphylococcus aureus* are more commonly the pathogens.¹⁶

HAP, VAP, and HCAP may be caused by a wide spectrum of organisms. HCAP, early onset HAP and VAP are commonly caused by enteric gram-negative bacilli in addition to the bacteria listed previously for CAP. Late-onset HAP and VAP are more likely to be caused by more resistant enteric gram-negative bacilli, *Pseudomonas aeruginosa*, *Acinetobacter* spp., or *S. aureus*. Rarely are viruses or fungi a cause of HAP, VAP, or HCAP. The number of infections caused by multidrug-resistant (MDR) bacteria is increasing significantly in hospitalized patients.^{4,13,17-19}

PATHOPHYSIOLOGY

Local Host Defenses

Local host defenses of both the upper and lower respiratory tract along with the anatomy of the airways are important in preventing infection. Upper respiratory defenses include the mucociliary apparatus of the nasopharynx, nasal hair,

Table 71-1

Common Pathogens by Type of Pneumonia

Type of Pneumonia	Common Pathogens
Community	Aerobic bacteria: <i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>M. catarrhalis</i> Atypical: <i>M. pneumoniae</i> , <i>C. pneumoniae</i> , <i>L. pneumophila</i> , respiratory viruses
Aspiration	Oral contents: Anaerobes, <i>Viridans</i> streptococci GI contents with pH increase Enteric gram-negative bacilli
Hospital	(Early onset, no risk factors for resistant pathogens)
Ventilator health care	<i>S. pneumoniae</i> , MSSA, <i>E. coli</i> , <i>K. pneumoniae</i> , (<i>M. pneumoniae</i> , <i>C. pneumoniae</i> are rare)
Hospital	(Late onset and/or risk factors for resistant pathogens)
Ventilator health care	MRSA, extended-spectrum β -lactamase-producing <i>K. pneumoniae</i> , <i>P. aeruginosa</i> , <i>Acinetobacter</i> spp.

MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-susceptible *S. aureus*.

normal bacterial flora, IgA, and complement. Local host defenses of the lower respiratory tract include cough, mucociliary apparatus of the trachea and bronchi, antibodies (IgA, IgM, and IgG), complement, and alveolar macrophages. Mucous lines the cells of the respiratory tract, forming a protective barrier for the cells. This minimizes the ability of organisms to attach to the cells and initiate the infectious process. The squamous epithelial cells of the upper respiratory tract are not ciliated, but those of the columnar epithelial cells of the lower tract are. The cilia beat in a uniform fashion upward, moving particles up and out of the lower respiratory tract.

Particles greater than 10 microns (μm) are efficiently trapped by mechanisms of the upper airway and are removed from the nasopharynx either by swallowing or by expulsion. The mucociliary apparatus of the trachea and bronchi along with the sharp angles of the bronchi often are effective at trapping and eliminating particles that are 2 to 10 μm in size. Particles in the range of 0.5 to 1 μm may consistently reach the alveolar sacs of the lung. Microorganisms fall within this size range, and if they reach the alveolar sacs, then infection may result if alveolar macrophages and other defenses cannot contain the organisms.

Aspiration

Aspiration of the oropharyngeal or gastric contents may lead to aspiration pneumonia or chemical (acid) pneumonitis. Risk factors for aspiration include dysphagia, change in oropharyngeal colonization, gastroesophageal reflux (GER), and decreased host defenses.

Dysphagia can be caused by stroke or other neurologic disorders, seizures, alcoholism, and aging.¹⁵ Oropharyngeal colonization may be altered by oral/dental disease, poor oral hygiene, tube feedings, or medications. This could result in a higher number of anaerobic organisms in the oral cavity or colonization with enteric gram-negative bacilli.¹⁵ GER occurs in all individuals to a degree; however, those with

GER disease (GERD) have it more frequently. Acid suppression is an important factor in the treatment of GERD, which may allow enteric gram-negative bacilli to colonize the gastric contents. Finally, impaired mucous production or cilia function, decreased immunoglobulin in secretions, and altered cough reflex may increase the likelihood of infection following an aspiration. The infection can result in a necrotizing pneumonia or lung abscess.

HAP, VAP, HCAP

Risk factors for the development of HAP fall into four general categories: intubation and mechanical ventilation, aspiration, oropharyngeal colonization, and hyperglycemia.

Intubation and mechanical ventilation increase the risk of HAP/VAP 6- to 21-fold.^{2,20} VAP may also be related to colonization of the ventilator circuit.²¹ Risk of aspiration is increased in these patients due to the supine positioning of the patient, the presence of the endotracheal tube preventing the closure of the epiglottis over the glottis, enteral feedings, GER, and medications.²¹ Oropharyngeal colonization is affected by the use of antibiotics, oral antiseptics, and poor infection control measures, which may decrease normal commensal flora and allow pathogenic organisms to colonize the oral cavity. Hyperglycemia may directly or indirectly promote infection; two proposed mechanisms are inhibiting phagocytosis and providing additional nutrients for bacteria.

Once breakdown of the local host defenses occurs and organisms invade the lung tissue, an inflammatory response is generated either by the organisms causing tissue damage or by the immune response to the presence of the organisms. This inflammatory response either can remain localized in the infected tissue or can become systemic. The role of the alveolar macrophages is two-fold. First, to engulf the organisms and to contain the infection, and second, to process the antigens for presentation in order to generate a specific immune response by either the cell-mediated or humoral system,

Patient Encounter 1, Part 1

A 36-year-old woman presents to your ED complaining of difficulty breathing and shortness of breath. Her physical examination reveals that she is alert and oriented $\times 3$, has decreased breath sounds on the right side compared with the left, and has rales and crackles in the right lower lobe. Her temperature is 38.6°C (101.5°F), respiratory rate is 18 breaths/min, and blood pressure is 120/80 mm Hg.

What are her signs and symptoms of pneumonia?

What are the top two organisms that could be causing the pneumonia?

What additional information do you need to know before creating a treatment plan for this patient?

Patient Encounter 2, Part 1

A 63-year-old man was admitted to the hospital secondary to a motor vehicle accident. Five days after admission he developed respiratory failure and was intubated. The chest x-ray revealed bilateral lower lobe infiltrates. He is sedated but does respond to commands. His temperature is 38.2°C (100.8°F), his blood pressure is 110/70 mm Hg, and his WBC is $16.8 \times 10^3/\text{mm}^3$ ($16.8 \times 10^9/\text{L}$) with a cell differential of 74% (0.74) neutrophils, 6% (0.06) bands, 17% (0.17) lymphocytes, and 3% (0.03) monocytes.

What are his signs and symptoms of pneumonia?

What are the top three organisms that could be causing the pneumonia?

What additional information do you need to know before creating a treatment plan for this patient?

or both. The macrophages release cytokines in the area of the infection, which result in increased mucous production, constricting the local vasculature and lymphatic vessels and attraction of other immune cells to the site. The increase in mucous is associated with symptoms such as cough and sputum production. If tumor necrosis factor alpha (TNF- α) and interleukins-1 and -6 are released systemically, then the symptoms become more severe and include hypotension, organ dysfunction, and/or a septic or septic-shock clinical presentation.

CLINICAL PRESENTATION AND DIAGNOSIS

Several scoring systems are available for assessing the severity of the pneumonia: the Pneumonia Severity Index

(PSI); Confusion, Uremia, Respiratory Rate, Blood pressure (CURB); CURB-65 (for those 65 years of age and older), and Systolic BP, Oxygenation, Age, and Respiratory rate (SOAR).^{10,13,22} Some of the characteristics evaluated with these models include but are not limited to age, comorbidities, blood pressure, mental status, respiratory rate, oxygenation, and organ function. PSI or CURB-65 scores less than or equal to 70 and less than 2 respectively, correlate with mild disease that should be treated in the outpatient setting. These models are used by physicians to help determine the severity of illness, prognosis (mortality risk), and the need for hospitalization and then to help guide in the selection of antimicrobial therapy, along with the use of published guidelines.^{10,13,14}

Clinical Presentation of CAP or Aspiration Pneumonia

General

Patients may experience nonrespiratory symptoms in addition to respiratory symptoms. With increasing age, both respiratory and nonrespiratory symptoms decrease in frequency.

4 Symptoms

- Respiratory—cough (productive or nonproductive), shortness of breath, and difficulty breathing
- Nonrespiratory—fever, fatigue, sweats, headache, myalgias, mental status changes

Signs

- Temperature may increase or decrease from baseline, but most often it is elevated. The temperature may be sustained or intermittent.
- Respiratory rate is often increased. Cyanosis, increased respiratory rate, and use of accessory muscles of respiration are suggestive of severe respiratory compromise.
- Breath sounds may be diminished. Rales or rhonchi may be heard.
- Confusion, lethargy, and disorientation are relatively common in elderly patients.

Diagnostic Tests

- Chest x-ray should reveal single or multiple infiltrates.
- Oxygen saturation should be over 90% (0.90), as determined by pulse oximetry.
- Arterial blood gases are beneficial primarily in patients with severe pneumonia.

Laboratory Tests

- The WBC may or may not be elevated. In elderly patients, a drop in WBCs also can be a sign of infection. The differential should show a predominance of

neutrophils if a bacterial infection is present. The presence of bands also could be an indicator of bacterial infection. Elevated lymphocytes are an indication of viral infection.

- Blood urea nitrogen (BUN) and serum creatinine are needed to dose antibiotics appropriately and to minimize or prevent drug toxicity (especially in the elderly patient).

Microbiology Tests

- Sputum Gram stain should demonstrate the presence of WBCs and the absence of squamous epithelial cells. It may or may not show a predominance of one type of organism.
- Sputum culture and susceptibility are not obtained in the outpatient setting. The value of culturing is debated owing to the rapidity in which *S. pneumoniae* dies in transport media and the inability to reliably or routinely culture atypical organisms.
- Bronchoscopy may be performed to improve the ability to diagnose pneumonia. Tracheal secretions often are better specimens than sputum owing to the lack of oral contamination.
- Serology (IgM and IgG) is useful in determining the presence of atypical organisms such as *Mycoplasma* and *Chlamydia*.
- Urinary Legionella antigen is used to diagnose *L. pneumophila*.
- Polymerase chain reaction (PCR) is being used more frequently to detect the DNA of respiratory pathogens.
- Blood cultures must be obtained in all patients hospitalized with pneumonia to comply with Joint Commission on Accreditation of Healthcare Organizations (JCAHO) pneumonia guidelines. Positive blood cultures are present in about 1% to 20% of patients with CAP.

Clinical Presentation of Severe CAP or Aspiration Pneumonia

General

In approximately 10% of patients, CAP will be severe enough to require intensive care or mechanical ventilation.

Symptoms 4

- Respiratory—cough (productive or nonproductive), shortness of breath, difficulty breathing
- Nonrespiratory—fever, fatigue, sweats, headache, myalgias, mental status changes

Signs

- Temperature may increase or decrease from baseline, but most often it is elevated. The temperature may be sustained or intermittent.
- Respiratory rate greater than 30 breaths per minute. Cyanosis and use of accessory muscles of respiration along with the increased respiratory rate are suggestive of severe respiratory compromise.
- Hypotension (systolic blood pressure less than 90 mm Hg or diastolic blood pressure less than 60 mm Hg).

- Requirement for vasopressors.
- Breath sounds may be diminished. Rales or rhonchi may be heard.
- Urine output less than 20 mL/h or less than 80 mL over 4 hours.
- Confusion, lethargy, and disorientation are relatively common in elderly patients.

Diagnostic Tests

As stated in the clinical presentation of community-acquired or aspiration pneumonia

Laboratory Tests

As stated in the clinical presentation of community-acquired or aspiration pneumonia

Microbiology Tests

As stated in the clinical presentation of community-acquired or aspiration pneumonia

Diagnosis of VAP

Clinical Strategy

- Chest x-ray should reveal a new infiltrate *plus* two of the following:
 - Temperature greater than 38.0°C (100.4°F)
 - Leukocytosis or leukopenia
 - Purulent secretions
 - Semiquantitative cultures are obtained to identify the pathogen(s)
- **Tracheal aspirates** grow more organisms than invasive quantitative cultures and often result in overuse of antibiotics
- The major limitation of the clinical strategy is the consistent overprescribing of antibiotics

Bacteriologic Strategy

- Uses quantitative culture of endotracheal aspirates, **bronchoalveolar lavage** (BAL), or **protected specimen brush** (PSB)
- Greater than or equal to 10⁶ cfu/mL (10⁹cfu/L) for endotracheal aspirates
- Greater than or equal to 10⁴ to 10⁵ cfu/mL (10⁷ to 10⁸cfu/L) for BAL
- Greater than or equal to 10³ cfu/mL (10⁶cfu/L) for PSB
- The advantage of this method is that it separates colonization from infection better than culturing tracheal aspirates.

- The limitation is the potential misinterpretation of negative culture results. These samples should be obtained prior to antibiotics being started.

Recommended Diagnostic Strategy

- Combination of the preceding two methods
- Obtain either a quantitative or semiquantitative culture of a lower respiratory sample. Initiate empirical broad-spectrum antibiotic therapy
- Days 2 and 3: Check culture results, and assess clinical response to therapy: temperature, WBCs, chest x-ray, oxygenation, purulent sputum, hemodynamic changes, and organ function
- Assess clinical improvement at 48 to 72 hours:
 - Improvement and culture negative—stop antibiotics
 - Improvement and culture positive—narrow antibiotic therapy
 - No improvement and culture negative—consider other pathogens, complications, or other diagnosis
 - No improvement and culture positive—change antibiotic therapy and consider other pathogens, complications, or other diagnosis

TREATMENT

Desired Outcomes

5 The goal of antibiotic therapy is to eliminate the patient's symptoms, minimize or prevent complications, and decrease mortality. Potential complications secondary to pneumonia include further decline in pulmonary function in patients with underlying pulmonary disease, prolonged mechanical ventilation, bacteremia/sepsis/septic shock, and death. Use of an antimicrobial agent with the narrowest spectrum of activity that covers the suspected pathogen(s) without having activity against organisms not involved in the infection is preferred to minimize the development of resistance.

General Approach to Treatment

Designing a therapeutic regimen for any patient with any type of pneumonia begins with three general categories of consideration:

1. Patient specific factors that will impact therapy.
2. The top one to three organisms likely causing the infection and resistance issues associated with each organism.
3. The antimicrobials that will cover these organisms. The spectrum should not be too broad or narrow; they should penetrate into the site of infection and be the most cost effective.

Patient factors that need to be considered include age, renal function, drug allergies and/or drug intolerances, immune status (diabetes, neutropenia, or immunocompromised host), cardiopulmonary disease, pregnancy, medical insurance and prescription coverage, exposure to resistant organisms, and prior antibiotic exposure(s) (what agents and when).

- The most common pathogens vary with the type of pneumonia, and they are listed in Table 71-1. *M. pneumoniae* lack a cell wall; therefore, β -lactam drugs have no activity against this organism. The atypical organisms have not changed in recent years with respect to antibiotic resistance. β -Lactamase production in *H. influenzae* has remained relatively steady over the last 5 to 10 years, and the rate is approximately 25%.²³ *S. pneumoniae* has developed resistance mechanisms against many classes of antimicrobials, and the mechanisms include:
 - Alteration of the penicillin-binding proteins (PBPs), inactivating β -lactams
 - Efflux or methylation of the ribosome-inactivating macrolides
 - Ribosome protection (tetM gene) inactivating tetracyclines
 - Alteration of DNA gyrase or topoisomerase IV inactivating fluoroquinolones

Resistance to commonly prescribed antimicrobials such as the penicillins and macrolides/azalides dramatically increased in the late 1980s through the mid- to late 1990s and has remained relatively flat in the 2000s. Resistance information

Patient Encounter 1, Part 2: Medical History, Physical Examination, and Diagnostic Tests

A 36-year-old woman presents to your ED complaining of difficulty breathing and shortness of breath.

PMH: IDDM for 15 years; hypertension for 1 year, currently controlled

FH: Father died of lung cancer at the age of 68 years; mother died of natural causes

SH: Denies tobacco and alcohol use. Lives with her husband and 2 children aged 4 and 7 years. The past 3 days she has been caring for her 4-year-old daughter who has been home from daycare with acute otitis media and possible URI. She is 5 ft 3 in (160 cm) and weighs 180 lb (81.8 kg).

Allergies: NKDA

Meds: Humalog 75/2540 units once daily; Lisinopril 10 mg orally once daily

ROS: (+) difficulty breathing and shortness of breath; (–) chest pain, N/V/D, change in appetite

PE:

VS: BP 120/80, P 82, RR 28, T 38.6°C (101.5°F)

CV: RRR, normal S₁, S₂; no murmurs, rubs, or gallops

Lungs: Decreased breath sounds on the right side compared with the left with rales and crackles in the right lower lobe

Abd: Soft, nontender, nondistended; (+) bowel sounds, no hepatosplenomegaly, heme (–) stool

Neuro: Oriented $\times 2$, somewhat confused and disoriented to place

Diagnostic Tests: Chest x-ray: right lower lobe infiltrates; oxygen saturation 86% (0.86) on room air

Labs: WBCs $19.2 \times 10^3/\text{mm}^3$ ($19.2 \times 10^9/\text{L}$) with a cell differential of 70% (0.70) neutrophils, 8% (0.08) bands, 16% (0.16) lymphocytes, and 6% (0.06) monocytes; BUN 9 mg/dL (3.2 mmol/L), SCr 0.9 mg/dL (80 $\mu\text{mol}/\text{L}$), glucose 360 mg/dL (20.0 mmol/L); sputum Gram stain: moderate gram-positive diplococci, many WBCs; sputum culture is pending

Given this additional information, what is your assessment of the patient's condition?

Identify your treatment goals for the patient.

collected nationally using the Tracking Resistance in the US Today (TRUST) surveillance database, along with susceptibility testing for a new antimicrobials, demonstrates that average national rates of resistance to penicillin and macrolides were approximately 13% and 38%, respectively.^{24,25} Resistance to trimethoprim/sulfamethoxazole is approximately 25%, and fluoroquinolone resistance remains less than 0.5%.²⁵ Susceptibility results alone do not account for

clinical success or failures when treating pneumonia. Therefore, despite the 13% and 32% resistance to penicillin and macrolides, the clinical failure rate is less than this. Because CAP in the outpatient setting is treated empirically, establishing a meaningful clinical failure rate with any therapy is difficult to do. No studies have been performed establishing a correlation between clinical failure rates with a particular antimicrobial agent and the percentage of resistance.

For HCAP, HAP, and VAP, the risk of infection from an MDR pathogen is relatively high. The number and type of organisms that are MDR vary from hospital to hospital, making it more difficult to generate guidelines for treatment. Therefore, the treatment recommendations may be too broad or too narrow for any given institution. Treating patients with HCAP, HAP, or VAP is more complex than treating patients with CAP. There are many factors to consider, and one of those relates to the timing of infection to the most likely pathogens. Early-onset infection is less likely to be caused by MDR pathogens than late-onset infection. In early-onset infection, community pathogens such as pneumococcus, *Legionella*, and *Mycoplasma* need to be considered as well as some of the hospital pathogens. Patients developing late-onset pneumonia are at increased risk of have a resistant pathogen or MDR pathogen such as MRSA, enteric gram-negative bacilli, *Pseudomonas*, and *Acinetobacter*. Another issue is how HCAP and HAP are studied compared with VAP. The majority of studies were performed using patients that were intubated. Therefore, the body of literature supporting the treatment recommendations is greatest for VAP and not for HCAP or HAP. The evidence-based guidelines generated by the American Thoracic Society and Infectious Diseases Society of America were derived from VAP and applied to HCAP and HAP.

Risk factors for developing infection caused by a resistant pathogen are generally related to the prior use of antibiotics, insertion of catheters or other invasive devices, and hospitalization in a unit contaminated/colonized with resistant organisms. The following is a more complete list of factors influencing infection from a resistant organism.

- Antimicrobial therapy in preceding 90 days
- Current hospitalization of at least 5 days
- High occurrence of antibiotic resistance in the community or in the specific hospital unit
- Immunosuppressive disease and/or therapy
- Presence of risk factors for HCAP:
 - Hospitalization for 2 days or more in the preceding 90 days
 - Residence in a nursing home or extended-care facility
 - Home infusion therapy (including antibiotics)
 - Peritoneal or hemodialysis within 30 days
 - Home wound care
 - Close contact family member with MDR pathogen

Once these issues are addressed, antimicrobial therapy can be selected and initiated. The patient- and drug-related categories are common to all types of pneumonia, but the organisms vary with the type of pneumonia. Guidelines have been

Patient Encounter 2, Part 2: Medical History, Physical Examination, and Diagnostic Tests

A 63-year-old man was admitted to the hospital secondary to a motor vehicle accident. Five days after admission he developed respiratory failure and was intubated. The chest x-ray revealed bilateral lower lobe infiltrates. He is sedated but does respond to commands.

PMH: Two surgeries in the last 5 days for fractures of the femur, tibia and humerus; hypertension for 15 years, currently controlled

FH: Father and mother deceased from natural causes. Both had hypertension.

SH: Smoked 1 pack per week \times 40 years, quit 3 years ago; drinks 2–3 beers per week. He lives with his wife; occupation—carpenter. He is 5 ft 10 in (178 cm) and weighs 80 kg (176 lb).

Allergies: Penicillin—hives

Meds: Losartan 50 mg orally once daily

PE:

VS: BP 110/70, P 78, T 38.2°C (100.8°F)

CV: RRR, normal S_1 , S_2 ; no murmurs, rubs, or gallops

Abd: Soft, nontender, nondistended; (+) bowel sounds, no hepatosplenomegaly, incision looks good and is healing

Diagnostic Tests: Chest x-ray: bilateral lower lobe infiltrates; oxygen saturation 98% (0.98) on ventilator

Labs: WBC is $16.8 \times 10^3/\text{mm}^3$ ($16.8 \times 10^9/\text{L}$) with a cell differential of 74% (0.74) neutrophils, 6% (0.06) bands, 17% (0.17) lymphocytes, and 3% (0.03) monocytes; BUN 10 mg/dL (3.6 mmol/L), SCr 0.9 mg/dL (80 $\mu\text{mol/L}$); sputum gram stain: many gram-negative bacilli, moderate Gram-positive cocci in clusters, many WBCs; sputum culture is pending

generated by experts in the field for all types of pneumonia. These guidelines were generated to provide practitioners with evidence-based therapeutic options for the management of patients with pneumonia.

Pharmacologic Therapy for CAP

6 *Treatment of CAP is predominantly empiric, that is, treatment is started without knowing the causative pathogen.* As a way of incorporating an evidence-based approach to antibiotic selection, several different organizations have generated guidelines for the treatment of bacterial or atypical CAP in adults. The most recent guidelines are the result of a collaboration between the Infectious Diseases Society of America and the American Thoracic Society.²⁶ The approach to patient

Table 71-2

Summary of CAP Treatment**Adult outpatient otherwise healthy**

Empirical coverage against *S. pneumoniae*, *M. pneumoniae*, *C. pneumoniae*, and *H. influenzae*

Adult outpatient comorbidities

Empirical coverage against *S. pneumoniae*, *M. pneumoniae*, *C. pneumoniae*, and *H. influenzae*

Adult inpatient (non-ICU)

Empirical coverage against *S. pneumoniae*, *H. influenzae*, *M. pneumoniae*, and *C. pneumoniae*

Adult inpatient ICU (no Pseudomonas)

Empirical coverage against *S. pneumoniae*, *L. pneumophila*, *H. influenzae*, enteric GNB, and *S. aureus*

Adult inpatient ICU (Pseudomonas is a concern)

Empirical coverage against *P. aeruginosa*, *S. pneumoniae*, *L. pneumophila*, *H. influenzae*, enteric GNB, and *S. aureus*

Adult inpatient non-ICU or ICU (CA-MRSA is a concern)

Empirical coverage against *S. pneumoniae*, *L. pneumophila*, *H. influenzae*, enteric GNB, and *S. aureus* (*Pseudomonas* if ICU)

Pediatric outpatient

Empirical coverage against *S. pneumoniae*, *M. pneumoniae*, and *C. pneumoniae*

Pediatric inpatient (non-ICU)

Empirical coverage against *S. pneumoniae*, *H. influenzae*, *M. pneumoniae*, and *C. pneumoniae*

Pediatric inpatient ICU

Empirical coverage against *S. pneumoniae*, *L. pneumophila*, *H. influenzae*, enteric GNB, and *S. aureus*

Monotherapy

Azithromycin, clarithromycin, erythromycin, doxycycline

Combination therapy

High-dose amoxicillin, high-dose amoxicillin-clavulanate (alternatives are cefpodoxime, or cefuroxime, or ceftriaxone) *plus* azithromycin, or clarithromycin or, doxycycline

Monotherapy

Gemifloxacin, levofloxacin, moxifloxacin

Combination therapy

Cefotaxime, or ceftriaxone, or ampicillin-sulbactam, or ertapenem *plus* azithromycin, or clarithromycin, or doxycycline

Monotherapy

Gemifloxacin, levofloxacin, moxifloxacin

Combination therapy

Cefotaxime or ceftriaxone *plus* azithromycin, or levofloxacin, or moxifloxacin

Combination therapy

Cefepime, or ceftazidime, or piperacillin-tazobactam, or imipenem, or meropenem *plus* ciprofloxacin or levofloxacin or an aminoglycoside. If an aminoglycoside is chosen, then add azithromycin or levofloxacin or moxifloxacin

Add vancomycin or linezolid to the regimens listed above

Monotherapy

High-dose amoxicillin, or high-dose amoxicillin-clavulanate, or intramuscular ceftriaxone, or azithromycin, or clarithromycin

Combination therapy

IV cefuroxime, or cefotaxime, or ceftriaxone, or ampicillin-sulbactam *plus* azithromycin, or clarithromycin

Combination therapy

Cefotaxime, or ceftriaxone *plus* azithromycin, or clarithromycin

CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus*; GNB, gram-negative bacteria; ICU, intensive care unit.

care is based on the classification of patients into two broad categories, outpatient and inpatient, and then further dividing the groups by comorbid conditions and location in the hospital, respectively. These guidelines use patient-specific data along with predominant pathogen information to design appropriate empirical antimicrobial regimens. Table 71-2 summarizes these therapeutic options. If influenza virus is the cause, supportive care is the best medical intervention available; antiviral agents against influenza are not effective.

► Adult Outpatient Previously Healthy

First-line therapeutic options for treating previously healthy adults include use of a macrolide (erythromycin, clarithromycin) or an azalide (azithromycin) or doxycycline.²⁶ If a patient has failed therapy with a macrolide, azalide, or doxycycline, one has to consider why the patient failed. The most common reasons are either medication adherence

issues or the presence of resistant organisms. If a resistant organism is suspected, then use of one of the respiratory fluoroquinolones active against *S. pneumoniae* (gemifloxacin, levofloxacin, or moxifloxacin) is warranted.

► Adult Outpatient With Comorbid Conditions

The comorbid conditions that can impact therapy and outcomes in patients with CAP include diabetes mellitus; COPD; chronic heart, liver, or renal disease; alcoholism; malignancy; asplenia; and immunosuppressive condition or use of immunosuppressive drugs.²⁶ If the patient did not receive antibiotics in the last 3 months, then either a respiratory fluoroquinolone alone or a combination of an oral β -lactam agent *plus* a macrolide or azalide is recommended. If the patient received an antibiotic in the last 3 months, the recommendation is to use an agent from a different class. Doxycycline is an acceptable alternative to a macrolide or azalide.

Patient Encounter 1, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for this patient's pneumonia. Your plan should include:

- (a) *The goals of therapy*
- (b) *A patient-specific detailed therapeutic plan*
- (c) *A plan for follow-up to determine whether the goals have been achieved and adverse effects avoided*

The preferred β -lactam agents are high-dose (3 g daily) amoxicillin or high-dose (4 g daily) amoxicillin-clavulanate. Alternative β -lactams are second- and third-generation cephalosporins such as cefuroxime, cefpodoxime, or ceftriaxone.

Telithromycin, a ketolide antibiotic approved for the treatment of mild to moderate CAP, is not included in the recommendations because of safety issues related to hepatotoxicity, loss of consciousness, and visual disturbances. Telithromycin is similar in spectrum of activity to clarithromycin and azithromycin in that it covers primarily the respiratory pathogens and not gram-negative bacilli.

► Adult Inpatient Not in the ICU

For patients admitted to the hospital with CAP, the severity of illness is generally increased (caused either by the organism itself or underlying comorbidities in the patient), and the pathogens are essentially the same as in the outpatient setting. Recommendations are to use either a respiratory fluoroquinolone alone or a combination of an IV β -lactam agent plus an advanced macrolide/azalide (clarithromycin/azithromycin) or doxycycline. The recommended β -lactams include cefotaxime, ceftriaxone, ampicillin-sulbactam, or ertapenem.²⁶ Therapy should be initiated in the emergency room; however, due to the controversy with a first antibiotic dose time of less than 4 or 8 hours, no recommendations have been made regarding time to the first antibiotic dose. Conversion to oral therapy should occur when the patient is hemodynamically stable, improving clinically, and able to take oral medications, which often is within 48 to 72 hours for most patients. Discharge from the hospital should be as soon as the patient is stable and without other medical complications. The need to observe the patient in the hospital on their oral antibiotic is not necessary.²⁶

► Adult Inpatient in the ICU

Patients admitted to the ICU have severe pneumoniae, and the likely etiology includes *S. pneumoniae* and *H. influenzae* as in the other categories; however, the incidence of *L. pneumophila* increases in this setting and should be considered a potential pathogen. In addition, enteric gram-negative bacilli and *S. aureus* are more frequently the cause of the pneumonia in these patients. The recommendations are to treat with

an IV β -lactam plus either azithromycin or a respiratory fluoroquinolone. This combination therapy minimizes the risk of treatment failure due to a resistant pathogen as well as provides coverage against all of the potential pathogens.²⁶ The preferred β -lactams are ceftriaxone, cefotaxime, or ampicillin-sulbactam. If the patient is allergic to β -lactams, then aztreonam plus a respiratory fluoroquinolone are preferred.

If *P. aeruginosa* is suspected, then the antimicrobial treatment must be broadened to cover *Pseudomonas* as well as the organisms listed previously. Owing to the high resistance rates observed in *Pseudomonas*, the recommended regimens empirically double cover the *Pseudomonas* to ensure at least one of the antibiotics is active against *Pseudomonas*. The regimens include the use of an antipneumococcal, antipseudomonal β -lactam (cefepime, ceftazidime, piperacillin/tazobactam, imipenem, or meropenem), plus either ciprofloxacin or levofloxacin or an aminoglycoside. If the aminoglycoside is chosen, then either IV azithromycin or a respiratory fluoroquinolone should be added to cover *S. pneumoniae* and the atypical bacterial organisms.²⁶

If CA-MRSA is suspected in the patient, then the addition of vancomycin or linezolid to the preceding regimen should be considered. Daptomycin cannot be used because surfactant in the lung inactivates the drug, thus rendering it ineffective for pneumonia. CA-MRSA can cause a necrotizing pneumonia, and the cause is believed to be due to its many virulence factors, including the Panton-Valentine leukocidin toxin.⁷ In these patients the use of an agent that decreases toxin production may be beneficial. Linezolid decreases toxin production; the other recommended agents to decrease toxin production and added to vancomycin therapy are clindamycin or a respiratory fluoroquinolone.²⁶

► Influenza

Influenza viruses A and B can cause pneumonia in pediatric and adult patients. Amantadine and rimantadine are available oral agents with activity against influenza virus type A. If started within 48 hours of the onset of the first symptoms, they reduce the duration of the illness by about 1.3 days. Oseltamivir and zanamivir also are oral agents active against both type A and B influenza that reduce the duration of the illness by about 1.3 days if initiated within 40 to 48 hours of the first symptoms.²⁷ For active infection beyond the first 48 hours, none of these agents are effective in treating infection, and supportive care is the best treatment for these patients.

► Aspiration

Anaerobes and *Streptococcus* spp. are the primary pathogens if a patient aspirates his or her oral contents and develops pneumonia. Antibiotics active against these organisms include penicillin G, ampicillin/sulbactam, and clindamycin. If the patient aspirates oral and gastric contents, then anaerobes and gram-negative bacilli are the primary pathogens. The preferred treatment regimen is a β -lactam/ β -lactamase inhibitor combination (ampicillin/sulbactam, amoxicillin/clavulanate, piperacillin/tazobactam, or ticarcillin/clavulanate).²⁶

Patient Encounter 2, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for this patient's pneumonia. Your plan should include:

- (a) *The goals of therapy*
- (b) *A patient-specific detailed therapeutic plan*
- (c) *A plan for follow-up to determine whether goals have been achieved and adverse effects avoided*

► Pediatric Outpatient

Guidelines have been published for treating CAP in children. The most predominant pathogens in preschool children in the outpatient setting are viruses, and often supportive therapy (maintaining hydration, antipyretics) is all that is needed.²⁸ For appropriately immunized infants, children, and adolescents with mild-to-moderate pneumonia in an area lacking high-level penicillin-resistant pneumococcus, high-dose amoxicillin is the recommended first-line therapy. If atypical organisms are considered likely, then a macrolide is recommended. If moderate to severe CAP is diagnosed and it is during influenza season, then treatment with oseltamivir, zanamivir (Relenza), amantadine, or rimantadine is recommended.²⁸ Fluoroquinolones and tetracyclines should not be used in children younger than 5 years of age. Dosing of antibiotics for pediatric patients is presented in [Table 71-3](#).

► Pediatric Inpatient

If the infant or child is fully immunized, then the guidelines recommend the use of IV penicillin G or ampicillin. If an atypical organism is highly suspected, then azithromycin in combination with a β -lactam is recommended. Alternative

β -lactams include IV cefotaxime or ceftriaxone. If the infant or child is not fully immunized, then the third-generation cephalosporins (cefotaxime or ceftriaxone) should be administered.²⁸ Again, if atypical organisms are suspected, add azithromycin to the β -lactam. If community-acquired MRSA is suspected, then vancomycin or clindamycin should be added to the regimen.²⁸

Pharmacologic Therapy for HCAP/HAP/VAP

Nosocomial pneumonia was the term used to describe pneumonia that developed in patients in an institutional setting. This has since been replaced by the terms *healthcare-associated pneumonia*, *hospital-associated pneumonia*, and *ventilator-associated pneumonia*. **7** *Empirical selection of antimicrobial therapy for ventilator-, healthcare-, and hospital-associated pneumonia is broad spectrum; however, once culture and susceptibility information are available, the therapy should be narrowed (de-escalation) to cover the identified pathogen(s).* Two factors important to the empirical selection of antibiotics for these types of pneumonia are onset time after admission and risk factors for MDR organisms. If it is early onset (less than or equal to 5 days since admission), and there are no risk factors for MDR organisms, then the most frequent pathogens include *S. pneumoniae*, *H. influenzae*, methicillin-susceptible *Staphylococcus aureus* (MSSA), and enteric gram-negative bacilli. Recommendations for therapy include third-generation cephalosporins such as ceftriaxone or cefotaxime; a respiratory fluoroquinolone such as gemifloxacin, levofloxacin, or moxifloxacin; ampicillin/sulbactam; or ertapenem.²⁹ If it is late-onset pneumonia and/or there are risk factors for MDR organisms, then the pathogen list includes *P. aeruginosa*, extended-spectrum β -lactamase-producing *K. pneumoniae*, *Acinetobacter spp.*, and MRSA. Empirical antibiotic selection must cover *P. aeruginosa*, which often then covers the other gram-negative pathogens. Available antibiotics

Table 71-3

CAP Antimicrobial Dosing in Pediatric Patients

Drug (Route)	Body Weight Less Than 2,000 g		Body Weight Greater Than 2,000 g		Greater Than 28 Days Old
	0-7 Days Old	7-28 Days Old	0-7 Days Old	7-28 Days Old	
Amoxicillin (orally)				15 mg/kg every 12 hours	17 mg/kg every 8 hours
Amoxicillin-clavulanate (orally)			15 mg/kg every 12 hours	15 mg/kg every 12 hours	45 mg/kg every 12 hours
Cefotaxime (IV)	50 mg/kg every 12 hours	50 mg/kg every 8 hours	50 mg/kg every 12 hours	50 mg/kg every 8 hours	50 mg/kg every 8 hours
Ceftriaxone (IM/IV)	25 mg/kg every 24 hours	50 mg/kg every 24 hours	25 mg/kg every 24 hours	50 mg/kg every 24 hours	50 mg/kg every 24 hours
Cefuroxime (orally)					15 mg/kg every 12 hours
Azithromycin (orally/IV)	5 mg/kg every 24 hours	10 mg/kg every 24 hours	5 mg/kg every 24 hours	10 mg/kg every 24 hours	10 mg/kg every 24 hours
Clarithromycin (orally)					7.5 mg/kg every 12 hours

Table 71-4

Empirical Therapy for Late-Onset HAP, HCAP, or VAP in Adults

Antibiotic (Route)	CrCl ^a Greater Than 50 mL/min (0.83 mL/s)	CrCl 30–50 mL/min (0.50–0.83 mL/s)	CrCl 10–30 mL/min (0.17–0.50 mL/s)	CrCl Less Than 10 mL/min (0.17 mL/s)
Cefepime (IV)	1–2 g every 12 hours	1–2 g every 24 hours	1 g every 24 hours	0.5–1 g every 24 hours
Ceftazidime (IV)	1–2 g every 8 hours	1–2 g every 12 hours	1–2 g every 12–24 hours	1–2 g every 24 hours
Imipenem (IV)	500 mg every 6 hours or 1 g every 8 hours	500 mg every 6–8 hours	500 mg every 8–12 hours	250 mg every 12 hours
Meropenem (IV)	1 g every 8 hours	1 g every 12 hours	500 mg every 12 hours	500 mg every 24 hours
Piperacillin-tazobactam (IV)	4.5 g every 6 hours or 3.375 g every 4 hours	4.5 g every 8 hours or 3.375 g every 6 hours	4.5 g every 8–12 hours or 3.375 g every 6–8 hours	4.5 g every 12 hours or 3.375 g every 8 hours or 2.25 g every 6 hours
Ticarcillin-clavulanate (IV)	3.1 g every 4–6 hours	2 g every 4–6 hours	2 g every 8 hours	2 g every 12 hours
Levofloxacin (IV/orally)	750 mg every 24 hours	750 mg every 48 hours	750 mg × 1 then 500 mg every 48 hours	750 mg × 1 then 500 mg every 48 hours
Ciprofloxacin (IV)	400 mg every 8 hours	400 mg every 8 hours	400 mg every 12 hours	400 mg every 24 hours
Ciprofloxacin (orally)	750 mg every 8 hours	750 mg every 8 hours	750 mg every 12 hours	750 mg every 24 hours
Gentamicin or Tobramycin ^b (IV)	5–7 mg/kg every 24 hours	1.7–2 mg/kg every 12–24 hours	1.7–2 mg/kg every 36 hours	1.7–2 mg/kg every 48 hours
Amikacin ^b (IV)	20 mg/kg every 24 hours	7.5 mg/kg every 12–24 hours	7.5 mg/kg every 36 hours	7.5 mg/kg every 48 hours
Vancomycin ^c (IV)	15–20 mg/kg every 12 hours	15–20 mg/kg every 24 hours	15–20 mg/kg every 48 hours	15–20 mg/kg every 72 hours
Linezolid (IV/orally)	600 mg every 12 hours	600 mg every 12 hours	600 mg every 12 hours	600 mg every 12 hours

^aCrCl, creatinine clearance.

^bTrough concentrations ideally should be nondetectable; less than 1 mcg/mL for gentamicin (1 mg/L; 2 μmol/L) and tobramycin (1 mg/L; 2 μmol/L) and less than 4 to 5 mcg/mL (4–5 mg/L; 7–9 μmol/L) for amikacin are potentially acceptable.

^cTrough concentrations should be between 15 and 20 mcg/mL (15 and 20 mg/L; 10 and 14 μmol/L).

include cefepime, ceftazidime, imipenem, meropenem, piperacillin/tazobactam, ticarcillin/clavulanate, levofloxacin, ciprofloxacin, gentamicin, tobramycin, and amikacin. Empirical therapy for late-onset pneumonia (listed in [Table 71-4](#)) could include any of the β-lactams, carbapenems, or fluoroquinolones alone or in combination with one of the aminoglycosides. If MRSA is suspected, then either vancomycin or linezolid should be added to the regimen. Recommendations for vancomycin trough concentrations of 15 to 20 mcg/mL (15 to 20 mg/L; 10 to 14 μmol/L) were based on expert opinion, not evidence from clinical trials.²⁹

Currently there is debate over whether or not double coverage for *Pseudomonas* is required. In vitro studies have shown that aminoglycosides exhibit synergistic killing against gram-negative bacilli when combined with β-lactams. Dosing of the aminoglycosides is dependent on the patient's renal function. A high-dose once-daily regimen (e.g., 4 to 7 mg/kg gentamicin or tobramycin or 15 to 20 mg/kg amikacin) can be utilized in patients with good renal function. Most of the studies enrolled patients with estimated creatinine clearances of at least 70 mL/min (1.17 mL/s). Meta-analyses have shown high-dose once-daily regimens to be as efficacious as and less toxic than divided daily dosing.^{30–34} Divided daily dosing (e.g., 1 to 2 mg/kg gentamicin or tobramycin or 7.5 mg/kg amikacin) has been utilized since the 1970s,

and the dosing interval is based on the patient's renal function to achieve a trough concentration of less than 2 mcg/mL (2 mg/L; 4 μmol/L) for gentamicin and tobramycin and less than 5 mcg/mL (5 mg/L; 9 μmol/L) for amikacin.

In addition to obtaining a synergistic effect, another reason for double coverage when treating VAP, HAP, or HCAP is to broaden the coverage empirically to increase the likelihood of covering the majority of resistant pathogens. VAP is the most studied of these types of pneumonias and is often the most severe. There is an increase in mortality when inadequate therapy is initiated for VAP. Crude mortality ranges are quite large (35% to 92%) compared with estimates of attributable mortality (approximately 9%); however, attributable mortality studies are limited by the large sample size needed to accurately measure this outcome.^{35–37}

7 Once a pathogen or pathogens have been identified, therapy should be narrowed to cover only those pathogens. Use of broad-spectrum antibiotics for prolonged durations increases the risk of colonization with MDR pathogens.

Duration of Antimicrobial Therapy

8 The duration of therapy for pneumonia should be kept as short as possible and depends on several factors: type of pneumonia, inpatient or outpatient status, patient comorbidities,

bacteremia/sepsis, and the antibiotic chosen. If the duration of therapy is too prolonged, then it can have a negative impact on the patient's normal flora in the respiratory and gastrointestinal tracts, vaginal tract of women, and on the skin. This can result in colonization with resistant pathogens, *Clostridium difficile* colitis, or overgrowth of yeast. In addition, the longer antibiotics are administered, the greater the chance for toxicity from the agent, as well as an increase in cost.

For treating adult outpatient CAP, two antibiotics are approved for a 5-day duration of therapy, levofloxacin (the 750-mg dose) and azithromycin. The recommended duration of therapy for all other therapies is 7 to 10 days. For treatment of CAP in adult patients admitted to the hospital, the duration is dependent on whether or not blood cultures were positive. In the absence of positive blood cultures, the duration of therapy is 7 to 10 days. If blood cultures were positive, the duration of therapy should be 2 weeks from the day blood cultures first became negative. The duration of therapy in pediatric patients is 10 days for uncomplicated CAP, with the exception of azithromycin, which is approved for 5 days.²⁸

The duration of therapy cited in the literature for HCAP, HAP, or VAP ranges from 10 to 21 days. Efforts should be made to shorten the duration of therapy from the traditional 14 to 21 days to periods as short as 7 days, provided that the etiologic pathogen is not *P. aeruginosa* and that the patient has a good clinical response with resolution of clinical features of infection. Shortening the duration of therapy is acknowledged as beneficial because of the colonization, toxicity, and cost issues. Several studies evaluated mortality, clinical success, recurrence, or the development of resistance with shorter courses of therapy for VAP and found no differences when compared with longer courses of therapy.^{36,38} The Clinical Pulmonary Infection Score (CPIS) has been used to determine when to end therapy for VAP. Luna and colleagues³⁹ used the CPIS and found that patients who survived VAP and were treated with adequate therapy clinically improved within 3 to 5 days. This study was instrumental in recommending a shortened duration of therapy of 6 days.

OUTCOME EVALUATION

For CAP, outcomes include preventing hospitalization, shortening the duration of hospitalization, and minimizing mortality. For patients admitted to the hospital, if antibiotics are initiated within 4 hours of presentation, the duration of hospitalization is decreased compared with when antibiotics are started after 4 hours.⁴⁰

Improvement of symptoms should occur within 48 to 72 hours after initiation of therapy for most patients with CAP. Response to therapy could be slowed in patients with underlying pulmonary disease such as moderate to severe asthma, COPD, or emphysema. In patients not responding to therapy and when there are no underlying factors that would suggest a slowed response to therapy, then other infectious and noninfectious reasons must be considered. The infection could be caused by a pathogen not covered by the initial therapy, a drug-resistant isolate could be present, or more

Patient Care and Monitoring

9 *Monitoring response to therapy is essential for determining efficacy, identifying adverse reactions, and determining the duration of therapy.*

1. Assess the patient's symptoms and status (i.e., inpatient, outpatient, or intubated) to determine the type of pneumonia and comorbid conditions. Does the patient have moderate to severe asthma, COPD, or emphysema or is a current smoker?
2. Review any available diagnostic data to determine severity of the disease.
3. Obtain a history of prescription and nonprescription medication use, as well as allergies and drug intolerances, noting the severity of the reaction.
4. What are the top two to three organisms associated with the type of pneumonia the patient has?
5. Select an appropriate empirical antibiotic regimen for the patient, ensuring that the doses are correct for renal function.
6. Develop a plan to assess the effectiveness of the antibiotic therapy after 24 to 72 hours. If the patient is not improving, then reevaluate the diagnosis and pathogen list, and make appropriate changes to therapy. Develop a plan to assess the effectiveness of the antibiotic therapy again at the end of therapy. When can conversion from IV to oral therapy occur?
7. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
8. For patients who meet the qualifications, discuss the value of vaccination against *S. pneumoniae* and/or influenza.

severe infection could be present (nonpulmonary), and the patient should be reevaluated. Noninfectious reasons to consider include pulmonary embolus, congestive heart failure, carcinoma, lymphoma, intrapulmonary hemorrhage, and certain inflammatory lung diseases.

Outcome parameters for VAP, HAP, and HCAP are similar to those with CAP. Clinical improvement should occur within 48 to 72 hours of the start of therapy. If a patient is not responding to therapy, then, again, consider infectious and noninfectious reasons. Infectious explanations are the same as for CAP, but noninfectious are not. They include atelectasis, acute respiratory distress syndrome (ARDS), pulmonary embolism or hemorrhage, cancer, empyema, or lung abscess.

PREVENTION

10 *Prevention of both pneumococcal and influenza pneumonia by use of vaccination is a national goal. Vaccination is used to prevent or minimize the severity of pneumonia caused by *S. pneumoniae* or the influenza virus.*

The influenza vaccine is available in two forms, injectable and nasal inhalation. There are two forms of the injectable inactivated vaccine (containing killed virus). The regular influenza vaccine is approved for use in people older than 6 months of age, including healthy people and people with chronic medical conditions. Fluzone® intradermal vaccine is indicated for adults 18 through 64 years of age against influenza disease caused by virus subtypes A and type B. This vaccine utilizes a microinjection delivery system with a needle significantly smaller than other intradermal needles, which may decrease the fear associated with injections and increase immunization rates. The high-dose influenza vaccine is recommended for those 65 years of age and older. The nasal-spray influenza vaccine is made with live, weakened influenza viruses that do not cause the influenza (live attenuated influenza vaccine). This formulation is approved for use in healthy people 2 to 49 years of age who are not pregnant. The ability of influenza vaccine to protect a person depends on two key factors: the age and health status of the person getting the vaccine, and the similarity or “match” between the virus strains in the vaccine and those in circulation. Given these factors, the vaccine is effective and protective antibodies are detected approximately 2 weeks after vaccination. In February 2010, the Centers for Disease Control and Prevention (CDC) adopted a universal influenza vaccination policy, thus recommending all persons 6 months of age and older to be vaccinated annually. The CDC identifies high risk groups in whom vaccination is especially important⁴¹:

1. Pregnant women
2. Children younger than 5, but especially children younger than 2 years old
3. People 50 years of age and older
4. People of any age with certain chronic medical conditions
5. People who live in nursing homes and other long-term care facilities
6. People who live with or care for those at high risk for complications from flu, including:
 - Healthcare workers
 - Household contacts of persons at high risk for complications from the flu
 - Household contacts and out-of-home caregivers of children less than 6 months of age (these children are too young to be vaccinated)

There are three pneumococcal vaccines, 7- and 13-valent conjugated vaccines for children younger than 5 years of age (6 years if chronic health conditions are present) and a 23-purified-capsular polysaccharide antigen vaccine for children 5 years of age and older and adults. The 7-valent conjugated vaccine has been replaced with the 13-valent conjugated vaccine. The serotypes in the 13-valent conjugated vaccine include those in the 7-valent, along with six serotypes that emerged as disease-causing strains after the implementation of the 7-valent vaccine.^{42,43} The minimum age to receive the conjugated vaccine is 6 weeks, and the recommended age range is between 12 and 15 months. A reliable immunologic response

to the 13-valent conjugated vaccine has been demonstrated, along with a favorable safety profile.^{43,44} The 23 capsular types in the vaccine represent at least 85% to 90% of the serotypes that cause invasive pneumococcal infections among children and adults in the United States. Ten years after vaccination, a sample of elderly individuals demonstrated significant quantity of protective antibodies.⁴⁵ Those who should receive the polysaccharide vaccine include the following⁴¹:

1. All adults 65 years of age or older should receive one dose.
2. Anyone over 6 years of age who has a long-term health problem such as heart disease, lung disease, sickle cell disease, diabetes, alcoholism, cirrhosis, and leakage of cerebrospinal fluid.
3. Anyone over 6 years of age who has a disease or condition or is taking any drug that lowers the body's resistance to infection, such as Hodgkin's disease, lymphoma, leukemia, kidney failure, multiple myeloma, nephrotic syndrome, HIV infection or AIDS, damaged spleen or no spleen, organ transplant, long-term steroids, certain cancer drugs, or radiation therapy.

Abbreviations Introduced in This Chapter

ARDS	Acute respiratory distress syndrome
ATS	American Thoracic Society
BUN	Blood urea nitrogen
CA-MRSA	Community-acquired methicillin-resistant <i>Staphylococcus aureus</i>
CAP	Community-acquired pneumonia
CDC	Center for Disease Control and Prevention
COPD	Chronic obstructive pulmonary disease
CPIS	Clinical Pulmonary Infection Score
DFA	Direct fluorescence antigen
GER(D)	Gastroesophageal reflux (disease)
H	Hemagglutinin
HCAP	Health care-associated pneumonia
HAP	Hospital-acquired pneumonia
IDDM	Insulin-dependent diabetes mellitus
IDSA	Infectious Diseases Society of America
MDR	Multidrug resistant
MRSA	Methicillin-resistant <i>Staphylococcus aureus</i>
MSSA	Methicillin-susceptible <i>S. aureus</i>
N	Neuraminidase
Pao ₂ /Fio ₂	Arterial oxygen pressure/fraction of inspired oxygen
PBP	Penicillin-binding protein
PCR	Polymerase chain reaction
TNF-α	Tumor necrosis factor alpha
TRUST	Tracking Resistance in the United States Today
VAP	Ventilator-associated pneumonia

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

72 Upper Respiratory Tract Infections

Heather L. VandenBussche

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. List the most common bacterial pathogens that cause acute otitis media (AOM), acute bacterial rhinosinusitis (ABRS), and acute pharyngitis.
2. Explain the pathophysiologic causes of and risk factors for AOM, bacterial rhinosinusitis, and acute pharyngitis.
3. Identify clinical signs and symptoms associated with AOM, bacterial rhinosinusitis, streptococcal pharyngitis, and the common cold.
4. List treatment goals for AOM, bacterial rhinosinusitis, streptococcal pharyngitis, and the common cold.
5. Develop an appropriate antibiotic regimen for each infection based on patient-specific data.
6. Recommend appropriate adjunctive therapy for a patient with AOM or ABRS.
7. Recommend an appropriate treatment plan for a patient with the common cold.
8. Create a monitoring plan for a patient being treated for an upper respiratory tract infection (URI) using patient-specific information and prescribed therapy.
9. Educate patients about URIs and proper use of antibiotic therapy.

KEY CONCEPTS

- 1 Most upper respiratory tract infections (URIs) are caused by viruses, have nonspecific symptoms, and resolve spontaneously.
- 2 Antibiotic resistance greatly influences the treatment options for bacterial URIs.
- 3 Proper diagnosis of bacterial URIs is essential to identify when antibiotic use is appropriate.
- 4 Antibiotic therapy for acute otitis media (AOM) should be reserved for children who are most likely to benefit from therapy and is dependent on patient age, illness severity, and diagnostic certainty.
- 5 For AOM, high-dose amoxicillin (80 to 90 mg/kg/day) is the drug of choice, but high-dose amoxicillin-clavulanate is an alternative agent for children with severe illness or when a broader spectrum agent is desired.
- 6 Antibiotic therapy for sinusitis should be reserved for patients with moderate persistent symptoms, clinical decompensation, or severe symptoms.
- 7 Amoxicillin and amoxicillin-clavulanate are first-line antibiotics for acute bacterial rhinosinusitis (ABRS).
- 8 The goals of therapy for streptococcal pharyngitis are to eradicate infection, reduce symptoms and infectivity, and prevent complications.
- 9 Penicillin is the drug of choice for streptococcal pharyngitis.
- 10 Treatment for the common cold focuses on symptom relief and is influenced by patient age, comorbid conditions, and balance of medication effectiveness and safety.

INTRODUCTION

Upper respiratory tract infection (URI) is a term that encompasses many upper airway infections, including otitis media, sinusitis, pharyngitis, laryngitis, and the common cold. More than 1 billion URIs occur annually in the United States, triggering millions of ambulatory care visits each year.¹ 1 Most URIs are caused by viruses, have nonspecific symptoms, and resolve spontaneously.² Antibiotics do not impact the resolution of viral URIs, and their excessive use for these infections has contributed to antibiotic resistance. Guidelines have been established to reduce inappropriate antibiotic therapy for viral URIs.² This chapter focuses on acute otitis media (AOM), sinusitis, and pharyngitis because these infections are

frequently caused by bacteria, and their complications can be minimized with appropriate antibiotic therapy. Proper management of the common cold is also reviewed.

OTITIS MEDIA

Otitis media, or inflammation of the middle ear, is the most common illness treated with antibiotics in children. It usually results from a nasopharyngeal viral infection and can be subclassified as AOM or **otitis media with effusion** (OME). AOM is a rapid, symptomatic infection with effusion, or presence of fluid, in the middle ear. OME does not have signs of acute illness but is characterized by the presence of middle ear fluid. It is important to distinguish between AOM and OME because antibiotics are only useful for the treatment of AOM.

EPIDEMIOLOGY AND ETIOLOGY

Otitis media occurs in all age groups but is most common in children between 6 months and 2 years of age. By 3 years of age, up to 85% of children have had at least one episode of otitis media, and up to 20% have recurrent infections by 12 months of age.³ In 2000, approximately 13 million antibiotic prescriptions were written in the United States for otitis media, resulting in \$2 billion in direct costs.^{4,5} From 1995 to 2006, rates of antibiotic prescriptions for otitis media declined by 36%, but the proportion of healthcare visits for otitis media that resulted in antibiotic prescriptions remained stable at 80%.⁶ Many factors (**Table 72-1**) predispose children to otitis media, and some are associated with antibiotic resistance, such as daycare attendance, prior antibiotic exposure, and age younger than 2 years.^{3,7,8}

Bacteria are isolated from middle ear fluid in up to 70% of children with AOM, but viruses can also cause AOM.⁷ Historically, *Streptococcus pneumoniae* was the most

common organism, responsible for up to half of bacterial cases.^{4,9} *Haemophilus influenzae* and *Moraxella catarrhalis* caused 15% to 30% and 3% to 20% of cases, respectively. After the introduction of routine childhood pneumococcal vaccination, the prevalence of *H. influenzae* increased, and it now causes more than half of all bacterial cases.⁹⁻¹¹ Bacteria that are less frequently associated with AOM include *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Pseudomonas aeruginosa*. Viruses such as respiratory syncytial virus, influenza, parainfluenza, enteroviruses, rhinovirus, and adenoviruses are isolated from middle ear fluid with or without concomitant bacteria in about half of AOM cases.^{7,12} Lack of improvement with antibiotic treatment is often a result of viral infection and subsequent inflammation rather than antibiotic resistance.

2 **Antibiotic resistance has great influence on the treatment options for AOM.** Penicillin-resistant *S. pneumoniae* (PRSP) exhibit either intermediate resistance (minimum inhibitory concentrations between 0.1 and 1.0 mcg/mL [0.1 and 1.0 mg/L]) or high-level resistance (minimum inhibitory concentration of 2.0 mcg/mL [2.0 mg/L] and higher). Altered penicillin-binding proteins cause penicillin resistance in approximately 40% of pneumococcal isolates, almost half of which are highly penicillin-resistant.¹³ Amoxicillin-clavulanate resistance is less common, occurring in approximately 17% of pneumococci.¹³ PRSP are commonly resistant to other drug classes, including sulfonamides, macrolides, and clindamycin, but are usually susceptible to levofloxacin. Treatment should be aimed at *S. pneumoniae* because pneumococcal AOM is unlikely to resolve spontaneously and commonly results in recurrent infections.⁷ β -Lactamase production occurs in 30% and nearly 100% of *H. influenzae* and *M. catarrhalis*, respectively.¹⁴ Although infections caused by these organisms are more likely to resolve without treatment, they should be considered in cases of treatment failure.

PATHOPHYSIOLOGY

AOM is caused by an interplay of multiple factors. Nasopharyngeal viral infections impair eustachian tube function and cause mucosal inflammation, which impairs mucociliary clearance and promotes bacterial proliferation and infection. Children are predisposed to AOM because their eustachian tubes are shorter, more flaccid, and more horizontal than those of adults, which make them less functional for drainage and protection of the middle ear from bacterial entry.⁷ Clinical manifestations of AOM are the result of host immune response and cellular damage from inflammatory mediators such as tumor necrosis factor and interleukins that are released from bacteria.³

Viscous middle ear effusions caused by allergy or irritant exposure may contribute to impaired mucociliary clearance and AOM in susceptible individuals.³ Middle ear effusions can persist for up to 6 months after an episode of AOM. OME occurs chronically in atopic children and may require **tympanostomy tube** placement to reduce complications such as hearing and speech impairment and recurrent otitis media.

Table 72-1

Risk Factors for Otitis Media

Allergies	Native American or Inuit ethnicity
Anatomic defects such as cleft palate	Pacifier use
Daycare attendance ^a	Positive family history/genetic predisposition
Gastroesophageal reflux	Siblings
Immunodeficiency	Tobacco smoke exposure
Lack of breast-feeding	Viral respiratory tract infection/winter season
Low socioeconomic status	Young age at first diagnosis ^a
Male sex	

^aRisk factors for infection with a resistant pathogen (daycare attendee, age under 2 years, recent antibiotic use in previous 3 months).

From Refs. 3, 7, and 8.

Patient Encounter 1, Part 1

A 22-month-old boy presents to the evening pediatric clinic with 2 days of fever (38.6°C [101.5°F]), nasal congestion, and fussiness. His mother reports that he was rubbing his left ear throughout the day. She states that he is more irritable than usual and was crying intermittently throughout the night last night. He is not eating as much as usual today. He attends daycare 5 days a week and has a 4-year-old sister who recently had a cold.

What information is suggestive of acute otitis media (AOM)?

What risk factors does this child have for AOM?

Is there any additional information you need to know before recommending a treatment plan?

TREATMENT**Desired Outcomes**

Treatment for AOM focuses on symptom relief and prevention of complications. The goals of treatment are to alleviate ear pain and fever, if present; eradicate infection; prevent complications; and minimize unnecessary antibiotic use.

General Approach to Treatment

1 *The majority of uncomplicated AOM cases resolve spontaneously without significant morbidity. Untreated AOM improves in almost 80% of all children between days 2 and 7 of illness without increasing the risk of complications.¹⁵ Antibiotics improve ear pain in only 6% of all children between days 2 and 7 of therapy while increasing the risk of adverse events by 5%.¹⁵ Antibiotics significantly improve recovery in children younger than 2 years of age with bilateral AOM and in those with AOM and otorrhea.¹⁵ Children younger than 2 years of age have a higher incidence of PRSP infections, and children between 6 months and 3 years of age have higher clinical and bacteriologic failure rates and complications when not treated initially with antibiotics as compared with older children.^{4,16} Patients with severe illness, defined by degree of fever and pain severity, have lower spontaneous recovery rates than those with less severe disease, particularly in children less than 2 years of age.^{13,17} 3 4 Therefore, antibiotics should be reserved for children most likely to benefit from therapy, which is dependent on patient age, illness severity, and diagnostic certainty. Current guidelines recommend stratifying patients based on these criteria in order to identify those most likely to benefit from antibiotic therapy.⁴*

Nonpharmacologic Therapy

Watchful waiting and “safety-net” antibiotic prescriptions (to be filled only if symptoms do not resolve after 48 to 72 hours

Clinical Presentation and Diagnosis of Acute Otitis Media

It is important to differentiate AOM from OME because they are treated differently. Patients with AOM usually have cold symptoms, including rhinorrhea, cough, or nasal congestion, before or at diagnosis.

Symptoms

- Young children: ear tugging, irritable, poor sleeping and eating habits
- Older patients: ear pain (mild, moderate, or severe), ear fullness, hearing impairment

Signs^{4,7}

- Fever: present in fewer than 25% of patients; often in younger children
- Middle ear effusion
- Otorrhea (middle ear perforation with fluid drainage): uncommon
- Bulging tympanic membrane
- Limited or absent mobility of tympanic membrane
- Distinct erythema of tympanic membrane
- Opaque or cloudy tympanic membrane obscuring or reducing visibility of middle ear

Laboratory Tests

Gram stain, culture, and sensitivities of ear fluid if draining spontaneously or obtained via tympanocentesis (not performed routinely in practice)

Complications

- Infectious: mastoiditis, meningitis, osteomyelitis, intracranial abscess
- Structural: perforated eardrum, **cholesteatoma**
- Hearing and/or speech impairment

Diagnosis⁴

Certain AOM: Requires *all* the following:

- Rapid onset of signs and symptoms
- Middle ear effusion findings with **pneumatic otoscopy**
- Inflammation indicated by either otoscopic evidence (distinct erythema) or otalgia

Uncertain AOM: not all three criteria are present

Severe AOM: moderate to severe ear pain or fever of 39°C (102.2°F) or greater

Nonsevere AOM: mild ear pain and fever of less than 39°C (102.2°F) in past 24 hours

of observation) are approaches being used more frequently to attenuate microbial resistance and avoid unnecessary adverse events and costs of antibiotics. Delayed antibiotic therapy in older children and those with less severe disease does not result in more infectious complications, such as mastoiditis or meningitis, when compared with routine initial antibiotic treatment.^{15,18} Use of an observation approach or use of a safety-net antibiotic prescription can reduce antibiotic use by 67% without increasing complications.¹⁸ Observation or delayed antibiotic therapy should be considered only in otherwise healthy children without recurrent disease (Fig. 72-1) and only if proper follow-up and good communication exist between clinicians and the parent/caregiver.^{3,4,18}

Other nondrug approaches include the use of external heat or cold to reduce postauricular pain and surgery. Tympanostomy tubes are most useful for patients with recurrent disease or chronic OME with impaired hearing or speech. Adenoidectomy may be necessary for children with chronic nasal obstruction, but tonsillectomy is rarely indicated.³

Pharmacologic Therapy

► Antibiotic Therapy

When antibiotic therapy is needed, many factors influence initial drug selection. Clinicians must consider drug factors such as antimicrobial spectrum, likelihood of clinical response, middle ear fluid penetration, incidence of side

effects, drug interactions, and cost, as well as patient factors, including risk factors for bacterial resistance, allergies, ease of dosing regimen, medication palatability, and presence of other medical conditions. Studies in uncomplicated AOM have not revealed significant differences between antibiotics in clinical response rates, but most were confounded by spontaneous resolution in children likely to have had viral illnesses. Bacteriologic response varies among antibiotics and does not always correlate well with clinical response but is considered important when selecting an agent.^{4,7}

Guidelines from the American Academy of Pediatrics and the American Academy of Family Physicians are available for children between 2 months and 12 years of age with uncomplicated AOM (Fig. 72-2) and are based on published trials and expert opinion.⁴ **5** *Amoxicillin is the drug of choice in most patients because of its proven effectiveness in AOM, high middle ear concentrations, excellent safety profile, low cost, good-tasting suspension, and relatively narrow spectrum of activity (Table 72-2).* High-dose amoxicillin (80 to 90 mg/kg/day) is preferred over conventional doses (40 to 45 mg/kg/day) because higher middle ear fluid concentrations can overcome pneumococcal penicillin resistance without substantially increasing adverse effects.¹⁹ **5** *In cases of severe illness or when coverage for β -lactamase-producing organisms is desired, high-dose amoxicillin-clavulanate is the preferred agent.* Pneumococcal resistance to trimethoprim-sulfamethoxazole and macrolides is problematic and strikingly common in PRSP, making these agents less desirable

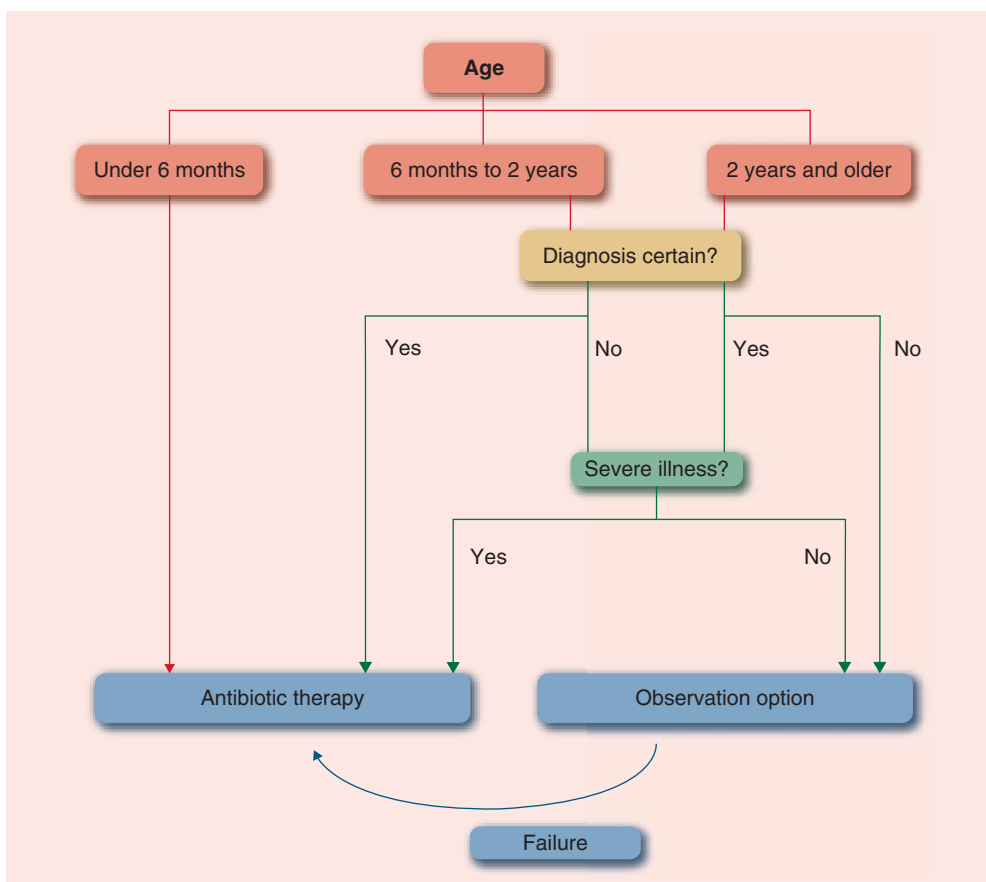

FIGURE 72-1. Treatment algorithm for initial antibiotics or observation in children with suspected or certain uncomplicated AOM. (From American Academy of Pediatrics and American Academy of Family Physicians. Diagnosis and management of acute otitis media. Pediatrics 2004;113:1451–1465.)

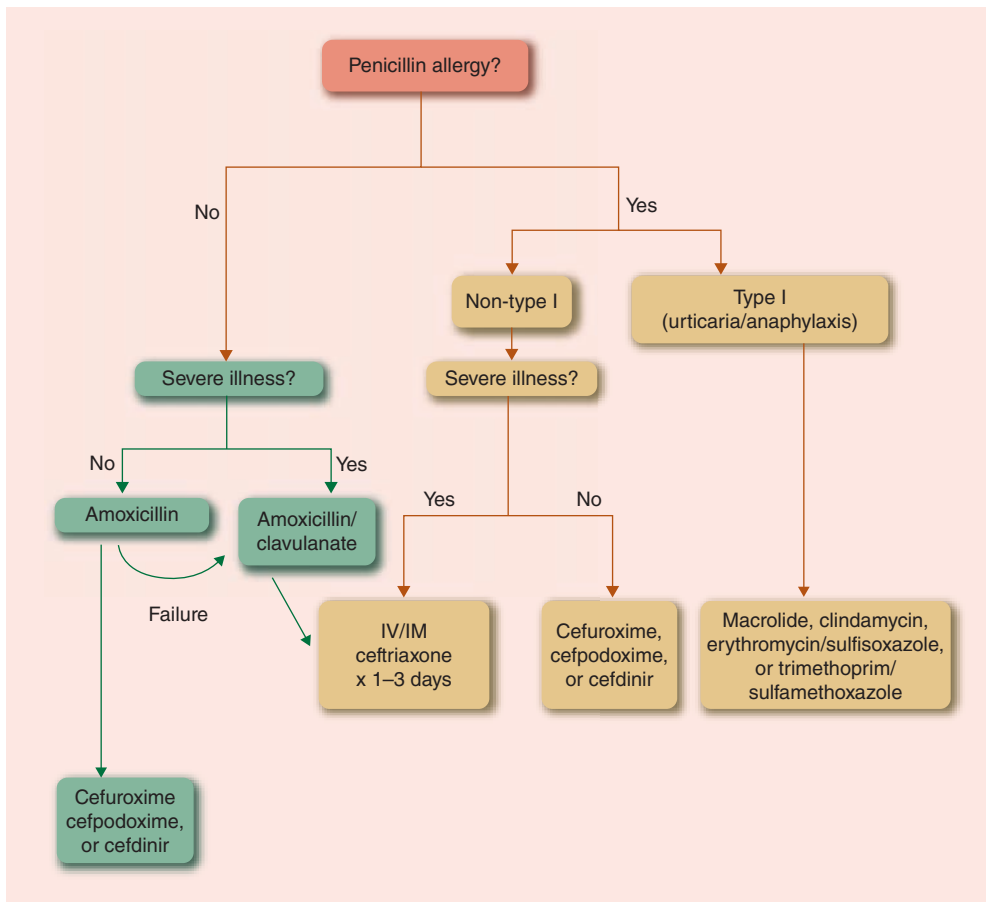

FIGURE 72-2. Treatment algorithm for uncomplicated AOM in children 2 months to 12 years of age. (From Refs. 4 and 8.)

for most patients.^{8,13} Patients with penicillin allergies require alternative first-line therapy (Fig. 72-2). Children who have received an antimicrobial in the previous month are more likely to harbor resistant organisms and should also receive alternative therapy (Table 72-2).⁸ A single dose of intramuscular ceftriaxone is effective for children who cannot tolerate oral medications, but a 3-day course may be preferred because of increasing pneumococcal resistance and reports of treatment failure with single doses.²⁰ Otopical antibiotics are an alternative to systemic agents for AOM in patients with otorrhea or tympanostomy tubes.²¹

If there is a lack of improvement or worsening with initial therapy during the first 48 to 72 hours, antibiotic selection must be reassessed and other contributing diseases must be excluded.^{4,8} **Tympanocentesis** can assist with guiding therapy in difficult cases.

The duration of antibiotic therapy depends on antibiotic selection, patient characteristics, and acceptability of clinical failure if a short treatment course is used. Standard 10-day oral therapy is more effective than shorter courses when comparing clinical outcomes between 8 and 19 days after initiating antibiotics, but failure rates are equivalent at 30 days following antibiotic initiation.²² Failure rates of short-course therapy are significantly higher in children with perforated eardrums and in children less than 2 years of age treated with azithromycin.²² Short-course antibiotics may result in fewer gastrointestinal adverse events but only when compared with 10-day treatment courses of amoxicillin-clavulanate.²²

Short-course ceftriaxone is no more effective than standard 10-day oral regimens and is associated with significantly more gastrointestinal adverse effects.²² Clinicians must balance the increased risk of failure with short-course therapies against the inconvenience of longer courses when selecting a duration of treatment.

► Adjunctive Therapy

Pain is a central feature of AOM but its management is often overlooked. Acetaminophen and ibuprofen are commonly used nonprescription agents for mild to moderate pain. Ibuprofen has a longer duration of effect than acetaminophen but is not used routinely in children younger than 6 months of age because of increased toxicity concerns. Alternating ibuprofen with acetaminophen is not recommended because of the potential for dosing confusion and error in an ambulatory setting and a lack of safety and efficacy data with combination therapy exceeding 24 to 48 hours. Topical anesthetic drops such as benzocaine (in Auralgan) provide pain relief within 30 minutes of administration and may be preferred over systemic analgesics when fever is absent. **Myringotomy** provides immediate relief but is performed rarely. Other medications such as decongestants, antihistamines, and corticosteroids have no role in the treatment of AOM and can, in some cases, prolong effusion duration.^{4,23} Data are lacking on the safety and efficacy of complementary and alternative treatments.

Table 72-2

Antibiotics^a for the Treatment of Acute Otitis Media

Drug	Usual Dose and Schedule	Common Adverse Effects	Relative Cost ^b	Comments
Amoxicillin	80–90 mg/kg/day in 2 doses (adult: 875 mg twice daily)	Nausea, vomiting, diarrhea, rash	\$	Drug of choice for AOM; experts recommend high-dose to overcome penicillin resistance
Amoxicillin-clavulanate	80–90 mg/kg/day in 2 doses (adult: 875 mg twice daily)	Nausea, vomiting, diarrhea, rash, diaper rash	\$\$\$–\$\$\$\$	More diarrhea than amoxicillin, amoxicillin:clavulanate ratio of 14:1 preferred because of lower daily clavulanate component
Cefuroxime axetil	30 mg/kg/day in 2 doses (max 1 g/day with suspension; adult: 250 mg twice daily)	Nausea, vomiting, diarrhea, rash, diaper rash	\$\$\$	Suspension gritty and bitter tasting, not interchangeable with tablets (less bioavailable)
Cefdinir	14 mg/kg/day in 1–2 doses (adult: 300 mg twice daily or 600 mg once daily)	Diarrhea, rash, vomiting, diaper rash, yeast infections	\$\$\$	Preferred oral cephalosporin (good taste); separate from Al or Mg antacids and Fe supplements by 2 hours
Cefpodoxime proxetil	10 mg/kg/day in 2 doses (adult: 200 mg twice daily)	Diarrhea, diaper rash, vomiting, rash, yeast infections	\$\$\$	Suspension is bitter tasting
Ceftriaxone	50 mg/kg IM or IV for 1–3 days (max 1 g/dose)	Injection site pain, swelling, or erythema, diarrhea, rash	\$\$\$–\$\$\$\$	3-day regimen preferred for PRSP; avoid in children under 2 months because of kernicterus risk
Azithromycin	10 mg/kg × 1 day, 5 mg/kg/day × 4 days; 10 mg/kg/day × 3 days; or 30 mg/kg single dose (adult dose 500 mg × 1 day, 250 mg × 4 days)	Nausea, vomiting, diarrhea, abdominal pain	\$\$	Separate from Al or Mg antacids by 2 hours; diarrhea/vomiting more common with single-dose regimen; 3- or 5-day courses preferred; increasing pneumococcal resistance; many failures with <i>H. influenzae</i> infection
Clarithromycin	15 mg/kg/day in 2 doses (adult: 250 mg twice daily)	Diarrhea, vomiting, rash, abnormal taste, abdominal pain	\$\$	Many drug interactions (inhibits cytochrome P-450 3A4); suspension cannot be refrigerated and has metallic taste; same microbiologic issues as azithromycin
Erythromycin-sulfisoxazole	50 mg/kg/day of erythromycin component in 3–4 doses	Nausea, vomiting, abdominal pain, diarrhea, rash	\$\$	Many drug interactions (like clarithromycin), contraindicated in children under 2 months because of kernicterus risk; increasing pneumococcal resistance
Trimethoprim-sulfamethoxazole	8–10 mg/kg/day of trimethoprim component in 2 doses	Nausea, vomiting, anorexia, rash, urticaria	\$	Increasing pneumococcal resistance; contraindicated in children under 2 months because of kernicterus risk
Clindamycin	20–30 mg/kg/day in 3–4 doses (adult: 300 mg 4 times daily or 450 mg 3 times daily)	Nausea, diarrhea, <i>C. difficile</i> colitis, anorexia	\$	Oral liquid poor tasting; only for pneumococcal infection

^aOther FDA-approved antibiotics for AOM not included in AAP/AAFP guidelines: cefaclor, cephalixin, cefprozil, cefixime, loracarbef, and ceftibuten.

^bApproximate cost per course: \$ (under \$25), \$\$ (\$25–\$50), \$\$\$ (\$50–\$100), \$\$\$\$ (over \$100).

AOM, acute otitis media. Al, aluminum; Mg, magnesium; Fe, iron; IM, intramuscular; PRSP, penicillin-resistant *S. pneumoniae*.

From American Academy of Pediatrics and American Academy of Family Physicians. Diagnosis and management of acute otitis media. Pediatrics 2004;113:1451–1465.

► Prevention

Vaccinations may prevent AOM in certain patients, such as older children and those with recurrent infections. Influenza vaccine is more effective in preventing AOM in children older than 2 years of age than in younger patients, possibly from impaired immune responses and immature host defenses in infants and toddlers.²⁴ The live attenuated influenza vaccine

is more effective than the injectable inactivated influenza vaccine in protecting children older than 2 years against influenza-associated AOM.²⁵ Pneumococcal conjugate vaccine is protective against infection by vaccine serotypes only with a limited overall benefit for AOM.²⁶ Antibiotic prophylaxis is not recommended for otitis-prone children because of antibiotic resistance trends. Avoidance or minimization

Patient Encounter 1, Part 2

On further questioning, you discover that the child is allergic to amoxicillin. He developed a nonurticarial rash last year during treatment for a urinary tract infection. He has not received antibiotics since that time, and this is his first ear infection.

Immunizations: up-to-date

Medications: acetaminophen drops 120 mg orally every 4 to 6 hours as needed for fever

ROS: (+) nasal congestion and rhinorrhea, (-) vomiting, diarrhea, or cough

PE:

- **Gen:** irritable child but consolable
- **VS:** BP 100/60 mm Hg, P 124 beats/min, RR 20 breaths/min, T 38.4°C (101.1°F)
- **HEENT:** erythema and bulging of the left tympanic membrane with the presence of middle ear fluid; the right tympanic membrane is obscured with cerumen.

Identify your treatment goals for this child.

Given this information, what nonpharmacologic and pharmacologic therapy do you recommend?

of risk factors associated with otitis media, such as tobacco smoke and bottle feeding, is advised, but the effects of these interventions remain unproven.

OUTCOME EVALUATION

Improvement of signs and symptoms (i.e., pain, fever, and tympanic membrane inflammation) should be evident by 72 hours of therapy. Children can appear clinically worse during the first 24 hours of treatment but often stabilize during the second day with defervescence and improved eating and sleeping patterns. If symptoms persist or worsen, reevaluation must occur to determine the proper diagnosis and treatment. Counsel patients and caregivers regarding common antibiotic adverse events such as rash, diarrhea, and vomiting that may prompt additional medical attention.

Presence of middle ear effusion in the absence of symptoms is not an indicator of treatment failure. Persistent effusion greater than 3 months in duration requires a hearing evaluation in children who are otherwise healthy.²⁷ Preschool-aged and younger children or those at risk for developmental difficulties may need reexamination earlier because speech and hearing impairment is more difficult to assess in these populations.

SINUSITIS

Sinusitis, or inflammation of the paranasal sinuses, is often described as **rhinosinusitis** because it involves inflammation of contiguous nasal mucosa, which occurs in nearly all cases of viral respiratory infections. Acute rhinosinusitis is characterized

Patient Care and Monitoring of Acute Otitis Media (AOM)

1. Assess the patient's signs and symptoms. Are they consistent with AOM?
2. Review diagnostic information to determine whether acute infection is present. Are all three diagnostic criteria present? Was the proper method used for diagnosis (pneumatic otoscopy)?
3. Does the patient require antibiotic therapy, or is observation an appropriate option?
4. Obtain a complete medication history, including prescription drugs, nonprescription drugs, and natural product use, as well as allergies and adverse effects.
5. Determine what medication should be used for pain, if present.
6. If applicable, determine which antibiotic to use and the duration of therapy.
7. Develop a plan to assess effectiveness of the chosen therapy and course of action to take if the patient does not improve or worsens.
8. Provide patient education on:
 - What to expect from prescribed medication, including potential adverse effects
 - Avoidance of antihistamines and decongestants
 - Signs of treatment failure
9. Stress the importance of adherence to therapy, including antibiotic resistance concerns.
10. Determine the need for influenza and pneumococcal vaccinations.
11. Educate the family regarding risk factors for otitis media.

by symptoms that persist for up to 4 weeks, whereas chronic rhinosinusitis manifests as cough, rhinorrhea, and/or nasal obstruction for more than 12 weeks. Acute bacterial rhinosinusitis (ABRS) refers to an acute bacterial infection of the sinuses that occurs independently of or is superimposed on chronic sinusitis. This section will focus on ABRS and its appropriate treatment.

EPIDEMIOLOGY AND ETIOLOGY

Rhinosinusitis is one of the most common medical conditions in the United States, affecting about 1 billion people annually.¹ It is caused mainly by respiratory viruses but can also be triggered by allergies or environmental irritants. Viral rhinosinusitis is complicated by secondary bacterial infection in 0.2% to 2% of adults and 5% to 13% of children.^{1,28} Upper respiratory infections of less than 7 days' duration are usually viral, whereas more prolonged disease or severe symptoms are often caused by bacteria. Risk factors

Table 72-3

Risk Factors for Acute Bacterial Rhinosinusitis

Allergic or nonallergic rhinitis	Intranasal medications or illicit drugs
Anatomic defects (e.g., septal deviation)	Mechanical ventilation
Aspirin allergy, nasal polyps, and asthma	Nasogastric tubes
Cystic fibrosis or ciliary dyskinesia	Swimming or diving
Dental infections or procedures	Tobacco smoke exposure
Female sex	Traumatic head injury
Immunodeficiency	Viral respiratory tract infection or winter season

From Refs. 29 and 30.

for ABRS include prior viral respiratory infection, allergic rhinitis, anatomic defects, and certain medical conditions (Table 72-3).^{29,30}

Bacteria that cause sinusitis are similar to those that cause AOM. *S. pneumoniae* and *H. influenzae* are responsible for more than half of the cases in all patients, with an additional 20% of cases caused by *M. catarrhalis* in children.^{29,30} Similar to AOM, an increased prevalence of *H. influenzae* has been reported in ABRS, and certain factors predict the presence of drug-resistant pathogens.^{1,31} Other bacteria that cause sinusitis include *S. pyogenes* (up to 5%), anaerobic organisms such as *Bacteroides* and *Peptostreptococcus* species (up to 9% of adults), and *S. aureus* (up to 10% of adults).^{29,32} Chronic sinusitis is often polymicrobial with a higher incidence of anaerobes, gram-negative bacilli, and fungi.

PATHOPHYSIOLOGY

- Rhinosinusitis is caused by mucosal inflammation and local damage to mucociliary clearance mechanisms from viral infection or allergy. Increased mucus production and reduced clearance of secretions can lead to blockage of the sinus ostia, or the opening of the sinuses to the upper airway. This environment is ideal for bacterial growth and promotes a cycle of local inflammatory response and mucosal injury characterized by increased concentrations of interleukins, histamine, and tumor necrosis factor.^{29,30} Factors that contribute to sinus invasion include nose blowing, reduced local immunity, viral virulence, and nasopharyngeal colonization with bacteria.^{29,33} Damage to the host defense system perpetuates bacterial overgrowth and persistence of infection.

TREATMENT**Desired Outcomes**

- The goals of treatment for ABRS are to eradicate bacteria and prevent serious sequelae. Specific aims are to relieve symptoms, normalize the nasal environment, use antibiotics when appropriate and select effective antibiotics that minimize resistance, and prevent development of chronic disease or complications.

General Approach to Treatment

Initial management of rhinosinusitis focuses on symptom relief for patients with mild disease of less than 7 to 10 days in duration. Clinicians often inappropriately prescribe antibiotics for rhinosinusitis, which usually is viral and self-limited.

Clinical Presentation and Diagnosis of Acute Bacterial Rhinosinusitis

Sinusitis symptoms typically last 7 to 10 days after a viral infection and are caused by activation of the immune system and parasympathetic nervous system.

Acute Signs and Symptoms^{28,29,33}

- Adults:** nasal congestion or obstruction, purulent nasal or postnasal discharge, facial pain or pressure or fullness (especially unilateral in a sinus area), diminished sense of smell, fever, cough, maxillary tooth pain, fatigue, ear fullness or pain
- Children:** purulent nasal or postnasal drainage, nasal congestion and mouth breathing, persistent cough (particularly at night) or throat clearing, fever, pharyngitis, ear discomfort, halitosis, morning periorbital edema or facial swelling, fatigue, facial or tooth pain

Complications

Orbital cellulitis or abscess, periorbital cellulitis, meningitis, cavernous sinus thrombosis, ethmoid or frontal sinus

erosion, chronic sinusitis, and exacerbation of asthma or bronchitis

3 Diagnosis^{28,29,33}

- Clinical diagnosis:** most common method; acute rhinosinusitis signs and symptoms (as noted previously) that have not resolved after 10 days or that worsen within 10 days after initial improvement. Respiratory secretion color is unreliable for diagnosis of bacterial infection because neutrophil presence causes color and can be found in viral sinusitis.
- Radiographic studies:** useful for assessing presence of abscess or intracranial complication
- Paranasal sinus puncture:** "gold standard"; not performed routinely but can be useful in complicated or chronic cases
- Laboratory studies/nasopharyngeal cultures:** not recommended for routine diagnosis

Studies comparing antibiotics to placebo in ABRS report a high spontaneous improvement rate of more than 70% after 7 to 12 days of nonsevere symptoms and only modest symptom improvements but more adverse events in patients treated with antibiotics.^{33,34} Withholding antibiotics is an option in nonsevere ABRS for up to 7 to 10 days duration if adequate follow-up can be assured.^{1,33} **6** *Antibiotic therapy should be reserved for persistent, worsening, or severe ABRS, such as patients with moderately severe symptoms that have persisted for greater than 10 days or worsened within 10 days after initial improvement and patients with severe symptoms regardless of duration.*^{28,29,33} Empiric antibiotic selection is usually employed and should target commonly infecting bacteria because sinus cultures are rarely obtained.

Nonpharmacologic Therapy

- Ancillary treatments such as humidifiers, vaporizers, and saline nasal sprays or drops are used to moisturize the nasal canal and impair crusting of secretions along with promoting ciliary function. Although many patients report benefit from such therapies, there are no controlled studies that support their use.
- Nasal irrigation with isotonic or hypertonic saline may improve quality of life, reduce medication usage, and improve symptoms, especially in patients with recurrent or chronic sinusitis.³³

Pharmacologic Therapy

► Adjunctive Therapy

- Medications that target URI symptoms are used widely in patients with rhinosinusitis, particularly in the early stage of infection. There is a lack of evidence supporting their use in ABRS, but they may provide temporary relief in certain patients.^{28,33} Analgesics are used to treat fever and pain from sinus pressure. Oral decongestants relieve congested nasal passages but should be avoided in children younger than

4 years and patients with ischemic heart disease or uncontrolled hypertension. Intranasal decongestants can be used for severe congestion in most patients 6 years of age or older, but use should be limited to 3 days or less to avoid rebound nasal congestion. Guaifenesin, a mucolytic, has no evidence to support its use in rhinosinusitis. Antihistamines should be avoided because they thicken mucus and impair its clearance, but they may be useful in patients with predisposing allergic rhinitis or chronic sinusitis. Similarly, intranasal corticosteroids usually are reserved for patients with allergies or chronic sinusitis, but they may be beneficial as monotherapy or with antibiotics in ABRS.³⁵

► Antibiotic Therapy

Although many antibiotics have been studied for ABRS, no randomized, double-blind, placebo-controlled studies have used pre- and posttreatment sinus aspirate cultures as an outcome measure. In some studies, antibiotics result in faster symptom resolution and lower failure rates and complications compared with no treatment, particularly in more severe disease.^{28,33} Because diagnosis is based on clinical presentation and not sinus aspirate cultures, clinicians must attempt to differentiate ABRS from viral rhinosinusitis in order to minimize inappropriate antibiotic use. **3** **6** *Antibiotic use should be limited to cases where infection is unlikely to resolve without causing prolonged disease: patients with moderately severe symptoms that persist for greater than 10 days or worsen after initial improvement and patients with severe symptoms.*^{28,29,33}

Treatment guidelines outline antibiotic choices that are likely to result in favorable clinical and bacteriologic outcomes based on causative pathogens, spontaneous resolution rates, and nationwide resistance patterns.^{28,29,33} **2** *These guidelines (Figs. 72-3 and 72-4) stratify therapy based on disease severity and risk of infection with resistant bacteria, defined as antibiotic use within the previous 4 to 6 weeks. Other risk factors for resistance include daycare attendance, frequent*

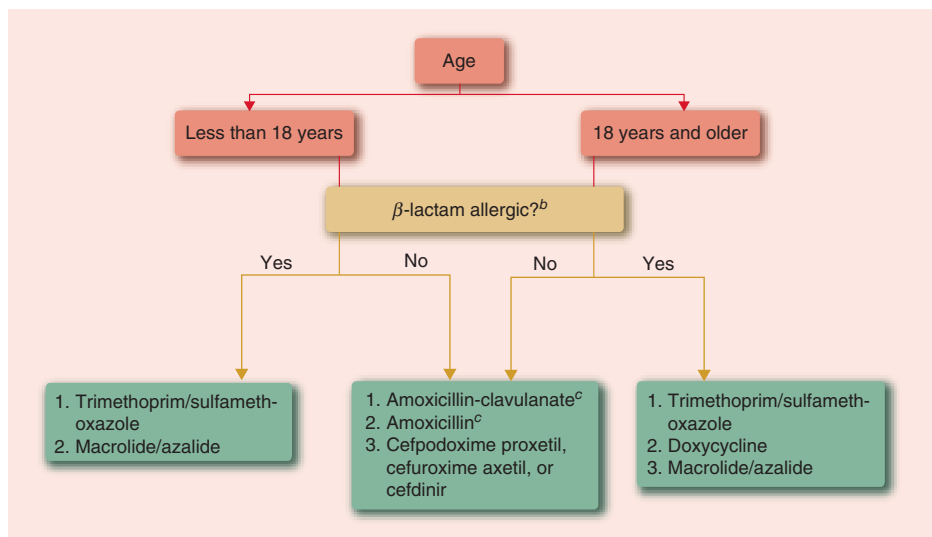

FIGURE 72-3. Treatment algorithm^a for ABRS in patients with mild disease without recent antibiotic exposure. ^aAntibiotics are listed in order of predicted efficacy based on predicted clinical and bacteriologic efficacy rates, clinical studies, safety, and tolerability. Doses can be found in Table 72-4. ^bCephalosporins should be considered for patients with non-type I hypersensitivity to penicillins; they are more likely to be effective than the alternative agents. ^cHigh doses are recommended for adults with daycare contacts or frequent infections and most children. (From Refs. 28 and 29.)

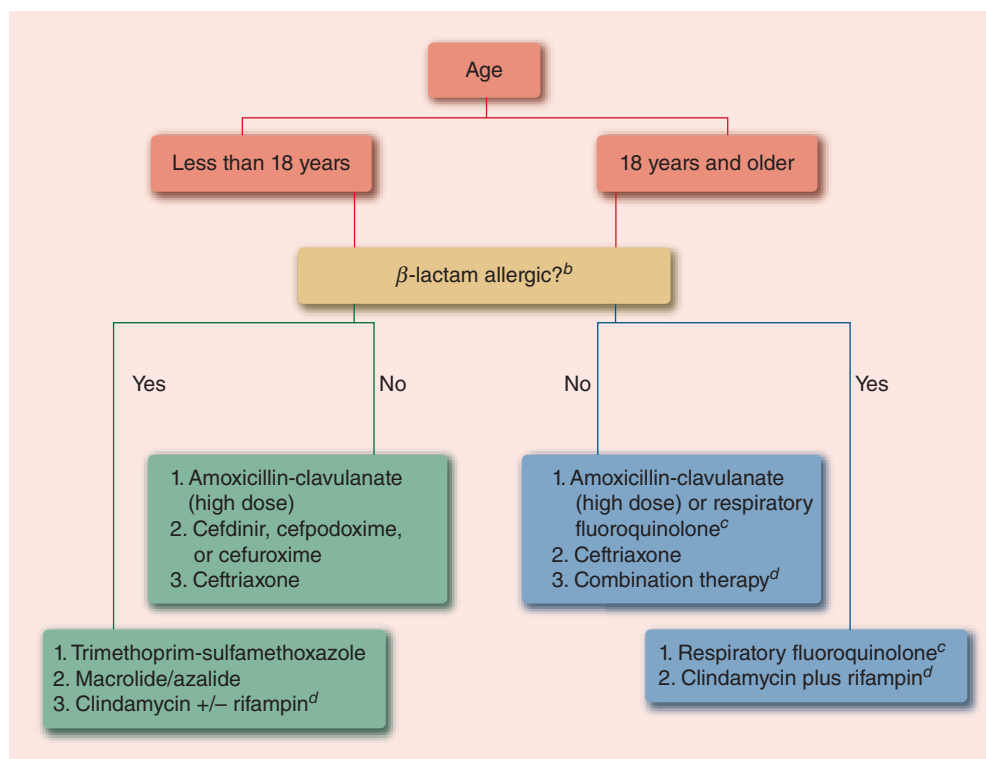

FIGURE 72-4. Treatment algorithm^a for ABRS in patients with mild disease and recent antibiotic exposure or moderate disease. ^aAntibiotics are listed in order of predicted efficacy based on predicted clinical and bacteriologic efficacy rates, clinical studies, safety, and tolerability. Doses can be found in Table 72-4. ^bCephalosporins should be considered for patients with non-type I hypersensitivity to penicillins; they are more likely to be effective than the alternative agents. ^cRespiratory fluoroquinolone = levofloxacin, moxifloxacin. ^dCombination therapy should provide gram-positive and gram-negative coverage. Examples are high-dose amoxicillin or clindamycin plus rifampin or cefixime. There are no published clinical studies to support such combinations. (From Refs. 28 and 29.)

exposure to children in daycare, and recurrent disease. Severe disease requires evaluation and treatment in conjunction with specialized physicians such as otolaryngologists.

Antibiotic therapy (Table 72-4) should target *S. pneumoniae*, but consideration must be given to other bacteria, including *H. influenzae*, *M. catarrhalis*, *S. aureus*, and PRSP.

7 Patients with mild disease and no prior antibiotic exposure should receive initial therapy with amoxicillin or amoxicillin-clavulanate. Amoxicillin is effective for most mild infections and covers most PRSP when used in high doses. It is less expensive and better tolerated than amoxicillin-clavulanate, which provides expanded coverage against β -lactamase-producing bacteria. Patients who are allergic to penicillins can be treated with an appropriate cephalosporin; severe penicillin allergies require treatment with alternative agents that may be less effective based solely on bacterial resistance trends and not clinical data^{13,28,29} (Fig. 72-3). Initial therapy for patients with moderate symptoms or those with recent antibiotic exposure includes high-dose amoxicillin-clavulanate or a respiratory fluoroquinolone^{23,24} (Fig. 72-4).

Failure to respond to initial therapy within 7 days requires reevaluation to consider changing therapy to cover resistant

organisms and to examine for complications.³³ Antibiotics traditionally have been given for at least 10 to 14 days, with up to 21 days needed for resolution in some patients.²⁹ Five-day treatment courses of some fluoroquinolones or β -lactams are as effective as longer courses in adults with uncomplicated acute maxillary sinusitis.³⁶ Treatment success is influenced by medication adherence to the prescribed regimen, where once- or twice-daily agents are preferred over multiple daily doses.

OUTCOME EVALUATION

Clinical improvement should be evident within 7 days of therapy, as demonstrated by defervescence, reduction in nasal congestion and discharge, and improvements in facial pain or pressure and other symptoms. Monitor for common adverse effects and refer to a specialist if clinical response is not obtained with first- or second-line therapy. Referral is also important for severe, recurrent, or chronic sinusitis or acute disease in immunocompromised patients. Surgery may be indicated in complicated cases.

Table 72–4

Antibiotics^a for the Treatment of Acute Bacterial Rhinosinusitis

Drug	Adult Dose	Pediatric Dose ^b	Comments
Amoxicillin	1.5–4 g/day in 2–3 doses	90 mg/kg/day in 2 doses	Lacks coverage against β -lactamase producers
Amoxicillin-clavulanate	1.75–4 g/day in 2–3 doses	90 mg/kg/day in 2 doses	Broad coverage particularly with high doses; Augmentin XR (2 g every 12 hour) targeted toward PRSP
Cefdinir	600 mg/day in 1–2 doses	14 mg/kg/day in 1–2 doses	Preferred oral liquid cephalosporin owing to good palatability
Cefpodoxime proxetil	200 mg twice daily	10 mg/kg/day in 2 doses	
Cefuroxime axetil	250–500 mg twice daily	15–30 mg/kg/day in 2 doses	
Ceftriaxone	1 g IM/IV every 24 hour	50 mg/kg IM/IV every 24 hour	Experts recommend a 5-day treatment course
Trimethoprim-sulfamethoxazole	160/800 mg (1 DS tablet) twice daily	8–10 mg/kg/day of trimethoprim component in 2 doses	Considerable pneumococcal resistance limits use of this agent
Azithromycin	500 mg \times 1 day, 250 mg/day \times 4 days; 500 mg/day \times 3 days; 2 g \times 1 dose	10 mg/kg \times 1 day, 5 mg/kg/day \times 4 days; 10 mg/kg/day \times 3 days	Increasing pneumococcal resistance and limited <i>H. influenzae</i> activity; single-dose regimen has high incidence of nausea, vomiting, and diarrhea
Clarithromycin	500 mg twice daily or 1 g once daily (XL only)	15 mg/kg/day in 2 doses	XL tablets reported to have fewer GI problems and taste disturbances than twice-daily preparation
Doxycycline	100 mg twice daily	Avoid in children under 8 years	Can cause photosensitivity, GI problems, tooth staining in young children; many drug–drug interactions (antacids, iron, calcium)
Levofloxacin	500–750 mg once daily (750 mg \times 5 days)	Not available	Common fluoroquinolone side effects are nausea, vaginitis, diarrhea, dizziness; many drug–drug interactions (antacids, iron, calcium); tendon rupture, photosensitivity, QT prolongation possible; cost similar to amoxicillin/clavulanate
Moxifloxacin	400 mg once daily	Not available	
Clindamycin	150–450 mg 3–4 times daily	20–40 mg/kg/day in 3–4 doses	No gram-negative coverage; use in combination

^aRefer to Table 72–2 for more information on antibiotics. Other FDA-approved antibiotics for ABRS not included in the Sinus and Allergy Health Partnership or American Academy of Pediatrics guidelines: cefaclor, cefprozil, cefixime, ciprofloxacin, erythromycin, loracarbef.

^bMaximum dose not to exceed adult dose.

ABRS, acute bacterial rhinosinusitis; PRSP, penicillin-resistant *S. pneumoniae*; IM, intramuscular.

From Refs. 28 and 29.

PHARYNGITIS

Pharyngitis is an acute and often painful inflammation of the throat typically caused by viral or bacterial infection. Other conditions, such as gastroesophageal reflux, postnasal drip, or allergies, also can cause pharyngitis and must be distinguished from infectious causes. Acute pharyngitis is responsible for 1% to 2% of physician visits in adults and 6% to 8% of pediatric visits, but it is generally self-limited without serious sequelae.^{37,38} Antibiotics are frequently prescribed because of the inability to easily distinguish between viral and bacterial infections and the fear of untreated streptococcal illness.

EPIDEMIOLOGY AND ETIOLOGY

Pharyngitis is a common manifestation of upper respiratory infections caused by rhinovirus, coronavirus, adenovirus, influenza virus, parainfluenza virus, or Epstein-Barr virus.

- Group A *Streptococcus*, or *S. pyogenes*, is the most common bacterial cause of acute pharyngitis, responsible for 20% to 30% of cases in children and 5% to 15% of adult infections.³⁹ Infection is most common in late winter and early spring and is spread easily through direct contact with contaminated secretions. Clusters of infection are common within families, classrooms, and other crowded areas. Less common causes of bacterial pharyngitis are *Corynebacterium diphtheriae*,

Patient Encounter 2

A 39-year-old female presents to her primary care physician with purulent postnasal discharge, nasal congestion, headache, and fatigue. She reports that her symptoms began 7 days ago and have worsened over the past 2 days. She states that she has painful facial pressure when she bends forward and she notices that her upper molars ache when she eats or brushes her teeth. She tried acetaminophen and pseudoephedrine but received no relief. She has a history of sinus infections (1 to 2 per year). Her last course of antibiotics was 7 months ago when she received amoxicillin for sinusitis. She has a 3-year-old daughter who attends daycare.

Immunizations: up-to-date

Meds: cetirizine 10 mg orally daily, intranasal fluticasone one spray each nostril twice daily, multivitamin daily, acetaminophen 500 mg orally as needed, pseudoephedrine 60 mg orally as needed

Allergies: dust mites, cat and dog dander

PE:

Gen: tired-appearing, moderate distress, appears uncomfortable

VS: BP 108/62 mm Hg, P 88 beats/min, RR 14 breaths/min, T 38.2°C (100.8°F), wt 56.8 kg (125 lb)

HEENT: thick, purulent green-brown postnasal discharge; nasal mucosal irritation and edema; right maxillary facial pain and right upper molar hypersensitivity upon tapping; no oral lesions; erythematous pharynx with mild tonsillar hypertrophy

What information is suggestive of acute bacterial rhinosinusitis (ABRS)?

What risk factors are present?

What other diagnostic studies, if any, should be performed?

What are the treatment goals for this patient?

Create a care plan for this patient that includes nonpharmacologic and pharmacologic therapies and a monitoring plan.

groups C and G streptococci, *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, and *Neisseria gonorrhoeae*. This section will focus on group A streptococcal disease in which antimicrobial therapy is indicated.

PATHOPHYSIOLOGY

- Pharyngeal colonization with group A streptococci occurs in up to 20% of children and is a risk factor for developing streptococcal pharyngitis after a break in upper respiratory mucosal integrity.⁴⁰ Clinicians should recognize that the symptoms of streptococcal pharyngitis usually are self-limited

Patient Care and Monitoring of Acute Bacterial Rhinosinusitis (ABRS)

1. Assess the patient's signs and symptoms. Are they consistent with ABRS?
2. How long have the patient's symptoms been present? If symptoms are mild and present for fewer than 10 days, viral sinusitis is likely. Persistent moderate or acute severe symptoms are more indicative of bacterial infection.
3. Does the patient require antibiotic therapy? Avoid antibiotic use in viral disease.
4. Obtain a complete medication history, including prescription drugs, nonprescription drugs, and natural product use, as well as allergies and adverse effects.
5. Determine what adjunctive therapies should be used for symptoms, such as pain and congestion.
6. If applicable, determine which antibiotic to use and the duration of therapy.
7. Develop a plan to assess effectiveness of the chosen therapy and course of action to take if the patient does not improve or worsens.
8. Provide patient education on:
 - What to expect from the antibiotic and other medications, including potential adverse effects
 - Avoidance of antihistamines, if appropriate
 - Signs of treatment failure
 - Role of viral infections in sinusitis and how to prevent disease transmission
9. Stress the importance of adherence to therapy, including antibiotic resistance concerns.

and resolve within 7 days of onset without antibiotic treatment.³⁹ Historically, untreated or inappropriately treated disease caused acute **rheumatic fever**, potential permanent heart valve damage, and infectious complications such as peritonsillar and retropharyngeal abscesses. Delayed antibiotic therapy given up to 9 days after symptom onset can prevent these particular sequelae, so **3** *proper diagnosis is important to minimize unnecessary antibiotic use for viral pharyngitis and prevent complications of untreated streptococcal infection.*^{37,39–41}

TREATMENT

Desired Outcomes

- 8** *The goals of therapy for streptococcal pharyngitis are to eradicate infection in order to shorten the disease course, reduce infectivity and spread to close contacts, and prevent complications.* Antibiotic use only prevents peritonsillar or retropharyngeal abscesses, cervical lymphadenitis, and rheumatic fever. Immune-mediated, nonsuppurative complications

Patient Care and Monitoring of Streptococcal Pharyngitis

1. Assess the patient's signs and symptoms. Are they consistent with streptococcal pharyngitis? Are symptoms of viral infection present?
2. Perform laboratory testing to confirm the presence of group A streptococci.
3. Does the patient require antibiotic therapy? Avoid antibiotic use in viral illness.
4. Obtain a complete medication history, including prescription drugs, nonprescription drugs, and natural product use, as well as allergies and adverse effects.
5. Recommend antipyretic or analgesic therapy, if needed.
6. If applicable, determine which antibiotic to use and the duration of therapy.
7. Develop a plan to assess effectiveness of chosen therapy and course of action to take if the patient does not improve or worsens.
8. Provide patient education on:
 - What to expect from the antibiotic, including potential adverse effects
 - Avoidance of close contacts for 24 hours
 - Signs of treatment failure
9. Stress the importance of medication adherence and the need to complete therapy, including antibiotic resistance concerns.

of streptococcal infection are not impacted by antibiotic treatment. These conditions include acute **glomerulonephritis** and reactive arthritis.³⁷

Pharmacologic Therapy

Pain is often a central feature of pharyngitis, regardless of its cause. Oral analgesics such as acetaminophen or ibuprofen provide pain relief and can allow patients to maintain normal eating and drinking habits. **3** *Antibiotics should be used only in cases of laboratory-documented streptococcal pharyngitis that is associated with clinical symptoms in order to avoid unnecessary treatment (Fig. 72-5).*^{37,39-41} Effective therapy (**Table 72-5**) reduces the infectious period from approximately 10 days to 24 hours and shortens symptom duration by 1 to 2 days. **9** *Treatment guidelines recommend penicillin*

as the drug of choice because of its narrow antimicrobial spectrum, documented safety and history of nasopharyngeal streptococcal eradication, and low cost.^{37,40,41} Amoxicillin is an alternative first-line agent, particularly for children requiring a liquid formulation because of its improved taste as compared with penicillin and its enhanced adherence with once-daily dosing.⁴¹ Studies proving that antibiotics prevent rheumatic fever used intramuscular procaine penicillin, but other antibiotics can also eradicate nasopharyngeal streptococci and presumably are effective for preventing rheumatic heart disease.^{37,41} Cephalosporins may be more effective than penicillin for relapse prevention and nasopharyngeal eradication of streptococci, particularly in asymptomatic carriers.^{39,41,42} Usual duration of antibiotic therapy is 10 days, but 5-day courses of certain cephalosporins are just as effective for streptococcal eradication as 10 days of penicillin.⁴³

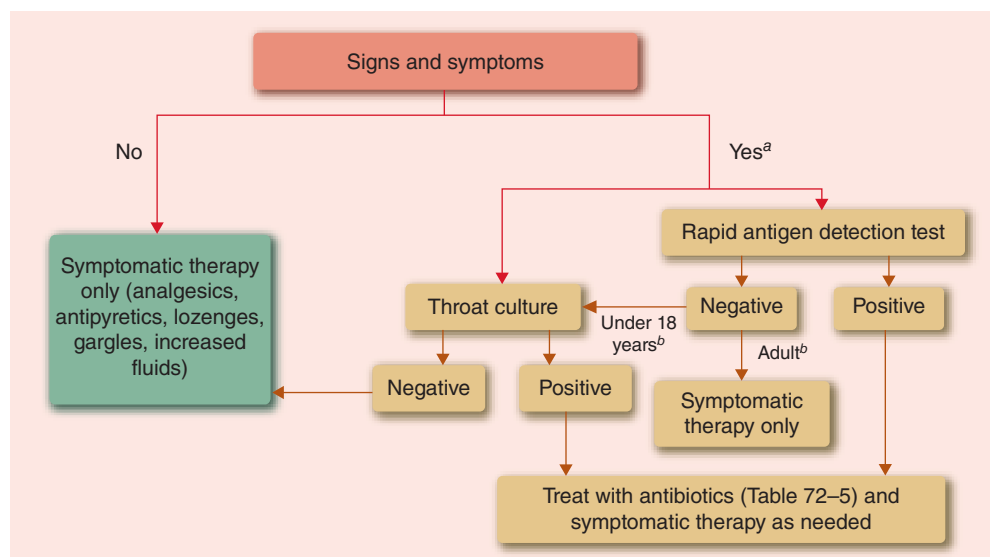

FIGURE 72-5. Treatment algorithm for management of pharyngitis in children and adults. ^aRapid antigen detection tests (RADTs) are preferred if the test sensitivity exceeds 80%. ^bParents, teachers, or other adults with significant pediatric contact should also be cultured if RADT is negative. (From Bisno AL, Gerber MA, Gwaltney JM, et al. Practice guidelines for the diagnosis and management of group A streptococcal pharyngitis. Clin Infect Dis 2002;35:113-125.)

Table 72-5

Antibiotics^a for the Treatment of Streptococcal Pharyngitis

Drug	Adult Dose	Pediatric Dose	Duration	Comments
Penicillin V	500 mg 2–3 times daily	250 mg 2–3 times daily (if less than or equal to 27 kg), 500 mg 2–3 times daily (if more than 27 kg)	10 days	Drug of choice but increasing reports of treatment failures
Penicillin G benzathine	1.2 million units	600,000 units (if less than or equal to 27 kg); 1.2 million units (if more than 27 kg)	1 IM dose	Useful for patients with poor adherence or emesis; painful injection but pain can be reduced if warmed to room temperature prior to administration
Amoxicillin	775 mg–1 g once daily (Moxatag 775 mg is a time-released formulation given once daily for patients 12 years of age and older)	50 mg/kg once daily; max 1 g	10 days	Preferred drug for young children because of improved palatability and once daily dosing
Cephalexin	250–500 mg 4 times daily	25–50 mg/kg/day in 4 doses	10 days	Recommended in non–type I penicillin allergy
Cefadroxil	500 mg twice daily	30 mg/kg/day in 2 doses	10 days	Recommended in non–type I penicillin allergy
Cefuroxime axetil	250 mg twice daily	20 mg/kg/day in 2 doses	10 days	Broad spectrum; expensive
Cefdinir	300 mg twice daily or 600 mg once daily	14 mg/kg/day in 1–2 doses	5–10 days	
Azithromycin	500 mg once daily	12 mg/kg once daily	5 days	Recommended in immediate-type penicillin hypersensitivity; increasing resistance
Clindamycin	300 mg 3 times daily	20 mg/kg/day in 3 doses	10 days	Recommended in immediate-type penicillin hypersensitivity; useful for recurrent infections

^aOther FDA-approved agents include amoxicillin-clavulanate, cefixime, cefaclor, cefprozil, cefpodoxime, erythromycin, clarithromycin, and others.

IM, intramuscular.

From Refs. 40 and 41.

Antibiotic resistance plays a smaller role in pharyngitis therapy compared with other URIs. **2** *Penicillin resistance has not been documented in group A streptococci, but resistance and clinical failures occur more frequently with tetracyclines, trimethoprim-sulfamethoxazole, and to a lesser degree macrolides.* As such, patients with penicillin allergies should be treated with a first-generation cephalosporin (if non–type I allergy), a macrolide/azalide, or clindamycin.^{40,41} Recurrent infections or treatment failures caused by reinfection, poor adherence, or true antibiotic failure can be retreated with the same antibiotic or treated with amoxicillin-clavulanate, a first-generation cephalosporin, clindamycin, or penicillin G benzathine.^{40,41}

OUTCOME EVALUATION

Antibiotics relieve symptoms of streptococcal pharyngitis within 3 to 5 days, and patients can return to work or school if improved clinically after the first 24 hours of therapy. Lack of improvement or worsening of symptoms after 72 hours

Patient Encounter 3

A 9-year-old girl presents to the pediatrician with a sore throat and fever of 39.0°C (102.2°F) for the past 18 hours. She complains of throat pain while swallowing, so she is unable to eat or drink as much as usual. She does not have any other symptoms, has no known drug allergies, and takes no medications. Her mother reports that two of her child's friends had "strep throat" recently. Physical examination reveals halitosis, pharyngeal and tonsillar erythema with exudates, and painful cervical lymphadenopathy.

Does this child have streptococcal pharyngitis?

Is antibiotic therapy indicated? If so, what agent should be initiated and for how long?

What education should be provided to her mother regarding treatment?

Clinical Presentation and Diagnosis of Streptococcal Pharyngitis

Children between 5 and 15 years of age have the highest incidence of streptococcal pharyngitis. Parents and adults with significant pediatric contact are also at increased risk.

Signs and Symptoms of Streptococcal Pharyngitis³⁹⁻⁴¹

- Sudden onset of sore throat with severe pain on swallowing
- Fever
- Headache, abdominal pain, nausea, or vomiting (especially in children)
- Pharyngeal and tonsillar erythema with possible patchy exudates
- Tender, enlarged anterior cervical lymph nodes
- Swollen and red uvula
- Halitosis
- Soft palate petechiae

• Scarlatiniform rash

- General absence of conjunctivitis, hoarseness, cough, rhinorrhea, discrete ulcerations, and diarrhea (suggestive of viral etiology)

Diagnosis^{37,40,41}

- Rapid antigen detection test (RADT): 80% to 90% sensitivity; results available within minutes.
- Throat swab and culture: “gold standard”; results available within 24 to 48 hours. Should be performed in all negative RADTs in children and adolescents, and adults with significant pediatric contact. Also recommended in outbreaks and to monitor for antibiotic resistance.
- These tests should be performed *only* if there is a clinical suspicion of streptococcal pharyngitis. Pharyngeal carriage of group A streptococci is 5% to 20% in children.

of therapy requires reevaluation. Follow-up throat cultures are not recommended to test for bacterial eradication unless symptoms persist or recur. Recurrent symptoms following an appropriate treatment course should prompt reevaluation for possible retreatment.

must be aware of evidence regarding the use of cough and cold products in order to make appropriate treatment recommendations for this commonly encountered condition.

COMMON COLD

The common cold is a self-limited viral URI that occurs frequently throughout life. It is responsible for millions of missed school and work days and is associated with significant health-care resource utilization, including physician office and emergency department visits and nearly universal use of cough and cold medication for treatment or prevention.^{44,45} Clinicians

EPIDEMIOLOGY AND ETIOLOGY

Hundreds of different viruses cause the common cold, including rhinoviruses (most common), coronaviruses, parainfluenza viruses, respiratory syncytial virus, and adenoviruses. Infection rates increase during the fall through spring seasons and are highest in the winter months. Adults experience 2 to 4 colds each year, whereas children have 6 to 10 colds per year.^{44,46} Colds can last for 10 to 14 days and can be complicated by bacterial superinfections, including AOM and ABRS. Factors associated with an increased incidence

Clinical Presentation and Diagnosis of the Common Cold

Symptoms begin 24 to 72 hours after infectious contact. They usually peak around day 3 to 4 and begin to wane by day 7; colds typically last 10 to 14 days.

Signs and Symptoms^{44,45}

- *Onset*: malaise, fatigue, headache, pharyngitis, low-grade fever (can be higher in infants and children); these symptoms usually resolve over a few days.
- *Secondary*: nasal and/or postnasal drainage (often clear at onset, but can become thick and purulent); nasal congestion; cough and/or throat clearing; sneezing; conjunctivitis; irritability; loss of smell or taste

Complications

AOM, bacterial sinusitis, chronic bronchitis, bronchiolitis (in infants and children under 2 years of age), pneumonia, asthma exacerbation

Diagnosis

- *Clinical diagnosis*: most common method; based on history, presence of symptoms, and physical examination
- *Radiographic studies*: not recommended routinely; useful for assessing complications such as pneumonia
- *Laboratory studies*: not recommended routinely; rapid viral antigen tests and nasopharyngeal cultures helpful for epidemiology and diagnosis in acutely ill young infants

of colds are young age, contact with school-age children, crowded conditions and poorly ventilated areas, and cigarette smoking. Children are more likely than adults to transmit viruses because of poorer hand hygiene, closer casual contacts, and sharing of toys.⁴⁵ Viral antigenic drifts and host immune system evasion contribute to the persistence of URIs in the community.

PATHOPHYSIOLOGY

Viruses enter the upper respiratory tract mucosa via inhalation of aerosols or infected droplets or direct contact with contaminated secretions. After cell entry, viral replication and shedding occur for several days to weeks. Clinical symptoms arise from epithelial cell damage, inflammation, vasodilation, edema from increased vascular permeability, increased mucus production, and impaired mucociliary clearance. Tracheobronchial inflammation and irritation induce cough via afferent nerve impulse transmission to the medulla.⁴⁵ Antibody production halts viral replication and inflammation as symptoms diminish.

TREATMENT

Desired Outcomes

- The treatment goal for the common cold is to minimize discomfort from symptoms to allow patients to function as normally as possible. Preventative measures are also a focus to limit the spread of infection to others.

General Approach to Treatment

Antibiotics have no role in the treatment of the common cold. They are often prescribed inappropriately to patients with viral URIs and purulent secretions, which has contributed to increased antibiotic resistance.² Antimicrobials do not shorten symptom severity or duration and do not prevent bacterial complications from occurring in patients with the common cold.^{2,44} Treatment measures should focus on symptom relief.

Nonpharmacologic Therapy

Patient discomfort can be managed with supportive measures that include cool mist air humidification, use of intranasal saline drops or sprays with or without bulb suctioning, increased fluid intake, throat lozenges or saline gargles, and rest. Nasal strips have been advocated to relieve congestion by lifting the nares and opening the anterior nasal passages. These nondrug measures are particularly important for infants, children under 6 years of age, and pregnant women, for whom medication safety is a significant concern. Although studies proving their benefits are lacking, these nondrug treatments are safe.

Pharmacologic Therapy

Nonprescription cough and cold preparations are used frequently to manage cold symptoms despite the lack of evidence to support their safety and efficacy. Reports of serious adverse events and deaths have led to efforts to eliminate use of nonprescription cough and cold medications in young children.⁴⁷ Manufacturers have removed product labeling for all children under 4 years of age.

Hundreds of nonprescription cough and cold products are available to manage cold symptoms. **10** *Choice of therapy is influenced by patient age, presence of comorbid conditions, and balance of effectiveness and safety.* Single-ingredient agents are preferred over multi-ingredient products in order to target only symptoms that are present and to minimize the toxicity and overdose risk that can result from confusion and lack of knowledge on active ingredients in marketed formulations. Cautious use of nonprescription preparations is warranted in certain patient populations: pregnant and/or lactating women, elderly, those with cardiovascular disease including hypertension, patients with diabetes, and patients with glaucoma. **Table 72–6** summarizes some of the available nonprescription agents used for cold symptoms. Antipyretics and analgesics can be used for fever, pain, and discomfort from cold symptoms. Local anesthetics (e.g., benzocaine, dyclonine) relieve throat pain and are available in lozenges and sprays. Decongestants cause vasoconstriction that can modestly improve nasal airway resistance and congestion, but use of intranasal products should be limited to 3 days to avoid rebound congestion.^{44,49}

Antihistamines should be avoided when treating cold symptoms: first-generation antihistamines may help dry watery secretions through their anticholinergic effects, but they impair mucociliary clearance of thick mucus, which can worsen congestion, and studies have not shown clear benefits for cough or cold symptoms.^{44,49} Cough suppressant use is not supported by strong evidence showing benefit. They can cause significant neurologic adverse effects and have been linked to abuse by teens for their euphoric effects in high doses.^{44–46,49} Guaifenesin, an expectorant, may reduce cough frequency and sputum thickness in adults, but it has been poorly studied in children.⁴⁹ Routine high-dose vitamin C (more than 200 mg/day) supplementation does not significantly impact cold severity or duration, but it may be useful for prevention in certain populations exposed to severe physical exercise or cold stress.⁴⁹ Use of *Echinacea purpurea* extracted from aerial parts may have benefit in adults when started early for treatment, but its use is discouraged for prevention and in all children.⁵⁰ Other forms of echinacea have not shown consistent benefit for treatment of cold symptoms. Zinc lozenges are not effective for treating cold symptoms, and concerns exist regarding the loss of smell with intranasal zinc preparations, so they should be avoided.

PREVENTION

Prevention of the common cold is best achieved by minimizing contact with infected people and secretions.

Table 72-6

Select Nonprescription Medications for the Common Cold for Patients 6 Years of Age and Above

Class/Drug	Adult Dose ^a	Pediatric Dose ^b	Comments
Analgesics/Antipyretics			
Acetaminophen ^{c,d}	325–1,000 mg every 4–6 hours (max 4 g/day)	10–15 mg/kg/dose every 4–6 hours (max 5 doses/day)	Use with caution in preexisting liver disease
Ibuprofen ^e	200–400 mg every 6–8 hours (max 1,200 mg/day)	5–10 mg/kg/dose every 6–8 hours (max 4 doses/day)	Use with caution in cardiovascular disease; avoid use in elderly, renal impairment, and heart failure; avoid in third trimester of pregnancy
Decongestants			
<i>Intranasal:</i>			
Oxymetazoline 0.05% ^d	2–3 sprays every 12 hours (max 2 doses/24 hours)	1–2 sprays every 12 hours (max 2 doses/24 hours)	Limit use of intranasal decongestants to 3 to 5 days to minimize risk of rebound congestion; use with caution in patients with cardiovascular disease
Phenylephrine 0.25%, 0.5%, 1%	2–3 sprays no more than every 4 hours	2–3 sprays no more than every 4 hours (0.25% only)	
<i>Systemic:</i>			
Pseudoephedrine	60 mg every 4–6 hours (max 240 mg/day)	30 mg every 4–6 hours (max 120 mg/day)	Avoid use in patients with cardiovascular disease; children and elderly have increased risk of adverse effects (cardiovascular or CNS stimulation); use with caution in patients with diabetes, hyperthyroidism, prostatic hypertrophy; avoid in first trimester of pregnancy
Phenylephrine	10 mg every 4 hours (max 60 mg/day)	5 mg every 4 hours (max 30 mg/day)	
Cough Suppressants			
Dextromethorphan ^d	10–20 mg every 4 hours or 30 mg every 6–8 hours or 60 mg every 12 hours (max 120 mg/day)	5–10 mg every 4 hours or 15 mg every 6–8 hours or 30 mg every 12 hours (max 60 mg/day)	Increased adverse effects in children and poor metabolizers (5–10% of white patients); can cause dysphoria and serotonin syndrome; use caution in those taking psychotropic medications
Expectorants			
Guaifenesin	200–400 mg every 4 hours or 600–1,200 mg every 12 hours (max 2.4 g/day)	100–200 mg every 4 hours (max 1.2 g/day)	May cause nausea and abdominal pain, particularly in higher doses
Anticholinergics			
Intranasal ipratropium 0.06% ^d	2 sprays 3–4 times/day	2 sprays 3 times/day	Used for rhinorrhea only; does not improve congestion, postnasal drip, or sneezing

^aAlso for children greater than 12 years of age.

^bFor children 6 to 12 years of age.

^cPreferred antipyretic/analgesic for children; can be used in newborns.

^dSafe to use in pregnancy.

^eCan be used in children older than 6 months of age.

From Refs. 44 and 48.

Frequent handwashing with soap and water or use of alcohol-based products is the cornerstone of prevention. Coughing and sneezing into the arm sleeve should be taught rather than using tissues or covering the mouth and nose with hands. Other methods that are often advocated for preventing the spread of colds include smoking cessation, maintenance of a healthy lifestyle through diet and exercise, and minimizing stress.

OUTCOME EVALUATION

Most colds will resolve within 7 to 10 days. Monitor patients for symptoms that persist for longer than 10 to 14 days, worsening symptoms, and complications such as wheezing, difficulty breathing, moderate to severe facial or ear pain, and high fevers. If complications are suspected, referral to a physician is warranted.

Patient Encounter 4

A 20-year-old female presents to the university health center clinic with a “sinus infection.” Three days ago, she developed a sore throat and a “runny nose.” Today, the nasal discharge is a thicker and yellow-green color, and she has a mild headache. She also has nasal congestion and a dry, nonproductive cough that started yesterday. She took acetaminophen 650 mg this morning, which provided some headache relief. She has no medical conditions, but she does experience colds three to four times per year. She attends college and lives in an apartment with three friends. Two of her roommates also have similar symptoms.

Immunizations: up-to-date; needs influenza vaccine this season

Meds: vitamin C 1,000 mg orally daily, Ortho Tri-Cyclen orally daily

Allergies: sulfa drugs (rash)

PE:

Gen: no apparent distress; pleasant

VS: BP 126/78 mm Hg, P 72 beats/min, RR 18 breaths/min, T 37.5°C (99.5°F), wt 61.4 kg (135 lb)

HEENT: conjunctiva clear; no photophobia; green-yellow nasal discharge with mucosal hypertrophy and narrowed passages; erythematous pharynx with no exudates; no facial pain upon palpation; tympanic membranes normal appearing

Lungs: clear to auscultation; occasional wheeze with cough; no crackles

What signs and symptoms are suggestive of the common cold? Which are suggestive of ABRs?

What other diagnostic studies, if any, should be performed?

Create a care plan that includes nonpharmacologic and pharmacologic therapies and a monitoring plan. Include preventative measures in your plan.

Patient Care and Monitoring of Common Cold

1. Assess the patient's signs and symptoms. Are they consistent with the common cold?
2. How long have the patient's symptoms been present? If symptoms have been present for fewer than 7 to 10 days, the common cold is likely. Persistent moderate or acute severe symptoms are more indicative of bacterial infections.
3. Has the patient tried any medications or nonpharmacologic methods to treat the symptoms? If yes, do they provide any relief?
4. Obtain a medication and medical history, including prescription and nonprescription drugs, natural product use, allergies, and current medical conditions.
5. Determine whether nonprescription medications should be used to alleviate symptoms, such as pain and congestion.
6. Develop a treatment plan (including use of nonpharmacologic measures) to assess effectiveness of the chosen therapy and course of action to take if the patient does not improve or worsens.
7. Provide patient education on:
 - Role of viruses in colds, symptom resolution expectations, and how to prevent transmission to others
 - What to expect from the chosen therapy, including proper dosing and potential adverse effects
 - Avoidance of antibiotics to treat colds
 - When to seek additional medical care
8. Stress the importance of handwashing and limiting spread to others.

Abbreviations Introduced in This Chapter

ABRS	Acute bacterial rhinosinusitis
AOM	Acute otitis media
OME	Otitis media with effusion
PRSP	Penicillin-resistant <i>S. pneumoniae</i>
RADT	Rapid antigen detection test
URI	Upper respiratory tract infection

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Skin and Soft Tissue Infections

Jaime R. Hornecker

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Discuss characteristics of the skin that render it resistant to infection.
2. Describe the epidemiology, etiology, pathogenesis, clinical manifestations, diagnostic criteria, and complications associated with skin and soft tissue infections (SSTIs).
3. Identify the desired therapeutic outcomes for patients with SSTIs.
4. Recommend appropriate empirical and definitive antimicrobial regimens when given a diagnosis, patient history, physical examination, and laboratory findings.
5. Monitor chosen antimicrobial therapy for safety and efficacy.

KEY CONCEPTS

- 1 Impetigo commonly afflicts young children, is usually caused by group A streptococci or *Staphylococcus aureus*, and is characterized by numerous blisters that rupture and form crusts. Dicloxacillin, cephalixin, and topical mupirocin are considered the antibiotics of choice for treatment of impetigo.
- 2 Folliculitis, furuncles, and carbuncles refer to the inflammation of one or more hair follicles, often attributed to infection with *S. aureus*. Treatment depends on severity and may involve local heat, incision and drainage, and/or oral or topical antibiotic therapy.
- 3 Erysipelas is a superficial infection of the upper dermis and superficial lymphatics distinguished from cellulitis by its well-defined borders and slightly raised lesions. It is usually caused by β -hemolytic streptococci and treated with penicillin.
- 4 Cellulitis, a bacterial infection of the dermis and subcutaneous tissue, is most commonly caused by *S. aureus* and β -hemolytic streptococci. Although β -lactams active against penicillinase-producing strains of *S. aureus* have historically been the drugs of choice, in areas with high rates of community-acquired methicillin-resistant *S. aureus* (CA-MRSA), or in patients with risk factors for CA-MRSA infection, treatment with antibiotics active against this organism should be initiated due to its increasing prevalence.
- 5 Persons who are immunocompromised, have diabetes or vascular insufficiency, or use injection drugs are at risk for polymicrobial cellulitis, often requiring broad-spectrum antibiotic coverage.
- 6 Necrotizing fasciitis (NF) is an uncommon, rapidly progressive, life-threatening infection that causes necrosis of the subcutaneous tissue and fascia. Immediate surgical débridement is key to reducing its associated mortality.
- 7 The pathogenesis of diabetic foot infection stems from three key factors: neuropathy, angiopathy, and immunopathy. Aerobic gram-positive cocci, such as *S. aureus* and β -hemolytic streptococci, are the predominant pathogens in acutely infected diabetic foot ulcers. However, chronically infected wounds are subject to polymicrobial infection and require treatment with broad-spectrum antibiotics.
- 8 Prevention is key in the management of pressure sores. Mild superficial pressure sore infections may be treated with topical antimicrobial agents. Systemic antibiotics are indicated for serious pressure ulcer infections, including those associated with spreading cellulitis, osteomyelitis, or bacteremia.
- 9 Bite wound infections generally are polymicrobial. Amoxicillin-clavulanate is the drug of choice for treating infected bite wounds and is also used as infection prophylaxis for human bites, deep punctures, and bites to the hand, or those requiring surgical repair.
- 10 Every patient receiving treatment for skin and soft tissue infections (SSTIs) must be educated on prevention measures and monitored for efficacy and safety. Efficacy typically is manifested by reductions in temperature, white blood cell count, erythema, edema, and pain that begin within 48 to 72 hours after treatment initiation. To ensure safety, adjust antibiotic dosages for renal and hepatic dysfunction as appropriate, and monitor for and minimize adverse drug reactions, allergic reactions, and drug interactions.

Skin and soft tissue infections (SSTIs) are frequently encountered in both acute and ambulatory care settings. They can range in severity from mild, superficial, and self-limiting, to life-threatening deep tissue infections that require intensive care, surgical intervention, and IV broad-spectrum antibiotics. *S. aureus* and β -hemolytic streptococci (*Streptococcus pyogenes* and *Streptococcus agalactiae*) are the most common causative bacteria.¹⁻³ Complicated infections that may involve deeper layers of the skin, fascia, or muscle in persons with immune suppression, diabetes, vascular insufficiency, burns, decubitus ulcers, or traumatic wounds are often polymicrobial.³

The role of methicillin-resistant *S. aureus* (MRSA), particularly community-acquired methicillin-resistant *S. aureus* (CA-MRSA), is of increasing importance. In many U.S. cities, MRSA has become the most frequently isolated pathogen from patients presenting to emergency departments with SSTI.⁴ From 2000 to 2004, hospital admissions for SSTIs increased by 29%, presumably due to the emergence of CA-MRSA.⁵ MRSA infections were historically associated with exposures to healthcare settings (including hospitals or long-term care facilities), but have recently become problematic in previously healthy persons. Although risk factors for acquisition of CA-MRSA are not well established, outbreaks of CA-MRSA infection have occurred in prison inmates, homosexual males, injection drug users, athletes, military recruits, Native Americans, individuals with lower socioeconomic status, and children, especially those with daycare exposure. In both adults and children, recent antibiotic exposure is also associated with a dose-dependent increase in the risk of CA-MRSA infection.^{6,7} In these high-risk groups, in those with recurrent infections or infections that persist despite appropriate antimicrobial therapy, or in areas with high rates of CA-MRSA, empiric therapy including antibiotics active against this pathogen must be considered.³ This chapter covers the epidemiology, pathogenesis, clinical manifestations, and pharmacologic management of the more common and severe bacterial SSTIs.

Intact skin generally is resistant to infection. In addition to providing a mechanical barrier, its relative dryness, slightly acidic pH, colonizing bacteria, frequent desquamation, and production of various antimicrobial defense chemicals, including sweat (which contains IgG and IgA), prevent invasion by various microorganisms.⁸ Conditions that predispose a patient to SSTIs include: (a) high bacterial load (greater than 10^5 microorganisms); (b) excessive skin moisture; (c) decreased skin perfusion; (d) availability of bacterial nutrients; and (e) damage to the corneal layer of the skin.⁹

IMPETIGO

EPIDEMIOLOGY AND ETIOLOGY

- Impetigo, which stems from the Latin word for “attack,” is a common skin infection worldwide.¹⁰ ① *It predominately afflicts children between 2 and 5 years of age but may occur in any age group.*² β -Hemolytic streptococci and *S. aureus* are the most common causative pathogens.^{2,10} Impetigo is a

superficial infection and is spread easily, especially in settings of poor hygiene and crowding, and particularly during the summer months. The offending microorganisms colonize the skin surface and invade through abrasions, insect bites, or other small traumas. The scabby, crusty eruption of impetigo ensues. These lesions may occur anywhere on the body, but are most common on the face and extremities.²

CLINICAL PRESENTATION AND DIAGNOSIS

- Impetigo lesions are numerous, well-localized, and **erythematous**. ① *They develop either as small, thin-walled blisters (impetigo contagiosum), or as larger blisters (bullous impetigo), which may be associated with mild systemic symptoms.*^{2,10,11} *S. aureus* is most often implicated in bullous impetigo. The blisters rupture easily, leaving behind a **friable** crust reminiscent of cornflakes. The lesions of impetigo are rarely painful, but are **pruritic**. Scratching the lesions can spread the infection to other areas of the body.¹⁰

In order to avoid further spread and complications, antibiotic therapy is usually indicated. If left untreated, mild, localized cases of impetigo typically resolve within 2 to 3 weeks.^{10,11} Sequelae of impetigo are uncommon, and when complications do occur, they seem to be more frequent in adults. Rarely, glomerulonephritis secondary to group A *Streptococcus* (GAS) may occur in nonbullous impetigo. Development of impetigo into more serious infections such as cellulitis or sepsis is another rare, but serious consequence.

TREATMENT

Desired Outcomes

- The primary goals of therapy for impetigo include preventing the spread of infection within the patient and to others, resolution of infection, and preventing recurrence. Secondly, relief of symptoms associated with impetigo, such as itching, and improving cosmetic appearance are also important. Prevention of the rare, but serious complications of impetigo is an alternative goal.¹²

Nonpharmacologic Treatment

Because impetigo is rarely painful, there is often a delay in seeking medical attention. However, the lesions will often resolve with time and increased hygiene. Soaking and cleansing the lesions with mild soap and water and the use of skin emollients to dry skin areas may reduce spread.¹⁰

Pharmacologic Treatment

- Antibiotic therapy is recommended to achieve the desired outcomes of preventing the spread of infection and complications. Because GAS historically has been the primary causative organism, penicillin has been the mainstay of therapy. ① *However, the incidence of *S. aureus* impetigo is increasing significantly, so oral penicillinase-stable penicillins or first-generation cephalosporins are now preferred.* Clindamycin

or a macrolide are alternative choices when penicillin allergy is a concern; however, erythromycin-resistant strains of staphylococci and streptococci are increasing in prevalence.

1 *Topical mupirocin or retapamulin may be used alone in mild cases with few lesions.*^{2,11}

FOLLICULITIS, FURUNCLES, AND CARBUNCLES

See [Table 73-1](#).

CELLULITIS AND ERYSIPELAS

EPIDEMIOLOGY AND ETIOLOGY

- Cellulitis and erysipelas are bacterial infections involving the skin. 3 and 4 *Cellulitis is an infection of the dermis and subcutaneous tissue, whereas erysipelas is a more superficial infection of the upper dermis and superficial lymphatics. Although both can occur on any part of the body, about 90% of infections involve the leg.*¹⁴ These infections develop after a break in skin integrity, resulting from trauma, surgery, ulceration, burns, tinea infection, or other skin disorder.

Table 73-1

Folliculitis, Furuncles, and Carbuncles

	Folliculitis	Furuncles	Carbuncles
Epidemiology/etiology	2 <i>Folliculitis is a superficial inflammatory reaction involving the hair follicle. The most familiar form of folliculitis is acne.</i> It can be infectious, caused by microorganisms such as <i>S. aureus</i> , <i>Pseudomonas</i> , and <i>Candida</i> . Folliculitis can also be chemically induced.	Also known as boils, furuncles might be described as a deep form of folliculitis. A furuncle is a bacterial infection that has spread into the subcutaneous skin layers but still only involves individual follicles. Furuncles occur primarily in young men. Diabetes and obesity are other predisposing factors. Staphylococci are the most common cause.	Carbuncles share all the characteristics of furuncles. However, a carbuncle is larger and involves several adjacent follicles and may extend into the subcutaneous fat. Carbuncles are more likely to occur in patients with diabetes and tend to form on the back of the neck.
Presentation and diagnosis	Folliculitis presents as small, pruritic, erythematous papules. Location of the lesions and a good patient history are often all that are required in the diagnosis of folliculitis. Although Gram stain and culture of the papules may be considered to help determine the causative agent, they are not generally required as folliculitis typically resolves spontaneously.	Furuncles most commonly develop on the face, neck, axilla, and buttock. A furuncle typically starts as a small, red, tender nodule. Within a few days, the nodule becomes painful and pustular. Typically, a furuncle will spontaneously discharge pus, heal, and leave a small scar.	Carbuncles are similar to furuncles; only they are larger and exquisitely painful.
Desired outcomes	The goals of therapy for folliculitis, furuncles, and carbuncles are resolution of infection with no or minimal scarring. A secondary goal of therapy for larger furuncles and all carbuncles is to minimize the risk of endocarditis or osteomyelitis by reducing bloodstream invasion.		
Nonpharmacologic treatment	2 <i>Warm compresses are generally sufficient.</i>	<i>Moist heat is indicated to facilitate drainage. Large furuncles require incision and drainage.</i>	<i>Incision and drainage are indicated.</i>
Pharmacologic treatment	2 <i>Often resolves spontaneously. A topical antibiotic or antifungal may be used to control the spread of infection but generally is unnecessary.</i> For staphylococcal or streptococcal folliculitis, antibiotic ointments such as mupirocin might be administered three times daily. Antifungal shampoo can be used for dermatophytes.	<i>Carbuncles and furuncles that have surrounding cellulitis and fever or are located midline on the face must be treated systemically with an antibiotic that will cover <i>S. aureus</i>, such as dicloxacillin or cephalexin. Trimethoprim-sulfamethoxazole DS, doxycycline, or clindamycin are preferred if CA-MRSA is suspected or if the patient has a severe allergy to penicillin.</i> Treatment should continue until acute inflammation has resolved, usually a 5- to 10-day course. Prevention for recurrent episodes may be warranted, including adequate skin hygiene with the use of antimicrobial soap and water, and handwashing after contact with lesions. Proper care of clothing and dressings is also recommended to prevent autoinoculation.	

From Refs. 2, 11, and 13.

Patient Encounter 1, Part 1: Cellulitis

A 49-year-old woman presents to the ambulatory care clinic with a 3-day history of progressively worsening pain and swelling of her right lower extremity. Upon examination, you notice that in addition to the patient's complaints, the area is visibly erythematous. Poorly defined areas of redness and streaking extend from just below the knee up toward her hip. A small, nonpurulent scabbed area is present over the kneecap. She reports running a low-grade fever and some feelings of fatigue, but otherwise feels fine. When questioned, she indicates that she recently fell on the sidewalk and "skinned" her knee after tripping while walking her dog. Her vitals at the clinic reveal a temperature of 38.2°C, pulse 92 beats/min, blood pressure 122/82 mm Hg, and respiratory rate 18 breaths/min. The physician diagnoses the patient with cellulitis.

What subjective and objective clinical manifestations are suggestive of cellulitis?

What additional information do you need before developing a therapeutic plan for this patient?

However, they may occur after an inapparent break in the skin, and the skin may appear previously intact. In rare cases, cellulitis develops from bloodborne or contiguous spread of pathogens.^{2,15}

Etiologic microorganisms vary according to the area involved, host factors, and exposures. **3** *Erysipelas* is generally

caused by β -hemolytic streptococci, mainly GAS, and rarely by *S. aureus*. **4** The predominant pathogens associated with cellulitis are *S. aureus*, including methicillin-resistant strains, and β -hemolytic streptococci. **5** Persons who are immunocompromised, have diabetes or vascular insufficiency, or use injection drugs are at risk for polymicrobial cellulitis.^{2,3}

CLINICAL PRESENTATION AND DIAGNOSIS

- The manifestations of and diagnostic criteria for erysipelas and cellulitis are presented in [Table 73–2](#). Once diagnosed, cellulitis may be characterized as complicated or uncomplicated. Complicated infections are those that involve abnormal skin or wounds, occur in immunocompromised hosts, require substantial surgical intervention, or are polymicrobial in origin.¹⁶

With early diagnosis and appropriate therapy, the prognoses for cellulitis and erysipelas are excellent. Severe or repeated episodes can cause lymphedema. Rare complications include the spread of infection to deeper skin and soft tissue layers, bacteremia, and sepsis.² Although rates of bacteremia were traditionally low, prevalence may be increasing and associated with increased length of hospitalization and costs, and higher readmission rates.¹⁷ If the circumference of an extremity is cellulitic, **compartment syndrome** becomes a concern, and a surgical consult may be required. Recurrent cellulitis can be problematic. About 30% of patients hospitalized with cellulitis will develop a recurrent episode within 3 years. Vascular and lymphatic insufficiencies increase the risk of recurrences.¹⁵

Table 73–2

Presentation of Erysipelas and Cellulitis

Symptoms

- The infected area is described as painful or tender. In the case of erysipelas, the patient may complain of "burning pain" at the lesion site. CA-MRSA infections often start as a localized skin lesion and may be described by the patient as looking like a "spider bite."

Signs

- Both erysipelas and cellulitis are manifested by rapidly spreading areas of redness, edema, and heat. **Lymphangitis** and regional lymphadenopathy may be observed.
- Important clinical differences between erysipelas and cellulitis exist:
 - In erysipelas, low-grade fever and flu-like illness are common prior to development of the lesion. The lesion is fiery red, raised above the level of surrounding skin, and has well-defined borders. The affected area may have an "orange peel" appearance.
 - In cellulitis, the lesion is not raised and has poorly defined margins.

Laboratory Tests

- Leukocytosis may be present.
- Cultures and sensitivities:
 - Blood cultures should be obtained for complicated or severe cases, although their yield is often low as bacteremia is an infrequent, but growing, occurrence; facial cellulitis may increase risk. Cultures aspirated from the lesion have an organism isolation rate of less than 20%, but also may be considered.
 - Abscess drainage and débrided tissue, if obtainable, should be cultured and will yield the causative organism(s) up to 90% of the time.

Imaging Studies

- Imaging studies may identify abscess formation, gas in the soft tissues, or osteomyelitis.

From Refs. 2, 14, and 15.

TREATMENT

Desired Outcomes

The goals of therapy for cellulitis and erysipelas are rapid and successful eradication of the infection and prevention of related complications.

Nonpharmacologic Treatment

Nonpharmacologic treatment includes elevating and immobilizing the involved limb to decrease swelling. Sterile saline dressings should be placed on any open lesions to cleanse them of **purulent** materials. Surgical débridement is indicated occasionally for severe infection. Drainage of abscesses is imperative to achieving clinical cure and may be the only treatment necessary if the abscess is small (less than 5 cm) with limited cellulitis.^{15,18}

Pharmacologic Treatment

Most patients with erysipelas or cellulitis are not hospitalized. Hospitalization and treatment with IV antibiotics should be considered if there are systemic signs and symptoms of infection (e.g., fever, chills, or hypotension), the patient has significant comorbid conditions (e.g., immunocompromise, diabetes, cirrhosis, cardiac failure, or renal insufficiency), or the cellulitis is spreading rapidly, involves a large area of the body, or is chronic.¹⁵

3 *Penicillin is the treatment of choice for erysipelas.* In uncomplicated cases, a 5-day course is as effective as a 10-day course.² Other agents that are acceptable for treatment include clindamycin, cephalexin, and dicloxacillin.

4 Although β -lactams, such as dicloxacillin, active against penicillinase-producing strains of *S. aureus* (commonly known as methicillin-sensitive *S. aureus*, or MSSA), have historically been the drugs of choice for acute bacterial cellulitis in otherwise healthy individuals, the increasing prevalence of infection with CA-MRSA is concerning, particularly in patients presenting with abscess.^{2,19,20} Even in settings in which a drainable abscess is absent but the cellulitis is purulent or exudative, empiric therapy for CA-MRSA should be initiated.²¹ Treatment active against CA-MRSA should also be initiated in areas with a high prevalence (e.g., greater than 15% of community *S. aureus* isolates show methicillin resistance) and in patients with risk factors for CA-MRSA infection.^{3,19} Vancomycin continues to be the drug of choice for severe cellulitis due to MRSA because of its efficacy, safety, and low cost. Daptomycin, linezolid, telavancin, or ceftaroline are also acceptable and should be considered over vancomycin when the isolated organism has a minimum inhibitory concentration (MIC) of greater than 2 mcg/mL (greater than 2 mg/L) (e.g., vancomycin-intermediate *S. aureus* [VISA] or vancomycin-resistant *S. aureus* [VRSA]).²¹ Tigecycline is an alternative; however, due to its broad spectrum of activity, it is best reserved for patients with intolerances to the aforementioned drugs or in those with polymicrobial infections. For less severe, uncomplicated infections, many CA-MRSA strains can be treated with clindamycin (isolates resistant to erythromycin should be evaluated with a D-test), doxycycline, minocycline, or trimethoprim-sulfamethoxazole.^{2,3,19–22} However, it should be mentioned that although these agents are widely used for uncomplicated SSTI, this is an off-label use supported predominantly by data from observational and small interventional trials.²³ Also, trimethoprim-sulfamethoxazole

Patient Encounter 1, Part 2: Cellulitis: Medical History, Physical Examination, and Diagnostic Tests

PMH: GERD. C-section \times 2.

FH: Father (age 70) and mother (age 68) are both alive. Father has type 2 diabetes; mother is otherwise healthy. One sister, age 43, is healthy.

SH: Denies alcohol or illicit drug use. Married, with two sons who attend the local community college. Works part-time in retail sales.

Meds: Omeprazole 20 mg daily prn, multivitamin daily.

Allergies: No known drug allergies.

ROS: (+) pain, edema, and erythema in the right lower extremity; (–) headache, chest pain, shortness of breath, cough, nausea, vomiting, diarrhea, and weight loss.

PE:

Gen: Patient is in no acute distress. Wt 68.0 kg (149.6 lb); ht 5 ft 5 in (165 cm).

Chest: Lungs bilaterally clear to auscultation.

CV: Regular rate, rhythm. No murmurs/rubs/gallops.

Ext: Right lower extremity with erythema and edema from the knee to just below the hip. Warm to the touch. LLE within normal limits.

Labs: WBC $15.8 \times 10^3/\text{mm}^3$ ($15.8 \times 10^9/\text{L}$), serum creatinine 0.8 mg/dL (71 $\mu\text{mol/L}$).

What are the most likely causative organisms in this case of cellulitis?

What are the goals of therapy for this patient?

What nonpharmacologic interventions would you recommend for her?

What antimicrobial therapy would you recommend? Include drug, dosage, route, interval, and duration of therapy.

How would you monitor your selected regimen for safety and efficacy?

How would your initial choice of an antimicrobial agent change if this patient was at high risk for CA-MRSA?

and doxycycline have less than optimal activity against GAS and should be empirically combined with an agent with such activity (e.g., cephalexin) if GAS is also a suspected causative organism.^{19,20}

5 In addition to being at risk for staphylococcal and streptococcal cellulitis, patients with immune suppression, diabetes, vascular insufficiency, or wounds are also at risk for disease caused by gram-negative bacilli such as *Escherichia coli* and *Pseudomonas aeruginosa*, with or without anaerobes.³ Empirical broad-spectrum antimicrobial coverage, including coverage for resistant organisms such as healthcare-associated MRSA (HA-MRSA) and *P. aeruginosa*, is appropriate for severe cellulitis and/or severe systemic illness. The clinician should be diligent in attempting to isolate a causative pathogen in these individuals.²

Injection drug use also predisposes individuals to polymicrobial cellulitis. The antecubital region of the arm is usually the site of infection. *S. aureus*, the most common isolate, is frequently associated with abscess formation. Because some injection drug users lick their needles to “clean” them, antibiotics that cover oropharyngeal anaerobes should be included. Occasionally, *Candida* spp. are isolated, and the patient may require antifungal therapy.²⁴

Table 73–3 lists some recommended antibiotic regimens for the treatment of cellulitis. Because antimicrobial susceptibilities vary considerably between geographic locations, clinicians should select empirical treatment based on the antibiograms at their respective institutions. To decrease the spread of resistance, antibiotic therapy should be narrowed based on culture and sensitivity results whenever possible. The duration of therapy for uncomplicated cellulitis typically ranges from 7 to 10 days. For complicated cellulitis, therapy with IV antibiotics is generally initiated, and a switch to oral therapy can be made once the patient is afebrile and skin findings begin to resolve. Typically, this is done after 3 to 5 days. The complete duration of therapy can range from 10 to 14 days and longer in cases in which abscess, tissue necrosis, underlying skin wounds, or delayed response to therapy are involved.^{2,15}

Patient Encounter 1, Part 3: Cellulitis: Clinical Course

Three days later, the patient returns to the clinic with moderate improvement of her cellulitis, but with a new presentation of a maculopapular skin rash. It is presumed that she has developed an allergy to penicillin.

What would you suggest for modification of her antimicrobial regimen?

How would you monitor her new regimen for safety and efficacy?

How would your choice of an agent change if this patient's cellulitis was severe enough to warrant hospitalization?

NECROTIZING FASCIITIS

EPIDEMIOLOGY AND ETIOLOGY

• Necrotizing fasciitis (NF) is an uncommon, rapidly progressive, life-threatening infection that causes necrosis of the subcutaneous tissue and fascia. When due to GAS infection, its associated mortality rate approaches 25%.²⁵ NF can affect any age group. Although the risk of NF is higher in injection drug users and in patients with diabetes, immune suppression, or obesity, healthy hosts can become infected as well.²⁶

NF typically erupts after an initial trauma, which can range from a small abrasion to a deep penetrating wound. The infection begins in the fascia, where bacteria replicate and release toxins that facilitate their spread.²⁷

In approximately 70% of cases, NF is polymicrobial and typically involves anaerobes (i.e., *Bacteroides* or *Peptostreptococcus*), **facultative anaerobes** (i.e., β -hemolytic streptococci), and Enterobacteriaceae (e.g., *Escherichia coli*, *Enterobacter*, *Klebsiella*). *P. aeruginosa* is occasionally implicated as well.²⁶ Polymicrobial NF develops in the following clinical settings: after surgery or deep penetrating wounds involving the bowel; from decubitous ulcer, perianal, or vulvovaginal infection; or from the injection site in an IV drug user.^{2,11}

The remaining 30% are monomicrobial, caused by invasive GAS, or less frequently, *Clostridium perfringens*. CA-MRSA is being implicated in these infections as well.²⁶ Monomicrobial NF is generally more severe than polymicrobial NF. GAS NF often occurs after minor trauma, such as an insect bite or abrasion, whereas infection with *C. perfringens* typically develops from surgical or traumatic wounds.^{2,28} Once introduced, these organisms produce toxins that induce systemic toxicity, multiorgan failure, and shock.^{28,29} Clostridial **myonecrosis** is more commonly known as gas gangrene.^{2,28}

CLINICAL PRESENTATION AND DIAGNOSIS

• Patient outcomes rely on the clinician's ability to recognize NF early in the course of disease. This is often difficult because early disease tends to be indistinguishable from cellulitis. The clinical presentation of NF is presented in **Table 73–4**.

NF is perhaps the most devastating SSTI. Left untreated, it can invade the muscles and circulation, resulting in myonecrosis and septic shock, respectively. Half of the cases caused by GAS are accompanied by GAS toxic shock–like syndrome. The syndrome is endotoxin-mediated, manifested by hypotension and multiorgan dysfunction, and highly lethal.^{9,26} Amputation is required in up to 50% of patients with extremity infections.³⁰ Once the patient recovers from acute NF, he or she often requires skin and/or muscle grafting and consequent physical rehabilitation depending on the amount and types of tissues removed during surgical intervention and the duration of hospital stay.³¹

Table 73–3

Empirical Antimicrobial Therapy for Cellulitis

Host Factors	Probable Etiologic Bacteria	Mild Infection or Step-Down Therapy ^a (Oral Antibiotic Therapy)	Moderate–Severe Infection ^a (IV Antibiotic Therapy)
Previously healthy	MSSA GAS CA-MRSA	Dicloxacillin 500 mg every 6 hours Cephalexin 500 mg every 6 hours Clindamycin 300–600 mg every 6–8 hours CA-MRSA suspected or allergy to PCNs: Clindamycin ^b 300–600 mg every 6–8 hours Trimethoprim-sulfamethoxazole DS ^c 1–2 tabs every 12 hours Doxycycline ^e 100 mg every 12 hours Minocycline ^e 100 mg every 12 hours	Nafcillin 1–2 g every 4 hours Cefazolin 1–2 g every 8 hours Clindamycin 600–900 mg every 8 hours CA-MRSA suspected or allergy to PCNs: Vancomycin 15–20 mg/kg every 8–12 hours (individualize dose to achieve a trough of 15–20 mcg/mL [15–20 mg/L; 10.4–13.8 μmol/L]) Linezolid 600 mg every 12 hours Daptomycin 4 mg/kg every 24 hours Telavancin 10 mg/kg every 24 hours Ceftaroline ^f 600 mg every 12 hours
Immunocompromise, diabetes mellitus, vascular insufficiency, pressure ulcer infection, or other polymicrobial infection suspected	MSSA HA-MRSA CA-MRSA Enterobacteriaceae <i>P. aeruginosa</i> Anaerobes	Amoxicillin-clavulanate ^d 875 mg every 12 hours Levofloxacin ^e 750 mg every 24 hours + clindamycin 300–600 mg every 6 hours Moxifloxacin ^d 400 mg every 24 hours	Vancomycin, daptomycin, linezolid or telavancin ^g In combination with one of the following choices: Piperacillin-tazobactam ^e 3.375 g every 6 hours Ampicillin-sulbactam 3 g every 6 hours Imipenem-cilastatin ^e 500 mg every 6 hours Ertapenem 1 g every 24 hours Meropenem 500 mg every 8 hours Cefepime ^e 2 g every 12 hours ± metronidazole 500 mg every 8 hours Ceftazidime ^e 2 g every 8 hours + clindamycin 600–900 mg every 8 hours Levofloxacin ^e 750 mg every 24 hours ± clindamycin 600 mg every 8 hours OR Ceftaroline 600 mg every 12 hours + clindamycin 600–900 mg every 8 hours or metronidazole 500 mg every 8 hours OR Tigecycline 100 mg load, then 50 mg every 12 hours

^aDoses given are for adults with normal renal function. IV therapy can be switched to oral therapy (as for mild infection) when the patient is afebrile and signs of infection are resolving.

^bCA-MRSA isolates resistant to erythromycin should be evaluated for inducible clindamycin resistance via a D-test.

^cLimited clinical data exist for the treatment of MRSA infections. Poor activity against GAS; consider using in combination with clindamycin or cephalexin if empirical coverage for GAS is desired.

^dIf CA-MRSA suspected, clindamycin, trimethoprim-sulfamethoxazole, or doxycycline must be added to this regimen.

^e*P. aeruginosa* generally is susceptible to this agent.

^fUse caution in patients with known hypersensitivity to beta-lactam antibiotics.

^gMRSA coverage indicated for patients with severe cellulitis or systemic illness, who have risk factors for HA-MRSA or CA-MRSA infection, or reside in areas with high CA-MRSA prevalence. Otherwise, the broad-spectrum regimens listed below, without MRSA coverage, are appropriate.

From Refs. 2, 3, 11, 15, and 18–23.

Table 73–4

Presentation of Necrotizing Fasciitis**Symptoms**

- Early: Severe pain that is disproportionate to clinical signs and extends beyond the margins of the infected area.
- Late: Area may become numb secondary to muscle and nerve involvement.

Signs

- Early: Skin is erythematous, edematous, and warm; the clinical presentation is similar to that of cellulitis.
- Intermediate (within 24–48 hours): Blisters and bullae indicate severe skin and tissue ischemia.
- Late: The skin becomes violaceous and progressively gangrenous; hemorrhagic bullae may be present. Systemic signs may include fever, tachycardia, hypotension, and shock.

Laboratory Tests

- White blood count, serum creatinine, and C-reactive protein may be elevated.
- Deep tissue specimens obtained during surgical irrigation and débridement should be sent for Gram stain, culture, and sensitivity.

Imaging Studies

- MRI and CT scans may reveal fluid and gas along fascial planes.
- Typically, imaging studies are avoided when making a diagnosis because they may delay surgical intervention and increase mortality.

NF, Necrotizing fasciitis.

From Refs. 2, 26, and 27.

TREATMENT**Desired Outcomes**

- The goals of therapy for NF include eradication of infection and reduction of related morbidity and mortality.

Nonpharmacologic Treatment

- **6** After resuscitation and hemodynamic stabilization, *prompt surgical intervention is key in the treatment of NF. Delayed operative débridement increases mortality.*^{2,27} Some clinicians recommend hyperbaric oxygen (HBO) as an adjunct treatment for NF, although its use is controversial. Clinical data supporting the use of HBO in NF are inconsistent, with some trials showing reduced mortality rates and others showing no benefit.³²

Pharmacologic Treatment

- As an adjunct to surgery, high-dose, broad-spectrum IV antibiotic therapy should be initiated immediately in patients with NF. Piperacillin-tazobactam or a carbapenem is appropriate for empiric therapy. These agents should be used in combination with vancomycin, daptomycin, or linezolid until MRSA infection is ruled out. The protein synthesis

inhibitors clindamycin or linezolid are often utilized to decrease bacterial toxin production, thereby limiting tissue damage. This is particularly beneficial in streptococcal or clostridial infection.²⁶

If GAS or *C. perfringens* is identified as the sole causative organism from deep tissue culture, antimicrobial therapy can be narrowed to high-dose IV penicillin G plus clindamycin. Antibiotic therapy should be continued until further operative débridements are unnecessary, the patient displays substantial clinical improvement, and fevers have abated for at least 48 to 72 hours.²

IV immune globulin (IVIG) dosed at 2 g/kg may also be a useful adjunctive treatment in patients with GAS NF who present with shock. Anecdotal evidence and data from small studies strongly support its use in improving 30-day survival and reducing mortality.^{33,34}

DIABETIC FOOT INFECTIONS**EPIDEMIOLOGY AND ETIOLOGY**

- Foot ulcers and related infections are among the most common, severe, and costly complications of diabetes mellitus. Fifteen percent of all patients with diabetes develop at least one foot ulcer, resulting in direct healthcare expenditures of approximately \$9 billion annually in the United States.³⁵

Infected diabetic foot ulcers typically contain a multitude of microorganisms. **7** *Aerobic gram-positive cocci, such as S. aureus and β -hemolytic streptococci, are the predominant pathogens in acutely infected diabetic foot ulcers. However, chronically infected wounds are subject to polymicrobial infection.* The clinician should suspect the involvement of gram-negative (Enterobacteriaceae and *P. aeruginosa*) and possibly low-virulence pathogens (including enterococci and *S. epidermidis*) in chronic or necrotic wounds. Foul-smelling, necrotic, or gangrenous wounds are also commonly infected with anaerobic bacteria. Patients recently hospitalized or treated with broad-spectrum antibiotics are at risk for infection with antibiotic-resistant organisms, including MRSA and vancomycin-resistant enterococci (VRE).³⁶

PATHOPHYSIOLOGY

- **7** *The pathogenesis of diabetic foot infection stems from three key factors: neuropathy, angiopathy, and immunopathy.*^{37,38} Neuropathy, the most prominent risk factor for diabetic foot ulcers, develops when continuously high blood glucose levels damage motor, autonomic, and sensory nerves. Damage to motor neurons that supply the small intrinsic muscles of the foot causes deformation, resulting in altered muscular balance, abnormal areas of pressure on tissues and bone, and repetitive injuries. Damage to autonomic neurons results in the shunting of blood through direct arteriole-venous communications, thereby decreasing

Patient Encounter 2, Part 1: Diabetic Foot Infection

A 63-year-old man with type 2 diabetes mellitus presents to the emergency department with complaints of soreness and swelling of his left foot, accompanied by difficulty walking. Upon examination, you see a purulent lesion on the plantar aspect of his left great toe approximately 3 cm (1.2 in.) in diameter. His foot is erythematous, warm, and foul-smelling, and cellulitis and lymphangitic streaking extend beyond his ankle. The patient indicates that his doctor told him at his last visit 8 months ago that his feet had some areas of redness that should be watched, especially with his history of a prior amputation, but because of ongoing chronic back pain and diabetic neuropathy, the patient admits to poor foot hygiene at home. The patient is afebrile, and other vital signs are within normal limits.

What signs and symptoms present in this patient are indicative of a diabetic foot infection?

Based on presentation, classify this patient's diabetic foot infection using the PEDIS grading scale.

What additional information do you need before developing a therapeutic plan for this patient?

capillary flow. The secretion of sweat and oil is also diminished, producing dry, cracked skin that is more prone to infection. Finally, damage to sensory neurons produces a loss of protective sensation so that the patient becomes unaware of injury or ulceration.^{37,38}

Angiopathy of large (macroangiopathy) and small (microangiopathy) vessels is also the result of high blood glucose concentrations. Angiopathy results in ischemia and skin breakdown.^{37,38}

Finally, persons with diabetes have altered immune function that predisposes them to infection. Although their humoral immune responses remain intact, leukocyte function and cell-mediated immunity are compromised in poorly controlled disease. Achieving and maintaining tightly controlled blood glucose levels can wholly or partially reverse diabetic immunopathy.^{37,38}

CLINICAL PRESENTATION AND DIAGNOSIS

- Not all diabetic foot ulcers are infected. However, infection is often difficult to detect when perfusion and the inflammatory response are limited in the patient with diabetes. The common signs and symptoms (i.e., pain, erythema, and edema) of infection may be absent.³⁹ Still,

Patient Encounter 2, Part 2: Diabetic Foot Infection: Medical History, Physical Examination, and Diagnostic Tests

PMH: Type 2 diabetes mellitus × 19 years, hypertension, hypertriglyceridemia, peripheral neuropathy, and chronic back pain. Right second toe amputation secondary to diabetic foot infection.

FH: Father died of an MI at age 69; mother (age 87) is living with Alzheimer's dementia, type 2 diabetes mellitus. One sister alive with type 2 diabetes mellitus.

SH: Married, three grown children. Retired truck driver. Denies alcohol and tobacco use.

Meds: Lantus 50 units at bedtime, Humalog 10 units with meals, losartan 100 mg daily, hydrochlorothiazide 25 mg daily, gemfibrozil 600 mg twice daily, gabapentin 600 mg three times daily, hydrocodone/APAP 5/500 mg every 6 hours as needed, and aspirin 81 mg daily.

Allergies: Sulfa (rash), lisinopril (cough).

ROS: (+) left foot findings per HPI; (–) headache, chest pain, shortness of breath, cough, nausea, vomiting, diarrhea, and weight loss.

PE:

Gen: Patient is in no acute distress. Wt 96.4 kg (212 lb); ht 5 ft 9 in (175 cm).

Chest: CTAB.

CV: RRR. No murmurs/rubs/gallops.

Ext: 3-cm purulent, erythematous lesion present on the plantar aspect of the left great toe. 1+ edema in the left foot; diminished sensation bilaterally. Lymphangitic streaking present; wound probe 1.5 cm deep.

Labs: Most recent labs were drawn at last visit 8 months ago: BUN 14 mg/dL (5.0 mmol/L), SCr 1.0 mg/dL (88 μmol/L), Glu 154 mg/dL (8.5 mmol/L), A1C 8.8% (0.088; 73 mmol/mol hemoglobin).

The patient is diagnosed with a diabetic foot infection and is admitted to the local hospital.

Explain the role of neuropathy, angiopathy, and immunopathy in the development of this patient's diabetic foot infection.

What are the best preventative strategies for diabetic foot infections and complications such as lower extremity amputation?

Antimicrobial therapy for this patient's infection should provide coverage for which microorganisms?

What antimicrobial therapy would you recommend? Include drug, dosage, route, interval, and duration of therapy.

How would you monitor your selected regimen for safety and efficacy?

the diagnosis of diabetic foot infection depends mostly on clinical evaluation.

Purulent drainage from the ulcer is indicative of infection. When pus and inflammatory symptoms are not present, the clinician must be astute to more subtle findings. These include delayed healing, increase in lesion size, prolonged exudate production, malodor, and tissue friability. Abnormal granulation tissue also may be present, as evidenced by color change (from bright red to dark red, brown, or gray) and increased bleeding. The ability to probe the ulcer to the underlying bone is highly indicative of osteomyelitis.³⁹

Diabetic foot infections are classified into four categories based on clinical presentation using the PEDIS scale (perfusion, extent/size, depth/tissue loss, infection, sensation). Grade 1 signifies no infection; grade 2, involvement of skin and subcutaneous tissue only; grade 3, extensive cellulitis or deeper infection; and grade 4, systemic inflammatory response syndrome.³⁶ Grade 2 infections are classified as non-limb-threatening infections, whereas grade 3 and 4 infections are limb-threatening.^{36,38} **Table 73–5** provides detailed information regarding these grades.

Imaging studies, such as x-ray and magnetic resonance imaging (MRI), can identify osteomyelitis. Blood cultures should be obtained from all patients with signs and symptoms of systemic illness. Deep tissue cultures may help to direct therapy. Bone also may be sent for culture in cases of osteomyelitis. Superficial cultures of ulcers are unreliable and should be avoided.³⁶

Spreading soft tissue infection and osteomyelitis are often the first complications that develop from diabetic foot infection. Some patients develop bacteremia and sepsis.

The most feared complication of infected diabetic foot ulcers is lower extremity amputation. More than 60% of all nontraumatic lower extremity amputations performed each year in Western nations are linked to diabetic foot infection; nearly 71,000 were performed in the United States in 2004.⁴⁰

TREATMENT

Desired Outcomes

- The goals of therapy for diabetic foot infection are eradication of the infection and avoidance of soft tissue loss and amputation.

Prevention

- Comprehensive foot care programs can reduce the rate of diabetic foot ulcers and associated amputations by 45% to 85%.³⁷ Periodic foot examinations with monofilament testing and patient education regarding proper foot care, optimal glycemic control, and smoking cessation are key preventative strategies. Custom orthotic footwear and prophylactic reconstructive foot surgeries also may be effective in reducing the incidence of foot ulcers.³⁵

Patient Encounter 2, Part 3: Diabetic Foot Infection: Clinical Course

The patient received the empiric therapy you recommended for his diabetic foot infection. Two days later, deep wound cultures were reported positive for *P. aeruginosa*. Blood cultures revealed no growth. The patient remained hospitalized for an additional week, during which time his cellulitis improved on directed antimicrobial therapy. He was discharged to complete his antibiotic therapy and to follow up as an outpatient in 1 week.

*What modifications would you make to this patient's antimicrobial regimen knowing that the causative agent is *P. aeruginosa*?*

What individualized foot care strategies can you suggest to this patient to prevent further infections?

Table 73–5

Clinical Classification of a Diabetic Foot Infection

Infection Severity	PEDIS Grade	Clinical Manifestations of Infection
Uninfected	1	Wound lacking purulence or any manifestations of inflammation
Mild	2	Presence of at least two manifestations of inflammation (purulence or erythema, pain, tenderness, warmth, or induration), but any cellulitis/erythema extends no more than 2 cm around the ulcer, and infection is limited to the skin or superficial subcutaneous tissues; no other local complications or systemic illness
Moderate	3	Infection (as above) in a patient who is systemically well and metabolically stable but who has at least one of the following characteristics: cellulitis extending greater than 2 cm, lymphangitic streaking, spread beneath the superficial fascia, deep tissue abscess, gangrene, and involvement of muscle, tendon, joint, or bone
Severe	4	Infection in a patient with systemic toxicity or metabolic instability (e.g., fever, chills, tachycardia, hypotension, confusion, vomiting, leukocytosis, acidosis, severe hyperglycemia, or azotemia)

From Lipsky BA, Berendt AR, Deery G, et al. Diagnosis and treatment of diabetic foot infections. *Clin Infect Dis* 2004;39:885–910.

Nonpharmacologic Treatment

The nonpharmacologic treatment of diabetic foot ulcers may include off-loading, chemical or surgical débridement of necrotic tissue, wound dressings, HBO, vascular or orthopedic surgery, and the use of human skin equivalents.³⁸

Pharmacologic Treatment

The severity of a patient's infection, based on the PEDIS scale, guides the selection of empirical antimicrobial therapy. Although most patients with grade 2 diabetic foot infections can be treated as outpatients with oral antimicrobial agents,

all grade 4 and many grade 3 infections require hospitalization, stabilization of the patient, and broad-spectrum IV antibiotic therapy.³⁶

Multiple antibiotic options exist for the treatment of diabetic wound infections. **Table 73–6** provides both general treatment strategies and specific, although not all-inclusive, antibiotic recommendations. The duration of therapy correlates with infection severity. Antibiotics should be continued until the infection has resolved, but not necessarily until the ulcer has healed. Grade 2 infections generally require 7 to 14 days of therapy, whereas grade 3 to 4 necessitate treatment durations of 14 to 28 days.

Table 73–6

Empirical Pharmacologic Treatment of Diabetic Foot Infection

Infection Severity	PEDIS Grade	General Approach to Empirical Pharmacologic Treatment	Examples of Appropriate Empirical Antibiotics ^a
Uninfected	1	None. Avoid treating uninfected diabetic foot ulcers.	Not applicable
Mild	2	Oral, narrow-spectrum antibiotic therapy with activity against <i>S. aureus</i> and streptococcal species. Include coverage for MRSA (HA- or CA-MRSA) according to patient history and resistance patterns in the area.	MRSA not suspected: cephalexin, dicloxacillin, or clindamycin HA-MRSA suspected: vancomycin (IV), daptomycin (IV), linezolid, telavancin (IV), or ceftaroline (IV) CA-MRSA suspected: clindamycin ^b , trimethoprim-sulfamethoxazole ^c , doxycycline ^c , or minocycline ^c
Moderate	3	Difficult to define a general approach. In many patients, highly bioavailable oral therapy is appropriate. IV therapy should be initiated in patients with more extensive or chronic infections, or those with abscess, deep tissue or bone involvement or gangrene.	Oral options for grade 3 infections: Amoxicillin-clavulanate, levofloxacin ^d + clindamycin, or moxifloxacin CA-MRSA suspected: Include clindamycin ^b , trimethoprim-sulfamethoxazole ^c , doxycycline ^c , or minocycline ^c
Severe	4	Parenteral, broad-spectrum antibiotic therapy should be initiated. Ideally, drugs with activity against gram-positive, gram-negative, and anaerobic bacteria (especially if wound is malodorous) should be selected. Include coverage for MRSA.	IV options for grade 3–4 infection: Vancomycin, daptomycin, linezolid, or telavancin ^e In combination with one of the following choices: Piperacillin-tazobactam ^d , ampicillin-sulbactam, imipenem-cilastatin ^d , ertapenem, moxifloxacin, levofloxacin ^d + clindamycin, cefepime ^d + metronidazole, ceftazidime ^d + clindamycin OR Ceftaroline ^f + clindamycin or metronidazole OR Tigecycline ^f monotherapy

^aPlease refer to Table 73–3 for dosing in adults with normal renal function.

^bCA-MRSA isolates resistant to erythromycin should be evaluated for inducible clindamycin resistance via a D-test.

^cLimited clinical data exist for the treatment of MRSA infections. Poor activity against GAS; consider using in combination with clindamycin or cephalexin if empirical coverage for GAS is desired.

^d*P. aeruginosa* generally is susceptible to this agent.

^eMRSA coverage indicated for patients with severe cellulitis or systemic illness who have risk factors for HA-MRSA or CA-MRSA infection, or reside in areas with high CA-MRSA prevalence. Otherwise, the broad-spectrum regimens listed below, without MRSA coverage, are appropriate.

^fNot currently approved for the treatment of diabetic foot infections.

From Refs. 36 and 40–42.

If osteomyelitis is present, treatment duration depends on whether infected and necrotic bone is surgically debrided. In the case of amputation, where all infected bone and tissue is removed, 2 to 5 days of therapy is sufficient. Residual infection, status-postsurgical debridement, requires 2 to 6 weeks of antibiotic therapy. Without surgery, antibiotic therapy should continue for at least 12 weeks.³⁶

INFECTED PRESSURE SORES

EPIDEMIOLOGY AND ETIOLOGY

- Pressures sores, also known as *decubitus ulcers* or *bedsores*, affect approximately 7% to 24% of long-term care and 10% to 18% of hospitalized patients. Patients of advanced age and those with spinal cord or orthopedic injuries are at highest risk.⁴³

A pressure sore is a chronic wound that results from continuous pressure on the tissue overlying a bony prominence. This pressure impedes blood flow to the dermis and subcutaneous fat, resulting in tissue damage and necrosis.^{44,45}

Pressure sore infections develop from breaks in skin integrity and contamination from dirty areas of close proximity. Pressure sore infections generally are polymicrobial.⁴⁶

CLINICAL PRESENTATION AND DIAGNOSIS

- Approximately two-thirds of all pressure sores occur on the sacrum and heels. The remaining one-third occur predominately on the elbows, ankles, trochanters, ischia, knees, scapulas, shoulders, or occiput.⁴⁷ Pressure sores are classified according to the extent of tissue destruction.⁴⁸ The most commonly used system for staging of pressure sores is presented in [Table 73–7](#).

Bacterial colonization of pressure sores is common. Because infection impairs wound healing and may require systemic antimicrobial therapy, the clinician must be able to distinguish it from colonization. [Table 73–8](#) describes the clinical presentation of infected pressure sores.

Most complications are infectious. The most common is osteomyelitis, which is present in approximately 38% of infected pressure sores.⁴⁴ Less frequently, NF, clostridial myonecrosis, and sepsis can occur.

TREATMENT

Desired Outcomes

- The goals of therapy for infected pressure sores include resolution of infection, promotion of wound healing, and establishment of effective infection control.⁴⁵

Prevention

- 8** *Prevention is the most humane and cost-effective component in the management of pressure sores.* Key prevention strategies include monitoring of high-risk patients, reducing skin

Table 73–7

Staging of Pressure Ulcers

Suspected Deep Tissue Injury

- Intact skin with localized area of purple or maroon discoloration or presence of a blood-filled blister
- The area may be preceded by tissue that is painful, firm, mushy, boggy, and warmer or cooler as compared with adjacent tissue

Stage I

- Intact skin with localized area of nonblanchable redness, usually over a bony prominence
- May be difficult to detect in darkly pigmented skin; its color may differ from the surrounding area

Stage II

- Partial-thickness loss of dermis presenting as a shallow open ulcer with a red pink wound bed or an intact or ruptured serum-filled blister
- This stage should not be used to describe skin tears, tape burns, perineal dermatitis, maceration, or excoriation

Stage III

- Full-thickness tissue loss. Subcutaneous fat may be visible, but bone, tendon, or muscle are not exposed. Slough may be present but does not obscure the depth of tissue loss. May include undermining and tunneling.

Stage IV

- Full-thickness tissue loss with exposed bone, tendon, or muscle. Slough or eschar may be present on some parts of the wound bed. Often include undermining and tunneling.

Unstageable

- Full-thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black) in the wound bed
- Until enough slough and/or eschar is removed to expose the base of the wound, the true depth, and therefore stage, cannot be determined. Stable (dry, adherent, intact without erythema or fluctuance) eschar on the heels serves as “the body’s natural (biological) cover” and should not be removed.

From National Pressure Ulcer Advisory Panel. Updated staging system [online]. 2007. [cited 2011 Oct 10]. Available from: <http://www.npuap.org/pr2.htm>.

exposure to pressure and moisture, and promoting good nutritional status.

Careful monitoring and preventative care of high-risk patients can begin once these patients are identified. Intrinsic or host-related risk factors for the development of pressure sores include age greater than 75 years, limited mobility, loss of sensation, unconsciousness or altered sense of awareness, and malnutrition. Extrinsic or environmental risk factors include pressure, **friction, shear stress**, and moisture.⁴⁴

Turning and repositioning the patient at least every 2 hours can reduce skin pressure and prevent pressure sores. However, because this level of care is difficult to achieve in most hospital and nursing home environments, multitudes of pressure-reducing mattresses have been manufactured. Although these can help to decrease

Table 73–8

Presentation of Infected Pressure Sores**Symptoms**

- Because many high-risk patients lack sensation, pain may not be a primary symptom.

Signs

- Infection generally is diagnosed when erythema and edema of the surrounding skin, purulent drainage, malodor, or delayed wound healing are present.
- Patients with bacteremia often develop fever, chills, confusion, and/or hypotension.

Laboratory Tests

- Deep tissue cultures may help to direct therapy. Bone also may be sent for culture in cases of osteomyelitis. Superficial cultures are unreliable and should be avoided.

Imaging Studies

- Imaging studies, such as CT, MRI, or bone scan, can be used to detect osteomyelitis and to determine the depth and extent of tissue destruction.

From Refs. 45 and 47.

pressure on susceptible areas, they do not negate the need for position changes.⁴⁴

Maintaining a clean, dry environment can prevent skin **maceration** and subsequent tissue damage. This can be accomplished with frequent changes of bed sheets and clothing, thorough drying of skin after bathing, and prompt disposal of incontinent stool or urine.

Malnutrition is a significant but reversible risk factor. High-protein diets have been shown in multiple studies to improve wound healing in patients with pressure sores.⁴⁴

Nonpharmacologic Treatment

Pressure relief, adequate nutrition (high-protein diet), and surgical débridement or abscess drainage are the mainstays of nonpharmacologic treatment.⁴⁵

Pharmacologic Treatment

8 *Systemic antibiotics are indicated for serious pressure ulcer infections, including those associated with spreading cellulitis, osteomyelitis, or bacteremia.*⁴⁵ Pressure ulcer infections are generally polymicrobial. Thus antimicrobial agents with a broad spectrum of activity should be initiated and narrowed according to the results of cultures obtained surgically. The duration of treatment is generally 10 to 14 days, unless osteomyelitis is present.⁴⁵

Mild superficial infections, such as those that present clinically with delayed wound healing or minimal cellulitis, may be treated with topical antimicrobial agents such as silver sulfadiazine 1% cream or combination antibiotic ointments.⁴⁴ Systemic options for more extensive cellulitis are available in Table 73–3.

INFECTED BITE WOUNDS**EPIDEMIOLOGY AND ETIOLOGY**

- Fifty percent of Americans will be bitten by an animal at least once during their lifetimes. Although most of these injuries are minor, approximately 20% will require medical treatment.²

Dogs cause approximately 80% of all bites, of which approximately 15% to 25% become infected. These bites most commonly involve the extremities, and young children are particularly at risk.⁴⁹

Cat bites are the second most common animal bite, most often occurring in women and elderly individuals. Most involve the hand. Because cats have long, thin teeth that cause puncture wounds, their bites are more likely to become infected than a dog bite. Approximately 50% of cat bites become infected.⁴⁹

Human bites are third most common and the most serious. Before the availability of antibiotics, up to 20% resulted in amputation. Currently, human bite-associated amputation rates remain at 5%, secondary to vascular compromise and infectious complications.⁴⁹

There are two types of human bite injuries. Occlusal injuries are inflicted by actual biting, whereas clenched-fist injuries are sustained when a person's closed fist hits another's teeth. Of the two, clenched-fist injuries typically are more prone to infectious complications.⁴⁹

9 *Bite wound infections generally are polymicrobial.* On average, five different bacterial species can be isolated from an infected animal bite wound.² Both the normal flora of the biter's mouth and that of the bite recipient's skin can be implicated. The bacteriology of the cat and dog mouth is quite similar. *Pasteurella multocida*, a gram-negative aerobe, is one of the predominant pathogens, isolated in up to 50% of dog and 75% of cat bites. Viridans streptococci are the most frequently cultured bacteria from human bite wounds, although empiric treatment should also provide coverage for *Eikenella corrodens*.^{2,49} Table 73–9 provides a comprehensive list of cat-, dog-, and human bite-wound pathogens.

CLINICAL PRESENTATION AND DIAGNOSIS

- The clinical presentation of infected bite wounds is presented in Table 73–9.

Complications of infected bite wounds include **lymphangitis**, abscess, septic arthritis, tenosynovitis, and osteomyelitis. Bites to the hand are particularly complication-prone.⁴⁹

TREATMENT**Desired Outcomes**

- The goals of therapy for an infected bite wound are rapid and successful eradication of infection and prevention of related complications.

Table 73–9

Etiology and Presentation of Infected Bite Wounds**Bacterial Pathogens**

- *Dog and cat: Pasteurella multocida*, staphylococci, streptococci *Moraxella* spp., *Eikenella corrodens*, *Capnocytophaga canimorsus*, *Actinomyces*, *Fusobacterium*, *Prevotella*, and *Porphyromonas* spp.
- *Human: Viridans streptococci, S. aureus, E. corrodens, Haemophilus influenzae*, and β -lactamase-producing anaerobic bacteria

Signs and Symptoms

- The onset of infectious symptomatology is typically 12–24 hours after the bite.
- Pain at the wound site is common.
- Erythema, edema, and purulent or malodorous drainage at the wound site are manifestations of infected wounds. The patient may be febrile.
- Limited range of motion may be present, especially if the hand is bitten.

Laboratory Tests

- Leukocytosis may be present.
- The clinician should obtain anaerobic and aerobic wound cultures only if the wound appears clinically infected.

Imaging Studies

- X-rays should be obtained if the bite is on the hand, could have damaged bone or joints, or if an embedded object or tooth fragment is suspected.

From Bower MG. Managing dog, cat, and human bite wounds. *Nurs Pract* 2001;26:36–38, 41, 42, 45.

Nonpharmacologic Treatment

Thorough irrigation with normal saline is the first step in the care of an infected bite wound. The wound should be elevated and immobilized. Surgical closure may be advocated, especially for facial wounds. Wounds that are infected, at higher risk for infection, or older than 24 hours should be left open because premature closure can lead to disastrous infectious complications. **9** *Wounds at higher risk for infection include human bites, deep punctures, and bites to the hand.*⁴⁹

Pharmacologic Treatment

Most bite wounds require antibiotic therapy only when clinical infection is present. *However, prophylactic therapy is recommended for wounds at higher risk for infection and bites requiring surgical repair.*⁴⁹

The most effective agent for the treatment (and prophylaxis) of human and animal bite-wound infections is amoxicillin-clavulanate. Alternatives for patients with significant penicillin allergies include either a fluoroquinolone (e.g., ciprofloxacin) or trimethoprim-sulfamethoxazole in combination with clindamycin. The durations of prophylaxis and treatment generally are 3 to 5 and 10 to 14 days, respectively.²

If the wound is associated with significant cellulitis and edema, systemic signs of infection, or possible joint or bone involvement, hospitalization and IV antibiotics (typically

ampicillin-sulbactam 3 g IV every 6 hours) should be initiated. Bone and joint infections will require longer durations of therapy of up to 6 weeks.^{2,49}

OUTCOME EVALUATION

- Education of the patient, caregivers, and household members is important to limit further spread of infection and is a key component in SSTI case management. **Table 73-10** lists several key prevention messages for patients with SSTIs.
- **10** *Patients receiving antibiotic therapy for SSTIs require monitoring for efficacy and safety. Efficacy typically is manifested by reductions in temperature, white blood cell count, erythema, edema, and pain.* Initially, signs and symptoms of infection may worsen owing to toxin release from certain organisms (i.e., GAS); however, they should begin to resolve within 48 to 72 hours of treatment initiation. If no response or worsening infection is noted after the first 3 days of antibiotics, reevaluate the patient.² Lack of response may be due to a noninfectious or nonbacterial diagnosis, a pathogen not covered by or resistant to current antibiotic therapy, poor patient adherence, drug or disease interactions causing decreased antibiotic absorption or increased clearance, immunodeficiency, or the need for surgical intervention. *To ensure the safety of the regimen, dose antibiotics according to renal and hepatic function as appropriate, and monitor for or minimize adverse drug reactions, allergic reactions, and drug interactions.*

Table 73–10

Prevention Education for Patients with SSTIs

1. Draining wounds should be covered with clean, dry bandages.
2. Hands should be cleaned regularly with soap and water (or with alcohol-based hand gel if not visibly soiled) and immediately after touching infected skin or any item directly contacting a draining wound.
3. General hygiene should be maintained with regular bathing.
4. Items that may become contaminated with wound drainage or that directly touch the skin should not be shared.
5. Wash and dry thoroughly any clothing that has come in contact with wound drainage after each use.
6. If the wound is unable to be covered with a clean, dry bandage at all times, avoid activities with skin-to-skin contact until the wound is healed.
7. Equipment and environmental surfaces with bare skin contact should be cleaned with *S. aureus*-active detergents or disinfectants.

From Gorwitz RF, Jernigan DB, Powers JH, et al. Strategies for clinical management of MRSA in the community: summary of an experts' meeting convened by the Centers for Disease Control and Prevention [online]. 2006. [cited 2011 Oct 10]. Available from: http://www.cdc.gov/ncidod/dhqp/ar_mrsa_ca.html.⁵⁰

Patient Care and Monitoring

Choosing antibiotic therapy for SSTIs:

1. To select the most effective *empirical* antibiotic agent(s) for SSTIs, review the following:

- The diagnosis
- Clinical manifestations and severity of illness (to assess the need for IV versus oral therapy)
- Past medical history, chronic disease states (to determine suspected pathogens)
- Patient's ability to adhere to the regimen (if outpatient treatment indicated)

In pediatric patients especially, consider duration of therapy, frequency of dosing, method and ease of administration, and palatability and tolerability of oral formulations.

2. To ensure the safety of your selected antibiotic agent(s), review the following:

- Current medications (over-the-counter, prescription, and alternative) for potential drug interactions
- History of medication allergies and adverse effects
- Current laboratory analyses to determine renal and hepatic function
- Chronic disease states or acute conditions that could be worsened by certain antimicrobial agents (e.g., QT prolongation or acute renal failure)
- Other disease modifiers that may preclude use (e.g., pregnancy, age)

Monitoring antibiotic therapy for SSTIs:

1. Ensure that antimicrobial therapy is effective by monitoring for:

- Resolution of local and systemic signs and symptoms of infection
- Resolution of laboratory evidence of infection

2. Narrow antibiotic coverage when possible with the use of culture and sensitivity data.

3. Assess patient adherence.

4. Ensure that antimicrobial therapy is safe by monitoring for and treating (as appropriate):

- Common and severe adverse effects
- Drug interactions

Patient education regarding antibiotic therapy for SSTIs:

1. It is imperative to take the antibiotic as prescribed and to finish the therapy.
2. If no symptomatic improvement is noted within 3 days, contact your healthcare provider.
3. Many antibiotics cause diarrhea. If it is severe, contact your healthcare provider.
4. Consider health initiatives to improve wound healing, such as smoking cessation and glycemic control.

Abbreviations Introduced in This Chapter

CA-MRSA	Community-acquired methicillin-resistant <i>S. aureus</i>
GAS	Group A <i>Streptococcus</i> (also known as <i>Streptococcus pyogenes</i> , one of the β -hemolytic streptococci)
HA-MRSA	Health care-associated methicillin-resistant <i>S. aureus</i>
HBO	Hyperbaric oxygen
MIC	Minimum inhibitory concentration
MRI	Magnetic resonance imaging
MRSA	Methicillin-resistant <i>S. aureus</i>
MSSA	Methicillin-sensitive <i>S. aureus</i>
NF	Necrotizing fasciitis
SSTI	Skin and soft tissue infection
VISA	Vancomycin-intermediate <i>S. aureus</i>
VRE	Vancomycin-resistant enterococci
VRSA	Vancomycin-resistant <i>S. aureus</i>

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Ronda L. Akins and Katie E. Barber

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Differentiate the causes and development of infective endocarditis (IE).
2. Identify the clinical presentation and laboratory evaluation for IE.
3. Assess diagnostic criteria used to evaluate a patient suspected of having IE.
4. Describe the most likely causative organisms of IE, particularly in specific patient populations.
5. Develop appropriate pharmacologic treatment recommendations for patients with IE.
6. Define appropriate patient populations requiring prophylactic treatment, and differentiate appropriate drug regimens.
7. Devise a monitoring plan for patients with IE to determine treatment efficacy and discern any adverse effects.

KEY CONCEPTS

- 1 For infective endocarditis (IE) to develop, several factors are required, including alterations to the endocardial surface that allow bacterial adherence and eventual infection.
- 2 Persistent fever is the most common symptom present in patients with IE.
- 3 Blood cultures are the essential laboratory test for the diagnosis and treatment of IE. Typically, patients with IE have a low-grade consistent bacteremia. Blood culture results are critical for determining the most appropriate therapy.
- 4 Echocardiograms are used for detecting the presence of a vegetation. Either a transthoracic echocardiogram (TTE) or a transesophageal echocardiogram (TEE) may be used depending on certain patient characteristics.
- 5 Choosing the appropriate antimicrobial therapy is crucial to achieve adequate organism kill.
- 6 An extended treatment course of 4 to 6 weeks (in most cases) is required to achieve an adequate cure.
- 7 The overall goal of therapy is to eradicate the infection and minimize/prevent any complications.
- 8 In an effort to prevent the development of IE, prophylactic treatment generally is considered appropriate for patients with high-risk factors.

- 9 Monitoring the patient's clinical course is necessary to assess the effectiveness of therapy, detect the potential development of bacterial resistance, and determine outcome.

Infective endocarditis (IE) is a serious infection affecting the lining and valves of the heart. Although this disease is mostly associated with infection of the heart valves, the septal defects may become involved in some cases. Infections also occur in patients with prosthetic or mechanical devices or who are intravenous drug users (IVDUs). Bacteria are the primary cause of IE; however, fungi and atypical organisms may also be responsible pathogens.

Typically IE is classified into two categories: acute or subacute. The difference between the two categories is based on the progression and severity of the disease. Acute disease is more aggressive, characterized by high fevers, leukocytosis, and systemic toxicity, with death occurring within a few days to weeks. This type of IE is often caused by more virulent organisms, particularly *Staphylococcus aureus*. Subacute disease is typically caused by less virulent organisms, such as viridans group streptococci, producing a slower and more subtle presentation. It is characterized by weakness, fatigue, low-grade fever, night sweats, weight loss, and other nonspecific symptoms, with death occurring in several months.

Successful management of patients with IE is based on proper diagnosis, treatment with adequate therapy, and monitoring for complications, adverse events, or development of resistance. The treatment and management of IE are best

determined through identification of the causative organism. IE has varied clinical presentations; therefore, patients with this infection may be found in any medical subspecialty (i.e., medicine, surgery, critical care, etc.).

EPIDEMIOLOGY AND ETIOLOGY

Despite IE being a fairly uncommon infection, in the United States, there are about 10,000 to 20,000 new cases annually, and IE accounts for an incidence of approximately five to seven cases per 100,000 persons-years.¹ Although the exact number of cases is often difficult to determine owing to the diagnostic criteria and reporting methods for this disease, it continues to rise. IE is now considered the fourth leading cause of serious infectious disease syndromes following urosepsis, pneumonia, and intra-abdominal sepsis.² Men are affected more commonly than women at a ratio of 1.7:1. Although IE occurs at any age, more than 50% of cases occur in patients older than 50 years.¹ IE in children continues to be uncommon and is mainly associated with underlying structural defects, surgical repair of the defects, or nosocomial catheter-related bacteremia.¹ With the increased use of mechanical valves, **prosthetic-valve endocarditis** (PVE) now accounts for approximately 10% to 30%.³ Patients who are IVDUs are also at an increased risk for IE, with 150 to 2,000 cases per 100,000 persons per year, most being younger adults.⁴ Additionally, other patients at high risk for IE include patients with any congenital or structural cardiac

defects, including valvular disease; long-term hemodialysis; diabetes mellitus; poor oral hygiene; major dental treatment; previous endocarditis; hypertrophic cardiomyopathy; and mitral valve prolapse with regurgitation.^{5–8}

Although almost any type of microorganism is capable of causing IE, the majority of cases are caused by gram-positive organisms. These consist primarily of streptococci, staphylococci, and enterococci. Consideration of gram-negative, fungal, and other atypical organisms must be taken into account, particularly in certain patient populations. In [Table 74–1](#),

Patient Encounter, Part 1

A 72-year-old man with a history of hypertension, benign prostate hyperplasia (BPH), and coronary artery diseases (CAD) s/p tricuspid valve replacement 2 years ago presents to the emergency department with complaints of weakness, fever, and chills. His current weight is 50 kg (110 lb). On interviewing the patient, you determine that he had a transurethral resection (TUR) of the prostate to treat his BPH 21 days ago. He denies any use of alcohol, illicit drugs, or smoking.

What information would make you suspect IE?

Does he have any risk factors for IE?

What additional information would you like to know before deciding on an empirical treatment for this patient?

Table 74–1

Etiologic Organisms of Infective Endocarditis

Organism	Percent of Cases					
	Native-Valve IE		PVE (Indicated in Months After Valve Surgery)			IVDU (Right- and Left-Sided) Total
	Community-Acquired	Healthcare-Associated	Less Than 2	2–12	Greater Than 12	
Streptococci ^a	40	9	1	9	31	12
Pneumococci	2	—	—	—	—	—
Enterococci	9	13	8	12	11	9
<i>Staphylococcus aureus</i>	28	53 ^b	22	12	18	57
CNS	5	12	33	32	11	—
HACEK group	3	—	—	—	6	—
Gram-negative bacilli	1	2	13	3	6	7
Fungi (<i>Candida</i> spp.)	Less than 1	2	8	12	1	4
Polymicrobial/miscellaneous	3	4	3	6	5	7
Diphtheroids	—	Less than 1	6	—	3	0.1
Culture-negative	9	5	5	6	8	3

CNS, coagulase-negative staphylococci; HACEK, *Haemophilus* spp. (primarily *H. paraprofitilis*, *H. parainfluenzae*, and *H. aphrophilus*), *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*.

^aIncludes viridans group streptococci; *S. bovis*; other nongroup A, groupable streptococci; and nutritionally variant streptococci.

^bMethicillin resistance is common among these *S. aureus* strains.

Modified from Karchmer AW. Infective endocarditis. In: Fauci AS, Braunwald E, Kasper DL, Hauser SL, Longo DL, Jameson JL, Loscalzo J, eds. Harrison's Principles of Internal Medicine. 18th ed. New York: McGraw Hill; 2012: Chap. 124.

approximate percentages are given for each organism based on the type of IE, including native valve (community-acquired versus health care-associated), prosthetic valve (grouped by months postsurgery), and IVDUs.

PATHOGENESIS AND PATHOPHYSIOLOGY

1 For IE to develop, the occurrence of several factors is required. Typically, there must be an alteration of the endothelial surfaces of the heart valves to allow for organism attachment and colonization. These alterations may be produced by an inflammatory process such as rheumatic heart disease or by injury from turbulent blood flow. Platelets and fibrin now deposit on the damaged valves, forming a **nonbacterial thrombotic endocarditis (NBTE)**. At this point, bacteria through hematogenous spread (i.e., bacteremia) adhere to and colonize the **nidus**, forming a vegetation. Further deposits of platelets and fibrin cover the bacteria, providing a protective coating that allows for the development of a suitable environment for continued organism and vegetation progression, often producing an organism density of 10^9 to 10^{10} **colony-forming units (CFU)** per gram. This sequence of events is summarized in **Figure 74-1**.

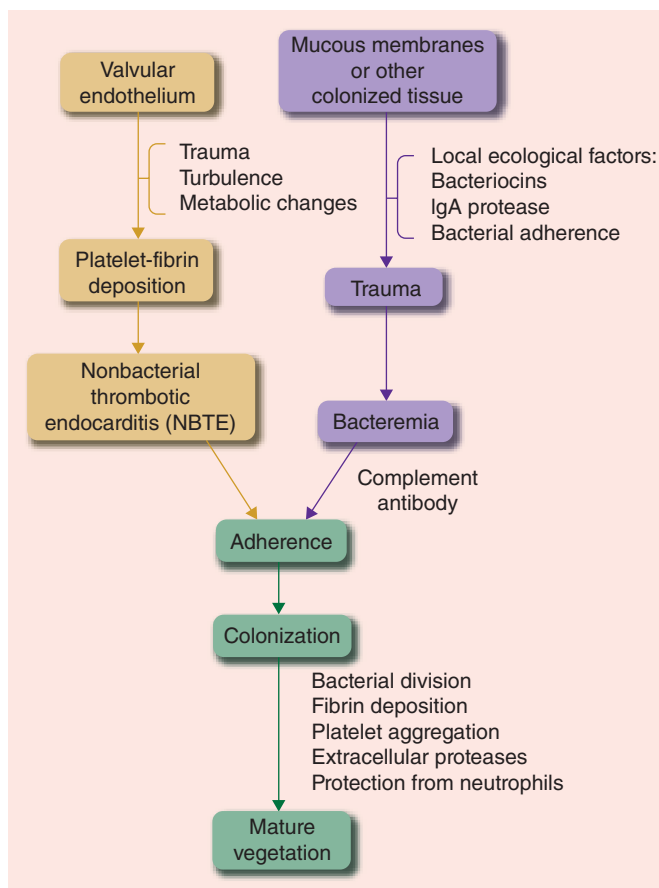

FIGURE 74-1. Pathogenesis of infective endocarditis. (From Fowler VG Jr, Scheld WM, Bayer AS. Endocarditis and intravascular infections. In: Mandell GL, Bennett JE, Dolin R, eds. Principles and Practice of Infectious Diseases, 6th ed. Philadelphia, PA: Elsevier; 2005:975-1022; With permission from Elsevier.)

Acquisition of PVE differs in early stages, where direct inoculation may occur during surgery instead of through hematogenous seeding. In addition, causative organisms in early PVE are typically nosocomial, with more likelihood of being drug resistant.^{8,9} The prosthetic valve also has a greater propensity for organism colonization than native valves.⁹ However, in late PVE, the process of colonization and vegetation formation is similar to that of native-valve IE, as described earlier.^{8,9}

Typically, vegetations are located on the line along valve closure on the atrial surface of the atrioventricular valves (tricuspid and mitral) or on the ventricular surface of the semilunar valves (pulmonary and aortic) (**Fig. 74-2**). The vegetations can vary significantly in size, ranging from millimeters to several centimeters and may be single or multiple masses. Often, destruction of underlying tissue occurs and may cause perforation of the valve leaflet or rupture of the chordae tendinae, interventricular septum, or papillary muscle. Valve ring abscesses may occur, resulting in fistulas penetrating into the myocardium or pericardial sac, particularly with staphylococcal endocarditis.

Embolic events are also common. Embolization occurs as portions of the friable vegetation break loose and enter the bloodstream. These infected pieces are called *septic emboli*. Pulmonary abscesses are commonly formed as a result of septic emboli from right-sided IE (tricuspid and pulmonary valves). However, left-sided IE (mitral and aortic valves) is more likely to have an embolus travel to any organ system, especially the kidneys, spleen, and brain. Along with emboli, immune complex deposition may occur in organ

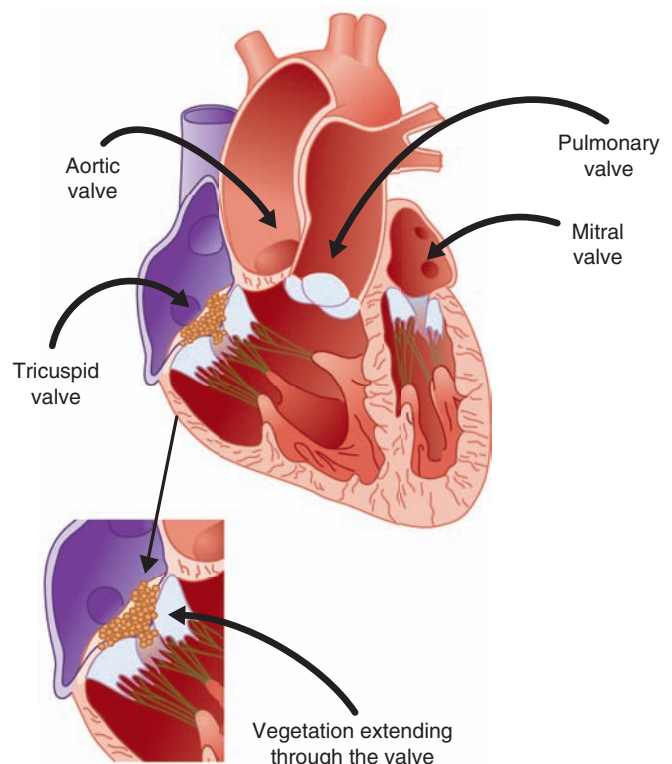

FIGURE 74-2. Diagram of the heart indicating common sites of infection.

systems, causing extracardiac manifestations of the disease. This commonly occurs in the kidneys, producing abscesses, infarction, or glomerulonephritis. Immune complexes or emboli also may produce skin manifestations of the disease, as seen with petechiae, Osler's nodes, and Janeway's lesions, or within the eye (e.g., Roth's spots).

CLINICAL PRESENTATION AND DIAGNOSIS

The clinical presentation for IE is quite variable and often nonspecific. **2** *A fever is the most frequent and persistent symptom in patients but may be blunted with previous antibiotic use, congestive heart failure, chronic liver or renal failure, or infection caused by a less virulent organism (i.e., subacute disease).*^{1,3,4} Other signs and symptoms that also may occur are listed in the Clinical Presentation box, with some discussed further in detail next.

Heart murmurs are heard frequently on auscultation (more than 85% of cases), but a new murmur or change in murmurs is only found in 3% to 5% or 5% to 10%, respectively.¹ Additionally, more than 90% of patients who have a new murmur will develop congestive heart failure, which is a major cause of morbidity and mortality. Splenomegaly and mycotic aneurysms are also noted in many cases of IE.

This disease is also characterized by the following peripheral manifestations. Some of these clinical findings are found in up

to one-half of adult patients with IE, although recently the prevalence has been decreasing and are rarely seen in children.^{1,3,10}

- **Skin:** *Petechiae* are very small (usually less than 3 mm), pinpoint, flat red spots beneath the skin surface caused by microhemorrhaging. They occur in 20% to 40% of patients with chronic IE and are often found on the buccal mucosa, conjunctivae (Fig. 74–3A), and extremities.¹ *Splinter hemorrhages* appear as small dark streaks beneath the finger- or toenails and occur most commonly proximally with IE, typically occurring as a result of local vasculitis or microemboli occurring in about 20% of patients (Fig. 74–3B). *Osler's nodes* are small (usually 2 to 15 mm), painful, tender subcutaneous nodules located on the pads of the fingers and toes (Fig. 74–3D) caused primarily by either septic emboli or vasculitis. These nodes are rare in acute disease but are also nonspecific for IE despite occurring in 10% to 25% of all patients.¹ *Janeway's lesions* are small, painless, hemorrhagic macular plaques on the palms of the hands or soles of the feet due to septic emboli (in approximately 5% of patients) and more commonly associated with acute *S. aureus* IE (Fig. 74–3E).
- **Extremities:** *Clubbing* of the finger tips typically occurs in long-standing illness and is present in approximately 10% to 20% of patients (Fig. 74–3C).¹
- **Eye:** *Roth's spots* occur rarely and are (in less than 5% of IE cases) oval-shaped retinal hemorrhages with a pale center near the optic disc (Fig. 74–3F).

Clinical Presentation of IE 2 3 4

General

Patients typically present with nonspecific and variable signs or symptoms.

Symptoms

Complaints from patients may include:

- Fever
- Chills
- Night sweats
- Weakness
- Dyspnea
- Weight loss
- Myalgia or arthralgias

Signs

- Fever is the most common sign of IE
- New or changing heart murmur
- Embolic phenomena (emboli affect the heart, lungs, abdomen, or extremities)
- Skin manifestations (e.g., petechiae, splinter hemorrhages, Osler's nodes, Janeway's lesions)

- Splenomegaly
- Clubbing of extremities

Laboratory Tests

- Blood cultures are the most important laboratory assessment for persistent bacteremia, which occurs commonly in IE. A minimum of three blood culture sets should be collected during the initial 24 hours
- Hematologic tests for anemia (normochromic, normocytic)
- WBC count may be elevated in acute disease but could be normal in subacute IE
- Nonspecific findings such as thrombocytopenia, elevated erythrocyte sedimentation rate or C-reactive protein, and abnormal urinalysis (i.e., proteinuria or microscopic hematuria)

Other Diagnostic Tests

An echocardiogram (TTE or TEE) should be performed on any patient with suspected IE to detect the presence of vegetations.

FIGURE 74-3. **A.** Conjunctival petechiae. (From Wolff K, Johnson RA, Suurmond D. In: Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology. 5th ed. New York: McGraw Hill. Copyright 2005.) **B.** Splinter hemorrhage. (From Collins SP. In: Atlas of Emergency Medicine. 2nd ed. New York: McGraw Hill. Copyright 2002.) **C.** Clubbing of finger. (From Tosti A, Piraccini BM. In: Fitzpatrick's Dermatology in General Medicine. 7th ed. New York: McGraw Hill. Copyright 2007.) **D.** Osler's nodes. (From Collins SP. In: Atlas of Emergency Medicine. 2nd ed. New York: McGraw Hill. Copyright 2005.) **F.** Roth's spots (From Effron D, Forcier BC, Wyszynski RE. In: Atlas of Emergency Medicine. 2nd ed. New York: McGraw Hill. Copyright 2002.)

Laboratory Studies

3 Blood cultures are the essential laboratory test for the diagnosis and treatment of IE. Typically, patients with IE have a low-grade consistent bacteremia, with approximately 80% of cases having less than 100 CFU/mL (100,000 CFU/L) in the bloodstream.¹ Blood culture results are critical for determining the most appropriate therapy. Three blood culture sets should be drawn within the initial 24 hours to determine the etiologic agent. Approximately 90% of the first two cultures will yield a positive result. If a positive blood culture is not obtained from a patient with suspected IE, the microbiology laboratory should be notified and cultures requested to be monitored for growth of fastidious organisms for up to 1 month.

4 Another important tool aiding in the diagnosis of IE is the echocardiogram. This imaging tool is used to visualize

vegetations. Two methods of the echocardiogram are used: the transthoracic echocardiogram (TTE) and the transesophageal echocardiogram (TEE). The TTE has been used since the 1970s; however, it is less sensitive (45% to 65%) than the TEE (85% to 95%).³ Despite the TEE being more sensitive, use of the TTE for patients with suspected native-valve IE is usually sufficient.^{11,12} The TEE may be used as a secondary test for patients whose TTE was negative and in whom a high clinical suspicion of IE exists. Additionally, a TEE is often preferred in patients who have complicated disease, including left-sided IE, prosthetic valves, or perivalvular extension of the vegetation.^{2,12,13} Echocardiograms also may be employed to assess the need for surgical intervention or to determine the possible source of emboli.^{10,12}

Additional nonspecific tests for IE may be performed. These include hematologic parameters to determine whether the patient is anemic, which occurs in a majority of patients. The WBCs may be elevated, particularly in acute disease. However, in a subacute infection, the WBCs may be normal. An erythrocyte sedimentation rate (ESR) may also be obtained to determine the presence of inflammation, although this test is highly nonspecific and almost always elevated in IE.

Diagnostic Criteria

A definitive diagnosis of IE would consist of a biopsy or culture directly from pathologic specimens from the endocardium. However, this would be a highly invasive test. Therefore, diagnosis of IE relies on clinical presentation as well as laboratory and echocardiogram results. To guide this clinical diagnosis, criteria have been established to assess major and minor criteria for IE.^{4,15} (Table 74-2A). Depending on the number of major or minor criteria a patient demonstrates, he or she will be classified as having a definite, possible, or rejected diagnosis of IE (Table 74-2B).

Causative Organisms

Gram-positive bacteria are the most common organisms that produce IE. Streptococci and staphylococci species account for the majority of cases at more than 80%.^{1,8} Viridans group streptococci have been considered the primary pathogens in IE. However, staphylococci have been increasing in prevalence as causative organisms and are the dominant causative organisms in some reports (Table 74-1).^{5,15,16} Other gram-positive, gram-negative, atypical, and fungal organisms are less common but still must be considered in certain patient populations.

► Streptococci

Streptococci causing IE are most commonly a group of species called viridans group streptococci. The most common of this group are *Streptococcus salivarius*, *Streptococcus mutans*, *Streptococcus mitis*, and *Streptococcus sanguis*. This group of bacteria, considered normal flora in the human mouth, is α -hemolytic, and typically, most clinical microbiology laboratories do not differentiate the exact species. These organisms

Table 74–2

Modified Duke's Criteria for IE**2A. Definitions of Modified Duke's Criteria****Major Criteria***Blood culture positive for IE:*

Typical microorganisms consistent with IE from two separate blood cultures:

Viridans streptococci, *S. bovis*, HACEK group, *S. aureus*, or community-acquired enterococci in the absence of a primary focus, or

Microorganisms consistent with IE from persistently positive blood cultures, defined as follows:

At least two positive cultures of blood samples drawn greater than 12 hours apart, or

All of three or a majority of four separate cultures of blood (with first and last sample drawn at least 1 hour apart)

Single positive blood culture for *C. burnetii* or antiphase I IgG antibody titer greater than 1:800*Evidence of endocardial involvement:*

Echocardiogram positive for IE (TEE recommended in patients with prosthetic valves, rated at least "possible IE" by clinical criteria, or complicated IE [paravalvular abscess] TTE as first test in other patients), defined as follows:

Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant, or on implanted material in the absence of an alternative anatomic explanation, or

Abscess, or

New partial dehiscence of prosthetic valve

New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)

Minor Criteria

Predisposition: predisposing heart condition or injection drug use

Fever: temperature greater than 38°C (100.4°F)

Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway's lesions

Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, and rheumatoid factor

Microbiologic evidence: positive blood culture but does not meet a major criterion as noted above^a or serologic evidence of active infection with organism consistent with IE**2B. Modified Duke's Criteria for the Diagnosis of IE****Definite IE***Pathologic criteria:*

(1) Microorganisms demonstrated by culture or histologic examination of a vegetation that has embolized, or an intracardiac abscess specimen, or

(2) Pathologic lesions; vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis

Clinical criteria^b:

(1) Two major criteria, or

(2) One major criterion and three minor criteria, or

(3) Five minor criteria

Possible IE

(1) One major criterion and one minor criterion, or

(2) Three minor criteria

Rejected

(1) Firm alternate diagnosis explaining evidence of IE, or

(2) Resolution of IE syndrome with antibiotic therapy for less than or equal to 4 days, or

(3) No pathologic evidence of IE at surgery or autopsy, with antibiotic therapy for less than or equal to 4 days, or

(4) Does not meet criteria for possible IE, as above

CNS, coagulase-negative staphylococci; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography.

^aExcludes single positive cultures for CNS and organisms that do not cause endocarditis.^bSee above for definitions of major and minor criteria.

From Li JS, Sexton DJ, Mick N, et al. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. Clin Infect Dis 2000;30:633–638; With permission. University of Chicago Press, 2000 by the Infectious Diseases Society of America. All rights reserved.

may cause bacteremia after dental procedures, which can lead to the development of IE in at-risk patients. Viridans group streptococci are also the predominant pathogen of IE associated with mitral valve prolapse and native valves and in children.¹⁸ Another streptococci species that is commonly associated with IE is *Streptococcus bovis*, classified as group D streptococci, found in the GI tract. However, owing to the similarities of these streptococci, including microbiologic susceptibility, treatment is similar regardless of the species.

IE caused by these streptococci typically has a subacute clinical course. The current cure rate is often greater than 90% unless complications occur, and they do occur in more than 30% of patients.^{18,19} The majority of viridans group streptococci remain very susceptible to penicillin, with most strains having a **minimum inhibitory concentration (MIC)** of less than 0.125 mcg/mL (0.125 mg/L).²⁰ Isolation of organisms with decreased susceptibilities is increasing. Therefore, antibiotic susceptibilities need to be assessed in order to determine the most appropriate treatment regimen.

► Staphylococci

Staphylococcal endocarditis is increasing in prevalence, causing 30% or more of all cases of IE, with the majority (80% to 90%) being due to *S. aureus* (a coagulase-positive staphylococci).^{17,21} This increase in staphylococci has been primarily attributed to expanded use of venous catheters, more frequent valve replacement, and increased IVDU.²¹ Coagulase-negative staphylococci (CNS) also cause IE; however, these organisms typically infect prosthetic valves or indwelling catheters.²²

Historically, *S. aureus* was considered community acquired²¹; however, now almost half the cases are nosocomial in origin.¹⁷ Any patient who is bacteremic with *S. aureus* is at an increased risk of developing IE. *S. aureus* also may infect “normal” heart valves (no prior detected valvular disease) in a third of cases.^{1,21} Therefore, it is imperative to assess these patients adequately for the presence of vegetations. Any heart valve may be affected; however, when the mitral or aortic valve is involved, it often results in extensive systemic infection with a mortality rate of approximately 20% to 65%.^{1,21} When treating *S. aureus* IE, one must consider whether the isolate displays methicillin resistance, the location of the infection (right or left side), presence of prosthetic valves, and history of IVDU. Despite significant resistance to penicillinase-resistant penicillins (e.g., methicillin and nafcillin), most isolates remain susceptible to vancomycin. However, there is an increasing incidence of *S. aureus* intermediately resistant or fully resistant to vancomycin.^{23–25} Fortunately, they are not widespread enough to affect empirical antibiotic selection. Susceptibility reports should be assessed to ensure antibiotic activity.

Over the past decade there has been an increasing emergence of community-acquired methicillin-resistant *S. aureus* (CA-MRSA) that differs from healthcare-associated MRSA. This organism tends to be less resistant to many antibiotics, with sensitivity to clindamycin, trimethoprim-sulfamethoxazole, and minocycline, as well as vancomycin, linezolid, and daptomycin. However, this organism has a virulence gene (Panton-Valentine leukocidin), which produces a toxin that causes

necrosis. To date this organism primarily causes skin/skin-structure infections or pneumonias (see Chap. 73, Skin and Soft Tissue Infections). There have been a limited number of cases of IE caused by CA-MRSA.²⁶ If CA-MRSA is suspected, treatment with vancomycin with or without gentamicin and/or rifampin remains the standard of care.

The predominant coagulase-negative organism causing IE has been *S. epidermidis*. However, in the past few years, an increase in isolation of another coagulase-negative species (*S. lugdunensis*) has been noted.^{27–29} Typically, coagulase-negative staphylococcal IE has a subacute course with numerous complications. Treatment (with or without surgical intervention) is usually successful. On the other hand, *S. lugdunensis* produces a more virulent infection and, despite similar antibiotic susceptibilities, has a much higher mortality rate.^{28,29}

► Enterococci

Enterococci are normal flora of the human GI tract and sometimes found in the anterior urethra. Historically, enterococci were considered part of the streptococci genus but now are separated despite similarities, such as group D classification and causing subacute disease. Frequently affected patients are older males who have undergone genitourinary manipulations or younger females who have had obstetric procedures. Although enterococci are a less common cause of IE, there are two predominant species: *Enterococcus faecium* and *Enterococcus faecalis*. *E. faecalis* is the most common and the more susceptible of the strains. However, enterococci overall are more intrinsically resistant, with enterococcal IE representing one of the most problematic gram-positive infections to treat and cure. Frequently, enterococci display resistance to multiple antibiotics, including penicillins, vancomycin, aminoglycosides, and has been described in some of the newer agents (e.g., linezolid or quinupristin/dalfopristin, daptomycin).³⁰

► Gram-Negative Organisms

Gram-negative IE is much less common (approximately 2%) but is typically much more difficult to treat than gram-positive infections.^{1,31} Fastidious organisms, such as the HACEK group, tend to be seen most commonly, causing approximately 3% of all IE.^{4,32,33} This group consists of *Haemophilus* spp. (primarily *H. paraphrophilus*, *H. parainfluenzae*, and *H. aphrophilus*), *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*. The clinical presentation of IE by these organisms is subacute, with approximately 50% of patients developing complications. These complications are primarily due to the presence of large, friable vegetations and numerous emboli along with the development of acute congestive heart failure often requiring valve replacement.^{33,34} It is important to allow cultures sufficient incubation time (often 2 to 3 weeks) in order to isolate these organisms. Often these organisms may not be isolated on culture and thus present as **culture-negative IE**.

Other gram-negative organisms, such as *Pseudomonas* spp., cause IE, especially in IVDUs and patients with prosthetic valves. Additionally, IE may be caused by *Salmonella* spp.,

Escherichia coli, *Citrobacter* spp., *Klebsiella* spp., *Enterobacter* spp., *Serratia marcescens*, *Proteus* spp., and *Providencia* spp.^{1,31}

Historically, gram-negative IE typically had a poor prognosis with high mortality rates. However, as nondrug therapy advances to include cardiac surgery in more than half of patients, the in-hospital mortality has improved to 24%.^{1,31} Treatment usually consists of high-dose combination therapy, with valve replacement often a necessity in many patients.

► Culture Negative

Negative blood cultures are reported in approximately 5% of confirmed IE cases, often delaying diagnosis and treatment.^{1,4,35} Sterile cultures may be the result of previous antibiotic use, subacute right-sided disease, slow growth of fastidious organisms, nonbacterial endocarditis (e.g., fungal or intracellular parasitic infections), noninfective endocarditis, or improper collection of blood cultures. If nonbacterial or fastidious organisms are suspected, additional testing is essential. The choice of treatment regimen depends on patient history and risk factors.

► Other Organisms

Numerous bacteria, including gram-positive bacilli, unusual gram-negative bacteria, atypical bacteria, and anaerobes, as well as spirochetes, may cause IE, but these infections are rare.³² Some of the more common organisms include *Legionella*, *Coxiella burnetii* (Q fever), and *Brucella*. These rare organisms occur primarily in at-risk patients such as those who have a prosthetic valve or are IVDUs. A comprehensive discussion of these organisms is not feasible for this chapter; for further information, other references sources (particularly references 1 to 5) should be examined. Treatment of these organisms is difficult, and cure rates are low. Therefore, consulting an infectious diseases specialist is warranted.

► Fungi

Fungal endocarditis is quite uncommon but has significant mortality, typically affecting patients who have had cardiovascular surgery, received a prolonged course of broad-spectrum antibiotics, have long-term catheter placement, are immunocompromised, or are IVDUs.^{3,36,37} Survival rates have remained poor, at approximately 15%, but improvements (survival rates approximately 30%) have been reported owing to advances in diagnosis and treatment.³⁶ The poor prognosis has been attributed to large vegetations, propensity for organism invasion into the myocardium, extensive septic emboli, poor antifungal penetration into the vegetation, and low toxic-to-therapeutic ratio and lack of cidal activity of certain antifungals.^{33,36} The two most commonly associated organisms are *Candida* spp. and *Aspergillus* spp. Lack of clinical studies makes treatment decisions difficult. Typically, combination and/or high-dose therapy in conjunction with surgery is required.

TREATMENT

Therapeutic Considerations

Treatment of IE often is complicated and difficult. Numerous factors involving the vegetation influence the effectiveness of the antimicrobial agents. The vegetation consists of a fibrin matrix (as discussed earlier) that provides an environment where organisms are relatively free to replicate unimpeded, allowing the microbial density to reach very high concentrations (10^9 to 10^{10} CFU/g). Once the organism density has reached this level, the organisms are virtually in a static growth phase. These factors hinder host defenses, as well as the ability of antimicrobials to produce sufficient kill. This is seen often with β -lactams and glycopeptides because their effectiveness can be significantly affected by the bacterial inoculum.

5 Selection of an appropriate antimicrobial agent must combine characteristics such as the ability to penetrate into the vegetation, the ability to achieve adequate drug concentrations, and the ability to be minimally affected by high bacterial inoculum in order to achieve adequate kill rates.

6 To accomplish this, antimicrobials typically have to be given parenterally at high doses, with an extended treatment course of 4 to 6 weeks (in most cases). Other desirable drug characteristics include bactericidal and synergistic activity.

Empirical Therapy

7 The overall goal of therapy is to eradicate the infection and minimize/prevent any complications. Patients with suspected IE should be evaluated for risk factors that may provide some indication of the most likely organism causing the infection. If no risk factors can be determined, empirical therapy should primarily cover gram-positive organisms. Generally, if streptococci are suspected, empirical treatment should consist of penicillin plus gentamicin. However, if staphylococci or enterococci are suspected, empirical treatment should consist of vancomycin plus gentamicin. It is important to monitor the patient's response to therapy closely until cultures and susceptibilities are determined to ensure adequate treatment.

Specific Therapy

- The American Heart Association (AHA) has published guidelines for the management of IE, including specific treatment recommendations.⁵ A summary of these treatments for the most common organisms (streptococci, staphylococci, and enterococci) is provided in **Tables 74-3** through **74-6**. However, for more detailed information (including dosing, length of treatment, etc.) for these organisms or less common organisms, refer to the complete guidelines.⁵ These guidelines include primary and alternative regimens, as indicated in the treatment tables under strength of recommendation.

► Streptococci

Most isolates are highly susceptible to penicillin; therefore, penicillin G remains the regimen of choice. However, ceftriaxone may be used as an alternative agent if the patient is

Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH

- CAD s/p tricuspid valve replacement 2 years ago
- BPH s/p TUR of the prostate 21 days ago

FH

Mother had a history of CAD and died at the age of 70 from a heart attack; father died at 81 from prostate cancer

SH

Denies alcohol, illicit drugs, and smoking

Meds

- Simvastatin 80 mg daily
- Lisinopril 20 mg daily
- Warfarin 5 mg Monday through Friday, 7.5 mg Saturday and Sunday

Allergies: penicillin (patient reports hives)

ROS

Fatigue, decreased appetite

PE

- Vital signs: BP 174/90 mm Hg, P 105 beats/minute, RR 22 breaths/minute, T 39.0°C
- Cardiovascular: Tachycardia, positive new murmur
- Abdomen: Underweight, soft, nontender, nondistended; (+) bowel sounds

Labs

Within normal limits, except WBC = $18.6 \times 10^3/\mu\text{L}$ ($18.6 \times 10^9/\text{L}$)

Identify your empirical treatment recommendations for this patient.

What other information would be beneficial to obtain?

Patient Encounter, Part 3: Additional Laboratory and Diagnostic Tests

Blood cultures

All cultures are positive for gram-positive cocci in pairs and chains. *Enterococcus faecalis*.

Labs

Within normal limits.

Echo

0.7–1.2 cm vegetation on the tricuspid valve.

Given this additional information, are there any changes in your assessment of the patient?

How would you tailor your treatment based on these new data?

What would be your treatment goals, including length of treatment?

What other information would be beneficial to have?

or equal to 0.5 mcg/mL [0.5 mg/L]), treatment doses are increased, and 4 weeks of treatment is suggested. In addition, combination therapy with gentamicin is recommended during the first 2 weeks. In patients who are allergic or intolerant to either of the β -lactams, vancomycin is an alternative treatment option. Additionally, in patients with resistant strains of viridans group streptococci (MIC greater than 0.5 mcg/mL [0.5 mg/L]), treatment should employ antimicrobial agents for enterococcal IE (precise agents determined by the susceptibility report).

Patients with PVE caused by penicillin-susceptible strains of viridans streptococci require treatment for 6 weeks with penicillin G or ceftriaxone with or without gentamicin during the initial 2 weeks of therapy. However, if the organism demonstrates less susceptibility to penicillin (MIC greater than 0.12 mcg/mL [0.12 mg/L]), a combination therapy with penicillin G or ceftriaxone plus gentamicin should be given for the entire 6 weeks. Vancomycin remains the primary alternative if the patient is allergic to β -lactams (e.g., penicillins, cephalosporins).

► *Staphylococci*

It is important to determine (a) whether the isolate is methicillin-susceptible versus methicillin-resistant and (b) whether the patient has a native valve versus prosthetic valve. For patients with no prosthetic material, methicillin-susceptible staphylococci treatment should consist of a penicillinase-resistant penicillin (e.g., nafcillin or oxacillin) with or without gentamicin, and for methicillin-resistant strains, therapy should consist of vancomycin (see Table 74–4). Combination therapy with aminoglycosides, when used in these patients, typically is given only during the first 3 to 5 days of therapy to decrease the bacterial burden. In the absence of prosthetic material, some treatment guidelines do not recommend combination therapy against MRSA.

allergic or resistance is suspected to penicillin. Typically, the length of treatment is 4 weeks and remains the most common regimen. However, a shorter course (i.e., 2 weeks) may be employed for a patient with uncomplicated IE due to highly penicillin-susceptible strains with no extracardiac infection or whose creatinine clearance is greater than 20 mL/min (0.33 mL/s). If the shorter length of therapy is chosen, gentamicin should be added to the previous regimens for the entire course (i.e., 2 weeks). Recommended therapies for highly penicillin-susceptible viridans streptococci are summarized in Table 74–3.

When penicillin MICs for viridans group streptococci increase (greater than 0.12 mcg/mL [0.12 mg/L] but less than

However, many clinicians may combine either gentamicin or rifampin with vancomycin if the patient is unresponsive to monotherapy.

Increasing resistance of staphylococci necessitates the expanded use of alternative therapies. A clinical study demonstrated similar activity for daptomycin compared with

standard therapy (i.e., penicillinase-resistant penicillin for methicillin-sensitive *S. aureus* [MSSA] or vancomycin for MRSA) in staphylococcal IE.³⁸ Based on this study, the FDA has approved an indication of daptomycin for the treatment of right-sided IE or bacteremia caused by *S. aureus*. Recommended dosing for these indications are 6 mg/kg/day

(unless renal adjustments are necessary); although dosages of 8 to 10 mg/kg/day have been suggested in IE.^{38,39} This study, along with another retrospective study, reported daptomycin to be safe and well tolerated.^{38,40} Additionally, other antibiotics, such as ceftaroline, linezolid, quinupristin/dalfopristin and telavancin, or tigecycline alone or in combination, have been used in patients who were unresponsive to standard therapy, although they have had variable response rates.^{41–44} These

therapies often are reserved for patients who have been unresponsive to traditional therapy (e.g., β-lactams or vancomycin) or for organisms that remain susceptible to these agents when resistant to traditional therapy.

For staphylococcal PVE, treatment length increases significantly, typically requiring a minimum of 6 weeks (see Table 74–5). For MSSA, a penicillinase-resistant penicillin is still employed, as well as vancomycin for MRSA. However,

with either regimen, the addition of both gentamicin for first 2 weeks and rifampin for the entire length of treatment is recommended.

► **Enterococci**

For enterococci, it is imperative to determine species and antibiotic susceptibilities. If the organism is susceptible to penicillin and vancomycin, treatment may consist of high-dose penicillin G, ampicillin, or vancomycin plus an aminoglycoside (gentamicin [see Table 74–6] or streptomycin for gentamicin-resistant strains). Treatment length is usually 4 to 6 weeks, with the aminoglycoside used over the entire course. As resistance develops to penicillin, ampicillin and vancomycin remain treatment options. Once the isolate becomes resistant to ampicillin, vancomycin is considered the treatment of choice.

If the isolate is determined to be vancomycin-resistant, it is most important to know the exact species because some of the treatment options, such as quinupristin/dalfopristin, are not active against *E. faecalis*. Currently, the treatment options for vancomycin-resistant enterococci (VRE) are not well established by clinical studies or patient experience. The treatment recommendations for vancomycin-resistant *E. faecium* include linezolid or quinupristin/dalfopristin for a minimum of 8 weeks. However, newer agents, such as daptomycin, may provide another option for treatment for either enterococci species (*E. faecium* and *E. faecalis*). Additionally, guidelines suggest the use of imipenem/cilastatin plus ampicillin or ceftriaxone plus ampicillin for the treatment of *E. faecalis*, with a minimum of 8 weeks of therapy. Consultation with an infectious diseases specialist is recommended.

► **Gram-Negative Organisms**

Identification of the exact isolate is crucial in gram-negative IE because treatment decisions depend on which organism is isolated. Therapy is usually targeted to the most susceptible antibiotics. Combination therapy (usually the addition of an aminoglycoside) is commonly used. For example, *Pseudomonas* spp. are treated with an antipseudomonal (e.g., piperacillin/tazobactam, ceftazidime, imipenem/cilastatin) plus high-dose aminoglycoside (typically tobramycin 8 mg/kg/day). However, exact dosing of antibiotics depends on the organism isolated. Length of treatment is usually a minimum of 6 weeks.

► **HACEK Group**

The HACEK group is difficult to isolate, often taking weeks for identification. If one of these organisms is suspected (e.g., subacute disease, embolism, large vegetations), it is important to initiate appropriate empirical treatment. The preferred regimen is ceftriaxone (or another third- or fourth-generation cephalosporin), followed by ampicillin-sulbactam. However, for patients who are intolerant of these treatments, ciprofloxacin may be used. The length of treatment typically is 4 weeks for these organisms.

► **Culture-Negative**

Treatment for culture-negative IE presents a significant dilemma. Therapeutic regimens are guided by specific isolated organisms. When cultures fail to identify a specific organism, decisions regarding treatment should cover the most common causative organisms. If the patient is unresponsive to this initial treatment, then additional coverage for less common organisms is warranted. An infectious diseases specialist should be consulted for managing a patient with this type of infection.

► **Fungi**

Treatment of fungal IE is exceptionally difficult. There is a significant lack of studies to identify and recommend the most appropriate therapy. Currently, amphotericin B is the most common treatment. However, valve replacement surgery is often considered an adjunct therapy. IV antifungal therapy requires high doses for a minimum of 8 weeks of treatment. Oral azoles (e.g., fluconazole) are used as long-term suppressive therapy to prevent relapse. The exact role of some of the newer antifungals (e.g., voriconazole and caspofungin) is unknown, but they should provide a viable option.^{45,46}

Surgery

Surgical intervention has become an integral therapy in combination with pharmacologic management of IE. Valve replacement is the predominant intervention, and it is used in almost one-half of all cases of IE.¹ Surgery may be indicated if the patient has unresolved infection, ineffective antimicrobial therapy (often associated with fungal IE), more than one episode of serious emboli, refractory congestive heart failure, significant valvular dysfunction, a mycotic aneurysm requiring resection, local complications (perivalvular or myocardial abscesses), or a prosthetic-valve infection associated with a pathogen that demonstrates higher antimicrobial resistance (e.g., staphylococci, gram-negative organisms, and fungi).^{47,48} Often a patient's hemodynamic status (i.e., blood pressure, heart rate, pulmonary artery pressure, etc.) is used to determine when surgical intervention is warranted.¹ Despite appropriate medical management and cure, a significant number of people who develop native-valve endocarditis require valve replacement surgery. Involvement of the aorta or development of IE complications is considered an indication for surgery in the majority of patients with PVE.^{49,50}

Dosing Considerations

The majority of antibiotic and antifungal agents used for the treatment of IE require dosing modifications based on renal or hepatic function. However, the most closely monitored are vancomycin and aminoglycosides. This is due in part because (a) therapeutic levels are normally monitored, and (b) the increased likelihood of developing toxicities (i.e., nephrotoxicity) if the level is too high or adverse outcomes (i.e., clinical failure or resistance development) if level is too low.

Table 74-7

Dosage Considerations for Standard Antibiotics for Treatment of IE^a

Drug	Renal Adjustments	Hepatic Adjustments	Comments
Penicillin G	Required	None	Extension of dosing interval primarily used for adjustment
Ampicillin	Required	None	Seizures most common AE if dosing not adjusted
Nafcillin	None	Severe (see comment)	Adjustments necessary ONLY in patients with severe hepatic AND renal impairment
Oxacillin	Severe (see comment)	None	Adjustments for CrCl less than 10 mL/min (0.17 mL/s) to lower range of normal dose
Cefazolin	Required	None	Dose and/or dosing interval require adjustment. Based on patient's CrCl
Ceftriaxone	Severe (see comment)	None	Do not exceed 2 g/day if patient has BOTH severe renal AND hepatic impairment
Vancomycin	Required	None	Monitor therapeutic levels to guide dosage adjustments (see treatment guidelines for target ranges)
Gentamicin	Required	None	Used for synergy only with gram-positives. Therapeutic levels vary for gram-negative organisms Monitor therapeutic levels to guide dosage adjustments Synergy target levels: peak 3–4 mcg/mL (3–4 mg/L; 6.3–8.4 μmol/L) and trough less than 1 mcg/mL (1 mg/L; 2.1 μmol/L)
Rifampin	None	Required	Adjustment based on hepatic dysfunction
Newer and Salvage Drugs			
Ceftaroline	Required	None	Adjustments in dose (33–67% reduction) are based on patient's CrCl. Suggested dosages in off-label use for IE are higher than standard dosing (i.e., 600 mg every 8 hours).
Daptomycin	Required	None	Adjustment in dosing interval CrCl less than 30 mL/min (0.50 mL/s) CPK should be monitored prior to and during therapy
Linezolid	None	None	Metabolites may accumulate in severe renal impairment Monitor for hematologic AE Use in severe hepatic impairment not established
Quinupristin/dalfopristin	None	Possibly	Adjustments suggested based on pharmacokinetic data. However, no specific recommendations are described
Telavancin	Required	None	Decrease daily dose by 25% if CrCl 30–50 mL/min (0.50–0.83 mL/s) or if CrCl less than 30 mL/min (0.50 mL/s)—extend interval to every 48 hours
Tigecycline	None	Severe (see comment)	In severe hepatic impairment (Child-Pugh class C)—decrease maintenance dose 50%
Streptomycin	Required	None	Used for synergy only with gram-positives. Therapeutic levels vary for gram-negative organisms Monitor therapeutic levels to guide dosage adjustments Synergy target levels: peak 20–35 mcg/mL (20–35 mg/L; 34–60 μmol/L) and trough less than 10 mcg/mL (10 mg/L; 17 μmol/L)

AE, adverse event; CPK, creatinine phosphokinase; CrCl, creatinine clearance.

^aGram-negative bacteria, fungal, or atypical treatments are not listed. It is suggested that an Infectious Diseases Consult be obtained if a patient has IE caused by one of these organisms due to the complexity and difficulty in managing these patients.

General dosing considerations are included in [Table 74-7](#) for the most commonly used drugs for treating IE. However, specific dosing adjustments for individual patients should be determined by referring to an appropriate drug dosing reference.

Prophylaxis

8 Certain conditions have been associated more commonly with IE due to preexisting cardiac disease in the presence of

transient bacteremia. In an effort to prevent the development of IE, prophylactic treatment generally is considered appropriate for these at-risk patients. Although there are no well-controlled clinical studies of these recommendations, it is thought that if antibiotics are given just prior to a procedure, the number of bacteria may be decreased in the bloodstream and prevent the bacteria from adhering to the valves.

Cardiac conditions in which prophylaxis is reasonable include presence of prosthetic valves or material, prior IE,

Patient Encounter, Part 4: Additional Laboratory

Susceptibility Report: *Enterococcus faecalis*

Drug	Ampicillin	Vancomycin	Gentamicin	Streptomycin
			Synergy	Synergy
MIC (mg/L)	2	4	More than 500	Less than 1,000

Given this additional information, are there any changes in your assessment of the patient?

Do you need to adjust your treatment regimen based on these data?

Would your treatment goals, particularly length of treatment, change?

Patient Encounter, Part 5: Create a Care Plan

Based on this patient's information, create a care plan for the management of his IE. Be sure to include:

(a) A statement regarding treatment requirements and/or possible problems

(b) Goals of therapy

(c) A patient-specific plan, including preventive plans

(d) A follow-up plan to assess whether the goals have been met and to determine whether the patient experienced any adverse effects

congenital cardiac disease (specific forms only), and cardiac transplant patients with cardiac valvulopathy (Table 74-8).⁷ Although many patients have other cardiac dysfunction, only patients with these conditions are considered to be at a high

Table 74-8

Cardiac Conditions Associated With the Highest Risk of Adverse Outcome From Endocarditis for Which Prophylaxis With Dental Procedures Is Reasonable^a

Prosthetic cardiac valve or prosthetic material used for cardiac-valve repair

Previous IE

Congenital heart disease^b

Unrepaired cyanotic congenital heart disease, including palliative shunts and conduits

Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure^c

Repaired congenital heart disease with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)

Cardiac transplantation recipients who develop cardiac valvulopathy

^aAll dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa is reasonable to give prophylaxis in the patient conditions listed above.

^bExcept for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD.

^cProphylaxis is reasonable because endothelialization of prosthetic material occurs within 6 months after the procedure.

risk of developing IE. No prophylaxis is advised in other patients.

Transient bacteria may occur due to many types of dental and surgical procedures. However, the AHA has recently published new guidelines significantly limiting the types of procedures where prophylaxis is appropriate. Only dental procedures involving manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa are considered to increase the likelihood that high-risk patients will develop IE.⁷ Viridans group streptococci are the primary bacteria targeted for prophylaxis in this circumstance. On the other hand, prophylaxis for GI or genitourinary surgeries primarily targets enterococci.

The AHA guidelines include suggested antibiotic regimens for dental procedures for which prophylaxis is warranted.⁷ Recommended regimens for dental procedures are listed in Table 74-9. These guidelines recommend a single oral or intramuscular/IV dose initiated shortly before the procedure. The regimen for dental procedures consists primarily of a penicillin as first choice, with a cephalosporin for nonanaphylactic penicillin-allergic patients and clindamycin or a macrolide for penicillin-allergic patients. A second prophylactic dose is not recommended. However, if an infection develops at the procedure site, additional antibiotics (i.e., a therapeutic course) may be required.

OUTCOME EVALUATION

Monitoring for successful therapy is critical in this serious infection to prevent complications, prevent resistance development, and decrease mortality. Routine assessment of clinical signs and symptoms, as well as laboratory tests (i.e., repeat blood cultures), microbiologic testing, and serum drug concentrations (if appropriate), must be performed.

Resolution of signs and symptoms typically occurs within a few days to a week in most cases. Monitor the patient daily for febrile episodes, as well as other vital signs, with expected normal values within 2 to 3 days of initiating antimicrobial

Table 74–9

Prophylactic Regimens for Dental Procedure

Situation	Agent	Regimen: Single Dose 30–60 Minutes Before Procedure	
		Adults	Children
Oral	Amoxicillin	2 g	50 mg/kg
Unable to take oral medications	Ampicillin or Cefazolin or Ceftriaxone	2 g IM or IV	50 mg/kg IM or IV
Allergic to penicillins or ampicillin—oral	Cephalexin ^{a,b} or Clindamycin or Azithromycin or Clarithromycin	2 g 600 mg 500 mg	50 mg/kg 20 mg/kg 15 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medications	Cefazolin or Ceftriaxone ^b or Clindamycin	1g IM or IV 600 mg IM or IV	50 mg/kg IM or IV 20 mg/kg IM or IV

IM, intramuscular.

^aOr other first- or second-generation oral cephalosporin in equivalent adult or pediatric dosage.

^bCephalosporins should not be used in an individual with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin.

therapy.⁴ Persistent signs or symptoms could be indicative of inadequate treatment or development of resistance.

Blood cultures are the primary laboratory evaluation to assess response to therapy. Typically, with appropriate treatment, they should become negative within 3 to 7 days. Use subsequent blood cultures if the patient appears not to be responding to therapy or on completing treatment to confirm eradication of infection. Evaluate all susceptibility reports to assess antimicrobial therapy.

Additionally, the patient needs to be counseled on the necessity of prophylactic antibiotics prior to major dental treatments (in appropriate patients) in order to prevent recurrent infections. This is critical in patients with risk factors that predispose them to developing IE, such as prosthetic heart valves, other valvular defects, or previous IE.

Develop a follow-up plan to determine whether the patient has achieved a cure, which includes a clinical evaluation of signs/symptoms, repeat blood cultures, and possibly a repeat echocardiogram. The patient should also be assessed for any adverse events. This should be performed usually within a few weeks after the completion of therapy.

9 Patient Care and Monitoring

1. Assess the patient's symptoms and/or laboratory results to determine whether the empirical therapy is effective. Is the patient's fever resolving? Is the patient's WBC decreasing?
2. Review available microbiologic cultures and sensitivity to assess whether the initial antimicrobial regimen needs to be tailored?
3. Review any additional diagnostic tests to determine if treatment may be needed to prevent/minimize complications (e.g., emboli, congestive heart failure).
4. Evaluate therapeutic serum drug concentrations as appropriate (e.g., vancomycin and gentamicin).
5. Monitor serum creatinine in order to make appropriate renal adjustments of the antimicrobials as necessary.
6. Assess any repeat blood cultures and vital signs to determine continued treatment effectiveness.
7. Evaluate the patient for occurrence of any adverse drug reactions and possible drug allergies and/or drug interactions.
8. Develop a plan if the patient is going to continue therapy at home. Once defervescence has occurred, the patient may complete therapy outside the hospital by receiving the antimicrobials from an outpatient infusion center or through a home health agency.
9. Develop a follow-up plan to assess the resolution of infection once the patient has completed therapy. Assessment of any adverse events also should be conducted at this time.
10. Educate high-risk patients on the importance of taking prophylactic antibiotics prior to having certain dental procedures in an effort to prevent the future development of another infection. Stress the potential complications as well as the morbidity and mortality that are associated with IE and that taking precautions can minimize or prevent them.

Abbreviations Introduced in This Chapter

AHA	American Heart Association
CFU	Colony-forming units
CNS	Coagulase-negative staphylococci
ESR	Erythrocyte sedimentation rate
HACEK	Group of bacteria consisting of <i>Haemophilus</i> spp., <i>Actinobacillus actinomycetemcomitans</i> , <i>Cardiobacterium hominis</i> , <i>Eikenella corrodens</i> , and <i>Kingella kingae</i>
IE	Infective endocarditis

IVDUs	Intravenous drug users
MIC	Minimum inhibitory concentration
MRSA	Methicillin-resistant <i>S. aureus</i>
MSSA	Methicillin-sensitive <i>S. aureus</i>
NBTE	Nonbacterial thrombotic endocarditis
PVE	Prosthetic-valve endocarditis
TEE	Transesophageal echocardiogram
TTE	Transthoracic echocardiogram
VRE	Vancomycin-resistant enterococci

Tuberculosis

Charles Peloquin and Rocsanna Namdar

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Compare the risk for active tuberculosis (TB) disease among patients based on their age, immune status, place of birth, and time since exposure to an active case.
2. Design an appropriate therapeutic plan for an immunocompetent, immunocompromised, pregnant, and pediatric patient with pulmonary TB.
3. Distinguish between the diagnostic tests used for patients potentially infected with tuberculosis.
4. Assess the effectiveness of therapy in TB patients.
5. Describe the common and important adverse drug effects caused by TB drugs.
6. Select patients for whom therapeutic drug monitoring (TDM) may be valuable and identify the necessary laboratory monitoring parameters for patients on antituberculosis medications.
7. Design appropriate antimicrobial regimens for the treatment of **latent TB infection** (LTBI) in all patient populations.

KEY CONCEPTS

- 1 Tuberculosis (TB) is the most prevalent communicable infectious disease on earth and remains out of control in many developing nations. These nations require medical and financial assistance from developed nations in order to control the spread of TB globally.
- 2 In the United States, TB disproportionately affects ethnic minorities as compared with whites, reflecting greater ongoing transmission in ethnic minority communities. Additional TB surveillance and preventive treatment are required within these communities.
- 3 Coinfection with HIV and TB accelerates the progression of both diseases, thus requiring rapid diagnosis and treatment of both diseases.
- 4 Mycobacteria are slow-growing organisms; in the laboratory, they require special stains, special growth media, and long periods of incubation to isolate and identify.
- 5 TB can produce atypical signs and symptoms in infants, the elderly, and immunocompromised hosts, and it can progress rapidly in these patients.
- 6 Latent tuberculosis infection (LTBI) can lead to reactivation disease years after the primary infection occurred.
- 7 The patient suspected of having active TB disease must be isolated until the diagnosis is confirmed and he or she is no longer contagious. Often, isolation takes place in specialized “negative pressure” hospital rooms to prevent the spread of TB.
- 8 Isoniazid and rifampin are the two most important drugs to treat TB; organisms resistant to both these drugs (multidrug-resistant tuberculosis [MDR-TB]) are much more difficult to treat.
- 9 Never add only a single antituberculosis drug to a failing regimen for active TB!
- 10 **Directly observed therapy** (DOT) should be used whenever possible to reduce treatment failures and the selection of drug-resistant isolates.

INTRODUCTION

Worldwide, tuberculosis (TB) kills about 1.5 million people each year, more than any other infectious organism. TB is caused by *Mycobacterium tuberculosis*, and it presents either as latent TB infection (LTBI) or as progressive active disease.¹ The latter typically causes progressive destruction of the lungs, leading to death in most patients who do not receive treatment. Currently, one-third of the world’s population is infected, and drug resistance is increasing in many areas.¹

EPIDEMIOLOGY

1 Roughly one of every three people on earth is infected by *Mycobacterium tuberculosis*.¹⁻³ The distribution is uneven, with the highest incidences found in southern Asia and sub-Saharan Africa. In the United States, about 13 million people have LTBI, evidenced by a positive skin test (**purified protein derivative** (PPD)) but no signs or symptoms of disease. Such patients have roughly a one in 10 chance of active disease during their lives, with the greatest risk in the first 2 years after infection. In 2010, about 11,182 TB cases were reported in the United States; a 3.1% decline from 2009.

The most recent data from the Centers for Disease Control and Prevention (CDC) indicate that TB deaths in the United States have decreased by 7%, from 590 deaths in 2008 to 547 deaths in 2009.⁴ (For details, visit the CDC website at www.cdc.gov/nchstp/tb.)

Risk Factors for Infection

► Location and Place of Birth

California, New York, Florida, and Texas accounted for 50% of all TB cases in 2011, reflecting the high immigration rates into these states.⁴ Mexico, the Philippines, Vietnam, India, and China account for the largest numbers of these immigrants.⁴ TB is most prevalent in large urban areas and is exacerbated by crowding in poor immigrant neighborhoods.^{3,4} Those in close contact with patients with active pulmonary TB are most likely to become infected.^{2,3} These include family members, coworkers, or co-residents in places such as prisons, shelters, and nursing homes.

► Race, Ethnicity, Age, and Gender

2 In the United States, the incidence of TB is more concentrated in nonwhite individuals. In 2010, Hispanics accounted for 29% of new TB cases, followed by Asians (28%) and non-Hispanic blacks (24%), whereas non-Hispanic whites accounted for only 16% of new TB cases.⁵ TB is most common among people 25 to 44 years of age (33% of all cases), followed by those 45 to 64 years of age (31%) and 65 or more years of age (20%).⁵

► Coinfection with HIV

3 HIV is the most important risk factor for active TB because the immune deficit prevents patients from containing the initial infection.^{2,3,5,6} In 2010, data on HIV status was available in approximately 70% of reported TB cases. Based on this information, roughly 9% of TB patients ages 25 to 44 years are coinfecting with HIV.^{4,5} Consistent with HIV in general, HIV-associated TB is most common among 25- to 44-year-olds. Substance abuse and other risk factors are shared among some TB and HIV-infected individuals, promoting the spread of both diseases.^{2,7}

Risk Factors for Disease

Once infected with *M. tuberculosis*, a person's lifetime risk of active TB is about 10%, with about half this risk evident during the first 2 years after infection.^{2,3,6} Young children, the elderly, and immunocompromised patients have greater risks. HIV-infected patients with *M. tuberculosis* infection

are roughly 100 times more likely to develop active TB than normal hosts due to the lack of normal cellular immunity.^{3,8,9}

ETIOLOGY

4 Microscopic examination of infected material ("smear") detects about 8 to 10×10^3 organisms/mm³ (8 to 10×10^9 /L) of specimen using the older AFB (acid-fast bacillus) stain. The newer auramine-rhodamine fluorescent technique is one-third more sensitive. A smear-negative patient still can grow *M. tuberculosis* on culture, which is more sensitive than either staining technique. Unfortunately, culture is much slower than staining due to the roughly 20-hour doubling time of the bacilli. Further, microscopic examination cannot determine which of over 90 mycobacterial species is present. The usual practice is to assume the worst (TB) until confirmed by genetic probe or positive culture.

Culture and Susceptibility Testing

Susceptibility testing is essential for directing proper treatment. The most common agar method, known as the *proportion method*, takes many weeks to produce results. The recently discontinued BACTEC and newer mycobacterial growth indicator tube (MGIT) systems use liquid media and detect live

Patient Encounter, Part 1

HPI: AF is a 56-year-old HIV-positive man who presents to the medical clinic complaining of a 1-month history of a persistent cough that has become productive over the past 2 weeks. He also complains of malaise and a 6-kg (13-lb) weight loss over the past 2 months.

PMH: HIV positive; last CD4⁺ 28% (0.28); type 2 diabetes mellitus (NIDDM)—well controlled; hypertension (HTN) × 5 years—well controlled

FH: Mother and father died in an MVA 10 years ago; one brother, age 54, lives with the patient; one sister, age 50, is alive and has had breast cancer

SH: Single, one daughter. He reports IV drug use but last use was 20 years ago. He had a 20-year history of alcohol abuse but has been sober for 10 years. He owns his own import/export business and travels internationally.

Meds: Atripla (emtricitabine, efavirenz, tenofovir) 1 tablet daily; lisinopril 20 mg daily; amlodipine 5 mg daily; metformin 500 mg twice daily. Patient reports that he tries to be compliant with his therapies and takes them regularly except when he is unable to get his refills; over the past 2 months, he has only gone 3 to 4 days without medication.

What information is suggestive of TB?

What factors place this patient at increased risk for acquiring TB?

mycobacteria in about 2 weeks.^{1,10,11} Rapid-identification tests include nucleic acid probes and DNA fingerprinting using restriction fragment length polymorphism (RFLP) analysis, and polymerase chain reaction (PCR).^{1,6,10,12–15} The Hain (pronounced “Hine”) GenoType® MTBDR plus test, a new and improved molecular test for multidrug-resistant tuberculosis (MDR-TB), has been approved in Europe.¹⁴ The Cepheid MTB/RIF Assay performed on the GeneXpert® System is a qualitative test designed for rapid detection of *M. tuberculosis* and rifampicin resistance.¹⁵ New tests looking for specific mutations such as the *katG* gene associated with isoniazid resistance may facilitate rapid drug therapy decisions in the future. Nitrate reductase assays and porous ceramic support systems are among other rapid drug susceptibility testing techniques currently being investigated.¹⁶

PATHOPHYSIOLOGY

Primary Infection

M. tuberculosis is transmitted from person to person by coughing or sneezing.^{2,6,17,18} This produces small particles known as *droplet nuclei* that float in the air for long periods of time. Primary infection usually results from inhaling droplet nuclei that contain *M. tuberculosis*.^{2,6,17} The progression to clinical disease depends on three factors: (1) the number of *M. tuberculosis* organisms inhaled (infecting dose), (2) the virulence of these organisms, and (3) the host’s cell-mediated immune response.^{2,4,6,12,18,19} If pulmonary macrophages inhibit or kill the bacilli, the infection is aborted.¹⁸ If not, *M. tuberculosis* eventually spreads throughout the body through the bloodstream.^{2,6,18} *M. tuberculosis* most commonly infects the posterior apical region of the lungs, where conditions are most favorable for its survival.

T lymphocytes become activated over the course of 3 to 4 weeks, producing interferon- γ (IFN- γ) and other cytokines. These stimulate microbicidal macrophages to surround the tuberculous foci and form granulomas to prevent further extension.¹⁸ At this point, the infection is largely under control, and bacillary replication falls off dramatically. Any remaining mycobacteria are believed to reside primarily within granulomas or within macrophages that have avoided detection and lysis. Over 1 to 3 months, tissue hypersensitivity occurs, resulting in a positive tuberculin skin test.^{2,6,17}

5 *Progressive primary disease* occurs in roughly 5% of patients, especially children, the elderly, and immunocompromised patients.^{20,21} This presents as a progressive pneumonia and frequently spreads, leading to meningitis and other severe forms of TB, even before patient skin tests become positive.²⁰

Reactivation Disease

6 About 10% of infected patients develop reactivation TB, with half occurring in the first 2 years after infection.^{2,6,12} Upper lobe pulmonary disease is the most common (85% of cases).² *Caseating granulomas* result from the vigorous immune response, and liquefaction leads to local spread. Eventually, a pulmonary cavity results, and this provides a

portal to the outside that allows for person-to-person spread. Bacterial counts in the cavities can be as high as 10^8 /mL (10^{11} /L) of cavitory fluid.^{2,18} Prior to the chemotherapy era, pulmonary TB usually was associated with hypoxia, respiratory acidosis, and eventually death.

Extrapulmonary and Miliary Tuberculosis

Caseating granulomas, regardless of location, can undergo liquefaction, spread tubercle bacilli, and cause symptoms.^{2,6} Because of muted or altered symptoms, the diagnosis of TB is difficult and often delayed in immunocompromised hosts.^{2,3,6} HIV-infected patients may present with only extrapulmonary TB, which is uncommon in HIV-negative persons. A widely disseminated form of the disease called *miliary TB* can occur, particularly in children and immunocompromised hosts, and it can be rapidly fatal.¹⁷ Immediate treatment is required.

Influence of HIV Infection on Pathogenesis

HIV infection is the most important risk factor for active TB.^{2,6,17} As CD4⁺ lymphocytes multiply in response to the mycobacterial infection, HIV multiplies within these cells and selectively destroys them, gradually eliminating the TB-fighting lymphocytes.¹⁷ Patients coinfecting with HIV and TB have a substantially higher risk of early mortality compared with HIV-negative patients with TB. Approximately 5% of HIV-infected patients with pulmonary TB will have positive results on acid-fast staining yet have a normal chest radiograph.

CLINICAL PRESENTATION AND DIAGNOSIS

Fever, night sweats, weight loss, fatigue, and a productive cough are the classic symptoms of TB.^{1,2,6,19} Onset may be gradual, and the diagnosis is easily missed if the symptoms are muted, such as in the elderly.^{2,6,19} Progressive pulmonary disease leads to cavitation visible on x-ray. Physical examination is nonspecific but may be consistent with pneumonia. Dullness to chest percussion, rales, and increased vocal **fremitus** may be observed on examination. Laboratory data often are uninformative, but a modest increase in the white blood cell (WBC) count with a lymphocyte predominance can be seen.

Atypical presentations are common in patients coinfecting with HIV.^{1,2,6,19,24,25} HIV-positive patients often have negative skin tests and fail to produce **cavitary lesions**, and fever may be absent.^{22,23} Symptoms for these patients range from classic pulmonary to muted and nonspecific. Extrapulmonary TB typically presents as a slowly progressive decline in organ function, and lymphadenopathy is relatively common.^{26,18,19} Abnormal behavior, headaches, or convulsions suggest tuberculous meningitis, although other acute CNS infections must be excluded.^{6,19}

The Elderly

5 Many clinical findings are muted in the elderly or absent altogether, so there can be considerable diagnostic uncertainty.

Positive skin tests, fevers, night sweats, sputum production, or hemoptysis may be absent, making TB hard to distinguish from other bacterial or viral infections or chronic lung diseases.^{2,19,26,27}

In contrast, mental status changes are twice as common in the elderly, and CNS disease must be considered when TB is entertained. Mortality is six times higher in the elderly in part owing to delays in diagnosis.^{2,19,26} Ethnic distributions of disease are different in the elderly and include more white patients because these patients often were infected decades ago, when TB was more prevalent in the United States.

Children

5 Because children less than 5 years old have immature cellular immunity, TB can be particularly dangerous in this population. TB in children may present as atypical bacterial pneumonia, called progressive primary TB, and often involves the lower and middle lobes.^{17,19–21} Extrapulmonary TB is more common in children; dissemination is fairly common to the lymph nodes, GI and genitourinary tracts, bone marrow, and meninges. For these reasons, **Bacille Calmette-Guérin** (BCG) vaccinations are administered in countries where TB remains common. BCG appears to stimulate children's immune systems just enough to ward off the most serious forms of the disease. However, BCG does not block infection, and these same children often experience reactivation TB as young adults. Because cavitory lung lesions are uncommon, children do not spread TB readily. From the public health perspective, pediatric TB is the clearest indication of recent spread of TB.

Skin Testing

TB skin testing with the 5-TU strength of Tubersol PPD, also known as the *Mantoux test*, is a method for skin testing.^{2,19,22} The product is injected into the skin (not subcutaneously) with a fine (27-gauge) needle and produces a small, raised, blanched wheal to be read by an experienced professional in

48 to 72 hours. Criteria for interpretation are listed in **Table 75–1**.^{1,2,6,19,22} The chance of a false-negative result is increased when the patient is immunosuppressed.

The CDC does not recommend the routine use of anergy panels.^{22,28} The “booster effect” occurs in patients who do not respond to an initial skin test but show a positive reaction if retested 1 to 3 weeks later.^{19,28} In order to reduce the likelihood that a boosted reaction is misinterpreted as a new infection, the two-step method is recommended at the time of initial testing for individuals such as healthcare workers or nursing home residents who may be tested periodically. If the first PPD skin test is negative, repeat the test in 1 to 3 weeks. If the second test is positive, it is most likely a boosted reaction, and the person should be classified as previously infected.

Newer Diagnostic Tests

The sensitivity and specificity of the PPD tests are estimated to be 71% and 66%, respectively. Newer technology has led to the development of blood tests or interferon- γ release assays (IGRAs) that may replace the PPD test.^{28–33} These methods measure the release of interferon- γ in blood in response to TB antigens. The sensitivity of IGRAs ranges from 76% to 90%, and specificity ranges from 92% to 97%. The IGRAs do not cause the booster phenomenon and are unaffected by BCG, or infection by most nontuberculosis mycobacteria. Results of the IGRAs are available in less than 24 hours, versus the 3 days required for the traditional PPD skin test. Data are limited for use of IGRAs in children younger than 5 years of age, persons recently exposed to TB, healthcare workers, and immunodeficient patients.²⁸ The CDC has concurred with the use of these tests in all circumstances in which the PPD is currently used. IGRAs are approved for the diagnosis of LTBI in HIV-infected patients, but they are not recommended for the diagnosis of active TB in HIV-infected persons.²⁸ As seen with the PPD test, there is a theoretical concern that the sensitivity of the IGRA test may be lower in patients with advanced immunodeficiency.

Table 75–1

Criteria for Tuberculin Positivity, by Risk Group

Reaction Greater Than or Equal to 5 mm of Induration	Reaction Greater Than or Equal to 10 mm of Induration	Reaction Greater Than or Equal to 15 mm of Induration
HIV-positive persons	Recent immigrants (i.e., within the last 5 years) from high-prevalence countries	Persons with no risk factors for TB
Patients with TB	Injection drug users	
Fibrotic changes on chest radiograph consistent with prior TB	Residents and employees ^a of the following high-risk congregate settings: prisons and jails, nursing homes and other long-term facilities for the elderly, hospitals and other healthcare facilities, residential facilities for patients with AIDS, and homeless shelters	
Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of 15 mg/d or more of prednisone for 1 month or more) ^b	Mycobacteriology laboratory personnel, persons with the following clinical conditions that place them at high risk: silicosis, diabetes mellitus, chronic renal failure, some hematologic disorders, other specific malignancies, gastrectomy, and jejunioileal bypass	
	Children younger than 4 years of age or infants, children, and adolescents exposed to adults at high risk	

^aFor persons who are otherwise at low risk and are tested at the start of employment, a reaction of 15 mm or more of induration is considered positive.

^bRisk of TB in patients treated with corticosteroids increases with higher dose and longer duration.

IGRAs are preferred for testing patients who have received BCG and in patients who have poor rates of return for PPD skin test reading. Testing with both PPD and IGRA generally is not recommended, but may be useful in certain situations (e.g., if the initial PPD test is negative and the risk for infection, clinical suspicion, or the risk for poor outcome is high; or if the initial PPD test is positive and additional evidence of

infection is required; or the patient has a low risk of infection or progression).^{31–33}

Additional Tests

Morning sputum collections have the highest yield of organisms.^{2,10,19} Daily sputum collections over 3 consecutive

CXR: Bilateral upper lobe infiltrates with cavitation on left; small left pneumothorax

Clinical Course: The patient was admitted and placed on respiratory isolation. Three separate sputum AFB stain specimens were reported to contain 3+ AFB. IFGA was sent and a PPD tuberculin skin test was placed. Sputum samples were sent for AFB, fungi, and bacterial cultures and sensitivities. After 48 hours, the PPD skin test was read as a 5-mm area of induration

Assessment: Active pulmonary TB in an HIV-positive patient; pneumothorax; HTN; type 2 diabetes mellitus

Which signs, symptoms, and other findings are consistent with active TB infection?

days improve the yield of positive results. Sputum induction with aerosolized hypertonic saline may produce a diagnostic sample in patients unable to produce sputum. Bronchoscopy or aspiration of gastric fluid via a nasogastric tube may be attempted in selected patients, the latter being used more often in children.¹⁹ For patients with suspected extrapulmonary TB, samples of draining fluid, biopsies of the infected site, or both may be attempted. Blood cultures are positive occasionally, especially in AIDS patients who have low CD4⁺ counts.^{19,25,29}

Advances in TB diagnosis include methods for rapid identification of patients with suspected TB. Improved smear microscopy, automated liquid cultures, nucleic acid amplification tests, antibody detection tests, and antigen detection tests are under development.³⁰ The Hain and the Cepheid tests, described earlier, are for the rapid identification of certain types of drug resistance.^{14,15}

TREATMENT

General Approaches to Treatment

Monotherapy can be used only for infected patients who do not have active TB (LTBI, as shown by a positive skin test or IGRA in the absence of signs or symptoms of disease). Once active disease is present, a minimum of two drugs and typically *three or four drugs* must be used simultaneously from the outset of treatment.^{2,6,12,34} For most patients, the shortest duration of treatment is 6 months, and 2 to 3 years of treatment may be necessary for advanced cases of MDR-TB.^{2,6,12,34} Directly observed treatment (DOT) is a method used to ensure compliance in which patients are directly observed by a healthcare worker while taking their antituberculosis medication.³⁵ This is also a cost-effective way to ensure completion of treatment.^{2,6,12,34–36}

Nonpharmacologic Therapy

7 Steps should be taken to (a) prevent the spread of TB (respiratory isolation); (b) find where TB has already spread (contact investigation); and (c) return the patient to a state of normal weight and well-being. The older term for TB is *consumption* because wasting was a primary symptom of disease progression in the prechemotherapy era and remains descriptive today. Items (a) and (b) are performed by public health departments. Clinicians involved in the treatment of TB should verify that the local health department has been notified of all new cases of TB. Surgery may be needed to remove destroyed lung tissue, space-occupying infected lesions (tuberculomas), and certain extrapulmonary lesions.^{2,12,34}

Pharmacologic Therapy

► Treating LTBI

Isoniazid is used for treating LTBI.^{2,6,12,34} Typically, isoniazid 300 mg daily (5–10 mg/kg of body weight) is given alone for 9 months. Lower doses usually are less effective.^{2,37} The treatment of LTBI reduces a person's lifetime risk of active TB from about 10% to about 1%.²² Rifampin 600 mg daily for 4 months can be used when isoniazid resistance is suspected or when

the patient cannot tolerate isoniazid.^{2,21,37,38} Rifabutin 300 mg daily might be substituted for rifampin in patients at high risk of drug interactions. The combination of pyrazinamide and rifampin is no longer recommended because of unacceptable rates of hepatotoxicity.³⁹ Recently, 12 directly observed, once-weekly doses of isoniazid 900 mg and rifapentine 900 mg were shown to be as effective as 9 months of self-administered isoniazid 300 mg daily.⁴⁰ When resistance to isoniazid and rifampin is suspected in the isolate causing infection, there is no regimen proven to be effective.³⁴ (Table 75–2). Note that patients with LTBI are not expelling organisms, so there is no isolate on which to perform susceptibility testing. Susceptibility patterns must be inferred based on the most likely source of infection. This is in contrast to active disease, described next.

► Treating Active Disease

In the United States, all patients diagnosed with TB can receive treatment free of charge through the local health department, and this is encouraged because local health departments generally have the greatest expertise. Treating active TB disease requires combination chemotherapy. Generally, *four drugs* are given at the onset of treatment. **8** *Isoniazid and rifampin should be used together for most cases because they are the best drugs for preventing drug resistance.*^{2,6,34,40,41} Drug susceptibility testing should be done on the initial isolate for all patients with active TB and should be used to guide the selection of drugs over the course of treatment.^{2,6,12,34} Susceptibility testing may be repeated in cases where the patient remains culture-positive 8 weeks or more into therapy.

8 *The standard TB treatment regimen is isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months, followed by isoniazid and rifampin for 4 months, for a total of 6 months of treatment.*^{2,12,34} *Extending treatment to 9 months of isoniazid and rifampin treatment is recommended for patients at greater risk of failure and relapse, including those with cavitation on initial chest radiograph or positive cultures at the completion of the initial 2-month phase of treatment, as well as for patients treated initially without pyrazinamide. Treatment should be continued for at least 6 months from the time that patients convert to a negative smear and culture.*^{2,6,12,34} Some authors recommend therapeutic drug monitoring (TDM) for such patients because one of the proven reasons for treatment failure is malabsorption of orally administered drugs.^{2,34,41,42} Table 75–3 shows the recommended treatment regimens for TB. When intermittent therapy is used, DOT is essential. Doses missed during an intermittent TB regimen decrease the efficacy of the regimen and increase the relapse rate. Further, outcomes appear to be worse for immunocompromised patients when intermittent treatment, especially twice-weekly treatment, is used. Therefore, HIV-positive TB patients should receive TB drugs daily during the first 2 months of treatment, and at least three times weekly thereafter.⁴³ When the patients' **sputum smears** convert to negative, the risk of them infecting others is greatly reduced, but it is not zero.^{2,15,34} Such patients can be removed from respiratory isolation, but they must be careful not to cough on others and should meet only in well-ventilated places.

Table 75-2

Recommended Drug Regimens for Treatment of LTBI in Adults

Drug	Interval and Duration	Comments	Rating ^a HIV-	Evidence HIV+
Isoniazid	Daily for 9 months ^{c,d}	In HIV-infected patients, isoniazid may be administered concurrently with nucleoside reverse transcriptase inhibitors (NRTIs), protease inhibitors, or non-NRTIs (NNRTIs)	A (II)	A (II)
	Twice weekly for 9 months ^{c,d}	Directly observed treatment (DOT) must be used with twice-weekly dosing	B (II)	B (II)
Isoniazid	Daily for 6 months ^d	Not indicated for HIV-infected persons, those with fibrotic lesions on chest radiographs, or children	B (I)	C (I)
	Twice weekly for 6 months ^d	DOT must be used with twice-weekly dosing	B (II)	C (I)
Rifampin	Daily for 4 months	For persons who are contacts of patients with isoniazid-resistant rifampin-susceptible TB In HIV-infected patients, protease inhibitors or NNRTIs generally should not be administered concurrently with rifampin; rifabutin can be used as an alternative for patients treated with indinavir, nelfinavir, amprenavir, ritonavir, or efavirenz, and possibly with nevirapine or soft-gel saquinavir ^e	B (II)	B (III)

^aStrength of recommendation: A = preferred; B = acceptable alternative; C = offer when A and B cannot be given.

^bQuality of evidence: I = randomized clinical trial data; II = data from clinical trials that are not randomized or were conducted in other populations; III = expert opinion.

^cRecommended regimen for children younger than 18 years.

^dRecommended regimens for pregnant women. Some experts would use rifampin and pyrazinamide for 2 months as an alternative regimen in HIV-infected pregnant women, although pyrazinamide should be avoided during the first trimester.

^eRifabutin should not be used with hard-gel saquinavir or delavirdine. When used with other protease inhibitors or NNRTIs, dose adjustment of rifabutin may be required.

Table 75-3

Drug Regimens for Culture-Positive Pulmonary Tuberculosis Caused by Drug-Susceptible Organisms

Regimen	Initial Phase		Continuation Phase		
	Drugs	Interval and Doses ^a (Minimal Duration)	Drugs	Interval and Doses ^{a,b} (Minimal Duration)	Range of Minimal Doses (mg)
1	Isoniazid	7 days/wk for 56 doses (8 weeks) or 5 days/wk for 40 doses (8 weeks) ^c	Isoniazid/Rifampin	7 days/wk for 126 doses (18 weeks) or 5 days/wk for 90 doses (18 weeks) ^c	182-130 (26 weeks)
	Rifampin		Isoniazid/Rifampin		
	Pyrazinamide		Isoniazid/Rifapentine		
	Ethambutol		Twice weekly for 36 doses (18 weeks)	92-76 (26 weeks) ^d	
			Once weekly for 18 doses (18 weeks)	74-58 (26 weeks)	
2	Isoniazid	7 days/wk for 14 doses (2 weeks) ^c , then twice weekly for 12 doses (6 weeks) or 5 days/wk for 10 doses (2 weeks), then twice weekly for 12 doses (6 weeks)	Isoniazid/Rifampin	Twice weekly for 36 doses (18 weeks)	62-58 (26 weeks) ^d
	Rifampin		Isoniazid/Rifapentine		
	Pyrazinamide				
	Ethambutol		Once weekly for 18 doses (18 weeks)	44-40 (26 weeks)	
3	Isoniazid	3 × weekly for 24 doses (8 weeks)	Isoniazid/Rifampin	3 × weekly for 54 doses (18 weeks)	78 (26 weeks)
Rifampin					
Pyrazinamide					
	Ethambutol				
4	Isoniazid	7 days/wk for 56 doses (8 weeks) or 5 days/wk for 40 doses (8 weeks) ^c	Isoniazid/Rifampin	7 days/wk for 217 doses (31 weeks) or 5 days/wk for 155 doses (31 weeks) ^c	273-195 (39 weeks)
	Rifampin				
	Ethambutol				
			Isoniazid/Rifampin	Twice weekly for 62 doses (31 weeks)	118-102 (39 weeks)

Adjustments to the regimen should be made once the susceptibility data are available.^{2,12,34} Drug resistance should be expected in patients who have been treated previously for TB. Two or more drugs with in vitro activity against the patient's isolate and that were not used previously should be added to the regimen as needed.^{2,12,34} When isoniazid and rifampin cannot be used, treatment durations typically become 2 years or more, regardless of immune status.^{2,12,34,41} TB specialists should be consulted regarding cases of drug-resistant TB or in any setting where there is uncertainty regarding appropriate treatment.^{2,12,34} **9** *It is critical to avoid adding only a single drug to a failing regimen.*^{2,12,34}

Special Populations

Patients with CNS TB usually are treated for longer periods (up to 12 months instead of 6 months) because the consequences of undertreatment are severe.^{2,12,34} Isoniazid and pyrazinamide cross the blood-brain barrier well, but rifampin, ethambutol, and streptomycin can penetrate inflamed meninges. TB of the bone typically is treated for up to 9 months, occasionally with surgical débridement.^{2,12,34} Drug selection is the same as for pulmonary disease. Extrapulmonary TB of the soft tissues can be treated with conventional regimens.^{2,12,34}

- TB in children may be treated with regimens similar to those used in adults, although some physicians extend treatment to 9 months.^{2,12,19,20,34,38,43} Pediatric doses of isoniazid and rifampin on a milligram per kilogram basis are higher than those used in adults³⁴ (Table 75-4).
- Pregnant women receive the usual treatment of isoniazid, rifampin, and ethambutol for 9 months.^{2,34,38,41} Pyrazinamide has not been studied in large numbers of pregnant women, but anecdotal data suggest that it may be safe.³⁴ B vitamins should be provided. Streptomycin, other aminoglycosides, capreomycin, and ethionamide generally are avoided because they have been associated with toxic effects on the fetus.^{34,44} Para-aminosalicylic acid and cycloserine are used sparingly.⁴⁴ Quinolones generally are avoided in pregnancy because of concern about adverse effects on cartilage development.^{34,44} Although most antituberculosis drugs are excreted in breast milk, the amount of drug received by the infant through nursing appears to be insufficient to cause toxicity. Quinolones should be avoided in nursing mothers, if possible, for the same reason as mentioned previously.

► Human Immunodeficiency Virus

- The recommended regimen for susceptible TB in HIV-infected adults is a 6-month regimen consisting of an initial phase of isoniazid, a rifamycin, pyrazinamide, and ethambutol for the first 2 months followed by a continuation phase of isoniazid and a rifamycin for 4 months.^{2,12,34} Some clinicians extend treatment for 9 months for such patients. Rifabutin is the rifamycin of choice in this population due to drug interactions with some protease inhibitors and non-nucleoside reverse transcriptase inhibitors. Because of the large pill burden, overlapping toxicities, and the risk of immune reconstitution

inflammatory syndrome when TB and HIV treatments are initiated simultaneously, most clinicians elect to begin TB treatment first. Recent data support the early introduction of antiretroviral therapy (within 2 weeks of starting TB drugs) in patients with low CD4⁺ counts (less than or equal to 50/mm³ [less than or equal to 50 × 10⁶/L]).⁴⁵⁻⁴⁷ Treatment for HIV has been recommended to start after 2 months of TB treatment, although individual circumstances often dictate the exact timing. Highly intermittent regimens (twice or once weekly) are not recommended for HIV-positive TB patients.³⁴ It is advisable that such patients are managed by TB-HIV experts because the challenges are many. Prognosis has been particularly poor for HIV-infected patients infected with MDR-TB. Some patients with AIDS malabsorb their oral medications, and drug interactions are common so therapeutic drug monitoring can be useful.^{2,34,41,42} Recommendations for regimens for the concomitant treatment of tuberculosis and HIV infection are provided in Table 75-5.

► Multidrug-Resistant TB

Drug-resistant TB may be suspected based on a patient's history or epidemiologic information. If drug-resistant TB is suspected, the empiric regimen should be modified based on patterns of suspected resistance. Once susceptibilities are confirmed, regimens can be modified appropriately. Patients with MDR-TB are at high risk of failure and should be treated by specialists.

► Renal Failure

Because they are primarily hepatically cleared, isoniazid and rifampin usually do not require dose modification in renal failure.^{41,44,48} Pyrazinamide and ethambutol typically are reduced to three times weekly to avoid accumulation of the parent drug (ethambutol) or metabolites (pyrazinamide).^{34,48} Renally cleared TB drugs include the aminoglycosides (e.g., amikacin, kanamycin, streptomycin), capreomycin, ethambutol, cycloserine, and levofloxacin.^{34,41,44} Dosing intervals need to be extended for these drugs. Serum concentration monitoring should be performed for cycloserine and ethambutol to avoid dose-related toxicities in renal failure patients.^{37,41,42}

► Hepatic Failure

Elevations of serum transaminase concentrations generally are not correlated with the residual capacity of the liver to metabolize drugs, so these markers cannot be used directly as guides for residual metabolic capacity. Hepatically cleared TB drugs include isoniazid, rifampin, pyrazinamide, ethionamide, and *p*-aminosalicylic acid.⁴⁴ Ciprofloxacin and moxifloxacin are about 50% cleared by the liver. Further, isoniazid, rifampin, pyrazinamide, and to a lesser degree ethionamide, *p*-aminosalicylic acid, and rarely ethambutol may cause hepatotoxicity.^{34,41,44} These patients require close monitoring, and serum concentration monitoring may be the most accurate way to dose them.

Table 75-4

Antituberculosis Drugs for Adults and Children^a

Drug	Daily Doses ^b	Adverse Effects	Monitoring
Isoniazid	<i>Adults:</i> 5 mg/kg (300 mg) <i>Children:</i> 10–15 mg/kg (300 mg)	Asymptomatic elevation of aminotransferases, clinical hepatitis, fatal hepatitis, peripheral neurotoxicity, CNS system effects, lupus-like syndrome, hypersensitivity, monoamine poisoning, diarrhea	LFT monthly in patients who have preexisting liver disease or who develop abnormal liver function that does not require discontinuation of drug Dosage adjustments may be necessary in patients receiving anticonvulsants or warfarin
Rifampin	<i>Adults:</i> 10 mg/kg (600 mg) <i>Children:</i> 10–20 mg/kg (600 mg)	Cutaneous reactions, GI reactions (nausea, anorexia, abdominal pain), flu-like syndrome, hepatotoxicity, severe immunologic reactions, orange discoloration of bodily fluids (sputum, urine, sweat, tears), drug interactions owing to induction of hepatic microsomal enzymes	Rifampin causes many drug interactions. For a complete list of drug interactions and effects, refer to CDC website: www.cdc.gov/nchstp/tb/tb
Rifabutin	<i>Adults:</i> 5 mg/kg (300 mg) <i>Children:</i> Appropriate dosing unknown	Hematologic toxicity, uveitis, GI symptoms, polyarthralgias, hepatotoxicity, pseudojaundice (skin discoloration with normal bilirubin), rash, flu-like syndrome, orange discoloration of bodily fluids (sputum, urine, sweat, tears)	Drug interactions are less problematic than rifampin
Rifapentine	<i>Adults:</i> 10 mg/kg (continuation phase) (600 mg) dosed weekly. <i>Children:</i> The drug is not approved for use in children	Similar to those associated with rifampin	Drug interactions are being investigated and are likely similar to rifampin
Pyrazinamide	<i>Adults:</i> Based on IBW: 40–55 kg: 1,000 mg; 56–75 kg: 1,500 mg; 76–90 kg: 2,000 mg <i>Children:</i> 15–30 mg/kg	Hepatotoxicity, GI symptoms (nausea, vomiting), nongouty polyarthralgia, asymptomatic hyperuricemia, acute gouty arthritis, transient morbilliform rash, dermatitis	Serum uric acid can serve as a surrogate marker for compliance LFTs in patients with underlying liver disease
Ethambutol ^d	<i>Adults:</i> Based on IBW: 40–55 kg: 800 mg; 56–75 kg: 1,200 mg; 76–90 kg: 1,600 mg <i>Children:</i> 15–20 mg/kg daily	Retrolbulbar neuritis, peripheral neuritis, cutaneous reactions	Baseline visual acuity testing and testing of color discrimination Monthly testing of visual acuity and color discrimination in patients taking greater than 15–20 mg/kg, renal insufficiency, or receiving the drug for greater than 2 months
Cycloserine	<i>Adults:</i> 10–15 mg/kg/day, usually 500–750 mg/day in 2 doses <i>Children:</i> 10–15 mg/kg/day	CNS effects	Monthly assessments of neuropsychiatric status Serum concentration may be necessary until appropriate dose is established
Ethionamide	<i>Adults:</i> 15–20 mg/kg/day, usually 500–750 mg/day in a single daily dose or 2 divided doses <i>Children:</i> 15–20 mg/kg/day	GI effects, hepatotoxicity, neurotoxicity, endocrine effects	Baseline LFTs Monthly LFTs if underlying liver disease is present TSH at baseline and monthly intervals
Streptomycin	<i>Adults:</i> ^g <i>Children:</i> 20–40 mg/kg/day	Ototoxicity, neurotoxicity, nephrotoxicity	Baseline audiogram, vestibular testing, Romberg testing and SCr Monthly assessments of renal function and auditory or vestibular symptoms
Amikacin/ kanamycin	<i>Adults:</i> ^g <i>Children:</i> 15–30 mg/kg/day IV or intramuscular as a single daily dose	Ototoxicity, nephrotoxicity	Baseline audiogram, vestibular testing, Romberg testing and SCr Monthly assessments of renal function and auditory or vestibular symptoms

(Continued)

Table 75-4

Antituberculosis Drugs for Adults and Children^a (Continued)

Drug	Daily Doses ^b	Adverse Effects	Monitoring
Capreomycin	Adults ^a Children: 15–30 mg/kg/day as a single daily dose	Nephrotoxicity, ototoxicity	Baseline audiogram, vestibular testing, Romberg testing and SCr Monthly assessments of renal function and auditory or vestibular symptoms Baseline and monthly serum K ⁺ and Mg ²⁺
<i>p</i> -Aminosalicylic acid (PAS)	Adults: 8–12 g/day in 2 or 3 doses Children: 200–300 mg/kg/day in 2–4 divided doses	Hepatotoxicity, GI distress, malabsorption syndrome, hypothyroidism, coagulopathy	Baseline LFTs and TSH TSH every 3 months
Levofloxacin	Adults: 500–1,000 mg daily Children ^h : Not recommended	GI disturbance, neurologic effects, cutaneous reactions	No specific monitoring recommended
Moxifloxacin	Adults: 400 mg daily Children ⁱ : Not recommended		

IBW, ideal body weight; LFT, liver function test; SCr, serum creatinine; TSH, thyroid-stimulating hormone.

^aFor purposes of this document, adult dosing begins at age 15 years.

^bDose per weight is based on ideal body weight. Children weighing more than 40 kg should be dosed as adults.

^cDose may need to be adjusted when there is concomitant use of protease inhibitors or nonnucleoside reverse transcriptase inhibitors.

^dThe drug likely can be used safely in older children but should be used with caution in children younger than 5 years, in whom visual acuity cannot be monitored. In younger children, ethambutol at the dose of 15 mg/kg/day can be used if there is suspected or proven resistance to isoniazid or rifampin.

^eIt should be noted that although this is the dose recommended generally, most clinicians with experience using cycloserine indicate that it is unusual for patients to be able to tolerate this amount. Serum concentration measurements are often useful in determining the optimal dose for a given patient.

^fThe single daily dose can be given at bedtime or with the main meal.

^gDose: 15 mg/kg/day (1 g) and 10 mg/kg in persons older than 50 years of age (750 mg). Usual dose: 750–1,000 mg administered intramuscularly or IV, given as a single dose 5–7 days/wk, and reduced to 2–3x per week after the first 2–4 months or after culture conversion, depending on the efficacy of the other drugs in the regimen.

^hThe long-term (more than several weeks) use of levofloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. However, most experts agree that the drug should be considered for children with TB caused by organisms resistant to both isoniazid and rifampin. The optimal dose is not known.

ⁱThe long-term (more than several weeks) use of moxifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.

Patient Encounter, Part 3

Based on the information provided, what are the goals of therapy for this patient?

Select and recommend a therapeutic plan for treatment of this patient's TB infection. What drugs, dose, schedule, and duration of therapy are best for this patient?

How should any contacts infected by this patient be evaluated and treated?

Who else should be tested and how should they be treated?

The TB Drugs

The interested reader is referred to several other publications for more detailed information regarding these drugs.^{2,11,34,41–42,44} A summary of daily doses, adverse effects, and monitoring

parameters of first- and common second-line antituberculosis drugs is provided in Table 75-4.³⁴ Isoniazid and rifampin are considered the two key drugs for the treatment of active TB, followed by pyrazinamide, which has a special role in the first 2 months of treatment. Other drugs are used to suppress the emergence of drug resistance in conjunction with the first-line drugs or for preexisting drug-resistant TB. In general, the most important toxicity with first-line drugs is hepatotoxicity, whereas various organs may be affected by each of the second-line drugs. Pyridoxine can reduce the risk of peripheral neuropathy associated with isoniazid. Quinolones such as moxifloxacin are gaining interest in the treatment of TB. The role of these agents in the first 2-month intensive phase of therapy is currently being evaluated. In the future these agents may be considered drugs of first choice.^{49–50} Other new therapies include investigational vaccines, and investigational drugs such as PA-824, OPC-67683 (Delamanid), TMC 207 (Bedaquiline), and SQ109, which are in clinical trials.⁵¹

Table 75-5

Recommendations for Regimens for the Concomitant Treatment of Tuberculosis and HIV Infection

Combined Regimen for Treatment of HIV and Tuberculosis	PK Effect of the Rifamycin	Tolerability/Toxicity	Antiviral Activity When Used With Rifampin	Recommendation (Comments)
Efavirenz-based antiretroviral therapy ^a with rifampin-based TB treatment	Well-characterized, modest effect	Low rates of discontinuation	Excellent	Preferred (efavirenz should not be used during the first trimester of pregnancy)
PI-based antiretroviral therapy ^a with rifabutin-based TB treatment	Little effect of rifabutin on PI concentrations, but marked increases in rifabutin concentrations	Low rates of discontinuation (if rifabutin is appropriately dose-reduced)	Favorable, though published clinical experience is not extensive	Preferred for patients unable to take efavirenz ^b
Nevirapine-based antiretroviral therapy with rifampin-based TB treatment	Moderate effect	Concern about hepatotoxicity when used with isoniazid, rifampin, and pyrazinamide	Favorable	Alternative for patients who cannot take efavirenz and if rifabutin not available
Zidovudine/lamivudine/abacavir/tenofovir with rifampin-based TB treatment	50% decrease in zidovudine, possible effect on abacavir not evaluated	Anemia	No published clinical experience	Alternative for patients who cannot take efavirenz and if rifabutin not available
Zidovudine/lamivudine/tenofovir with rifampin-based TB treatment	50% decrease in zidovudine, no other effects predicted	Anemia	Favorable, but not evaluated in a randomized trial	Alternative for patients who cannot take efavirenz and if rifabutin not available
Zidovudine/lamivudine/abacavir with rifampin-based TB treatment	50% decrease in zidovudine, possible effect on abacavir not evaluated	Anemia	Early favorable experience, but this combination is less effective than efavirenz-based regimens in persons not taking rifampin	Alternative for patients who cannot take efavirenz and if rifabutin not available
Super-boosted lopinavir-based ART with rifampin-based TB treatment	Little effect	Hepatitis among healthy adults, but favorable experience, among young children (younger than 3 years)	Good, among young children (younger than 3 years)	Alternative if rifabutin not available; preferred for young children when rifabutin not available

ART, antiretroviral therapy; PK, pharmacokinetic; TB, tuberculosis.

^aWith two nucleoside analogues.

^bIncludes patients with NNRTI-resistant HIV, those unable to tolerate efavirenz, and women during the first 1–2 trimesters of pregnancy.

OUTCOME EVALUATION

Effectiveness of TB therapy is determined by AFB smears and cultures. Sputum samples should be sent for AFB staining and microscopic examination (smears) every 1 to 2 weeks until two consecutive smears are negative. This provides early evidence of a response to treatment.³⁴ Once on maintenance therapy, **sputum cultures** can be performed monthly until two consecutive cultures are negative, which generally occurs over 2 to 3 months. If sputum cultures continue to be positive after 2 months, drug susceptibility testing should be repeated, and serum concentrations of the drugs should be checked.

10 *The most serious problem with TB therapy is patient nonadherence to the prescribed regimens.^{35,52} Unfortunately, there is no reliable way to identify such patients a priori. The most effective way to achieve this end is with DOT.^{2,11,34} The use of DOT in noncompliant patients will be of benefit.⁵³ DOT also provides increased opportunities*

to observe the patient for any apparent toxicities, thus improving overall care.⁵³
