Acute pancreatitis can progress to several distinct consequences. Acute peripancreatic fluid collections are located in or around the pancreas. They form within the first 4 weeks of acute pancreatitis and are not walled off. They are usually sterile but can become infected or hemorrhagic. Acute peripancreatic fluid collections are expected to resolve spontaneously and intervention may introduce infection.⁴

Pancreatic pseudocysts are formed at least 4 weeks after the start of acute pancreatitis and are walled-off collections of tissue, pancreatic enzymes, and blood. Many pancreatic pseudocysts resolve spontaneously, but some require surgical or percutaneous drainage. Rupture of a pancreatic pseudocyst is the most serious complication and can lead to peritonitis and GI bleeding.⁴

Pancreatic necrosis is a diffuse inflammation of the pancreas containing both necrotic tissue and fluid that over time undergoes liquefaction. Necrosis is due to pancreatic enzyme damage to the pancreatic tissue. **2** *Pancreatic necrosis occurs within the first 2 weeks of acute pancreatitis and develops in 10% to 20% of patients with acute pancreatitis.* Infected necrotic fluid collections occur in 16% to 47% of patients, usually due to bacteria normally present in the GI tract. These organisms include *Escherichia coli*, Enterobacteriaceae, *Staphylococcus aureus*, viridans group streptococci, and anaerobes. Disseminated infection may result from pancreatic necrosis.^{4,5}

Walled-off pancreatic necrosis, or pancreatic abscess, is pancreatic necrosis that is surrounded by granulation tissue and occurs weeks after acute pancreatitis. Pancreatic abscess is usually less life threatening than pancreatic necrosis and can be managed with percutaneous drainage, ideally after the third or fourth week to allow demarcation.⁴

CLINICAL PRESENTATION AND DIAGNOSIS

Patients with acute pancreatitis may develop many severe local and systemic complications. Multiorgan failure is a poor prognostic indicator. Early aggressive care should be sought for those presenting with more severe disease.

Disease severity can be predicted in many ways. The Ranson criteria, Glasgow severity scoring system, Acute

Clinical Presentation of Acute Pancreatitis

Symptoms

- Sudden upper abdominal pain is the most common presenting symptom. Pain can be due to intestinal immobility or chemical peritonitis induced by pancreatic enzymes.
- Pain and abdominal distention may also be due to local complications such as fluid collection, necrosis, or abscess in the pancreas.
- Pain may radiate to the back, and ecchymoses may be present in the flank and periumbilical areas.
- Nausea and vomiting are other common symptoms.

Signs

- Tachycardia, hypotension, fever, and abdominal distention may be present.
- There may be a positive Cullen's sign (bluish discoloration of the periumbilical skin indicating blood in the peritoneum).
- After 2 to 3 days of acute hemorrhagic pancreatitis, there may be a positive Turner's sign (local areas of bruising and induration of the skin near the umbilicus due to extravasation of blood).

Laboratory Tests

- The serum amylase may be elevated to greater than three times the upper limit of normal within the first 12 hours of the onset of acute pancreatitis. The degree of elevation does not correlate with the severity of disease.
- As acute pancreatitis progresses, serum lipase becomes elevated.
- Other possible laboratory abnormalities include elevated WBC count, hyperglycemia, hypocalcemia, hyperbilirubinemia, elevated serum lactate dehydrogenase (LDH), and hypertriglyceridemia.

to normal prior to hospital presentation in some patients.⁷ Serum lipase remains elevated for days after the onset of the acute event. Elevated hepatic enzymes may indicate gallstone pancreatitis, and triglycerides should be checked to rule out hypertriglyceridemia as the cause of pancreatitis.^{6,7}

Abdominal ultrasound is able to identify gallstones and sludge in the common bile duct but is limited in its sensitivity. Computed tomography (CT) may be more useful in staging pancreatitis or identifying complications. Magnetic resonance imaging (MRI) and magnetic resonance cholangiopancreatography (MRCP) are more costly options that can be used to evaluate severity and pancreatic abnormalities.^{6,7}

TREATMENT

Desired Outcomes

The goals of treatment for acute pancreatitis include: (a) resolution of nausea, vomiting, abdominal pain, and fever; (b) ability to tolerate oral intake; (c) normalization of serum amylase, lipase, and white blood cell (WBC) count; and (d) resolution of abscess, pseudocyst, or fluid collection as measured by CT scan.

Nonpharmacologic Therapy

Many medications can precipitate an attack of acute pancreatitis. If a medication is determined to be the cause of acute pancreatitis, it should be discontinued and an alternative therapy should be considered. If the medication is deemed clinically necessary, it is appropriate to rechallenge if there is not strong evidence that pancreatitis was due to the medication.²

- 3 *Therapy of acute pancreatitis is primarily supportive unless a specific etiology is identified (Fig. 23–2). Supportive therapy involves fluid repletion, nutrition support, and analgesia.*
- Patients with acute pancreatitis are administered IV fluids to maintain hydration and blood pressure. Fluids may be given in the form of crystalloids (e.g., 0.9% sodium chloride for infusion) or colloids (e.g., hetastarch or albumin for infusion). The rate and amount of fluids administered should

Physiology and Chronic Health Evaluation II (APACHE II), and sequential organ failure assessment (SOFA) have all been used to predict mortality. A Ranson or Glasgow score of 3 or greater or an APACHE II score of 8 or greater is predictive of severe acute pancreatitis and may signal the need for treatment in an intensive care unit.⁶

DIAGNOSIS

Diagnosis of acute pancreatitis is based on the patient's history, signs and symptoms, and laboratory values. The history can identify risk factors for acute pancreatitis including alcohol abuse and medications. A serum lipase greater than three times the normal limit supports the diagnosis. The serum lipase has greater sensitivity and specificity for acute pancreatitis than does the serum amylase. The serum amylase is also elevated early in the disease process but may return

Patient Encounter 1, Part 1

JR is a 45-year-old man who presents to the emergency department with a 2-day history of nausea and vomiting. He also complains of abdominal pain that is unrelieved and persistent. He has not eaten in the past 2 days because food exacerbates the pain. Upon examination, his abdomen is found to be distended.

What information about the patient presentation is consistent with acute pancreatitis?

What tests may be helpful in the diagnosis of acute pancreatitis?

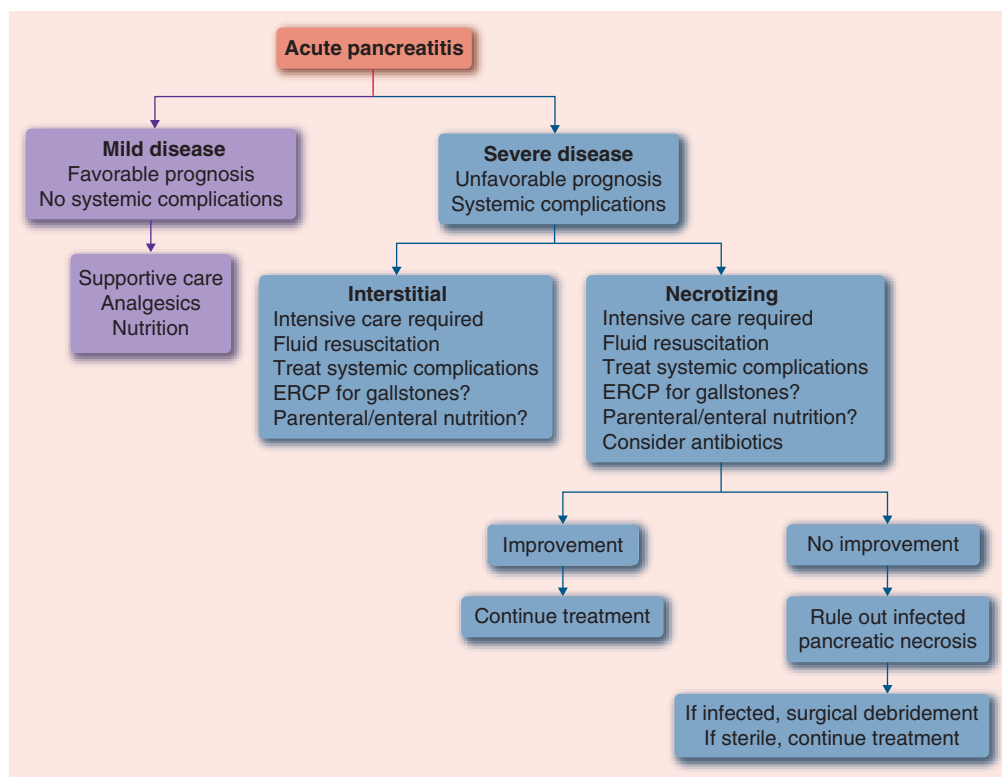

FIGURE 23–2. Algorithm for evaluation and treatment of acute pancreatitis. (ERCP, endoscopic retrograde cholangiopancreatography.) (From Bolesta S, Montgomery PA. Pancreatitis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011; Figure 46–3, with permission.)

be based on vital signs and urine output. Assessment of fluid requirements should be more frequent for patients with concomitant cardiac, renal, and liver disease.⁶ An increase in hematocrit as a marker of dehydration is a poor prognostic sign.^{5,8} Electrolytes such as potassium and magnesium may be added to the infusions if necessary. Hyperglycemia can be managed with insulin-containing IV infusions.

It is common practice to discontinue oral feedings during an attack of acute pancreatitis. In fact, this practice does not prevent further damage because the secretion of trypsin is reduced during acute pancreatitis.⁵ In mild to moderate pancreatitis, the patient's diet should be advanced based on resolution of nausea, vomiting, and pain. In severe pancreatitis, enteral nutrition should be started as early as possible and may include nasogastric or nasojejunal feedings. Nasojejun tube feedings feed the patient beyond the ampulla of Vater, minimizing stimulation of the pancreas. Early use of enteral nutrition has been shown to decrease surgical interventions and infectious complications. In severe pancreatitis, enteral nutrition can be supplemented with total parenteral nutrition to maintain adequate nutrition.^{5,7,9}

If pancreatic necrosis or abscesses are present, surgical or interventional procedures should be considered. CT-guided percutaneous drainage may be used to drain abscesses or as a bridge to surgery. Endoscopic **necrosectomy** and open

necrosectomy may be required and may involve repeat procedures until all of the necrotic tissue is removed.⁷ An ERCP may be used early in the course of treatment if there are retained bile duct stones or signs of cholangitis. Delayed intervention with ERCP may be indicated if symptoms resolve.⁷

Pharmacologic Therapy

► Analgesics

Meperidine has historically been the most popular analgesic in acute pancreatitis because it is purported to cause less spasm and resulting pain in the **sphincter of Oddi** than other opioids. However, the importance of this has not been confirmed in clinical studies. As a result, patients with acute pancreatitis should be given the most effective analgesic. Hydromorphone, morphine, and fentanyl are reasonable alternatives to meperidine and may be more desirable due to other adverse effects associated with meperidine. Refer to Chapter 34 on pain management for guidance in selecting an analgesic dose.

► Antibiotics

Empiric antibiotics are not indicated if the patient has mild disease or a noninfectious etiology of acute pancreatitis. Antibiotics have not been shown to prevent the formation of

Patient Encounter 1, Part 2

PMH: Hypertension, hypercholesterolemia

Allergies: Penicillin (anaphylaxis)

FH: Father—MI at 48 years of age, CHF, COPD; mother—osteoporosis, breast cancer, gallstones

SH: History of heaving drinking but stopped 12 years ago when his first child was born; no tobacco; no recreational drugs

Meds: Enalapril, atorvastatin, and an over-the-counter “stomach pill”

ROS: Positive for sharp RUQ abdominal pain that radiates to the right shoulder and back, nausea, vomiting; negative for substernal chest pain

PE:

VS: BP 105/60 seated, 90/50 standing, P 120 bpm, RR 22 breaths/min, T 37.9°C (100.2°F), pain score 9/10, wt 91 kg (200 lb), ht 6'1" (185 cm)

CV: Regular rate and rhythm, no murmurs

Abd: Distended, (+) rebound tenderness, (+) bowel sounds, (+) guarding

Labs: Amylase 90 IU/L (1.5 μ kat/L), lipase 1250 IU/L (20.8 μ kat/L), WBC 15.8 $10^3/\text{mm}^3$ (15.8 $10^9/\text{L}$), Hgb 10.9 g/dL (109 g/L, 6.77 mmol/L), Hct 30% (0.30), platelets 250 $10^3/\text{mm}^3$ (250 $10^9/\text{L}$), BUN 19 mg/dL (6.8 mmol/L), SCr 1.2 mg/dL (106 μ mol/L), glucose 220 mg/dL (12.2 mmol/L), AST 520 IU/L (8.67 μ kat/L), ALT 480 IU/L (8.00 μ kat/L), LDH 1,050 IU/L (17.50 μ kat/L)

Abdominal x-ray and ultrasound: Pending

What is your assessment of this patient given the above findings?

What additional information is needed at this point?

What treatment(s) would you initiate?

pancreatic abscess or necrosis when given early in the course of acute pancreatitis.

In pancreatic necrosis, 40% to 70% of patients have infected necrotic tissue. Multiple studies have found no clear mortality benefit with the use of prophylactic antibiotics in necrotizing pancreatitis. However, antibiotics may be appropriate in

patients with multiorgan failure or in those with suspected infection. The use of prophylactic antibiotics may lead to more resistant infections or a change in the infecting flora to gram-positive or fungal organisms. As such, the decision to use antibiotics is highly individualized. Consideration should be given to discontinuing antibiotics if no source of infection is confirmed. Selected IV antibiotic regimens are shown in [Table 23–2](#). If necrosis is confirmed, antibiotics are insufficient as sole therapy; surgical debridement is necessary for cure.^{5,7,10}

Broad-spectrum antibiotics with activity against enteric gram-negative bacilli are appropriate. It is often difficult to narrow the spectrum of activity of the antibiotic choice because the infections are usually polymicrobial. As such, patients may receive long courses of broad-spectrum antibiotics such as meropenem and may develop superinfections due to resistant bacteria. Antifungal agents such as fluconazole may be considered if peritonitis or GI perforation develops due to the presence of fungi such as *Candida albicans* in the GI tract.¹¹

► Ineffective Therapies

Several pharmacologic therapies have been proven to be ineffective in reducing morbidity or mortality from the disease.

4 *Ineffective therapies include reducing pancreatic secretion by administering somatostatin or atropine, reducing gastric acidity and decreasing pancreatic secretion with histamine₂-receptor antagonists, probiotics, and immunomodulation. Nasogastric suction has only been effective in patients with ileus or persistent vomiting.^{6,7}*

OUTCOME EVALUATION

- Monitor hydration status closely. Administer fluids using crystalloids or colloids, and replete electrolytes as necessary.
- Provide patients with analgesia and monitor pain severity using validated scales.
- Initiate nutrition support as early as possible. Enteral nutrition is preferred, but parenteral nutrition may be considered if enteral nutrition is not tolerated.
- Monitor patients with moderate to severe pancreatitis in an intensive care setting where frequent monitoring of vital signs can be provided.
- Continually assess patients for signs of infection including fever, leukocytosis, and other signs of sepsis.

Table 23–2

Selected IV Antimicrobial Regimens for Pancreatic Necrosis

Drug	Usual Dose ^a	Notes
Meropenem	1 g every 8 hours	Risk of superinfection
Piperacillin/tazobactam	3.375 g every 6 hours	Avoid if allergic to penicillin
Cefepime + metronidazole	2 g every 12 hours + 500 mg every 6 hours	Will not cover enterococci
Aztreonam + vancomycin + metronidazole	1 g every 8 hours + 15 mg/kg every 8–12 hours + 500 mg every 6 hours	Option for penicillin-allergic patients

^aDoses must be adjusted for the degree of renal impairment.

CHRONIC PANCREATITIS

EPIDEMIOLOGY AND ETIOLOGY

The incidence of chronic pancreatitis (CP) ranges from 3.5 to 10 per 100,000 population. **1** *The most common cause of chronic pancreatitis in adults in Western countries is ethanol abuse.* Other causes of CP include genetic predisposition, obstructive disease (secondary to ductal strictures or pseudocysts), autoimmune pancreatitis, abnormal cystic fibrosis transmembrane conductance regulator (CFTR) function as seen in cystic fibrosis (CF) patients, tropical pancreatitis, and idiopathic pancreatitis.^{3,12,13} More recently, cigarette smoking was identified as an independent risk factor for CP.¹⁴

PATHOPHYSIOLOGY

- Chronic pancreatitis is an inflammatory process that occurs over time leading to impaired endocrine and exocrine function secondary to diffuse scarring and fibrosis.^{12,13} There are multiple hypotheses to the pathogenesis of ethanol-induced pancreatitis including: (a) precipitation of secreted pancreatic proteins within small pancreatic ducts leading to acinar atrophy and fibrosis, (b) disruption of acinar cells leading to early activation of digestive enzymes and autodigestive pancreatic injury, and (c) oxidative pancreatic stress caused by toxic metabolites of ethanol.¹²
- 5** *Long-term sequelae of chronic pancreatitis include dietary malabsorption, impaired glucose tolerance, cholangitis, and potential addiction to opioid analgesics.* As patients lose exocrine function of the pancreas, they have a decreased ability to absorb lipids and protein ingested with normal dietary intake. Weight loss from nutritional malabsorption is a common symptom of CP. Fatty- or protein-containing stools are also common; carbohydrate absorption is usually

unaffected. Even though patients with CP have decreased ability to absorb lipid from the GI tract, they do not appear to have a higher incidence of fat-soluble vitamin deficiency.^{12,15}

CLINICAL PRESENTATION AND DIAGNOSIS

The symptoms, signs, and laboratory abnormalities associated with CP are shown in the accompanying text box. Pancreatic biopsy with histologic examination is the gold standard for diagnosis for CP, but it is rarely performed. In the absence of histology, abdominal ultrasound, CT, MRCP, or ERCP can assist in the diagnosis.^{3,12}

Clinical Presentation of Chronic Pancreatitis

General

- The presentation of chronic pancreatitis can be similar to that of acute pancreatitis.

Symptoms

- Pain is the most common symptom, and it typically starts in the epigastrium and may radiate to the back or scapula. Pain can be sharp or dull, and it may be relieved by leaning forward or sitting upright. The pain is not relieved by antacids and can be provoked by ethanol ingestion or a fatty meal.
- The pain may be associated with nausea and vomiting, causing patients to avoid food.
- Weight loss can result from chronic fat and protein malabsorption.

Signs

- Steatorrhea** (due to fat malabsorption), malnutrition, and glucose intolerance are often present in advanced CP.^{3,13}
- GI bleeding can result from erosion of intestinal blood vessels by pancreatic enzymes or as a result of thrombosis.
- Chronic obstruction of the common bile duct by the inflamed pancreas can cause icterus, cholangitis, and biliary cirrhosis.

Laboratory Tests

- Glucose intolerance may occur because of chronic destruction of the endocrine function of the pancreas.
- Serum amylase and lipase concentrations may be normal to slightly elevated in CP, and they are not particularly useful in the diagnosis of CP.^{12,13}
- The serum bilirubin or alkaline phosphatase may be elevated due to inflammation near the common bile duct.

Patient Encounter 1, Part 3

JR has now been hospitalized for 10 days with continued pain and food intolerance. This morning his WBC count is elevated at $21.2 \times 10^3/\text{mm}^3$ ($21.2 \times 10^9/\text{L}$), and he has a temperature of 38.7°C (101.6°F). He is hypotensive with a MAP of 60 mm Hg, and his HR is 115 bpm. His respiratory rate is 28 breaths/min and his SCr is 2.0 mg/dL ($177 \mu\text{mol/L}$). A CT scan demonstrates pancreatic necrosis, and antibiotics are started. His APACHE II score is calculated to be 13.

Based on his APACHE II score of 13, should JR be considered for transfer to the intensive care unit?

Which microorganisms should empiric antibiotics cover?

What antimicrobials would be appropriate to initiate at this time?

Besides antibiotics, what other pharmacologic treatments may need to be optimized?

TREATMENT

Desired Outcomes

The goals of pharmacotherapy for CP include: (a) relief of acute and chronic abdominal pain, (b) correction of dietary malabsorption with exogenous pancreatic enzymes, and (c) treatment of endocrine insufficiency and associated diabetes.¹²

Nonpharmacologic Therapy

Lifestyle modifications are an important part of the therapy for CP. **6** *Avoidance of ethanol, cigarette smoking, and fatty meals can decrease the pain of chronic pancreatitis.* There is evidence that alcohol and cigarette abstainers have slower disease progression and better response to pain therapy than nonabstainers.^{3,12,14} Patients should also be advised to consume a diet consisting of frequent small low-fat meals (less than 20 g fat/day) or one with medium-chain triglycerides where absorption requires only minimal amounts of pancreatic enzymes.^{12,13,16}

Many surgical procedures have been employed to reduce the inflammation or remove the strictures that cause pain in CP. However, most procedures (e.g., nerve blocks) have not been studied in clinical trials and carry a high risk of morbidity and mortality.¹²

Pharmacologic Therapy

► Analgesics

6 *Pain management is an important component of therapy and similar to that of acute pancreatitis.* Nonopioid analgesics (e.g., acetaminophen, nonsteroidal anti-inflammatory drugs [NSAIDs]) are preferred, but the severe and persistent nature of the pain often requires opioid therapy. Patients can require chronic doses of opioid analgesics, with a resulting risk of addiction.^{13,17} Patients should also be assessed for neuropathic pain and treated accordingly (e.g., tricyclic antidepressants, pregabalin).^{17,18} Refer to Chapter 34 on pain management for guidance in selecting an analgesic dose.

► Pancreatic Enzymes

Pancreatic enzyme supplementation is indicated in symptomatic patients with steatorrhea. The goal is to deliver exogenous enzyme to the duodenum without causing further GI side effects, risking noncompliance due to the large number of dosage units required, or causing undue medication expense.^{16,19} **6** *Supplementation with pancreatic enzymes may reduce the pain and fatty diarrhea associated with chronic pancreatitis (Table 23–3).* Common pancreatic enzyme supplements (PESs) contain lipase, amylase, and protease in varying proportions. The half-life of endogenous lipase is based on the presence of its substrates (i.e., triglycerides), and therefore dietary fat restriction should be reconsidered when pancreatic enzyme replacement is used.¹⁶

PESs were previously exempt from the Food, Cosmetic and Drug Act of 1938 and therefore did not require FDA approval

Table 23–3

Frequently Used Pancreatic Enzyme Preparations

Product	Dosage Form	Enzyme Content (Units) ^a		
		Lipase	Amylase	Protease
Creon-6	Microsphere	6,000	30,000	19,000
Creon-12	Microsphere	12,000	60,000	38,000
Creon-24	Microsphere	24,000	76,000	120,000
Pancreaze-4	Microtablet	4,200	17,500	10,000
Pancreaze-10	Microtablet	10,500	43,750	25,000
Pancreaze-16	Microtablet	16,800	70,000	40,000
Pancreaze-21	Microtablet	21,000	61,000	37,000
Pancrelipase	Beads	5,000	27,000	17,000
Zenpep-3	Beads	3,000	16,000	10,000
Zenpep-5	Beads	5,000	27,000	17,000
Zenpep-10	Beads	10,000	55,000	34,000
Zenpep-15	Beads	15,000	82,000	51,000
Zenpep-20	Beads	20,000	109,000	68,000

^aAll listed products are supplied as capsules with delayed-release, enteric-coated delivery systems. All products are porcine derived.

prior to marketing. In the past, PESs were available in a variety of formulations including microsphere, microcapsule, enteric-coated, and non-enteric-coated products. These PES were considered to be effective, but treatment failures sometimes occurred when patients switched to a different unapproved product. This prompted the FDA to review the various products; the agency found large differences in clinical response between the products. In 2004, the FDA required all PESs to gain new drug application (NDA) approval by April 2010.²⁰

There are currently three FDA-approved PESs in the United States (Table 23–3). Each product is enteric coated and releases enzymes in the alkaline environment (pH 5.5) of the duodenum, thus minimizing enzyme destruction in the stomach. Enteric-coated PESs require fewer daily dosage units than their non-enteric-coated predecessors. However, in patients with delayed gastric emptying, the efficacy of the enteric-coated PES may be decreased due to the early activation of the lipase enzymes. Addition of an H₂-blocker or proton pump inhibitor will decrease the acidity in the stomach, thereby enhancing delivery of the PES to the site of action.¹⁶

Pancreatic enzyme supplements should be taken immediately prior to meals and snacks to aid in the digestion and absorption of food. Dosing is based on body weight, clinical symptoms, and stool fat content. A normal starting dose is 500 units/kg/meal of lipase with half of the mealtime dose administered with snacks. Doses of lipase more than 10,000 units/kg/day should be used with caution because they may be associated with colonic stricture and fibrosis. Capsules may be opened; however, the contents of the capsule should not be crushed or chewed.

► Other Therapies

In patients with autoimmune pancreatitis, prednisolone 30 to 40 mg/day tapered over a 3-month period may provide

Patient Encounter 2

KS is a 53-year-old woman who presents to the emergency department complaining of a chronic dull pain in her abdomen for several months that is no longer relieved with over-the-counter analgesics. She has also had light-colored liquid stools for the past month and has lost 10 pounds because of decreased appetite.

PMH: Hypothyroidism, depression, recurrent acute pancreatitis

SH: Consumes a six-pack of beer/day and has a 35 pack-year history of cigarette smoking

Meds: Citalopram 20 mg daily, levothyroxine 50 mcg every morning, recent use of ibuprofen 400 mg every 4 hours without pain relief

ROS: (+) for RUQ abdominal pain that radiates to her back, decreased appetite, 10-lb (4.5-kg) weight loss and fatty diarrhea for the past month. (–) for chest pain or shortness of breath.

PE:

VS: BP 125/79 mm Hg, HR 75 bpm, RR 15 breaths/min, T 37.1°C (98.8°F), weight 63.2 kg (139 lb), height 5'4" (163 cm)

CV: Regular rate and rhythm, no murmurs noted

Abd: Distended, (+) rebound tenderness, (+) bowel sounds

Labs: Amylase 50 IU/L (0.83 μ kat/L), lipase 100 IU/L (1.7 μ kat/L); BUN 19 mg/dL (6.8 mmol/L), SCr 0.75 mg/dL (66 μ mol/L), glucose 248 mg/dL (13.8 mmol/L), AST 32 IU/L (0.53 μ kat/L), ALT 29 IU/L (0.48 μ kat/L)

CT scan abdomen: Diffuse pancreatic scarring and calcifications

What signs and symptoms are consistent with chronic pancreatitis?

Why are the serum amylase and lipase normal?

What lifestyle modifications would you recommend for this patient?

What, if any, treatment regimens would you initiate, and how would you monitor their effects?

rapid relief of symptoms. Antioxidants such as methionine, ascorbic acid, and selenium may reduce the number of painful days per month in patients with CP.³

OUTCOME EVALUATION

- Monitor pain control and adjust analgesics accordingly.
- Encourage lifestyle modifications such as abstinence from ethanol and cigarettes.
- Counsel patients to monitor for weight gain or loss and fatty stool output as a marker of malabsorption.
- Educate patients that adherence with dietary pancreatic enzyme supplementation is key to improved outcomes.^{13,16,19}

Patient Care and Monitoring

1. Determine whether ethanol is a contributing causative factor. If so, reinforce counseling on the need for abstinence and provide appropriate resources to maintain abstinence (e.g., professional counseling, Alcoholics Anonymous).
2. Obtain a thorough history of prescription, nonprescription, and dietary supplement use to identify products that may exacerbate chronic pancreatitis.
3. Refer the patient for nutritional counseling if there is decreased caloric intake and weight loss. Compare actual body weight to ideal body weight.
4. Make a plan for analgesia, in conjunction with a pain management service if possible, to control and prevent pain. Recommend an analgesic with ease of dosing and minimal side effects, realizing that patients with chronic pancreatitis may require large doses of opioids.
5. Pancreatic enzyme supplementation should be initiated in patients with steatorrhea. Doses should start at 500 units/kg/meal of lipase with half of the dose administered with snacks.
6. Develop a plan for reassessing pancreatic enzyme supplementation and analgesia on an outpatient basis.
7. Assess improvement in quality-of-life measures such as physical, psychological, and social functioning and well-being.

Abbreviations Introduced in This Chapter

APACHE II	Acute Physiology and Chronic Health Evaluation II
CF	Cystic fibrosis
CFTR	Cystic fibrosis transmembrane conductance regulator
CP	Chronic pancreatitis
CT	Computed tomography
ERCP	Endoscopic retrograde cholangiopancreatography
MAP	Mean arterial pressure
MRCPP	Magnetic resonance cholangiopancreatography
PES	Pancreatic enzyme supplement
RUQ	Right upper quadrant
SOFA	Sequential organ failure assessment

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Viral Hepatitis

Juliana Chan

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Differentiate the five types of viral hepatitis by their epidemiology, etiology, pathophysiology, clinical presentation, and natural history.
2. Identify modes of transmission and risk factors among the major types of viral hepatitis.
3. Evaluate hepatic serologies to understand how the type of hepatitis is diagnosed.
4. Create treatment goals for a patient infected with viral hepatitis.
5. Recommend appropriate pharmacotherapy for prevention of viral hepatitis.
6. Develop a pharmaceutical care plan for treatment of chronic viral hepatitis.
7. Formulate a monitoring plan to assess adverse effects of pharmacotherapy for viral hepatitis.

KEY CONCEPTS

- 1 Prevention and treatment of viral hepatitis may prevent progression to chronic hepatitis, cirrhosis, end-stage liver disease, and hepatocellular carcinoma.
- 2 Acute viral hepatitis is primarily managed with supportive care.
- 3 Good personal hygiene and proper disposal of sanitary waste are required to prevent fecal–oral transmission of the hepatitis A and E virus.
- 4 Individuals may minimize the risk of acquiring both hepatitis B and C infection by avoiding contaminated blood products and not partaking in high-risk behavior such as illicit IV drug use.
- 5 Persons at high risk of acquiring viral hepatitis A, B, or C infection should be vaccinated with the hepatitis A and/or B vaccine to prevent complications of liver disease.
- 6 A vaccine that combines both inactivated hepatitis A and recombinant hepatitis B (Twinrix) is approved for immunizing individuals older than 18 years with indications for both hepatitis A and B vaccines.
- 7 The drug of choice for chronic hepatitis B depends on the patient's past medical history, alanine aminotransferase (ALT) level, hepatitis B virus (HBV) DNA level, hepatitis B envelope antigen (HBeAg) status,

severity of liver disease, and history of previous HBV therapy.

- 8 Treatment for chronic hepatitis C depends on the patient's past medical history, previous hepatitis C virus (HCV) treatment history, severity of liver disease, and HCV genotype.

INTRODUCTION

The most common types of viral hepatitis include hepatitis A (HAV), B (HBV), C (HCV), D (HDV), and E (HEV). Acute hepatitis may be associated with all five types of hepatitis and rarely exceeds 6 months in duration. Chronic hepatitis (disease lasting longer than 6 months) is usually associated with hepatitis B, C, and D. 1 *Chronic viral hepatitis may lead to the development of cirrhosis and may result in end-stage liver disease (ESLD) and hepatocellular carcinoma (HCC).* Complications of ESLD include ascites, edema, hepatic encephalopathy, infections (e.g., spontaneous bacterial peritonitis), hepatorenal syndrome, and esophageal varices. Therefore, prevention and treatment of viral hepatitis may prevent ESLD and HCC.

Viral hepatitis may occur at any age and is the most common cause of liver disease in the world. The true prevalence and incidence may be underreported because most patients are asymptomatic. The epidemiology, etiology, and pathogenesis vary depending on the type of hepatitis and are considered separately below.

EPIDEMIOLOGY AND ETIOLOGY

Hepatitis A

Hepatitis A (HAV) affects 1.4 million people yearly worldwide.¹ The prevalence is highest in underdeveloped countries including Africa, parts of South America, the Middle East, and Southeast Asia. Australia, parts of western and northern Europe, Japan, and the United States have a lower prevalence. This is primarily due to vaccination programs, but outbreaks may still occur, as evidenced in 2003 by a food outbreak in Pennsylvania and in 2009 with international adoptees from countries known to have high or intermediate endemicity.^{2,3} The number of infections and hospitalizations due to acute HAV infection annually have decreased markedly since the introduction of the HAV vaccine in 1996.^{4,5}

HAV is primarily detected in contaminated feces and infects people via the fecal–oral route.⁵ Outbreaks occur primarily in areas of poor sanitation.^{1,5} Individuals at greatest risk of acquiring HAV are listed in [Table 24–1](#).⁵ Approximately 50% of the reported cases have no identifiable risk factors.⁵

To date, there are no documented cases of chronic hepatitis A.^{1,5} Death associated with HAV is rare and mostly associated with fulminant hepatitis, with which approximately 100 people die annually.⁵

Table 24–1

Risk Factors for Acquiring Viral Hepatitis

Hepatitis A

International travelers to endemic areas (e.g., Africa, Asia, and parts of South America)
Sexual contact with infected persons (e.g., men having sex with other men)
Shellfish infected with HAV (e.g., raw oysters)
Daycare centers or household contacts with people infected with HAV
Healthcare workers
IV drug users using unsterilized needles
Workers involved with nonhuman primates
Food service handlers
Patients with clotting factor disorders
Individuals residing in healthcare institutions

Hepatitis B and D

Men having sex with other men
Individuals with multiple heterosexual partners
IV drug users using unsterilized needles
Recipients of blood products
Household contacts with acute hepatitis B with open cuts
Healthcare providers in contact with contaminated needles
Patients undergoing dialysis

Hepatitis C

Recipients of blood products
Healthcare providers in contact with infected needles
Individuals having multiple sexual partners
Perinatal transmission (less than 5%)
Unprofessional body piercing and tattooing

Hepatitis E

International travelers to endemic areas (e.g., parts of Asia, Africa, and Mexico)
Ingesting foods and drinks contaminated with bodily waste

Hepatitis B

Hepatitis B is a bloodborne infection affecting approximately 2 billion people worldwide.⁶ About 350 million people have chronic hepatitis B (CHB) infection that may lead to cirrhosis and complications of ESLD.⁶ Annually, an estimated 1 million deaths are associated with hepatitis B.⁶ Despite having an effective vaccine against HBV, more than 300,000 newly diagnosed infections emerge each year. Less than 1% of individuals in North America and western Europe are chronically infected compared with 8% to 10% in developing areas such as Southeast Asia.⁶

The highest concentration of the HBV is found in blood and serous fluids. The primary modes of transmission are either by blood or body fluids through perinatal, sexual, or percutaneous exposure ([Table 24–1](#)).⁷ Infants born to mothers who are infected with actively replicating HBV have a 90% risk of becoming chronic HBV carriers.^{8–10} Approximately 33% of the reported cases have no identifiable risk factors.⁷

Hepatitis C

More than 170 million people are infected with hepatitis C worldwide, and it is estimated that 3.2 million have the disease in the United States.^{11,12} The prevalence is higher among non-Hispanic blacks than non-Hispanic whites, and men are more likely to be infected than women.¹³ Additionally, genotypes are geographically specific. For example, genotype 1 is common in the United States, whereas genotype 4 is common in the Middle East.¹² Approximately 75% with HCV in the United States have genotype 1, and about 14% and 5% have genotypes 2 and 3, respectively.¹¹ Genotype does not indicate disease severity or clinical outcomes but is used to determine the duration of therapy and the likelihood of therapeutic response.¹³

IV drug users using contaminated paraphernalia are responsible for about 60% of HCV transmissions ([Table 24–1](#)).¹² Because of the routine screening of blood products, the risk of HCV transmission via blood transfusion is very low (0.004% to 0.0004% per unit transfused).^{12,14} Approximately 10% of individuals with HCV have no identifiable risk factors.¹⁴

Hepatitis D

Hepatitis D affects approximately 15 million people worldwide.¹⁵ Parts of Asia, including Indonesia and Vietnam, have the lowest prevalence of HDV despite having a high prevalence of HBV infections.¹⁵ Areas with the highest prevalence of HDV include the Middle East, parts of Africa, Western and Central Asia, parts of South America, and the South Pacific islands.¹⁵

Eight genotypes associated with HDV have been identified, with genotype 1 the most prevalent.¹⁵ Genotype 1 primarily affects individuals residing in North America, Europe, the Middle East, and East Asia. Individuals residing in Japan and Taiwan are mostly diagnosed with genotype 2. Patients in northern parts of South America are mostly infected with genotype 3.¹⁵

Patient Encounter, Part 1

AB is a 29-year-old black woman who is at the doctor's office for a yearly check-up. Her only complaint is fatigue for 6 months. She was in Mexico vacationing 2 months ago. She states that she got sick for about a week while on the trip, but by the time she returned home she was getting better so did not seek medical treatment.

PMH: Rosacea, joint pain, mild depression, hypertension

PSH: Caesarean section 2 years ago (required a blood transfusion) and at age 5 had fractured ribs from falling out of a tree.

FH: Mother with osteoporosis; father alive and well. Has one brother with diabetes. Married with a 2-year-old daughter and 3-year-old son.

SH: She is in a monogamous relationship. Has never smoked tobacco. Used illicit drugs at age 15. Drinks alcohol socially. Had one tattoo placed unprofessionally. Employed as a secretary at a law firm.

Meds: Multivitamin daily, atenolol 100 mg daily, calcium with vitamin D twice daily, St. John's wort, birth control pills

ROS: Complains of irritability and insomnia; no nausea, vomiting, diarrhea, abdominal pain, or anorexia; never experienced an episode of jaundice, pale stools, or tea-colored urine

PE:

VS: BP 132/86 mm Hg, P 80 bpm, RR 20/minute, T 37.0°C (98.6°F), wt 70 kg (154 lb), ht 5'9" (175 cm)

Abd: Soft, nontender, normal liver span; no hepatosplenomegaly, no ascites.

The remainder of the examination was within normal limits.

Labs:

- Sodium 141 mEq/L (141 mmol/L), potassium 4.1 mEq/L (4.1 mmol/L), chloride 99 mEq/L (99 mmol/L), CO₂ 21 mEq/L (21 mmol/L), BUN 20 mg/dL (7.1 mmol/L), serum creatinine 1.2 mg/dL (106 μmol/L), glucose 122 mg/dL (6.8 mmol/L)
- Hemoglobin 13.1 g/dL (131 g/L or 8.13mmol/L), hematocrit 38% (0.38), WBC 5.1 × 10³/mm³ (5.1 × 10⁹/L), platelets 135 × 10³/mm³ (135 × 10⁹/L)
- AST 69 IU/L (1.15 μkat/L), ALT 92 IU/L (1.53 μkat/L)
- Total bilirubin 1.0 mg/dL (17.1 μmol/L), albumin 3.7 g/dL (37 g/L), alkaline phosphatase 164 IU/L (2.73 μkat/L), TSH 1.3 μIU/mL (1.3 mIU/L)
- Anti-HAV IgM (–), anti-HAV IgG (+), anti-HBs (–), HBsAg (–), HBeAg (–), anti-HBc IgG (–), anti-HBc IgM (–), anti-HBe (–), anti-HCV (+), genotype 1a; HCV RNA 751,230 IU/mL (751,230 kIU/L)
- Liver biopsy: Mild inflammation and moderate fibrosis (grade 1, stage 2 disease) consistent with chronic hepatitis C

What information is suggestive of viral hepatitis?

What risk factors does she have for viral hepatitis?

What additional information do you need before creating a treatment plan for this patient?

The most likely modes of transmitting HDV are similar to those of HBV, including IV drug use with unsterilized needles and administration of contaminated blood products (Table 24–1). Sexual and perinatal transmissions are rare for HDV.¹⁵

Hepatitis E

Hepatitis E is found worldwide, but acute cases occur primarily in Central and Southeast Asia, the Middle East, North Africa, and Mexico.¹⁶ Hepatitis E affects industrialized as well as underdeveloped countries. In the United States, up to 30% of the people may test positive for the HEV compared with 70% in developing countries.¹⁷ The HEV is primarily transmitted by the fecal–oral route via fecally contaminated water.^{16,17}

PATHOPHYSIOLOGY

Hepatitis A

Hepatitis A is a nonenveloped single-stranded RNA virus classified as the *Hepatovirus* genus under the Picornaviridae family.¹⁴ The primary host for the HAV is humans, with hepatic cells as the main site for viral replication. As part of the viral degradation process, the HAV is released into the

biliary system causing elevated concentrations of the virus in the feces.¹⁸ Hepatitis A infections are usually self-limiting and do not lead to chronic disease; they may rarely result in fulminant hepatitis.^{1,18}

Hepatitis B

The hepatitis B virus (also known as the Dane particle) belongs to the Hepadnaviridae family.⁹ It is a partially double-stranded DNA virus with a phospholipid layer containing hepatitis B surface antigen (HBsAg) that surrounds the nucleocapsid. The nucleocapsid contains the core protein that produces hepatitis B core antigen (HBcAg), which is undetectable in the serum. Hepatocellular injury from HBV is thought to be due to a cytotoxic immune reaction that occurs when HBcAg is expressed on the surface of the hepatic cells. Fortunately, antibodies against hepatitis B core antigen (anti-HBc) are measurable in the blood, where anti-HBc to immunoglobulin M (IgM) indicates active infection and anti-HBc to IgG relates to either chronic infection or possible immunity against HBV.

Viral replication occurs when the hepatitis B envelope antigen (HBeAg) is present and circulating in the blood. The serum HBV DNA concentration is a measure of viral infectivity and quantifies viral replication. Once the hepatitis B

infection resolves, antibodies against the hepatitis B envelope (anti-HBe) and antibodies against hepatitis B surface antigen (anti-HBs) develop, and HBV DNA levels become undetectable. However, if these antibodies do not develop, the likelihood of developing CHB increases. This depends primarily on the host's immune system at the time of the infection. In immunocompetent individuals, the disease resolves spontaneously and does not lead to further complications. In immunocompromised persons, the HBV is less likely to be eradicated, thus causing persistent infection. This often leads to hepatic cell damage and inflammation that may lead to cirrhosis and hepatocellular carcinoma.¹⁹

Chronic HBV occurs in less than 5% of those who are older than 5 years, whereas the rate is more than 90% in infants born to mothers infected with HBV.⁷ Approximately 90% of adults infected with the HBV develop anti-HBs, which results in lifelong immunity. About 30% of adults with initial symptoms of HBV present with jaundice or fatigue, and about 0.5% exhibit fulminant hepatitis.⁷ Cirrhosis and HCC are the two major complications associated with CHB hepatitis B infections.¹⁹

Hepatitis C

Hepatitis C, first known as non-A, non-B hepatitis, is a bloodborne infection caused by a single-stranded RNA virus belonging to the Flaviviridae family and the *Hepacivirus* genus.¹⁴ There are 11 genotypes (numbered 1 to 11) and more than 90 subtypes (genotypes 1a, 1b, 2a, 3b, etc.) that are unique to hepatitis C.¹¹

Antibodies against HCV (anti-HCV) in the blood indicate infection. If the infection persists for more than 6 months and viral replication is confirmed by HCV RNA levels, the person has chronic hepatitis C.

Only 10% to 15% of patients have acute hepatitis C that resolves without any further complication. In more than 70% of cases, hepatitis C develops into a chronic disease that is asymptomatic in about 60% to 80% of patients.^{11,14} Chronic disease may be due to an ineffective host immune system, with cytotoxic T lymphocytes being unable to eradicate the HCV, thereby allowing persistent damage to hepatic cells. Therefore, individuals who are

immunocompromised are less likely to eradicate the virus. Risk factors for developing hepatic fibrosis include obesity, diabetes, heavy alcohol use, male sex, and acquiring HCV when older than 40 years.²⁰

Approximately 70% of chronic cases progress to mild, moderate, or severe hepatitis. Cirrhosis and its complications occur in 15% to 20% of patients infected with HCV. In 10% to 20% of cases, 20 to 40 years may elapse between the time of exposure and the development of cirrhosis. Once cirrhosis is confirmed, the rate of developing HCC increases by 1% to 4% per year.

Hepatitis D

The hepatitis D virus (originally called delta hepatitis) belongs to the genus *Delta virus* of the Deltaviridae family.¹⁵ The HDV virion is a defective single-stranded circular RNA virus that requires the presence of HBV for HDV viral replication. This is because the HDV antigen (HDVAg) is coated by the HBsAg.¹⁵ The mechanism of hepatic damage is undetermined, but it is known that replication of HDV cannot occur without HBV present causing either coinfection (both hepatitis B and D infection occurring simultaneously) or superinfection (acquiring HDV after having long-standing disease with HBV).¹⁵

Hepatitis E

Hepatitis E is a nonenveloped single-stranded messenger RNA virus of the Hepevirus genus.¹⁷ The HEV is similar to HAV in that the virus is found in contaminated feces, thus infecting people via the fecal–oral route. High HEV levels in the bile often prompt viral shedding in the feces. Hepatitis E infections are usually self-limiting and rarely result in hepatic complications. Chronic hepatitis E occurs rarely and is more likely to occur in immunocompromised individuals such as patients with human immunodeficiency virus (HIV) or posttransplant recipients.¹⁶

CLINICAL PRESENTATION AND DIAGNOSIS

See text box below for the clinical presentation of viral hepatitis.

Clinical Presentation of Viral Hepatitis

Symptoms

- Most patients infected with any type of viral hepatitis have no symptoms.
- Symptomatic patients may experience a flu-like syndrome, fevers, fatigue/malaise, anorexia, nausea, vomiting, diarrhea, dark urine, pale-appearing stools, pruritus, and abdominal pain.

Signs

- Jaundice may be evident in the whites of the eyes (scleral icterus) or skin.

- An enlarged liver (hepatomegaly) and spleen (splenomegaly) may be present.
- In fulminant hepatitis with hepatic encephalopathy, patients may have **asterixis** and coma.
- In rare instances, extrahepatic symptoms may develop: arthritis, postcervical lymphadenopathy, palmar erythema, cryoglobulinemia, and vasculitis.

Laboratory Tests

- See Table 24–2.

Diagnosis of Viral Hepatitis

Diagnosing viral hepatitis may be difficult because most infected individuals are asymptomatic.^{5,7,14} Because symptoms cannot identify the specific type of hepatitis, laboratory serologies must be obtained (Table 24–2). In addition, liver function tests may aid in assessing the extent of cholestatic and hepatocellular injury. However, the definitive test to determine the amount of damage and inflammation of hepatic cells is a **liver biopsy**.

► Hepatitis A

The diagnosis of hepatitis A is made by detecting immunoglobulin antibodies to the capsid proteins of the HAV. The presence of IgM anti-HAV in the serum indicates an acute infection. IgM appears approximately 3 weeks after exposure and becomes undetectable within 6 months. In contrast, IgG anti-HAV appears in the serum at approximately the same time IgM anti-HAV develops but indicates protection and lifelong immunity against hepatitis A.¹

Table 24–2

Interpretation of Viral Hepatitis Serology Panels

Type	Laboratory Test	Result	Interpretation of Panel
Hepatitis A	IgM anti-HAV	Negative	Susceptible to infection
	IgG anti-HAV	Negative	
	IgM anti-HAV	Positive	Acutely infected
	IgG anti-HAV	Positive	Immune due to either natural infection or HAV vaccine
Hepatitis B ^a	HBsAg	Negative	Susceptible to infection
	Anti-HBc	Negative	
	Anti-HBs	Negative	
	HBsAg	Negative	Immune due to natural infection
	Anti-HBc	Positive	
	Anti-HBs	Positive	
	HBsAg	Negative	Immune due to hepatitis B vaccination
	Anti-HBc	Negative	
	Anti-HBs	Positive	
	HBsAg	Positive	Acutely infected
	Anti-HBc	Positive	
	IgM anti-HBc	Positive	
Anti-HBs	Negative		
HBsAg	Positive	Chronically infected	
Anti-HBc	Positive		
IgM anti-HBc	Negative		
Anti-HBs	Negative		
Hepatitis C	Anti-HCV	Negative	Susceptible to infection
	Anti-HCV	Positive	Acutely or chronically infected
	Anti-HBs	Negative	Four interpretations possible: (a) Resolved infection (most common); (b) false-positive anti-HBc, thus susceptible; (c) low-level chronic infection; (d) resolving acute infection
Hepatitis D ^b	IgM anti-HDV	Positive	Acute HBV-HDV coinfection
	HDVAg	Positive	
	HBsAg	Positive	
	HBeAg	Positive	
	Anti-HBc	Positive	
Hepatitis E	IgM anti-HEV	Negative	Susceptible to infection
	IgG anti-HEV	Negative	
	IgM anti-HEV	Positive	Acutely infected
	IgG anti-HEV	Positive	Immune due to natural infection

Anti-HAV, hepatitis A antibody; anti-HBc, hepatitis B core antibody; anti-HBs, hepatitis B surface antibody; HBsAg, hepatitis B surface antigen; anti-HCV, hepatitis C antibody; anti-HDV, hepatitis D antibody; anti-HEV, hepatitis E antibody; HAV, hepatitis A virus; HBV, hepatitis B virus; HDV, hepatitis D virus; HDVAg, hepatitis D antigen; IgG, immunoglobulin G; IgM, immunoglobulin M.

^aCenters for Disease Control and Prevention. Hepatology [Internet]. Available at: <http://www.cdc.gov/hepatitis/HBV/PDFs/SerologicChartv8.pdf>.

^bHepatitis D should be suspected in those who have HBsAg positivity. Hepatitis D may present as either coinfection where both HDV and HBV serologies appear simultaneously, whereas for superinfection, HBV has been present for some time and later HDV develops.

► Hepatitis B

Hepatitis B is diagnosed when HBsAg is detectable in the serum. The nucleocapsid of the HBsAg contains the core protein that produces HBcAg, which is undetectable in the serum. The presence of antibodies against HBcAg to IgM indicates active infection. Anti-HBc to IgG relates to either chronic infection or possible immunity against HBV.^{6,7}

In most cases, HBeAg is detected in the blood indicating active viral replication. Measurement of HBV DNA is used to determine viral infectivity and quantify viral replication. Once the hepatitis B infection resolves, antibodies to HBeAg (anti-HBe) develop, indicating viral replication has ceased, and eventually anti-HBs develop. Patients may develop antibodies to HBeAg and still have active viral replication because of a mutation in the HBV.⁹ Therefore, chronic hepatitis B infections may be differentiated as either HBeAg-positive or HBeAg-negative.^{9,10}

► Hepatitis C

Hepatitis C is diagnosed by testing for anti-HCV in the serum and confirmed by the presence of HCV RNA. HCV RNA levels quantify viral replication and are used to determine if antiviral treatment for HCV is effective. Once an infection has been confirmed, an HCV genotype should be obtained to determine the likelihood of response to antiviral therapy and the duration of treatment required.^{11,14}

► Hepatitis D

Hepatitis D infection requires the presence of HBV for HDV viral replication. Measuring HDV RNA levels in the serum by polymerase chain reaction (PCR) confirms the presence of the HDV and is the most accurate diagnostic test. The presence of IgM antibodies to HDV Ag (IgM anti-HD) indicates active disease, and IgG anti-HD also becomes detectable if the infection does not resolve spontaneously. HDV antibodies do not confer immunity.¹⁵

► Hepatitis E

The diagnosis of hepatitis E is based on the presence of anti-HEV antibodies (IgM anti-HEV). IgG anti-HEV emerges when the acute phase of the HEV infection resolves.¹⁶ A blood test for hepatitis E RNA levels is available, but its use is currently limited to clinical trials.

PREVENTION AND TREATMENT OF VIRAL HEPATITIS

Desired Outcomes

- General desired outcomes for treating hepatitis are to (a) prevent the spread of the disease, (b) prevent and treat symptoms, (c) suppress viral replication, (d) normalize hepatic aminotransferases, (e) improve histology on liver biopsy, and

(f) decrease morbidity and mortality by preventing cirrhosis, HCC, and ESLD.

For hepatitis B, additional treatment goals include (a) seroconversion or loss of HBsAg, (b) seroconversion or loss of HBeAg, and (c) achieving undetectable HBV DNA levels. An additional goal for chronic hepatitis C is achieving undetectable HCV RNA 6 months after hepatitis C therapy by achieving a sustained virologic response (SVR).

General Approach

Managing viral hepatitis involves both prevention and treatment. Prevention of hepatitis A and B (and indirectly for hepatitis D) can be achieved with immune globulin or vaccines. **2** *Acute viral hepatitis is primarily managed with supportive care.* Mild to moderate symptoms rarely require hospitalization, but admission is recommended in individuals experiencing significant nausea, vomiting, diarrhea, and encephalopathy. Liver transplantation may be required in rare instances if fulminant hepatitis develops. Treatment is available for chronic liver disease (HBV, HCV, and HDV) to prevent ESLD and ultimately HCC.

Hepatitis A Prevention

3 *Good personal hygiene and proper disposal of sanitary waste are required to prevent fecal-oral transmission of the HAV.*^{1,5} This includes frequent hand washing with soap and water after using the bathroom and prior to eating meals. Drinking bottled water and avoiding fruits, vegetables, and raw shellfish harvested from sewage-contaminated water in areas where HAV is most endemic also minimizes the risk of becoming infected with hepatitis A.

Individuals at high risk of acquiring hepatitis A (Table 24–1) should receive either serum immune globulin or the hepatitis A vaccine, depending on their personal circumstances, as described below.^{5,21}

► Immune Globulin

Immune globulin (IG) is a solution containing antibodies from sterilized pooled human plasma that provides passive immunization against various infectious diseases, including hepatitis A.⁵ IG is available for either IV (IGIV) or intramuscular (IGIM) administration, but only IGIM is used for prevention of hepatitis A. IGIM does not confer lifelong immunity, but it is effective in providing pre- and postexposure prophylaxis against HAV.⁵

IGIM should be injected into a deltoid or gluteal muscle. It does not affect the immune response of inactivated vaccines, oral polio virus, or yellow fever vaccine. The administration of live vaccines (e.g., measles, mumps, rubella [MMR] vaccine) concomitantly with IGIM may decrease the immune response significantly; thus MMR and varicella vaccines should be delayed for at least 3 and 5 months, respectively, after IGIM has been administered. Additionally, IGIM should not be given within 2 weeks of the MMR

administration or within 3 weeks of the varicella vaccine to maximize the efficacy of the immunization.⁵

Preexposure Prophylaxis Preexposure prophylaxis with IGIM is indicated for individuals at high risk of acquiring the HAV who (a) are younger than 12 months, (b) elect not to receive the hepatitis A vaccine, or (c) cannot receive the hepatitis A vaccine (e.g., because of allergy to the components alum or 2-phenoxyethanol). Because active vaccine immunity takes several weeks to develop, travelers who are older than 40 years, are immunocompromised, or have chronic liver disease or other chronic medical conditions who plan to depart for endemic areas within 2 weeks *and* have not received the hepatitis A vaccine should receive IGIM. If the duration of travel is less than 3 months, these individuals should receive a dose of IGIM 0.02 mL/kg and hepatitis A vaccine at the same time but administered at different injection sites.^{5,21}

If travel duration is expected to be greater than 2 months, IGIM at a dose of 0.06 mL/kg should be administered to provide immunity up to 5 months. If protection against HAV is required beyond 5 months, readministration of IGIM is recommended.^{5,21}

Postexposure Prophylaxis Individuals in contact with people infected with acute HAV (including household and sexual partners), staff and children from daycare facilities, and food handlers of restaurant establishments may be candidates for postexposure prophylaxis. IGIM is preferred in individuals who are younger than 12 months or older than 40 years of age, immunocompromised, diagnosed with chronic liver disease, or have contraindications to the hepatitis A vaccine.^{5,21}

The risk of infection may be decreased by 90% if IGIM 0.02 mL/kg is given within 2 weeks of being exposed to the HAV. IGIM may still be beneficial if given more than 2 weeks after exposure to a known case of HAV because it may decrease the severity of hepatic damage.^{5,21}

► Hepatitis A Vaccine

Persons at risk of acquiring HAV should receive the hepatitis A vaccine when appropriate. The vaccine is effective in providing pre- and postexposure prophylaxis against

clinical hepatitis A infections when given in two injections 6 months apart (referred to as months 0 and 6).^{5,21} Two inactivated hepatitis A vaccines, HAVRIX and VAQTA, are available in the United States. These vaccines are considered interchangeable, and doses depend on age (Table 24-3).⁵

Efficacy is defined by measuring antibody response with the modified enzyme immunoassay. Protective levels are considered to be greater than 20 mIU/mL (20 IU/L) for HAVRIX and greater than 10 mIU/mL (10 IU/L) for VAQTA. After administration of the first dose of vaccine, 94% to 100% of adults and 97% to 100% of children and adolescents develop protective antibody concentrations. All recipients older than 2 years receiving the second dose at month 6 have 100% antibody coverage; therefore, postvaccination measurement of antibody response is not required.⁵

For preexposure prophylaxis, the hepatitis A vaccine is recommended for travelers to endemic hepatitis A countries. It should be administered to healthy international travelers 40 years of age and younger regardless of the scheduled dates for departure. This recommendation does not apply to adults older than 40 years, the immunocompromised, or those with chronic medical conditions with or without chronic liver disease. Individuals who plan to depart to an endemic country in less than 2 weeks should receive both the hepatitis A vaccine and IGIM (0.02 mL/kg).²¹

For postexposure prophylaxis, the hepatitis A vaccine is effective in preventing clinical infection in healthy individuals between 12 months and 40 years of age when administered within 14 days after exposure.²¹ Individuals outside these age ranges or with significant comorbid conditions should receive IGIM for postexposure prophylaxis rather than the hepatitis A vaccine because this population has not been studied.²¹

The hepatitis A vaccine may provide effective immunity for 8 years in adults and children. Kinetic models have theorized that immunity may last longer than 20 years, but this has not been confirmed in clinical trials.⁵ The most common and often self-limiting adverse effects in adults include injection site reactions (e.g., tenderness, pain, and warmth), headaches within 5 days after vaccination, and fatigue. Infants and children may have feeding disturbances. Local reactions may be minimized by using an appropriate

Table 24-3

Recommended Intramuscular Doses of Hepatitis A Vaccines

Product	Recipient Age (years)	Dose	Volume (mL)	No. of Doses	Schedule (months)
VAQTA	1–18	25 units	0.5	2	0, 6–18
	19 or more	50 units	1	2	0, 6
HAVRIX	1–18	720 ELISA units	0.5	2	0, 6–12
	19 or more	1,440 ELISA units	1	2	0, 6–12

ELISA, enzyme-linked immunosorbent assay.

From Chan J. Viral hepatitis. Pharmacotherapy Self-Assessment Program, 5th ed. Kansas City, MO: American College of Clinical Pharmacy, 2005:1, 4, with permission.

needle length based on the person's age and size and by administering intramuscularly in the deltoid muscle. Hepatitis A vaccine given during pregnancy has not been evaluated in clinical trials. Because both brands of vaccine are made from inactivated HAV, the risk of developing fetal complications should be minimal.⁵

Hepatitis B Prevention

4 Individuals may minimize their risk of acquiring the hepatitis B infection by avoiding contaminated blood products or participating in high-risk behavior such as IV drug use. In addition, those at high risk of acquiring the HBV (Table 24–1) should be vaccinated with the hepatitis B vaccine.⁷ Screening pregnant women for hepatitis B and providing universal hepatitis B vaccinations to all newborns is effective in preventing hepatitis B infections.²² In some cases, postexposure prophylaxis with hepatitis B immune globulin (HBIG) may be recommended to prevent the development of acute infection and complications associated with HBV.

► Hepatitis B Immune Globulin

Hepatitis B immune globulin (HBIG) is a sterile solution containing antibodies prepared from pooled human plasma that has a high concentration of anti-HBs. HBIG provides passive immunization for postexposure prophylaxis against HBV. A single dose of HBIG 0.06 mL/kg is effective in preventing chronic hepatitis B infections in adults.⁷ Similar to IGIM, HBIG should only be administered intramuscularly.

The most common side effects of HBIG include erythema at the injection site, headaches, myalgia, fatigue, urticaria, nausea, and vomiting. Serious adverse effects are rare and may include liver function test abnormalities,

arthralgias, and anaphylactic reactions. HBIG should be used with caution in individuals who have experienced hypersensitivity reactions to immune globulin or those who have immunoglobulin A deficiency. Similar to IGIM, concomitant administration of HBIG and live vaccines should be avoided because the efficacy of the immunization may decrease significantly.

► Hepatitis B Vaccine

The two hepatitis B vaccines available in the United States are Recombivax HB and Engerix-B. These vaccines are produced with recombinant DNA technology by inserting the gene for HBsAg into the plasmid that is synthesized by *Saccharomyces cerevisiae* cells. **5** Persons at high risk (Table 24–1) of acquiring the hepatitis B virus should be vaccinated with the hepatitis B vaccine at months 0, 1, and 6. The hepatitis B vaccine dose depends on the person's age (Table 24–4).

In addition to preexposure prophylaxis, the hepatitis B vaccine is indicated after exposure to prevent CHB. Adults acutely exposed to blood containing HBsAg from an accidental needlestick, sexual contacts, or IV drug use should receive the hepatitis B vaccine with or without HBIG, preferably within 24 hours of exposure based on the source of exposure and the vaccination status of the exposed person (Table 24–5).⁷ Postexposure prophylaxis for perinatal exposure depends on several factors including maternal HBsAg status and the newborn's weight.²² For mothers who are HBsAg-positive, newborns should be immunized within 12 to 24 hours after birth with the hepatitis B vaccine and HBIG 0.5 mL. If the mother is HBsAg-negative, the newborn should receive only the hepatitis B vaccine (Table 24–6).

For optimal response, the hepatitis B vaccine should be administered intramuscularly (into the anterolateral thigh region in neonates and infants and into the deltoid region in older children and adults) and not IV or intradermally.

Table 24–4

Recommended Intramuscular Dosing Regimens for Hepatitis B Vaccines

Product	Patient Categories	Dose (mcg)	Volume (mL)	No. of Doses	Schedule (months)
Recombivax HB	0–19 years of age	5	0.5	3	0, 1, 6
	11–15 years of age ^a	10	1	2	1, 4–6
	20 years of age or older	10	1	3	0, 1, 6
	Hemodialysis ^b younger than 20 years of age	5	0.5	3	0, 1, 6
	Hemodialysis 20 years of age or older	40	1	3	0, 1, 6
Engerix-B	0–19 years of age	10	0.5	3	0, 1, 6
	20 years of age or older	20	1	3	0, 1, 6
	Hemodialysis ^b younger than 20 years of age	10	0.5	3	0, 1, 6
	Hemodialysis 20 years of age or older	40 ^c	2	4	0, 1, 2, 6

^aAdolescents 11 through 15 years of age may receive either the 5-mcg three-dose pediatric formulation or a 10-mcg two-dose regimen using the adult formulation.

^bHigher doses might be more immunogenic, but no specific recommendations have been made.

^cTwo 1.0-mL doses administered at one site.

Table 24-5

Recommendations for Prophylaxis After Nonoccupational Exposure to the Hepatitis B Virus

Exposed Person's Vaccination Status	Treatment to Administer If Serology Test of Source Person Is:	
	HBsAg-Positive	Unknown HBsAg Status
Unvaccinated	HBIG × 1 and initiate HB vaccine series	Initiate HB vaccine series
Previously vaccinated ^a	Administer HB vaccine booster dose	No treatment

HB, hepatitis B; HBsAg, hepatitis B surface antigen; HBIG, hepatitis B immune globulin.

^aA person who has written documentation of a complete hepatitis B vaccine series and did not receive postvaccination testing.

Table 24-6

Recommendations for Hepatitis B Prophylaxis to Prevent Perinatal Transmission

Treatment	Mother's HBsAg Status		
	Positive	Negative	Unknown
HBIG ^a	Given within 12 hours of birth	None	Test HBsAg. If positive, give within 7 days; if negative, give none
AND Hepatitis B vaccine ^b			
Dose 1	Within 12 hours of birth	Based on infant's weight ^c	Within 12 hours of birth
Dose 2	At month 1–2	At month 1–2	At month 1–2
Dose 3 ^d	At month 6	At month 6–18	At month 6

^a0.5 mL intramuscularly in a different site from vaccine.

^bSee Table 24-4 for appropriate hepatitis B vaccine dose.

^cFull-term infants who are medically stable and weigh 2,000 g or more born to HBsAg-negative mothers should receive the hepatitis B vaccine before hospital discharge. Preterm infants weighing less than 2,000 g born to HBsAg-negative mothers should receive the first dose of hepatitis B vaccine 1 month after birth or at hospital discharge.

^dThe final dose in the vaccine series should not be administered before age 24 weeks (164 days).

From Mast EE, Margolis HS, Fiore AE, et al. A comprehensive immunization strategy to eliminate transmission of hepatitis B virus infection in the United States: Recommendations of the Advisory Committee on Immunization Practices (ACIP) part 1: Immunization of infants, children, and adolescents. *MMWR Recomm Rep* 2005; 54(RR-16):1–31.

The vaccine should not be given in the gluteal region because it may result in lower rates of immunity.^{7,22}

The hepatitis B vaccine is effective when antibody concentrations are greater than 10 mIU/mL (10 IU/L). Because most people completing the vaccination series obtain adequate antibody levels, postvaccination testing is not routinely recommended. The immunogenicity rate in healthy adults younger than 40 years is greater than 90% at completion of the three-dose hepatitis B immunization series.^{7,22} Effective immunity may last for more than 20 years in healthy individuals. However, patients with poor immune systems may have an anamnestic response and may require titers to be checked periodically with booster doses given.^{7,22}

The most frequent adverse effects are local reactions at the injection site (pain, tenderness, erythema, swelling, and pruritus), fever, headaches, dizziness, and irritability. Anaphylaxis, a serum sickness–like hypersensitivity syndrome, chronic fatigue syndrome, and neurologic diseases (leukoencephalitis,

optic neuritis, and transverse myelitis) have been reported rarely.⁷ Hepatitis B vaccine is not contraindicated during pregnancy.⁷

► Hepatitis A and B Combination Vaccine

6 A vaccine that combines both inactivated hepatitis A and recombinant hepatitis B (Twinrix) is approved for immunizing individuals older than 18 years with indications for both hepatitis A and B vaccines.^{7,23} A 1-mL dose of Twinrix contains the antigenic components of not less than 720 enzyme-linked immunosorbent assay (ELISA) units of HAVRIX and 20 mcg of recombinant HBsAg protein of Engerix-B and should be administered at months 0, 1, and 6. Twinrix may also be given at day 0, 7, 21 to 31, and the fourth dose at month 12.²³ Antibody seroconversion for hepatitis A and B was greater than 98% in adult volunteers tested 1 month after a three-dose vaccine series and with similar antibody protection with the four-dose series.^{7,23} The side-effect profile of Twinrix is similar to giving each vaccine separately.

Chronic Hepatitis B Treatment

According to the American Association for the Study of Liver Diseases (AASLD) guidelines, patients with HBeAg-positive CHB (also known as wild-type CHB) with persistently elevated ALT (more than two times the upper limit of normal) and elevated HBV DNA levels greater than 20,000 IU/mL (20,000 kIU/L) require treatment to delay progression to cirrhosis and prevent the development of ESLD.²⁴ Similar treatment criteria apply to patients infected with HBeAg-negative CHB (also known as precore mutant or promoter mutant) with the exception of HBV DNA levels; therapy should be initiated when viral levels are greater than 2,000 IU/mL (2,000 kIU/L).²⁴

The treatment endpoints for HBeAg-positive patients are different from those who are HBeAg-negative because the latter disease does not allow for HBeAg seroconversion. Thus an undetectable HBV DNA level, not seroconversion, is considered a treatment endpoint. Additionally, the ideal treatment should induce a biochemical response (decrease or normalize ALT levels) and histological response (decrease liver biopsy scores).²⁴ HBeAg-negative HBV infections are more likely to develop liver fibrosis and may require lifelong treatment because undetectable HBV DNA levels are difficult to achieve.

7 *The drug of choice for CHB depends on the patient's past medical history, ALT, HBV DNA level, HBeAg status, severity of liver disease, and history of previous HBV therapy.* The safety and efficacy profile of the medication and the likelihood of developing drug resistance should also be considered. There are seven approved agents for the treatment of HBV: two interferons and five nucleoside/nucleotide analogs.

Entecavir and tenofovir are recommended as first line due to profound HBV DNA suppression and minimal resistance.²⁴ Pegylated interferon- α_{2a} is also considered a first-line agent for patients with compensated liver disease because it lacks drug resistance. Pegylated interferon has replaced unmodified interferon because the pegylated form may be given subcutaneously once weekly rather than three times weekly.

Adefovir is second line to tenofovir because the drug is less potent in suppressing hepatitis B viral replication in treatment-naïve patients. Lamivudine is no longer recommended as first-line therapy due to a high rate of resistance.^{24,25} Patients currently on adefovir or lamivudine and responding to treatment should continue with the regimen. However, if there is inadequate virologic response or drug resistance develops, adding another hepatitis B antiretroviral agent or switching to a more potent drug should be considered. The role of telbivudine in HBV therapy is limited due to its intermediate rate of resistance.²⁴ Each therapeutic agent is described briefly in the sections that follow.

► Interferon and Pegylated Interferon

Interferon- α_{2b} and pegylated interferon- α_{2a} are the only interferon therapies approved for treatment of chronic

hepatitis B. Pegylated interferon is interferon attached to a polyethylene glycol molecule that increases the half-life of the drug, thereby allowing once-weekly dosing versus thrice-weekly administration of unmodified interferon. Unlike other antiretroviral treatments, interferon therapy is effective in suppressing, and in some cases ceasing, viral replication without inducing resistance.²⁴ Approximately a third of HBeAg-positive patients achieved HBeAg seroconversion after 48 weeks of pegylated interferon therapy.^{24,25} Patients with HBeAg-negative hepatitis B may require at least 48 weeks of pegylated interferon to attain undetectable HBV DNA levels.²⁶ Factors in achieving a greater chance of HBeAg seroconversion include low baseline HBV DNA concentrations, high pretreatment ALT levels, and high histological activity.^{24,26}

Pegylated interferon is well tolerated with similar or better efficacy than unmodified interferon; thus it is recommended over unmodified interferon for the treatment of CHB.²⁴ The approved dose of pegylated interferon- α_{2a} (Pegasys) for HBeAg-positive CHB is 180 mcg subcutaneously once weekly for 48 weeks. The same dose of pegylated interferon is recommended for HBeAg-negative CHB; however, the duration of therapy may be greater than 48 weeks to increase sustained responses.²⁴

Even though the advantages of interferon or pegylated interferon include a finite duration of treatment, lack of resistance, and possible HBsAg loss or seroconversion (development of anti-HBs), there are several significant disadvantages. These include the need for subcutaneous injections and a pronounced adverse-effect profile that may require dosage reductions or treatment discontinuation. Refer to the subsequent section on hepatitis C for the type and management of pegylated interferon adverse effects. Approximately 35% of patients develop an ALT flare when treated with interferon. An increase in ALT has been associated with a positive response, but it may lead to hepatic decompensation, which can be fatal. Therefore, only patients with compensated liver disease and stable medical comorbidities should be considered for treatment with pegylated interferon.

► Entecavir

Entecavir (Baraclude) is a guanosine nucleoside analog that is highly effective in suppressing HBV DNA polymerase. Entecavir is approved for HBeAg-positive, HBeAg-negative, and lamivudine-resistant CHB.²⁴⁻²⁶ Resistance rates are low (1% to 2%) in patients treated with entecavir for up to 5 years in lamivudine-naïve individuals. For patients previously treated with lamivudine and switched to entecavir, the resistance rate is approximately 50% at 5 years.^{24,25}

The dose of entecavir is 0.5 mg once daily for patients with compensated liver disease and naïve to lamivudine therapy. Higher doses of entecavir at 1 mg once daily are recommended for lamivudine or telbivudine resistance or decompensated liver disease. Entecavir should be given on an empty stomach. Dosage adjustments are required in patients with renal dysfunction. The side-effect profile for entecavir is

similar to lamivudine and adefovir dipivoxil. Patients treated with entecavir should be monitored for signs and symptoms of lactic acidosis and severe hepatomegaly with steatosis because some cases have been fatal.

The labeling for entecavir contains a black box warning stating that monotherapy should not be recommended for patients coinfecting with HIV and HBV because there is a greater potential for developing resistance to HIV antiretroviral agents. Therefore, patients coinfecting with HIV and HBV should only receive entecavir if highly active antiretroviral therapy (HAART) therapy is also prescribed.

► **Tenofovir Disoproxil Fumarate**

Tenofovir disoproxil fumarate (Viread) is an acyclic adenine nucleotide reverse transcriptase inhibitor that is similar in structure to adefovir dipivoxil. Tenofovir inhibits HIV and hepatitis B viral replication and is indicated for HBeAg-positive and HBeAg-negative CHB and HIV when prescribed with other HAART therapies.

Tenofovir is preferred over adefovir for CHB infections because of greater effectiveness in inhibiting viral replication and lack of resistance at week 72.²⁵ Patients who developed resistance to lamivudine, entecavir, or adefovir may benefit from tenofovir.^{24,25}

The dose of tenofovir is 300 mg orally once daily taken on an empty stomach. Dose adjustments are required in patients with renal dysfunction because tenofovir is primarily renally excreted. Tenofovir is well tolerated with adverse effects similar to adefovir and other hepatitis B oral agents. Several case reports have implicated tenofovir in causing nephrotoxicity and Fanconi's syndrome.^{24,26} Decreased bone mineral density and osteomalacia have been reported in HIV patients undergoing tenofovir treatment. It would be prudent to monitor for creatinine clearance, phosphate levels, liver function tests, and bone mineral density prior to initiating treatment and during the course of therapy. Patients should also be monitored for signs and symptoms of lactic acidosis and severe hepatomegaly with steatosis because some cases have been fatal. Hepatic function should be carefully monitored if treatment is to be discontinued because severe acute exacerbations of hepatitis have been reported.

► **Adefovir Dipivoxil**

Adefovir dipivoxil (Hepsera) is a prodrug of adefovir, an adenosine nucleotide analog that inhibits DNA polymerase. Adefovir dipivoxil is indicated for CHB in patients older than 12 years. Resistance to adefovir dipivoxil is minimal for the first few years of treatment but increases to approximately 30% after 5 years of therapy.²⁴ Because adefovir and tenofovir are structurally similar, there is a high likelihood of developing cross-resistance when switching from adefovir to tenofovir. HIV resistance may develop if adefovir dipivoxil is given as monotherapy; therefore, it is recommended to test individuals to ensure they are not HIV positive.

The dose of adefovir dipivoxil is 10 mg once daily taken with or without food. The most common side effects include asthenia, abdominal pain, diarrhea, dyspepsia, headaches,

nausea, and flatulence. Adefovir dipivoxil is also associated with nephrotoxicity. Serum creatinine monitoring is recommended at baseline and every 3 months to detect renal tubular injury.²⁴ The dose must be reduced in patients with renal insufficiency. Monitor for signs and symptoms of lactic acidosis and severe hepatomegaly with steatosis because some cases have been fatal. Hepatic function should be carefully monitored if treatment is discontinued because severe acute exacerbations of hepatitis have been reported.

► **Lamivudine**

Lamivudine (Epivir-HBV) is an oral synthetic cytosine nucleoside analog having antiviral effects against HIV and hepatitis B virus. Lamivudine is effective in suppressing hepatitis B viral replication, normalizing ALT levels, and improving liver histology. Patients may have a similar or a superior response in achieving these end points when compared with interferon or pegylated interferon. Prolonged lamivudine therapy (up to 5 years) may be needed to sustain seroconversion, but this leads to lamivudine resistance as high as 60% to 70% at 5 years.^{25,26} Due to the high rate of resistance, lamivudine is no longer recommended as first-line therapy for CHB.²⁴

The adult dose of lamivudine is 100 mg orally once daily for treatment of CHB without HIV coinfections. Lamivudine at 3 mg/kg once daily up to a maximum dose of 100 mg is approved for pediatric patients (2 to 17 years of age). It may be taken with or without food. The dose must be adjusted in patients with renal dysfunction. Prior to prescribing lamivudine for CHB, it is important to confirm that the individual is not infected with HIV because treating with lamivudine alone for HIV will result in resistance.

Adverse effects are minimal and include fatigue, diarrhea, nausea, vomiting, and headaches. ALT levels should be monitored carefully because a two- to threefold increase may be observed. ALT should be monitored closely when therapy is discontinued because increased levels may indicate a flare in disease activity leading to liver failure. Similar to the other oral antihepatitis B agents, signs and symptoms of lactic acidosis and severe hepatomegaly should be monitored.

► **Telbivudine**

Telbivudine (Tyzeka) is an L-nucleoside analog that inhibits HBV replication. It is indicated for patients 16 years or older with HBeAg-positive or HBeAg-negative CHB with compensated liver disease. Telbivudine offers a slightly more effective reduction in HBV DNA levels and normalization of aminotransferases than lamivudine. Telbivudine resistance is lower than with lamivudine, but rates are significant with continued treatment; therefore, this drug is not highly recommended for hepatitis B infections.²⁴ Telbivudine may be considered if there is adefovir or tenofovir resistance.

The dose of telbivudine is 600 mg orally once daily with or without food. Dosage adjustments are required in patients with renal dysfunction. Adverse effects are similar to other HBV oral agents including lactic acidosis and severe hepatomegaly. Patients should also be monitored for

signs and symptoms of myopathy characterized by elevated creatine kinase levels and muscle weakness.²⁷ Peripheral neuropathy has also occurred, mostly in patients who were treated concomitantly with pegylated interferon.^{24,26} ALT and AST levels may become elevated while on treatment at rates similar to lamivudine. Telbivudine is not recommended for use in patients coinfecting with HIV and HBV because HIV drug resistance may develop with telbivudine monotherapy.

Hepatitis C Prevention

The risk factors for hepatitis C and hepatitis B are quite similar; thus the risk of acquiring HCV is minimized by avoiding contaminated blood products and high-risk behaviors such as sharing needles among IV drug users. The risk of HCV transmission through a blood transfusion is 1 in 2 million. No vaccines are available for preventing hepatitis C, but several are under development.²⁸ High-risk individuals (Table 24-1) should be tested for HCV because most patients will be asymptomatic and unaware they are infected.¹⁴

Chronic Hepatitis C Treatment

Individuals with confirmed chronic hepatitis C should be evaluated for treatment to prevent the development of cirrhosis, liver cancer, and ESLD.²⁹⁻³¹ The primary goal of HCV treatment is to achieve a sustained virologic response (SVR). Several other virological responses have been defined to determine if HCV treatment should be continued or discontinued. An undetectable HCV RNA level at week 4 of therapy is called a rapid virologic response (RVR), and an undetectable level at week 12 is an early virologic response (EVR). RVR is an important time point used in response-guided therapy (RGT) to determine the duration of HCV therapy, whereas an EVR is an indicator to discontinue treatment if the HCV RNA is still detectable. Additional goals of therapy include normalizing hepatic aminotransferases and improving liver histology.

8 *Treatment for chronic hepatitis C depends on the patient's past medical history, previous HCV treatment history, severity of liver disease, and HCV genotype. The most important predictor of response to therapy is the hepatitis C*

genotype. Individuals with genotype 2 or 3 achieve a higher SVR than patients with genotype 1.^{29,30} The genotype also determines the duration of therapy.

Interferon- α_{2a} (Roferon A), interferon- α_{2b} (Intron-A), and interferon alfacon-1 (Infergen) were first approved for chronic hepatitis C but are no longer recommended because less than 10% of patients with genotype 1 and about 30% with genotype 2 or 3 achieve a SVR.²⁹ Pegylated interferon- α_{2a} (Pegasys) and pegylated interferon- α_{2b} (PEG-Intron) were later introduced in the early 2000s for the treatment of hepatitis C. Pegylated interferons have an extended half-life that allows for once-weekly administration. The SVR to pegylated interferon alone (25% to 40%) can be increased by adding ribavirin, a synthetic guanosine analog that inhibits viral polymerase (45% to 55%). Based on the second National Institutes of Health (NIH) 2002 Consensus Development Conference, pegylated interferon plus ribavirin is the regimen of choice for chronic hepatitis C.²⁹ The recommended treatment duration is 24 weeks for genotypes 2 and 3 and 48 weeks for genotype 1.²⁹

Boceprevir and telaprevir are protease inhibitors that belong to a new class of drugs known as direct-acting antivirals (DAAs). They are approved for the treatment of HCV genotype 1 disease and must be coadministered with pegylated interferon and ribavirin. Pegylated interferon, ribavirin, and the two DAAs are discussed further in the sections that follow.

► Pegylated Interferon and Ribavirin

Pegylated interferon- α_{2a} and pegylated interferon- α_{2b} are indicated for chronic hepatitis C infections. The recommended dose of pegylated interferon- α_{2a} (Pegasys) is 180 mcg once weekly, and the adult dose of pegylated interferon- α_{2b} (PEG-Intron) is 1.5 mcg/kg/week, both administered subcutaneously. Patients with renal impairment (creatinine clearance less than 50 mL/min [0.83 mL/s]) should have the dose of pegylated interferon modified.

The dose of ribavirin is weight based according to genotype (Table 24-7). Doses higher than the recommended 15 mg/kg may be considered to increase the chance of SVR.^{30,31} The ribavirin dose must be adjusted in patients with creatinine clearance less than 50 mL/min (0.83 mL/s).

Most patients treated with pegylated interferon experience flulike symptoms (fevers, chills, rigors, and myalgias). These symptoms may be mild to moderate in severity and usually occur with the first injection and diminish with continued treatment. Flulike symptoms may be minimized by premedication with acetaminophen or nonsteroidal anti-inflammatory drugs. Patients may also self-administer pegylated interferon prior to bedtime so they can sleep through the symptoms.

Psychiatric adverse effects occur frequently and may include irritability, depression, and, rarely, suicidal ideation. Patients developing mild to moderate psychiatric symptoms may require antidepressants or anxiolytics. Those with severe symptoms including suicidal ideation should discontinue treatment immediately.^{29,30}

Patient Encounter, Part 2: Creating a Care Plan

Based on the information presented, create a care plan for this patient's hepatitis. Your plan should include:

- (a) a statement of the drug-related needs and/or problems;*
- (b) the goals of therapy;*
- (c) a patient-specific detailed therapeutic plan;*
- (d) a follow-up plan to determine whether the goals have been achieved; and*
- (e) a follow-up plan to identify potential adverse effects of therapy.*

Table 24-7

Dosing Recommendation for Pegylated Interferon and Ribavirin¹ for Chronic Hepatitis C**Genotype 1 disease; creatinine clearance (CrCl) greater than 50 mL/min (0.83 mL/s)**

Dose and Duration of Therapy	Pegylated interferon- α_{2a} (Pegasys)	Pegylated interferon- α_{2b} (PEGINTRON)
Pegylated interferon (weekly dose)	180 mcg ²	1.5 mcg/kg
Ribavirin (in 2 divided daily doses)	1000 mg if less than or equal to 75 kg ² 1200 mg if more than 75 kg ²	800 mg if less than or equal to 65 kg 1000 mg if more than 65–85 kg 1200 mg if more than 85–105 kg 1400 mg if more than 105 kg
Planned duration	Response guided therapy	Response guided therapy

Genotype 2/3 disease; CrCl greater than 50 mL/min (0.83 mL/s)

Dose and Duration of Therapy	Pegylated interferon- α_{2a} (Pegasys)	Pegylated interferon- α_{2b} (PEGINTRON)
Pegylated interferon (weekly dose)	180 mcg ²	1.5 mcg/kg
Ribavirin (in 2 divided daily doses)	800 mg ²	800 mg
Planned duration	24 weeks	24 weeks

Dose adjustment of pegylated interferon and ribavirin based on CrCl.

CrCl	Pegylated interferon- α_{2a} (Pegasys)	Pegylated interferon- α_{2b} (PEGINTRON)	Ribavirin (Copegus) ³
30–50 mL/min (0.50–0.83 mL/s)	180 mcg	reduce by 25%	Alternating doses: 200 mg and 400 mg every other day
Less than 30 mL/min (0.50 mL/s)	135 mcg	reduce by 50%	200 mg daily
Hemodialysis	135 mcg	reduce by 50%	200 mg daily

¹Generic ribavirin may be used instead of proprietary products (Copegus, Rebetol).

²Doses of pegylated interferon and ribavirin must be renally adjusted base on CrCl.

³These dosing recommendations reflect the package labeling for Copegus; labeling for Rebetol states that it should not be used in patients with CrCl below 50 mL/min (0.83 mL/s).

Up to 35% of patients treated with pegylated interferon and ribavirin require either a dosage reduction or drug discontinuation due to the hematologic complications of thrombocytopenia, neutropenia, or anemia.^{32,33} A decrease in platelet count of 25% to 30% usually occurs within 6 to 8 weeks after initiation of treatment. The pegylated interferon dose should either be reduced or discontinued if the platelet count declines significantly or symptoms of bruising and bleeding are present. Neutropenia associated with pegylated interferon plus ribavirin therapy may be more pronounced when boceprevir is also administered. Neutropenia usually occurs within the first 2 weeks after initiating treatment, with the WBC count and ANC levels stabilizing by week 4 or 6. Neutropenia is reversible upon discontinuing the medications. Granulocyte colony-stimulating factor has been used as an adjunctive therapy for neutropenia.^{29,30}

Ribavirin causes a dose-related hemolytic anemia.³⁴ Patients treated with pegylated interferon and ribavirin with or without DAAs may require dosage reductions when hemoglobin levels decrease to less than 10.5 g/dL (105 g/L or 6.52 mmol/L) or when intolerable symptoms such as shortness of breath or severe fatigue develop. Reducing the dose of ribavirin and blood transfusions may be necessary in rare cases when hemoglobin levels fall below 8.5 g/dL (85 g/L or 5.28 mmol/L) when being treated with DAAs. If warranted, epoetin alfa or darbepoetin may be used as adjunctive therapy for anemia.^{29,30}

Because ribavirin can be teratogenic and embryocidal, all women of childbearing age and men who are able to father a child must use two forms of contraception with hepatitis C therapy and for 6 months after treatment.³⁰

Adherence to therapy is an important factor in increasing and maintaining SVR. Patients who were adherent with pegylated interferon and ribavirin therapy (taking more than 80% of doses for more than 80% of the treatment duration) had an SVR of 52%, whereas those who were not adherent had an SVR of 44%.³⁵

► Boceprevir

Boceprevir (Victrelis) is a protease inhibitor that inhibits HCV viral replication in patients with genotype 1 disease.^{30,31} Boceprevir is indicated for adult naive or previously treated patients with compensated liver disease who failed previous treatment with interferon or pegylated interferon plus ribavirin. Monotherapy is not recommended because of drug resistance; therefore, it must be coadministered with pegylated interferon and ribavirin.^{30,31,36} The SVR rate with boceprevir triple therapy is 63% to 66% compared with the pegylated interferon plus ribavirin SVR of about 50%.³¹ In addition to the possible adverse effects of pegylated interferon and ribavirin, patients receiving triple therapy have a higher incidence of anemia and neutropenia.^{30,31} Complete blood

counts with differential should be obtained at baseline and at least every 4 weeks during therapy. Dysgeusia, skin rash, itching, and dry skin were also more common with boceprevir.

The dose of boceprevir is 800 mg (four 200-mg capsules) three times a day with food in combination with pegylated interferon and ribavirin. Using a “lead-in” phase, pegylated interferon and ribavirin are given in recommended doses for 4 weeks, and boceprevir is added during week 5.³¹ The duration of therapy is based on the patient’s viral load at weeks 8, 12, and 24, known as response-guided therapy (RGT). If the HCV RNA level is greater than 100 IU/mL (100 kIU/L) at week 12 or continues to be detectable at week 24, all three medications are to be discontinued.

► Telaprevir

Telaprevir (Incivek) is a protease inhibitor that inhibits HCV replication. It is indicated for hepatitis C genotype 1 disease in treatment-naïve patients or those who failed prior pegylated interferon plus ribavirin treatment. Telaprevir must be administered as a triple therapy with pegylated interferon and ribavirin to reduce the likelihood of drug resistance.³⁶ The SVR rates with telaprevir, pegylated interferon, and ribavirin range from 72% to 79%.^{29,31}

The most common side effects of telaprevir are anemia, skin rash and pruritus, nausea, diarrhea, and anorectal discomfort. The dose of telaprevir is 750 mg (two 375-mg tablets) three times a day with food in combination with pegylated

interferon and ribavirin. The meal taken with telaprevir must contain at least 20 g of fat and must be ingested within 30 minutes prior to each dose to increase systemic absorption.³⁰ Telaprevir is administered with pegylated interferon and ribavirin from day 1 up to week 12 if the HCV RNA level is undetectable at week 4.

Boceprevir and telaprevir are potent CYP3A4 inhibitors; therefore, serum concentrations of concomitantly administered drugs may be elevated, prolonging their therapeutic and adverse effects. Therefore a thorough medication history including prescription, over-the-counter, and dietary and herbal supplements must be obtained prior to prescribing DAAs.

Hepatitis D Prevention and Treatment

Hepatitis D infection is possible only if the patient is also infected with HBV; therefore, hepatitis B vaccination can indirectly prevent hepatitis D infections. The recommended treatment for HDV is pegylated interferon for 48 to 72 weeks.¹⁵ First-line oral agents for treating HBV infections (e.g., tenofovir) may be considered in patients coinfecting with HDV and HBV if HBV DNA levels are high. Monotherapy with nucleoside/nucleotide analogs is ineffective in reducing HDV DNA levels but may decrease hepatitis B viral loads.¹⁵

Hepatitis E Prevention and Treatment

Because hepatitis E is transmitted via the fecal–oral route, good personal hygiene and proper disposal of sanitary waste are the most effective ways to prevent viral acquisition. There are no commercial vaccines available to prevent hepatitis E; however, a recombinant hepatitis E vaccine undergoing Phase II/III study has produced promising preliminary results.^{16,37}

Patient Encounter, Part 3

The patient received treatment for hepatitis C for 4 weeks, and the following laboratory results have just been obtained:

- Sodium 138 mEq/L (138 mmol/L), potassium 4.0 mEq/L (4.0 mmol/L), chloride 98 mEq/L (98 mmol/L), CO₂ 19 mEq/L (19 mmol/L), BUN 21 mg/dL (7.5 mmol/L), serum creatinine 1.0 mg/dL (88 μmol/L), glucose 103 mg/dL (5.7 mmol/L)
- Hemoglobin 10.1 g/dL (101 g/L or 6.3 mmol/L), hematocrit 30.3% (0.303), WBC 2.2 × 10³/mm³ (2.2 × 10⁹/L), platelets 104 × 10³/mm³ (104 × 10⁹/L), ANC 0.92 × 10³/mm³ (0.92 × 10⁹/L)
- AST 41 IU/L (0.68 μkat/L), ALT 32 IU/L (0.53 μkat/L)
- Total bilirubin 1.0 mg/dL (17.1 μmol/L), albumin 3.6 g/dL (36 g/L), alkaline phosphatase 168 IU/L (2.8 μkat/L)
- HCV RNA level: 530 IU/mL (530 kIU/L)

What questions should you ask the patient?

What action should you take to treat any complaints the patient may have?

What action should you take based on the patient’s week 4 HCV RNA level?

● OUTCOME EVALUATION

Monitoring for efficacy in patients treated for chronic hepatitis B or C includes evaluating aminotransferase levels and hepatitis B or C viral levels.

Hepatitis B

- Obtain an ALT at baseline and then every 3 to 6 months during hepatitis B treatment.
- Monitor HBV DNA levels every 3 to 6 months to determine treatment response in patients with CHB undergoing HBV therapy.
- Monitor HBeAg and anti-HBe every 6 months to determine if seroconversion to anti-HBe occurred or HBeAg was lost in patients with HBeAg-positive CHB.^{24,25}
- Monitor HBsAg every 6 to 12 months to determine if HBsAg was lost or anti-HBs developed in patients with HBeAg-negative chronic hepatitis B with persistently undetectable serum HBV DNA levels.^{24,25}
- Reevaluate the patient at month 6 and either switch or add a more potent hepatitis B antiviral agent to the

current hepatitis B regimen if the HBV DNA level has not decreased by 2 logs at 6 months of therapy.²⁴

- Continue treatment in patients with HBeAg-positive CHB until HBeAg seroconversion has been attained along with undetectable HBV DNA levels. Once anti-HBe appears, complete an additional 6 months of hepatitis B therapy.²⁴
- Continue treatment in patients with HBeAg-negative CHB until HBsAg is lost.²⁴
- Monitor all patients closely for hepatitis flare and viral relapse when discontinuing hepatitis B therapy.
- Obtain a CBC with differential every 4 weeks and thyroid-stimulating hormone (TSH) and fasting lipid panel every 12 weeks in patients receiving pegylated interferon therapy for hepatitis B.²⁴
- For patients receiving tenofovir or adefovir, monitor serum creatinine for nephrotoxicity at baseline and every 12 weeks.
- For patients taking telbivudine, monitor creatine kinase at baseline and periodically (e.g., every 12 weeks) because muscle weakness and myopathy have occurred.^{24,26}

Hepatitis C

- Sustained virologic response (SVR) is defined as having an undetectable HCV RNA level at 6 months posttreatment; this is the ultimate goal of HCV therapy and indicates a cure.^{29,31}
- Rapid virologic response (RVR) is defined as having an undetectable HCV RNA level at week 4 of treatment; this is an important time point to determine the duration of therapy with DAAs.
- Extended rapid virologic response (eRVR) is having undetectable HCV RNA level at week 4 and week 12 of treatment; this is a time point to determine if HCV treatment should be continued beyond 12 weeks.
- End of treatment response (ETR or EOT) is defined as having undetectable HCV RNA levels at the end of treatment.
- Response-guided therapy (RGT) is an approach used to determine the duration of therapy based on HCV RNA levels when treated with DAA agents.³¹
- Biochemical response is defined as normalization of ALT; monitor ALT levels every 4 weeks.
- Histologic response is defined as improving inflammation and fibrosis as documented by liver biopsy scores.
- Check the HCV RNA level at week 12 of therapy to determine the effectiveness of pegylated interferon and ribavirin. Discontinue treatment if the HCV RNA has not decreased by at least 2 logs or become undetectable by week 12.
- For patients with genotype 1 HCV: If the HCV RNA level is undetectable at week 12 of pegylated interferon and ribavirin therapy, continue treatment for at least another

36 weeks (48 weeks total). Obtain an HCV RNA level to determine ETR of the 48-week treatment, and repeat at 6 months posttherapy to determine SVR. This does not apply to DAAs.

- For patients treated with pegylated interferon and ribavirin with genotypes 2 and 3 HCV: Check the HCV RNA level at week 12. If HCV RNA is undetectable, continue treatment for a total of 24 weeks. Repeat the HCV RNA 24 weeks after completion of therapy to determine SVR.
- In patients receiving treatment with pegylated interferon with or without ribavirin, monitor the WBC, ANC, platelets, and hemoglobin levels either weekly or biweekly during the first month of therapy and monthly thereafter if stable.

Patient Encounter, Part 4

The patient has now been treated for a total of 12 weeks and the HCV RNA level is less than 12 IU/mL (12 kIU/L) at weeks 8 and 12

What action should you take based on the week 12 HCV RNA level?

What other information should you counsel the patient about in addition to the side effects associated with the hepatitis C therapy?

Patient Encounter, Part 5

AB's husband was recently tested for viral hepatitis and found to be positive for hepatitis B. His only past medical history is mild depression. He has not had any surgeries. He is not taking any medications, over-the-counter drugs, or dietary supplements.

All labs are normal except for the following:

- AST 69 IU/L (1.15 μ kat/L), ALT 92 IU/L (1.53 μ kat/L)
- Anti-HAV IgM (–), anti-HAV IgG (–), anti-HBs (–), HBsAg (+), HBeAg (–), anti-HBcIgG (+), anti-HBcIgM (–), anti-HBe (–), anti-HCV (–), HCV RNA less than 615 IU/mL (less than 615 kIU/L), HBV DNA 1,478,015 IU/mL (1,478,015 kIU/L).

Based on the information presented:

- create a detailed therapeutic care plan for the patient;*
- discuss adverse effects to monitor;*
- discuss a follow-up plan to determine whether the treatment goals have been achieved.*

Patient Care and Monitoring

- Evaluate the patient for risk factors for acquiring viral hepatitis (Table 24–1).
- Educate patients to avoid hepatotoxic agents (e.g., some dietary supplements).
- Educate patients to avoid consuming any alcohol if viral hepatitis has been diagnosed.
- Determine if the patient has been vaccinated against hepatitis A and B. If not, then vaccinate accordingly (Tables 24–3 and 24–4).
- Obtain a thorough past medical history focusing on psychiatric disorders, cardiac disorders, endocrine disease, and renal insufficiency.
- If available, review the liver biopsy report to determine the severity of liver damage and assess the need for chronic hepatitis B or C treatment.
- Assess for adverse effects in patients with hepatitis B or C.
- Encourage medication compliance with viral hepatitis treatments to increase the SVR.
- Encourage patients to drink at least 8 glasses of water daily to prevent dehydration.
- Educate all women of childbearing age and men who are able to father a child to use two forms of contraception during and for 6 months after ribavirin therapy.
- Provide patient education:
 - How to prevent viral hepatitis transmission
 - Who should be vaccinated against hepatitis A and B
 - Importance of taking all medications daily at scheduled times
 - Adverse effects of hepatitis B and C medications
 - How to self-administer pegylated interferon injections correctly
 - Importance of appropriate disposal of used injection needles

- Monitor TSH and fasting lipid panel every 12 weeks while on hepatitis C treatment.
- Monitor serum creatinine in patients receiving ribavirin to detect renal insufficiency that may result in ribavirin accumulation and toxicity (e.g., hemolytic anemia).

Abbreviations Introduced in This Chapter

ALT	Alanine aminotransferase
ANC	Absolute neutrophil count
Anti-HAV	Hepatitis A virus antibody
Anti-HBc	Hepatitis B core antibody
Anti-HBe	Hepatitis B envelope antibody
Anti-HBs	Hepatitis B surface antibody
Anti-HCV	Hepatitis C antibody
Anti-HDV	Hepatitis D antibody
Anti-HEV	Hepatitis E antibody
AST	Aspartate aminotransferase
CHB	Chronic hepatitis B infection
CrCl	Creatinine clearance
DAA	Direct acting antiretroviral
ETR	End of treatment response
ESLD	End-stage liver disease
eRVR	Extended rapid virologic response
EVR	Early virologic response
HAV	Hepatitis A virus
HBcAg	Hepatitis B core antigen
HBeAg	Hepatitis B envelope antigen

HBIG	Hepatitis B immunoglobulin
HBsAg	Hepatitis B surface antigen
HBV	Hepatitis B virus
HBV DNA	Hepatitis B deoxyribonucleic acid
HCV	Hepatitis C virus
HCV RNA	Hepatitis C virus ribonucleic acid
HDV	Hepatitis D virus
HDVAg	Hepatitis D antigen
HDV RNA	Hepatitis D virus ribonucleic acid
HEV	Hepatitis E virus
IgG	Immunoglobulin G
IgG anti-HD	IgG antibodies to hepatitis D virus antigen
IgM	Immunoglobulin M
IgM anti-HD	IgM antibodies to hepatitis D virus antigen
IG	Immune globulin
IGIM	Immune globulin for intramuscular administration
IGIV	Immune globulin for IV administration
MMR	Measles, mumps, rubella vaccine
PCR	Polymerase chain reaction
RVR	Rapid virologic response
SVR	Sustained virologic response

Acute Kidney Injury

Mary K. Stamatakis

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Assess a patient's kidney function based on clinical presentation, laboratory results, and urinary indices.
2. Identify pharmacotherapeutic outcomes and endpoints of therapy in a patient with acute kidney injury (AKI).
3. Apply knowledge of the pathophysiology of AKI to the development of a treatment plan.
4. Design a diuretic regimen based on the pharmacokinetic and pharmacodynamic characteristics of the drug.
5. Select pharmacotherapy to treat complications associated with AKI.
6. Develop strategies to minimize the occurrence of AKI.
7. Monitor and evaluate the safety and efficacy of the therapeutic plan.

KEY CONCEPTS

- 1 Equations to estimate creatinine clearance (CrCl) that incorporate a single serum creatinine concentration (e.g., Cockcroft-Gault) typically overestimate kidney function.
- 2 There is currently no drug therapy that hastens patient recovery in AKI, decreases length of hospitalization, or improves survival.
- 3 Loop diuretics are the diuretics of choice for the management of volume overload in AKI.
- 4 There is no indication for the use of low-dose dopamine in the treatment of AKI.
- 5 Identifying patients at risk for development of AKI and implementing preventive methods to decrease its occurrence or severity is critical.

Acute kidney injury (AKI) is a potentially life-threatening clinical syndrome that occurs primarily in hospitalized patients and frequently complicates the course of the critically ill. It is characterized by a rapid decrease in **glomerular filtration rate** (GFR) and the resultant accumulation of nitrogenous waste products (e.g., creatinine and urea nitrogen), with or without a decrease in urine output. The term *acute renal failure* (ARF) has largely been replaced by AKI in recent years because AKI more completely encompasses the entire spectrum of acute injury to the

kidney, from mild changes in kidney function to end-stage kidney disease requiring renal replacement therapy (RRT). Furthermore, the definition of ARF has been inconsistent in the literature, and a recent survey showed more than 30 different definitions in the literature.¹ Efforts to standardize the definition of ARF has led to a change in terminology to AKI as well as the development of a consensus definition and severity staging for AKI.²

The first consensus definition/classification for AKI was the *RIFLE* classification system, which categorizes patients into groups based on their change in serum creatinine or GFR from baseline, or decreased urine output.³ The categories of kidney dysfunction in the *RIFLE* classification include patients at risk (R), those with kidney injury (I), and those with kidney failure (F). Two additional categories of clinical outcomes are sustained loss (L), which requires RRT for at least 4 weeks; and end stage (E), which necessitates RRT for at least 3 months. Patients are assigned a class based on their indicator with the greatest severity. The complete schematic for the *RIFLE* classification system is depicted in **Figure 25-1**.

Subsequent to the development of the *RIFLE* criteria, the Acute Kidney Injury Network (AKIN) has adopted and further modified the *RIFLE* definition and staging for AKI. This system uses three stages (stages 1 to 3) and includes an absolute increase in serum creatinine of 0.3 mg/dL (27 μ mol/L) or greater in stage 1. This highlights the importance that even small increases in serum creatinine concentration can be associated with high morbidity and

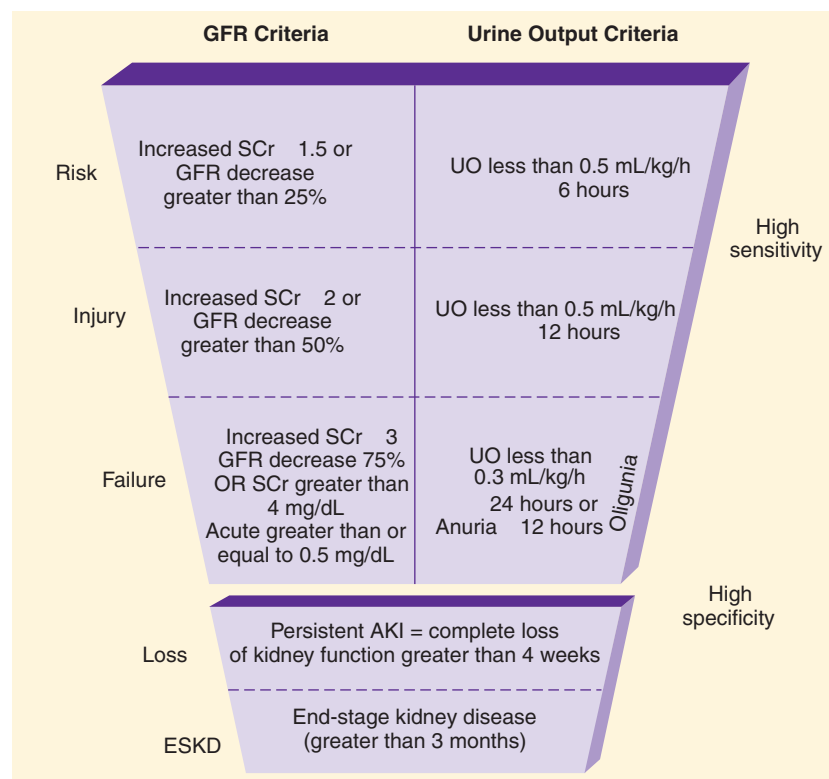

FIGURE 25-1. Algorithm for classification of acute kidney injury. The classification system includes separate criteria for creatinine and urine output. A patient can fulfill the criteria through changes in serum creatinine or changes in urine output, or both. The criteria that lead to the worst possible classification should be used. Note that the F component of RIFLE (Risk of renal dysfunction, Injury to the kidney, Failure of kidney function, Loss of kidney function, and End-stage kidney disease) is present even if the increase in SCr is under threefold as long as the new SCr is greater than 4 mg/dL (350 $\mu\text{mol/L}$) in the setting of an acute increase of at least 0.5 mg/dL (44 $\mu\text{mol/L}$). The designation RIFLE-FC should be used in this case to denote “acute-on-chronic” disease. Similarly, when the RIFLE-F classification is achieved by urine output criteria, a designation of RIFLE-FO should be used to denote oliguria. The shape of the figure denotes the fact that more patients (high sensitivity) will be included in the mild category, including some without actually having renal failure (less specificity). In contrast, at the bottom of the figure the criteria are strict and therefore specific, but some patients will be missed. (AKI, acute kidney injury; GFR, glomerular filtration rate; SCr, serum creatinine concentration; UO, urine output.) (From Bellomo R, Ronco C, Kellum, et al.; the ADQI Workgroup. Acute renal failure—definition, outcome measures, animal models, and information technology needs: The Second International Consensus Conference of the Acute Dialysis Quality Initiative (ADQI) Group. *Crit Care* 2004;8:R204–R212.)

mortality, and early detection is critical. It also includes a time constraint of 48 hours for diagnosis and categorizes all patients receiving RRT into stage 3, regardless of the length of RRT.⁴ The AKIN three-stage classification of AKI is shown in [Table 25-1](#).

EPIDEMIOLOGY AND ETIOLOGY

Approximately 5% to 7% of all hospitalized patients develop AKI. AKI is 5 to 10 times more prevalent in the hospital setting than in the community setting.⁵ About 5% to 20% of critically ill patients develop AKI,⁵ and 30% to 40% of survivors progress to chronic kidney disease.⁶ Despite improvements in the medical care of individuals with AKI, mortality generally exceeds 50%.⁷

PATHOPHYSIOLOGY

There are typically three categories of AKI: prerenal, intrinsic, and postrenal AKI. The pathophysiologic mechanisms differ for each of the categories.

Prerenal AKI

Prerenal AKI is characterized by reduced blood delivery to the kidney. A common cause is intravascular volume depletion due to conditions such as hemorrhage, dehydration, or GI fluid losses. Early restoration of volume replacement can prevent progression and improve recovery because no structural damage to the kidney has occurred.⁸ Conditions of reduced cardiac output (e.g., congestive heart failure [CHF] or myocardial infarction)

Table 25-1

AKIN Classification/Staging System for AKI

Stage	Absolute Serum Creatinine Increase from Baseline	Percentage Serum Creatinine Increase from Baseline	Urine Output	Need for Renal Replacement Therapy
1	Greater than or equal to 0.3 mg/dL (27 μ mol/L)	150–200% (1.5–2-fold)	Less than 0.5 ml/kg per hour for more than 6 hours	No
2	—	200–300% (2–3-fold)	Less than 0.5 ml/kg per hour for more than 12 hours	No
3	Greater than or equal to 4 mg/dL (354 μ mol/L) with an acute increase of at least 0.5 mg/dL (44 μ mol/L)	300% or greater (greater than 3-fold)	Less than 0.3 ml/kg for 24 hours or anuria for 12 hours	Need for renal replacement therapy indicates stage 3 regardless of serum creatinine or urine output

Based on the Acute Injury Network Classification/staging system for AKI.⁴ Only one of the three criteria needs to be met in order to qualify for the higher stage. Change in serum creatinine or urine output must occur within 48 hours.

and hypotension can also reduce renal blood flow, resulting in decreased glomerular perfusion and prerenal AKI. With a mild to moderate decrease in renal blood flow, intraglomerular pressure is maintained by dilation of afferent arterioles (arteries supplying blood to the glomerulus), constriction of efferent arterioles (arteries removing blood from the glomerulus), and redistribution of renal blood flow to the oxygen-sensitive renal medulla. Drugs may cause a functional AKI when these adaptive mechanisms are compromised. Nonsteroidal anti-inflammatory drugs (NSAIDs) impair prostaglandin-mediated dilation of afferent arterioles. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) inhibit angiotensin II-mediated efferent arteriole vasoconstriction and cause prerenal AKI in 6% to 38% of treated patients.⁹ Cyclosporine and tacrolimus, particularly in high doses, are potent renal vasoconstrictors. All of these agents can reduce intraglomerular pressure, with a resultant decrease in GFR. Prompt discontinuation of the offending drug can often return kidney function to normal. Other causes of prerenal AKI are renovascular obstruction (e.g., renal artery stenosis), hyperviscosity syndromes (e.g., multiple myeloma), or systemic vasoconstriction (e.g., hepatorenal syndrome). Prerenal AKI occurs in approximately 10% to 25% of patients diagnosed with AKI.

Intrinsic AKI

Intrinsic renal failure is caused by diseases that can affect the integrity of the tubules, glomerulus, interstitium, or blood vessels. Damage is within the kidney; changes in kidney structure can be seen on microscopy.¹⁰ **Acute tubular necrosis** (ATN) is a term that is often used synonymously with intrinsic renal failure, but it relates more specifically to a pathophysiologic condition that results from toxic (e.g., aminoglycosides, contrast agents, or amphotericin B) or ischemic insult to the kidney only. ATN results in necrosis of the proximal tubule epithelium and basement membrane, decreased glomerular capillary permeability, and back leak of glomerular filtrate into the venous circulation.¹¹ ATN

accounts for 50% of all cases of AKI.⁹ Glomerular, interstitial, and blood vessel diseases may also lead to intrinsic AKI but occur with a much lower incidence. Examples include glomerulonephritis, systemic lupus erythematosus, interstitial nephritis, and vasculitis. In addition, prerenal AKI can progress to intrinsic AKI if the underlying condition is not promptly corrected.¹⁰

Postrenal AKI

Postrenal AKI is due to obstruction of urinary outflow. Causes include benign prostatic hypertrophy, pelvic tumors, and precipitation of renal calculi.¹⁰ Rapid resolution of postrenal AKI without structural damage to the kidney can occur if the underlying obstruction is corrected. Postrenal AKI accounts for less than 10% of cases of AKI.

ASSESSMENT OF KIDNEY FUNCTION

The most common measure of overall kidney function is GFR. It is defined as the volume of plasma filtered across the glomerulus per unit time and correlates well with the filtration, secretion, reabsorption, endocrine, and metabolic functions of the kidney. In addition to aiding in the diagnosis and assessment of the severity of AKI, an accurate estimate of GFR can assist in proper dosing of drugs that undergo renal elimination. In an individual with normal kidney function, GFR ranges from approximately 90 to 120 mL/min (1.5 to 2.0 mL/s). Because GFR is difficult to measure directly, it is routinely estimated by determining the renal clearance of a substance that is filtered at the glomerulus and does not undergo significant tubular reabsorption or secretion. Creatinine is an endogenous substance that is a normal by-product of muscle metabolism. Ninety percent of creatinine is eliminated by glomerular filtration; tubular secretion is responsible for the remaining 10%.

- Direct measurement of **creatinine clearance** (CrCl) requires collection of urine over an extended time interval (usually 24 hours) with measurement of urine volume, urine

Table 25-2

Equations for Estimation of CrCl

Urine Collection Method

$$\text{CrCl (mL/min)} = \frac{(\text{Ucr})(V)}{(\text{SCr})(T)}$$

Ucr = urine creatinine concentration, mg/dL
 V = volume of urine, mL
 SCr = serum creatinine concentration, mg/dL
 T = time of urine collection, minute
 (Note: Time equals 1,440 minutes for a 24-hour collection)

Cockcroft–Gault Equation for Adults¹¹

$$\text{CrCl (mL/min)} = \frac{(140 - \text{Age}) \times (\text{BW})}{(\text{SCr}) \times 72} \quad (0.85 \text{ if women})$$

Age, years
 BW = actual body weight, kg^a
 SCr = serum creatinine concentration, mg/dL

Jelliffe Equation for Changing Renal Function¹⁴

Males

$$E^{SS} = \text{IBW} [(29.3 - 0.203 (\text{age}))]$$

$$E_{\text{corr}}^{SS} = E^{SS} [1.035 - 0.0337 (\text{SCr})]$$

$$E = \frac{E_{\text{corr}}^{SS} - [4 \times \text{IBW} \times (\text{SCr}_2 - \text{SCr}_1)]}{\Delta t}$$

$$\text{CrCl (mL/min/1.73 m}^2) = \frac{E}{[(14.4)(\text{SCr})]}$$

Females

$$E^{SS} = \text{IBW} [25.1 - 0.175 (\text{age})]$$

$$E_{\text{corr}}^{SS} = E^{SS} [1.035 - 0.0337 (\text{SCr})]$$

$$E = \frac{E_{\text{corr}}^{SS} - [4 \times \text{IBW} \times (\text{SCr}_2 - \text{SCr}_1)]}{\Delta t}$$

$$\text{CrCl (mL/min/1.73 m}^2) = \frac{E}{[(14.4)(\text{SCr})]}$$

E^{SS} = steady-state creatinine excretion
 Δt = time in days between measurement of SCr_1 and SCr_2
 IBW = ideal body weight, kg

Age, years

E_{corr}^{SS} = corrected steady-state creatinine excretion
 SCr_1 = first serum creatinine concentration
 SCr_2 = second serum creatinine concentration

E = creatinine excretion

^aTypically substituted with ideal body weight, or adjusted body weight when body weight is significantly greater (i.e., greater than 130%) than ideal body weight: Adjusted body weight = Ideal body weight + 0.25 (Actual body weight – Ideal body weight).

CrCl, creatinine clearance. For conversion of mg/dL to $\mu\text{mol/L}$ creatinine multiply by 88.4.

creatinine concentration, and serum creatinine concentration (SCr; Table 25-2). Although 24-hour urine collections have been used to measure CrCl in clinical practice, difficulty in collection of accurate 24-hour specimens renders this method time consuming and error prone. Collection intervals as short as 8 hours have yielded estimates similar to those obtained with 24-hour collections in several studies, and they may minimize overcollection or undercollection of urine that can occur with a 24-hour collection.

Because kidney function can fluctuate significantly during AKI, this method may also underestimate or overestimate kidney function depending on whether AKI is worsening or resolving.

Numerous equations have been developed for a quick bedside estimate of CrCl or GFR. They incorporate patient-specific variables such as SCr, body weight, age, and gender. One of the most widely used equations is the Cockcroft-Gault equation (Table 25-2).¹¹ It is generally considered acceptable in individuals whose renal function is relatively constant, as defined as a daily change in serum creatinine of less than 10% to 15% within 24 hours. **1** Equations to estimate creatinine clearance (CrCl) that incorporate a single serum creatinine concentration such as the Cockcroft-Gault equation typically overestimate kidney function.¹² A 10% to 15% overestimation of CrCl occurs due to secretion of creatinine into the tubules, particularly at lower GFRs, where the contribution of creatinine secretion can become significant.

In instances where kidney function is fluctuating, several equations (Jelliffe, Brater, Chiou) have been developed to assess unstable kidney function.¹³⁻¹⁵ These equations estimate CrCl by considering the change in serum creatinine over a specified time period (Table 25-2, Jelliffe equation). Although they are more mathematically difficult to calculate, they take into consideration a change in serum creatinine compared with an equation that only includes a single creatinine concentration. It should be noted that these methods have not been validated, and drug dosage adjustments based on CrCl estimates from these formulas in patients with AKI have not been evaluated. Calculations of CrCl in AKI must be viewed as best estimates under variable conditions, and ongoing patient monitoring is necessary to avoid drug toxicity.

Estimating CrCl is only one part of evaluating a patient's overall kidney function. Other factors, such as symptomatology, laboratory test results, urinary indices, and results of diagnostic procedures, will aid in the diagnosis and assessment of the severity of disease. By monitoring SCr on a routine basis, it can be estimated whether kidney function is improving or worsening. Kidney function can also be evaluated based on urine output. **Oliguria** and **anuria** are defined as urine outputs of less than 400 mL and 50 mL over 24 hours, respectively. Patients with reduced urine output often have an increased mortality and may represent a more severe form of AKI. Nonoliguric AKI is defined as a urine output of greater than 400 mL/day. It may still represent severe AKI but is associated with better patient outcomes.¹⁶

Clinical Presentation and Diagnosis of AKI

While some clinical and laboratory findings assist in the general diagnosis of AKI, others are used to differentiate among prerenal, intrinsic, and postrenal AKI. For example, patients with prerenal AKI typically demonstrate enhanced sodium reabsorption, which is reflected by a low urine sodium concentration and a low fractional excretion of sodium. Urine is typically more concentrated with prerenal AKI, and there is a higher urine osmolality and urine-to-plasma creatinine ratio compared with intrinsic and postrenal AKI.

Signs and Symptoms of Uremia

- Peripheral edema
- Weight gain
- Nausea/vomiting/diarrhea/anorexia
- Mental status changes
- Fatigue
- Shortness of breath
- Pruritus
- Volume depletion (prerenal AKI)
- Weight loss (prerenal AKI)
- Anuria alternating with polyuria (postrenal AKI)
- Colicky abdominal pain radiating from flank to groin (postrenal AKI)

Physical Examination Findings

- Hypertension
- Jugular venous distention (JVD)
- Pulmonary edema
- Rales
- Asterixis
- Pericardial or pleural friction rub
- Hypotension/orthostatic hypotension (prerenal AKI)
- Rash (acute interstitial nephritis)
- Bladder distention (postrenal bladder outlet obstruction)
- Prostatic enlargement (postrenal AKI)

Laboratory Tests

- Elevated SCr (normal range approximately 0.6 to 1.2 mg/dL [53 to 106 μ mol/L])
- Elevated BUN concentration (normal range approximately 8 to 25 mg/dL [2.9 to 8.9 mmol/L])
- Decreased CrCl (normal range: 90 to 120 mL/min [1.5 to 2.0 mL/s])
- BUN-to-creatinine ratio greater than 20:1 for units of mg/dL (prerenal AKI); less than 20:1 for units of mg/dL (intrinsic or postrenal AKI)
- Hyperkalemia
- Metabolic acidosis

Urinalysis

- Sediment
 - Scant or bland (prerenal or postrenal AKI)
 - Brown, muddy granular casts (highly indicative of ATN)
 - Proteinuria (glomerulonephritis or allergic interstitial nephritis)
 - Eosinophiluria (acute interstitial nephritis)
 - Hematuria/red blood cell casts (glomerular disease or bleeding in urinary tract)
 - WBCs or casts (acute interstitial nephritis or severe pyelonephritis)

Urinary Indices	Prerenal AKI	Intrinsic and Postrenal AKI
Urine osmolality (concentration of solutes in the urine in mOsm/kg or mmol/kg)	Greater than 500	Less than 350
Urine sodium concentration (mEq/L or mmol/L)	Less than 20	Greater than 40
Specific gravity	Greater than 1.020	Less than 1.015
Urine-to-plasma creatinine ratio	Greater than 40:1	Less than 20:1
Fractional excretion of sodium (FENa)	Less than 1%	Greater than 1%

$$\text{Fractional excretion of sodium (FENa)} = 100 \times \frac{\left(\frac{\text{Urinary sodium concentration} \times \text{Plasma creatinine concentration}}{\text{Plasma sodium concentration} \times \text{Plasma creatinine concentration}} \right)}{\left(\frac{\text{Plasma sodium concentration} \times \text{Plasma creatinine concentration}}{\text{Plasma creatinine concentration}} \right)}$$

FENa is a measure of the percentage of sodium excreted by the kidney. A FENa less than 1% may indicate prerenal AKI because it represents the response of the kidney to decreased renal perfusion by decreasing sodium excretion. Loop diuretics such as furosemide enhance sodium excretion and increase FENa, confounding the interpretation of the test.

Common Diagnostic Procedures

- Urinary catheterization (insertion of a catheter into a patient's bladder; an increase in urine output may occur with postrenal obstruction)
- Renal ultrasound (uses sound waves to assess size, position, and abnormalities of the kidney; dilatation of the urinary tract can be seen with postrenal AKI)
- Renal angiography (administration of IV contrast dye to assess the vasculature of the kidney)
- Retrograde pyelography (injection of contrast dye into the ureters to assess the kidney and collection system)
- Kidney biopsy (collection of a tissue sample of the kidney for the purpose of microscopic evaluation; may aid in the diagnosis of glomerular and interstitial diseases)

TREATMENT

Desired Outcomes

- A primary goal in the care of patients with AKI is ameliorating any identifiable underlying causes of AKI such as hypovolemia, nephrotoxic drug administration, or ureter obstruction. Prerenal and postrenal AKI can be reversed if the underlying problem is promptly identified and corrected, whereas treatment of intrinsic renal failure is more supportive in nature. 2 *There is no evidence that drug therapy hastens patient recovery in AKI, decreases length of hospitalization, or improves survival.* Therefore, options are limited to supportive therapy, such as fluid, electrolyte, and nutritional support, RRT, and treatment of nonrenal complications such as sepsis and GI bleeding while regeneration of the renal epithelium occurs. In addition, prevention of adverse drug reactions by discontinuing nephrotoxic drugs or adjustment of drug dosages based on the patient's renal function is desired.

Pharmacologic Therapy

► Loop Diuretics

There is significant controversy over the role of loop diuretics in the treatment of AKI. Theoretical benefits of loop diuretics in hastening recovery of renal function include decreased tubular oxygen requirements of the kidney, increased resistance to ischemia, increased urine flow rates that reduce intraluminal obstruction and filtrate back leak, and renal vasodilation. Theoretically, these effects could

lead to increased urine output, decreased need for dialysis, improved renal recovery, and ultimately, increased survival. However, there are conflicting reports in the literature over the efficacy of loop diuretics. Most studies demonstrate an improvement in urine output but with no effect on survival or need for dialysis. There are some reports that loop diuretics may worsen kidney function.¹⁷ This may be due in part to excessive preload reduction that results in renal vasoconstriction. Thus loop diuretics are limited to instances of volume overload and edema, and they are not intended to hasten renal recovery or improve survival.

Loop diuretics (furosemide, bumetanide, torsemide, and ethacrynic acid) are all equally effective when given in equivalent doses. Therefore, selection is based on the side-effect profile, cost, and pharmacokinetics of the agents. The incidence of ototoxicity is significantly higher with ethacrynic acid compared with the other loop diuretics; therefore, its use is limited to patients who are allergic to the sulfa component in the other loop diuretics.¹⁸ Although ototoxicity is a well-established side effect of furosemide, its incidence may be greater when administered by the IV route at a rate exceeding 4 mg/min. Torsemide has not been reported to cause ototoxicity.

There are several pharmacokinetic differences between loop diuretics. Fifty percent of a dose of furosemide is excreted unchanged by the kidney with the remainder undergoing glucuronide conjugation in the kidney.¹⁹ In contrast, liver metabolism accounts for 50% and 80% of the elimination of bumetanide and torsemide, respectively.¹⁹ Thus patients with AKI may have a prolonged half-life of furosemide. The bioavailability of both torsemide and

Patient Encounter, Part I

JD is a 65-year-old woman who presents to the clinic for follow-up evaluation of her type 2 diabetes and dyslipidemia. She also has a past medical history of stage 2 chronic kidney disease with proteinuria, hypothyroidism, gout, hypertension, allergic rhinitis, and chronic back pain. She reports having nausea, vomiting, and a low-grade fever last week. Her grandson had similar symptoms, and she did not seek treatment. Her fever resolved with ibuprofen, but she still feels weak and nauseated. She states that she feels like she is "holding on to water." Her weight is usually about 135 pounds (61 kg), and she now weighs 140 lbs (64 kg). Upon preliminary examination, she was found to have 2+ pitting edema, elevated blood pressure, and crackles on auscultation.

Meds:

Fexofenadine 180 mg orally once daily
Valsartan 160 mg orally once daily
Hydrochlorothiazide 25 mg orally once daily

Atorvastatin 10 mg orally daily
Metformin 500 mg orally twice daily
Glipizide 5 mg orally daily
Metoprolol 25 mg orally twice daily
Allopurinol 300 mg orally daily
Levothyroxine 25 mcg orally daily
Acetaminophen 500 mg 1 to 2 tablets orally every 6 hours as needed
Ibuprofen 400 to 800 mg as needed for arthritis pain and fever

What signs and symptoms suggest AKI?

What risk factors does she have for developing AKI?

What additional laboratory and physical examination information do you need to fully assess the patient?

What questions would you ask her regarding her pharmacotherapy?

bumetanide is higher than for furosemide. The IV-to-oral ratio for bumetanide and torsemide is 1:1, bioavailability of oral furosemide is approximately 50%, with a reported range of 10% to 100%.²⁰

Furosemide and bumetanide are both available in generic formulations and generally less expensive than torsemide.

The pharmacodynamic characteristics of loop diuretics are similar when equivalent doses are administered. Because loop diuretics exert their effect from the luminal (urinary) side of the tubule, urinary excretion correlates with diuretic response. Substances that interfere with the organic acid pathway, such as endogenous organic acids that accumulate in renal disease, competitively inhibit secretion of loop diuretics into the lumen of the tubules. Therefore, large doses of loop diuretics may be required to ensure that adequate drug reaches the nephron lumen. In addition, loop diuretics have a ceiling effect where maximal natriuresis occurs.^{19,21} Thus very large doses of furosemide (e.g., 1 g) are generally not considered necessary and may unnecessarily increase the risk of ototoxicity.

Several adaptive mechanisms by the kidney limit effectiveness of loop diuretic therapy. Postdiuretic sodium retention occurs as the concentration of diuretic in the loop of Henle decreases. This effect can be minimized by decreasing the dosage interval (i.e., dosing more frequently) or by administering a continuous infusion.²² In patients with a CrCl of 25 mL/min (0.42 mL/s) or higher, furosemide at a dose of 10 mg/h would be a reasonable starting dose.¹⁹ A starting dose of 20 mg/h would be reasonable in patients with a CrCl less than 25 mL/min (0.42 mL/s).¹⁹ With a continuous infusion, a loading dose is recommended. Continuous infusion loop diuretics may be easier to titrate than bolus dosing, requires less nursing administration time, and may lead to fewer adverse reactions.

Prolonged administration of loop diuretics can lead to a second type of diuretic resistance. Enhanced delivery of sodium to the distal tubule can result in hypertrophy of distal convoluted cells.¹⁹ Subsequently, increased sodium chloride absorption occurs in the distal tubule that diminishes the effect of the loop diuretic on sodium excretion. Addition of a distal convoluted tubule diuretic, such as metolazone or hydrochlorothiazide, to a loop diuretic can result in a synergistic increase in urine output. There are no data to support the efficacy of one distal convoluted tubule diuretic over another. The common practice of administering the distal convoluted tubule diuretic 30 to 60 minutes prior to the loop diuretic has not been studied, although this practice may first inhibit sodium reabsorption at the distal convoluted tubule before it is inundated with sodium from the loop of Henle.

A usual starting dose of IV furosemide for the treatment of AKI is 40 mg (Fig. 25-2). Reasonable starting doses for bumetanide and torsemide are 1 mg and 20 mg, respectively.¹⁹ Efficacy of diuretic administration can be determined by comparison of a patient's hourly fluid balance. Other methods to minimize volume overload, such as fluid restriction and concentration of IV medications, should be initiated as

needed. If urine output does not increase to about 1 mL/kg/h, the dosage can be increased to a maximum of 160 to 200 mg of furosemide or its equivalent (Fig. 25-2).²⁰ Dosing frequency is based on the patient's response, the ability to restrict sodium intake, and the duration of action of the diuretic. Other methods to improve diuresis can be initiated sequentially, such as (a) shortening the dosage interval, (b) adding hydrochlorothiazide or metolazone, and (c) switching to a continuous infusion loop diuretic. A loading dose should be administered prior to both initiating a continuous infusion and increasing the infusion rate. When high doses of loop diuretics are administered, especially in combination with distal convoluted tubule diuretics, the hemodynamic and fluid status of the patient should be monitored every shift, and the electrolyte status of the patient should be monitored at least daily to prevent profound diuresis and electrolyte abnormalities, such as hypokalemia. Patients will not benefit from switching from one loop diuretic to another because of the similarity in mechanisms of action.

► Other Diuretics

Thiazide diuretics, when used as single agents, are generally not effective for fluid removal. Mannitol is also not recommended for the treatment of volume overload associated with AKI. Mannitol is removed by the body by glomerular filtration. In patients with renal dysfunction, mannitol excretion is decreased, resulting in expanded blood volume and hyperosmolality. Potassium-sparing diuretics, which inhibit sodium reabsorption in the distal nephron and collecting duct, are not sufficiently effective in removing fluid. In addition, they increase the risk of hyperkalemia in patients already at risk. **3** *Thus loop diuretics are the diuretics of choice for the management of volume overload in AKI.*

► Dopamine

Low-dose dopamine (LDD), in doses ranging from 0.5 to 3 mcg/kg/min, predominantly stimulates dopamine-1 receptors, leading to renal vascular vasodilation and increased renal blood flow. Although this effect has been substantiated in healthy euvoletic individuals with normal kidney function, a lack of efficacy data exists in patients with AKI. The most comprehensive study evaluating efficacy of LDD, the Australian and New Zealand Intensive Care Society (ANZICS) Clinical Trials Group study, did not find that LDD alters peak SCr, need for RRT, duration of stay in the intensive care unit, or survival to discharge compared with placebo.²³ A meta-analysis was performed on all published human trials that used LDD in the prevention or treatment of AKI.²⁴ A total of 61 studies were identified that randomized more than 3,300 patients to LDD or placebo. Results reveal no significant difference between the treatment and control groups for mortality, requirement for RRT, or adverse effects. Based on the results of the ANZICS trial, the lack of conclusive evidence in many earlier studies, and several meta-analyses, **4** *there is no indication for the use of LDD in the treatment of AKI.*

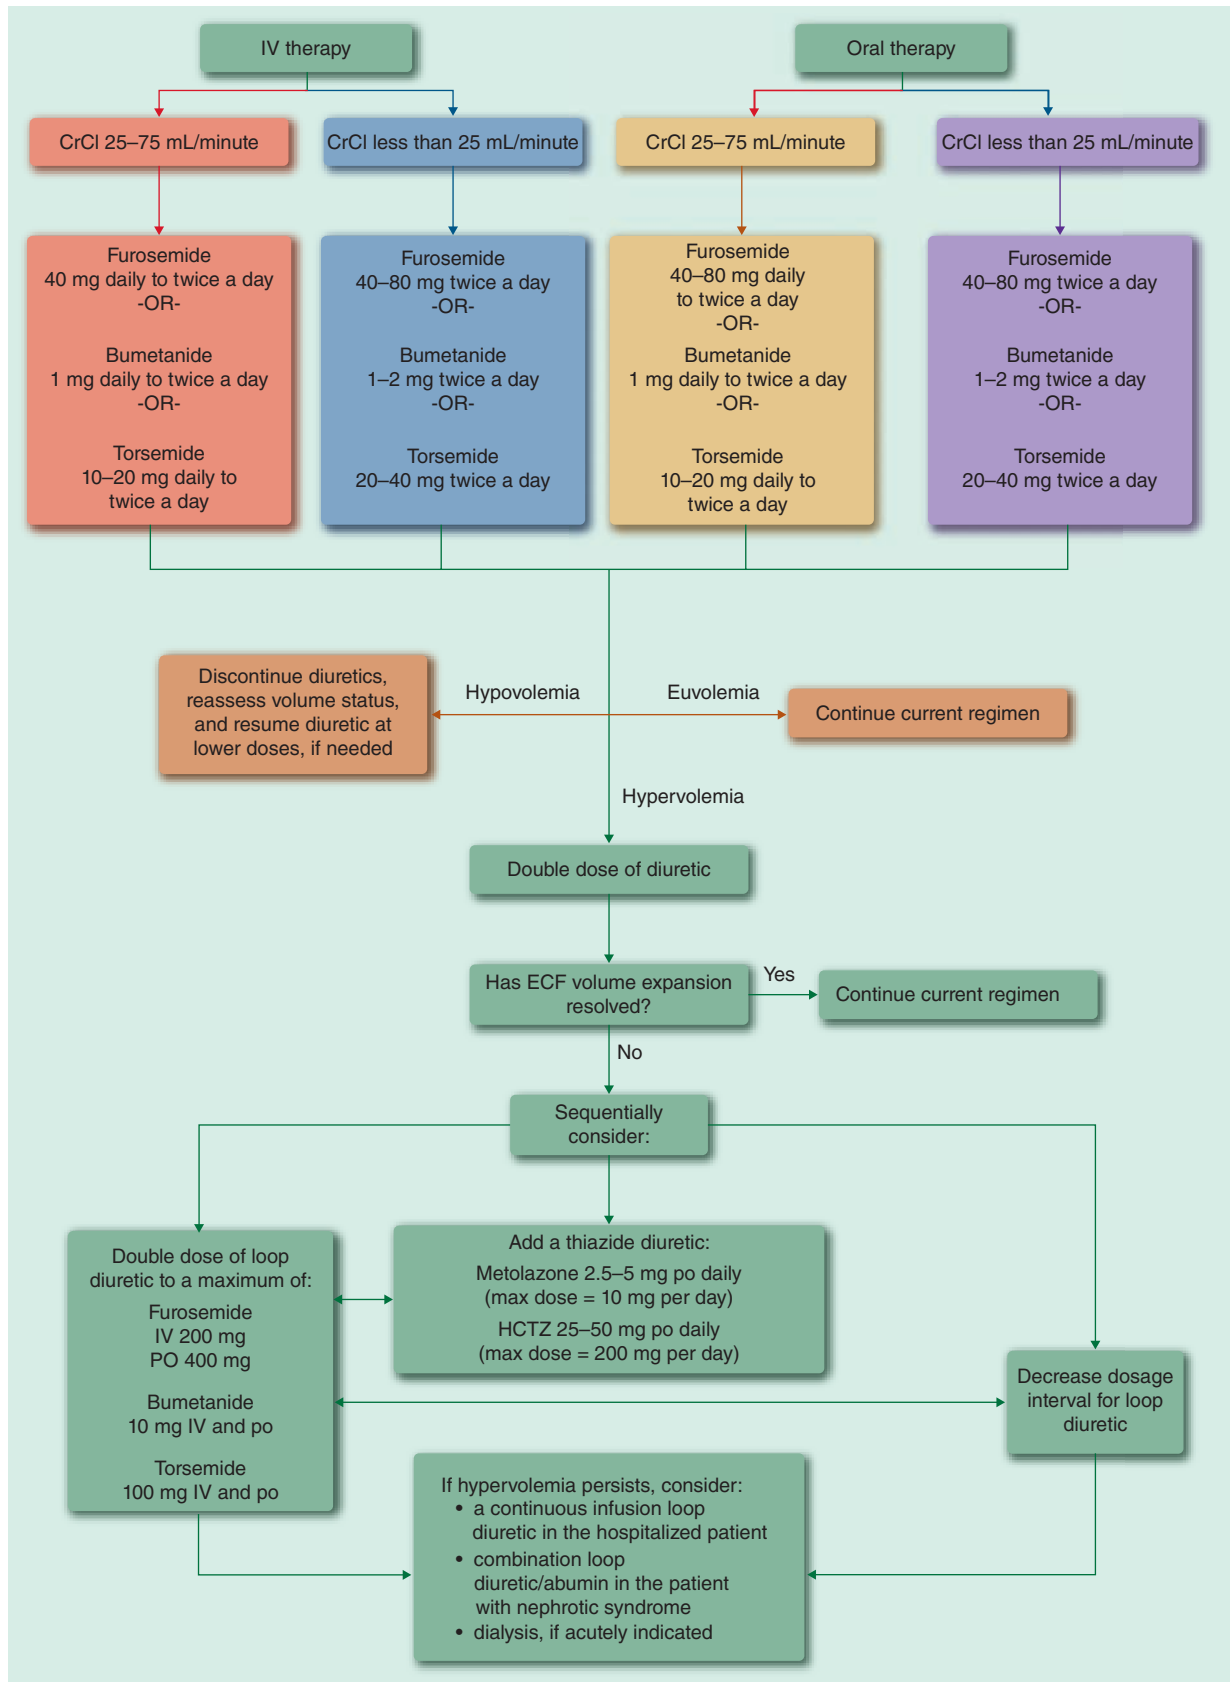

FIGURE 25-2. Algorithm for treatment of extracellular fluid expansion. (CrCl, creatinine clearance; ECF, extracellular fluid; HCTZ, hydrochlorothiazide; po, oral.)

► Fenoldopam

Fenoldopam is a selective dopamine-1 receptor agonist that is approved for short-term management of severe hypertension. Because it does not stimulate dopamine-2, α -adrenergic, and β -adrenergic receptors, fenoldopam causes vasodilation in the renal vasculature with potentially fewer nonrenal effects than dopamine. In normotensive individuals with normal kidney function, IV fenoldopam increases renal blood flow without lowering systemic blood pressure. A prospective randomized study comparing fenoldopam to placebo in early ATN did not find a difference in need for dialysis or mortality.²⁵ A second prospective randomized study in septic patients did find less of an increase in SCr in the fenoldopam group compared with placebo but no difference in survival or need for RRT.²⁶

Nonpharmacologic Treatment

► Renal Replacement Therapy

RRT may be necessary in patients with established AKI to treat volume overload that is unresponsive to diuretics, to minimize the accumulation of nitrogenous waste products, and to correct electrolyte and acid–base abnormalities while renal function recovers. There is wide variation in practice on indications for RRT, timing of initiation/discontinuation of RRT, intensity of treatment, and optimal type of RRT,

and well-controlled studies are needed to guide treatment. Absolute indications for dialysis usually include:

- BUN greater than 100 mg/dL (35.7 mmol/L)
- Potassium greater than 6 mEq/L (6 mmol/L)
- Magnesium greater than 9.7 mg/dL (4 mmol/L)
- Metabolic acidosis with a pH less than 7.15
- Diuretic-resistant fluid overload.²⁷

A BUN greater than 76 mg/dL (27.1 mmol/L) is a relative indicator for RRT. Approximately 5% to 30% of patients with AKI treated with dialysis will not have recovery of their renal function and will need to remain on long-term dialysis. This may be due in part to underlying illnesses because AKI is often seen in the setting of multiorgan failure.

The two types of dialysis modalities commonly used in AKI are intermittent hemodialysis (IHD) and continuous renal replacement therapy (CRRT). IHD is a higher efficiency form of dialysis that is provided for several hours a day at a variable frequency (usually daily or three to five times per week) at a higher blood flow rate. CRRT is a pump-driven form of dialysis that provides slow fluid and solute removal on a continuous 24-hour basis. The primary advantage of CRRT is hemodynamic stability and better volume control, particularly in patients who are unable to tolerate rapid fluid removal. The primary disadvantages associated with CRRT are continuous nursing requirements, continuous

PE:

VS: BP 165/95, pulse 85 bpm, RR 22/min, temperature 37.6°C, weight 62 kg, ht 5'7" (170 cm)

Chest: Basilar crackles, inspiratory wheezes

CV: RRR, S₁, S₂ normal

MS/Ext: 2 + pitting edema

Urinalysis: Color, yellow; character, hazy; glucose (–); ketones (–); specific gravity 1.010; pH 5; (+) protein; no bacteria; nitrite (–); blood (–); osmolality 325 mOsm/kg (325 mmol/kg); urinary sodium 77 mEq/L (77 mmol/L); creatinine 25 mg/dL (2.21 mmol/L)

Laboratory values: Sodium 136 mEq/L (136 mmol/L), potassium 4.2 mEq/L (4.2 mmol/L), chloride 105 mEq/L (105 mmol/L), bicarbonate 22 mEq/L (22 mmol/L), BUN 32 mg/dL (11.4 mmol/L), SCr 1.8 mg/dL (159 μ mol/L), magnesium 1.6 mg/dL (0.66 mmol/L), glucose 120 mg/dL (6.7 mmol/L), WBC 6.9×10^3 (6.9×10^9 /L), hemoglobin 14.4 g/dL (144 g/L; 8.94 mmol/L), and hematocrit 42% (0.42).

Interview information: Patient takes all of her medications as prescribed. She checks her fasting glucose each morning. It ranges from 110 to 125 mg/dL (6.1 to 6.9 mmol/L). She takes acetaminophen about three or four times a day for back pain. She recently started taking ibuprofen 3 weeks ago because her neighbor told her it was better for pain. She takes it about two or three times a day.

Given this additional information, what is your assessment of the patient's condition?

Identify your treatment goals for the patient.

anticoagulation, frequent clotting of the dialyzer, patient immobility, and increased cost. There is no conclusive evidence that one type of dialysis is preferred to another in terms of mortality and recovery of renal function. Thus selection of CRRT over IHD is often governed by the critical illness of the patient and by the comfort level of the institution with one particular type of dialysis. Mortality in critically ill patients receiving CRRT is 40% to 53%.^{28,29}

Studies are underway to identify new markers for early detection of AKI (e.g., cystatin C, neutrophil gelatinase-associated lipocalin, N-acetyl- β -d-glucosaminidase, kidney injury molecule-1) that can assist not only in the early diagnosis of AKI, but also to guide decisions on when to initiate RRT.³⁰

► Supportive Therapy

Supportive therapy in AKI includes adequate nutrition, correction of electrolyte and acid-base abnormalities (particularly hyperkalemia and metabolic acidosis), fluid management, and correction of any hematologic abnormalities. Because AKI is often associated with multiorgan failure, treatment includes the medical management of infections, cardiovascular and GI conditions, and respiratory failure. Finally, all drugs should be reviewed and dosage adjustments made based on an estimate of the patient's GFR.

PREVENTION OF ACUTE RENAL FAILURE

Avoidance

- The best preventive measure for AKI, especially in individuals at high risk, is to avoid medications that are known to precipitate AKI. Nephrotoxicity is a significant side effect of aminoglycosides, ACE inhibitors, angiotensin receptor antagonists, amphotericin B, NSAIDs, cyclosporine, tacrolimus, and radiographic contrast agents.⁸ Unfortunately, an effective, nonnephrotoxic alternative may not always be appropriate for a given patient, and the risks and benefits of selecting a drug with nephrotoxic potential must be considered. For example, serious gram-negative infections may require double antibiotic coverage, and based on culture and sensitivity reports, aminoglycoside therapy may be necessary. In cases such as this, other measures to reduce the risk of AKI should be instituted. **5** *Thus identifying patients at high risk for development of AKI and implementing preventive methods to decrease its occurrence or severity is critical.*

• Drug-Induced ARF

► Aminoglycosides

Aminoglycosides (gentamicin, tobramycin, and amikacin) causes nonoliguric intrinsic AKI in about 10% to 25% of treated patients.³¹ Injury is due to binding of aminoglycosides to proximal tubular cells in the renal cortex, and subsequent cellular uptake and cell death. In addition, aminoglycosides cause renal vasoconstriction and mesangial contraction.³² In clinical practice, all aminoglycosides have comparable nephrotoxicity; thus similar precautions should be used for

all of the agents. High cumulative drug exposure increases the incidence of aminoglycoside-induced AKI. Additional risk factors include a prolonged course of aminoglycoside therapy (typically after 7 to 10 days of therapy), preexisting chronic kidney disease, increased age, and concurrent administration with other nephrotoxic drugs. Alternative antibiotics should be considered in individuals with AKI or those who are at a high risk for developing AKI, although resistance of some strains of gram-negative organisms to other antibiotics may necessitate their use.

Methods to minimize drug exposure with conventional (multiple doses per day) dosing include maintaining trough concentrations less than 2 mcg/mL (2 mg/L; 4.2 μ mol/L) for gentamicin and tobramycin and less than 10 mcg/mL (10 mg/L; 17.1 μ mol/L) for amikacin, minimizing length of therapy, and avoiding repeated courses of aminoglycosides. Concurrent exposure to other nephrotoxic medications and dehydration may also worsen AKI. There is conflicting evidence as to whether the combination of vancomycin and an aminoglycoside has a higher incidence of AKI than aminoglycoside therapy alone. Aminoglycoside-induced AKI is usually reversible upon drug discontinuation; however, dialysis may be needed in some individuals while kidney function improves.

Another method to minimize toxicity is with extended-interval dosing (e.g., once daily). The goal of extended-interval dosing is to provide greater efficacy against the microorganism with a lower incidence of nephrotoxicity. Aminoglycosides demonstrate concentration-dependent killing and a prolonged postantibiotic effect.³¹ The mechanism by which extended-interval aminoglycoside dosing reduces the incidence of nephrotoxicity is by providing high transient concentrations of drug that saturate proximal tubule uptake sites. Once saturated, the remaining aminoglycoside molecules pass through the proximal tubule and are excreted in the urine.³³ Thus less drug is available for cellular uptake during a 24-hour period. A consistent finding in studies is that extended-interval aminoglycoside dosing is as effective as conventional dosing and is not more nephrotoxic, and in some studies it is less nephrotoxic than conventional dosing. Aminoglycosides can also cause hearing loss and/or vestibular toxicity, although the incidence of ototoxicity appears to be similar with extended-dosing and conventional dosing. Prolonged exposure to the drug, repeated courses of therapy, and concurrent use of other ototoxic drugs increase toxicity. Extended-interval dosing is not recommended in patients with preexisting kidney disease, conditions where high concentrations are not needed (e.g., urinary tract infections), hyperdynamic patients that may demonstrate increased drug clearance (e.g., burn patients), and others where you would suspect altered pharmacokinetics or increased risk of ototoxicity.

• ► Amphotericin B

The reported incidence of amphotericin B-induced AKI varies widely in the literature, from about 30% to as high as 80% of patients treated with the conventional desoxycholate

formulation.³⁴ Nephrotoxicity is due to renal arterial vasoconstriction and distal renal tubule cell damage. Risk factors for development of AKI include high daily dosage, large cumulative dose (greater than 2 to 3 g), preexisting kidney dysfunction, dehydration, and concomitant use of other nephrotoxic drugs. Tubular abnormalities manifesting as hypomagnesemia and hypokalemia often occur within the first 2 weeks of treatment, followed by the overt development of AKI. Three lipid-based formulations of amphotericin B have been developed in an attempt to improve efficacy and limit toxicity, particularly nephrotoxicity: amphotericin B lipid complex, amphotericin B colloidal dispersion, and liposomal amphotericin B. The range of nephrotoxicity reported is 15% to 25% for these formulations. The mechanism for decreased nephrotoxicity has not been completely elucidated, but it is thought to be due to preferential delivery of amphotericin B to the site of infection, with less of an affinity for the kidney.³⁵ Costs for liposomal formulations is significantly higher than the convention formulation; thus lipid-based formulations are typically recommended for individuals with risk factors for AKI. Administration of IV normal saline may also attenuate nephrotoxicity associated with amphotericin B.

Whether there are significant differences in nephrotoxicity between the three lipid-based formulations remains unclear. In a recent meta-analysis of eight studies evaluating the nephrotoxicity of liposomal amphotericin B compared with amphotericin B lipid complex, nephrotoxicity was generally similar.³⁶ However, large prospective studies comparing the incidence of nephrotoxicity between liposomal formulations are needed to ascertain differences in nephrotoxicity.

► Radiocontrast Agents

Intravascular radiographic contrast agents are administered during radiologic studies and carry with them the well-documented risk of AKI. Patients at risk for developing AKI include patients with chronic kidney disease, diabetic nephropathy, dehydration, and higher doses of contrast dye.³⁷ Contrast agents are water-soluble, triiodinated, benzoic acid salts that cause an osmotic diuresis due to their osmolality, which exceeds that of plasma. The mechanism of nephrotoxicity is not fully understood; however, direct tubular toxicity, renal ischemia, and tubular obstruction have been implicated.³⁸ Diatrizoate and iohalamate are ionic contrast agents. Iohexol, iopamidol, ioversol, and iopromide represent nonionic agents. The incidence of nephrotoxicity with ionic and nonionic agents is similar in patients at low risk for developing AKI; however, in high-risk patients, nephrotoxicity is significantly greater when ionic contrast agents are used. In diabetic patients with chronic kidney disease and a SCR greater than 1.5 mg/dL (133 μ mol/L), nephrotoxicity occurred in 33.3% and 47.7% of patients receiving nonionic and ionic contrast agents, respectively.³⁹ The cost of nonionic agents is approximately 10-fold higher, which may limit their routine use in all patients undergoing radiographic studies.

Therapeutic measures that have been used to decrease the incidence of contrast-induced nephropathy include extracellular volume expansion, minimization of the amount

of contrast administered, and treatment with oral acetylcysteine. Theophylline, fenoldopam, loop diuretics, mannitol, dopamine, and calcium antagonists have no effect or may worsen AKI.

The most effective therapeutic maneuver to decrease the incidence of contrast-induced nephropathy is extracellular volume expansion.⁴⁰ Several studies have compared the efficacy of isotonic sodium chloride (0.9%) to half normal saline (0.45%) or to oral hydration.^{41,42} Isotonic fluid is superior to hypotonic fluid in prevention of nephropathy. A common regimen is IV isotonic sodium chloride (1 mL/kg of body weight/hour) administered for 12 hours before and 12 hours after the procedure. Fluid should be administered cautiously to patients with CHF, left ventricular dysfunction, and significant renal dysfunction. Recent evidence suggests that hydration, plus sodium bicarbonate to alkalinize renal tubule fluid, may reduce free radical formation and lead to less oxidant damage, although studies have been conflicting.^{43,44} Most studies investigating sodium bicarbonate hydration administered therapy at a rate of 3 mL/kg/h (154 mEq/L [154 mmol/L]) for 1 hour before the procedure, and 1 mL/kg/h during and 6-hour postcontrast. A large randomized clinical trial that provides definitive conclusions is needed.

Minimizing the quantity of contrast media administered may be beneficial in preventing nephropathy. Some studies, but not all, have directly associated dose of contrast media with nephrotoxicity. Avoidance of contrast dye by using alternative diagnostic procedures should be considered in high-risk patients but may not always be feasible. In addition, avoidance of multiple contrast studies in a short time period will allow renal function to return to normal between procedures.

Because production of reactive oxygen species has been implicated in the pathophysiology of contrast-induced AKI, prophylactic administration of the antioxidant acetylcysteine has been investigated. An oral dose of 600 mg twice daily the day before and the day of the procedure decreased the incidence of AKI in one small study, although patient outcomes such as mortality and length of hospitalization were not evaluated.⁴⁵ Since then, more than 30 additional studies evaluating the efficacy of oral acetylcysteine have been conducted, with mixed results. In addition, a series of meta-analyses have also analyzed the results of the studies with varying conclusions. The studies were varied in terms of study population, sample size, definition of contrast nephropathy, type of contrast agent used, hydration, and formulation of acetylcysteine administered, thus making collective interpretation of the results difficult. It is routinely used in many hospitals due to its low cost and safe side-effect profile at low oral doses, although data are not conclusive that it prevents development of AKI or alters patient outcomes such as mortality, need for dialysis, and length of hospitalization. The recommended dose of acetylcysteine is 600 to 1,200 mg orally every 12 hours, with the first dose administered prior to the contrast procedure and three doses postexposure. It is noted that acetylcysteine is not considered a replacement for adequate hydration, which remains the standard of care for prevention of contrast nephropathy.

► Cyclosporine and Tacrolimus

Cyclosporine and tacrolimus are calcineurin inhibitors that are administered as part of immunosuppressive regimens in kidney, liver, heart, lung, and bone marrow transplant recipients. In addition, they are used in autoimmune disorders such as psoriasis and multiple sclerosis. The pathophysiologic mechanism for AKI is renal vascular vasoconstriction.⁴⁶ It often occurs within the first 6 to 12 months of treatment and can be reversible with dose reduction or drug discontinuation. Risk factors include high dose, elevated trough blood concentrations, increased age, and concomitant therapy with other nephrotoxic drugs.⁴⁶ Cyclosporine and tacrolimus are extensively metabolized by the liver through the cytochrome P450 3A4 pathway, and drugs that inhibit their metabolism (e.g., erythromycin, clarithromycin, fluconazole, ketoconazole, verapamil, diltiazem, and nifedipine) can precipitate AKI. Because AKI is dose dependent, careful monitoring of cyclosporine or tacrolimus trough concentrations can minimize its occurrence; however, AKI can still occur with normal or low blood concentrations. In addition, there is some evidence that calcium channel blockers have a renoprotective effect through dilation of the afferent arterioles and are often used preferentially as antihypertensive agents in kidney transplant recipients.

It is often difficult to differentiate AKI from acute rejection in the kidney transplant recipient because both conditions may present with similar symptoms and physical examination findings. However, fever and graft tenderness are more likely to occur with rejection, whereas neurotoxicity is more likely to occur with cyclosporine or tacrolimus toxicity. Kidney biopsy is often needed to confirm the diagnosis of rejection.

► ACE Inhibitors and ARBs

In instances of decreased renal blood flow (e.g., kidney disease, renal artery stenosis), production of angiotensin II increases, resulting in efferent arteriole vasoconstriction and maintenance of glomerular capillary pressure and GFR. ACE inhibitors or ARB result in a decrease in angiotensin II synthesis, thereby dilating efferent arterioles and decreasing glomerular capillary pressure and GFR.³³ When initiating therapy with an ACE inhibitor or ARB, a modest increase in SCr should be anticipated within the first week of starting therapy due to the drug's mechanism of action.³³ However, large increases (greater than a 30% increase in SCr above baseline) that do not plateau after several weeks of therapy is indicative of AKI, and the drug should be discontinued.³³ Risk factors for developing AKI are preexisting renal dysfunction, severe atherosclerotic renal artery stenosis, volume depletion, and severe CHF. Discontinuation of the drug usually results in the return of renal function to baseline. Initiating therapy with low doses of a short-acting agent such as captopril is recommended for patients at risk of developing AKI. If tolerated, patients can later be converted to a longer-acting agent.

► Nonsteroidal Anti-inflammatory Drugs

NSAIDs (e.g., ibuprofen, naproxen, sulindac) can likewise cause prerenal AKI through inhibition of prostaglandin-mediated renal vasodilation. Risk factors are similar to those of ACE inhibitors and ARBs. Additional risk factors include hepatic disease with ascites, systemic lupus erythematosus, and advanced age. The onset is often within days of initiating therapy, and patients typically present with oliguria. It is usually reversible with drug discontinuation. Agents that preferentially inhibit cyclooxygenase-2 pose a similar risk as traditional nonselective NSAIDs.³³

► Other Drugs

Other drugs that are commonly implicated in causing AKI include acyclovir, adefovir, carboplatin, cidofovir, cisplatin, foscarnet, ganciclovir, indinavir, methotrexate, pentamidine, ritonavir, sulfapyrazone, and tenofovir.⁴⁷ A list of drugs that commonly cause AKI and their mechanism is found in [Table 25-3](#).

Table 25-3

Drugs Implicated in Causing Acute Kidney Injury by Mechanism for Commonly Prescribed Drugs

Prerenal AKI (Hemodynamic mediated)	<ul style="list-style-type: none"> • Angiotensin-converting enzyme inhibitors • Angiotensin receptor blockers • Nonsteroidal anti-inflammatory drugs • Cyclosporine • Tacrolimus
Intrarenal Acute tubular necrosis	<ul style="list-style-type: none"> • Aminoglycosides • Amphotericin B • Cisplatin and carboplatin
Acute interstitial nephritis	<ul style="list-style-type: none"> • β-Lactam antibiotics • Fluoroquinolones • Thiazide diuretics • Loop diuretics • Allopurinol • Sulfonamides • Nonsteroidal anti-inflammatory drugs
Postrenal AKI (nephrolithiasis)	<ul style="list-style-type: none"> • Rifampin • Acyclovir • Methotrexate • Indinavir

Patient Encounter, Part 3

JD is admitted to the hospital for AKI. Based on the information available, create a care plan for this patient's AKI and provide overall recommendations for her drug therapy. The plan should include (a) a statement of the drug related needs and/or problems, (b) a patient-specific detailed therapeutic plan, and (c) monitoring parameters to assess efficacy and safety.

OUTCOME EVALUATION

Goals of therapy are to maintain a state of euvolemia with good urine output (at least 1 mL/kg/h), to return serum creatinine to baseline, and to correct electrolyte and acid-base abnormalities. In addition, appropriate drug dosages based on kidney function and avoidance of nephrotoxic drugs are goals of therapy. Assess vital signs, weight, fluid intake, urine output, BUN, creatinine, and electrolytes daily in the unstable patient.

DRUG DOSING CONSIDERATIONS IN AKI

Determining the optimal dose of drugs in AKI is challenging. A variety of factors influence drug dosing, such as (1) alterations in drug pharmacokinetics that occur during AKI, (2) difficulties in accurately quantifying kidney function in AKI, (3) the influence of intermittent or continuous RRT on drug clearance, and (4) challenges in interpreting information from the literature and applying it to a specific patient. **Table 25–4** provides a more complete list of different considerations when dosing medications in patients with AKI.

For drugs with a narrow therapeutic window, serum drug concentration monitoring may be available to guide drug dosing. If drug monitoring is not available, conservative dosing based on an estimated creatinine clearance is recommended, with frequent reassessment of kidney function and evaluation of the patient's status to assess efficacy and

adverse effects of the patient's therapy. Selection of a drug with hepatic elimination rather than renal excretion is a reasonable alternative, if possible.

DRUG DOSING CONSIDERATIONS IN CRRT

Hemodialysis removes solutes from the body by diffusion, where substances move from the higher concentration in the blood to the lower concentration in the dialysis solution, across a semipermeable membrane. Poor size of the membrane governs drug removal. For low flux membranes, drugs with a molecular weight less than 1,000 Da are removed. With high flux membranes that have larger pore sizes, drugs in the range of 10,000 to 20,000 Da can be removed. Because the dialysis solution moves in a countercurrent direction to blood flow through the dialysis membrane, the concentration gradient is maximized.

With hemofiltration, water moves across a hemofiltration membrane due to hydrostatic pressure into the ultrafiltrate compartment and drags along dissolved solute through a process known as convection. Because no dialysis solution is pumped through the dialyzer, diffusion does not occur. Larger molecules are removed up to the molecular weight cutoff of the hemofilters, usually about 40,000 Da.

There are primarily three types of CRRT commonly used in AKI, based on these principles of hemodialysis and hemofiltration: continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF).

Table 25–4

Drug Dosing Considerations in AKI

Alteration in drug pharmacokinetics	<ul style="list-style-type: none"> • Increase in volume of distribution due to fluid retention may occur • Reduction in excretion of both drugs and metabolites eliminated by the kidney • Nonrenal clearance of some drugs may be reduced
Difficulty in quantifying an accurate assessment of kidney function in AKI	<ul style="list-style-type: none"> • Cockcroft-Gault and MDRD equations not meant for AKI population; equations are based on a single SCr • SCr as a marker for kidney function influenced by non-renal factors (such as nutritional status and liver function) • Equations to estimate kidney function in cases of changing kidney function have not been well studied
AKI patients undergoing dialysis	<ul style="list-style-type: none"> • Different types of dialysis modalities results in differences in drug removal (e.g., IHD vs. CRRT) • Differences in intensity of dialysis dose may affect drug removal (eg, length of dialysis treatment, blood and dialysate flow rate) • Populations studied in literature are likely to be different than the specific patient being treated (e.g., different types of dialysis, length of treatment).
Textbook dosing and literature recommendations	<ul style="list-style-type: none"> • Studies in patients with AKI are sparse • Many drug information recommendations on dosing are based on the manufacturer's original pharmacokinetics information, often in patients with chronic kidney disease • Most drug dosing guidelines were developed prior to standardization of SCr measurements between labs; thus today's SCr measurements are 5–10% higher than those reported prior to 2010⁴⁹ • There is a growing body of support for incorporation of the MDRD equation in future pharmacokinetic studies and to guide drug dosing, although use of this equation is limited to chronic kidney disease

MDRD = Modification of Diet in Renal Disease Equation.

In these procedures, drug removal is governed by either diffusion (CVVHD), convection (CVVH), or a combination of the two (CVVHDF).

In addition to molecular weight, there are three additional characteristics of a drug that governs removal during dialysis: percentage of drug eliminated by the kidney, volume of distribution, and protein binding. Removal during CRRT is greater when renal clearance accounts for 30% or more of total body clearance of the drug, volume of distribution is less than 1 L/kg, and protein binding is less than 50% because dialysis cannot remove protein-bound drugs.⁴⁸ Other factors that affect drug clearance with CRRT include type of CRRT (i.e., CVVH, CVVHD); characteristics of the dialysis membrane; and blood, ultrafiltrate, and dialysis flow rates. In general, drug removal is greatest with CVVHDF, followed by CVVH and then IHD.⁴⁹

Drug information references may provide general drug dosing recommendations in CRRT; however, they must be interpreted cautiously due to the variability in CRRT techniques used.

Mathematical models can be used to calculate drug dosages based on the patient's residual renal clearance and dialysis clearance compared with clearance in a patient with normal kidney function. In addition, plasma concentrations should be used to guide treatment if available. Close monitoring of the patient's clinical response is critical.

Patient Care and Monitoring

1. Assess kidney function by evaluating a patient's signs and symptoms, laboratory test results, and urinary indices. Calculate a patient's CrCl to evaluate the severity of kidney disease.
2. Obtain a thorough and accurate drug history including the use of nonprescription drugs such as NSAIDs.
3. Evaluate a patient's current drug regimen to:
 - Determine if drug therapy may be contributing to AKI. Consider not only drugs that can directly cause AKI (e.g., aminoglycosides, amphotericin B, NSAIDs, cyclosporine, tacrolimus, ACE inhibitors, and ARBs) but also drugs that can predispose a patient to nephrotoxicity or prerenal AKI (i.e., diuretics and antihypertensive agents).
 - Determine if any drugs need to be discontinued, or alternative drugs selected, to prevent worsening of renal function.
 - Adjust drug dosages based on the patient's CrCl or evidence of adverse drug reactions or interactions.
4. Develop a plan to provide symptomatic care of complications associated with AKI, such as diuretic therapy to treat volume overload. Monitor the patient's weight, urine output, electrolytes (such as potassium), and blood pressure to assess efficacy of the diuretic regimen.

Abbreviations Introduced in This Chapter

ACE	Angiotensin-converting enzyme
AKI	Acute kidney injury
ANZICS	Australian and New Zealand Intensive Care Society
ARB	Angiotensin receptor blocker
ARF	Acute renal failure
ATN	Acute tubular necrosis
BW	Body weight
BUN	Blood urea nitrogen
CHF	Congestive heart failure
CrCl	Creatinine clearance
CRRT	Continuous renal replacement therapy
DM	Diabetes mellitus
FENa	Fractional excretion of sodium
GFR	Glomerular filtration rate
IBW	Ideal body weight
IHD	Intermittent hemodialysis
JVD	Jugular venous distention
LDD	Low-dose dopamine
MDRD	Modification of Diet in Renal Disease
NSAIDs	Nonsteroidal anti-inflammatory drugs
PGE ₂	Prostaglandin E ₂
RRT	Renal replacement therapy
SCr	Serum creatinine concentration

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Chronic and End-Stage Renal Disease

Kristine S. Schonder

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. List the risk factors for development and progression of chronic kidney disease (CKD).
2. Explain the mechanisms associated with progression of CKD.
3. Outline the desired outcomes for treatment of CKD.
4. Develop a therapeutic approach to slow progression of CKD including lifestyle modifications and pharmacologic therapies.
5. Identify specific consequences associated with CKD.
6. Design an appropriate therapeutic approach for specific consequences associated with CKD.
7. Recommend an appropriate monitoring plan to assess the effectiveness of pharmacotherapy for CKD and specific consequences.
8. Educate patients with CKD about the disease state, the specific consequences, lifestyle modifications, and pharmacologic therapies used for treatment of CKD.

KEY CONCEPTS

- 1 **Chronic kidney disease** (CKD) is defined by a staging system based on glomerular filtration rate (GFR) level, which also accounts for evidence of kidney damage in the absence of changes in GFR, as in stage 1 CKD.
- 2 CKD is a progressive disease that eventually leads to kidney failure (end-stage kidney disease [ESKD]).
- 3 Early detection and treatment of CKD are fundamental factors in minimizing morbidity and mortality associated with CKD.
- 4 Declining kidney function disrupts the homeostasis of the systems regulated by the kidney, leading to fluid and electrolyte imbalances, anemia, and metabolic bone disease.
- 5 Angiotensin-converting enzyme inhibitors (ACE-Is) and angiotensin II receptor blockers decrease protein excretion and are the drugs of choice for hypertension in patients with CKD.
- 6 The most common complication of CKD is anemia, which is caused by a decline in erythropoietin production by the kidneys and can lead to cardiovascular disease (CVD).
- 7 Bone and mineral metabolism disorders stem from disruptions in calcium, phosphorus, and vitamin D homeostasis through the interaction with the parathyroid hormone.
- 8 The management of **secondary hyperparathyroidism** (sHPT) involves correction of serum calcium and phosphorus levels, and decreasing parathyroid hormone secretion.
- 9 Patient education and planning for **dialysis** should begin at stage 4 CKD, before ESKD is reached, to allow for time to establish appropriate access for dialysis.
- 10 Dialysis involves the removal of metabolic waste products and excess fluids and electrolytes by **diffusion** and **ultrafiltration** from the bloodstream across a semipermeable membrane into an external dialysate solution.

The kidney is made up of approximately 2 million **nephrons** that are responsible for filtering, reabsorbing, and excreting solutes and water. As the number of functioning nephrons declines, the primary functions of the kidney that are affected include:

- Production and secretion of **erythropoietin**
- Activation of vitamin D
- Regulation of fluid and electrolyte balance
- Regulation of acid–base balance

Chronic kidney disease (CKD), also known as chronic kidney insufficiency, progressive kidney disease, or nephropathy, is

defined as the presence of kidney damage or decreased **glomerular filtration rate** (GFR) for 3 months or more.¹ Generally, CKD is a progressive decline in kidney function (a decline in the number of functioning nephrons) that occurs over a period of several months to years. A decline in kidney function that occurs more rapidly, over a period of days to weeks, is known as acute kidney injury (AKI), which is discussed in Chapter 25. The decline in kidney function in CKD is often irreversible. Therefore, measures to treat CKD are aimed at slowing the progression to end-stage kidney disease (ESKD).

EPIDEMIOLOGY AND ETIOLOGY

1 The National Kidney Foundation (NKF) developed a classification system for CKD (**Table 26-1**).¹ The staging system defines the stages of CKD based on GFR level but also accounts for evidence of kidney damage in the absence of changes in GFR, as in stage 1 CKD. The GFR is calculated using the abbreviated IDMS-traceable Modification of Diet in Renal Disease study equation²:

$$\text{GFR} = 175 \times (\text{SCr})^{-1.154} \times (\text{age})^{-0.203} \times (0.742 \text{ if female}) \times (1.21 \text{ if African American}) \text{ for serum creatinine expressed in mg/dL (serum creatinine expressed in } \mu\text{mol/L must first be divided by 88.4 to convert to mg/dL to calculate accurate eGFR by this equation)}$$

Alternatively, GFR can be calculated using the Chronic Kidney Disease Epidemiology Collaboration equation (CKD-EPI):³

$$\text{GFR} = 141 \times \min(\text{SCr}/\kappa, 1)^\alpha \times \max(\text{SCr}/\kappa, 1)^{-1.209} \times 0.993^{\text{Age}} \times 1.018 \text{ [if female]} \times 1.159 \text{ [if African American]}, \text{ where } \kappa \text{ is } 0.7 \text{ for females and } 0.9 \text{ for males, } \alpha \text{ is } -0.329 \text{ for females and } -0.411 \text{ for males, min indicates the minimum of } \text{SCr}/\kappa \text{ or } 1, \text{ max indicates the maximum of } \text{SCr}/\kappa \text{ or } 1, \text{ and SCr is expressed in mg/dL (serum creatinine expressed in } \mu\text{mol/L should first be divided by 88.4 to convert to mg/dL to calculate accurate eGFR by this equation).}$$

Table 26-1

NKF-K/DOQI Classification for CKD

State	GFR (mL/min/1.73 m ²) ^b
1	90 ^a or higher
2	60–89, or kidney damage
3	30–59
4	15–29
5	Less than 15 (includes patients on dialysis)

GFR, glomerular filtration rate; NKF-K/DOQI, National Kidney Foundation-Dialysis Outcome Quality Initiative.

^aCKD can be present with a normal or near normal GFR if other markers of kidney disease are present such as proteinuria, hematuria, biopsy results showing kidney damage, or anatomical abnormalities (e.g., cysts).

^bTo convert of SI units of mL/s/m², multiply by 0.00963.

The CKD-EPI formula provides better estimates than the MDRD at higher GFRs and may be preferred for determining GFR in earlier stages of CKD.

The United States Renal Data System (USRDS), using data from the National Health and Nutrition Examination Survey (NHANES), estimates the prevalence of CKD in the United States is 15.1%, corresponding to nearly 31 million people.⁴ This number is increased from 12.8% reported with the previous NHANES report from 1988 to 1994,⁴ which is attributed to the increased prevalence of diabetes and hypertension, and the aging population.⁵

2 CKD is a progressive disease that eventually leads to ESKD. The prevalence of ESKD has increased more than fivefold since 1980 to more than 570,000 people in 2009 with over 116,000 new cases of ESKD diagnosed in 2009.⁴ The prevalence of ESKD is related to ethnicity, affecting 3.5 times more African Americans and 1.9 times more Native Americans as whites.⁴ This is likely because these ethnicities have increased risk and prevalence of the causes of CKD, including diabetes mellitus (DM) and hypertension, and other vascular diseases.¹ The incidence of CKD is greatly influenced by the patient's access to medical care.

Because of the progressive nature of CKD, determination of risk factors for CKD is difficult. Risk factors identified for CKD are classified into three categories (**Table 26-2**):

- **Susceptibility factors**, which are associated with an increased risk of developing CKD but are not directly proven to cause CKD. These factors are generally not modifiable by pharmacologic therapy or lifestyle modifications.
- **Initiation factors**, which directly cause CKD. These factors are modifiable by pharmacologic therapy.

Table 26-2

Risk Factors Associated with CKD

Susceptibility

- Advanced age
- Reduced kidney mass
- Low birth weight
- Racial/ethnic minority
- Family history of kidney disease
- Low income or education
- Systemic inflammation
- Dyslipidemia

Initiation

- Diabetes mellitus
- Hypertension
- Autoimmune disease
- Polycystic kidney disease
- Drug toxicity
- Urinary tract abnormalities (infections, obstruction, stones)

Progression

- Hyperglycemia: Poor blood glucose control (in patients with diabetes)
- Hypertension: Elevated blood pressure
- Proteinuria
- Tobacco smoking

- **Progression factors**, which result in a faster decline in kidney function and cause worsening of CKD. These factors may also be modified by pharmacologic therapy or lifestyle modifications to slow the progression of CKD.

Susceptibility Factors

Susceptibility factors can be readily used to develop screening programs for CKD. For example, older patients, those with low kidney mass or birth weight, and those with a family history of kidney disease should be routinely screened for CKD. Minority and low socioeconomic communities may be targets for more widespread CKD screening programs. Other factors, such as hyperlipidemia, are not directly proven to cause CKD but can be modified by drug therapies.

► Hyperlipidemia

Patients with CKD have a higher prevalence of dyslipidemia compared with the general population. More than 81% of patients with a GFR less than 60 mL/min/1.73 m² (0.58 mL/s/m²) had hyperlipidemia.⁴ The dyslipidemia in CKD is manifested primarily as elevated triglycerides and lipoprotein(a) levels, and decreased high-density lipoprotein cholesterol (HDL-C) levels. Total cholesterol and low-density lipoprotein cholesterol (LDL-C) levels generally remain within normal limits.⁶ Kidney disease alters lipid metabolism, allowing lipoproteins to remain in circulation longer.⁶ In contrast, patients with nephrotic syndrome, which is characterized by urine protein rates that exceed 3 g/24 hours, often have elevated total cholesterol and LDL-C. It is hypothesized that nephrotic syndrome is associated with increased hepatic lipid production and decreased LDL-receptor activity.⁷ Dyslipidemia can promote kidney injury and subsequent progression of CKD. Endothelial dysfunction results from inflammation and monocyte activation, whereas deposition of lipids results in glomerulosclerosis and glomerular mesangium dysfunction.⁶

Initiation Factors

- The three most common causes of CKD in the United States are DM, hypertension, and **glomerulonephritis**. Together these account for about 75% of the cases of CKD (37% for diabetes, 24% for hypertension, and 14% for glomerulonephritis).⁴ These are discussed in further detail below.

► Diabetes

DM is the most common cause of CKD, causing 38% of all ESKD, which is an increase from 18% in 1985.⁴ The risk of developing diabetic kidney disease (DKD) associated with DM is closely linked to hyperglycemia and is similar for both type 1 and type 2. The prevalence of **microalbuminuria** is 25% to 40% in patients with type 1 DM after 15 to 25 years⁸ and 43% in patients with type 2 DM.⁹

► Hypertension

The second most common cause of CKD is hypertension.⁴ It is more difficult to determine the true risk of developing CKD in patients with hypertension because the two are so closely linked, with CKD also being a cause of hypertension. The prevalence of hypertension is correlated with the degree of kidney dysfunction (decreased GFR) with 40% of patients with CKD stage 1, 55% of patients with CKD stage 2, and over 81% of patients with CKD stage 3 presenting with hypertension.⁴ The risk of developing ESKD increases with the degree of hypertension and is linked to both systolic and diastolic blood pressure.¹⁰

► Glomerulonephritis

The term *glomerulonephritis* includes many specific diseases that can affect glomerular function. These include such diseases as IgA nephropathy, Wegener's granulomatosis, and glomerulonephritis associated with systemic lupus erythematosus and streptococcal disease, among many others. The etiologic and pathophysiologic features of glomerular diseases vary with the specific disease, making it difficult to extrapolate the risk for progression of CKD in patients affected by glomerular diseases. Certain glomerular diseases are known to rapidly progress to ESKD; others progress more slowly or may be reversible.

Progression Factors

- Progression factors can be used as predictors of CKD. The most important predictors of CKD include **proteinuria**, elevated blood pressure, hyperglycemia, and tobacco smoking.

► Proteinuria

The presence of protein in the urine is a marker of glomerular and tubular dysfunction. The degree of proteinuria correlates with the risk for progression of CKD.¹¹ The effects of proteinuria appear to be worse with milder stages of CKD. Compared with patients with no proteinuria, proteinuric patients with stage 3 CKD are 15 times more likely to double serum creatinine; patients with stage 4 CKD are 8 times more likely to double serum creatinine.¹¹ The mechanisms by which proteinuria potentiates CKD are discussed later. Microalbuminuria (30 to 300 mg albumin excreted per day) is also linked with vascular injury and increased cardiovascular mortality.⁹

► Elevated Blood Pressure

Systemic blood pressure correlates with glomerular pressure, and elevations in both systemic blood pressure and glomerular pressure contribute to glomerular damage. The rate of GFR decline is related to elevated systolic blood pressure and mean arterial pressure. The decline in GFR is estimated to be 14 mL/min per year (0.23 mL/s per year) with a sustained systolic blood pressure of 180 mm Hg. Conversely, the decline in GFR decreases to 2 mL/min per year (0.03 mL/s per year) with a systolic blood pressure of 135 mm Hg.¹²

► Elevated Blood Glucose

The reaction between glucose and protein in the blood produces advanced glycation end products (AGEs), which are metabolized in the proximal tubules. Hyperglycemia increases the synthesis of AGEs in patients with diabetes. Accumulation of AGEs affects glomerular, tubular, and vascular function in the kidney. AGEs are known to affect the activity of **podocytes**, the epithelial cells responsible for filtering blood, in the glomerulus, which contributes to proteinuria, which, in turn, damages tubules.¹³

► Tobacco Smoking

Smoking is also an independent and dose-dependent risk factor for development of CKD and microalbuminuria, and progression to ESKD.^{14,15} The risk is more pronounced in men compared with women (odds ratio [OR]: 2.4), independent of other risk factors.¹⁵ The risk of developing CKD increases with the dose (greater than 20 cigarettes per day, OR: 1.51), duration (greater than 40 years, OR: 1.45), and cumulative consumption (greater than 30 pack-years, OR: 1.52).¹⁶

The effects of smoking on the kidney are multifactorial and occur in both healthy individuals and those with CKD.

Smoking induces endothelial dysfunction and atherosclerosis systemically and in the glomerulus.¹⁴ These effects are related to nicotine and other components of cigarette smoking, including tar and smoke.¹⁴

PATHOPHYSIOLOGY

A number of factors can cause initial damage to the kidney. The resulting sequelae, however, follow a common pathway that promotes progression of CKD and results in irreversible damage leading to ESKD (Fig. 26-1).

The initial damage to the kidney can result from any of the initiation factors listed in Table 26-2. Regardless of the cause, however, the damage results in a decrease in the number of functioning nephrons. The remaining nephrons hypertrophy to increase glomerular filtration and tubular function, both reabsorption and secretion, in an attempt to compensate for the loss of kidney function. Initially, these adaptive changes preserve many of the clinical parameters of kidney function, including **creatinine** and electrolyte excretion. However, as time progresses, angiotensin II is required to maintain the hyperfiltration state of the functioning nephrons. Angiotensin II is a potent vasoconstrictor of both the afferent

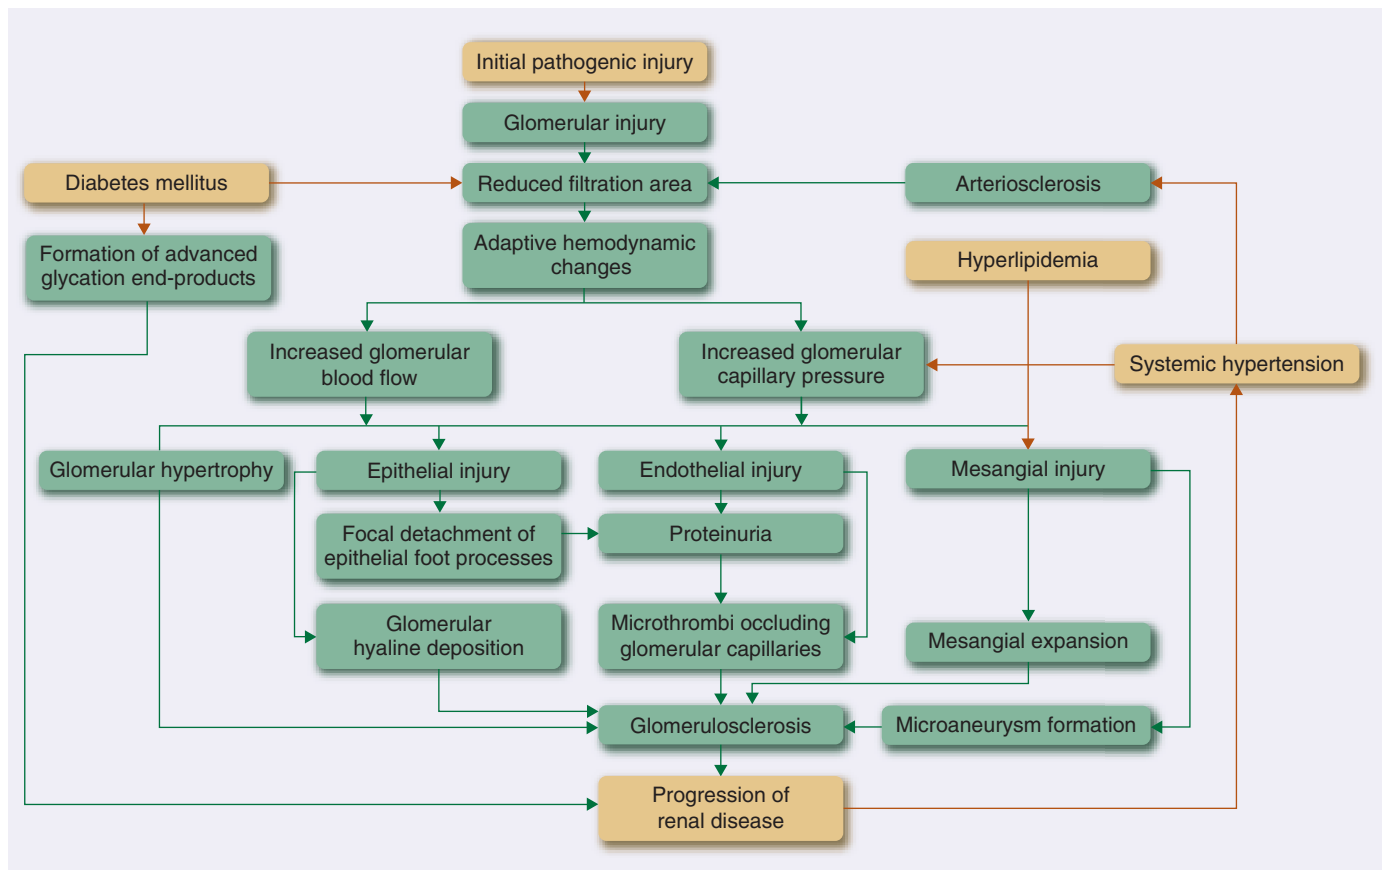

FIGURE 26-1. Proposed mechanisms for progression of kidney disease. (From Derebail VK, Kshirsagar AV, Joy MS. Chronic kidney disease: Progression-modifying therapies. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011:771, with permission.)

and efferent arterioles but has a preferential effect to constrict the efferent arteriole, thereby increasing the pressure in the glomerular capillaries. Increased glomerular capillary pressure expands the pores in the glomerular basement membrane, altering the size-selective barrier and allowing proteins to be filtered through the glomerulus.¹⁷

Protein excretion through the nephron, or proteinuria, increases nephron loss through various complex mechanisms. Filtered proteins are reabsorbed in the renal tubules, which activates the tubular cells to produce inflammatory and vasoactive cytokines and triggers complement activation.¹⁶ These cytokines cause interstitial damage and scarring in the renal tubules, leading to damage and loss of more nephrons. Ultimately, the process leads to progressive loss of nephrons to the point where the number of remaining functioning nephrons is too small to maintain clinical stability, and kidney function declines.

ASSESSMENT

Because CKD often presents without symptoms, assessment for CKD relies on appropriate screening strategies in all patients with risk factors for developing CKD (Table 26–2). Evaluation for CKD and the subsequent treatment strategies depend on the diagnosis, comorbid conditions, severity and complications of disease, and risk factors for the progression of CKD. **3** *Early treatment of CKD and the associated complications of CKD are the most important factors to decrease morbidity and mortality associated with CKD.* However, the probability of patients not diagnosed with CKD to have an assessment of serum creatinine (SCr) is 0.77, whereas the probability of having an assessment of urine protein excretion was only 0.1.⁴ Screening for CKD should be performed in all people with an increased risk for developing CKD including patients with DM, hypertension, genitourinary abnormalities, autoimmune disease, increased age, or a family history of kidney disease. The assessment for CKD should include measurement of SCr, urinalysis, blood pressure, serum electrolytes, and/or imaging studies.

The primary marker of structural kidney damage is proteinuria, even in patients with normal GFR. Clinically significant proteinuria is defined as urinary protein excretion greater than 300 mg/day or greater than 20 mcg/min in a timed urine collection. Significant proteinuria can also be determined by a spot urine dipstick greater than 30 mg/dL (300 mg/L) or a urine protein/creatinine ratio greater than 200 mg/g (22.6 mg/mmol creatinine).¹ Microalbuminuria is defined as 30 to 300 mg of albumin excreted in the urine per day or a urine albumin-to-creatinine ratio of 30 to 300 mg/g (3.4 to 34 mg/mmol creatinine).¹ The NKF recommends routine assessment of proteinuria to detect CKD. A urine dipstick positive for the presence of protein warrants quantification of proteinuria. Patients with a urine protein-to-creatinine ratio greater than 200 mg/g (22.6 mg/mmol creatinine) or urine albumin-to-creatinine ratio greater than 30 mg/g (3.4 mg/mmol creatinine) should undergo diagnostic evaluation; patients with values below

these levels should be reevaluated routinely.¹ Assessment of microalbuminuria is particularly important in patients with DM. Screening for microalbuminuria should be performed 5 years after the diagnosis of type 1 DM and at the time of diagnosis of type 2 DM.¹⁸

- Other markers for structural kidney damage that can be used in place of proteinuria include abnormalities in urinary sediment, such as hematuria, or abnormalities in imaging studies or kidney biopsy.¹

Complications

- 4** *The decline in kidney function is associated with a number of complications, which are discussed later in the chapter, including:*

- Hypertension
- Fluid and electrolyte disorders
- Anemia
- Metabolic bone disease

TREATMENT

Desired Outcomes

- The primary goal is to slow and prevent the progression of CKD. This requires early identification of patients at risk for CKD to initiate interventions early in the course of the disease.

Nonpharmacologic Therapy

► Nutritional Management

- Reduction in dietary protein intake has been shown to slow the progression of kidney disease.¹⁸ However, protein restriction must be balanced with the risk of malnutrition in patients with CKD. Patients with a GFR less than 25 mL/min/1.73 m² (0.24 mL/s/m²) received the most benefit from protein restriction¹⁹; therefore, patients with a GFR above this level should not restrict protein intake. The NKF recommends that patients who have a GFR less than 25 mL/min/1.73 m² (0.24 mL/s/m²) who are not receiving dialysis, however, should restrict protein intake to 0.6 g/kg/day. If patients are not able to maintain adequate dietary energy intake, protein intake may be increased up to 0.75 g/kg/day.¹⁹ Malnutrition is common in patients with ESKD for various reasons, including decreased appetite, hypercatabolism, and nutrient losses through dialysis. For this reason, patients receiving dialysis should maintain protein intake of 1.2 g/kg/day to 1.3 g/kg/day.

Protein intake can have unique contributions to kidney damage in patients with DM. Dietary protein, particularly protein from animal sources, produces AGEs, which are an important cause of kidney damage in patients with DM.¹² The NKF recommends that patients with DM with CKD stages 1 to 4 should limit protein intake to 0.8 g/kg/day to reduce proteinuria and stabilize kidney function.¹⁹

Clinical Presentation and Diagnosis of CKD

General

The development of CKD is usually subtle in onset, often with no noticeable symptoms.

Symptoms

Stages 1 and 2 CKD are generally asymptomatic.

Stages 3 and 4 CKD may be associated with minimal symptoms.

Stage 5 CKD can be associated with pruritus, dysgeusia, nausea, vomiting, constipation, muscle pain, fatigue, and bleeding abnormalities.

Signs

Cardiovascular: Worsening hypertension, edema, dyslipidemia, left ventricular hypertrophy, electrocardiographic changes and chronic heart failure.

Musculoskeletal: Cramping.

Neuropsychiatric: Depression, anxiety, impaired mental cognition.

GI: Gastroesophageal reflux disease, GI bleeding, and abdominal distention.

Genitourinary: Changes in urine volume and consistency, "foaming" of urine (indicative of proteinuria), and sexual dysfunction.

Laboratory Tests

Stages 1 and 2 CKD: Increased blood urea nitrogen (BUN) and serum creatinine (SCr) and decreased GFR.

Stages 3, 4, and 5 CKD: Increased BUN and SCr; decreased GFR.

Advanced stages: Increased potassium, phosphorus, and magnesium; decreased bicarbonate (metabolic acidosis); calcium levels are generally low in earlier stages of CKD and may be elevated in stage 5 CKD, secondary to the use of calcium-containing phosphate binders.

Decreased albumin, if inadequate nutrition intake in advanced stages.

Decreased red blood cell (RBC) count, hemoglobin (Hgb) and hematocrit (Hct); iron metabolism may also be altered (iron level, total iron binding capacity [TIBC], serum ferritin level, and transferrin saturation [TSAT]). Erythropoietin levels are not routinely monitored and are generally normal to low. Urine positive for albumin or protein.

Increased parathyroid hormone (PTH) level; decreased vitamin D levels (stages 4 or 5 CKD).

Stool may be Hemocult-positive if GI bleeding occurs from uremia.

Other Diagnostic Tests

Structural abnormalities of kidney may be present on diagnostic examinations.

Pharmacologic Therapy

► Intensive Blood Glucose Control (for Patients with Diabetes)

The target glycated hemoglobin level (HbA1c) should be less than 7.0% (0.07; 53 mmol/mol Hgb) for patients with DM to decrease the incidence of proteinuria and albuminuria in patients with and without documented DKD.¹⁸ This generally involves intensive insulin therapy for type 1 DM or insulin-dependent type 2 DM with administration of insulin three or more times daily to maintain preprandial blood glucose levels between 70 and 120 g/dL (3.9 to 6.7 mmol/L) and postprandial blood glucose levels less than 180 g/dL (10.0 mmol/L). This strategy has been proven to be effective in delaying the development and progression of DKD in patients with type 1²¹ and type 2 DM.¹⁸ A decrease in HbA1c levels by 0.9% (0.009; 10 mmol/mol Hgb) has been shown to decrease the relative risk for microalbuminuria by 30% in patients with type 2 DM.²⁰ Oral hypoglycemic agents can also be used in non-insulin-dependent type 2 DM to maintain similar blood glucose levels.

► Optimal Blood Pressure Control

Reductions in blood pressure are associated with a decrease in proteinuria, leading to a decrease in the rate of progression of kidney disease. The NKF recommends a goal blood pressure of less than 130/80 mm Hg in patients with stages 1 through 4 CKD.²¹

In patients with stage 5 CKD who are receiving hemodialysis, cardiovascular mortality is affected by blood pressure levels both before and after hemodialysis.²² Elevated blood pressure levels after hemodialysis increases cardiovascular risk. Both systolic blood pressure greater than 180 mm Hg and diastolic blood pressure greater than 90 mm Hg are independently associated with an increased risk of cardiovascular mortality (relative risk: 1.96 and 1.73, respectively).²² Likewise, low blood pressure levels either before or after hemodialysis are also associated with increased cardiovascular mortality. A systolic blood pressure less than 110 mm Hg before hemodialysis is associated with a fourfold increase in cardiovascular mortality; the same blood pressure at the end of hemodialysis is associated with a 2.62 relative risk.²² Therefore, the NKF recommends

achieving a goal blood pressure less than 140/90 mm Hg before hemodialysis and less than 130/80 mm Hg after hemodialysis.²³ These goals are controversial, however; one study demonstrated an increased risk of mortality for patients who achieved the target blood pressure recommended by the guidelines (hazards ratio: 1.9).²⁴ Newer evidence suggests that blood pressure on nonhemodialysis days may be a more appropriate measure.

Because hypertension and kidney dysfunction are linked, blood pressure control can be more difficult to attain in patients with CKD compared with patients with normal kidney function. All antihypertensive agents have similar effects on reducing blood pressure. However, three or more agents are generally required to achieve the blood pressure goal of less than 130/80 mm Hg in CKD patients.²¹ Timing of blood pressure medications may also be important. A recent study suggested that administration of at least one antihypertensive medication at bedtime decreased cardiovascular risk by 14% in patients with CKD compared with taking all antihypertensive medications in the morning.²⁵

► Reduction in Proteinuria

- Reduction of proteinuria within the first year of therapy predicts long-term renal and cardiovascular prognosis.²⁶
- The ability of antihypertensive agents to reduce protein excretion differs. Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) decrease glomerular capillary pressure and volume because of their effects on angiotensin II. This, in turn, reduces the amount of protein filtered through the glomerulus, independent of the reduction in blood pressure,²⁶ which ultimately decreases the progression of CKD. **5** *The ability of ACEIs and ARBs to reduce proteinuria is greater than that of other antihypertensives, up to 35% to 40%,²⁶ making ACEIs and ARBs the antihypertensive agents of choice for all patients with CKD, unless contraindicated.* All patients with documented proteinuria should receive an ACE-I or ARB, regardless of blood pressure.²⁶ Because diabetes is associated with an early onset of microalbuminuria, all patients with diabetes should also receive an ACE-I or ARB, regardless of blood pressure.²⁶ When initiating ACE-I or ARB therapy, the dose should be titrated to the maximum tolerated dose, even if the blood pressure is less than 130/80 mm Hg. **Figure 26–2** depicts an algorithm for the treatment of hypertension in patients with CKD. Combining ACE-Is and ARBs should be done with caution. Some studies have demonstrated that combination therapy leads to greater reductions in protein excretion with the combination,²⁷ whereas others have demonstrated worsening of progression of CKD.²⁸

The nondihydropyridine calcium channel blockers (CCBs) have been shown to also decrease protein excretion in patients with and without diabetes,²⁹ but the reduction in proteinuria appears to be related to the reductions in blood pressure. The maximal effect of nondihydropyridine CCBs on proteinuria is seen with a blood pressure reduction to less than 130/80 mm Hg, and no additional benefit is seen with increased doses.

Dihydropyridine CCBs, however, do not have the same effects on protein excretion. In fact, dihydropyridine CCBs worsen protein excretion, despite similar reductions in blood pressure as nondihydropyridine CCBs.²⁹

Other Interventions to Limit Progression of CKD

► Hyperlipidemia Treatment

Hyperlipidemia plays a role in the development of cardiovascular disease (CVD) in patients with CKD. The primary goal of treatment of dyslipidemias is to decrease the risk of atherosclerotic CVD. A secondary goal in patients with CKD is to reduce proteinuria and decline in kidney function. Treatment of hyperlipidemia in patients with CKD has been demonstrated to increase GFR by 1 mL/min per year (0.016 mL/s per year) of treatment with antihyperlipidemic agents.⁶

- The NKF suggests that CKD should be classified as a coronary heart disease (CHD) risk equivalent and the goal LDL-C level should be below 100 mg/dL (2.59 mmol/L) in all patients with CKD.^{23,30} The most frequently used agents for the treatment of dyslipidemias in patients with CKD are the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (“statins”) and the fibric acid derivatives. However, other treatments have been studied in patients with CKD and should be considered if first-line therapies are contraindicated.

► Smoking Cessation

Although the effects of smoking on the development and progression of CKD are well established, as discussed previously, the effect of smoking cessation on CKD progression has not been studied. Data are emerging that suggest that smoking cessation may be a practical approach to slow the progression of CKD. Smoking cessation has been shown to reduce the risk of myocardial infarction by 50% to 70%, regardless of previous nicotine exposure.³¹ However, smoking cessation does not reverse existing kidney dysfunction in former smokers.

► Anemia Treatment

Anemia decreases oxygen delivery to the renal tubules, promoting the release of inflammatory and vasoactive cytokines, which contribute to the progression of CKD.

- Treatment of anemia in patients with CKD reduces the cardiovascular effects of anemia and has been demonstrated to decrease morbidity and mortality by as much as 20%.³² Studies have demonstrated that treatment of anemia may slow the progression of CKD.³³ The management of anemia is discussed later.

Outcome Evaluation

- Monitor SCr and potassium levels and blood pressure within 1 week after initiating ACE-I or ARB therapy. Discontinue the medication and switch to another agent if a sudden increase

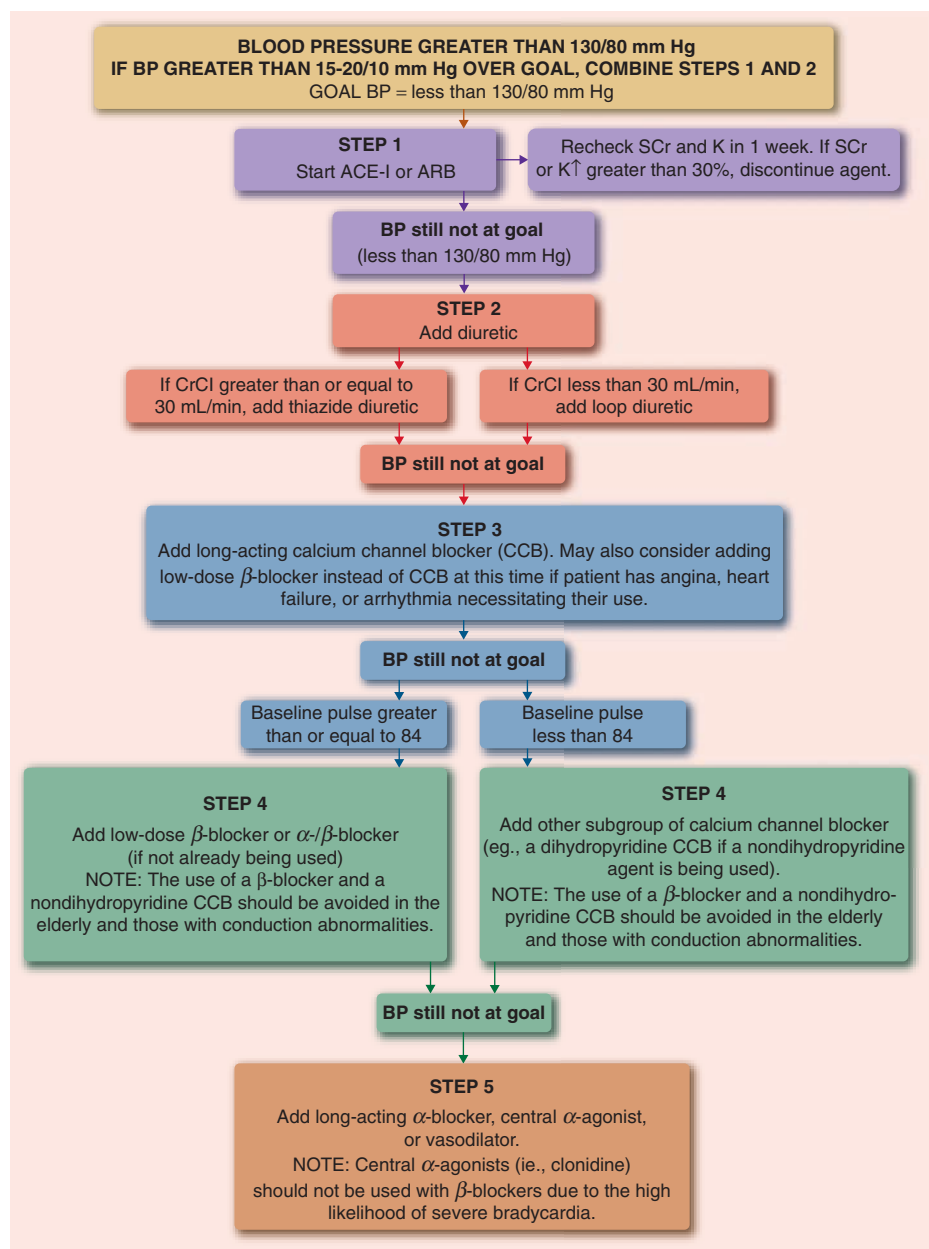

FIGURE 26-2. Hypertension management algorithm for patients with CKD. Dosage adjustments should be made every 2 to 4 weeks as needed. The dose of one agent should be maximized before another is added. (ACE-I, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; CAD, coronary artery disease; CCB, calcium channel blocker; CHF, congestive heart failure; MI, myocardial infarction; UP:Cr, urinary protein-to-creatinine ratio.) (From Derebail VK, Kshirsagar AV, Joy MS. Chronic kidney disease: Progression-modifying therapies. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011:775, with permission.)

in SCr greater than 30% occurs, hyperkalemia develops, or the patient becomes hypotensive. Titrate the dose of the ACE-I or ARB every 1 to 3 months to the maximum tolerable dose. If blood pressure is not reduced to less than 130/80 mm Hg, add another agent to the regimen. Refer the patient to a nephrologist to manage complications associated with CKD. As CKD progresses to stage 4, begin discussion to prepare the patient for renal replacement therapy (RRT).

CONSEQUENCES OF CKD AND ESKD

Impaired Sodium and Water Homeostasis

Sodium and water balance are primarily regulated by the kidney. Reductions in the number of functioning nephrons decrease glomerular filtration and subsequent reabsorption of sodium and water, leading to edema.

► Pathophysiology

Sodium and water balance can be maintained despite wide variations in intake with normal kidney function. The fractional excretion of sodium (FE_{Na}) is approximately 1% to 3% with normal kidney function, allowing sodium balance to be maintained with a sodium intake of 120 to 150 mEq (120 to 150 mmol) per day. Urine osmolality can range from 50 to 1,200 mOsm/kg (50 to 1,200 mmol/kg) with normal kidney function, allowing for water balance to be maintained with a wide range of fluid intake. As the number of functioning nephrons decreases, the remaining nephrons increase sodium excretion, and FE_{Na} may increase up to 10% to 20%.³⁴ This produces an osmotic diuresis that impairs the ability of the kidneys to concentrate and dilute urine, and the urine becomes fixed at an osmolality close to that of the plasma, approximately 300 mOsm/kg (300 mmol/kg).

Patient Encounter 1

A 58-year-old African American man presents to the clinic for a routine checkup. He has been watching his diet closely and losing weight to control his blood sugars but has been unable to get his blood pressure under control.

PMH: Diabetes mellitus, diagnosed 3 years ago; hypertension, diagnosed 10 years ago.

SH: He is unemployed; he denies smoking but drinks alcohol two to three times weekly; he denies illicit drug use.

Meds: Hydrochlorothiazide 25 mg orally daily; amlodipine 10 mg orally daily; glipizide-metformin 5 mg/500 mg orally twice daily.

ROS: Unremarkable.

PE:

VS: BP 168/102 mm Hg; P 85 bpm; T 98.8°F (37.1°C); ht 6'1" (185 cm); wt 215 lb (97.7 kg)

CV: RRR, normal S₁, S₂; no murmurs, rubs or gallops; lungs clear

Abd: Obese; no organomegaly, bruits or tenderness, (+) bowel sounds; heme (-) stool

Exts: Trace pedal edema bilaterally; decreased sensation in feet to light touch; no lesions

Labs (Fasting): Sodium 139 mEq/L (139 mmol/L); potassium 3.9 mEq/L (3.9 mmol/L); chloride 101 mEq/L (101 mmol/L); carbon dioxide 25 mEq/L (25 mmol/L); blood urea nitrogen (BUN) 28 mg/dL (10.0 mmol/L); serum creatinine (SCr) 1.8 mg/dL (159 μmol/L); glucose 102 mg/dL (5.7 mmol/L); total cholesterol 187 mg/dL (4.84 mmol/L); low-density lipoprotein cholesterol (LDL-C) 120 mg/dL (3.10 mmol/L); high-density lipoprotein cholesterol (HDL-C) 42 mg/dL (1.09 mmol/L); triglycerides 125 mg/dL (1.41 mmol/L); hemoglobin_{A1C} (Hb_{A1C}) 6.9% (0.069; 52 mmol/mol Hgb); urine microalbumin 150 mg/dL (1.5 g/L)

What risk factors does the patient have for the development of CKD?

What signs and symptoms are consistent with CKD?

How would you classify his CKD?

What lifestyle modifications would you recommend for this patient with CKD?

What pharmacologic alternatives are available for this patient for treatment of CKD?

The inability of the kidney to concentrate the urine results in nocturia in patients with CKD, usually presenting as early as stage 3 CKD.

As the number of functioning nephrons continues to decline, the sodium load overwhelms the remaining nephrons and total sodium excretion is decreased, despite the increase in sodium excretion by the functioning nephrons. Sodium retention increases thirst and also causes fluid retention that increases intravascular volume and raises systemic blood pressure. Severe volume overload can lead to pulmonary edema.

► Treatment

Nonpharmacologic Therapy The kidney is unable to adjust to abrupt changes in sodium intake in patients with severe CKD. Therefore, patients should be advised to refrain from adding salt to their diet but should not restrict sodium intake. Changes in sodium intake should occur slowly over a period of several days to allow adequate time for the kidney to adjust urinary sodium content. Sodium restriction produces a negative sodium balance, which causes fluid excretion to restore sodium balance. The resulting volume contraction can decrease perfusion of the kidney and hasten the decline in GFR. Saline-containing IV solutions should be used cautiously in patients with CKD because the salt load may precipitate volume overload.

Fluid restriction is generally unnecessary as long as sodium intake is controlled. The thirst mechanism remains intact in

Clinical Presentation and Diagnosis of Impaired Sodium and Water Homeostasis

General

Alterations in sodium and water balance in CKD manifests as increased edema.

Symptoms

Nocturia can present in stage 3 CKD.

Edema generally presents in stage 4 CKD or later.

Signs

Cardiovascular: Worsening hypertension, edema.

Genitourinary: Change in urine volume and consistency.

Laboratory Tests

Increased blood pressure.

Sodium levels remain within the normal range.

Urine osmolality is generally fixed at 300 mOsm/kg (300 mmol/kg).

CKD to maintain total body water and plasma osmolality near normal levels. Fluid intake should be maintained at the rate of urine output to replace urine losses, usually fixed at approximately 2 L/day as urine concentrating ability is lost. Significant increases in free water intake orally or

IV can precipitate volume overload and hyponatremia. Patients with stage 5 CKD require RRT to maintain normal volume status. Fluid intake is often limited in patients receiving hemodialysis to prevent fluid overload between dialysis sessions.

- **Pharmacologic Therapy** Diuretic therapy is often necessary to prevent volume overload in patients with CKD in those who still produce urine. Loop diuretics are most frequently used to increase sodium and water excretion. Thiazide diuretics are ineffective when used alone in patients with a GFR less than 30 mL/min/1.73 m² (0.29 mL/s/m²).²¹ As CKD progresses, higher doses, as much as 80 to 1,000 mg/day of furosemide, or continuous infusion of loop diuretics may be needed, or combination therapy with loop and thiazide diuretics to increase sodium and water excretion.²¹

► Outcome Evaluation

- Monitor edema after initiation of diuretic therapy. Monitor fluid intake to ensure obligatory losses are being met and avoid dehydration. If adequate diuresis is not attained with a single agent, consider combination therapy with another diuretic.

Impaired Potassium Homeostasis

Potassium balance is also primarily regulated by the kidney via the distal tubular cells. Reduction in the number of functioning nephrons decreases the overall tubular secretion of potassium, leading to hyperkalemia. Hyperkalemia is estimated to affect more than 50% of patients with stage 5 CKD.³⁵

► Pathophysiology

The distal tubules secrete 90% to 95% of the daily dietary intake of potassium. The fractional excretion of potassium (FE_K) is approximately 25% with normal kidney function.³⁶ The GI tract excretes the remaining 5% to 10% of dietary potassium intake. Following a large potassium load, extracellular potassium is shifted intracellularly to maintain stable extracellular levels.

- As the number of functioning nephrons decreases, both the distal tubular secretion and GI excretion are increased in the functioning nephrons because of aldosterone stimulation. Functioning nephrons increase FE_K up to 100% and GI excretion increases as much as 30% to 70% in CKD,³⁷ as a result of aldosterone secretion in response to increased potassium levels.³⁷ This maintains serum potassium concentrations within the normal range through stages 1 to 4 CKD. Hyperkalemia begins to develop when GFR falls below 20% of normal, when the number of functioning nephrons and renal potassium secretion is so low that the capacity of the GI tract to excrete potassium has been exceeded.³⁷
- Medications can increase the risk of hyperkalemia in patients with CKD, including ACE-I and ARBs, used for the treatment of proteinuria and hypertension. Potassium-sparing

Clinical Presentation and Diagnosis of Hyperkalemia

General

Hyperkalemia is generally asymptomatic in patients with CKD until serum potassium levels are greater than 5.5 mEq/L (5.5 mmol/L), when cardiac abnormalities present.

Symptoms

Mild hyperkalemia is generally not associated with overt symptoms.

Symptoms generally appear in stage 4 or 5 CKD, such as muscle weakness, fatigue, nausea, and paresthesias.

Signs

Cardiovascular: ECG changes (peaked T waves, widened QRS complex, loss of P wave).

Laboratory Tests

Increased serum potassium levels.

diuretics, used for the treatment of edema and chronic heart failure, can also exacerbate the development of hyperkalemia, and they should be used with caution in patients with stage 3 CKD or higher.

► Treatment

Nonpharmacologic Therapy Patients with CKD should

- avoid abrupt increases in dietary intake of potassium because the kidney is unable to increase potassium excretion with an acute potassium load, particularly in latter stages of the disease. Hyperkalemia resulting from an acute increase in potassium intake can be more severe and prolonged. Patients who develop hyperkalemia should restrict dietary intake of potassium to 50 to 80 mEq (50 to 80 mmol) per day. Potassium concentrations can also be altered in the **dialysate** for patients receiving hemodialysis and peritoneal dialysis to manage hyperkalemia. Because GI excretion of potassium plays a large role in potassium homeostasis in patients with stage 5 CKD, a good bowel regimen is essential to minimize constipation, which can occur in 40% of patients receiving hemodialysis.³⁶ Severe hyperkalemia is most effectively managed by hemodialysis.
- **Pharmacologic Therapy** Patients with acute hyperkalemia usually require other therapies to manage hyperkalemia until dialysis can be initiated. Patients who present with hyperkalemia-induced cardiac abnormalities, which manifest as peaked T waves, a widened QRS complex, or loss of P waves, should receive calcium gluconate or chloride (1 g IV) to reverse the cardiac effects. Temporary measures can be employed to shift extracellular potassium into the intracellular compartment to stabilize cellular membrane effects of excessive serum potassium levels. Such measures

include the use of regular insulin (5 to 10 units IV) and dextrose (5% to 50% IV), or nebulized albuterol (salbutamol) (10 to 20 mg). Sodium bicarbonate should not be used to shift extracellular potassium intracellularly in patients with CKD unless severe metabolic acidosis (pH less than 7.2) is present. These measures will decrease serum potassium levels within 30 to 60 minutes after treatment, but potassium must still be removed from the body. Shifting potassium to the intracellular compartment, however, decreases potassium removal by dialysis. Often, multiple dialysis sessions are required to remove potassium that is redistributed from the intracellular space back into the serum.

Sodium polystyrene sulfonate (SPS, 15 to 30 g orally or rectally), a sodium–potassium exchange resin, promotes potassium excretion from the GI tract. The onset of action is within 2 hours after administration of SPS, but the maximum effect on potassium levels may not be seen for up to 6 hours, which limits the utility in patients with severe hyperkalemia.

Of note, loop diuretics are often used to decrease potassium levels in patients with normal or mildly decreased kidney function, but they are not useful in patients with stage 5 CKD to decrease potassium concentrations. Fludrocortisone is a mineralocorticoid that mimics the effects of aldosterone and increases potassium excretion in the distal tubules and through the GI tract. However, fludrocortisone causes significant sodium and water retention, which exacerbates edema and hypertension, and it may not be tolerated by many CKD patients.

► Outcome Evaluation

Monitor ECG continuously in patients with cardiac abnormalities until serum potassium levels drop below 5 mEq/L (5 mmol/L) or cardiac abnormalities resolve. Evaluate serum potassium and glucose levels within 1 hour in patients who receive insulin and dextrose therapy. Evaluate serum potassium levels within 2 to 4 hours after treatment with SPS or diuretics. Repeat doses of diuretics or SPS if necessary until serum potassium levels fall below 5 mEq/L (5 mmol/L). Monitor blood pressure and serum potassium levels in 1 week in patients who receive fludrocortisone.

Anemia of CKD

The progenitor cells of the kidney produce 90% of the hormone erythropoietin (EPO), which stimulates red blood cell (RBC) production. **6** *Reduction in the number of functioning nephrons decreases renal production of EPO, which is the primary cause of anemia in patients with CKD. The development of anemia of CKD results in decreased oxygen delivery and utilization, leading to increased cardiac output and left ventricular hypertrophy (LVH), which increase the cardiovascular risk and mortality in patients with CKD.*

► Epidemiology and Etiology

Current Kidney Disease Improving Global Outcomes (KDIGO) guidelines define anemia as a hemoglobin (Hgb)

level less than 13 g/dL (130 g/L or 8.06 mmol/L) in males and less than 12 g/dL (120 g/L or 7.45 mmol/L) in females.³⁸ A number of factors can contribute to the development of anemia including deficiencies in vitamin B₁₂ or folate, hemolysis, bleeding, or bone marrow suppression. Many of these can be detected by alterations in RBC indices, which should be included in the evaluation for anemia. A complete blood cell count is also helpful in evaluating anemia to determine overall bone marrow function.

The prevalence of anemia correlates with the degree of kidney dysfunction. More than 26% of patients with a GFR greater than 60 mL/min/1.73 m² (0.58 mL/s/m²) are estimated to have Hgb levels less than 12 g/dL (120 g/L or 7.45 mmol/L), and the number increases to 75% in patients with a GFR less than 15 mL/min/1.73 m² (0.14 mL/s/m²).³⁹ The risk of developing anemia also increases as GFR declines, doubling for patients with stage 3 CKD, increasing to 3.8-fold in patients with stage 4 CKD, and to 10.5-fold for patients with stage 5 CKD, compared with stages 1 and 2 CKD.³⁹

► Pathophysiology

The primary cause of anemia in patients with CKD is a decrease in EPO production. With normal kidney function, as Hgb, hematocrit (Hct), and tissue oxygenation decrease, the plasma concentration of EPO increases exponentially. As the number of functioning nephrons decrease, EPO production also decreases. Thus, as Hgb, Hct, and tissue oxygenation decrease in patients with CKD, plasma EPO levels remain constant within the normal range but low relative to the degree of hypoxia present. The result is a normochromic, normocytic anemia.

Several other factors also contribute to the development of anemia in patients with CKD. **Uremia**, the accumulation of toxins that results from declining kidney function, decreases the lifespan of RBCs from a normal of 120 days to as low as 60 days in patients with stage 5 CKD. Iron deficiency and blood loss from regular laboratory testing and hemodialysis also contribute to the development of anemia in patients with CKD.

However, as CKD progress, adaptive mechanisms develop that protect the body from the decreased oxygen-carrying capacity associated with lower Hgb levels. As oxygen saturation decreases with lower Hgb levels, the affinity of 2,3-diphosphoglycerate (2,3-DPG) for Hgb is increased, allowing oxygen to more readily dissociate from Hgb at the tissue site. Acidosis and uremia also contribute to the increased affinity of 2,3-DPG, increasing oxygen delivery to tissues to minimize the potential for hypoxemia.⁴⁰

► Treatment

General Approach to Therapy Studies have demonstrated that initiation of treatment for anemia before stage 5 CKD decreases mortality in patients with ESKD receiving dialysis, particularly in the elderly.⁴¹ The treatment of anemia can decrease morbidity, increase exercise capacity and tolerance, and slow the progression of CKD if target Hgb levels are achieved.⁴²

Clinical Presentation and Diagnosis of Anemia of CKD

General

Anemia of CKD generally presents with fatigue and decreased quality of life.

Symptoms

Anemia of CKD is associated with symptoms of cold intolerance, shortness of breath, and decreased exercise capacity.

Signs

Cardiovascular: Left ventricular hypertrophy, ECG changes, congestive heart failure.

Neurologic: Impaired mental cognition.

Genitourinary: Sexual dysfunction.

Laboratory Tests

Decreased RBC count, Hgb, and Hct.

Decreased serum iron level, TIBC, serum ferritin, and TSAT.

- Patients with CKD should be evaluated for anemia when the GFR falls below 60 mL/min (1.0 mL/s) or if the SCr rises above 2 mg/dL (20 g/L or 177 mmol/L). An anemia workup should be performed if the Hgb is less than 13 g/dL (130 g/L or 8.06 mmol/L) in males or less than 12 g/dL (120 g/L or 7.45 mmol/L) in females. The workup for anemia should rule out other potential causes for anemia (see Chapter 66).
- Abnormalities found during the anemia workup should be corrected before initiating **erythropoiesis-stimulating agents** (ESAs), particularly iron deficiency, because iron is

an essential component of RBC production. If Hgb is below 10 g/dL (100 g/L or 6.21 mmol/L) when all other causes of anemia have been corrected, EPO deficiency should be assumed. EPO levels are not routinely measured and have little clinical significance in monitoring progression and treatment of anemia in patients with CKD.

Generally, treatment for anemia of CKD requires a combination of iron supplementation and ESAs. The goals for iron supplementation are:

- Serum ferritin levels greater than 500 ng/mL (500 mcg/L; 1,123 pmol/L)
- Transferrin saturation (TSAT): greater than 30% (0.3).³⁸

ESAs may be considered if Hgb levels remain persistently low to improve symptoms of anemia. In patients not receiving dialysis, the decision to initiate ESAs should be based on the rate of Hgb decline, prior response to anemia treatment, risks associated with ESAs and the patient's symptoms. The KDIGO guidelines recommend considering to initiate ESAs when Hgb is less than 10 g/dL (100 g/L or 6.2 mmol/L) in patients not receiving dialysis.³⁸ In patients receiving dialysis, most clinicians initiate ESAs when Hgb is less than 9 g/dL (90 g/L or 5.58 mmol/L). However, the target for Hgb is unclear because use of ESAs to increase Hgb levels beyond 12 g/dL (120 g/L or 7.44 mmol/L) is associated with increased mortality.⁴³

The approach to the management of anemia of CKD with iron supplementation and ESAs is illustrated in **Figure 26-3**.

Nonpharmacologic Therapy Approximately 1 to 2 mg of iron is absorbed daily from the diet. This small amount is generally not adequate to preserve adequate iron stores to promote RBC production. RBC transfusions have been used in the past as the primary means to maintain Hgb and Hct levels in patients with anemia of CKD. This treatment

Patient Encounter 2, Part 1

A 43-year-old white man with a history of IgA nephropathy presents to your clinic for a routine checkup. He complains of getting fatigued easily at work. He works as a mechanic and finds himself not able to keep up with the job as much as he had in the past. He notes that he feels winded when he walks even short distances.

Current meds: Atenolol 100 mg orally daily; lisinopril 20 mg orally daily; furosemide 20 mg orally daily.

ROS: Skin pale in color; fatigue daily throughout the day with minimal exertion; otherwise unremarkable.

PE:

VS: BP 132/82 mm Hg; P 88 bpm; T 97.2°F (36.2°C); ht 5'11" (180 cm); wt 215 lb (97.7 kg)

CV: RRR, normal S₁, S₂

Abd: Obese; no organomegaly, bruits or tenderness; (+) bowel sounds; heme (−) stool

Ext: 1+ pedal edema bilaterally

Labs: Sodium 141 mEq/L (141 mmol/L); potassium 4.9 mEq/L (4.9 mmol/L); chloride 99 mEq/L (99 mmol/L); carbon dioxide 19 mEq/L (19 mmol/L); BUN 42 mg/dL (15.0 mmol/L); Scr 3.2 mg/dL (283 μmol/L); glucose 78 mg/dL (4.3 mmol/L); white blood cell (WBC) count 5.6 × 10³ cells/mm³ (5.6 × 10⁹/L); red blood cell (RBC) count 2.7 × 10⁶ cells/mm³ (2.7 × 10¹²/L); hemoglobin (Hgb) 8.1 g/dL (81 g/L; 5.03 mmol/L); hematocrit 24% (0.24); platelets 325 × 10³ cells/mm³ (325 × 10⁹/L)

What signs and symptoms are consistent with anemia of CKD?

What additional information could you request to determine other causes of anemia in this patient?

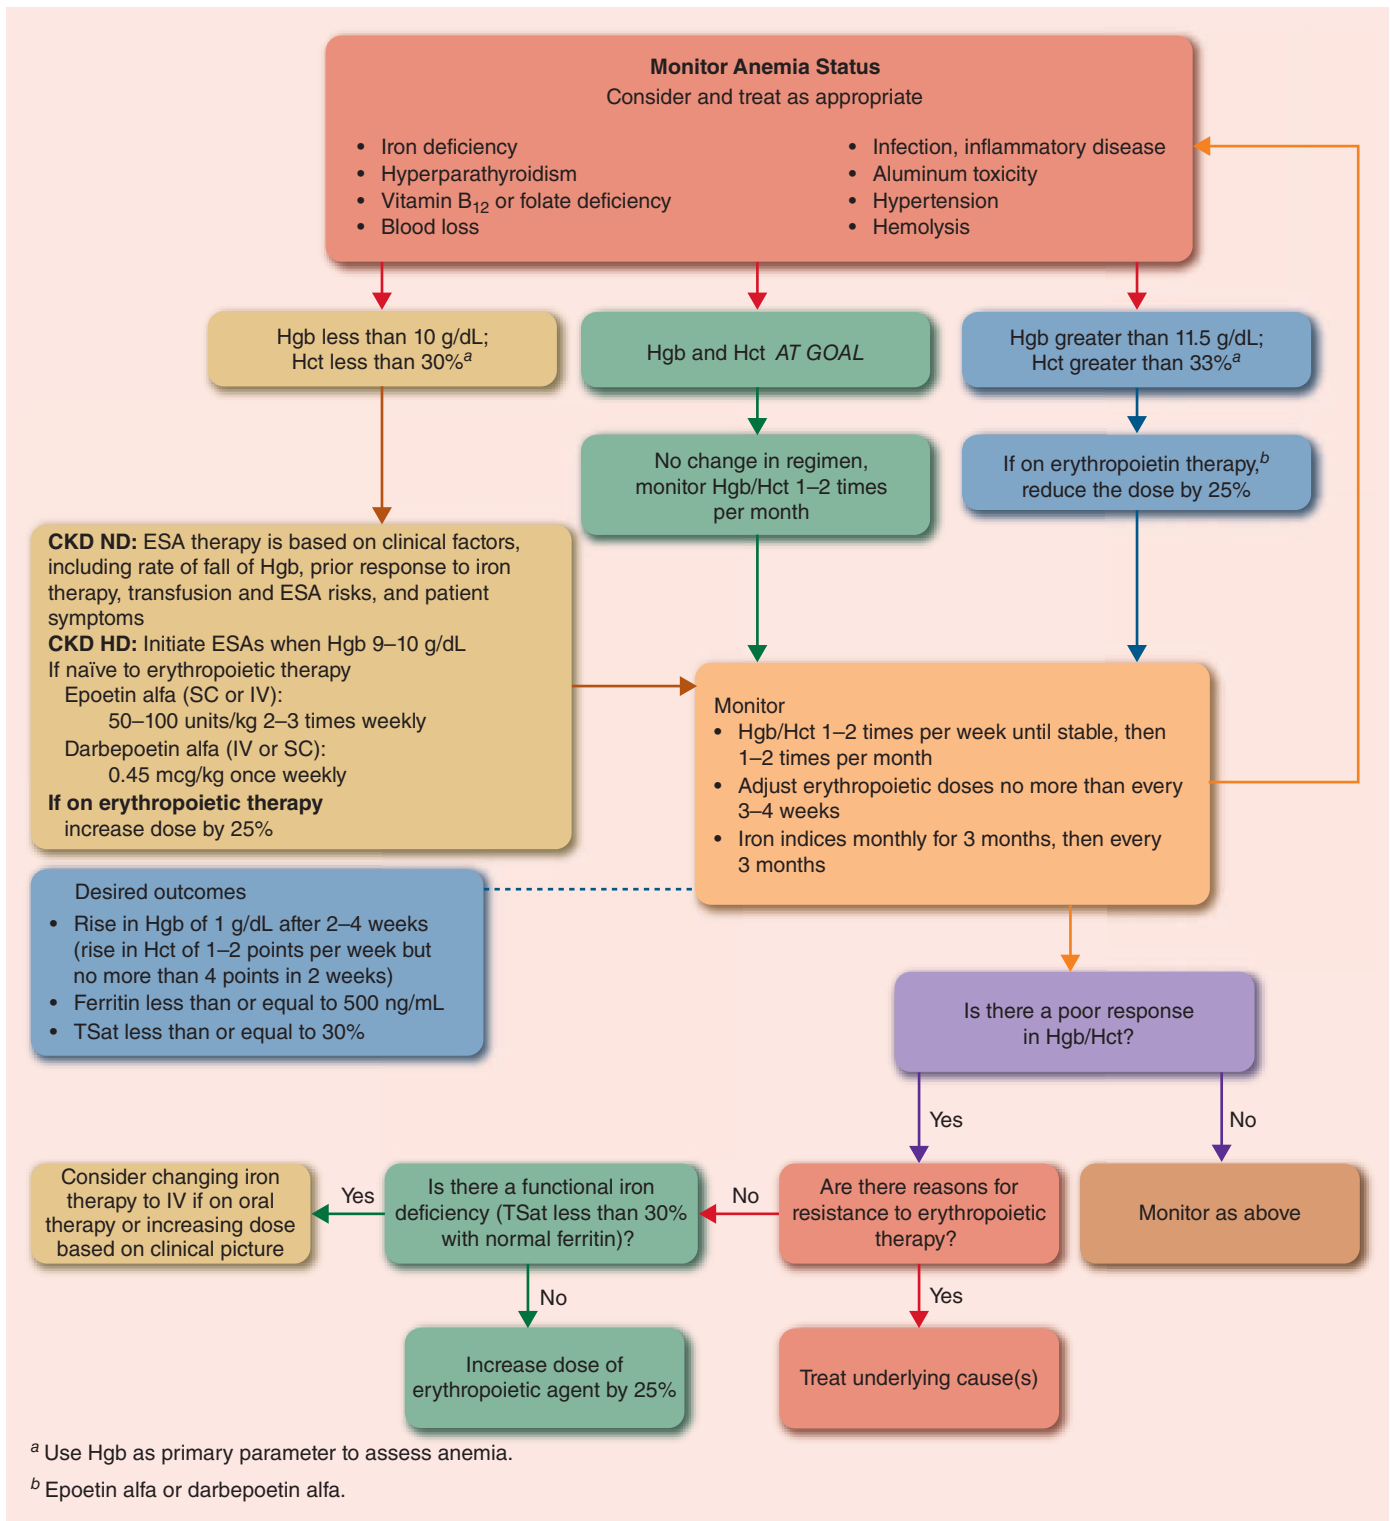

FIGURE 26-3. Algorithm for erythropoietic-stimulating agent therapy in the management of anemia of CKD. (CKD HD, chronic kidney disease receiving hemodialysis; CKD ND, chronic kidney disease not receiving dialysis; ESA, erythropoiesis-stimulating agent; Hb, hemoglobin; SC, subcutaneous; TSAT, transferrin saturation.) (Adapted from Hudson JQ. Chronic kidney disease: Management of complications. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 8th ed. New York, NY: McGraw-Hill, 2011:800, with permission.)

is still utilized today in patients with severe anemia or contraindications to ESAs, but it is considered a third-line therapy for anemia of CKD.

• **Pharmacologic Therapy** The first-line treatment for anemia of CKD involves replacement of iron stores with iron supplements. When iron supplementation alone is not sufficient to increase Hgb levels, ESAs are necessary to replace erythropoietin. ESAs are synthetic formulations of EPO produced by recombinant human DNA technology. Use of ESAs increases the iron demand for RBC production and iron deficiency is common, requiring iron supplementation to correct and maintain adequate iron stores to promote RBC production. Androgens were used extensively before the availability of ESAs but are no longer recommended for the treatment of anemia³⁸ primarily because of toxicity, namely, hepatotoxicity.

• **Iron Supplementation.** *Use of ESAs can lead to iron deficiency if iron stores are not adequately maintained.* If serum ferritin and TSAT fall below the goal levels, iron supplementation is required.

• Initiation of iron supplementation should be based on evaluation of iron stores. A serum ferritin level less than 500 ng/mL (500 mcg/L; 1,123 pmol/L) in conjunction with a TSAT level less than 30% (0.30) indicates absolute iron deficiency and is a clear indication for the need for iron replacement.³⁸ Serum ferritin is an acute phase reactant that may become elevated with inflammation and stress. Thus when serum ferritin is normal or elevated in conjunction with TSAT levels less than 30% (0.30), treatment should be based on the clinical picture of the patient. Iron supplementation may be indicated if Hgb levels are below the goal level.

Oral iron supplements are generally less costly than IV supplements and are generally the first-line treatment for iron supplementation for patients with CKD not receiving hemodialysis. When administering iron by the oral route, 200 mg of elemental iron should be delivered daily in divided doses to maintain adequate iron stores.³⁸

When oral iron is not effective to increase iron stores or for patients receiving hemodialysis, IV iron should be administered. General approach to IV iron replacement in CKD patients not receiving hemodialysis is to give a total of 1 g of IV iron, administered as a single large dose or in smaller, sequential doses. **Table 26-3** lists the FDA-approved doses of the currently available IV iron products. Patients receiving hemodialysis have ongoing blood losses with each hemodialysis session, which can lead to iron losses of 1–2 g per year.³⁸ For hemodialysis, IV iron may be administered in 1 g doses periodically based on routine surveillance of iron stores. An alternative method to administer IV iron is to give smaller maintenance doses of iron weekly or with each dialysis session (e.g., iron dextran or iron sucrose 20 to 100 mg/week; sodium ferric gluconate 62.5 to 125 mg/week). The latter approach of giving smaller maintenance doses may result in lower cumulative doses of iron and lower doses of ESAs.³⁸

IV iron preparations are equally effective in increasing iron stores. Iron dextran has been associated with side effects including anaphylactic reactions and delayed reactions, such as arthralgias and myalgias. A test dose of 25 mg iron dextran should be administered 30 minutes before the full dose to monitor for potential anaphylactic reactions. However, patients should be monitored closely when receiving iron dextran because anaphylactic reactions can occur in patients who safely received prior doses of iron dextran. For this reason, use of iron dextran has decreased dramatically in CKD patients in favor of the newer iron preparations, sodium ferric gluconate, iron sucrose, and ferumoxytol, which are associated with fewer severe reactions. The most common side effects seen with these preparations include hypotension, flushing, nausea, and injection site reactions. A test dose is not required prior to the administration of sodium ferric gluconate, iron sucrose, or ferumoxytol.

After administering a 1-g course of IV iron, iron status should be monitored to determine the effectiveness of the treatment. Serum ferritin and TSAT should be monitored no sooner than 1 week after the last dose of IV iron. If Hgb does not increase after a course of IV iron or serum ferritin is not greater than 500 ng/mL (500 mcg/L; 1,123 pmol/L) and TSAT greater than 30% (0.30), an additional 1 g of IV iron may be administered, based on the clinical situation.

Erythropoiesis-Stimulating Agents. *Erythropoietin is a growth factor that acts on erythroblasts formed from stem cells in the bone marrow, stimulating proliferation and differentiation into normoblasts, then reticulocytes, which are released into the bloodstream to eventually mature into erythrocytes (mature RBCs).* The ESAs currently available in the United States are:

- Epoetin alfa (distributed as Epogen by Amgen, Inc., Thousand Oaks, CA; and Procrit by Ortho Biotech, Johnson & Johnson, Raritan, NJ)
- Darbepoetin alfa (Aranesp by Amgen, Inc.)

Epoetin α and epoetin β , which is available outside the United States, have the same biological activity as endogenous EPO. Darbepoetin alfa differs from epoetin alfa by the addition of carbohydrate side chains that increase the half-life of darbepoetin alfa compared with epoetin alfa and endogenous EPO, allowing for less frequent dosing than that of epoetin alfa. All ESAs are equivalent in their efficacy and have a similar adverse-effect profile.

The most common adverse effect seen with ESA is increased blood pressure, which can occur in up to 23% of patients.³⁶ Antihypertensive agents may be required to control blood pressure in patients receiving ESAs. Caution should be used when initiating an ESA in patients with very high blood pressures (greater than 180/100 mm Hg). If blood pressures are refractory to antihypertensive agents, ESAs may need to be withheld. Darbepoetin has also been reported to increase the risk of strokes in patients with CKD.⁴⁴

Subcutaneous (SC) administration of ESA produces a more predictable and sustained response than IV administration, and it is therefore the preferred route of administration for

Table 26-3

IV Iron Products

Iron Formulation (Product)	FDA-approved Indications	FDA-Approved Dosing	Warnings	Dose Ranges ^a	How Supplied
Iron dextran (INFeD, Dextran)	Patients with iron deficiency in whom oral iron is unsatisfactory	IV push: 100 mg over 2 minutes (25 mg test dose required)	Black box (risk of anaphylactic reactions)	25–1,000 mg	2-mL vials containing 50 mg elemental iron per mL
Ferric gluconate (Ferrlecit)	Adult and pediatric HD patients age 6 years and older receiving ESA therapy	IV push (adult): 125 mg over 10 minutes IV infusion (adult): 125 mg in 100 mL of 0.9% NaCl over 60 minutes IV infusion (pediatric): 1.5 mg/kg in 25 mL of 0.9% NaCl over 60 minutes; maximum dose 125 mg	General	6.25–1,000 mg	5-mL ampules containing 62.5 mg elemental iron (12.5 mg/mL)
Iron sucrose (Venofer)	HD patients with CKD receiving ESA therapy	IV push: 100 mg over 2–5 minutes IV infusion: 100 mg in maximum of 100 mL of 0.9% NaCl over 15 minutes	General	25–1,000 mg	5-mL single-dose vials containing 100 mg elemental iron (20 mg/mL)
	Nondialysis-CKD patients receiving or not receiving ESA therapy	IV push: 200 mg over 2–5 minutes on five different occasions within 14-day period			
	PD patients receiving ESA therapy	IV infusion: 2 infusions 14 days apart, of 300 mg in maximum of 250 mL of 0.9% NaCl over 1.5 hour, followed by 1 infusion 14 days later, of 400 mg in maximum of 250 mL of 0.9% NaCl over 2.5 hours			
Ferumoxytol (Feraheme)	Adults with iron-deficiency anemia associated with CKD	IV: 510 mg (17 mL) as a single dose, followed by a second 510-mg dose 3–8 days after the initial dose (rate of 1 mL or 30 mg/second)	General	510 mg	17 mL vials containing 510 mg (0 mg/mL)

CKD, chronic kidney disease; ESA, erythropoietin-stimulating agent; HD, hemodialysis; PD, peritoneal dialysis.

^aSmall dosing ranges (e.g., 25 to 100 mg/week) generally used for maintenance regimens. Larger doses (e.g., 1 g) should be administered in divided doses.

both agents. IV administration is often utilized in patients who have established IV access or are receiving hemodialysis. Starting doses of ESAs depend on the patient's Hgb level, the target Hgb level, the rate of Hgb increase, and clinical circumstances.³⁸ The initial increase in Hgb should be 1 to 2 g/dL (10 to 20 g/L or 0.62 to 1.24 mmol/L) per month. The recommended starting dose of epoetin alfa is 50 to 100 units/kg/dose administered SC or IV two to three times weekly; the starting dose of darbepoetin alfa is 0.45 mcg/kg administered SC or IV once weekly (Table 26-4).

When prescribing ESAs, clinicians should not attempt to target "normal" Hgb levels (i.e., greater than 13 g/dL [130 g/L or 8.07 mmol/L] in males; greater than 12 g/dL [120 g/L or 7.45 mmol/L] in females). Several clinical trials have demonstrated that targeting Hgb levels greater

than 13 g/dL (130 g/L or 8.07 mmol/L) resulted in more cardiovascular complications or death, compared with target Hgb levels less than 11 g/dL (110 g/L or 6.83 mmol/L), with little or no benefit on the quality of life.^{43,45} Although not completely understood, the increased mortality is postulated to result from increased blood viscosity, which can trigger platelet activity, and hemoconcentration, which occurs when large amounts of fluid are removed during hemodialysis.⁴⁵ A third mechanism may relate to relative unphysiological concentrations of EPO that are achieved with intermittent dosing of ESAs, which may promote inflammation or thrombosis.⁴⁵

Further studies are needed to evaluate the appropriate target level for Hgb. Nonetheless, based on these findings, the U.S. FDA recommended addition of a black box warning

Table 26-4

Estimated Starting Doses of Darbepoetin Alfa Based on Previous Epoetin Alfa Dose

Previous Epoetin Alfa Dose (units/week)	Weekly Darbepoetin Alfa Dose (mcg/week)
Less than 2,500	6.25
2,500–4,999	12.5
5,000–10,999	25
11,000–17,999	40
18,000–33,999	60
34,000–59,999	100
60,000–89,999	150
90,000 or more	200

to the product information for all ESAs indicating the maximum target Hgb should not exceed 11 g/dL (110 g/L or 6.83 mmol/L) for patients who are receiving ESAs.

► Outcome Evaluation

Evaluate Hgb every 1 to 2 weeks when ESA therapy is initiated or the dose is adjusted to ensure Hgb does not exceed 11.5 g/dL (115 g/L or 7.13 mmol/L).³⁸ Once a stable Hgb is attained, evaluate Hgb every 2 to 4 weeks thereafter. While the patient is receiving ESA therapy, monitor iron stores monthly in patients who are not receiving iron supplements or every 3 months in patients who are receiving iron supplements. When the goal Hgb is reached, monitor iron stores every 3 months. Serum ferritin and TSat should be monitored no sooner than 1 week after the last dose of IV iron is administered.

Patient Encounter 2, Part 2

The patient returns to your clinic in 1 week and states that his symptoms have not changed. He is asking about the results of his laboratory studies.

Labs: WBC 6.1×10^3 cells/mm³ (6.1×10^9 /L); RBC 2.6×10^6 cells/mm³ (2.6×10^{12} /L); Hgb 8.1 g/dL (81 g/L; 5.03 mmol/L); hematocrit 25% (0.25); mean corpuscular volume (MCV) 82 fL; mean corpuscular hemoglobin concentration (MCHC) 34 g/dL (340 g/L); platelets 315×10^3 cells/mm³ (315×10^9 /L); iron 29 mcg/dL (5.2 μmol/L); total iron binding capacity (TIBC) 487 mcg/dL (87.2 μmol/L); ferritin 68 ng/mL (68 mcg/L); transferrin saturation (TSAT) 12% (0.12); stool guaiac negative × 3

What treatment would you recommend for this patient for treatment of anemia?

How would you evaluate the effectiveness of treatment of anemia?

CKD-Mineral and Bone Disorder and Secondary Hyperparathyroidism

► Epidemiology and Etiology

Increases in parathyroid hormone (PTH) occur early as kidney function begins to decline. The actions of PTH on bone turnover lead to CKD-mineral and bone disorders (CKD-MBD). As many as 75% to 100% of patients with stage 3 CKD have CKD-MBD.⁴⁶ The type of bone disease can vary based on the degree of bone turnover. High bone turnover is the most common cause of bone abnormalities in patients with CKD, present in as many as 75% of patients receiving dialysis,⁴⁶ and it is generally mediated by high levels of PTH. Adynamic bone disease, characterized by low bone turnover, is less common, although the prevalence appears to be increasing,⁴⁶ which may be related to more aggressive treatment of hyperparathyroidism. The development of CKD-MBD can dramatically affect morbidity in patients with CKD.

► Pathophysiology

As kidney function declines in patients with CKD, decreased phosphorus excretion disrupts the balance of calcium and phosphorus homeostasis. Decreased vitamin D activation in the kidney also decreases calcium absorption from the GI tract. Fibroblast growth factor 23 (FGF-23) is a hormone produced by osteocytes and osteoblasts that is stimulated by increased phosphate and calcitriol. In CKD, elevated phosphate concentrations increase expression of FGF-23, which downregulates vitamin D activation in the kidney.⁴⁷ Each of these stimulates the parathyroid glands. **7** *The parathyroid glands release PTH in response to decreased serum calcium and increased serum phosphorus levels. The actions of PTH include the following:*

- Increasing calcium resorption from bone
- Increasing calcium reabsorption from the proximal tubules in the kidney
- Decreasing phosphorus reabsorption in the proximal tubules in the kidney
- Stimulating activation of vitamin D by 1- α -hydroxylase to calcitriol (1,25-dihydroxyvitamin D₃) to promote calcium absorption in the GI tract and increased calcium mobilization from bone

All of these actions are directed at increasing serum calcium levels and decreasing serum phosphorus levels, although the activity of calcitriol also increases phosphorus absorption in the GI tract and mobilization from the bone, which can worsen hyperphosphatemia. Calcitriol also decreases PTH levels through a negative feedback loop. These measures are sufficient to correct serum calcium levels in the earlier stages of CKD.

As kidney function continues to decline and the GFR falls less than 30 mL/min/1.73 m² (0.29 mL/s/m²), phosphorus excretion continues to decrease and calcitriol production decreases,⁴⁸ causing PTH levels to begin to rise significantly, leading to **secondary hyperparathyroidism** (sHPT).

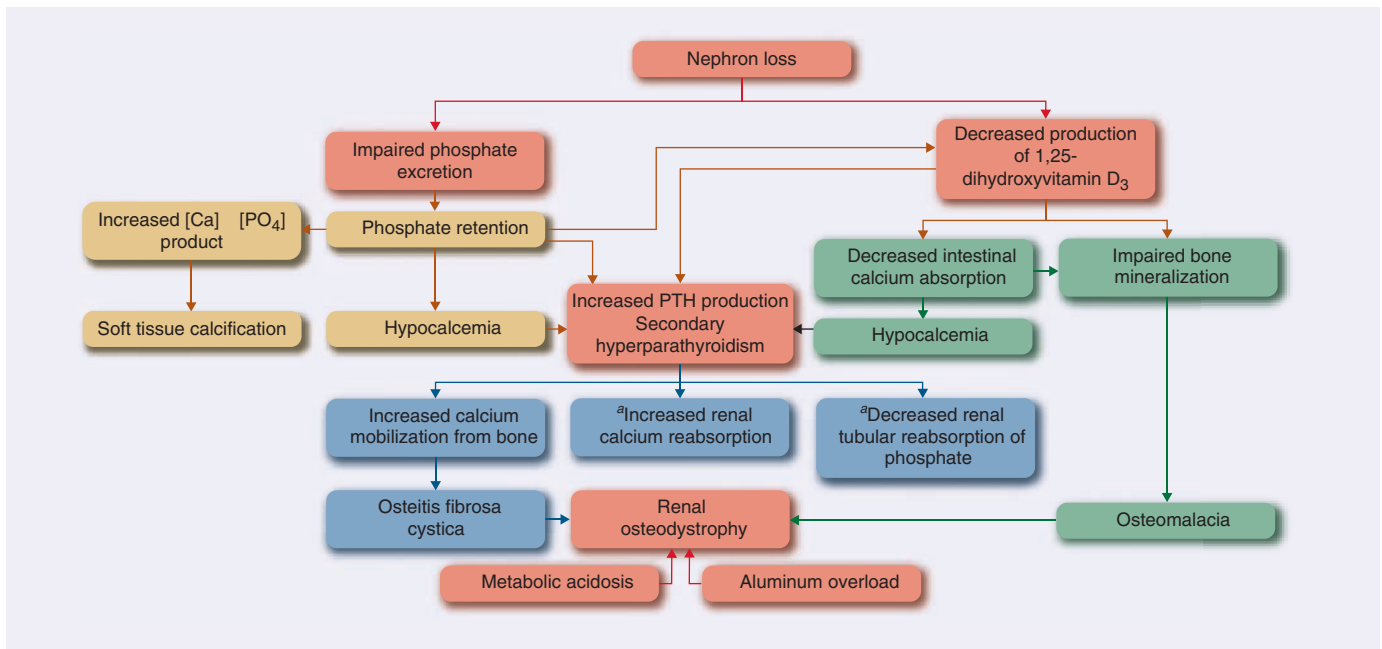

FIGURE 26-4. Pathogenesis of CKD-MBD and renal osteodystrophy. ^aThese adaptations are lost as kidney failure progresses. (From Hudson JQ. Chronic kidney disease: Management of complications. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 8th ed. New York, NY: McGraw-Hill, 2011:790, with permission.)

The excessive production of PTH leads to hyperplasia of the parathyroid glands, which decreases the sensitivity of the parathyroid glands to serum calcium levels and calcitriol feedback, further promoting sHPT.

The most dramatic consequence of sHPT is alterations in bone turnover and the development of **renal osteodystrophy** (ROD). Other complications of CKD can also promote ROD. Metabolic acidosis decreases bone formation by reducing hydroxyapatite solubility, inhibiting osteoblast activity, stimulating osteoclast activity, and reducing the sensitivity of the parathyroid gland to serum calcium levels.⁴⁹ Excessive aluminum levels cause aluminum uptake into bone in place of calcium, weakening the bone structure. The pathogenesis of sHPT and CKD-MBD are depicted in **Figure 26-4**.

► Treatment

General Approach **8** *Diagnosis and management of bone disease in CKD is based on corrected serum levels of calcium and phosphorus, and intact PTH levels (iPTH).*⁵⁰ In general, calcium, phosphorus, and PTH levels should be maintained in the normal range for all stages of CKD. For patients receiving dialysis, it is often difficult to achieve normal serum levels for these parameters. Attempts should be made to maintain calcium and phosphorus levels as close to normal as possible, but levels slightly above the normal range are acceptable in most cases. Target ranges for the various parameters are listed in **Table 26-5**.

The primary target for treatment is control of serum phosphorus levels because this is the initial parameter that disrupts homeostasis. However, serum phosphorus can be difficult to control, particularly in the latter stages

of CKD. Management of sHPT often requires supplemental treatment with vitamin D analogs or cinacalcet in addition to phosphorus management.

- **Nonpharmacologic Therapy** The first-line treatment for the management of hyperphosphatemia is dietary phosphorus restriction to 800 to 1,000 mg/day in patients with stage 3 CKD or higher who have phosphorus levels at the upper limit of the normal range or elevated iPTH levels.^{50,51} Foods high in phosphorus are also high in protein, which can make it difficult to restrict phosphorus intake while maintaining adequate protein intake to avoid malnutrition.
- Hemodialysis and peritoneal dialysis can remove up to 2 to 3 g of phosphorus per week. However, this is insufficient to control hyperphosphatemia, and pharmacologic therapy is necessary in addition to dialysis treatment.

Other nonpharmacologic strategies to manage sHPT and CKD-MBD include restriction of aluminum exposure and parathyroidectomy. Chronic ingestion of aluminum-containing antacids and other aluminum-containing products should be avoided in patients with stage 4 CKD or higher (GFR less than 30 mL/min/1.73 m² [0.29 mL/s/m²]) because of the risk of aluminum toxicity and potential uptake into the bone. Purification techniques for dialysate solutions also minimize the risk of exposure to aluminum.

Parathyroidectomy is a treatment of last resort for sHPT, but should be considered in patients with persistently elevated iPTH levels above 800 pg/mL (800 ng/L; 85.6 pmol/L) that is refractory to medical therapy to lower serum calcium and/or phosphorus levels.⁵⁰ A portion or all of the parathyroid tissue may be removed, and in some cases

Clinical Presentation and Diagnosis of sHPT and ROD

General

Onset of sHPT and ROD is subtle and may not be associated with symptoms.

Symptoms

sHPT and ROD are usually asymptomatic in early disease. Calcification in the joints can be associated with decreased range of motion.

Conjunctival calcifications are associated with a gritty sensation in the eyes, redness, and inflammation.

Signs

Cardiovascular: Increased stroke index, heart rate, and diastolic and mean arterial pressures.

Musculoskeletal: Bone pain, muscle weakness.

Dermatologic: Pruritus.

Laboratory Tests

Increased serum phosphorus levels.

Low to normal serum calcium levels.

Increased Ca–P product.

Increased PTH levels.

Decreased vitamin D levels.

Diagnostic Tests

Radiographic studies show calcium–phosphate deposits in joints and/or cardiovascular system.

Bone biopsy of the iliac crest.

a portion of the parathyroid tissue may be transplanted into another site, usually the forearm for easy surgical access. After parathyroidectomy, serum calcium levels can decrease dramatically due to the low levels of PTH after the parathyroid tissue is removed, which decreases intestinal calcium absorption and bone resorption. Therefore, serum

ionized calcium levels should be monitored frequently (every 4 to 6 hours for the first 48 to 72 hours) in patients receiving a parathyroidectomy. Calcium supplementation is usually necessary, administered IV initially, then orally (with vitamin D supplementation) once normal calcium levels are attained for several weeks to months after the procedure.

Table 26-5

Target Levels for Calcium, Phosphorus, and Intact PTH

Parameter	Guideline	Stage 3–4 CKD	Stage 5 CKD	Stage 5 CKD on dialysis
Corrected Calcium	KDOQI (2003)	“Normal”	8.4–9.5 mg/dL (2.1–2.38 mmol/L)	8.4–9.5 mg/dL (2.1–2.38 mmol/L)
	KDIGO (2009)	“Normal”	“Normal”	“Normal”
Phosphorus	KDOQI	2.7–4.6 mg/dL (0.87–1.49 mmol/L)	3.5–5 mg/dL (1.13–1.62 mmol/L)	3.5–5 mg/dL (1.13–1.62 mmol/L)
	KDIGO	“Normal”	“Normal”	“Near normal”
Ca–P Product	KDOQI	Less than 55 mg ² /dL ² (less than 4.44 mmol ² /L ²)	Less than 55 mg ² /dL ² (less than 4.44 mmol ² /L ²)	Less than 55 mg ² /dL ² (less than 4.44 mmol ² /L ²)
	KDIGO	Not recommended to use this parameter	Not recommended to use this parameter	Not recommended to use this parameter

Pharmacologic Therapy

● **Phosphate-Binding Agents.** When serum phosphorus levels cannot be controlled by restriction of dietary intake, phosphate-binding agents are used to bind dietary phosphate in the GI tract to form an insoluble complex that is excreted in the feces. Phosphorus absorption is decreased, thereby decreasing serum phosphorus levels. The drugs used for binding dietary phosphate are listed in [Table 26-6](#). These agents should be administered with each meal and can be tailored to the amount of phosphorus that is typically ingested during each meal. For example, patients can take a smaller dose with smaller meals or snacks, and a larger dose with larger meals. Although phosphate binders are not FDA approved for patients with CKD who are not receiving dialysis, they are used clinically when phosphorus levels are elevated, regardless of the stage of CKD.

Calcium-based phosphate binders, including calcium carbonate and calcium acetate, are effective in decreasing serum phosphate levels, as well as in increasing serum calcium levels. Calcium acetate binds more phosphorus than the carbonate salt, making it a more potent agent for binding dietary phosphate. Calcium citrate is usually not used as a phosphate-binding agent because the citrate salt can increase aluminum absorption. The calcium-containing phosphate binders also aid in the correction of metabolic acidosis, another complication of kidney failure. Calcium-based phosphate binders should not be used if serum calcium levels are near the upper end of the normal range or are elevated, if arterial calcifications are present, or if the patient has adynamic bone disease.⁵⁰ The dose of calcium-based phosphate binders should not provide more than 1,500 mg of elemental calcium per day, and the total elemental calcium intake per day should not exceed 2,000 mg including medication and dietary intake.⁵¹ The most common adverse effects of calcium-containing phosphate binders are constipation and hypercalcemia.

Aluminum- and magnesium-containing phosphate-binding agents are not recommended for chronic use in patients with CKD to avoid aluminum and magnesium accumulation.

● Aluminum-containing agents may be used for a short course of therapy (less than 4 weeks) if phosphorus levels are significantly elevated greater than 7 mg/dL (2.26 mmol/L), but should be replaced by other phosphate-binding agents after no more than 4 weeks. Excessive aluminum levels lead to aluminum intoxication, causing neurotoxicity that can manifest as encephalopathy or dementia, bone disease, and anemia. In addition to the risk of magnesium accumulation, the use of magnesium-containing agents is also limited by the GI side effects, primarily diarrhea.

● Phosphate-binding agents that do not contain calcium, magnesium, or aluminum include sevelamer hydrochloride, sevelamer carbonate, and lanthanum carbonate. These agents are particularly useful in patients with hyperphosphatemia who have elevated serum calcium levels or who have vascular or soft tissue calcifications. Sevelamer is a cationic polymer that is not systemically absorbed and binds to phosphate in the GI tract, and it prevents absorption and promotes

excretion of phosphate through the GI tract via the feces. Sevelamer has an added benefit of reducing LDL-C by up to 30% and increasing HDL-C levels.⁵¹ The most common side effects of sevelamer are GI complaints including nausea, constipation, and diarrhea. The cost of sevelamer is significantly higher compared with calcium-containing phosphate binders, which often makes sevelamer a second-line agent for controlling phosphorus levels. However, recent studies have demonstrated that sevelamer may decrease mortality in patients receiving hemodialysis compared with calcium-containing phosphate binders, primarily by decreasing the occurrence of calcifications in the coronary arteries.⁵⁰ Sevelamer carbonate may have added benefit to aid in the correction of metabolic acidosis.

Lanthanum is a naturally occurring trivalent rare earth element (atomic number 57). Lanthanum carbonate quickly dissociates in the acidic environment of the stomach, where the lanthanum ion binds to dietary phosphorus, forming an insoluble compound that is excreted in the feces. Lanthanum has been shown to be as effective as other phosphate binders and may improve bone turnover, compared with calcium-containing products.⁵⁰ Side effects of lanthanum include nausea, peripheral edema, and myalgias.

● **Vitamin D Therapy.** Exogenous vitamin D compounds that mimic the activity of calcitriol act directly on the parathyroid gland to decrease PTH secretion. This is particularly useful when reduction of serum phosphorus levels does not sufficiently reduce PTH levels. The most active form of vitamin D is calcitriol (1,25-dihydroxyvitamin D). The effects of calcitriol are mediated by upregulation of the vitamin D receptor in the parathyroid gland, which decreases parathyroid gland hyperplasia and PTH synthesis and secretion.

● Vitamin D supplementation ([Table 26-7](#)) can be used to lower serum PTH levels in patients with CKD. Ergocalciferol and cholecalciferol have been shown to be effective in lowering PTH secretion in patients with stage 3 CKD.⁵² However, as CKD progresses to stages 4 and 5, the kidney loses the ability to produce 1 α -hydroxylase, which is responsible for renal activation of vitamin D. In these later stages of CKD, activated vitamin D analogs must be used to decrease PTH secretion. Calcitriol (1,25-dihydroxyvitamin D₃, Rocaltrol by Roche Laboratories, Inc., Nutley, NJ, and Calcijex by Abbott Laboratories, North Chicago, IL). This analog has the same biologic activity as endogenous calcitriol. Doxercalciferol (1- α -hydroxyvitamin D₂) is another vitamin D analog that is hydroxylated in the liver to 1, 25-dihydroxyvitamin D₂, which has the same biologic activity as calcitriol. Both calcitriol and doxercalciferol upregulate vitamin D receptors in the intestines, which increases calcium and phosphorus absorption, increasing the risk of hypercalcemia and hyperphosphatemia. It is important that serum calcium and phosphorus levels are within the normal range for the stage of CKD prior to starting either of these therapies. Paricalcitol (19-nor-1,25-dihydroxyvitamin D₂, Zemplar by Abbott Laboratories, North Chicago, IL) is a vitamin D analog that has equal efficacy to calcitriol but may cause

Table 26-6

Phosphate-Binding Agents Used in the Treatment of Hyperphosphatemia in CKD

Compound	Trade Name	Dosage Form	Compound Content (mg)	Elemental Calcium Content (mg)	Starting Dose	Comments
Calcium carbonate (40% elemental calcium)	Tums	Chewable tablet	500, 750, 1,000; 1,250	200, 300, 400, 500	0.5–1 g (elemental calcium) three times a day with meals	First-line agent; dissolution characteristics and phosphorus-binding effect may vary from product to product; try to limit daily intake of elemental calcium to 1,500 mg/day Approximately 39 mg phosphorus bound per 1 g calcium carbonate
	Oscal-500	Tablet	1,250	500		
	Caltrate 600	Tablet	1,500	600		
	Nephro Calci	Tablet	1,500	600		
	LiquiCal	Liquid gelcap	1,200	480		
	Calci-Chew	Chewable tablet	1,250	500		
Calcium acetate (25% elemental calcium)	Phos-Lo	Tablet	667	167	0.5–1 g (elemental calcium) three times a day with meals	First-line agent; comparable efficacy to calcium carbonate with one-half the dose of elemental calcium; do not exceed 1,500 mg elemental calcium intake per day Approximately 45 mg phosphorus bound per 1 g calcium acetate
	Phoslyra	Suspension	667/5 mL			
Sevelamer HCl Sevelamer carbonate	Renagel	Tablet	400, 800	—	800 mg three times a day with meals	By prescription only First-line agent; lowers LDL-C More expensive than calcium products; preferred in patients at risk for extraskeletal calcification May require large doses to control phosphorus levels
	Renvela	Tablet	800			
Lanthanum	Fosrenol	Chewable tablet	250, 500	—	750–1,500 mg three times a day with meals	Second-line agent; more expensive than calcium products; preferred in patients at risk for extraskeletal calcification Most patients require 1,500–3,000 mg/day to control phosphorus
Aluminum hydroxide	AlternaGEL Amphojel	Suspension	600 mg/5 mL	—	300–600 mg three times a day with meals	Third-line agents; do not use concurrently with citrate-containing products Reserve for short-term use (4 weeks) in patients with hyperphosphatemia not responding to other binders
		Tablet	300, 600			
	Alu-Cap, Alu-Tab	Suspension Capsule, Tablet	320 mg/5 mL 400			
Aluminum carbonate	Basaljel	Tablet, capsule	500	—	450–500 mg three times a day with meals	Same as for aluminum hydroxide
Magnesium carbonate	Mag-Carb	Suspension Capsule	400 mg/5 mL 70	—	70 mg three times a day with meals	Third-line agent; diarrhea common; monitor serum magnesium
Magnesium hydroxide	Milk of magnesia	Tablet	300, 600	—	300–400 mg three times a day with meals	Same as for magnesium carbonate
		Suspension	400 mg/5 mL, 800 mg/5 mL			
Magnesium carbonate/ calcium carbonate	MagneBind 400	Tablet	400 mg (elemental magnesium)	80	400 mg three times a day with meals	Same as for calcium carbonate and magnesium carbonate

LDL-C, low-density lipoprotein cholesterol

Table 26-7

Available Treatments for Secondary Hyperparathyroidism

Generic Name	Trade Name	Dosage Range	Dosage Forms	Frequency of Administration
Vitamin D precursor				
Ergocalciferol	Vitamin D ₂	400–50,000 IU	PO	Daily (doses of 400–2000 IU)
Cholecalciferol	Vitamin D ₃			Weekly or monthly for higher doses (50,000 IU)
Active vitamin D				
Calcitriol	Calcijex	0.5–5 mcg	IV	Three times per week
	Rocaltrol	0.25–5 mcg	PO	Daily, every other day, or three times per week
Vitamin D analogs				
Paricalcitol	Zemplar	1–4 mcg	PO	Daily or three times per week
		2.5–15 mcg	IV	Three times per week
Doxercalciferol	Hectorol	5–20 mcg	PO	Daily or three times per week
		2–8 mcg	IV	Three times per week
Calcimimetics				
Cinacalcet	Sensipar	30–180 mg	PO	Daily

less hypercalcemia. Alfacalcidol (1- α -hydroxyvitamin D₃), falecalcitriol, and 22-oxacalcitriol (maxacalcitol) are only available outside the United States.

It is important to monitor vitamin D therapy aggressively to assure that PTH levels are not oversuppressed. Oversuppression of PTH levels can induce adynamic bone disease, which manifests as decreased osteoblast and osteoclast activity, decreased bone formation, and low bone turnover.

Calcimimetics Cinacalcet is a calcimimetic that increases the sensitivity of receptors on the parathyroid gland to serum calcium levels to reduce PTH secretion. In addition to lowering PTH levels, cinacalcet has been shown to reduce serum calcium levels by approximately 5% and serum

phosphorus levels by 2.6% to 8.4%.⁵³ This makes cinacalcet beneficial to use in patients with elevated PTH levels who have an increased calcium or phosphorus levels or cannot use vitamin D therapy. Because the effects of cinacalcet on PTH can reduce serum calcium levels and result in hypocalcemia, cinacalcet should not be used if serum calcium levels are below 8.4 mg/dL (2.1 mmol/L). Cinacalcet should also be used with caution in patients with seizure disorders because low serum calcium levels can lower the seizure threshold.⁵³

Reversal of Metabolic Acidosis Studies have demonstrated that reversal of metabolic acidosis can improve bone disease associated with CKD.⁴⁹ Serum bicarbonate levels should be maintained at 22 mEq/L (22 mmol/L) in patients

Patient Encounter 3

A 62 year-old African American woman with a history of type 2 diabetes mellitus presents to your clinic for a routine follow-up. She has no complaints at this time.

Current meds: Pioglitazone 30 mg orally daily; glipizide 5 mg orally twice daily; foscipril 40 mg orally daily; amlodipine 10 mg orally daily; furosemide 60 mg orally daily; ferrous sulfate 325 mg orally three times daily

ROS: Unremarkable.

PE:

VS: BP 142/92 mm Hg; P 72 bpm; T 98.4°F (36.9°C); ht 5'4" (163 cm); wt 164 lb (74.5 kg)

CV: RRR, normal S₁, S₂

Abd: Obese; no organomegaly, bruits, tenderness; (+) bowel sounds; heme (–) stool

Ext: 2+ edema bilaterally; lesion on L foot appears to be healing slowly; decreased sensation in LE

Labs: Sodium 143 mEq/L (143 mmol/L); potassium 5.1 mEq/L (5.1 mmol/L); chloride 101 mEq/L (101 mmol/L); carbon dioxide 17 mEq/L (17 mmol/L); BUN 38 mg/dL (13.6 mmol/L urea); SCr 2.4 mg/dL (212 μ mol/L); glucose 156 mg/dL (8.7 mmol/L); calcium 8.4 mg/dL 2.1 mmol/L; phosphate 7.9 mg/dL (2.55 mmol/L); albumin 3.2 g/dL (32 g/L); intact parathyroid hormone (iPTH) 478 pg/mL (478 ng/L; 51.1 pmol/L); WBC 4.8×10^3 cells/mm³ (4.8×10^9 /L); RBC 3.7×10^6 cells/mm³ (3.7×10^{12} /L); Hgb 10.4 g/dL (104 g/L; 6.46 mmol/L); Hct 31% (0.31); platelets 350×10^3 cells/mm³ (350×10^9 /L)

What signs are consistent with secondary hyperparathyroidism (sHPT)?

What treatment would you recommend for sHPT?

with bone disease associated with CKD.⁵¹ The treatment of metabolic acidosis is described later.

► Outcome Evaluation

- Monitor serum calcium and phosphorus levels regularly in patients receiving phosphate-binding agents. When initiating therapy, monitor serum levels every 1 to 4 weeks, depending on the severity of hyperphosphatemia. Titrate doses of phosphate binders to achieve the target levels of serum calcium and phosphorus and iPTH (Table 26–5). Once target levels are achieved, monitor serum calcium and phosphorus levels every 1 to 3 months. Monitor intact PTH levels monthly while initiating vitamin D therapy, then every 3 months once stable iPTH levels are achieved. When starting or increasing the dose of cinacalcet, monitor serum calcium and phosphorus levels within 1 week; iPTH levels should be monitored within 1 to 4 weeks. Once target levels are achieved, decrease monitoring to every 3 months.

Metabolic Acidosis

► Epidemiology and Etiology

Approximately 80% of patients with a GFR less than 20 to 30 mL/min/1.73 m² (0.19 to 0.29 mL/s/m²) develop metabolic acidosis.⁴⁹ Metabolic acidosis can increase protein catabolism and decrease albumin synthesis, which promote muscle wasting and alter bone metabolism. Other consequences associated with metabolic acidosis in CKD include worsening cardiac disease, impaired glucose tolerance, altered growth hormone and thyroid function, and inflammation.⁴⁹

► Pathophysiology

The kidney plays a key role in the management of acid–base homeostasis in the body by regulating excretion of hydrogen ions. With normal kidney function, bicarbonate that is freely filtered through the glomerulus is completely reabsorbed via the renal tubules. Hydrogen ions are generated at a rate of 1 mEq/kg (1 mmol/kg) per day during metabolism of ingested food and are excreted at the same rate by the kidney via buffers in the urine created by ammonia generation and phosphate excretion. As a result, the pH of body fluids is maintained within a very narrow range.

As kidney function declines, bicarbonate reabsorption is maintained, but hydrogen excretion is decreased because the ability of the kidney to generate ammonia is impaired. The positive hydrogen balance leads to metabolic acidosis, which is characterized by a serum bicarbonate level of 15 to 20 mEq/L (15 to 20 mmol/L), resulting in a pH less than 7.35. This picture is generally seen when the GFR declines below 20 to 30 mL/min/1.73 m² (0.19 to 0.29 mL/s/m²).⁴⁹

► Treatment

- Serum electrolytes should be monitored in patients with CKD for the development of metabolic acidosis. Metabolic acidosis in patients with CKD is generally characterized by

an elevated anion gap greater than 17 mEq/L (17 mmol/L), due to the accumulation of phosphate, sulfate, and other organic anions.

Nonpharmacologic Therapy Treatment of metabolic acidosis in CKD requires pharmacologic therapy. Other disorders that may contribute to metabolic acidosis should also be addressed. Altering bicarbonate levels in the dialysate fluid in patients receiving dialysis may assist with the treatment of metabolic acidosis, although pharmacologic therapy may still be required.

- **Pharmacologic Therapy** Pharmacologic therapy with sodium bicarbonate or citrate/citric acid preparations may be needed in patients with stage 3 CKD or higher to replenish body stores of bicarbonate. Calcium carbonate and calcium acetate, used to bind phosphorus in sHPT, also aid in increasing serum bicarbonate levels, in conjunction with other agents.

Sodium bicarbonate tablets are administered in increments of 325- and 650-mg tablets. A 650-mg tablet of sodium bicarbonate contains 7.7 mEq (7.7 mmol) each of sodium and bicarbonate. Sodium retention associated with sodium bicarbonate can cause volume overload, which can exacerbate hypertension and chronic heart failure. Patient tolerability of sodium bicarbonate is low because of carbon dioxide production in the GI tract that occurs during dissolution.

Solutions that contain sodium citrate/citric acid (Shohl's solution and Bicitra) provide 1 mEq/L (1 mmol/L) each of sodium and bicarbonate. Polycitra is a sodium/potassium citrate solution that provides 2 mEq/L (2 mmol/L) of bicarbonate but contains 1 mEq/L (1 mmol/L) each of sodium and potassium, which can promote hyperkalemia in patients with severe CKD. The citrate portion of these preparations is metabolized in the liver to bicarbonate; the citric acid portion is metabolized to CO₂ and water, increasing tolerability compared with sodium bicarbonate. Sodium retention is also decreased with these preparations. However, these products are liquid preparations, which may not be palatable to some patients. Citrate can also promote aluminum intoxication by augmenting aluminum absorption in the GI tract.

- When determining the dose of bicarbonate replacement, the goal for therapy is to achieve a normal serum bicarbonate level of 24 mEq/L (24 mmol/L). The dose is usually determined by calculating the base deficit: $[0.5 \text{ L/kg} \times (\text{body weight}) \times [(\text{normal CO}_2) - (\text{measured CO}_2)]]$. Because of the risk of volume overload resulting from the sodium load administered with bicarbonate replacement, the total base deficit should be administered over several days. Once the goal serum bicarbonate level is attained, a maintenance dose of bicarbonate is necessary and should be titrated to maintain serum bicarbonate levels.

► Outcome Evaluation

- Monitor serum electrolytes and arterial blood gases regularly. Correct metabolic acidosis slowly to prevent the development of metabolic alkalosis or other electrolyte abnormalities.

Other Therapeutic Considerations in CKD

► Uremic Bleeding

Uremia can lead to a number of alterations in clotting ability, resulting in hemorrhage. Bleeding complications associated with CKD include ecchymoses, prolonged bleeding from mucous membranes and puncture sites used for blood collection and hemodialysis, GI bleeding, intramuscular bleeding, and others. Most bleeding complications associated with CKD are mild. However, serious bleeding events including GI bleeds and intracranial hemorrhage can occur.

Pathophysiology Uremia alters a number of mechanisms that contribute to bleeding. Platelet function and aggregation are altered through decreased production of thromboxane.⁵⁴ Platelet–vessel wall interactions are also altered in patients with uremia because of decreased activity of von Willebrand’s factor⁵⁴ and are exacerbated by anemia in CKD patients. With a normal RBC count in the plasma, platelets skim the surface of the endothelial tissue in the blood vessels. In patients with anemia, RBC count is decreased and platelets circulate closer to the center of the vessels, which decreases the interaction with the vessel wall. The risk of bleeding is increased in patients receiving hemodialysis. Medications administered to prevent or treat clotting during hemodialysis or in vascular access sites, including heparin, warfarin, aspirin, and clopidogrel, exacerbate the risk of bleeding in these patients.

Treatment

Nonpharmacologic Therapy. The incidence and severity of bleeding associated with uremia has decreased since dialysis has become the mainstay of treatment for ESKD. Dialysis initiation improves platelet function and reduces bleeding time.⁵⁴ Improved care of the patient with ESKD, with anemia treatment and improvement in nutritional status, are also likely contributors to decreased uremic bleeding.

Pharmacologic Therapy. Treatments used to decrease bleeding time in patients with uremic bleeding include cryoprecipitate, which contains various components important in platelet aggregation and clotting, such as von Willebrand’s factor and fibrinogen. Cryoprecipitate decreases bleeding time within 1 hour in 50% of patients. However, cost and the risk of infection have limited the use of cryoprecipitate.

Desmopressin (DDAVP) increases the release of factor VIII (von Willebrand’s factor) from endothelial tissue in the vessel wall. Bleeding time is promptly reduced, within 1 hour of administration, and is sustained for 4 to 8 hours.⁵⁴

Doses used for uremic bleeding are 0.3 to 0.4 mcg/kg IV over 20 to 30 minutes, 0.3 mcg/kg subcutaneously, or 2 to 3 mcg/kg intranasally. Repeated doses can cause tachyphylaxis by depleting stores of von Willebrand’s factor. Side effects of DDAVP include flushing, dizziness, and headache.

Estrogens have also been used to decrease bleeding time. The onset of action is slower than that of DDAVP, but more sustained, and it depends on the route of administration.

IV doses of 0.6 mg/kg/day for 4 to 5 days decreases bleeding time within 6 hours of administration, and produces an effect that lasts up to 2 weeks after stopping therapy. The onset of action with oral doses of 50 mg/kg daily is within 2 days of treatment and is sustained for 4 to 5 days after stopping therapy. Transdermal patches providing 50 to 100 mcg/day have also been shown to be effective in decreasing bleeding time.⁵⁴ Side effects of estrogen use include hot flashes in both females and males, fluid retention, and hypertension.

► Pruritus

Pruritus can affect 25% to 86% of patients with advanced stages of CKD, and it is not related to the cause of kidney failure.⁵⁵ Pruritus can be significant and has been linked to mortality in patients receiving hemodialysis.⁵⁵

Pathophysiology The cause of pruritus is unknown, although several mechanisms have been proposed. Vitamin A is known to accumulate in the skin and serum of patients with CKD, but a definite correlation with pruritus has not been established. Histamine may also play a role in the development of pruritus, which may be linked to mast cell proliferation in patients receiving hemodialysis. Hyperparathyroidism has also been suggested as a contributor to pruritus, despite the fact that serum PTH levels do not correlate with itching. Accumulation of divalent ions, specifically magnesium and aluminum, may also play a role in pruritus in patients with CKD. Other theories that have been proposed include inadequate dialysis, dry skin, peripheral neuropathy, calcium-phosphate deposits, and opiate accumulation.⁵⁵

Treatment

Nonpharmacologic Therapy. Pruritus associated with CKD is difficult to alleviate. It is important to evaluate other potential dermatologic causes of pruritus to maximize the potential for relief. Adequate dialysis is generally the first line of treatment in patients with pruritus. However, this has not been shown to decrease the incidence of pruritus significantly. Maintaining proper nutritional intake, especially with regard to dietary phosphorus and protein intake, may lessen the degree or occurrence of pruritus. Patients who do not attain relief from other measures may benefit from ultraviolet B phototherapy.

Pharmacologic Therapy. Topical emollients have been used as treatment for pruritus in patients with dry skin, but they are often not effective in relieving pruritus associated with CKD. Antihistamines, such as hydroxyzine 25 to 50 mg or diphenhydramine 25 to 50 mg orally or IV, are used as first-line oral agents used to treat pruritus. Cholestyramine has also been used at doses of 5 g twice daily. Oral activated charcoal has also been used in doses of 1 to 1.5 g four times daily with some demonstrated efficacy. Gabapentin has also been shown to be effective, but it must be used with caution in patients with CKD to minimize risk of neurotoxicity. Other therapies that are often used in combination with other agents include oral serotonin reuptake inhibitors, ondansetron, and naloxone.

and topical capsaicin. Each has been reported to have efficacy in the treatment of pruritus associated with CKD.⁵⁵

Vitamin Replacement

Water-soluble vitamins removed by hemodialysis (HD) contribute to malnutrition and vitamin deficiency syndromes.

- Patients receiving HD often require replacement of water-soluble vitamins to prevent adverse effects. The vitamins that may require replacement are ascorbic acid, thiamine, biotin, folic acid, riboflavin, and pyridoxine. Patients receiving HD should receive a multivitamin B complex with vitamin C supplement, but they should not take supplements that include fat-soluble vitamins, such as vitamins A, E, or K, which can accumulate in patients with kidney failure.

RENAL REPLACEMENT THERAPY

- Patients who progress to ESKD require RRT. The modalities that are used for RRT are dialysis, including HD and peritoneal dialysis (PD), and kidney transplantation. The United States Renal Data Service (USRDS) reported that the number of patients with ESKD was 613,432, with 116,395 new cases diagnosed in 2009.⁴ Kidney transplantation is the preferred method of RRT, owing to improved patient survival. The 3-year survival of patients with ESKD is 81% for kidney transplantation, compared with only 50% for dialysis.⁴ However, organ availability limits the number of patients who can receive a kidney transplant. Only 2% of patients with newly diagnosed ESKD receive kidney transplants each year.⁴ Therefore, the most common form of RRT is dialysis, accounting for 70% of all patients with ESKD.⁴ The principles and complications associated with dialysis are discussed later. Chapter 55 discusses the principles of kidney transplantation.

Indications for Dialysis

- **9** *Planning for dialysis should begin when GFR falls less than 30 mL/min/1.73 m² (0.29 mL/s/m²) (stage 4 CKD),¹ when progression to ESKD is inevitable, to allow time to educate the patient and family on the treatment modalities and establish the appropriate access for the modality of choice.* Ideally, initiation of dialysis should be done at a point when the patient is ready to undergo treatment, rather than when the patient is in emergent need of dialysis.

Initiation of dialysis depends on the patient's clinical status and not based on laboratory values. Symptoms that may indicate the need for dialysis include persistent anorexia, nausea, vomiting, fatigue, and pruritus. Other criteria that indicate the need for dialysis include declining nutritional status, declining serum albumin levels, uncontrolled hypertension, and volume overload, which may manifest as chronic heart failure, and electrolyte abnormalities, particularly hyperkalemia. **Blood urea nitrogen (BUN)** and **SCr** levels may be used as a guide for the initiation of dialysis, but they should not be the

- absolute indicator. Dialysis is initiated in most patients

Table 26–8

Advantages and Disadvantages of Hemodialysis

Advantages

1. Higher solute clearance allows intermittent treatment
2. Parameters of adequacy of dialysis are better defined and therefore underdialysis can be detected early
3. The technique's failure rate is low
4. Even though intermittent heparinization is required, hemostasis parameters are better corrected with hemodialysis than peritoneal dialysis
5. In-center hemodialysis enables closer monitoring of the patient

Disadvantages

1. Requires multiple visits each week to the hemodialysis center, which translates into loss of control by the patient
2. Dysequilibrium, dialysis, hypotension, and muscle cramps are common. May require months before patient adjusts to hemodialysis
3. Infections in hemodialysis patients may be related to the choice of membranes; the complement-activating membranes are more deleterious
4. Vascular access is frequently associated with infection and thrombosis
5. Decline of residual renal function is more rapid compared with peritoneal dialysis

From Sowinski KM, Churchwell MD. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011:O338, with permission.

when the GFR falls below 15 mL/min/1.73 m² (0.14 mL/s/m²).¹ Patients should determine which modality of dialysis to use based on their own preferences. Advantages and disadvantages of hemodialysis and peritoneal dialysis are listed in **Tables 26–8** and **26–9**, respectively.

The goals of dialysis are to remove toxic metabolites to decrease uremic symptoms, correct electrolyte abnormalities, restore acid–base status, and maintain volume status to ultimately improve quality of life and decrease the morbidity and mortality associated with ESKD.

Hemodialysis

Hemodialysis is the most common method of RRT, initiated in 91% of patients with newly diagnosed ESKD each year, with a total of 370,264 patients receiving HD in 2009.⁴ Home HD is becoming increasingly more popular, but most patients continue to receive HD from a dialysis center.

► Principles of Hemodialysis

10 *Hemodialysis involves the exposure of blood to a semipermeable membrane (dialyzer) against which a physiologic solution (dialysate) is flowing (Fig. 26–5).* The dialyzer is composed of thousands of capillary fibers made up of the semipermeable membrane, which are enclosed in the dialyzer, to increase the surface area of blood exposure to maximize the efficiency of removing substances. The

Table 26-9

Advantages and Disadvantages of Peritoneal Dialysis**Advantages**

1. More hemodynamic stability (blood pressure) due to slow ultrafiltration rate
2. Increased clearance of larger solutes, which may explain good clinical status in spite of lower urea clearance
3. Better preservation of residual renal function
4. Convenient intraperitoneal route of administration of drugs such as antibiotics and insulin
5. Suitable for elderly and very young patients who may not tolerate hemodialysis well
6. Freedom from the “machine” gives the patient a sense of independence (for continuous ambulatory peritoneal dialysis)
7. Less blood loss and iron deficiency, resulting in easier management of anemia or reduced requirements for erythropoietin and parenteral iron
8. No systemic heparinization requirement
9. Subcutaneous versus IV erythropoietin or darbepoetin is usual, which may reduce overall doses and be more physiologic

Disadvantages

1. Protein and amino acid losses through the peritoneum and reduced appetite owing to continuous glucose load and sense of abdominal fullness predispose to malnutrition
2. Risk of peritonitis
3. Catheter malfunction, and exit site and tunnel infection
4. Inadequate ultrafiltration and solute dialysis in patients with a large body size, unless large volumes and frequent exchanges are employed
5. Patient burnout and high rate of technique failure
6. Risk of obesity with excessive glucose absorption
7. Mechanical problems such as hernias, dialysate leaks, hemorrhoids, or back pain may occur
8. Extensive abdominal surgery may preclude peritoneal dialysis
9. No convenient access for IV iron administration

From Sowinski KM, Churchwell MD. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011:O339, with permission.

dialysate is composed of purified water and electrolytes, and it is run through the dialyzer countercurrent to the blood on the other side of the semipermeable membrane. The process allows for the removal of several substances from the bloodstream, including water, urea, creatinine, electrolytes, uremic toxins, and drugs. Sterilization is not required for dialysate because the membrane prevents bacteria from entering into the bloodstream. However, if the membrane ruptures during hemodialysis, infection becomes a major concern for the patient.

Three types of membranes used for dialysis are classified by the size of the pores and the ability to remove solutes from the bloodstream:

- Conventional (standard) membranes have small pores, which limit solute removal to relatively small molecules, such as creatinine and urea.
- High-efficiency membranes also have small pores but have a higher surface area that increases removal of small molecules, such as water, urea, and creatinine from the blood.
- High-flux membranes have larger pores that allow for the removal of substances with higher molecular-weight, including some drugs, such as vancomycin, than conventional membranes.

Three primary processes are utilized for the removal of substances from the blood:

- Diffusion is the movement of a solute across the dialyzer membrane from an area of higher concentration (usually the blood) to a lower concentration (usually the dialysate). This process is the primary means for small molecules, such as electrolytes, to be removed from the bloodstream. At times, solutes can be added to the dialysate that are diffused into the bloodstream. Changing the composition of the dialysate allows for control of the amount of electrolytes that are being removed.

FIGURE 26-5. In hemodialysis, the patient's blood is pumped to the dialyzer at a rate of 300 to 600 mL/min. An anticoagulant (usually heparin) is administered to prevent clotting in the dialyzer. The dialysate is pumped at the rate of 500 to 1,000 mL/min through the dialyzer countercurrent to the flow of blood. The rate of fluid removal from the patient is controlled by adjusting the pressure in the dialysate compartment. (From Foote EF, Manley HJ. *Hemodialysis and peritoneal dialysis*. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 7th ed. New York, NY: McGraw-Hill, 2008:O106, with permission.)

Patient Encounter 4, Part 1

A 52-year-old white woman with a history of polycystic kidney disease (PCKD) presents to the clinic with complaints that she “feels awful.” She hasn’t felt like eating for several weeks and has lost 10 lb (4.51 kg) in the last 6 months.

Current medications: Valsartan 80 mg orally daily; atenolol 100 mg orally daily; furosemide 120 mg orally daily; sevelamer 800 mg orally three times a day; calcitriol 0.25 mcg orally daily; sodium bicarbonate 1,300 mg orally twice daily.

ROS: Lethargic female in mild distress.

PE:

VS: BP 190/118 mm Hg; P 88 bpm; T 98.6°F (37.0°C); ht 5’6” (168 cm); wt 127 lb (57.7 kg)

CV: RRR, normal S₁, S₂, S₄ present; (+) pericardial friction rub

Ext: 4+ bilateral lower extremity edema present to midcalf line

Labs: Sodium 141 mEq/L (141 mmol/L); potassium 5.9 mEq/L (5.9 mmol/L); chloride 103 mEq/L (103 mmol/L); carbon dioxide 17 mEq/L (17 mmol/L); BUN 75 mg/dL (26.8 mmol/L); SCr 3.5 mg/dL (309 μmol/L); glucose 67 mg/dL (3.7 mmol/L); calcium 8.9 mg/dL (2.23 mmol/L); phosphate 6.2 mg/dL (2.00 mmol/L); iPTH 429 pg/mL (429 ng/L; 45.9 pmol/L); WBC 6.1 × 10³ cells/mm³ (6.1 × 10⁹/L); RBC 3.5 × 10⁶ cells/mm³ (3.5 × 10¹²/L); Hgb 11.4 g/dL (114 g/L; 7.08 mmol/L); Hct 35% (0.35); platelets 327 × 10³ cells/mm³ (327 × 10⁹/L)

What indications does the patient have for dialysis?

What alternatives for renal replacement therapy exist for the patient?

What are the advantages and disadvantages of each modality for renal replacement?

- **Ultrafiltration** is the movement of solvent (plasma water) across the dialyzer membrane by applying hydrostatic or osmotic pressure, and it is the primary means for removing water from the bloodstream. Changing the hydrostatic pressure applied to the dialyzer or the osmotic concentration of the dialysate allows for control of the amount of water being removed.
- **Convection** is the movement of dissolved solutes across the dialyzer membrane by “dragging” the solutes along a pressure gradient with a fluid transport and is the primary means for larger molecules to be removed from the bloodstream, such as urea. Changing the pore size of the dialyzer membrane alters the efficiency of convection and allows for control of the amount of water removed in relation to the amount of solute being removed.

► Vascular Access

Long-term permanent access to the bloodstream is a key component of HD. There are three primary techniques used to obtain permanent vascular access in patients receiving HD: arteriovenous fistulas (AVFs), arteriovenous grafts (AVGs) and catheters. An AVF is the preferred access method because it has the longest survival rate and the fewest complications.⁵⁶ An AVF is made by creating an anastomosis between an artery and a vein, usually in the forearm of the nondominant arm (Fig. 26–6). An AVG results in a similar access site but uses a synthetic graft, usually made of polytetrafluoroethylene, to connect the artery and vein in the forearm (Fig. 26–6). The advantages of the AVG is that it is able to be used within 2 to 3 weeks, compared with 2 to 3 months for an AVF. However, AVGs are complicated by stenosis, thrombosis, and infections, which lead to a shorter survival time of the graft. Double-lumen venous catheters,

placed in the femoral, subclavian, or jugular vein, are often used as temporary access while waiting for the AVF or AVG to mature. The catheters are tunneled beneath the skin to an exit site to reduce the risk of infection. Venous catheters can also be used as permanent access in patients in whom arteriovenous access cannot be established.

► Complications of Hemodialysis

Complications associated with HD include hypotension, muscle cramping, thrombosis, and infection.

Hypotension Hypotension is the most common complication seen during hemodialysis. It has been reported to occur with approximately 10% to 30% of dialysis sessions but may be as frequent as 50% of sessions in some patients.⁵⁷

Pathophysiology. Hypotension associated with hemodialysis manifests as a symptomatic sudden drop of more than 30 mm Hg in mean arterial or systolic pressure or a systolic pressure drop to less than 90 mm Hg during the dialysis session. The primary cause is fluid removal from the bloodstream. Ultrafiltration removes fluid from the plasma, which promotes redistribution of fluids from extracellular spaces into the plasma. However, decreased serum albumin levels and removal of solutes from the bloodstream decrease the osmotic pressure of the plasma relative to the extracellular spaces, slowing redistribution during hemodialysis.⁵⁸ The decreased plasma volume causes hypotension. Other factors that can contribute to hypotension include antihypertensive medications prior to HD, a target “dry weight” (the target weight after HD session is complete) that is too low, diastolic or autonomic dysfunction, low dialysate calcium or sodium, high dialysate temperature, or ingesting meals prior to HD.

Risk factors that may increase the potential for hypotension include elderly age, diabetes, autonomic neuropathy, uremia,

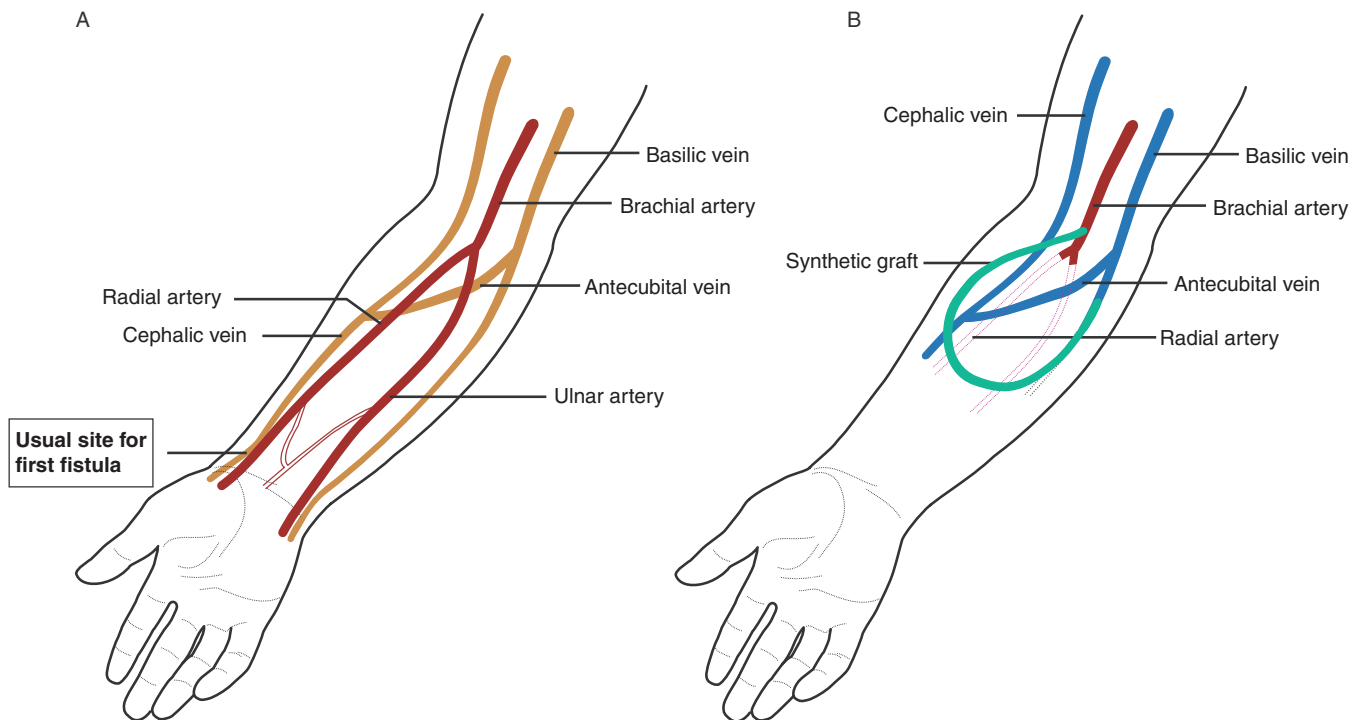

FIGURE 26-6. The predominant types of vascular access for chronic dialysis patients are (A) the arteriovenous fistula and (B) the synthetic arteriovenous forearm graft. The first primary arteriovenous fistula is usually created by the surgical anastomosis of the cephalic vein with the radial artery. The flow of blood from the higher-pressure arterial system results in hypertrophy of the vein. The most common AV graft (depicted in green) is between the brachial artery and the basilic or cephalic vein. The flow of blood may be diminished in the radial and ulnar arteries because it preferentially flows into the low pressure graft. (From Foote EF, Manley HJ. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 7th ed. New York, NY: McGraw-Hill, 2008:O106, with permission.)

and cardiac disease.⁵⁷ The symptoms associated with hypotension during dialysis include dizziness, nausea, vomiting, sweating, and chest pain.

- **Treatment.** Nonpharmacologic management of acute hypotension that occurs during dialysis involves placing the patient in the Trendelenburg position (with the head lower than the feet), decreasing the ultrafiltration rate, and cooling the dialysate. Pharmacologic management of acute hypotension during dialysis includes administration of normal saline (100 to 200 mL), hypertonic saline (23.4%, 10 to 20 mL), or mannitol (12.5 g) to restore intravascular volume.

Preventive measures for patients who may be prone to hypotension include accurate determination of the “dry weight” and maintaining a constant ultrafiltration rate. Midodrine is an α -adrenergic agonist that is effective in reducing hypotension in patients with autonomic dysfunction that is taken with each dialysis session or as chronic therapy. Midodrine can be administered at doses of 2.5 to 10 mg prior to HD or 5 mg twice daily for chronic hypotension. Side effects of midodrine include pruritus and paresthesias.

Hypotension may be related to alterations in levocarnitine levels during dialysis. Patients who have low levels of levocarnitine may benefit from supplementation. Levocarnitine is administered as doses of 20 mg/kg IV at

the end of each dialysis session. However, levocarnitine should not be used as a first-line agent for the treatment of hypotension because of the significant cost associated with the treatment. Other preventive measures that have not been well studied include caffeine, sertraline, or fludrocortisone.

Muscle Cramps Muscle cramps can occur with up to 20% of dialysis sessions.⁵⁹ The cause is often related to excessive ultrafiltration, which causes hypoperfusion of the muscles. Other contributing factors to the development of muscle cramps include hypotension and electrolyte and acid-base imbalances that occur during hemodialysis sessions.

- **Treatment.** Nonpharmacologic treatments of muscle cramping that occurs during hemodialysis include decreasing the ultrafiltration rate and accurately determining the “dry weight.” Pharmacologic measures include vitamin E, which is administered at doses of 400 IU daily. Other options that are not as well studied include oxazepam and prazosin.

Thrombosis Thrombosis associated with hemodialysis most commonly occurs in patients with venous catheter access for dialysis and is a common cause of catheter failure. However, thrombosis can occur in synthetic grafts and less frequently in AV fistulas.

- Nonpharmacologic management of thrombosis in a hemodialysis catheter involves saline flushes. Smaller clots

may be managed by balloon angioplasty to mechanically open the catheter. In severe cases when clots cannot be removed by either mechanical or pharmacologic therapy, the catheter may require replacement.

Pharmacologic management of thrombosis includes local administration of thrombolytic agents. Alteplase (2 mg per port) and reteplase (0.5 unit per port) are the two most commonly used agents today. Urokinase has been used in the past, but after its reintroduction to the U.S. market, the larger dosed vial size makes it less cost effective than the newer agents.

Infection Infections are an important cause of morbidity and mortality in patients receiving hemodialysis. The cause of infection is usually related to organisms found on the skin, namely *Staphylococcus epidermidis* and *S. aureus*. Methicillin-resistant *S. aureus* (MRSA) is a common cause of infections in patients receiving hemodialysis. Other organisms have also been found to cause access-related infections. The greatest risk to patients receiving hemodialysis is the development of bacteremia. As with thrombosis, venous catheters are most commonly infected, followed by synthetic AV grafts, and finally AV fistulas.

Blood cultures should be obtained for any patient receiving hemodialysis who develops a fever. Nonpharmacologic management of infections involves preventive measures with sterile technique, proper disinfection, and minimizing the use and duration of venous catheters for hemodialysis access.

Pharmacologic management of infections should cover the gram-positive organisms that most frequently cause access-related infections. Patients who have positive blood cultures should receive treatment tailored to the organism isolated. Preventive measures for access-related infections include mupirocin at the exit site and povidone-iodine ointment. The recommendations of the NKF for treatment of infections associated with hemodialysis are listed in [Table 26-10](#).

Peritoneal Dialysis

Peritoneal dialysis is initiated in 6% of patients with newly diagnosed ESKD each year. Currently, 27,559 patients were receiving PD dialysis in 2009.⁴ Peritoneal dialysis is associated with improved survival compared with hemodialysis.⁴ Peritoneal dialysis preserves residual renal function, which improves cardiovascular stability and may account for the improved survival. Thus PD may be the preferred method of dialysis in patients with residual renal function.⁶⁰

► Principles of Peritoneal Dialysis

PD utilizes similar principles as hemodialysis in that blood is exposed to a semipermeable membrane against which a physiologic solution is placed. In the case of PD, however, the semipermeable membrane is the peritoneal membrane, and a sterile dialysate is instilled into the peritoneal cavity. The peritoneal membrane is composed of a continuous single layer of mesothelial cells that covers the abdominal and pelvic walls on one side of the peritoneal cavity, and the visceral organs including the GI tract, liver, spleen, and diaphragm on the other side. The mesothelial cells are covered by microvilli that increase the surface area of the peritoneal membrane to approximate body surface area (1 to 2 m²). Blood vessels that supply the abdominal organs, muscle, and mesentery serve as the blood component of the system.

The gaps between the mesothelial cells allow for large solutes to pass through into the bloodstream. Both the interstitium and endothelial cells of the blood vessels provide resistance to limit the solute size that is removed from the blood. Diffusion is the most important component of solute transport in PD, which is enhanced by the large surface area and volume of dialysate, as well as contact time with the peritoneal membrane. Ultrafiltration is achieved in PD by

Table 26-10

Management of Hemodialysis Access Infections

AV Fistula	Treat as subacute bacterial endocarditis for 6 weeks Initial antibiotic choice should always cover gram-positive organisms (e.g., vancomycin 20 mg/kg IV with serum concentration monitoring or cefazolin 20 mg/kg IV three times per week) Gram-negative coverage is indicated for patients with diabetes, HIV infection, prosthetic valves, or those receiving immunosuppressive agents (gentamicin 2 mg/kg IV with serum concentration monitoring)
Synthetic Grafts (AVG)	
Local infection	Empiric antibiotic coverage for gram-positive, gram-negative, and <i>Enterococcus</i> (e.g., gentamicin plus vancomycin, then individualize after culture results become available); continue for 2–4 weeks
Extensive infection	Antibiotics as above plus total resection
Access less than 1-month old	Antibiotics as above plus removal of the graft
Tunneled Cuffed Catheters (Internal Jugular, Subclavian)	
Infection localized to catheter exit site	No drainage: topical antibiotics (e.g., mupirocin ointment) Drainage present: Gram-positive coverage (e.g., cefazolin 20 mg/kg IV three times a week)
Bacteremia with or without systemic signs or symptoms	Gram-positive coverage as above If stable and asymptomatic, change catheter and provide culture-specific antibiotic coverage for a minimum of 3 weeks

AV, arteriovenous.

Patient Encounter 4, Part 2

The patient returns to the dialysis clinic 6 months later for her scheduled hemodialysis session. Two hours into the session, she begins to complain of dizziness and lightheadedness.

PE:

VS: BP 98/58 mm Hg (was 146/94 mm Hg at the start of hemodialysis); P 100 bpm; T 96.7° F (35.9° C); wt 118 lb (53.6 kg)

CV: RRR, normal S_1 , S_2

What are the potential causes of her hypotension?

What are the treatment alternatives for hypotension in this patient?

What are potential alternatives to avoid hypotension in future dialysis sessions?

creating an osmotic pressure gradient between the dialysate and the blood. Traditionally, glucose has been used to create the osmotic gradient, but the solutions are not biocompatible with the peritoneal membrane, resulting in cytotoxicity of the cells. More recently, polymeric glucose derivatives such as icodextrin have been used to create a colloid-driven osmosis that results in ultrafiltration and convection of solute removal.

In PD, prewarmed dialysate is instilled into the peritoneal cavity where it “dwells” for a specified length of time (usually one to several hours, depending on the type of PD) to adequately clear metabolic waste products and excess fluids and electrolytes. At the end of the dwell time, the dialysate is drained and replaced with fresh dialysate. The continuous nature of PD provides for a more physiologic removal of waste products from the bloodstream, which mimics endogenous kidney function by decreasing the fluctuations seen in serum concentrations of the waste products. Similarly, water is removed at a more constant rate, lessening the fluctuations in intravascular fluid balance and providing for more hemodynamic stability.

Several types of PD are used:

- Continuous ambulatory peritoneal dialysis (CAPD) is the most common. The patient exchanges 1 to 3 L of dialysate every 4 to 6 hours throughout the day with a longer dwell time overnight.
- Automated peritoneal dialysis (APD) procedures involve the use of a cycler machine that performs sequential exchanges overnight while the patient is sleeping.
- Continuous cycling PD (CCPD) performs three to five exchanges throughout the night. The final exchange remains in the peritoneal cavity to dwell for the duration of the day.
- Nightly intermittent PD (NIPD) performs six to eight exchanges throughout the night. The final exchange of

dialysate is drained in the morning, and the peritoneal cavity remains empty throughout the day.

- Nocturnal tidal PD (NTPD) is similar to NIPD, with the exception that only a portion of the dialysate is exchanged throughout the night. The final exchange is drained in the morning, and the peritoneal cavity remains empty throughout the day.

► Peritoneal Access

Access to the peritoneal cavity requires placement of an indwelling catheter with the distal end of the catheter resting in the peritoneal cavity. The central portion of the catheter is generally tunneled under the abdominal wall and subcutaneous tissue where it is held in place by cuffs that provide stability and mechanical support to the catheter. The proximal portion of the catheter exits the abdomen near the umbilicus (Fig. 26-7). Several types of indwelling catheters are available; the most common is the Tenckhoff catheter. Placement and handling of the catheter during PD exchanges requires a sterile environment to minimize the risk of infectious complications.

► Complications of Peritoneal Dialysis

Complications associated with PD include mechanical problems related to the PD catheter, metabolic problems associated with the components of the dialysate fluid, damage to the peritoneal membrane, and infections (Table 26-11). Strategies to manage infectious complications of PD are discussed below.

Peritonitis Peritonitis is a leading cause of morbidity in PD patients, which often leads to loss of the catheter and subsequent change to HD as the treatment modality. However,

FIGURE 26-7. Diagram of the placement of a peritoneal dialysis catheter through the abdominal wall into the peritoneal cavity. (From Foote EF, Manley HJ. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach, 7th ed. New York, NY: McGraw-Hill, 2008:O110, with permission.)

Table 26–11

Common Complications During Peritoneal Dialysis**Mechanical Complications**

Kinking in catheter
 Catheter migration
 Catheter adherence to peritoneal tissue
 Excessive movement of catheter at exit site

Peritoneal Damage

Alterations in permeability of the peritoneal membrane
 Sclerosis of the peritoneal membrane

Pain

Impingement of the catheter tip on visceral organs
 Instillation pain

- Rapid inflow of dialysate
- Acidic pH of dialysate
- Chemical irritation from dialysate additives (e.g., antibiotics)
- Low dialysate temperature

Infections

Peritonitis
 Exit-site infections
 Tunnel infections

Metabolic Complications

Exacerbation of diabetes mellitus from glucose load
 Fluid overload

- Exacerbation of chronic heart failure
- Edema
- Pulmonary congestion

Electrolyte abnormalities
 Malnutrition

- Albumin and amino acid loss
- Muscle wasting
- Increased adipose tissue
- Fibrin formation in dialysate

recent advances with connectors used during instillation and drainage of dialysate and delivery systems have dramatically decreased the incidence of peritonitis. Peritonitis can be caused by chemical irritation or microorganisms.

Pathophysiology. Gram-positive organisms, namely *S. epidermidis*, are the most common cause of peritonitis. Other pathologic organisms include *S. aureus*, streptococcal species, enterococcus species, gram-negative organisms including *Escherichia coli* and *Pseudomonas* species, and fungal organisms. Peritonitis should be presumed if cloudy fluid is drained from the peritoneal cavity and the fluid should be evaluated by cultures. Antibiotic treatment should be initiated immediately, until cell counts and cultures prove otherwise.⁶¹ Patients with peritonitis may also complain of abdominal pain, although pain may be absent in some cases.

Treatment. The International Society of Peritoneal Dialysis (ISPD) revised the recommendations for the treatment of PD-related infections in 2010.⁶¹ Drug selection for empirical treatment of peritonitis should cover both gram-positive and gram-negative organisms specific to the dialysis center and be based on the protocols and sensitivity patterns of organisms known to cause peritonitis, as well as the history

of infections in the patient. First-generation cephalosporins, such as cefazolin, or vancomycin are recommended for empirical coverage of gram-positive organisms. Appropriate coverage for gram-negative organisms includes third- or fourth-generation cephalosporins, such as ceftazidime or cefepime, or aminoglycosides. Alternatives for gram-negative coverage include oral fluoroquinolones. An example of an appropriate empiric treatment for peritonitis includes cefazolin in combination with ceftazidime, cefepime, or an aminoglycoside. If the patient has a cephalosporin allergy, vancomycin in combination with an aminoglycoside is an alternative empirical treatment.⁶¹ It should be noted that aminoglycosides can decrease residual renal function in patients receiving peritoneal dialysis.

The preferred route of administration is intraperitoneal (IP) rather than IV to achieve maximum concentrations at the site of infection. Antibiotics can be administered IP intermittently as a single large dose in one exchange per day or continuously as multiple smaller doses with each exchange. Intermittent administration requires at least 6 hours of dwell time in the peritoneal cavity to allow for adequate systemic absorption and provides adequate levels to cover the 24-hour period. However, continuous administration is better suited for PD modalities that require more frequent exchanges (less than 6-hour dwell time). See the ISPD guidelines for dosing recommendations for IP antibiotics in CAPD and automated PD patients.⁶¹ The dose of the antibiotics should be increased by 25% for patients with residual kidney function who are able to produce more than 100 mL urine output per day.

Once the organism has been identified and sensitivities are known, drug selection should be adjusted to reflect the susceptibilities of the organism. Streptococcal, staphylococcal, and enterococcal species sensitive to β -lactam antibiotics should be treated with continuous IP dosing to increase efficacy and minimize resistance.⁶¹ Peritonitis caused by *S. aureus* or *P. aeruginosa* are often associated with catheter-related infections, which are difficult to treat and often require removal of the catheter. Rifampin 600 mg orally daily (in a single or divided dose) may be added to IP vancomycin for the treatment of methicillin-resistant *S. aureus* (MRSA) but should be limited to duration of 1 week to minimize the development of resistance. Two antibiotics are required for treatment of *P. aeruginosa* peritonitis.⁶¹ If multiple organisms are cultured, treatment should cover all of the organisms, including anaerobic organisms, and the patient should be evaluated for other intra-abdominal pathologies.⁶¹

Peritonitis caused by fungal organisms is associated with mortality in 25% of patients,⁶¹ which can be reduced by removing the catheter after fungal organisms are identified. Empirical treatment should include IP amphotericin B and flucytosine.⁶¹ Although IP amphotericin administration is associated with chemical irritation and pain, penetration of amphotericin into the peritoneal cavity is poor with IV administration. Fluconazole, voriconazole, or caspofungin may be suitable alternatives, depending on culture results.

Catheter-Related Infections Catheter-related infections generally occur at the exit site or the portion of the catheter

that is tunneled in the subcutaneous tissue. Previous infections increase the risk and incidence of catheter-related infections.

Pathophysiology. The major pathologic organisms responsible for causing catheter-related infections are *S. aureus* and *P. aeruginosa*. These organisms also cause the most serious catheter-related infections. *S. epidermidis* is found in less than 20% of catheter-related infections. Other organisms include diphtheroids, anaerobic bacteria, *Legionella*, and fungi.⁶¹

Exit-site infections present with purulent drainage at the site. Erythema may or may not be present with an exit-site infection. Tunnel infections are generally an extension of the exit-site infection and rarely occur alone. Symptoms of a tunnel infection may include tenderness, edema, and erythema over the tunnel pathway but are often asymptomatic. Ultrasound can be used to detect tunnel infections in asymptomatic patients. Exit-site infections caused by *S. aureus* and *P. aeruginosa* often spread to tunnel infections and are the most common causes of catheter-infection–related peritonitis.

Treatment. Exit-site infections may be treated immediately with empiric coverage, or treatment may be delayed until

infections should cover *S. aureus*. Coverage for *P. aeruginosa* should also be included if the patient has a history of infections with this organism.⁶¹ Cultures and sensitivity testing are particularly important in tailoring antibiotic therapy for catheter-related infections to ensure eradication of the organism and prevent recurrence or related peritonitis.

Less severe infections may be treated with topical antibiotic cream, although this practice is controversial. Oral antibiotics are also effective for treatment of catheter-related infections. Empiric or routine use of vancomycin for gram-positive infections should be avoided unless the infection is caused by MRSA. Rifampin may be added to therapy for severe infections or slowly resolving *S. aureus* infections, but monotherapy is not recommended.⁶¹ Oral fluoroquinolones are used as first-line agents to treat *P. aeruginosa*, which can be difficult to treat and require prolonged treatment. If the infection is slow to resolve or if it recurs, IP ceftazidime or a second agent should be added.⁶¹ Treatment of catheter-related infections should be continued until the exit site appears normal with no erythema or drainage. Generally, at least 2 weeks of therapy or longer are required to ensure complete eradication of the organism and prevent future recurrence, which is common with *S. aureus*

Patient Care and Monitoring

1. Assess the patient to determine if the patient should be evaluated for CKD. Does the patient have any risk factors for CKD?
2. Review any available laboratory data to determine the staging of CKD.
3. Obtain a thorough medical and medication history from the patient. Does the patient have any concomitant diseases such as diabetes or hypertension that should be treated to prevent the progression of CKD?
4. Determine if an ACE-I or ARB is appropriate for the patient. Does the patient have proteinuria?
5. Develop a plan to assess and optimize treatment of CKD.
6. Determine if the patient requires medical treatment for electrolyte imbalances. Does the patient have edema? Does the patient have an arrhythmia?
7. Educate the patient on dietary changes to manage electrolyte imbalances associated with CKD.
8. Assess the patient for the presence of anemia. Do the laboratory tests suggest the patient requires medical treatment?
9. Develop a plan to assess and optimize treatment for anemia.
10. Determine if the patient requires medical intervention to prevent the development of or treatment for sHPT.
11. Develop a plan to assess and optimize treatment for sHPT.
12. Establish if the patient requires RRT.
13. Evaluate the patient for complications associated with dialysis. Does the patient develop hypotension or cramps during hemodialysis? Does the patient have symptoms consistent with peritonitis or a catheter infection?
14. Develop a plan to assess and optimize treatment for complications associated with dialysis.
15. Stress the importance of adherence with the treatments for CKD and associated complications including lifestyle modifications and medications. Recommend a therapeutic regimen that is easy for the patient to accomplish.
16. Provide patient education with regard to CKD and the associated complications, lifestyle modifications, and drug therapy:
 - What causes CKD and what things to avoid.
 - Possible complications of CKD and symptoms associated with the complications.
 - When to take medications.
 - What potential adverse effects may occur.
 - Which drugs may interact with therapy.
 - Warning signs to report to the physician (edema, irregular heartbeat, fatigue, unusual bleeding).

and *P. aeruginosa*. Infections that do not resolve may require replacement of the PD catheter. Catheter-related infections that present in conjunction with or progress to peritonitis with the same organism require removal of the PD catheter until the peritonitis is resolved.⁶¹

Prophylaxis of Peritonitis and Catheter-Related Infections

Prevention of peritonitis and catheter-related infections starts when the catheter is placed. The exit site should be properly cared for until it is well healed before it can be used for PD. Patients should receive proper instructions for care of the catheter during this time period, which can last up to 2 weeks. Patients should also be instructed on the proper techniques to use for dialysate exchanges to minimize the risk of infections during exchanges, which is the most common cause of peritonitis.

Intranasal *S. aureus* increases the risk of *S. aureus* exit-site infections, tunnel infections, peritonitis, and subsequent catheter loss.⁶¹ Several measures have been used to decrease the risk of peritonitis caused by *S. aureus*, including mupirocin cream applied daily around the exit site, intranasal mupirocin cream twice daily for 5 days each month, or rifampin 300 mg orally twice daily for 5 days, repeated every 3 months.⁶¹ Mupirocin use is preferred over rifampin to prevent the development of resistance to rifampin, although mupirocin resistance has also been reported.⁶¹ Other measures that have been used to decrease both *S. aureus* and *P. aeruginosa* infections include gentamicin cream applied twice daily and ciprofloxacin otic solution applied daily to the exit site.⁶¹

Outcome Evaluation Clinical improvement should be seen within 48 hours of initiating treatment for peritonitis or catheter-related infections. Perform daily inspections of peritoneal fluid or the exit site to determine clinical improvement. Peritoneal fluid should become clear with improvement of peritonitis and erythema, and discharge should remit with improvement of catheter-related infections. If no improvement is seen within 48 hours, obtain additional cultures and cell counts to determine the appropriate alterations in therapy.

Abbreviations Introduced in This Chapter

2,3-DPG	2,3-Diphosphoglycerate
ACE-I	Angiotensin-converting enzyme inhibitor
AGE	Advanced glycation end-product
AKI	Acute kidney injury
APD	Automated peritoneal dialysis
ARB	Angiotensin receptor blocker
AVF	Arteriovenous fistula
AVG	Arteriovenous graft
BUN	Blood urea nitrogen
Ca-P	Calcium-phosphorus product
CAPD	Continuous ambulatory peritoneal dialysis
CCPD	Continuous cycling peritoneal dialysis
CHD	Coronary heart disease
CKD	Chronic kidney disease

CKD-EPI	Chronic Kidney Disease Epidemiology Collaboration equation
CKD-MBD	Chronic kidney disease mineral and bone disease
CVD	Cardiovascular disease
DDAVP	Desmopressin
DKD	Diabetic kidney disease
DM	Diabetes mellitus
ECG	Electrocardiogram
EPO	Erythropoietin
ESA	Erythropoiesis-stimulating agent
FE _K	Fractional excretion of potassium
FE _{Na}	Fractional excretion of sodium
GFR	Glomerular filtration rate
HbA1c	Hemoglobin _{1c}
Hct	Hematocrit
HD	Hemodialysis
HDL-C	High-density lipoprotein cholesterol
Hgb	Hemoglobin
HMG-CoA	3-Hydroxy-3-methylglutaryl coenzyme A
IP	Intraperitoneal
iPTH	Intact parathyroid hormone
ISPD	International Society of Peritoneal Dialysis
KDIGO	Kidney Disease: Improving Global Outcomes
LDL-C	Low-density lipoprotein cholesterol
LVH	Left ventricular hypertrophy
MCHC	Mean corpuscular hemoglobin concentration
MCV	Mean corpuscular volume
MDRD	Modification of Diet in Renal Disease (study)
MRSA	Methicillin-resistant <i>Staphylococcus aureus</i>
NIPD	Nightly intermittent peritoneal dialysis
NKF	National Kidney Foundation
NKF-K/DOQI	National Kidney Foundation-Dialysis Outcome Quality Initiative
NTPD	Nocturnal tidal peritoneal dialysis
PD	Peritoneal dialysis
PTH	Parathyroid hormone
RBC	Red blood cell
ROD	Renal osteodystrophy
RRT	Renal replacement therapy
SC	Subcutaneous
SCr	Serum creatinine
sHPT	Secondary hyperparathyroidism
SPS	Sodium polystyrene sulfonate
TIBC	Total iron binding capacity
TSAT	Transferrin saturation
USRDS	United States Renal Data Service

Fluids and Electrolytes

Mark A. Malesker and Lee E. Morrow

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Estimate the volumes of various body fluid compartments.
2. Calculate the daily maintenance fluid requirement for patients given their weight, and gender.
3. Differentiate among currently available fluids for volume resuscitation.
4. Identify the electrolytes primarily found in the extracellular and intracellular fluid compartments.
5. Describe the unique relationship between serum sodium concentration and total body water (TBW).
6. Review the etiology, clinical presentation, and management for disorders of sodium, potassium, calcium, phosphorus, and magnesium.

KEY CONCEPTS

- 1 Total body water (TBW) is approximately 50% of lean body weight in normal females and 60% of lean body weight in males. For clinical purposes, most clinicians generalize that total body water accounts for 60% of lean body weight in adults, regardless of gender. TBW is composed of the intracellular fluid (two-thirds of TBW) and the extracellular fluid (one-third of TBW). The extracellular fluid is made up of two major fluid subcompartments: the interstitial fluid and the intravascular fluid.
- 2 Therapeutic fluids include crystalloid and colloid solutions. The most commonly used crystalloids include normal saline, dextrose/half-normal saline, hypertonic saline, and lactated Ringer's solution. Examples of colloids include albumin, the dextrans, hetastarch, and fresh-frozen plasma (FFP).
- 3 The calculated serum osmolality helps determine deviations in TBW content.
- 4 Concentrated electrolytes (potassium chloride [KCl], potassium phosphate, and sodium chloride [NaCl] greater than 0.9%) should not be stored in patient care areas as a patient safety measure.
- 5 Hyponatremia is the most common electrolyte disorder in hospitalized patients and is defined as a serum sodium concentration below 136 mEq/L (136 mmol/L).
- 6 IV potassium infusions running at rates of greater than 10 mEq/h (10 mmol/h) require cardiac monitoring.
- 7 Calcium gluconate is the preferred peripherally infused calcium supplement because it is less irritating to the

veins. Calcium chloride (CaCl) must be infused via a central line.

- 8 Severe hypophosphatemia can result in impaired diaphragmatic contractility and acute respiratory failure.
- 9 Serum magnesium concentrations do not correlate well with total body magnesium stores. For this reason, magnesium supplementation is often given empirically to critically ill patients.

BODY FLUID COMPARTMENTS

A thorough understanding of the fundamentals of fluid and electrolyte homeostasis is essential given the frequency with which clinical disturbances are seen and the profound effects these disturbances can have on various aspects of patient care. However, the interplay of body fluids, serum electrolytes, and clinical monitoring is complex, and a thorough command of these issues is a challenging task even for advanced practitioners.¹ Practitioners must be familiar with the key concepts of body compartment volumes, calculation of daily fluid requirements, and the various types of fluid available for replacement. The management of disorders of sodium, potassium, calcium, phosphorus, and magnesium integrates these concepts with issues of dose recognition and patient safety.

The most fundamental concept to grasp is an assessment of total body water (TBW), which is directly related to body weight. 1 *TBW constitutes approximately 50% of lean body weight in healthy females and 60% of lean body weight in males.*

For clinical purposes, most clinicians generalize that total body water accounts for 60% of lean body weight in adults, regardless of gender. The percentage of TBW decreases as body fat increases and/or with age (75% to 85% of body weight is water for newborns). Unless the patient is obese (body weight greater than 120% of ideal body weight [IBW]), clinicians typically use a patient's actual body weight when calculating TBW.² In obese patients, it is customary to estimate TBW using lean body weight or IBW as calculated by the Devine–Devine method: males' lean body weight = 50 kg + (2.3 kg/in. [height in inches – 60]) and females' lean body weight = 45.5 kg + (2.3 kg/in. [height in inches – 60]).^{3–5} Note that 1 kg is equivalent to 2.2 lb, 1 in. is equivalent to 2.54 cm, and 1 L of water weighs 1 kg (2.2 lb).

The intracellular fluid (ICF) represents the water contained within cells and is rich in electrolytes such as potassium, magnesium, phosphates, and proteins. **1** The ICF is approximately two-thirds of TBW regardless of gender.

For a 70-kg person, this would mean that the TBW is 42 L and the ICF is approximately 28 L. Note that ICF represents approximately 40% of total body weight.

The extracellular fluid (ECF) is the fluid outside the cell and is rich in sodium, chloride, and bicarbonate. **1** The ECF is approximately one-third of TBW (14 L in a 70-kg person) and is subdivided into two compartments: the interstitial fluid and the intravascular fluid. The interstitial fluid represents the fluid occupying the spaces between cells and is about 25% of TBW (10.5 L in a 70-kg person). The intravascular fluid (also known as plasma) represents the fluid within the blood vessels and is about 8% of TBW (3.4 L in a 70-kg person). Because the exact percentages are cumbersome to recall, many clinicians accept that the ECF represents roughly 20% of body weight (regardless of gender) with 15% in the interstitial space and 5% in the intravascular space.⁶ Note that serum electrolytes are routinely measured from the ECF.

The transcellular fluid includes the viscous components of the peritoneum, pleural space, and pericardium, as well as the cerebrospinal fluid, joint space fluid, and the GI digestive juices. Although the transcellular fluid normally accounts for about 1% of TBW, this amount can increase significantly during various illnesses favoring fluid collection in one of these spaces (e.g., pleural effusions or ascites in the peritoneum). The accumulation of fluid in the transcellular space is often referred to as “third spacing.” To review the calculations of the body fluid compartments in a representative patient, see Patient Encounter 1.

Fluid balance is assessed by several means each of which has its limitations. Blood pressure (BP) measurements estimate fluid status relative to the amount of blood volume pumped

by the heart but are affected by cardiac function and vascular pliability. Patients with significant volume deficiency may appear hypotensive, but this is a late finding that may require greater than 20% of TBW to be lost. Patients with significant volume excess may appear edematous; however, third spacing may hide this finding until late in the course as well. The physical examination can indicate the presence of fluid deficits (dry mucous membranes) and fluid excess (peripheral edema, coarse breath sounds). More invasive assessments would include the use of an arterial catheter, a pulmonary artery catheter to measure left ventricular function and fluid status, and a central venous catheter that measures fluid status and right ventricular function. However, the correlation between these measured pressures and their associated volume is an area of debate.

To maintain fluid balance, the total amount of fluid gained throughout the day (input, or “ins”) must equal the total amount of fluid lost (output, or “outs”). Although most forms of the body's input and output can be measured, several cannot. For a normal adult on an average diet, ingested fluids are easily measured and average 1,400 mL/day. Other fluid inputs, such as those from ingested foods and the water by-product of oxidation, are not directly measurable. Fluid outputs such as urinary and stool losses are also easily measured and referred to as sensible losses. Other sources of fluid loss, such as evaporation of fluid through the skin and/or lungs, are not readily measured and are called insensible losses. **Table 27–1** shows the estimated ins and outs (I&Os) for a healthy 68-kg (150-lb) man.⁶ The measurable I&Os are routinely measured in hospitalized patients and are used to estimate total fluid balance for each 24-hour period. It is important to realize that in hospitalized patients, multiple other forms of fluid loss must be considered. These include losses from enteric suctioning (most commonly, nasogastric [NG] tubes), from surgical drains (e.g., chest tubes, nephrostomy tubes, and pancreatic drains), via fistulous tracts, and enhanced evaporative losses (burns and fever).

TBW depletion (often referred to as “dehydration”) is typically a gradual, chronic problem. Because TBW depletion represents a loss of hypotonic fluid (proportionally more water is lost than sodium) from all body compartments, a primary disturbance of **osmolality** is usually seen. The signs and symptoms of TBW depletion include CNS disturbances

Patient Encounter 1: Body Fluid Compartments

Calculate the total body water, ICF, and ECF in a 80-kg male.

Table 27–1

Approximate I&Os for a Healthy 68-kg (150-lb) Man

Input	mL/day	Output	mL/day
Ingested fluid ^a	1,400	Urine ^a	1,500
Fluid in food	850	Skin losses	500
Water of oxidation	350	Respiratory tract losses	400
		Stool	200
Total	2,600	Total	2,600

^aReadily quantifiable.

Table 27-2

Useful Calculations for the Estimation of Patient Maintenance Fluid Requirements

Neonate (1–10 kg) = 100 mL/kg
 Child (10–20 kg) = 1,000 mL + 50 mL for each kilogram greater than 10
 Adult (greater than 20 kg) = 1,500 mL + 20 mL for each kilogram greater than 20

(mental status changes, seizures, and coma), excessive thirst, dry mucous membranes, decreased skin turgor, elevated serum sodium, increased plasma osmolality, concentrated urine, and acute weight loss. Common causes of TBW depletion include insufficient oral intake, excessive insensible losses, diabetes insipidus, excessive osmotic diuresis, and impaired renal concentrating mechanisms. Elderly long-term care residents are frequently admitted to the acute care hospital with TBW depletion secondary to lack of adequate oral intake, often with concurrent excessive insensible losses.

The volume of fluid required to correct TBW depletion equals the basal fluid requirement plus ongoing exceptional losses plus the fluid deficit. Basal daily fluid requirements are calculated using the formulas in Table 27-2. For an adult, this represents 1,500 mL/day for the first 20 kg of body weight plus 20 mL/day for each additional kilogram. The volume of replacement fluids required for a given patient (the fluid deficit) can be estimated by the acute weight change in the patient (1 kg = 1 L of fluid). Because the precise weight change is not typically known, it is often calculated as follows: fluid deficit = normal TBW – present TBW. Normal TBW is estimated based on the patient's height using the formulas in Table 27-2, and the present TBW is estimated based on the patient's current body weight. The choice of fluids used for replacement is guided by the presence of concurrent electrolyte abnormalities. The adequacy of replacement is guided by each patient's objective response to fluid replacement (improved skin turgor, adequate urine output, normalization of heart rate, BP, etc.).

Once TBW has been restored, the volume of “maintenance” fluid equals the basal fluid requirement plus ongoing exceptional losses. If the pathophysiologic process leading to TBW depletion has not been identified and corrected (or accounted for in the calculation of maintenance fluid requirements), TBW depletion will quickly recur. To review the concepts involved in the calculation of replacement fluids for a representative patient, see Patient Encounter 2.

Patient Encounter 2: Fluid Requirements

Calculate the daily fluid requirement for a 85-kg adult male.

Compared with TBW depletion, ECF depletion tends to occur acutely. In this setting, rapid and aggressive fluid replacement is required to maintain adequate organ perfusion. Because ECF depletion is generally due to the loss of isotonic fluid (proportional losses of sodium and water), major disturbances of plasma osmolality are not common. ECF depletion manifests clinically as signs and symptoms associated with decreased tissue perfusion: dizziness, orthostasis, tachycardia, decreased urine output, increased hematocrit, decreased central venous pressure, and/or hypovolemic shock. Common causes of ECF depletion include external fluid losses (burns, hemorrhage, diuresis, GI losses, and adrenal insufficiency) and third spacing of fluids (septic shock, anaphylactic shock, or abdominal ascites).

In clinical practice, the most commonly encountered problem is depletion of TBW and ECF. Accordingly, the fluid resuscitation strategy should address both of these compartments. As these compartments are repleted, serum electrolytes must be monitored closely as discussed in subsequent sections of this chapter.

THERAPEUTIC FLUIDS**Crystalloids**

Therapeutic IV fluids include crystalloid solutions, colloid solutions, and oxygen-carrying resuscitation solutions.

Crystalloids are composed of water and electrolytes, all of which pass freely through semipermeable membranes and remain in the intravascular space for shorter periods of time. As such, these solutions are very useful for correcting electrolyte imbalances but result in smaller hemodynamic changes for a given unit of volume.

Crystalloids can be classified further according to their tonicity. Isotonic solutions (i.e., normal saline or 0.9% sodium chloride [NaCl]) have a tonicity equal to that of the ICF (approximately 310 mEq/L or 310 mmol/L) and do not shift the distribution of water between the ECF and the ICF. Because hypertonic solutions (i.e., hypertonic saline or 3% NaCl) have greater tonicity than the ICF (greater than 376 mEq/L or 376 mmol/L), they draw water from the ICF into the ECF. In contrast, hypotonic solutions (i.e., 0.45% NaCl) have less tonicity than the ICF (less than 250 mEq/L or 250 mmol/L) leading to osmotic pressure gradient that favors shifts of water from the ECF into the ICF. The tonicity, electrolyte content, and glucose content of selected fluids are shown in Table 27-3.

The tonicity of crystalloid solutions is directly related to their sodium concentration. The most commonly used crystalloids include normal saline, dextrose/half-normal saline, hypertonic saline, and lactated Ringer's solution. Excessive administration of any fluid replacement therapy, regardless of tonicity, can lead to fluid overload, particularly in patients with cardiac or renal insufficiency. Glucose is often added to hypotonic crystalloids in amounts that result in isotonic fluids (D₅W, D₅½NS, and D₅¼NS). These solutions are often used as maintenance fluids to provide basal amounts of calories and water.

Table 27-3

Electrolyte and Dextrose Content of Selected Crystalloid Fluids

IV Solution	Osmolarity (mOsm)	Dextrose) (g/L) mmol/L	Sodium (mEq/L) mmol/L	Potassium (mEq/L) mmol/L	Calcium (mEq/L) mmol/L	Chloride (mEq/L) mmol/L	Lactate (mEq/L) mmol/L
D5%	250	$\frac{50}{2.78}$					
D10%	505	$\frac{100}{5.55}$					
0.9% NaCl	308		154			154	
0.45% NaCl	154		77			77	
3% NaCl	1,025		512			512	
D5% and 0.45% NaCl	405	$\frac{50}{2.78}$	77			77	
D5% and 0.2% NaCl	329	$\frac{50}{2.78}$	34			34	
Ringer's injection	310		147	4	$\frac{5}{2.5}$	156	
Lactated Ringer's solution	274		130	4	$\frac{3}{1.5}$	109	28
Lactated Ringer's solution and D5%	525	$\frac{50}{2.78}$	130	4	$\frac{3}{1.5}$	109	28

D, dextrose; NaCl, sodium chloride.

► Normal Saline (0.9% NaCl or NS)

- Normal saline is an isotonic fluid composed of water, sodium, and chloride. It provides primarily ECF replacement and can be used for virtually any cause of TBW depletion. Common uses of normal saline include perioperative fluid administration; volume resuscitation of shock, hemorrhage, or burn patients; fluid challenges in hypotensive or oliguric patients; and hyponatremia. Normal saline can also be used to treat metabolic alkalosis (also known as contraction alkalosis).

► Half-Normal Saline (0.45% NaCl or ½ NS)

- Half-normal saline is a hypotonic fluid that provides free water in relative excess when compared with the sodium concentration. This crystalloid is typically used to treat patients who are hypertonic due to primary depletion of the ECF. Because half-normal saline is hypotonic, serum sodium must be closely monitored during administration.

► 5% Dextrose/Half-Normal Saline (D5 ½ NS)

- D5 ½ NS is a hypotonic fluid that is commonly used as a maintenance fluid. This crystalloid is typically used once fluids deficits have been corrected with normal saline or lactated Ringer's solution. Because half-normal saline is hypotonic, serum sodium must be closely monitored during administration.

► Hypertonic Saline (3% NaCl)

- Hypertonic saline is obviously hypertonic and provides a significant sodium load to the intravascular space. This solution is used very infrequently given the potential to cause significant shifts in the water balance between the ECF and the ICF. It is typically used to treat patients with severe hyponatremia who have symptoms attributable to low serum sodium. Hypertonic saline in concentrations of 7.5% to 23.4% has been used to acutely lower intracranial pressure in the setting of traumatic brain injury and stroke. The literature is inconsistent for the appropriate hypertonic concentration, dosing, timing of replacement, and goals for use in this population. Serum sodium and neurologic status must be very closely monitored whenever given.

► Ringer's Lactate

- This isotonic volume expander contains sodium, potassium, chloride, and lactate in concentrations that approximate the fluid and electrolyte composition of the blood. Ringer's lactate (also known as "lactated Ringer," or LR) provides ECF replacement and is most often used in the perioperative setting and for patients with lower GI fluid losses, burns, or dehydration. The lactate component of LR works as a buffer to increase the pH. Accordingly, large volumes of LR may cause iatrogenic metabolic alkalosis. Because patients with significant liver disease are unable to metabolize lactate

sufficiently, LR administration in this population may lead to accumulation of lactate with iatrogenic lactic acidosis.

► 5% Dextrose in Water (D₅W)

- D₅W solution is a combination of free water and dextrose that provides a modest amount of calories but no electrolytes. Although it is technically isotonic, it acts as a hypotonic solution in the body. It is commonly used to treat severe hypernatremia. D5W is also used in small volumes (100 mL) to dilute many IV medications or at a low infusion rate (10 to 15 mL/h) to “keep the vein open” (KVO) for IV medications.

Colloids

- In contrast to crystalloids, colloids do not dissolve into a true solution and therefore do not pass readily across semipermeable membranes. As such, colloids effectively remain in the intravascular space and increase the oncotic pressure of the plasma. This effectively shifts fluid from the interstitial compartment to the intravascular compartment. In clinical practice, these theoretical benefits are generally short lived (given metabolism of colloidal proteins/sugars), and for most patients there is little therapeutic advantage of colloids over crystalloids or vice versa. Examples of colloids include 5% albumin, 25% albumin, the dextrans, hetastarch, and fresh-frozen plasma (FFP). Because each of these agents contains a substance (proteins and complex sugars) that will ultimately be metabolized, the oncotic agent will be ultimately lost and only the remaining hypotonic fluid delivery agent will remain. As such, use of large volumes of colloidal agents is more likely to induce fluid overload compared with crystalloids. Although smaller volumes of colloids have equal efficacy as larger volumes of crystalloids, they generally must be infused more slowly. Often the net result is that the time to clinical benefit is the same regardless of which class of fluid is utilized. For example, 500 mL of normal saline is required to increase the systolic BP to the same degree as seen with approximately 250 mL of 5% albumin; however, the normal saline can be administered twice as fast.

► Albumin

- Albumin is a protein derived from fractionating human plasma. Because albumin infusion is expensive and may be associated with adverse events, it should be used for acute volume expansion and *not* as a supplemental source of protein calories. Historically, albumin was used indiscriminately in the intensive care unit until anecdotal publications suggested that albumin may cause immunosuppression. However, the recently completed Saline Versus Albumin Fluid Evaluation (SAFE) trial randomized nearly 7,000 hypovolemic patients to either albumin or normal saline therapy and found that the mortality for those who received albumin was the same as for those who received normal saline.⁷ A subsequent post hoc analysis reported that patients with traumatic brain injury had higher mortality rates when given

albumin for fluid resuscitation. These conflicting findings highlight the controversy and confusion surrounding the use of human albumin versus normal saline therapy for resuscitation of critically ill patients.^{8–10} Albumin combined with furosemide has been demonstrated to improve fluid balance, oxygenation, and hemodynamics in the subset of patients with acute lung injury who have low serum protein.¹¹

Recent events have resulted in an albumin shortage in the United States with ongoing allocation of all albumin products. In brief, albumin is obtained as a by-product of routine intravenous immunoglobulin (IVIG) processing. As a result, the albumin supply is driven by the amount of plasma fractionation for IVIG. Increased efficiency of the IVIG collection techniques and decreased IVIG consumption has led to an unintended shortage of albumin available for use. Based on this limited availability, health systems and hospitals have had to define the appropriate albumin indications for their patients and ration albumin accordingly. Evidence-based indications for albumin include plasmapheresis/apheresis, large-volume paracentesis (greater than 4 L removed), hypotension in hemodialysis, and the need for aggressive diuresis in hypoalbuminemic hypotensive patients. Inappropriate uses of albumin include nutritional supplementation, impending hepatorenal syndrome, pancreatitis, alteration of drug pharmacokinetics, or acute normovolemic hemodilution in surgery. Practitioners can keep up with medication shortages by checking the American Society of Health-System Pharmacists (ASHP) website (www.ashp.org).

► Hetastarch and Dextran

- While albumin is the most commonly used colloid, the other available products are not without their own risks and benefits. Hetastarch (various manufacturers) and Voluven contain 6% starch and 0.9% NaCl. These products have no oxygen-carrying capacity and are administered intravenously as plasma expanders. Limitations of these products include acquisition cost, hypersensitivity reactions, and bleeding. Dosing should be reduced in the presence of renal dysfunction. There is evidence to suggest that Voluven can be administered safely in a larger volume (4 L versus 1 L of hetastarch) for volume expansion to minimize the need for albumin. Hextend is a comparable plasma expander that contains 6% hetastarch in lactated electrolyte solution. Low molecular weight dextran (various manufacturers) and high molecular weight dextran (various manufacturers) are polysaccharide plasma expanders. Anaphylactic reactions and prolonged bleeding times have limited the use of these products. Potential mechanisms of colloid solution-induced bleeding include platelet inhibition or possible dilution of clotting factors via infusion of a large-volume colloid solution. Although FFP has been used as a volume expander in cases of excessive blood loss (surgery or trauma) and to prevent bleeding in the presence of abnormal coagulation studies, it is now rarely used for volume expansion given risks of anaphylaxis, potential for viral transmission, and increased nosocomial infection rates.

Fluid Management Strategies

Classic indications for IV fluid include maintenance of BP, restoring the ICF volume, replacing ongoing renal or insensible losses when oral intake is inadequate, and the need for glucose as a fuel for the brain.¹² Although large volumes of fluid are given during the resuscitation of most trauma patients, a recent analysis reported uncertainty about the use of early large-volume fluid replacement in patients with active bleeding, calling into question our understanding of the need for fluids in various patient populations.¹³

When determining the appropriate fluid to be utilized, it is important to first determine the type of fluid problem (TBW versus ECF depletion), and start therapy accordingly. For patients demonstrating signs of impaired tissue perfusion, the immediate therapeutic goal is to increase the intravascular volume and restore tissue perfusion. The standard therapy is normal saline given at 150 to 500 mL/h (for adult patients) until perfusion is optimized. Although LR is a therapeutic alternative, lactic acidosis may arise with massive or prolonged infusions. LR has less chloride content versus normal saline (109 mEq/L [109 mmol/L] versus 154 mEq/L [154 mmol/L]) and has the advantage of use when large volumes of normal saline produce acidosis during fluid resuscitation. In severe cases, a colloid or blood transfusion may be indicated to increase oncotic pressure within the vascular space. Once euolemia is achieved, patients may be switched to a more hypotonic maintenance solution (0.45% NaCl) at a rate that delivers estimated daily needs.

The clinical scenario and the severity of the volume abnormality dictate monitoring parameters during fluid replacement therapy. These may include the subjective sense of thirst, mental status, skin turgor, orthostatic vital signs, pulse rate, weight changes, blood chemistries, fluid input and output, central venous pressure, pulmonary capillary wedge pressure, and cardiac output. Fluid replacement requires particular caution in patient populations at risk of fluid overload, such as those with renal failure, cardiac failure, hepatic failure, or the elderly. Other complications of parenteral fluid therapy include IV site infiltration, infection, phlebitis, thrombophlebitis, and extravasation.

In summary, common settings for fluid resuscitation include hypovolemic patients (e.g., sepsis or pneumonia), hypervolemic patients (e.g., congestive heart failure [CHF], cirrhosis, or renal failure), euvoletic patients who are unable to take oral fluids in proportion to insensible losses (e.g., the perioperative period), and patients with electrolyte abnormalities (see below).

ELECTROLYTES

Normally, the number of anions (negatively charged ions) and cations (positively charged ions) in each fluid compartment are equal. Cell membranes play the critical role of maintaining distinct ICF and ECF spaces, which are biochemically distinct. Serum electrolyte measurements reflect the stores of ECF electrolytes rather than that of ICF electrolytes. [Table 27-4](#) lists the chief cations and anions along with their normal

Table 27-4

Normal Cation and Anion Concentrations in the ECF and ICF

Ion Species	ECF		ICF	
	Plasma (mEq/L or mmol/L)	Interstitial Fluid (mEq/L or mmol/L)	Ion Species	mEq/L or mmol/L
Cations				
Na ⁺	142	144	K ⁺	135
K ⁺	4	4	Mg ²⁺	43
Ca ²⁺	5	2.5		
Mg ²⁺	3	1.5

Total	154	152	Total	178

ECF, extracellular fluid; ICF, intracellular fluid.

concentrations in the ECF and ICF. The principal cations are sodium, potassium, calcium, and magnesium; the key anions are chloride, bicarbonate, and phosphate. In the ECF, sodium is the most common cation and chloride is the most abundant anion; in the ICF, potassium is the primary cation and phosphate is the main anion. Normal serum electrolyte values are listed in [Table 27-5](#).

Osmolality is a measure of the number of osmotically active particles per unit of solution, independent of the weight or nature of the particle. Equimolar concentrations of all substances in the undissociated state exert the same osmotic pressure. Although the normal serum osmolality is 280 to 300 mOsm/kg (280 to 300 mmol/kg), multiple scenarios exist where this value becomes markedly abnormal. **3** *The calculated serum osmolality helps determine deviations in TBW content.* As such, it is often useful to calculate the serum osmolality as follows:

Table 27-5

Normal Ranges for Serum Electrolyte Concentrations

Sodium	136–145 mEq/L or 136–145 mmol/L
Potassium	3.5–5.0 mEq/L or 3.5–5.0 mmol/L
Chloride	98–106 mEq/L or 98–106 mmol/L
Bicarbonate	21–30 mEq/L or 21–30 mmol/L
Magnesium	1.4–2.2 mEq/L or 0.7–1.1 mmol/L
Calcium:	
Total	4.4–5.2 mEq/L (9–10.5 mg/dL) or 2.2–2.6 mmol/L
Ionized	2.2–2.8 mEq/L (4.5–5.6 mg/dL) or 1.1–1.4 mmol/L
Phosphorus	3–4.5 mg/dL (1.0–1.4 mmol/L)

• Serum **osmolality** (mOsm/kg) =

$$2 (\text{Na mEq/L}) + (\text{glucose [mg/dL]})/18 + (\text{BUN [mg/dL]})/2.8.$$

Serum osmolality using SI units (mmol/kg) =

$$2 (\text{Na mmol/L}) + (\text{glucose mmol/L}) + (\text{BUN mmol/L})$$

Because the body regulates water to maintain osmolality, deviations in serum osmolality are used to estimate TBW stores. Water moves freely across all cell membranes, making serum osmolality an accurate reflection of the osmolality within all body compartments. An increase in osmolality is equated with a loss of water greater than the loss of solute (TBW depletion). A decrease in serum osmolality is seen when water is retained in excess of solute (CHF or hepatic cirrhosis). The difference between the measured serum osmolality and the calculated serum osmolality, using the equation just stated, is referred to as the **osmolar gap**. Under normal circumstances the osmolar gap should be 10 mOsm/kg or less. An increased osmolar gap suggests the presence of a small osmotically active agent and is most commonly seen with the ingestion of alcohols (ethanol, methanol, ethylene glycol, or isopropyl alcohol) or medications such as mannitol or lorazepam. Patient Encounter 3 illustrates the utility of serum osmolality in a clinical setting.

Many of the electrolyte disturbances discussed in the remainder of this chapter represent medical emergencies that call for aggressive interventions including the use of concentrated electrolytes. It is very difficult to immediately reverse the effects of concentrated electrolytes when they are administered improperly, and these solutions are a frequent source of medical errors with significant potential for patient harm. **4** As such, *The Joint Commission recommends that concentrated electrolyte solutions (KCl, potassium phosphate, and NaCl greater than 0.9%) be removed from patient care areas.* Hospitals should keep concentrated electrolytes in patient care areas only when patient safety necessitates their immediate use and precautions are used to prevent inadvertent administration. Collaborative cooperation among pharmacists, nurses, and physicians is essential. In addition,

Patient Encounter 3: Calculate the Plasma Osmolality

A 50-year-old homeless man is brought to the emergency department staggering and smelling like beer. Rapid respiration, tachycardia, and a BP of 90/60 mm Hg were noted. The sodium is 142 mEq/L (142 mmol/L), potassium 3.6 mEq/L (3.6 mmol/L), chloride 100 mEq/L (100 mmol/L), bicarbonate 12 mEq/L (12 mmol/L), glucose 180 mg/dL (10.0 mmol/L), and BUN 28 mg/dL (10.0 mmol/L). The measured osmolality is 360 mOsm/kg (360 mmol/kg).

Calculate the osmolality.

Calculate the osmolar gap.

What is the likely cause of an increased gap in this patient?

The Joint Commission recommends standardizing and limiting the number of drug concentrations available in each institution and the use of ready-to-administer dosage forms so as to further reduce the risk of medication errors and improve outcomes.¹⁴

Sodium

The body's normal daily sodium requirement is 1.0 to 1.5 mEq/kg (1.0 to 1.5 mmol/kg) (80 to 130 mEq, which is 80 to 130 mmol) to maintain a normal serum sodium concentration of 136 to 145 mEq/L (136 to 145 mmol/L).¹⁵ Sodium is the predominant cation of the ECF and largely determines ECF volume. Sodium is also the primary factor in establishing the osmotic pressure relationship between the ICF and ECF. All body fluids are in osmotic equilibrium, and changes in serum sodium concentration are associated with shifts of water into and out of body fluid compartments. When sodium is added to the intravascular fluid compartment, fluid is pulled intravascularly from the interstitial fluid and the ICF until osmotic balance is restored. As such, a patient's measured sodium concentration should *not* be viewed as an index of sodium need because this parameter reflects the balance between total body sodium content and TBW. Disturbances in the sodium concentration most often represent disturbances of TBW. Sodium imbalances cannot be properly assessed without first assessing body fluid status.

5 *Hyponatremia is the most common electrolyte disorder in hospitalized patients and defined as a serum sodium concentration below 136 mEq/L (136 mmol/L).* Clinical signs and symptoms appear at concentrations below 120 mEq/L (120 mmol/L) and typically consist of irritability, mental slowing, unstable gait/falls fatigue, headache, and nausea. With profound hyponatremia (less than 110 mEq/L [110 mmol/L]), confusion, seizures, stupor/coma, and respiratory arrest may be seen. Because therapy is also influenced by volume status, hyponatremia is further defined as (a) hypertonic hyponatremia, (b) hypotonic hyponatremia with an increased ECF volume, (c) hypotonic hyponatremia with a normal ECF volume, and (d) hypotonic hyponatremia with a decreased ECF volume.¹⁶

• Hypertonic hyponatremia is usually associated with significant hyperglycemia. Glucose is an osmotically active agent that leads to an increase in TBW with little change in total body sodium. For every 60 mg/dL (3.3 mmol/L) increase in serum glucose above 200 mg/dL (11.1 mmol/L), the sodium concentration is expected to decrease by approximately 1 mEq/L (1 mmol/L). Appropriate treatment of the hyperglycemia will return the serum sodium concentration to normal.¹⁵

• Hypotonic hyponatremia with an increase in ECF (hypervolemic hyponatremia) is also known as dilutional hyponatremia. In this scenario, patients have an excess of total body sodium and TBW; however, the excess in TBW is greater than the excess in total body sodium. Common causes include CHF, hepatic cirrhosis, and nephrotic syndrome. Treatment includes sodium and fluid restriction in conjunction with treatment of the underlying disorder—for example, salt and

water restrictions are used in the setting of CHF along with loop diuretics, angiotensin-converting enzyme inhibitors, and spironolactone.¹⁵

In hypotonic hyponatremia with a normal ECF volume (euvolemic hyponatremia), patients have an excess of TBW with relatively normal sodium content. In essence, there is a presence of excess free water. This is most frequently seen in patients with the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Common causes of SIADH include carcinomas (e.g., lung or pancreas), pulmonary disorders (e.g., pneumonias or tuberculosis), CNS disorders (e.g., meningitis, stroke, tumor, or trauma), and medications (e.g., sulfonyleureas, antineoplastic agents, barbiturates, morphine, antipsychotics, tricyclic antidepressants, nonsteroidal anti-inflammatory agents, selective serotonin reuptake inhibitors, dopamine agonists, and general anesthetics). These medications stimulate the release of antidiuretic hormone (ADH) from the pituitary gland resulting in water retention and dilution of the body's sodium stores.

Short-term treatment of euvolemic hyponatremia includes fluid restriction, isotonic normal saline, hypertonic saline, or conivaptan. Initial treatment generally consists of fluid restriction alone. Hypertonic saline is used only when the sodium concentration is less than 110 mEq/L (110 mmol/L) and/or severe symptoms (e.g., seizures) are present. Given the limitations associated with these treatment strategies (unpredictable therapeutic effects and side effects), the arginine vasopressin antagonist conivaptan (Vaprisol, Astellas Pharma) was developed for short-term treatment of euvolemic hyponatremia. While conivaptan can also be used to manage hypervolemic hyponatremia in hospitalized patients, it should not be used for hypovolemic hyponatremia. Conivaptan is dosed 20 mg IV over 30 minutes, followed by a 20-mg continuous infusion over 24 hours for up to 4 days. The initial formulation of conivaptan contained propylene glycol and was associated with infusion site reactions. The revised formulation is better tolerated.

Long-term treatment options for euvolemic hyponatremia include fluid restriction, demeclocycline, loop diuretics, saline, lithium, urea, and tolvaptan. Demeclocycline (available as generic) is dosed at 600 to 1,200 mg/day, takes days before clinical effect is realized, and can cause nephrotoxicity. Lithium (various generics) also has a slow onset of action and is limited by CNS side effects, GI disturbances and cardiotoxicity. Furosemide (various generics) or other loop diuretics allow relaxation of fluid restriction but can cause significant volume depletion and electrolyte disturbances, and it has the potential for ototoxicity. No specific USP formulation exists for urea and poor palatability, and side effects limits its use. Tolvaptan (Samsca [Otsuka]) is an oral alternative to IV conivaptan. This product is indicated for treatment of clinically significant hypervolemic and euvolemic hyponatremia (sodium less than 125 mEq/L [less than 125 mmol/L]) or less marked hyponatremia that is symptomatic and has resisted correction with fluid restriction. Patients with CHF, cirrhosis, and SIADH would be candidates for long-term use. Tolvaptan has a boxed warning for

initiation of treatment in a hospital setting because of the need for close sodium monitoring. The initial dose is 15 mg orally daily and may be titrated up to a max of 60 mg. Concurrent use with potent CYP 3A4 inhibitors should be avoided: ketoconazole (available as generic), clarithromycin (available as generic), ritonavir (Norvir, Abbott), diltiazem (available as generic), verapamil (available as generic), fluconazole (available as generic), and grapefruit juice.

In hypotonic hyponatremia with a decreased ECF volume (hypovolemic hyponatremia), patients usually have a deficit of both total body sodium and TBW, but the sodium deficit exceeds the TBW deficit. Common causes include diuretic use, profuse sweating, wound drainage, burns, GI losses (vomiting or diarrhea), hypoadrenalism (low cortisol and low aldosterone), and renal tubular acidosis. Treatment includes the administration of sodium to correct the sodium deficit and water to correct the TBW deficit. The sodium deficit can be calculated with the following equation²:

$$\text{Sodium deficit (mEq or mmol)} = (\text{TBW [in liters]})(\text{desired Na}^+ \text{ concentration [mEq/L or mmol/L]} - \text{current Na}^+ \text{ concentration}).$$

Although both water and sodium are required in this instance, sodium needs to be provided in excess of water to fully correct this abnormality. As such, hypertonic saline (3% NaCl) is often used. One can estimate the change in serum sodium concentration after 1 L of 3% NaCl infusion using the following equation¹⁶:

$$\text{Change in serum Na}^+ \text{ (mEq/L or mmol/L)} = (\text{infusate Na}^+ - \text{serum Na}^+) / (\text{TBW} + 1).$$

In this formula, TBW is increased by 1 to account for the addition of the liter of 3% NaCl. Patient Encounters 4 and 5 illustrate the concepts of calculating and correcting the sodium deficit.

Depending on the severity of the hyponatremia and acuity of onset, 0.9%, 3%, or 5% NaCl can be utilized. Most patients can be adequately managed with normal saline rehydration, which is generally the safest agent. Hypertonic

Patient Encounter 4: Calculation of Sodium Deficit

Calculate the sodium deficit for an 80-kg male with a serum sodium of 123 mEq/L (123 mmol/L).

Patient Encounter 5: Estimate the Anticipated Change in Serum Sodium

Estimate the anticipated change in serum sodium concentration after the infusion of 1 L of 3% NaCl in an 80-kg male with a serum sodium of 123 mEq/L (123 mmol/L).

saline (3% or 5% NaCl) is generally reserved for patients with severe hyponatremia (less than 120 mEq/L [120 mmol/L]) accompanied by coma, seizures, or high urinary sodium losses. Roughly one-third of the sodium deficit can be replaced over the first 12 hours as long as the replacement rate is less than 0.5 mEq/h (0.5 mmol/h). The remaining two-thirds of the deficit can be administered over the ensuing days. Overly aggressive correction of symptomatic hyponatremia (greater than 12 mEq/L [12 mmol/L] per day) can result in central pontine myelinolysis.¹⁷ Given the potential for irreversible neurologic damage if untreated or if improperly treated, acute hyponatremia is an urgent condition that should be promptly treated with careful attention to monitoring serial sodium values and adjusting therapeutic infusions accordingly.¹⁸

Hypernatremia is a serum sodium concentration greater than 145 mEq/L (145 mmol/L) and can occur in the absence of a sodium deficit (pure water loss) or in its presence (hypotonic fluid loss).¹⁹ The signs and symptoms of hypernatremia manifest with a serum sodium concentration greater than 160 mEq/L (160 mmol/L) and are usually the same as those found in TBW depletion: thirst, mental slowing, and dry mucous membranes. Signs and symptoms become more profound as hypernatremia worsens, with the patient eventually demonstrating confusion, hallucinations, acute weight loss, decreased skin turgor, intracranial bleeding, and/or coma. Many coexisting disorders and medications may complicate the diagnosis.

The classic causes of hypernatremia are associated with TBW depletion. These include dehydration from loss of hypotonic fluid from the respiratory tract or skin, decreased water intake, osmotic diuresis (e.g., mannitol, available as generic), and diabetes insipidus (e.g., decreased ADH; phenytoin, available as generic; lithium, available as generic).

Hypernatremia in hospitalized patients occurs secondary to inappropriate fluid management in patients at risk for increased free water losses and impaired thirst or restricted water intake.²⁰ Iatrogenic hypernatremia is occasionally caused by the administration of excessive hypertonic saline. Treatment of hypernatremia includes calculation of the TBW deficit followed by the administration of hypotonic fluids as previously described. The fluid volume should be replaced over 48 to 72 hours depending on the severity of symptoms and the degree of hypertonicity.²¹ For asymptomatic patients, the rate of correction should not exceed 0.5 mEq/L/h (0.5 mmol/L/h). One rule of thumb is to replace half the calculated TBW deficit over 12 to 24 hours and the other half of the deficit over the next 24 to 48 hours.^{2,19} Excessively rapid correction of hypernatremia may lead to cerebral edema and death. Patient Encounters 6 and 7 reinforce the concepts of calculating TBW deficit and expected changes in serum sodium concentration with therapy.

Potassium

The body's normal daily potassium requirement is 0.5 to 1 mEq/kg (0.5 to 1 mmol/kg) or 40 to 80 mEq (40 to 80 mmol) to maintain a serum potassium concentration of

Patient Encounter 6: Calculate Water Deficit

Calculate the water deficit in an 80-kg male with a serum sodium of 154 mEq/L (154 mmol/L).

Patient Encounter 7: Calculate the Anticipated Change in Serum Sodium

Calculate the anticipated change in serum sodium concentration after IV infusion of 1 L of 5% dextrose in a 80 kg male with a serum sodium of 156 mEq/L (156 mmol/L).

3.5 to 5 mEq/L (3.5 to 5 mmol/L). Potassium is the most abundant cation in the ICF, balancing the sodium contained in the ECF and maintaining electroneutrality of bodily fluids. Because the majority of potassium is intracellular, serum potassium concentration is not a good measure of total body potassium; however, clinical manifestations of potassium disorders correlate well with serum potassium. The acid-base balance of the body affects serum potassium concentrations: hyperkalemia is routinely seen in patients with decreased pH (acidosis). Potassium regulation is primarily under the control of the kidneys with excess dietary potassium being excreted in the urine. Although mild abnormalities of serum potassium are considered a nuisance, severe hyperkalemia or hypokalemia can be life threatening.²²⁻²⁴

Hypokalemia (serum potassium less than 3.5 mEq/L [3.5 mmol/L]) is a common clinical problem. While generally asymptomatic, signs and symptoms of hypokalemia include cramps, muscle weakness, polyuria, electrocardiogram (ECG) changes (flattened T waves and presence of U waves), and cardiac arrhythmias (bradycardia, heart block, atrial flutter, premature ventricular contractions, and ventricular fibrillation). Causes of hypokalemia include GI losses (vomiting, diarrhea, or NG tube suction), renal losses (high aldosterone and low magnesium), inadequate potassium intake (in IV fluids or oral), or alkalosis. Many medications can precipitate hypokalemia. β_2 -agonists (e.g., albuterol, available as generic) and insulin (multiple product formulations) lower potassium via cellular redistribution. The use of loop diuretics (furosemide [Lasix], also available as generic), thiazide diuretics (hydrochlorothiazide, available as generic), high-dose antibiotics (penicillin, available as generic), and corticosteroids (prednisone, available as generic) cause renal potassium wasting. In addition, amphotericin B (available as generic), cisplatin (available as generic), and foscarnet (available as generic) can also produce hypokalemia secondary to depletion of magnesium. Hypomagnesemia diminishes intracellular potassium concentration and produces potassium wasting. Given the potential for significant morbidity and mortality, serum potassium concentrations should be monitored closely for patients with known (or suspected) hypokalemia.^{2,24,25} Hypokalemia is a risk factor for digitalis toxicity.

Table 27-6

Potassium Content in Various Potassium Salt Preparations

Potassium Salt	mEq/g (mmol/L)
Potassium gluconate ^a	4.3
Potassium citrate ^a	9.8
Potassium bicarbonate ^a	10.0
Potassium acetate ^a	10.2
Potassium chloride ^b	13.4

^aFavored for hypokalemia and concurrent acidosis.

^bFavored for hypokalemia and concurrent alkalosis.

- Each 1 mEq/L (1 mmol/L) fall in serum potassium (i.e., from 4 to 3 mEq/L [4 to 3 mmol/L]) represents a loss of approximately 200 mEq (200 mmol) of potassium in the adult. However, when the serum potassium is below 3 mEq/L (3 mmol/L), each 1 mEq/L (1 mmol/L) fall in serum potassium represents a 200 to 400 mEq (200 to 400 mmol) reduction in serum concentration in the adult patient. Potassium repletion should be guided by close monitoring of serial serum concentrations instead of using empirically chosen amounts. Of the five potassium salts available, potassium acetate (10.2 mEq/K⁺/g or 10.2 mmol/K⁺/g) and KCl (13.4 mEq/K⁺/g or 13.4 mmol/K⁺/g) are the most commonly used forms. When hypokalemia occurs in the setting of alkalosis, KCl is the preferred agent; in acidosis, potassium should be provided in the form of acetate, citrate, bicarbonate, or gluconate salt. [Table 27-6](#) outlines the potassium content of each potassium salt preparation, and [Table 27-7](#) lists each of the oral potassium replacement products. Potassium acetate and chloride are available for IV infusions as premixed solutions. The usual dose of these agents is 10 to 20 mEq (10 to 20 mmol) diluted in 100 mL of normal saline.^{2,25,26}

Table 27-7

Oral Potassium Replacement Products

Product	Salt	Strength ^a
Extended/controlled-release tablets	Chloride	8 mEq (600 mg)
		10 mEq (750 mg)
		15 mEq (1,125 mg)
		20 mEq (1,500 mg)
Effervescent tablets	Chloride and bicarbonate	10 mEq
		20 mEq
		25 mEq
		50 mEq
Liquid	Chloride	20 mEq/15 mL (10%)
		40 mEq/15 mL (20%)
Powder packets	Chloride	20 mEq
		25 mEq

^aFor potassium, 1 mEq = 1 mmol.

- Moderate hypokalemia is defined as a serum potassium of 2.5 to 3.5 mEq/L (2.5 to 3.5 mmol/L) without ECG changes. In this setting, potassium replacement can usually be given orally at a dose of 40 to 120 mEq/day (40 to 120 mmol/day). Anecdotally, oral potassium supplementation (see [Table 27-7](#)) is often more effective in repleting moderate hypokalemia. For patients with an ongoing source of potassium loss, chronic replacement therapy should be considered. The potassium deficit is a rough approximation of the amount of potassium needed to be replaced and can be estimated as follows:

$$\text{Potassium deficit (mEq or mmol/L)} = (4.0 - \text{current serum potassium}) \times 100$$

- Severe hypokalemia is defined as a serum potassium less than 2.5 mEq/L (2.5 mmol/L) or hypokalemia of any magnitude that is associated with ECG changes (e.g., flattening of T wave or elevation of U wave) and cardiac arrhythmias. In these situations, IV replacement should be initiated urgently.
 - 6** Potassium infusion at rates exceeding 10 mEq/h (10 mmol/h) requires cardiac monitoring given the potential for cardiac arrhythmias. Although the maximally concentrated solution for potassium replacement is 80 mEq/L (80 mmol/L), the maximum infusion rate is 40 mEq/h (40 mmol/h) and must be administered via a central line. [Table 27-8](#) outlines current IV potassium replacement guidelines.

Caution must be exercised when repleting potassium with IV agents given possible vein irritation and/or thrombophlebitis. The risk of these complications is minimized by using less concentrated solutions and by giving infusions via central access if possible. Administration of potassium in vehicles containing glucose is discouraged because glucose facilitates the intracellular movement of potassium. Posttherapy improvements in serum potassium may be transient, and continuous monitoring is required. Patients with low serum magnesium will have exaggerated potassium losses from the kidneys and GI tract leading to refractory hypokalemia. In this situation, the magnesium deficit must be corrected in order to successfully treat the concurrent potassium deficiency. In the hypokalemic patient

Table 27-8

Recommended Potassium Dosage/Infusion Rate

Clinical Scenario	Maximum Infusion Rate ^a	Maximum Concentration ^a	Maximum 24-Hour Dose ^a
K ⁺ greater than 2.5 mEq/L and No ECG changes of hypokalemia	10 mEq/h	40 mEq/L	200 mEq
K ⁺ less than 2.5 mEq/L or ECG changes of hypokalemia	40 mEq/h	80 mEq/L	400 mEq

^aFor potassium, 1 mEq = 1 mmol.

with concurrent acidosis, potassium is often given as the acetate salt, given that acetate is metabolized to bicarbonate. In the patient with depleted phosphorus and potassium, therapy with potassium phosphate is the natural choice.^{22,27,28}

Hyperkalemia is defined as a serum potassium concentration greater than 5 mEq/L (5 mmol/L). Manifestations of hyperkalemia include muscle weakness, paresthesias, hypotension, ECG changes (e.g., peaked T waves, shortened QT intervals, and wide QRS complexes), cardiac arrhythmias, and a decreased pH. Causes of hyperkalemia fall into three broad categories: (a) increased potassium intake, (b) decreased potassium excretion, and (c) potassium release from the intracellular space.

Increased potassium intake results from excessive dietary potassium (salt substitutes), excess potassium in IV fluids, and other select medications (potassium-sparing diuretics, cyclosporine [available as generic], angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory agents, pentamidine [available as generic], unfractionated heparin, and low molecular weight heparins). Decreased potassium excretion results from acute renal failure, chronic renal failure, or Addison's disease. Excess potassium release from cells results from tissue breakdown (surgery, trauma, hemolysis, or rhabdomyolysis), blood transfusions, and metabolic acidosis.

In addition to discontinuing all potassium supplements, potassium-sparing medications, and potassium-rich salt substitutes, management of hyperkalemia addresses three concurrent strategies: (a) agents to antagonize the proarrhythmic effects of hyperkalemia, (b) agents to drive potassium into the intracellular space and acutely lower the serum potassium, and (c) agents that will definitively (but more gradually) lower the total body potassium content.²⁹ If the serum potassium concentration is greater than 7 mEq/L (7 mmol/L) and/or ECG changes are present, IV calcium is provided to stabilize the myocardium. Depending on the acuity of the situation, 1 g of calcium chloride (13.5 mEq or 6.75 mmol) is administered by direct injection or diluted in 50 mL of D₅W and delivered IV over 15 minutes. Clinical effects are seen within 1 to 2 minutes of infusion and persist for 10 to 30 minutes. Repeat doses may be administered as necessary. Because most patients with clinically significant hyperkalemia receive multiple boluses of calcium directed by ECG findings, iatrogenic hypercalcemia is a potential complication of hyperkalemia treatment. As such, total calcium concentration is commonly checked with each potassium concentration measurement. Ionized calcium measurements should be obtained in patients who have comorbid conditions that would lead to inconsistency between total serum calcium and free calcium (abnormal albumin, protein, or immunoglobulin concentrations).

Dextrose and insulin (with or without sodium bicarbonate) are typically given at the time of calcium therapy in order to redistribute potassium into the intracellular space. Dextrose 50% (25 g in 50 mL) can be given by slow IV push over 5 minutes or dextrose 10% with 20 units of regular insulin can be given by continuous IV infusion over 1 to 2 hours. The onset of action for this combination is 30 minutes; the

duration of clinical effects is 2 to 6 hours. High-dose inhaled β_2 -agonists (e.g., albuterol, available as generic) may also be used to acutely drive potassium into the intracellular space.

It is critically important to recognize that the treatments of hyperkalemia discussed thus far are transient, temporizing measures. They are intended to provide time to institute definitive therapy aimed at removing excess potassium from the body. Agents that increase potassium excretion from the body include sodium polystyrene sulfonate (Kayexalate, available as generic), loop diuretics, and hemodialysis or hemofiltration (used only in patients with renal failure). Sodium polystyrene sulfonate can be given orally, via NG tube, or as a rectal retention enema and is dosed at 15 to 60 g in four divided doses per day. In September 2009, MedWatch issued a safety alert that cases of colonic necrosis and other serious GI-adverse events (bleeding, ischemic colitis, perforation) had been reported in association with Kayexalate use. The majority of these cases reported the concurrent use of sorbitol. Concurrent administration of sorbitol is no longer recommended. Medication safety alerts are available at www.fda.gov/MedWatch.

Calcium

More than 99% of total body calcium is found in bone; the remaining less than 1% is in the ECF and ICF. Calcium plays a critical role in the transmission of nerve impulses, skeletal muscle contraction, myocardial contractions, maintenance of normal cellular permeability, and the formation of bones and teeth. There is a reciprocal relationship between the serum calcium concentration (normally 8.6 to 10.2 mg/dL [2.15 to 2.55 mmol/L]) and the serum phosphate concentration that is regulated by a complex interaction between parathyroid hormone, vitamin D, and calcitonin. About one-half of the serum calcium is bound to plasma proteins; the other half is free ionized calcium. Given that the serum calcium has significant protein binding, the serum calcium measurement must be corrected in patients who have low albumin concentrations (the major serum protein). The most commonly used formula adds 0.8 mg/dL (0.2 mmol/L) of calcium for each gram of albumin deficiency as follows:

$$\begin{aligned} \bullet \text{ Corrected [Ca mg/dL]} &= \\ & \text{Measured [Ca mg/dL]} \\ & + [0.8 \quad (4 - \text{measured albumin g/dL})]^{30-32} \end{aligned}$$

$$\begin{aligned} \bullet \text{ Corrected [Ca mmol/L]} &= \\ & \text{Measured [Ca mmol/L]} \\ & + [0.02 \quad (40 - \text{measured albumin g/L})] \end{aligned}$$

• Hypocalcemia is caused by inadequate intake (vitamin deficiency, poor dietary calcium sources, alcoholism) or excessive losses (hypoparathyroidism, renal failure, alkalosis, pancreatitis). Clinical manifestations of hypocalcemia are seen with total serum concentrations less than 6.5 mg/dL (1.63 mmol/L) or an ionized calcium less than 1.12 mmol/L and include tetany, circumoral tingling, muscle spasms, hypoactive reflexes, anxiety, hallucinations, hypotension, myocardial infarction, seizures, lethargy, stupor, and Trousseau's sign or Chvostek's sign.^{24,33} **Trousseau's sign** is

elicited by inflating a BP cuff on the patient's upper arm, whereby hypocalcemic patients will experience tetany of the wrist and hand as evidenced by thumb adduction, wrist flexion, and metacarpophalangeal joint flexion. **Chvostek's sign** is elicited by tapping on the proximal distribution of the facial nerve (adjacent to the ear). This will produce a brief spasm of the upper lip, eye, nose, or face in hypocalcemic patients. Ionized calcium concentrations are typically used to assess calcium status in the critically ill patient.

- Causes of hypocalcemia include hypoparathyroidism, hypomagnesemia, alcoholism, hyperphosphatemia, blood product infusion (due to chelation by the citrate buffers), chronic renal failure, vitamin D deficiency, acute pancreatitis, alkalosis, and hypoalbuminemia. In the setting of hypocalcemia, magnesium concentration should be checked and corrected if low. Given that hypocalcemia may be caused by hypomagnesemia, clinicians should be aware that the serum calcium concentrations may not normalize until serum magnesium is replaced. Medications that cause hypocalcemia include phosphate replacement products, loop diuretics, phenytoin (Dilantin, available as generic), phenobarbital (available as generic), corticosteroids, aminoglycoside antibiotics, and acetazolamide (available as generic).³⁴⁻³⁶

Oral calcium replacement products include calcium carbonate (Os-Cal [GlaxoSmithKline] and various generics; Tums [GlaxoSmithKline] and various generics) and calcium citrate (CitraCal [Mission Bayer] and various generics). IV calcium replacement products include calcium gluconate and calcium chloride (both products available as generic).

- 7** Calcium gluconate is preferred for peripheral use because it is less irritating to the veins; it may also be given intramuscularly. Each 10 mL of a 10% calcium gluconate solution provides 90 mg (4.5 mEq or 2.25 mmol) of elemental calcium.

- 7** Calcium chloride is associated with more venous irritation and extravasation and is generally reserved for administration via central line. Each 10 mL of a 10% calcium chloride solution contains 270 mg (13.5 mEq or 6.75 mmol) of elemental calcium. IV calcium products are given as a slow push or added to 500 to 1,000 mL of 0.9% normal saline for slow infusion.^{33,36} In addition to hypocalcemia, IV calcium may also be used for massive blood transfusions, calcium channel blocker overdose, and emergent hyperkalemia and hypermagnesemia.

- For acute symptomatic hypocalcemia, 200 to 300 mg of elemental calcium is administered IV and repeated until symptoms are fully controlled. This is achieved by infusing 1 g of calcium chloride or 2 to 3 g of calcium gluconate at a rate no faster than 30 to 60 mg of elemental calcium per minute. More rapid administration is associated with hypotension, bradycardia, or cardiac asystole. Total calcium concentration is commonly monitored in critically ill patients. Under normal circumstances, about half of calcium is loosely bound to serum proteins while the other half is free. Total calcium concentration measures bound and free calcium.

- Ionized calcium measures free calcium only. Under usual circumstances, a normal calcium concentration implies a normal

free ionized calcium concentration. Ionized calcium should be obtained in patients with comorbid conditions that would lead to inconsistency between total calcium and free serum calcium (abnormal albumin, protein, or immunoglobulin concentrations). For chronic asymptomatic hypocalcemia, oral calcium supplements are given at doses of 2 to 4 g/day of elemental calcium. Many patients with calcium deficiency have concurrent vitamin D deficiency that must also be corrected in order to restore calcium homeostasis.^{2,33,37}

Hypercalcemia is defined as a calcium concentration greater than 10.2 mg/dL (2.55 mmol/L). It may be categorized as mild if total serum calcium is 10.3 to 12 mg/dL (2.58 to 3.00 mmol/L), moderate if total serum calcium is 12.1 to 13 mg/dL (3.03 to 3.25 mmol/L), or severe when serum concentration is greater than 13 mg/dL (3.25 mmol/L). Causes of hypercalcemia include hyperparathyroidism, malignancy, Paget's disease, Addison's disease, granulomatous diseases (e.g., tuberculosis, sarcoidosis, or histoplasmosis), hyperthyroidism, immobilization, multiple bony fractures, acidosis, and milk-alkali syndrome. Multiple medications cause hypercalcemia and include thiazide diuretics, estrogens, lithium (available as generic), tamoxifen (Nolvadex, available as generic), vitamin A, vitamin D, and calcium supplements.^{2,33,36,37}

- Because the severity of symptoms and the absolute serum concentration are poorly correlated in some patients, institution of therapy should be dictated by the clinical scenario. All patients with hypercalcemia should be treated with aggressive rehydration: normal saline at 200 to 300 mL/h is a routine initial fluid prescription. For patients with mild hypercalcemia, hydration alone may provide adequate therapy. The moderate and severe forms of hypercalcemia are more likely to have significant manifestations and require prompt initiation of additional therapy. These patients may present with anorexia, confusion, and/or cardiac manifestations (bradycardia and arrhythmias with ECG changes). Total calcium concentrations greater than 13 mg/dL (3.25 mmol/L) are particularly worrisome because these concentrations can unexpectedly precipitate acute renal failure, ventricular arrhythmias, and sudden death.

- Once fluid administration has repleted the ECF, forced diuresis (with associated calcium loss) can be initiated with a loop diuretic. For this approach to be successful, normal kidney function is required. In renal failure patients, the alternative therapy is emergent hemodialysis. Other treatment options include bisphosphonates (zoledronic acid [Zometa, Novartis], pamidronate [Aredia, available as generic]), hydrocortisone (available as generic), calcitonin, and gallium. Given their efficacy and favorable side-effect profile, bisphosphonates are typically the agents of choice. **Table 27-9** outlines the treatment options for hypercalcemia including time to onset of effect, duration of effect, and efficacy.^{2,33,34,37}

Phosphorus

Phosphorus is primarily found in the bone (80% to 85%) and ICF (15% to 20%); the remaining less than 1% is found in the

Table 27-9

Selected Treatment Options for the Management of Hypercalcemia

Therapy	Dose	Onset	Duration	Efficacy ^a
Normal saline	3–6 L/day	Hours	Hours	1–2 mg/dL (0.25–0.50 mmol/L)
Furosemide (Lasix, available as generic)	80–160 mg/day	Hours	Hours	1–2 mg/dL (0.25–0.50 mmol/L)
Hydrocortisone (available as generic)	200 mg/day	Hours	Days	Mild/unpredictable
Calcitonin (Miacalcin, Novartis)	4–8 units/kg	Hours	Hours	1–2 mg/dL (0.25–0.50 mmol/L)
Pamidronate (Aredia, available as generic)	30–90 mg/week	Days	1–4 weeks	1–5 mg/dL (0.25–1.25 mmol/L)
Zoledronic acid (Zometa, Novartis)	4–8 mg	Days	Weeks	1–5 mg/dL (0.25–1.25 mmol/L)
Gallium (Ganite, Genta Inc.)	200 mg/m ²	Days	Days–weeks	1–5 mg/dL (0.25–1.25 mmol/L)

^aExpected decrease in serum Ca²⁺.

ECF. Note that phosphorus is the major anion within the cells. Given this distribution, serum phosphate concentration does not accurately reflect total body phosphorus stores. Phosphorus is expressed in milligrams (mg) or millimoles (mmol), not as milliequivalents (mEq). Because phosphorus is the source of phosphate for adenosine triphosphate (ATP) and phospholipid synthesis, manifestations of phosphorus imbalance are variable.

Dietary intake, parathyroid hormone levels, and renal function are the major determinants of the serum phosphorus concentration, which is normally 2.7 to 4.5 mg/dL (0.87 to 1.45 mmol/L).^{2,33,39,40} Hypophosphatemia is defined by a serum phosphorus concentration less than 2.5 mg/dL (0.81 mmol/L); severe hypophosphatemia occurs when the phosphorus concentration is less than 1 mg/dL (0.32 mmol/L). Hypophosphatemia can be caused by increased distribution to the ICF (hyperglycemia, insulin therapy, or malnourishment), decreased absorption (starvation, excessive use of phosphorus-binding antacids, vitamin D deficiency, diarrhea, or laxative abuse) or increased renal loss (diuretic use, diabetic ketoacidosis, alcohol abuse, hyperparathyroidism, or burns).^{35,37} **8** *Severe hypophosphatemia can result in impaired diaphragmatic contractility and acute respiratory failure.* Medications that cause hypophosphatemia include diuretics (acetazolamide [Diamox, available as generic], furosemide [Lasix, available as generic], hydrochlorothiazide [HydroDIURIL, available as generic]), sucralfate (Carafate, available as generic), corticosteroids, cisplatin (available as generic), antacids (aluminum carbonate, calcium carbonate, and magnesium

oxide [antacids all available as generic]), foscarnet (available as generic), phenytoin (Dilantin, available as generic), phenobarbital (available as generic), and phosphate binders (sevelamer [Renvela, Genzyme Corp.], and calcium acetate [PhosLo, available as generic]).

Signs and symptoms of hypophosphatemia include paresthesias, muscle weakness, myalgias, bone pain, anorexia, nausea, vomiting, red blood cell breakdown (hemolysis), acute respiratory failure, seizures, and coma.^{37,41} For mild hypophosphatemia, patients should be encouraged to eat a high-phosphorus diet including eggs, nuts, whole grains, meat, fish, poultry, and milk products. For moderate hypophosphatemia (1 to 2.5 mg/dL, 0.32 to 0.81 mmol/L), oral supplementation of 1.5 to 2 g/day (30 to 60 mmol/day) is usually adequate. Diarrhea may be a dose-limiting side effect with oral phosphate replacement products.

Injectable phosphate products are reserved for patients with severe hypophosphatemia or those in the intensive care unit.⁴² The available agents are provided as sodium or potassium salts; however, unless concurrent hypokalemia is present, sodium phosphate is usually used. Empirically, for a mild serum phosphorus deficiency (2.3 to 3.0 mg/dL, 0.74 to 0.97 mmol/L), the corresponding IV phosphorus dose is 0.32 mmol/kg; for a moderate deficiency of serum phosphorus 1.6 to 2.2 mg/dL (0.52 to 0.71 mmol/L), the replacement dose is 0.64 mmol/kg; and the dose is 1 mmol/kg when the serum phosphorus is less than 1.5 mg/dL (0.48 mmol/L).³⁶ IV phosphorus preparations are usually infused over 4 to 12 hours. **Table 27-10** compares the available phosphate replacement products.

Table 27-10

Phosphate Replacement Products

Product	Route	mgPO ₄ ⁻	mmolPO ₄ ⁻	mEq (mmol) Na ⁺	mEq (mmol) K ⁺
Potassium phosphate (KPO ₄ /mL), available as generic	IV	94	3	0	4.4
Sodium phosphate (NaPO ₄ /mL), available as generic	IV	94	3	4	0
Phos-NaK packets	Oral	250	8	7.2	7
K-Phos Neutral Tablets, Beach	Oral	250	8	13.1	1.4
Uro-KP-Neutral tablets, Star	Oral	250	8	10.9	1.27

Hyperphosphatemia is defined by a serum phosphorus concentration greater than 4.5 mg/dL (1.45 mmol/L). The manifestations of hyperphosphatemia are similar to findings of hypocalcemia (see earlier), and include paresthesias, ECG changes (prolonged QT interval and prolonged ST segment), and metastatic calcifications. Causes of hyperphosphatemia include impaired phosphorus excretion (hypoparathyroidism or renal failure), redistribution of phosphorus to the ECF (acid–base imbalance, rhabdomyolysis, muscle necrosis, or tumor lysis during chemotherapy), and increased phosphorus intake (various medications).³⁷ Medications that can cause hyperphosphatemia include enemas containing phosphorus (e.g., Fleet, Fleet), laxatives containing phosphate or phosphorus, parenteral or oral supplements (e.g., K-Phos Neutral, Beach), vitamin D supplements, and the bisphosphonates (e.g., pamidronate, various manufacturers).⁴³

Hyperphosphatemia is generally benign and rarely needs aggressive therapy. Dietary restriction of phosphate and protein is effective for most minor elevations. Phosphate binders such as aluminum-based antacids, calcium carbonate, calcium acetate (PhosLo, available as generic), sevelamer (Renvela, Genzyme), and lanthanum carbonate (Fosrenol, Shire) may be necessary for some patients (typically those with chronic renal failure).⁴⁹ If patients exhibit findings of hypocalcemia (tetany), IV calcium should be administered empirically.

Magnesium

The body's normal daily magnesium requirement is 300 to 350 mg/day to maintain a serum magnesium concentration of 1.5 to 2.4 mEq/L (0.75 to 1.20 mmol/L). Because magnesium is the second most abundant ICF cation, serum concentrations are a relatively poor measure of total body stores. Magnesium catalyzes and/or activates more than 300 enzymes, provides neuromuscular stability, and is involved in myocardial contraction. Magnesium is generally not part of standard chemistry panels and therefore must be ordered separately.^{2,33,43–45}

Hypomagnesemia is defined as a serum magnesium less than 1.5 mEq/L (0.75 mmol/L) and is most frequently seen in the intensive care and postoperative settings. Hypomagnesemia results from inadequate intake (alcoholism, dietary restriction, or inadequate magnesium in total parenteral nutrition [TPN]), inadequate absorption (steatorrhea, cancer, malabsorption syndromes, or excess calcium or phosphorus in the GI tract), excessive GI loss of magnesium (diarrhea, laxative abuse, NG tube suctioning, or acute pancreatitis), or excessive urinary loss of magnesium (primary hyperaldosteronism, certain medications, diabetic ketoacidosis, and renal disorders). Hypomagnesemia often occurs in the setting of hypokalemia and hypocalcemia. Clinicians should evaluate the magnesium concentration in these patients and correct if low. In order for calcium and potassium concentrations to normalize, magnesium supplementation is often required. Medications that

potentially can cause hypomagnesemia include aminoglycoside antibiotics, amphotericin B (available as generic), cisplatin (available as generic), insulin, cyclosporine (available as generic), loop diuretics, and thiazide diuretics. There is also a strong correlation between hypokalemia and hypomagnesemia.^{37,38,43,46} Clinicians should be alerted that the long-term use of proton pump inhibitors may be associated with unexplained hypomagnesemia, with subsequent hypokalemia or hypocalcemia.

The findings of hypomagnesemia include muscle weakness, cramps, agitation, confusion, tremor, seizures, ECG changes (increased PR interval, prolonged QRS complex, and increased QT interval), findings of hypocalcemia (see earlier), refractory hypokalemia (see earlier), metabolic alkalosis, and digoxin toxicity.^{43,47,48}

Asymptomatic mild magnesium deficiencies (1.0 to 1.5 mEq/L) (0.50 to 0.75 mmol/L) can be managed with increased oral intake of magnesium-containing foods or with oral supplementation. Magnesium oxide (Mag-Ox, Blaine Pharmaceuticals and various manufacturers) 400-mg tablets contain 241 mg (20 mEq or 10 mmol) of magnesium, and magnesium chloride hexahydrate tablets (Slow-Mag, Purdue) contains 64 mg of elemental magnesium. Diarrhea is often a dose-limiting side effect of oral supplementation. Severely deficient patients (less than 1.0 mEq/L) (0.50 mmol/L) and all deficient critically ill patients should be managed with IV magnesium sulfate. Ten milliliters of a 10% magnesium sulfate solution contains 1 g of magnesium, which is equivalent to 98 mg (8.12 mEq or 4.06 mmol) of elemental magnesium. IV magnesium supplementation may also be used in the setting of status asthmaticus, premature labor, and torsade de pointes. Magnesium concentrations need to be monitored closely in these patients. **9** *Because magnesium concentration does not correlate well with total body magnesium stores, magnesium is often administered empirically to critically ill patients.*^{2,33}

The most common causes of hypermagnesemia are renal failure, often in conjunction with magnesium-containing medications (cathartics, antacids, or magnesium supplements), and lithium therapy (available as generic). Hypermagnesemia is defined as a serum magnesium concentration greater than 2.4 mEq/L (1.20 mmol/L). Mild hypermagnesemia is present if the serum magnesium concentration is between 2.5 and 4 mEq/L (1.25 to 2.00 mmol/L) and manifests as nausea, vomiting, cutaneous vasodilation, and bradycardia. Moderate hypermagnesemia is present if the serum magnesium concentration is between 4 and 12 mEq/L (2 to 6 mmol/L) and may manifest with hyporeflexia, weakness, somnolence, hypotension, and ECG changes (increased QRS interval). Severe hypermagnesemia is present if the serum magnesium concentration is greater than 13 mEq/L (6.5 mmol/L) and can manifest as muscle paralysis, complete heart block, asystole, respiratory failure, refractory hypotension, and death.^{2,50}

All patients with hypermagnesemia should have all magnesium supplements or magnesium-containing medications discontinued.^{2,33} Iatrogenic hypermagnesemia has been observed after IV magnesium therapy for refractory asthma

or preeclampsia. Mild hypermagnesemia and moderate hypermagnesemia without cardiac findings can be treated with normal saline infusion and furosemide therapy (assuming the patient has normal renal function). Moderate hypermagnesemia with cardiac irritability and severe hypermagnesemia require concurrent IV calcium gluconate to reverse the neuromuscular and cardiovascular effects. Calcium gluconate given at typical doses of 1 to 2 g IV will have transient effects and can be repeated as clinically indicated. Hemodialysis may be necessary for those with severely compromised renal function.

Patient Encounter 8: Putting It All Together

DM, a 77-year-old male nursing home resident, is admitted to the hospital with a 3-day history of altered mental status. The patient was unable to give a history or review of systems. On physical examination, the vital signs revealed a BP of 100/60 mm Hg, pulse 110 beats per minute, respirations 14 per minute, and a temperature of 38.3°C (101°F). Rales and dullness to percussion were noted at the posterior right base. The cardiac examination was significant for tachycardia. No edema was present. Laboratory studies included sodium 160 mEq/L (160 mmol/L), potassium 4.6 mEq/L (4.6 mmol/L), chloride 120 mEq/L (120 mmol/L), bicarbonate 30 mEq/L (30 mmol/L), glucose 104 mg/dL (5.8 mmol/L), BUN 34 mg/dL (12.1 mmol/L), and creatinine 2.2 mg/dL (194 μmol/L). The CBC was within normal limits. Chest x-ray indicated a right lower lobe pneumonia. The patient is 5 ft 10 in. (178 cm) tall and currently weighs 72.7 kg (160 lb). His normal weight is 77.3 kg (170 lb).

What are the likely causes for the increased sodium concentration in this patient?

Calculate the TBW, ICF, and ECF for this patient.

Calculate DM's fluid deficit if one is present.

In the next 24 hours, the medical team wants to replace 50% of the fluid deficit plus an extra 240 mL to account for increased insensible losses in addition to the patient's maintenance needs. Using the equation (1,500 mL + 20 mL for each kilogram greater than 20 kg), calculate the rate of fluid administration for the total fluids needed in this 24-hour period and over the next 48 hours.

Calculate DM's daily maintenance fluids.

Calculate DM's fluid administration rate for the first 24 hours (hospital day 1).

Calculate DM's fluids for the subsequent 48 hours (hospital days 2 and 3) if the goal is to replete the remaining fluid deficit during that time.

What type of fluid should be used to treat DM's fluid disorder?

CONCLUSION

Because disturbances in fluid balance are routinely encountered in clinical medicine, it is essential to have a thorough understanding of body fluid compartments and the therapeutic use of fluids. Similarly, disturbances in serum sodium, potassium, calcium, phosphorus, and magnesium are ubiquitous and must be mastered by all clinicians. Dysregulation of fluid and/or electrolyte status has serious implications regarding the concepts of drug absorption, volumes of distribution, and toxicity. Similarly, many medications can disrupt fluid and/or electrolyte balance as an unintended consequence.

Abbreviations Introduced in This Chapter

ADH	Antidiuretic hormone
ASHP	American Society of Health-System Pharmacists
ATP	Adenosine triphosphate
BP	Blood pressure
BUN	Blood urea nitrogen
Ca ⁺⁺	Calcium
CHF	Congestive heart failure
Cl	Chloride
D5W	Dextrose 5% water
ECF	Extracellular fluid
ECG	Electrocardiogram
FFP	Fresh-frozen plasma
IBW	Ideal body weight
ICF	Intracellular fluid
IVIG	Intravenous immune globulin
I&Os	Ins and outs
JCAHO	Joint Commission on Accreditation of Healthcare Organizations
K ⁺	Potassium
KPO ⁴	Potassium phosphate
KVO	Keep the vein open
LR	Lactated Ringer's (solution)
Mg ⁺⁺	Magnesium
Na ⁺	Sodium
NaCl	Sodium chloride
NaPO ⁴	Sodium phosphate
NG	Nasogastric
NS	Normal saline
SI	Standardized international units
SIADH	Syndrome of inappropriate antidiuretic hormone secretion
TBW	Total body water
TPN	Total parenteral nutrition

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Acid–Base Disturbances

Lee E. Morrow and Mark A. Malesker

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Compare and contrast the four primary acid–base disturbances within the human body.
2. Apply simple formulas in a systematic manner to determine the etiology of simple acid–base disturbances and the adequacy of compensation.
3. Integrate the supplemental concepts of the anion gap and the excess gap to further assess for complex acid–base disturbances.
4. Discuss the most common clinical causes for each primary acid–base abnormality.
5. Describe the potential clinical complications of altered acid–base homeostasis.
6. Propose an appropriate treatment plan for patients with deranged acid–base physiology.

KEY CONCEPTS

- 1 Acid–base homeostasis is tightly regulated by the complex, but predictable, interactions of the kidneys, the lungs, and various buffer systems. The kidneys control serum bicarbonate (HCO_3^-) concentration through the excretion or reabsorption of filtered HCO_3^- , the excretion of metabolic acids, and synthesis of new HCO_3^- . The lungs control the arterial carbon dioxide (CO_2) concentration through changes in the depth and/or rate of respiration.
- 2 Respiratory acidosis and alkalosis result from primary disturbances in the arterial CO_2 concentration. Metabolic compensation of respiratory disturbances is a slow process, requiring days for the serum HCO_3^- to reach the steady state.
- 3 Respiratory acidosis is caused by respiratory insufficiency resulting in an increased arterial CO_2 concentration. The compensation for respiratory acidosis (if present for prolonged periods) is an increase in serum HCO_3^- .
- 4 Respiratory alkalosis is caused by hyperventilation resulting in a decreased arterial CO_2 concentration. The compensation for respiratory alkalosis (if present for prolonged periods) is a decrease in serum HCO_3^- .
- 5 Metabolic acidosis and alkalosis result from primary disturbances in the serum HCO_3^- concentration. Respiratory compensation of metabolic disturbances begins within minutes and is complete within 12 hours.
- 6 Metabolic acidosis is characterized by a decrease in serum HCO_3^- . The anion gap is used to narrow the differential diagnosis because metabolic acidosis may be caused by addition of acids (increased anion gap) or loss of HCO_3^- (normal anion gap). The compensation for metabolic acidosis is an increase in ventilation with a decrease in arterial CO_2 .
- 7 Metabolic alkalosis is characterized by an increase in serum HCO_3^- . This disorder requires loss of fluid that is low in HCO_3^- from the body or addition of HCO_3^- to the body. The compensation for metabolic alkalosis is a decrease in ventilation with an increase in arterial CO_2 .
- 8 Arterial blood gases, serum electrolytes, physical examination findings, the clinical history, and the patient's recent medications must be reviewed in order to establish the etiology of a given acid–base disturbance.
- 9 It is critical to treat the underlying causative process to effectively resolve most observed acid–base disorders. However, supportive treatment of the pH and electrolytes is often needed until the underlying disease state is improved.

Given its reputation for complexity and the need to memorize innumerable formulas, acid–base analysis intimidates many healthcare providers. In reality, acid–base disorders always obey well-defined biochemical and physiological principles. The pH determines a patient's acid–base status and an assessment of the bicarbonate (HCO_3^-)

and arterial carbon dioxide (P_{aCO_2}) values identifies the underlying process. Rigorous use of a systematic approach to arterial blood gases increases the likelihood that derangements in acid–base physiology are recognized and correctly interpreted. This chapter outlines a clinically useful approach to acid–base abnormalities and then applies this approach in a series of increasingly complex clinical scenarios.

Disturbances of acid–base equilibrium occur in a wide variety of illnesses and are among the most frequently encountered disorders in critical care medicine. The importance of a thorough command of this content cannot be overstated given that acid–base disorders are remarkably common and may result in significant morbidity and mortality. Although severe derangements may affect virtually any organ system, the most serious clinical effects are cardiovascular (arrhythmias and impaired contractility), neurologic (coma and seizures), pulmonary (dyspnea, impaired oxygen delivery, respiratory fatigue, and respiratory failure), and/or renal (hypokalemia). Changes in acid–base status also affect multiple aspects of pharmacokinetics (clearance and protein binding) and pharmacodynamics.

ACID–BASE HOMEOSTASIS

Acid–base homeostasis is responsible for maintaining blood hydrogen ion concentration $[H^+]$ near normal despite the daily acidic and/or alkaline loads derived from the intake and metabolism of foods. Acid–base status is traditionally represented in terms of pH, the negative logarithm of $[H^+]$. Because $[H^+]$ is equal to 24 times the ratio of P_{aCO_2} to HCO_3^- , the pH can be altered by a change in either the bicarbonate concentration or the dissolved carbon dioxide. A critically important concept is that $[H^+]$ depends only on the ratio of P_{aCO_2} to HCO_3^- and not the absolute amount of either. As such, a normal P_{aCO_2} or HCO_3^- alone does not guarantee that the pH will be normal. Conversely, a normal pH does not imply that either the P_{aCO_2} or HCO_3^- will be normal.¹

① *Acid–base homeostasis is tightly regulated by the complex, but predictable, interactions of the kidneys, the lungs, and various buffer systems. The kidneys control serum bicarbonate (HCO_3^-) concentration through the excretion or reabsorption of filtered HCO_3^- , the excretion of metabolic acids, and synthesis of new HCO_3^- . The lungs control arterial carbon dioxide (CO_2) concentrations through changes in the depth and/or rate of respiration. The net result is tight regulation of the blood pH by these three distinct mechanisms working in harmony: extracellular bicarbonate and intracellular protein buffering systems; pulmonary regulation of P_{aCO_2} , effectively allowing carbonic acid to be eliminated by the lungs as CO_2 ; and renal reclamation or excretion of HCO_3^- and excretion of acids such as ammonium.*

Because the kidneys excrete less than 1% of the estimated 13,000 mEq (13,000 mmol) of H^+ ions generated in an average day, renal failure can be present for prolonged periods before life-threatening imbalances occur. Conversely, cessation of breathing for minutes results in profound acid–base disturbances.¹

The best way to assess a patient's acid–base status is to review the results of an arterial blood gas (ABG) specimen.

Blood gas analyzers directly measure the pH and P_{aCO_2} , while the HCO_3^- value is calculated using the Henderson-Hasselbalch equation. A more direct measure of serum HCO_3^- is obtained by measuring the total venous carbon dioxide (tCO_2). Because dissolved carbon dioxide is almost exclusively in the form of HCO_3^- , tCO_2 is essentially equivalent to the measured serum HCO_3^- concentration. This value (HCO_3^-) is routinely reported on basic chemistry panels. In the remainder of this chapter, the pH and P_{aCO_2} values should be assumed to come from an ABG while HCO_3^- values should be considered to be measured serum concentrations.

BASIC PATHOPHYSIOLOGY

Under normal circumstances, the arterial pH is tightly regulated between 7.35 and 7.45. **Acidemia** is an abnormally low arterial blood pH (less than 7.35) while acidosis is a pathologic process that acidifies body fluids. Similarly, **alkalemia** is an abnormally high arterial blood pH (greater than 7.45) while **alkalosis** is a pathologic process that alkalizes body fluids. As such, although a patient can simultaneously have acidosis and alkalosis, the end result will be acidemia or alkalemia.

Changes in the arterial pH are driven by changes in the P_{aCO_2} and/or the serum HCO_3^- . Carbon dioxide is a volatile acid regulated by the depth and rate of respiration. Because CO_2 can be either “blown off” or “retained” by the respiratory system, it is referred to as being under respiratory control. ② *Respiratory acidosis and alkalosis result from primary disturbances in the arterial CO_2 concentration. Metabolic compensation of respiratory disturbances is a slow process, often requiring days for the serum HCO_3^- to reach the steady state.* ③ *Respiratory acidosis is caused by respiratory insufficiency resulting in an increased arterial CO_2 concentration. The compensation for respiratory acidosis (if present for prolonged periods) is an increase in serum HCO_3^- .* ④ *Respiratory alkalosis is caused by hyperventilation resulting in a decreased arterial CO_2 concentration. The compensation for respiratory alkalosis (if present for prolonged periods) is a decrease in serum HCO_3^- .*

A respiratory acid–base disorder is a pH disturbance caused by pathologic alterations of the respiratory system or its CNS control. Such an alteration may result in the accumulation of P_{aCO_2} beyond normal limits (greater than 45 mm Hg or 6.0 kPa), a situation termed *respiratory acidosis*, or it may result in the loss of P_{aCO_2} beyond normal limits (less than 35 mm Hg or 4.7 kPa), a condition termed *respiratory alkalosis*. Variations in respiratory rate and/or depth allow the lungs to achieve changes in the P_{aCO_2} very quickly (within minutes).

Bicarbonate is a base regulated by renal metabolism via the enzyme carbonic anhydrase. As such, bicarbonate is often referred to as being under metabolic control. ⑤ *Metabolic acidosis and alkalosis result from primary disturbances in the serum HCO_3^- concentration. Respiratory compensation of metabolic disturbances begins within minutes and is complete within 12 hours.* ⑥ *Metabolic acidosis is characterized by a*

decrease in serum HCO_3^- . The anion gap is used to narrow the differential diagnosis because metabolic acidosis may be caused by addition of acids (increased anion gap) or loss of HCO_3^- (normal anion gap). The compensation for metabolic acidosis is an increase in ventilation with a decrease in arterial CO_2 . **7 Metabolic alkalosis** is characterized by an increase in serum HCO_3^- . This disorder requires loss of fluid that is low in HCO_3^- from the body or addition of HCO_3^- to the body. The compensation for metabolic alkalosis is a decrease in ventilation with an increase in arterial CO_2 .

A metabolic acid–base disorder is a pH disturbance caused by derangement of the pathways responsible for maintaining a normal HCO_3^- concentration. This may result in a pathologic accumulation of HCO_3^- (greater than 26 mEq/L or mmol/L), a condition termed *metabolic alkalosis*, or it may result in the loss of HCO_3^- beyond normal (less than 22 mEq/L or mmol/L), a condition termed *metabolic acidosis*. In contrast to the lungs' rapid effects on CO_2 , the kidneys change the HCO_3^- very slowly (hours to days).

Respiratory and metabolic derangements can occur in isolation or in combination. If a patient has an isolated primary acid–base disorder that is not accompanied by another primary acid–base disorder, a **simple (uncomplicated) disorder** is present. The most common clinical disturbances are simple acid–base disorders. If two or three primary acid–base disorders are simultaneously present, the patient has a **mixed (complicated) disorder**. More complex clinical situations lead to mixed acid–base disturbances. Because CO_2 is a volatile acid, it can rapidly be changed by the respiratory system. If a respiratory acid–base disturbance is present for minutes to hours, it is considered an **acute disorder**, while if it is present for days or longer it is considered a **chronic disorder**. By definition, the metabolic machinery that regulates HCO_3^- results in slow changes, and all metabolic disorders are chronic.

Changes that follow the primary disorder and attempt to restore the blood pH to normal are referred to as compensatory changes. It should be stressed that compensation never normalizes the pH. Because all metabolic acid–base disorders are chronic and the normal respiratory system can quickly alter the Paco_2 , essentially all metabolic disorders are accompanied by some degree of respiratory compensation.^{2,3} Similarly, chronic respiratory acid–base disorders are typically accompanied by attempts at metabolic compensation.^{4,5} However, with acute respiratory acid–base disorders there is insufficient time for the metabolic pathways to compensate significantly.⁶ As such, acute respiratory derangements are essentially uncompensated.

The amount of compensation (metabolic or respiratory) can be reliably predicted based on the degree of derangement in the primary disorder. **Table 28-1** outlines the simple acid–base disorders and provides formulas for calculating the expected compensatory responses.⁷ Although it is not mandatory to memorize these formulas in order to interpret acid–base problems, they can be helpful tools. If the measured values differ markedly from the calculated values (the measured serum HCO_3^- is greater than 2 mEq/L [2 mmol/L] from the calculated value or the measured Paco_2 is more than

Table 28-1**The Six Simple Acid–Base Disorders**

Type of Disorder	pH	Paco_2^a	HCO_3^-
1. Metabolic acidosis	↓	Decreased ^b $\text{Paco}_2 = (1.5 \times \text{HCO}_3^-) + 8$	Decreased ^c
2. Metabolic alkalosis	↑	Increased ^b $\text{Paco}_2 = (0.9 \times \text{HCO}_3^-) + 15$	Increased ^c
3. Acute respiratory acidosis	↓	Increased ^c	Approximately normal $\Delta\text{HCO}_3^- = 0.1 \times \Delta\text{Paco}_2^a$
4. Chronic respiratory acidosis	↓	Increased ^c	Increased ^d $\Delta\text{HCO}_3^- = 0.35 \times \Delta\text{Paco}_2^a$
5. Acute respiratory alkalosis	↑	Decreased ^c	Approximately normal $\Delta\text{HCO}_3^- = 0.2 \times \Delta\text{Paco}_2^a$
6. Chronic respiratory alkalosis	↓	Decreased ^c	Decreased ^d $\Delta\text{HCO}_3^- = 0.4 \times \Delta\text{Paco}_2^a$

^a Paco_2 in mm Hg.

^bMeasured HCO_3^- more than 2 mEq/L (mmol/L) from the calculated value.

4 mm Hg [0.5 kPa] from the calculated value), a second acid–base disorder is present as outlined in **Table 28-2**.

APPLICATION OF BASIC PATHOPHYSIOLOGY

When given an ABG for interpretation, it is essential to use an approach that is focused yet comprehensive.⁸ An algorithm illustrating this concept is shown in **Figure 28-1**.

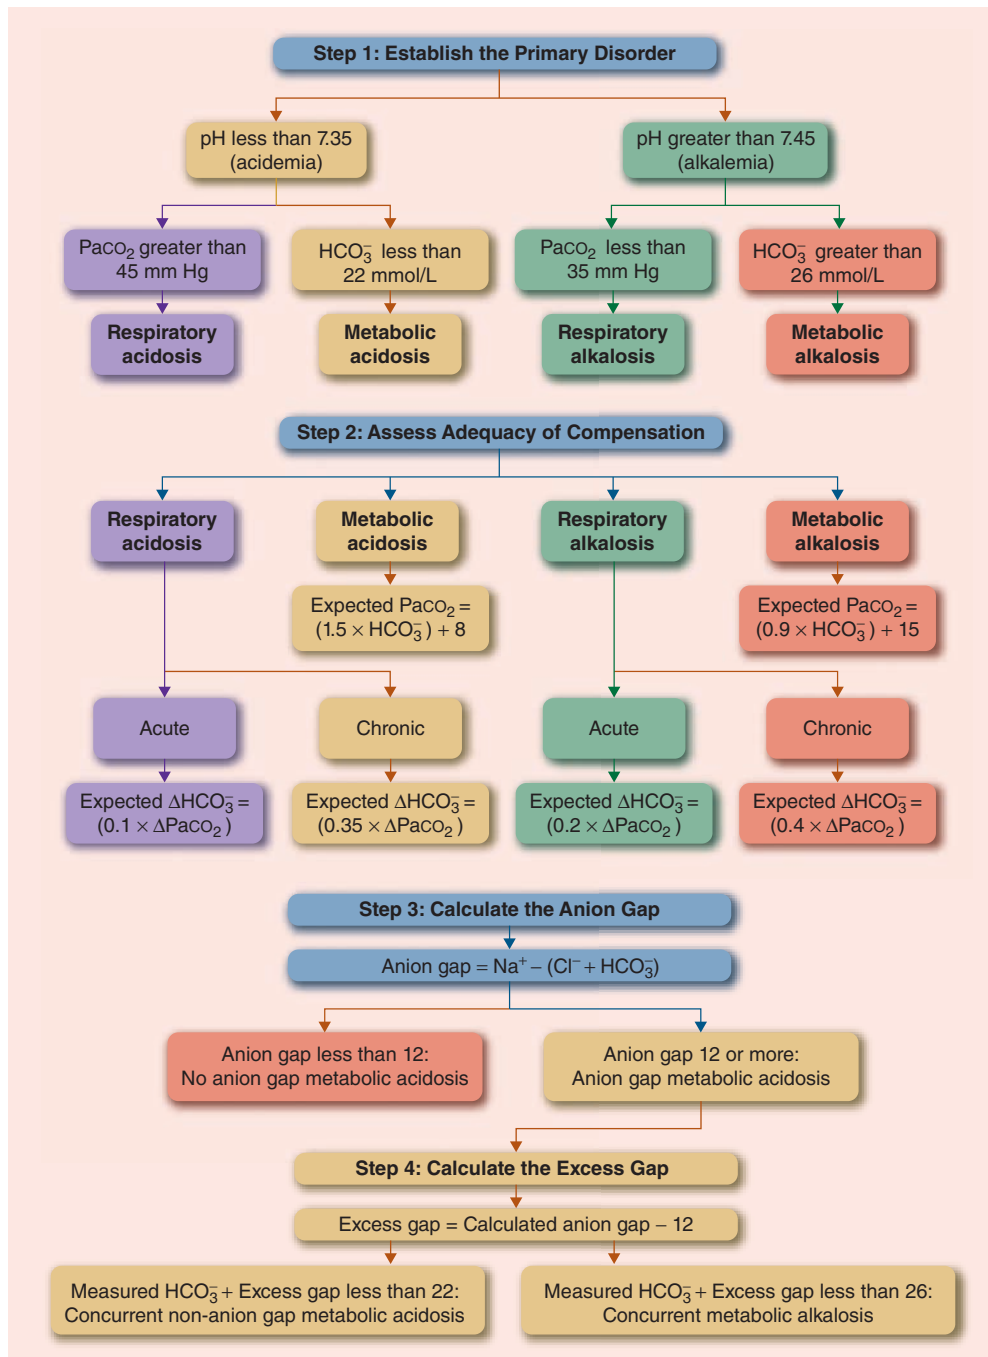

FIGURE 28-1. An algorithmic approach to acid–base disorders. Normal values: pH 7.35 to 7.45, Paco₂ 35 to 45 mm Hg (4.7 to 6.0 kPa), HCO₃⁻ 22 to 26 mEq/L (mmol/L), anion gap less than 12 mEq/L (mmol/L). Note that Paco₂ should be in millimeters of mercury to use the equations in the figure. (Cl⁻, chloride ion; HCO₃⁻, bicarbonate; Na⁺, sodium ion; Paco₂, partial pressure of arterial carbon dioxide.)

Using this algorithm, Step 1 is to identify all abnormalities in the pH, Paco₂, and/or HCO₃⁻ and then decide which abnormal values are primary and which are compensatory. This is best done by initially looking at the pH. Whichever side of 7.40 the pH is on, the process that caused it to shift to that side is the primary abnormality. If the arterial pH is lower than 7.40 (acidemia), an elevated Paco₂ (greater than 45 mm Hg or 6.0 kPa, **respiratory acidosis**) or a lowered HCO₃⁻ (less than 22 mEq/L or mmol/L, **metabolic acidosis**) would be the primary abnormality. If the arterial pH is higher than 7.40 (alkalemia), a decreased Paco₂ (less than 35 or 4.7 kPa, **respiratory alkalosis**) or an increased HCO₃⁻

(greater than 25 mEq/L or mmol/L, **metabolic alkalosis**) would be the primary abnormality. Once the primary disorder is established, step 2 is to apply the formulas from Table 28–1 to assess whether compensation is appropriate and to look for concurrent processes.⁷

An alternative to a diagnostic algorithm is use of a graphic nomogram.⁹ Nomograms are plots of the pH, Paco₂, and HCO₃⁻ that allow the user to rapidly determine whether arterial blood gas values are consistent with one of the six simple primary acid–base disturbances. Although nomograms are commonly used to identify acid–base disturbances in clinical practice, only individuals who

Patient Encounters 1 Through 5: Application of Basic Pathophysiology

Case Study 1

An unconscious 57-year-old man is brought to the emergency department by his wife who was unable to awaken him when she returned home from work. She discloses that he is on disability and has been taking “lots of pain pills” for his chronic low back pain. The initial ABG has a pH of 7.20, a Paco_2 of 65 mm Hg (8.6 kPa), and an HCO_3^- of 27 mEq/L (mmol/L).

What is the primary acid–base disorder?

Has compensation occurred?

Given the clinical history, what is the most likely explanation for the ABG findings?

Case Study 2

The next patient is a 69-year-old woman whose ongoing habit of smoking two packs of unfiltered cigarettes each day has led to advanced emphysema and the need for chronic oxygen therapy. During a routine office visit an ABG is checked to satisfy her insurance company’s requirements to certify her supplemental oxygen prescription. Her blood gas sample has a pH of 7.34, a Paco_2 of 65 mm Hg (8.6 kPa), and an HCO_3^- of 33 mEq/L (mmol/L).

What is the primary acid–base disorder?

Has compensation occurred?

Given the clinical history, what is the most likely explanation for the ABG findings?

Case Study 3

Now consider an otherwise healthy 80-year-old retired librarian. She has grown increasingly agitated because her pension check is late and the bank’s customer service representatives have been unable to assist her. She is

boisterous, breathless, and convinced the tingling in her lips is due to a stroke. Her ABG shows a pH of 7.50, a Paco_2 of 25 mm Hg (3.3 kPa), and an HCO_3^- of 21 mEq/L (mmol/L).

What is the primary acid–base disorder?

Has compensation occurred?

Given the clinical history, what is the most likely explanation for the ABG findings?

Case Study 4

This 55-year-old man has a history of viral myocarditis with cardiomyopathy: his subsequent chronic congestive heart failure requires daily furosemide therapy. When he presented to the emergency department with increasing dyspnea, an ABG was drawn and shows the following: pH of 7.50, a Paco_2 of 50 mm Hg (6.7 kPa), and an HCO_3^- of 40 mEq/L (mmol/L).

What is the primary acid–base disorder?

Has compensation occurred?

Given the clinical history, what is the most likely explanation for the ABG findings?

Case Study 5

The final patient in this section is a 44-year-old man with chronic renal insufficiency who has suffered from gastroenteritis with refractory diarrhea for the past 72 hours. His ABG shows a pH of 7.20, a Paco_2 of 20 mm Hg (2.7 kPa), and an HCO_3^- of 8 mEq/L (mmol/L).

What is the primary acid–base disorder?

Has compensation occurred?

Given the clinical history, what is the most likely explanation for the ABG findings?

fully comprehend the fundamental concepts of acid–base assessment should use these tools. Also, appreciate that nomograms have limited utility when dealing with complex acid–base derangements.

Acid–base disturbances are always manifestations of underlying clinical disorders. It is useful to specifically define the primary acid–base abnormality because each disorder is caused by a limited number of disease processes. Establishing the specific disease process responsible for the observed acid–base disorder is clinically important because treatment of a given disorder will only be accomplished by correcting the underlying disease process.

ADVANCED PATHOPHYSIOLOGY

The concepts in this section are used to further expand on steps 3 and 4 of the diagnostic algorithm shown in Figure 28–1. Under normal circumstances the serum is in the isoelectric state. This means that the positively charged entities reported in a standard chemistry panel (cations:

- sodium and potassium) should be exactly balanced by the negatively charged entities (anions: chloride and bicarbonate). However, this relationship is consistently incorrect because the measured cations are higher than the measured anions by 10 to 12 mEq/L (mmol/L). This discrepancy results from the presence of unmeasured anions (e.g., circulating proteins, phosphates, and sulfates). This apparent difference in charges, the serum **anion gap**, is calculated as follows:

$$\text{Anion gap} = \text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-).$$

Because the serum potassium content is relatively small and is very tightly regulated, it is generally omitted from the calculation.¹⁰

It is important to realize that the serum HCO_3^- concentration may be affected by the presence of unmeasured endogenous acids (lactic acid or ketoacids). Bicarbonate will attempt to buffer these acids, resulting in a 1 mEq (1 mmol) loss of serum HCO_3^- for each 1 mEq (1 mmol) of acid titrated. Because the cation side of the equation is not affected by this transaction, the loss of serum HCO_3^- results in an increase in

Table 28-3

Mnemonics for the Differential Diagnoses of Metabolic Acidosis

Elevated Anion Gap ^a	Normal Anion Gap ^a
M—Methanol, metformin	U—Ureteral diversion
U—Uremia	S—Saline infusion
D—Diabetic (or alcoholic) ketoacidosis	E—Exogenous acid
P—Paraldehyde, phenformin	D—Diarrhea
I—Isoniazid, iron	C—Carbonic anhydrase inhibitors
L—Lactic acidosis	A—Adrenal insufficiency
E—Ethylene glycol, ethanol	R—Renal tubular acidosis
S—Salicylates	

^aAnion gap = serum sodium concentration – (serum chloride concentration + serum bicarbonate concentration). Under normal circumstances, the anion gap should be 10 mEq/L (mmol/L) or less.

the calculated anion gap. Identification of an increased anion gap is very important because a limited number of clinical scenarios lead to this unique acid–base disorder. A mnemonic to recall the differential diagnosis for an anion gap acidosis is shown in **Table 28-3**. The concept of the increased anion gap is applied later in Patient Encounters 6 through 10.

Step 3 in Figure 28-1 suggests that any time an ABG is analyzed it is wise to concurrently inspect the serum chemistry values and to calculate the anion gap. The body does not generate an anion gap to compensate for a primary disorder. As such, if the calculated anion gap exceeds 12 mEq/L (mmol/L) there is a primary metabolic acidosis regardless of the pH or the serum HCO₃⁻ concentration. The anion gap may be artificially lowered by decreased serum albumin, multiple myeloma, lithium intoxication, or a profound increase in the serum potassium, calcium, or magnesium.¹¹

Step 4 in Figure 28-1 shows how calculation of the anion gap also facilitates determination of the **excess gap** or the degree to which the calculated anion gap exceeds the normal anion gap. The excess gap is calculated as follows:

$$\text{Excess gap} = \text{anion gap} - 12 = [\text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)] - 12.$$

The excess gap represents the amount of HCO₃⁻ that has been lost due to buffering unmeasured cations. The excess gap can be added back to the measured HCO₃⁻ to determine what the patient's HCO₃⁻ would be if these endogenous acids were not present. This is a very valuable tool that can be used in narrowing the differential diagnosis of certain acid–base disorders as well as in uncovering occult or mixed acid–base disorders.

In summary, the approach to assessment of acid–base status involves four key steps as outlined in Figure 28-1: step 1 = initial inspection of the pH, P_aCO₂, and HCO₃⁻; step 2 = assessment of the adequacy of compensation; step 3 = calculation of the anion gap; and step 4 = calculation of the excess gap.

ETIOLOGY AND TREATMENT

8 Arterial blood gases, serum electrolytes, physical examination findings, the clinical history, and the patient's recent medications must be reviewed in order to establish the etiology of a given acid–base disturbance. Tables 28-3 through 28-7 outline the most commonly encountered causes for each of the primary acid–base disorders. The therapeutic approach to each of these acid–base derangements should emphasize a search for the cause, as opposed to immediate attempts to normalize the pH.

9 It is critical to treat the underlying causative process to effectively resolve most observed acid–base disorders. However, supportive treatment of the pH and electrolytes is often needed until the underlying disease state is improved.^{12,13}

All patients with significant disturbances in their acid–base status require continuous cardiovascular and hemodynamic monitoring. Because frequent assessment of the patient's response to treatment is critical, an arterial line is often placed to minimize patient discomfort with serial ABG collections. If the anion gap was initially abnormal, serial chemistries should be followed to ensure that the anion gap resolves with treatment. Specific treatment decisions depend on the underlying pathophysiologic state (e.g., dialysis for renal failure, insulin for diabetic ketoacidosis, or improving tissue perfusion and oxygenation for lactic acidosis).

Metabolic Acidosis

Metabolic acidosis is characterized by a reduced arterial pH, a primary decrease in the HCO₃⁻ concentration, and a compensatory reduction in the P_aCO₂. The etiologies of metabolic acidosis are divided into those that lead to an increase in the anion gap and those associated with a normal anion gap and are listed in **Table 28-4**. Although there are numerous mnemonics to recall the differential diagnosis of the metabolic acidosis, two simple ones are shown in **Table 28-3**. High anion gap metabolic acidosis is most frequently caused by lactic acidosis, ketoacidosis, and/or renal failure. Although there is considerable variation, the largest anion gaps are caused by ketoacidosis, lactic acidosis, and methanol or ethylene glycol ingestion.¹⁴

Symptoms of metabolic acidosis are attributable to changes in cardiovascular, musculoskeletal, neurologic, or pulmonary functioning. Respiratory compensation requires marked increases in minute ventilation and may lead to dyspnea, respiratory fatigue, and respiratory failure. Acidemia predisposes to ventricular arrhythmias and reduces cardiac contractility, each of which can result in pulmonary edema and/or systemic hypotension.¹⁵ Neurologic symptoms range from lethargy to coma and are usually proportional to the severity of the pH derangement. Chronic metabolic acidosis leads to a variety of musculoskeletal problems including impaired growth, rickets, osteomalacia, or osteopenia. These changes are believed to be caused by the release of calcium and phosphate during bone buffering of excess H⁺ ions.

As previously discussed, in anion gap metabolic acidosis, the isoelectric state is maintained because unmeasured

Patient Encounters 6 through 10: Application of Advanced Pathophysiology

Case Study 6

A 21-year-old college student presents to the emergency department after ingesting an entire bottle of aspirin tablets as a suicide gesture. The presenting labs show a pH of 7.50, a P_{aCO_2} of 20 mm Hg (2.7 kPa), an HCO_3^- of 16 mEq/L (mmol/L), a sodium concentration of 140 mEq/L (mmol/L), and a chloride level of 103 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Case Study 7

A 51-year-old homeless man is brought to the emergency department by police for medical clearance before taking him to the city jail. They were called for reports of a “profoundly intoxicated” man who was vomiting off an overpass onto passing vehicles below. Shortly after arrival he has an episode of bloody emesis with witnessed aspiration and respiratory distress. He is urgently intubated and transferred to the intensive care unit where his blood work shows a pH of 7.50, a P_{aCO_2} of 20 mm Hg (2.7 kPa), an HCO_3^- of 15 mEq/L (mmol/L), a sodium concentration of 145 mEq/L (mmol/L), and a chloride level of 100 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Case Study 8

A 19-year-old diabetic woman is brought in by rescue squad after her friends found her unresponsive on the couch. They report that she has had several days of “stomach flu” with stomach cramps and frequent bouts of emesis. Given her limited oral intake, she stopped using her insulin pump a couple days ago. When they brought her soup today, they immediately called 911 given her unconsciousness and slow, shallow breaths. The blood work drawn prior to

urgent intubation shows a pH of 7.09, a P_{aCO_2} of 50 mm Hg (6.7 kPa), an HCO_3^- of 15 mEq/L (mmol/L), a sodium concentration of 145 mEq/L (mmol/L), and a chloride level of 100 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Case Study 9

A 63-year-old man with end-stage renal disease underwent urgent laparotomy for intestinal obstruction: widely disseminated colon cancer was discovered intraoperatively. Given his poor prognosis and multiple comorbidities he is now refusing hemodialysis. Given steady deterioration in his mental status, an ABG and chemistries are obtained and show pH of 7.40, P_{aCO_2} of 40 mm Hg (5.3 kPa), HCO_3^- of 24 mEq/L (mmol/L), sodium concentration of 145 mEq/L (mmol/L), and chloride level of 100 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Case Study 10

The final patient is a 37-year-old man who was admitted 8 hours ago for diabetic ketoacidosis. With appropriate therapy his hyperglycemia has improved and the serum ketones are improving. Because he continues to feel poorly, repeat blood work is ordered. Studies show a pH of 7.15, a P_{aCO_2} of 15 mm Hg (2.0 kPa), an HCO_3^- of 5 mEq/L (mmol/L), a sodium concentration of 140 mEq/L (mmol/L), and a chloride level of 110 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

anions are present. With a *normal* anion gap metabolic acidosis, the isoelectric state is maintained by an increase in the measured chloride. Because of this, normal anion gap metabolic acidosis is often referred to as hyperchloremic acidosis.

In patients with a normal anion gap metabolic acidosis, it is often helpful to calculate the urine anion gap (UAG).¹⁶ The UAG is calculated as follows:

$$UAG = (\text{Urine Na}^+ + \text{Urine K}^+) - \text{Urine Cl}^-.$$

The normal UAG ranges from 0 to 5 mEq/L (mmol/L) and represents the presence of unmeasured urinary anions. In metabolic acidosis, the excretion of NH_4^+ and concurrent Cl^- should increase markedly if renal acidification is intact. This results in UAG values from -20 to -50 mEq/L (mmol/L). This occurs because the urinary Cl^- concentration now markedly exceeds the urinary Na^+ and K^+ concentrations. Diagnoses consistent with an excessively negative UAG include proximal (type 2) renal tubular acidosis, diarrhea, or administration of acetazolamide or hydrochloric acid (HCl).

Table 28-4

Common Causes of Metabolic Acidosis

Elevated Anion Gap ^a	Normal Anion Gap ^a
Intoxications	Bowel fistula
Methanol	Diarrhea
Ethylene glycol	Dilutional acidosis
Salicylates	Drugs
Paraldehyde	Acetazolamide ^b
Isoniazid	Ammonium chloride ^b
Ketoacidosis	Amphotericin B ^b
Diabetic	Arginine
Ethanol	hydrochloride ^c
Starvation	Cholestyramine ^b
Lactic acidosis	Hydrochloric acid ^b
Carbon monoxide poisoning	Lithium ^b
Drugs	Parenteral nutrition ^b
IV lorazepam (due to vehicle) ^c	Topiramate ^b
Metformin ^b	Zonisamide ^b
Nitroprusside (due to cyanide accumulation) ^b	Lead poisoning
Nucleoside reverse transcriptase inhibitors ^b	Renal tubular acidosis
Propofol ^c	Surgical drains
Seizures	Ureteral diversion
Severe hypoxemia	Villous adenomas (some)
Shock	
Renal failure	

^aAnion gap = serum sodium concentration – (serum chloride concentration + serum bicarbonate concentration). Under normal circumstances, the anion gap should be 10 mEq/L (mmol/L) or less.

^bMay be observed with therapeutic doses or overdoses.

^cTypically observed only with overdoses.

Excessively positive values of the UAG suggest a distal (type 1) renal tubular acidosis.

In order to effectively treat metabolic acidosis, the *causative process* must be identified and treated.¹⁷ The precise role of adjunctive therapy with sodium bicarbonate (NaHCO₃) is not universally agreed upon. However, most practitioners accept that NaHCO₃ is indicated when renal dysfunction precludes adequate regeneration of HCO₃⁻ or when severe acidemia (pH less than 7.10) is present. The metabolic acidosis seen with lactic acidosis and ketoacidosis generally resolves with therapy targeted at the underlying cause, and NaHCO₃ may be unnecessary regardless of the pH. The metabolic acidosis of renal failure, renal tubular acidosis, or intoxication with ethylene glycol, methanol, or salicylates is much more likely to require NaHCO₃ therapy.

If NaHCO₃ is used, the plasma HCO₃⁻ should not be corrected entirely. Instead, aim at increasing HCO₃⁻ above an absolute value of 10 mEq/L (10 mmol/L). The total HCO₃⁻ deficit can be calculated from the current bicarbonate concentration (HCO₃⁻_{corr}), the desired bicarbonate concentration (HCO₃⁻_{post}), and the body weight (in kilograms) as follows:

$$\text{HCO}_3^- \text{ deficit} = [(2.4/\text{HCO}_3^-_{\text{corr}}) + 0.4] \times \text{weight} \times (\text{HCO}_3^-_{\text{corr}} - \text{HCO}_3^-_{\text{post}}).$$

No more than half of the calculated HCO₃⁻ deficit should be given initially to avoid volume overload, hypernatremia, hyperosmolarity, overshoot alkalemia, hypocalcemia and/or hypokalemia. The calculated HCO₃⁻ deficit reflects only the present situation and does not account for ongoing H⁺ production and HCO₃⁻ loss. When giving HCO₃⁻ therapy, serial blood gases are needed to monitor therapy.

Another option for patients with severe acidemia is tromethamine (THAM).¹⁸ This inert amino alcohol buffers acids and CO₂ through its amine (–NH₂) moiety:

Protonated THAM (with Cl⁻ or HCO₃⁻) is excreted in the urine at a rate that is slightly higher than creatinine clearance. As such, THAM augments the buffering capacity of the blood without generating excess CO₂. THAM is less effective in patients with renal failure, and toxicities may include hyperkalemia, hypoglycemia, and possible respiratory depression. THAM is particularly useful in patients with volume overload because it does not contain sodium.

THAM is often administered as an empiric dose of 18 g (150 mEq [150 mmol]) in 500 mL water via slow IV infusion. Additional infusions are given as dictated by the severity and progression of acidosis.

Chronic metabolic acidosis can successfully be managed using potassium citrate/citric acid (Polycitra-K, Cytra-K) or sodium citrate/citric acid (Bicitra, Oracit).

Metabolic Alkalosis

Metabolic alkalosis is characterized by an increased arterial pH, a primary increase in the HCO₃⁻ concentration, and a compensatory increase in the Paco₂. Patients will always hypoventilate to compensate for metabolic alkalosis—even if it results in profound hypoxemia. For a metabolic alkalosis to persist, there must concurrently be a process that elevates serum HCO₃⁻ concentration (gastric or renal loss of acids) and another that impairs renal HCO₃⁻ excretion (hypovolemia, hypokalemia, or mineralocorticoid excess). The etiologies of metabolic alkalosis are listed in [Table 28-5](#).

Patients with metabolic alkalosis rarely have symptoms attributable to alkalemia. Rather, complaints are usually related to volume depletion (muscle cramps, positional dizziness, weakness) or to hypokalemia (muscle weakness, polyuria, polydipsia).

In order to effectively treat metabolic alkalosis, the *causative process* must be identified and treated. The major causes of metabolic alkalosis are often readily apparent after carefully reviewing the patient's history and medication list. In hospitalized patients, always look for administration of compounds such as citrate in blood products and acetate in parenteral nutrition that can raise the HCO₃⁻ concentration. If the etiology of the metabolic alkalosis is still unclear, measurement of the urinary chloride may be useful. Some processes leading to metabolic alkalosis (vomiting, nasogastric suction losses, factitious diarrhea) will have low urinary

Table 28-5

Common Causes of Metabolic Alkalosis

Urine Cl ⁻ Less Than 10 mEq/L (Less Than 10 mmol/L)	Urine Cl ⁻ Greater Than 10 mEq/L (Greater Than 10 mmol/L)
Alkali administration IV bicarbonate therapy Oral alkali therapy	Drugs ^a Corticosteroid therapy Diuretics
Parenteral nutrition with acetate "Contraction alkalosis" postdiuretic use	Hypokalemia Mineralocorticoid excess Hyperaldosteronism
Decreased chloride intake Loss of gastric acid Vomiting Nasogastric suction	Bartter's syndrome Cushing's syndrome
Posthypercapnia Villous adenomas (some)	

^aMay be observed with therapeutic doses or overdoses.

Cl⁻ concentrations (less than 25 mEq/L or mmol/L) and are likely to respond to administration of saline. Other causes (diuretics, hypokalemia, and mineralocorticoid excess) will have higher urinary Cl⁻ concentrations (greater than 40 mEq/L or mmol/L) and are less likely to correct with saline infusion.

In general, contributing factors such as diuretics, nasogastric suction, and corticosteroids should be discontinued if possible. Any fluid deficits should be treated with IV normal saline. Again, patients with metabolic alkalosis and high urine Cl⁻ (while relatively uncommon) are generally resistant to saline loading. Potassium supplementation should always be given if it is also deficient.

In patients with mild or moderate alkalosis who require ongoing diuresis but have rising HCO₃⁻ concentrations, the carbonic anhydrase inhibitor acetazolamide can be used to reduce the HCO₃⁻ concentration. Acetazolamide is typically dosed at 250 mg every 6 to 12 hours as needed to maintain the pH in a clinically acceptable range. This agent results in gradual changes in the serum HCO₃⁻ and is not used to acutely correct a patient's acid-base status. If alkalosis is profound and potentially life threatening (due to seizures or ventricular tachyarrhythmias), hemodialysis or transient HCl infusion can be considered. The hydrogen ion deficit (in milliequivalents or millimoles) can be estimated from the current bicarbonate concentration (HCO₃⁻_{curr}), the desired bicarbonate concentration (HCO₃⁻_{post}), and the body weight (in kilograms) as follows:

$$H^+ \text{ deficit} = 0.4 \times \text{weight} \times (HCO_3^-_{\text{curr}} - HCO_3^-_{\text{post}}).$$

After estimating the H⁺ deficit, 0.1 to 0.2 N hydrochloric acid (HCl) is infused at 20 to 50 mEq/h (mmol/h) into a central vein. Arterial pH must be monitored at least hourly and the infusion stopped as soon as clinically feasible. Ammonium chloride and arginine hydrochloride, agents that result in the formation of HCl, are not commonly prescribed because they may lead to significant toxicity. Ammonium chloride may

cause accumulation of ammonia leading to encephalopathy while arginine hydrochloride can induce life-threatening hyperkalemia through unclear mechanisms.

Respiratory Acidosis

Respiratory acidosis is characterized by a reduced arterial pH, a primary increase in the arterial PaCO₂ and, when present for sufficient time, a compensatory rise in the HCO₃⁻ concentration. Because increased CO₂ is a potent respiratory stimulus, respiratory acidosis represents ventilatory failure or impaired central control of ventilation as opposed to an increase in CO₂ production. As such, most patients will have hypoxemia in addition to hypercapnia. The most common etiologies of respiratory acidosis are listed in Table 28-6.

- Severe, acute respiratory acidosis produces a variety of neurologic abnormalities. Initially these include headache, blurred vision, restlessness, and anxiety. These may progress to tremors, asterixis, somnolence, and/or delirium. If untreated, terminal manifestations include peripheral vasodilation leading to hypotension and cardiac arrhythmias.
- Chronic respiratory acidosis is typically associated with cor pulmonale and peripheral edema.

In order to effectively treat respiratory acidosis, the *causative process* must be identified and treated. If a cause is identified, specific therapy should be started. This may

Table 28-6

Common Causes of Respiratory Acidosis

CNS disease	Pneumonia
Brainstem lesions	Pneumonitis
Central sleep apnea	Pulmonary edema
Infection	Restrictive lung disease
Intracranial hypertension	Ascites
Trauma	Chest wall disorder
Tumor	Fibrothorax
Vascular	Kyphoscoliosis
Drugs ^a	Obesity
Aminoglycosides	Pleural effusion
Anesthetics	Pneumoconiosis
β-Blockers	Pneumothorax
Botulism toxin	Progressive systemic sclerosis
Hypnotics	Pulmonary fibrosis
Narcotics	Spinal arthritis
Neuromuscular blocking agents	Smoke inhalation
Organophosphates	Upper airway obstruction
Sedatives	Foreign body
Neuromuscular disease	Laryngospasm
Guillain-Barré syndrome	Obstructive sleep apnea
Muscular dystrophy	Others
Myasthenia gravis	Abdominal distention
Polymyositis	Altered metabolic rate
Pulmonary disease	Congestive heart failure
Lower airway obstruction	Hypokalemia
Chronic obstructive pulmonary disease	Hypothyroidism
Foreign body	Inadequate mechanical ventilation
Status asthmaticus	

^aMay be observed with therapeutic doses or overdoses.

include naloxone for opiate-induced hypoventilation or bronchodilator therapy for acute bronchospasm. Because respiratory acidosis represents ventilatory failure, an increase in alveolar ventilation is required. This can often be achieved by controlling the underlying disease (e.g., bronchodilators and corticosteroids in asthma) and/or physically augmenting ventilation.

Although their precise role and mechanisms of action are unclear, agents such as medroxyprogesterone, theophylline, and doxapram stimulate respiration and have been used to treat mild to moderate respiratory acidosis. Moderate or severe respiratory acidosis requires assisted ventilation. This can be provided to spontaneously breathing patients via bilevel positive airway pressure (BiPAP) delivered via a tight-fitting mask or by intubation followed by mechanical ventilation. In mechanically ventilated patients, respiratory acidosis is treated by increasing the minute ventilation. This is achieved by increasing the respiratory rate and/or tidal volume.

As with the treatment of metabolic acidosis, the role of NaHCO_3 therapy is not well defined for respiratory acidosis. Realize that administration of NaHCO_3 can paradoxically result in increased CO_2 generation ($\text{HCO}_3^- + \text{H}^+ \rightarrow \text{H}_2\text{CO}_3 + \text{CO}_2$) and worsened acidemia. Careful monitoring of the pH is required if NaHCO_3 therapy is started for this indication. The use of tromethamine in respiratory acidosis (see Metabolic Acidosis section earlier) has unproven safety and benefit.

The goals of therapy in patients with chronic respiratory acidosis are to maintain oxygenation and to improve alveolar ventilation if possible. Because of the presence of renal compensation it is usually not necessary to treat the pH, even in patients with severe hypercapnia. Although the specific treatment varies with the underlying disease, excessive oxygen and sedatives should be avoided because they can worsen CO_2 retention.

Respiratory Alkalosis

Respiratory alkalosis is characterized by an increased arterial pH, a primary decrease in the arterial Paco_2 and, when present for sufficient time, a compensatory fall in the HCO_3^- concentration. Respiratory alkalosis represents hyperventilation and is remarkably common. The most common etiologies of respiratory alkalosis are listed in [Table 28-7](#) and range from benign (anxiety) to life threatening (pulmonary embolism). Some causes of hyperventilation and respiratory acidosis are remarkably common (hypoxemia or anemia).

The symptoms produced by respiratory alkalosis result from increased irritability of the central and peripheral nervous systems. These include light-headedness, altered consciousness, distal extremity paresthesias, circumoral paresthesia, cramps, carpopedal spasms, and syncope. Various supraventricular and ventricular cardiac arrhythmias may occur in extreme cases, particularly in critically ill patients. An additional finding in many patients with severe respiratory alkalosis is hypophosphatemia, reflecting a shift

of phosphate from the extracellular space into the cells. Chronic respiratory alkalosis is generally asymptomatic.

It is imperative to identify serious causes of respiratory alkalosis and institute effective treatment. In spontaneously breathing patients, respiratory alkalosis is typically only mild or moderate in severity and no specific therapy is indicated. Severe alkalosis generally represents respiratory acidosis imposed on metabolic alkalosis and may improve with sedation or rebreathing maneuvers (rebreathing mask, paper bag). Patients receiving mechanical ventilation are treated with reduced minute ventilation achieved by decreasing the respiratory rate and/or tidal volume. If the alkalosis persists in the ventilated patient, high-level sedation or paralysis is effective.

SUMMARY

Acid-base disturbances are common clinical problems that are not difficult to analyze if approached in a consistent manner. The pH, Paco_2 , and HCO_3^- should be inspected to identify all abnormal values. This should lead to an assessment of which deviations represent the primary abnormality and which represent compensatory changes. The serum electrolytes should always be used to calculate the anion gap. In cases in which the anion gap is increased, the excess anion gap should be added back to the measured HCO_3^- . The anion gap and the excess gap are useful tools that can identify hidden disorders. This rigorous assessment of the patient's acid-base status, incorporated with the available clinical data, increases the likelihood that the clinician will successfully determine the cause of each identified disorder. Although supportive therapy is often required for profound acid-base disturbances, definitive therapy must target the underlying process that has led to the observed derangements.

Patient Care and Monitoring

1. Every patient with a suspected acid–base disturbance should have an arterial blood gas and a serum chemistry panel drawn concurrently. The results of these tests should be reviewed using a systematic approach to ensure proper interpretation.
2. What is the primary disorder? Has compensation occurred?
3. Is the anion gap excessively large? If so, does calculation of the excess gap identify another acid–base disorder?
4. Continuous cardiovascular and hemodynamic monitoring should be used for significant pH disturbances because the most serious sequelae of acid–base disorders include electrolyte abnormalities, cardiac dysrhythmias, and systemic hypotension.
5. All acid–base abnormalities result from underlying disease processes. Definitive therapy for these disturbances requires treatment of the illness that has disrupted the pH equilibrium.
6. Review each patient's history, physical examination, and current medication list for clues regarding potential causes of the observed acid–base disorder.
7. Serial arterial blood gases and serum chemistries should be compared because every patient's acid–base status is continuously changing based on the underlying disease state and any therapy initiated.

Abbreviations Introduced in This Chapter

ABG	Arterial blood gas
BiPAP	Bilevel positive airway pressure
Cl ⁻	Chloride ion
CO ₂	Carbon dioxide
Δ(delta)	Change
H ⁺	Hydrogen ion
HCl	Hydrochloric acid
HCO ₃ ⁻	Bicarbonate
HCO ₃ ⁻ _{curr}	Current bicarbonate
HCO ₃ ⁻ _{post}	Posttherapy bicarbonate
Hg	Mercury
K ⁺	Potassium ion
Na ⁺	Sodium ion
NaHCO ₃	Sodium bicarbonate
NH ₂	Terminal amine group

NH ₄ ⁺	Ammonium
pH	Logarithm of the hydrogen ion concentration
Paco ₂	Partial pressure of arterial carbon dioxide
tCO ₂	Total venous carbon dioxide
THAM	Tromethamine
UAG	Urine anion gap

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Alzheimer's Disease

Megan J. Ehret and Clayton English

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Describe the epidemiology of Alzheimer's disease (AD) and its effects on society.
2. Describe the pathophysiology, including genetic and environmental factors that may be associated with the disease.
3. Detail the clinical presentation of the typical patient with AD.
4. Describe the clinical course of the disease and typical patient outcomes.
5. Describe how nonpharmacologic therapy is combined with pharmacologic therapy for patients with AD.
6. Recognize and recommend treatment options for disease-specific symptoms as well as behavioral/noncognitive symptoms associated with the disease.
7. Develop an alternative treatment plan for patients with AD.
8. Educate patients and/or caregivers about the expected outcomes for patients with AD, and provide contact information for support/advocacy agencies.

KEY CONCEPTS

- 1 Alzheimer's disease (AD) is characterized by progressive cognitive decline including memory loss, disorientation, and impaired judgment and learning.
- 2 Pathologic hallmarks of the disease in the brain include *neurofibrillary tangles* and *neuritic plaques (senile plaques)* made up of various proteins that result in a shortage of the neurotransmitter acetylcholine.
- 3 The diagnosis of AD is established following an extensive history and physical examination, and by ruling out other potential causes of dementia.
- 4 Treatment is focused on delaying disease progression and preservation of functioning as long as possible.
- 5 The current gold standard of treatment for cognitive symptoms includes pharmacologic management with a cholinesterase inhibitor and/or an *N*-methyl-D-aspartate (NMDA) receptor antagonist.
- 6 Future therapies for AD may be based on disease-modifying therapies.
- 7 Treatment of behavioral symptoms should begin with nonpharmacologic treatments but may also include antipsychotic agents and/or antidepressants.
- 8 Therapeutic response in AD is genotype specific, depending on the genes associated with pathogenesis and/or genes responsible for drug metabolism.

1 *Alzheimer's disease (AD) is a nonreversible, progressive dementia manifested by gradual deterioration in cognition and behavioral disturbances.* It is primarily diagnosed by exclusion of other potential causes for dementias. There is no single symptom unique to AD; therefore, diagnosis relies on a thorough patient history. The exact pathophysiologic mechanism underlying AD is not entirely known, although certain genetic and environmental factors may be associated with the disease. There is currently no cure for AD; however, drug treatment can slow symptom progression over time.

Family members of AD patients are profoundly affected by the increased dependence of their loved ones as the disease progresses. Referral to an advocacy organization, such as the Alzheimer's Association, can provide early education and social support of both the patient and family. The Alzheimer's Association has developed a list of common warning signs ([Table 29-1](#)).¹

EPIDEMIOLOGY AND ETIOLOGY

- AD is the most common type of dementia, affecting an estimated 5.4 million Americans in 2011. It represents the sixth leading cause of death across all age groups in the United States, and it is the fifth leading cause of death for individuals 65 years of age and older.² Various classifications of dementia include dementia of the Alzheimer's type, vascular dementia, and dementia due to human

Table 29-1

Ten Warning Signs of AD

1. Memory loss that disrupts daily life.
2. Challenges in planning or solving problems.
3. Difficulty completing familiar tasks at home, at work, or at leisure.
4. Confusion with time or place.
5. Trouble understanding visual images and spatial relationships.
6. New problems with words in speaking or writing.
7. Misplacing things and losing the ability to retrace steps.
8. Decreased or poor judgment.
9. Withdrawal from work or social activities.
10. Changes in mood or personality.

From Alzheimer's Association [Internet]. Cited 2011 Oct 10. Available from: http://www.alz.org/alzheimers_disease_10_signs_of_alzheimers.asp, with permission.

immunodeficiency virus (HIV) disease, head trauma, Parkinson's disease, Huntington's disease, Pick's disease, or Creutzfeldt-Jakob disease.³ This chapter addresses only dementia of the Alzheimer's type.

The prevalence of AD increases with age. Of those affected, 6% were 65 to 74 years of age, 45% were between 75 and 84 years of age, and 45% were persons older than 85 years.² It is projected that by the year 2050, there will be a threefold increase in prevalence yielding potentially 11 to 16 million AD patients due to a population increase in persons older than 65 years.² Additionally, the cost to society will continually increase, as total spending for AD is projected to increase from \$183 billion in 2011 to over \$1 trillion in 2050.² Furthermore, the costs paid by Medicare and Medicaid for AD in 2050 will have increased from 2010 by more than 600% and 400%, respectively.⁴ The severity of AD also correlates with increasing age and is classified as mild, moderate, or severe. Other risk factors associated with AD besides age include family history, female gender, and vascular risk factors such as diabetes, hypertension, heart disease, and current smoking.⁵ However, it is unknown how other factors such as environment contribute and interact with the genetic predisposition for AD.

The mean survival time of persons with AD is reported to be approximately 6 years from the onset of symptoms until death. However, age at diagnosis, severity of AD, and other medical conditions affect survival time.⁶ Although AD does not directly cause death, it is associated with an increase in various risk factors that often contribute to death, such as senility, sepsis, stroke, pneumonia, dehydration, and decubitus ulcers.

The exact etiology of AD is unknown; however, it has been suggested that genetic factors may contribute to errors in protein synthesis resulting in the formation of abnormal proteins involved in the pathogenesis of AD.⁷ Early onset, which is defined as AD prior to age 60, accounts for approximately 1% of all AD. This type is usually familial and follows an autosomal dominant pattern in approximately 50% of cases of early-onset AD. Mutations in three genes, presenilin

1 on chromosome 14, amyloid precursor protein (APP) on chromosome 21, and presenilin 2 on chromosome 1, lead to an increase in the accumulation of amyloid beta ($A\beta$) in the brain, resulting in oxidative stress, neuronal destruction, and the clinical syndrome of AD.^{8,9}

The genetic basis for the more common late-onset AD appears more complex. Genetic susceptibility is more sporadic, and it may be more dependent on environmental factors.⁷ The apolipoprotein E (apo E) gene on chromosome 19 has been identified as a strong risk factor for late-onset AD. There are three variants of apo E; however, carriers of two or more of the apo E4 allele have an earlier onset of AD (approximately 6 years earlier) compared with noncarriers.⁷ Only 50% of AD patients have the apo E4 allele, thus indicating it is only a susceptibility marker.

PATHOPHYSIOLOGY

2 The pathologic hallmarks of the disease in the brain include neurofibrillary tangles and neuritic plaques made up of various proteins, which result in a shortage of the neurotransmitter acetylcholine (Ach). These are primarily located in brain regions involved in learning, memory, and emotional behaviors such as the cerebral cortex, hippocampus, basal forebrain, and amygdala.¹⁰

Tangles

Neurofibrillary tangles are intracellular and consist of abnormally phosphorylated tau (τ) protein, which is involved in microtubule assembly. Tangles interfere with neuronal function, resulting in cell damage, and their presence has been correlated with the severity of dementia.¹¹ Unfortunately, these tangles are insoluble even after the cell dies, and they cannot be removed once established. The neurons that provide most of the cholinergic innervation to the cortex are most prominently affected.¹² Therefore, prevention is the key to targeted therapy of these tangles.

Plaques

Neuritic or senile plaques are extracellular protein deposits of fibrils and amorphous aggregates of β -amyloid protein.¹⁰ This formed protein is central to the pathogenesis of AD. The β -amyloid protein is present in a nontoxic, soluble form in human brains. In AD, conformational changes occur that render it insoluble and cause it to deposit into amorphous diffuse plaques associated with dystrophic neuritis.¹³ Over time, these deposits become compacted into plaques, and the β -amyloid protein becomes fibrillar and neurotoxic. Inflammation occurs secondary to clusters of astrocytes and microglia surrounding these plaques.

Acetylcholine

The neurotransmitter Ach is responsible for transmitting messages between certain nerve cells in the brain. In AD,

the plaques and tangles damage these pathways, leading to a shortage of Ach, resulting in learning and memory impairment.¹⁴ The loss of Ach activity correlates with the severity of AD. The basis of pharmacologic treatment of AD has been to improve cholinergic neurotransmission in the brain. Acetylcholinesterase is the enzyme that degrades Ach in the synaptic cleft. Blocking this enzyme leads to an increased level of Ach with a goal of stabilizing neurotransmission.¹⁴

Glutamate

Glutamate is the primary excitatory neurotransmitter in the CNS; it is involved in memory, learning, and neuronal plasticity. It acts by providing information from one brain area to another and affects cognition through facilitation of connections with cholinergic neurons in the cerebral cortex and basal forebrain.¹⁵ In AD, one type of glutamate receptor, *N*-methyl-D-aspartate (NMDA), is less prevalent than normal. There also appears to be overactivation of unregulated glutamate signaling. This results in a rise in calcium ions that induces secondary cascades, which lead to neuronal death and an increased production of APP.¹⁴ The increased production of APP is associated with higher rates of plaque development and hyperphosphorylation of τ protein.¹⁵

Cholesterol

Increased cholesterol concentrations have been associated with AD. The cholesterol increases β -amyloid protein synthesis, which can lead to plaque formation.¹⁴ Also, the apo E4 allele is thought to be involved in cholesterol metabolism and is associated with higher cholesterol levels.¹⁴

Estrogen

Estrogen appears to have properties that protect against memory loss associated with normal aging. It has been suggested that estrogen may block β -amyloid protein production and even trigger nerve growth in cholinergic nerve terminals.¹⁶ Estrogen is also an antioxidant and helps prevent oxidative cell damage.¹⁶ It is important to note, however, that the Women's Health Initiative Memory Study reported that hormone replacement with either estrogen alone or estrogen plus medroxyprogesterone resulted in negative effects on memory.¹⁷

CLINICAL PRESENTATION AND DIAGNOSIS

3 *Diagnosing AD relies on a thorough medical and psychological history, mental status testing, and laboratory data to exclude other possible causes of dementia.* There are no biological markers other than those pathophysiological changes found at autopsy that can confirm AD, although the development of in vivo plaque detection methods may change this.

AD is a progressive disease that, over time, affects multiple areas of cognition. The symptoms of AD can be divided into cognitive symptoms, noncognitive symptoms, and functional symptoms for assessment and treatment purposes.

The National Institute on Aging and the Alzheimer's Association workgroup recently revised the 1984 criteria for AD dementia. The group defined all-cause dementia, probable AD dementia, possible AD dementia, and probable or possible AD dementia with evidence of the AD pathophysiological process. The routine use of AD biomarker tests for routine diagnostic purposes is not advocated at this time. These tests are reserved for research purposes. See [Tables 29-2, 29-3, and 29-4](#) for full criteria.¹⁸

Clinical Presentation and Diagnosis of Alzheimer's Disease

General

The diagnosis of AD relies on thorough mental status testing and neuropsychological tests, medical and psychiatric history, neurological examination, interview of caregivers and family members, and laboratory and imaging data to support the diagnosis and exclude other causes.

Signs and Symptoms

- Cognitive: memory loss, problems with language, disorientation to time and place, poor or decreased judgment, problems with learning and abstract thinking, misplacing things
- Noncognitive: Changes in mood or behavior, changes in personality, or loss of initiative
- Functional: Difficulty performing familiar tasks

Laboratory Tests

- MRI or CT is used to measure changes in brain size and volume and rule out stroke, brain tumor, or cerebral edema.
- Tests to exclude possible causes of dementia include a depression screen, vitamin B₁₂ deficiency, thyroid function tests (thyroid-stimulating hormone and free triiodothyronine and thyroxine), complete blood count, and chemistry panel.²¹
- Other diagnostic tests to consider for differential diagnosis: erythrocyte sedimentation rate, urinalysis, toxicology, chest x-ray, heavy metal screen, HIV testing, CSF examination, electroencephalography, and neuropsychological tests such as the Folstein Mini Mental Status Examination.

Table 29–2

Criteria for All-Cause Dementia: Core Clinical Criteria

Cognitive or behavioral (neuropsychiatric) symptoms that:

1. Interfere with the ability to function at work or at usual activities
2. Represent a decline from previous levels of functioning and performing
3. Are not explained by delirium or major psychiatric disorder
4. Is detected and diagnosed through a combination of:
 - a. History taking from the patient and a knowledgeable informant
 - b. Objective cognitive assessment
5. Involves a minimum of two of the following domains:
 - a. Impaired ability to acquire and remember new information
 - b. Impaired reasoning and handling of complex tasks; poor judgment
 - c. Impaired visuospatial abilities
 - d. Impaired language functions
 - e. Changes in personality, behavior, or comportment

From McKhann GM, Knopman DS, Chertkow H, et al. The diagnosis of dementia due to Alzheimer's disease: Recommendations from the National Institute on Aging and the Alzheimer's Association Workgroup. *Alzheimers Dement* 2011;7:263–269, with permission.

Table 29–3

Probable AD Dementia: Core Clinical Criteria

1. Meets criteria for dementia and has the following characteristics:
 - a. Insidious onset
 - b. Clear-cut history of worsening of cognition by report or observation
 - c. Initial and most prominent cognitive deficits are evident on history and examination in one of the following categories:
 - (i) Amnesic presentation: deficits include impairment in learning and recall of recently learned information; should be evidence of cognitive dysfunction in at least one other cognitive function
 - (ii) Nonamnesic presentation: language, visuospatial, or executive dysfunction presentation; deficits in other cognitive domains should be present
2. Should not be applied when there is evidence of:
 - a. Substantial concomitant cerebrovascular disease
 - b. Core features of dementia with Lewy bodies other than dementia itself
 - c. Prominent features of behavioral variant frontotemporal dementia
 - d. Prominent features of semantic or nonfluent/agrammatic variant primary progressive aphasia
 - e. Another concurrent, active neurologic disease, or nonneurologic medical comorbidity or use of medication that could have a substantial effect on cognition

From McKhann GM, Knopman DS, Chertkow H, et al. The diagnosis of dementia due to Alzheimer's disease: Recommendations from the National Institute on Aging and the Alzheimer's Association Workgroup. *Alzheimers Dement* 2011;7:263–269, with permission.

Table 29–4

Possible AD Dementia: Core Clinical Criteria

Diagnosis made in either of the following circumstances:

1. Atypical course: Meets the core clinical criteria in terms of the nature of the cognitive deficits for AD dementia but either has a sudden onset of cognitive impairments or demonstrates insufficient historical detail or objective cognitive documentation of progressive decline
2. Etiologically mixed presentation: Meets all core clinical criteria for all-cause dementia but has evidence of:
 - a. Concomitant cerebrovascular disease
 - b. Features of dementia with Lewy bodies other than the dementia itself
 - c. Another neurologic disease or a nonneurologic medical comorbidity or medication use that could have a substantial effect on cognition

From McKhann GM, Knopman DS, Chertkow H, et al. The diagnosis of dementia due to Alzheimer's disease: Recommendations from the National Institute on Aging and the Alzheimer's Association Workgroup. *Alzheimers Dement* 2011;7:263–269, with permission.

TREATMENT**Desired and Expected Outcomes**

Although there are currently four agents approved for the treatment of AD, none of these agents are curative or are known to directly reverse the disease process.

4 *Consequently, the primary desired outcome of treatment of AD is to symptomatically treat the cognitive symptoms of the patient and preserve the patient's functioning for as long as possible. Secondary goals include treating psychiatric and behavioral symptoms that may occur during the course of the disease.*

General Approach to Treatment

5 *The current gold standard of treatment for cognitive symptoms includes pharmacologic management with a cholinesterase (ChE) inhibitor and/or an NMDA antagonist. Donepezil, rivastigmine, and galantamine are three ChEs used for cognitive symptoms. The first ChE approved for AD was tacrine; however, it is currently no longer available on the U.S. market. The use of tacrine was limited in practice due to its propensity for hepatotoxicity, difficult titration schedule, four times daily dosing, poor bioavailability, and troublesome incidence of nausea, diarrhea, and urinary incontinence. The only NMDA antagonist is memantine. Psychiatric and behavioral symptoms that occur during the course of the disease should be treated as they occur.*

Essential elements in the treatment of AD include education, communication, and planning with the family/caregiver of the patient. Treatment options, legal and financial decisions, and course of the illness need to be discussed with the patient and family members. In this

Table 29-5

Basic Principles in the Management of Patients With AD

- Using a gentle, calm approach to the patient
- Giving reassurance when needed
- Empathizing with the patient's concerns
- Using distraction and redirection
- Maintaining daily routines
- Providing a safe environment
- Providing daytime activities
- Avoiding overstimulation
- Using familiar decorative items in the living area
- Bringing abrupt declines in function and the appearance of new symptoms to professional attention

Table 29-6

Treatment Algorithm for Cognitive Symptoms of AD

1. Patient diagnosed with AD
2. Assess all comorbid medical disorders and drug therapies that may affect cognition
3. Rule out comorbid depression
4. Evaluate for pharmacotherapy based on illness stage
 - a Mild AD: Cholinesterase inhibitor
 - b Moderate to severe AD: Cholinesterase inhibitor, memantine, or combination cholinesterase inhibitor and memantine
5. Deteriorating Mini Mental Status Exam (MMSE) score greater than 2–4 points after 1 year: Change to a different cholinesterase inhibitor
6. Stable MMSE: Continue regimen

regard, the clinician's emphasis should be on helping to maintain a therapeutic living environment while minimizing the burden of care resulting from the disease.

Nonpharmacologic Treatment

- Treatment of AD involves both pharmacologic and nonpharmacologic methods. Upon the initial diagnosis, the patient and family should be counseled on the course of the illness, prognosis, available treatments, legal decisions, and quality-of-life issues. The life of a patient with AD must become progressively more simple and structured as the disease progresses, and the caregiver must learn to keep requests and demands on the patient simple. Basic principles in the treatment of patients with AD are shown in [Table 29-5](#).

Conventional Pharmacologic Treatment for Cognitive Symptoms

► ChE Inhibitors (Donepezil, Rivastigmine, and Galantamine)

- The ChE inhibitors all have the indication for the treatment of dementia of the Alzheimer's type. Guidelines for the treatment of AD recommend the use of ChE inhibitors as a valuable treatment for AD and the use of memantine for moderate to severe AD.^{19–21} Few head-to-head studies comparing the ChE Inhibitors exist. The few available trials conclude no major difference in clinical outcomes, so the decision to use one ChE over another should be based on differences in mechanisms of action, adverse reactions, and titration schedules.²²
- Treatment should begin as early as possible in patients with a diagnosis of AD.²³ [Table 29-6](#) provides a recommended treatment algorithm for AD. Patients should be switched to another ChE inhibitor from their initial ChE inhibitor if they show an initial lack of efficacy, initially respond to treatment but lose clinical benefit, or experience

safety/tolerability issues. This switch should not be attempted until the patient has been on a maximally tolerated dose for a period of 3 to 6 months. The switch should also be based on realistic expectations of the patient and/or caregiver.²⁴ ChE inhibitor therapy should be discontinued in patients who experience poor tolerance or adherence, who show a lack of clinical improvement after 6 months at optimal dosing, who have failed attempts at monotherapy with at least two agents or combination therapy, who continue to deteriorate at the pretreatment rate, who demonstrate dramatic clinical deterioration following initiation of treatment, or who deteriorate to the point where there is no significant effect on quality of life. Patients with a Mini Mental Status Exam (MMSE) score less than 10 may also benefit from discontinuation of medication; however, this has not been substantially proven in clinical studies.²⁵

Donepezil

- Donepezil is a piperidine ChE inhibitor that reversibly and noncompetitively inhibits centrally active acetylcholinesterase.²⁶ Donepezil is approved for the treatment of mild to moderate AD. A dose of 10 mg/day has demonstrated efficacy in patients with either mild to moderate or moderate to severe forms of AD. A 23-mg dose of donepezil is also approved for patients with moderate to severe disease. The 23-mg dose showed a small improvement in cognitive symptoms over 10 mg/day; however, there was no improvement on overall patient functioning, and there was a higher incidence of adverse effects with the 23-mg dose.²⁷ [Table 29-7](#) describes the dosing strategies for all of the approved agents for AD. The most frequent adverse effects are mild to moderate gastrointestinal symptoms. Others include headache, dizziness, syncope, bradycardia, and muscle weakness. [Table 29-8](#) compares their major side effects.^{26,28–31}
- Only a small number of drug interactions have been reported with donepezil. In vitro studies show a low rate of

Table 29-7

Dosing Strategies for Cognitive Agents

	Donepezil (Aricept)	Rivastigmine (Exelon)	Galantamine (Razadyne)	Memantine (Namenda) ^a
Starting dose	5 mg daily	1.5 mg 2 × daily or 4.6 mg/24 h applied daily (patch)	4 mg 2 × daily or 8 mg daily	5 mg daily or 7 mg daily (ER formulation)
Maintenance dose	5–23 mg daily	3–6 mg 2 × daily or 9.5 mg/24 h applied daily (patch)	8–12 mg 2 × daily or 16–24 mg daily	10 mg 2 × daily or 28 mg daily (ER formulation)
Time between dose adjustments	4–6 weeks between 5 and 10 mg increment; 3 months between 10 and 23 mg increment	2 weeks for oral and 4 weeks for patch	4 weeks	1 week
Dosage adjustments for renal or hepatic impairment	None	None	Do not exceed 16 mg for moderately impaired hepatic or renal function; do not administer in severe renal or hepatic impairment	Caution should be taken in patients with severe hepatic impairment

^aMemantine XR is currently approved, but a launch date is unknown.

From Refs. 33, 35–38.

binding of donepezil to cytochrome P450 (CYP)3A4 or 2D6. Whether donepezil has the potential for enzyme induction is not known. Monitoring for possible increased peripheral side effects is advised when adding a CYP2D6 or 3A3/4 inhibitor to donepezil treatment. Also, inducers of CYP2D6 and 3A4 could increase the rate of elimination of donepezil.²⁶

Rivastigmine

Rivastigmine, which is approved for the treatment of mild to moderate dementia of AD, has central activity for both the acetylcholinesterase and butyrylcholinesterase enzymes.²⁸ Acetylcholinesterase is found in two forms:

Table 29-8

Adverse Effects for Currently Approved Medications for Alzheimer's Disease*

Adverse Event	Donepezil 5–10 mg/day (%) (n = 747)	Donepezil 23 mg/day (%) (n = 963)	Rivastigmine 6–12 mg/day (%) (n = 1,189)	Galantamine IR 16–24 mg/day (%) (n = 1,040)	Memantine IR 5–20 mg/day (%) (n = 940)	Memantine XR 28 mg/day (%) (n = 341)
Nausea	11	12	47	24	NR	NR
Vomiting	5	9	31	13	3	2
Diarrhea	10	8	19	9	NR	5
Headache	10	4	17	8	6	6
Dizziness	8	5	21	9	7	5
Muscle cramps	6	NR	NR	NR	NR	NR

Fatigue	5	2	9	5	2	3
Anorexia	4	5	17	9	NR	NR
Depression	3	NR	6	7	NR	3
Abnormal dreams	3	NR	NR	NR	NR	NR
Weight decrease	3	5	3	7	NR	NR
Abdominal pain	NR	NR	13	5	NR	2
Rhinitis	NR	NR	4	4	NR	NR

NR, not reported.

* Caution is urged in making comparisons between drugs based on these data because different clinical trials often collect adverse event data using different methodologies.

From Refs. 33, 35–38.

globular 4 and globular 1. In postmortem studies, globular 4 is significantly depleted, whereas globular 1 is still abundant. Thus blocking metabolism of globular 1 may lead to higher concentrations of Ach. Rivastigmine has higher activity at globular 1 than at globular 4. Theoretically, this may be advantageous because rivastigmine prevents the degradation of Ach via the acetylcholinesterase globular 1 over the course of the disease as compared with the other ChE inhibitors.

The dual inhibition of acetylcholinesterase and butyrylcholinesterase may lead to broader efficacy. As acetylcholinesterase activity decreases with disease progression, the acetylcholinesterase-selective agents may lose their effect, whereas the dual inhibitors may still be effective due to the added inhibition of butyrylcholinesterase. However, this has not been demonstrated clinically.

Rivastigmine, in addition to the oral formulation, is also available in a patch formulation. When switching from the oral formulation to the patch, if the patient is taking less than 6 mg/day of oral, then the 4.6 mg/24 h patch is recommended. If the patient is taking 6 to 12 mg/day of oral, then the 9.5 mg/24 h patch is recommended. The first patch should be applied on the day following the last oral dose.²⁸

Cholinergic side effects are common with rivastigmine, but they are usually well tolerated if the recommended dosing schedule is followed. If side effects cause intolerance, several doses can be held, then dosing can be restarted at the same or next lower dose. Drugs that induce or inhibit CYP450 metabolism are not expected to alter the metabolism of rivastigmine.²⁸

Galantamine

Galantamine, which is approved for the treatment of mild to moderate dementia of AD, is a ChE inhibitor, which elevates Ach in the cerebral cortex by slowing the degradation of Ach.²⁹ It also modulates the nicotinic Ach receptors to increase Ach release from surviving presynaptic nerve terminals. In addition, it may increase glutamate and serotonin levels. The clinical benefit of action of these additional neurotransmitters is unknown.

CYP3A4 and 2D6 are the major enzymes involved in the metabolism of galantamine. Pharmacokinetic studies with inhibitors of this system have resulted in increased galantamine concentrations or reductions in clearance. Similarly to donepezil, if inhibitors are given concurrently with galantamine, monitoring for increased cholinergic side effects should be done.²⁹

NMDA Receptor Antagonist

Memantine is a noncompetitive antagonist of the NMDA type of glutamate receptors, which are located ubiquitously throughout the brain. It regulates activity throughout the brain by controlling the amount of calcium that enters the nerve cell, a process essential for establishing an environment required for information storage. Overstimulation of the NMDA receptor by excessive glutamate allows too much

calcium into the cell, disrupting information processing. Blocking NMDA receptors with memantine may protect neurons from the effects of excessive glutamate without disrupting normal neurotransmission.^{30,31}

Memantine is indicated for the treatment of moderate to severe dementia of the Alzheimer's type. It can be given as a monotherapy or in combination with ChE inhibitors. Memantine is not indicated for mild AD, and currently there is a lack of evidence to use it in mild AD.³² An extended-release formulation of memantine is approved for once-daily administration, although the launch date of the product is currently unknown.³¹ The higher dose of memantine extended release (28 mg) has not been compared with the immediate-release formulation; thus it is unknown if the 28 mg/day dose of memantine is more effective than the traditional 20 mg/day maximum. Adverse reactions associated with memantine include constipation, confusion, dizziness, headache, coughing, and hypertension. Extra monitoring should be done if memantine is given concurrently with a ChE inhibitor.

In vitro studies have shown that memantine produces minimal inhibition of CYP450 enzymes CYP1A2, 2A6, 2C9, 2D6, 2E1, and 3A4. These data indicate that no pharmacokinetic interactions with drugs metabolized by these enzymes should be expected.^{30,31}

Future Therapies

6 Future therapies for AD may be based on disease-modifying therapies. Current investigations involving the amyloid hypothesis are reviewing various compounds in the secondary prevention of AD. Mechanisms by which these compounds are thought to work include⁸:

- Decreasing the production of A β
- Stimulation of clearance of A β formed

Patient Encounter, Part 1

A woman presents at the clinic with her 70-year-old mother, KE, complaining that her mother's memory is not getting better. The woman complains that her mother is continuing to forget things, including paying the bills and taking out the trash. Six months ago KE was started on donepezil 5 mg daily, which the daughter administers. The woman asks if there is anything else her mother could take to help her memory.

What counseling points about Alzheimer's disease would you provide to the daughter?

Where would you recommend the daughter find more information about Alzheimer's disease?

How would you address the daughter's question regarding the pharmacologic management of her mother's Alzheimer's disease?

- Prevention of aggregation of A β into amyloid plaques
- Prevention of neuronal damage by limiting inflammation and neurotoxicity caused by A β

Currently, bapineuzumab (AAB-001; Janssen/Elan/Pfizer), a humanized monoclonal antibody targeting the A β , is in phase 3 clinical trials for the treatment of AD.³³

Nonconventional Pharmacologic Treatment

Many other nonconventional treatments have been used as adjunctive treatments during the course of AD. Vitamin E was previously recommended for use as an adjunctive treatment because of its antioxidant properties, but a meta-analysis suggested that high doses (greater than 400 IU/day) should be avoided due to an increased all-cause mortality.³⁴ Currently, vitamin E is not recommended for the treatment of AD.²⁰ Estrogen has been investigated for use in AD, but as mentioned previously, it was associated with an increased risk of dementia. Nonsteroidal anti-inflammatory drugs (NSAIDs) have also been investigated. There is a lack of convincing data supporting efficacy, and significant adverse effects (gastritis and GI bleeds) are associated with their use, so they are not recommended for general use in the treatment or prevention of AD at this time.³⁵ Statins (3-hydroxy-3-methylglutaryl-CoA reductase inhibitors) should be reserved for those patients who have other indications for their use.³⁶ Ginkgo biloba has also been studied, and until this product has a more standardized manufacturing process and its long-term safety and efficacy are established, it should be recommended with caution.³⁷ The medical food caprylidene (AC-1202, Axona) is an approved medical food for the dietary management of metabolic processes associated with mild to moderate AD.³⁸ Reduced metabolic processing of glucose in neurons has been associated with AD. Ketone bodies can potentially be used as an alternative energy source for AD patients with reduced neuronal glucose metabolism.³⁸ Caprylidene is a medium chain triglyceride that is converted by the liver into the ketone body β -hydroxybutyrate (BHB). BHB crosses the blood–brain barrier and can be utilized by neurons as a potential energy source to generate ATP and increase pools of acetylcholine. Caprylidene is available only by prescription and is supplied in 40-g powder packets. One packet can be mixed with 4 to 8 ounces of liquid (~120 to 240 mL) and dosed once daily after a meal. The most common side effects are mild GI disturbances including nausea, diarrhea, flatulence, and dyspepsia.³⁹

Treatment of Behavioral Symptoms

7 *Treatment of behavioral symptoms should begin with nonpharmacologic treatments but may also include antipsychotic agents and/or antidepressants.* Nonpharmacologic recommendations for treatment include⁴⁰:

- Music
- Videotapes of family members
- Audiotapes of the voices of caregivers

- Walking and light exercise
- Sensory stimulation and relaxation

• Antipsychotics are frequently used in the management of neuropsychiatric symptoms associated with AD. A recent meta-analysis concluded that only 17% to 18% of dementia patients demonstrated treatment response to atypical antipsychotics.⁴¹ A double-blind placebo-controlled trial of olanzapine, quetiapine, or risperidone for the treatment of psychosis, aggression, or agitation in patients with AD concluded that adverse effects offset the advantages in the efficacy of atypical antipsychotics.⁴²

In April 2005, the FDA issued a statement requesting black-box warnings on all atypical antipsychotics stating that elderly people with dementia-related psychosis treated with an atypical antipsychotic are at an increased risk of death compared with those treated with placebo. Of a total of 17 placebo-controlled trials investigating olanzapine, aripiprazole, quetiapine, and risperidone in elderly demented patients with behavioral disorders, 15 showed a numerical increase in mortality in the drug-treated group compared with the placebo-treated groups (1.6 to 1.7 times increased risk of death). Specific causes for these deaths were heart-related events (heart failure and sudden death) and infections (mostly pneumonia).

The atypical antipsychotics are not currently approved for the treatment of elderly patients with dementia-related psychosis. Therefore, it is important to individually assess and balance the risk versus benefit of antipsychotic use in this population.

• Depressive symptoms occur in as many as 50% of patients with AD and can be difficult to differentiate from symptoms of dementia, so symptoms of depression should be documented for several weeks prior to initiating therapy for depression with AD.²⁰ The selective serotonin reuptake inhibitors (SSRIs) are most commonly used based on their side-effect profile and evidence of efficacy.²⁰ Indications for the use of antidepressants include depression characterized by poor appetite, insomnia, hopelessness, anhedonia, withdrawal, suicidal thoughts, and agitation. A recent trial has suggested a lack of benefit of sertraline and mirtazapine compared with placebo and an increased risk of adverse effects with them.⁴³

• Other miscellaneous therapies for AD include benzodiazepines for anxiety, agitation, and aggression. However, their routine use is not advised.²⁰ Additionally, benzodiazepines have been associated with an increase in falls leading to the potential for hip fractures in the elderly.⁴⁴ Mood stabilizer anticonvulsants, carbamazepine, valproic acid, or gabapentin may be used as alternatives, but the current evidence is conflicting.⁴⁵ Buspirone has shown benefit in treating agitation and aggression in a limited number of patients with minimal adverse effects.^{46,47} In open-label and controlled studies, selegiline decreased anxiety, depression, and agitation.^{48,49} Finally, trazodone has been shown to decrease insomnia, agitation, and dysphoria, and it has been used to treat sundowning in AD patients. **Table 29–9** provides dosing strategies for the noncognitive symptoms of AD.⁵⁰

Table 29–9

Medications Used in Noncognitive Symptoms of Dementia

Drugs	Starting Dose (mg)	Maintenance Dose in Dementia (mg/day)	Dosing Adjustment for Hepatic Impairment (mg)	Dosing Adjustment for Renal Impairment (mg)	Target Symptoms
Antipsychotics					
Haloperidol	0.25	1–3	None needed	None needed	Psychosis: hallucinations, delusions, suspiciousness Disruptive behaviors: agitation, aggression
Olanzapine	2.5	5–10	None needed	None needed	
Quetiapine	25	100–300	Lower starting dose and longer titration schedule to effective dose based on response and tolerability	None needed	
Risperidone	0.25	0.75–2	Lower starting dose and longer titration schedule to effective dose based on response and tolerability	Lower starting dose and longer titration schedule to effective dose based on response and tolerability	
Ziprasidone	20	40–160	None needed	None needed	
Antidepressants					
Citalopram	10	10–20	20 mg/day maximum; may increase only in nonresponsive patients	Mild to moderate impairment: none needed	Depression: poor appetite, insomnia, hopelessness, anhedonia, withdrawal, suicidal thoughts, agitation, anxiety
Escitalopram	5	20–40	10 mg/day maximum	Mild to moderate impairment: none needed	
Fluoxetine	5	10–40	A lower dose or less frequent schedule is recommended	None needed	
Paroxetine	10	10–40	10 mg/day; may increase by 10 mg/day at intervals of at least 1 week	10 mg/day; may increase by 10 mg/day at intervals of at least 1 week	
Sertraline	25	75–100	Lower or less frequent doses should be used	None needed	
Venlafaxine	25	75–225	Decrease usual dose by ≥50%	Decrease usual dose by 25% to 50%	
Trazodone	25	75–150	None needed	None needed	
Anticonvulsants					
Carbamazepine	100	200–600	Should not be used in aggravated liver dysfunction or active liver disease	None needed	Agitation or aggression
Valproic acid	125	500–1000	Should not be administered	None needed	

Adapted from Slattum PW, Swerdlow PH, Massey-Hill A. Alzheimer's disease. In: Dipiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach. 8th ed. New York, NY: McGraw-Hill; 2011:947–961, with permission.

Patient Encounter, Part 2

KE returns to the clinic in 6 months. She has been receiving 10 mg/day of donepezil. Her memory symptoms have slowed in their decline, but recently KE has been agitated at bedtime, talking to her deceased husband. The daughter is particularly concerned about the symptoms and wants to know what she could do to treat them. Her medical record is as follows:

PMH:

- Diabetes mellitus since age 55; it was well controlled until last year when it worsened because of increased confusion about when to take her medication
- Hypertension treated for 20 years and well controlled; has been hypotensive on a few occasions recently during physicals

FH: Father died of myocardial infarction at age 76; mother died of breast cancer at age 79

SH: Lives with daughter; denies drinking alcohol or smoking

Medications:

- Hydrochlorothiazide 25 mg orally once daily

- Losartan 50 mg orally twice daily
- Metformin 1,000 mg orally twice daily
- Donepezil 10 mg daily

ROS: (+) weight loss of 5.5 kg (12 lb); (–) N/V/D, change in appetite, heartburn, chest pain, or shortness of breath

PE:

VS: BP 128/62 mm Hg supine, P 77 beats/min, RR 15/min, T 37°C (98.6°F)

Gen: Poorly groomed, thin woman looks stated age

Neuro: Folstein Mini Mental Status Exam score 18/30; disoriented to month, date, and day of week, clinic name and floor; poor registration with impaired attention and short-term memory; good language skills but problems with commands

CT scan: Mild to moderate generalized cerebral atrophy

What do you recommend with regard to her current donepezil treatment?

What nonpharmacologic and pharmacologic interventions could be recommended for the agitation and psychosis?

GENOMICS

8 *Therapeutic response in AD is genotype specific, depending on the genes associated with pathogenesis and/or genes responsible for drug metabolism.* Recent investigations have demonstrated that the therapeutic response in AD is genotype specific, depending on genes associated with AD pathogenesis and/or genes responsible for drug metabolism. Apo E-4/4 carriers tend to show a faster disease progression and a poorer therapeutic response to all available treatments than any other polymorphic variants associated with AD. CYP450 enzyme extensive and intermediate metabolizers are the best responders to pharmacotherapy, while poor and ultrarapid metabolizers are the worst responders. The pharmacogenetic response in AD may depend on the interaction of genes involved in drug metabolism and the genes associated with AD pathogenesis.⁵¹

OUTCOME EVALUATION

- The success of therapy is measured by the degree to which the care plan decreases the pretreatment deterioration rate, preserves the patients' functioning, and treats psychiatric and behavioral symptoms. The primary outcome measure is thus subjective information

from the patient and the caregiver, although the MMSE can be a helpful tool. There are no physical examination or laboratory parameters that are used to evaluate the success of therapy.

- Once a tolerated agent is found, continue that therapy until poor tolerance or poor adherence occurs, no clinical improvement is seen with 3 to 6 months of optimal dosing, or the pretreatment deterioration rate continues.
- Inform the patient and the caregiver that the treatments available for AD are not curative but may slow the rate of deterioration.
- Treat behavioral and psychiatric issues as they arise. Consider the patient's choices of nonpharmacologic and pharmacologic options before recommending a treatment.
- Discontinue the pharmacologic treatments periodically to reevaluate the need for continued treatment.
- Develop a plan to assess the effectiveness of the ChE inhibitor in slowing the deterioration of cognitive functioning after an appropriate interval (3 to 6 months).
- Assess improvement in quality-of-life measures such as ability to function independently and for slowing of memory deterioration.

Patient Encounter, Part 3

KE returns to the clinic for follow-up 1 year later. Her daughter states her memory is slowly getting worse. Her current MMSE is 16/30. The addition of olanzapine 2.5 mg at bedtime helped with the agitation. Her daughter would like to know if there are any other choices to help treat her mom.

What changes to KE's current medications would you recommend?

- Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions at appropriate intervals.
- Continue to be a resource for the patient and caregiver throughout the long course of the disease.

CONCLUSION

- AD is a progressive deterioration of cognitive abilities, and patients are likely to have behavioral disturbances and personality changes in the later stages of the disease. In an effort to help prepare patients and their caregivers for the inevitable, the Alzheimer's Association has developed ten quick tips on "Living with Alzheimer's disease" (Table 29-10).⁵² The Alzheimer's Association can provide many resources as well as facilitate contacts with other organizations. Contact the association at:

Alzheimer's Association

Contact Center: 1-800-272-3900

Chicago, IL 60601-7633

Table 29-10

Living with AD: Ten Quick Tips

1. Carry with you a book of important notes and photos
2. Enroll in Alzheimer's Association Safe Return
3. Be open to accepting help from others
4. Keep doing the things you most enjoy
5. Talk to others who have AD
6. Find ways to laugh as often as you can
7. Maintain your physical health
8. Take steps to make your home safe
9. Extend the time you can live safely in your home with help from your family and friends
10. Put plans in place now for your future

From Alzheimer's Association [Internet]. If you have Alzheimer's disease [cited 2011 Oct 10]. Available from: www.alz.org/national/documents/brochure_ifyouhave_earlystage.pdf, with permission.

Patient Care and Monitoring

1. Assess the frequency and duration of the patient's cognitive and noncognitive symptoms. Could the patient be depressed?
2. Review any available diagnostic data from the medical and psychiatric history including interviews from family, neuropsychologic testing, and other labs.
3. Obtain a thorough history of prescription, nonprescription, and natural drug product use. Is the patient taking any medications that could contribute to cognitive changes in the elderly?
4. Educate both the patient and caregivers about lifestyle modification and refer them to support when needed.
5. Monitor pharmacotherapy initiation. Is it titrated correctly?
6. Develop a plan to monitor cognitive response to treatment over time.
7. Routinely assess medication adherence.
8. Educate patient and caregivers on what to expect from pharmacotherapy.
9. Regularly evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug-drug and drug-disease interactions.
10. Be a resource and give continuous support to the patient and caregivers throughout the long course of the disease.

Abbreviations Introduced in This Chapter

Ach	Acetylcholine
A β	Amyloid beta
AD	Alzheimer's disease
apo E	Apolipoprotein E
APP	Amyloid precursor protein
β HB	β -Hydroxybutyrate
ChE	Cholinesterase
CYP	Cytochrome P450
MMSE	Mini Mental Status Examination
NMDA	N-Methyl-D-aspartate
NSAID	Nonsteroidal anti-inflammatory drug
SSRI	Selective serotonin reuptake inhibitor
τ	Tau protein

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Multiple Sclerosis

Melody Ryan

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Identify risk factors for multiple sclerosis (MS).
2. Describe pathophysiologic findings of MS.
3. Distinguish between the forms of MS based on patient presentation and course of disease.
4. Compare and contrast MS disease-modifying treatment choices for a specific patient.
5. Determine appropriate symptomatic treatment choices and develop a detailed therapeutic plan for a specific patient.
6. Develop a monitoring plan for a patient placed on specific medications.

KEY CONCEPTS

- 1 Multiple sclerosis (MS) symptoms depend on the location of lesions within the central nervous system (CNS).
- 2 MS has four clinical patterns: relapsing remitting, secondary progressive, primary progressive, and progressive relapsing.
- 3 The McDonald criteria, using clinical examination in combination with magnetic resonance imaging (MRI) data, facilitates earlier diagnosis and thus earlier treatment initiation.
- 4 Acute relapses are treated with corticosteroids to speed recovery.
- 5 Disease-modifying therapies decrease the number of relapses, prevent permanent neurologic damage, and prevent disability.
- 6 Symptomatic treatment minimizes the impact of MS on quality of life.
- 7 Dose-response curves have been observed with the β -interferons.
- 8 There is no consensus on the best medication for initial therapy.
- 9 Mitoxantrone and natalizumab should be reserved for patients with rapidly advancing disease who have failed other therapies.
- 10 MS patients must be treated with agents specific for upper motor neuron **spasticity**.

Multiple sclerosis (MS) is an inflammatory disease of the CNS, variable in symptoms and presentation. *Multiple* describes the number of CNS lesions, and *sclerosis* refers to the demyelinated lesions, today called plaques.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

- Approximately 400,000 Americans have MS.¹ Diagnosis usually occurs between the ages of 20 and 50. Twice as many women as men develop MS.¹ Whites and people of northern European heritage are more likely to have MS.² Risk factors for MS include family history of MS, autoimmune diseases, or migraine; personal history of autoimmune diseases or migraine; and, in women, smoking and exposure to second-hand smoke. Prevalence decreases with decrease in latitude.²

Etiology

► Inheritance Theory

MS probably has a genetic component, likely carried in the human leukocyte antigen chromosomal region. Family members of MS patients have a 5% risk; monozygotic twins have a concordance rate of 25% to 30%.² A straightforward inheritance pattern cannot fully explain the etiology of MS because only a small proportion of patients report a family member with MS.

► Environment Theory

Currently, human herpes virus 6, herpes zoster virus, or Epstein-Barr virus are thought to be possible infectious etiologic agents.³ Infection with these viruses cannot fully explain MS because there is a high rate of seropositivity in the population, but MS is much less common. Another theory involves decreased sunlight exposure. Lower serum concentrations of 25-hydroxyvitamin D are associated with higher rates of MS diagnosis.²

PATHOPHYSIOLOGY

While the causative agent of MS is unclear, the result is the development of an autoimmune disorder with areas of CNS inflammation and degeneration.

Inflammation

- An unknown antigen presented by the major histocompatibility complex (MHC) class II molecules causes T cells to become autoreactive (Fig. 30-1). Autoreactive T cells enter lymphatic tissues to expand. Upon a signal involving sphingosine-1-phosphate, T cells reenter the circulation.⁴ Once activated, T cells penetrate the blood-brain barrier by attachment to upregulated adhesion molecules and production of matrix metalloproteinases (MMP) that cause blood-brain barrier breakdown. In the CNS, T cells come into contact with antigen-presenting cells (APCs) and proliferate. The T-helper cells differentiate into proinflammatory T-helper-1 cells (Th1 cells) and anti-inflammatory T-helper-2 cells (Th2 cells).⁴ Th1 cells secrete cytokines that enhance macrophage and microglial cells that attack myelin.⁴
- B cells cross previously damaged sections of the blood-brain barrier to arrive in the CNS, an area normally free of B cells. Autoreactive T cells trigger B cells to form myelin autoantibodies. B-cell antibodies also initiate the complement cascade, causing myelin degradation.⁴ These inflammatory processes probably cause relapses.⁴ All current MS therapies are targeted toward preventing or slowing the inflammatory processes.

Degeneration

Axonal injury and transection disrupts nerve signals completely. Growing evidence suggests cytotoxic T cells cause axonal injury as early as 2 weeks after diagnosis and throughout the disease.⁴ Axonal loss is likely responsible for MS progression.⁴

CLINICAL PRESENTATION, CLINICAL COURSE, AND DIAGNOSIS

Clinical Course

- 2 MS has four clinical patterns: relapsing remitting, secondary progressive, primary progressive, and progressive relapsing (Fig. 30-2). Relapsing remitting MS develops into secondary

Table 30-1

Clinical Rating Scales Used in MS

EDSS

Rates functional systems from 0 (normal) to 10 (death due to MS)
Emphasis is on ambulation over other symptoms

MSFC

Three-part tool rating ambulation, limb function, and cognitive function
Composite score is compared with standardized population
Correlates better with MRI data than EDSS

MS, multiple sclerosis; EDSS, Expanded Disability Status Scale; MSFC, multiple sclerosis functional composite.

From Refs. 12 and 13.

progressive MS in 50% of patients within 10 years and in 75% within 25 years of diagnosis.¹ Rating scales are used clinically (Table 30-1). MS reduces overall life expectancy by 10 years.¹⁴ Suicide is disproportionately high in MS patients, causing 15% of MS-related deaths.¹⁵

Diagnosis

MS diagnostic criteria were revised in 2010 (Fig. 30-3).¹⁶ Diagnosis of relapsing remitting MS requires plaque dissemination in time and space. Previously, diagnosis relied on clinical examination. 3 The McDonald criteria, which uses the clinical examination in combination with magnetic resonance imaging (MRI) data, facilitates earlier diagnosis and thus earlier treatment initiation. Primary progressive MS diagnosis requires 1 year of disease progression and two of the following: evidence for dissemination in space on MRI of the brain, evidence for dissemination in space on MRI in the spinal cord based on two or more T2-weighted lesions, and positive cerebrospinal fluid (CSF) (oligoclonal immunoglobulin G bands or elevated immunoglobulin G index).¹⁶

TREATMENT

Desired Outcomes and General Approach to Treatment

The goal of treatment is preventing permanent neurologic damage. There are three general approaches to treatment. 4 First, acute relapses are treated with corticosteroids to speed recovery. 5 Second, disease-modifying therapies decrease the number of relapses, prevent permanent neurologic damage, and prevent disability. 6 Third, symptomatic treatments minimize the impact of MS on quality of life.

Pharmacologic Treatment

► Treatment of Acute Relapses

The mechanism of action of corticosteroids is unclear but may involve:

FIGURE 30-1. Autoimmune theory of the pathogenesis of multiple sclerosis (MS). In MS, the immunogenic cells tend to be more myelin-reactive, and these T-cells produce cytokines mimicking a Th1-mediated proinflammatory reaction. T-helper cells (CD4+) appear to be key initiators of myelin destruction in MS. These autoreactive CD4+ cells, especially of the T-helper cells type 1 (Th1) subtype, are active in the periphery, perhaps following a viral infection, and express adhesion molecules on their surfaces that allow them to attach and roll along the endothelial cells that constitute the blood-brain barrier. For this reaction to occur, costimulation and MHC along with an antigen on an APC (macrophage, dendrite cell, B cell) must be present. The activated T cells also produce MMP that help to create openings in the blood-brain barrier, allowing entry of the activated T cells past the blood-brain barrier and into the CNS. Once inside the CNS, the T cells produce proinflammatory cytokines, especially interleukins (ILs) 1, 2, 12, 17, and 23, tumor necrosis factor (TNF)- α , and interferon (INF)- γ , which further create openings in the blood-brain barrier, allowing entry of B cells, complement, macrophages, and antibodies. The T cells also interact within the CNS with the resident microglia, astrocytes, and macrophages, further enhancing production of proinflammatory cytokines and other potential mediators of CNS damage, including reactive oxygen intermediates and nitric oxide. The role of modulating, or downregulating, cytokines such as IL-4, IL-5, IL-10, and transforming growth factor (TGF)- β also has been described. These cytokines are the products of CD4+, CD8+, and Th1 cells. New pathogenic mechanisms involve, but are not limited to, receptor-ligand-mediated T-cell entry via choroid plexus (CCR6-CCL20 axis), coupling of key receptor-ligands for inhibition of myelination/demyelination (LINGO-1/NOGO66/p75, or TROY complex, Jagged-Notch signaling). (AG, antigens; APC, antigen-presenting cell; DC, dendrite cell; IgG, immunoglobulin G; M ϕ , macrophage; Na⁺, sodium ion; MMP, matrix metalloproteinases; MHC, major histocompatibility complex; OPC, oligodendrocyte precursor cell; VLA, very late antigen; VCAM, vascular cell adhesion molecule.) (From Bainbridge JL, Corboy JR. Multiple sclerosis. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. *Pharmacotherapy: A Pathophysiologic Approach*. 8th ed. New York, NY: McGraw-Hill; 2011:963–978.)

Clinical Presentation of MS⁵⁻¹¹

1 MS symptoms depend on the location of lesions within the CNS. Myelin increases the speed of nerve impulse transmission; demyelination slows the speed. No impulses can be transmitted if the axon is transected. The primary symptoms of MS are caused by this delay or cessation of impulses. Secondary symptoms of MS result from the primary symptoms.

Primary Symptoms	Frequency of Occurrence (%)	Related Secondary Symptoms
Urinary symptoms	90	
Incontinence		Decubitus ulcers
Urinary retention		Urinary tract infections
Spasticity	60	Falls, care difficulties, pain, gait problems
Visual symptoms		
Optic neuritis	55	Falls, care difficulties
Diplopia		
Bowel symptoms		
Incontinence	29–51	Decubitus ulcers
Constipation	35–54	Pain
Depression	50	Suicide
Cognitive deficits	50	Care difficulties
Weakness		Falls, care difficulties, gait problems
Fatigue	76–92	
Uhthoff's phenomenon	80	
Sexual dysfunction		
Erectile dysfunction	70	
Female sexual dysfunction	72	
Tremor	25	
Pain		
Trigeminal neuralgia	2	
Lhermitte's sign	9	
Dysesthetic pain	18	

- Prevention of inflammatory cytokine activation
- Inhibition of T- and B-cell activation
- Prevention of immune cells from entering the CNS
- Increased regulatory T-cell activity that controls autoimmune T-cell formation^{17,18}

IV adrenocorticotropic hormone, IV methylprednisolone, or oral prednisone hasten functional recovery.¹⁹ Traditionally, IV methylprednisolone was used because an **optic neuritis** study demonstrated reduced recurrence with IV methylprednisolone but not oral prednisone.²⁰ More recent studies show equal efficacy of equivalent doses of IV and oral dosage forms, and oral dosing avoids discomfort, inconvenience, and expense of IV therapy.²¹

Adverse Effects The most common adverse effects are GI upset, insomnia, and mood swings.²²

Dosing and Administration Methylprednisolone is given 1 g/day IV as one dose or in divided doses for 3 to 5 days. Oral prednisone 1,250 mg/day given every other day for five doses provides an equivalent dose.

Clinical improvement usually begins during treatment. Neurologic recovery is equivalent with or without a subsequent oral prednisone taper.²³

► Outcome Evaluation

- Monitor for symptom improvement
- Educate regarding adverse effects

Disease-Modifying Therapies

Seven agents are indicated for MS: subcutaneous interferon β -1a (Rebif); intramuscular interferon β -1a (Avonex); interferon β -1b (Betaseron, Extavia); glatiramer acetate (Copaxone); mitoxantrone (Novantrone); natalizumab (Tysabri); and fingolimod (Gilenya). Generally, these immunomodulators reduce annualized relapse rates 30% to 70%.²⁴⁻²⁶

► β -Interferons

Pharmacology and Mechanism of Action The mechanism of action of β -interferons is unknown. The following properties are thought to be important:

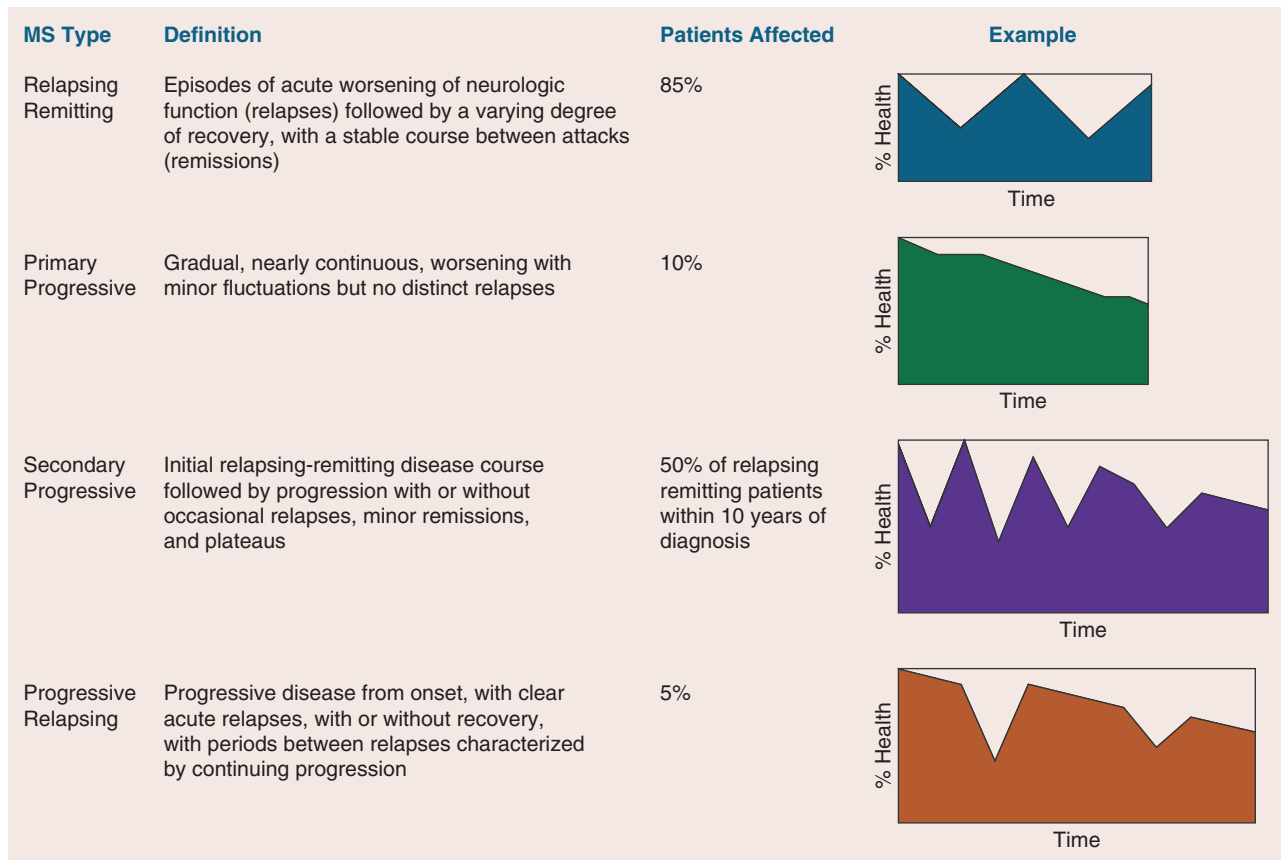

FIGURE 30-2. Comparison of clinical course of MS by type.

Patient Encounter, Part 1

SN is a 30-year-old white woman who visits the emergency department today with complaints of weakness and tingling in her right arm that developed over several hours. She has never experienced symptoms like this previously. She has been generally healthy but has experienced occasional migraine headaches since puberty. She has recently moved to your area to work at the university. Before that, she lived in Minnesota her entire life.

What information is suggestive of multiple sclerosis (MS)?

What risk factors does she have for MS?

What additional information or testing would assist in making the diagnosis of MS?

What treatment could be provided to SN for the current acute event?

- Decrease in T-cell activation, decreasing cytokine secretion, and preserving myelin
- Prevention of upregulation of adhesion molecules on activated T cells, limiting the number of T cells that can get into the brain

- Suppression of MMPs, maintaining the integrity of the blood–brain barrier
- Decrease in microglial proliferation, preserving myelin
- Promotion of formation of Th2 cells rather than Th1 cells, decreasing inflammation
- Inhibition of viruses, important if MS has a viral etiology²⁷

► Efficacy

Patients with Relapsing Remitting MS β -Interferons reduce relapses by about one-third, compared with placebo.²⁸ Early treatment after a first clinical attack delayed time to a second attack by 9 to 13 months compared with placebo^{29,30} and was associated with a lower incidence of developing clinically definite MS compared with delaying treatment.^{31,32}

Patients with Secondary Progressive MS Who Experience Relapses β -Interferons have mixed results for slowing disease progression in secondary progressive MS. Treatment is most likely to be effective if clinical relapses or MRI signs of inflammatory activity are present.³³

Adverse Effects Adverse effects are common with β -interferons (Table 30-2). Flu-like symptoms include fever, fatigue, muscle aches, malaise, and chills. Symptoms begin a few hours postinjection and dissipate within 8 to 24 hours.³⁴ Injection site reactions range from redness to necrosis. There

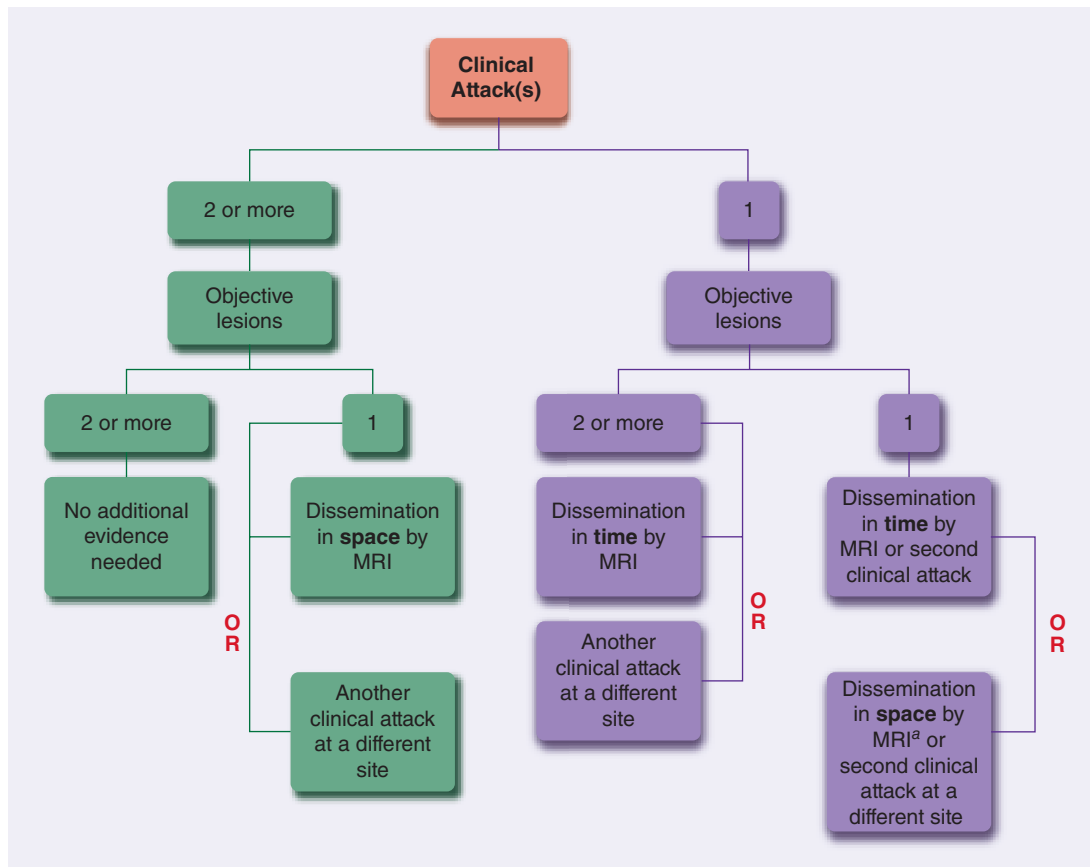

FIGURE 30-3. McDonald diagnostic criteria for MS.¹⁶ An attack is defined as a patient-reported or objectively observed event typical of an acute inflammatory demyelinating event in the CNS with a duration of at least 24 hours in the absence of fever or infection. Magnetic resonance imaging (MRI) evidence of dissemination over time is a new T2-weighted lesion after the initial clinical event or the simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions at any time.
^aDissemination in space by MRI evidence of one or more T2-weighted lesions in at least two of the following areas: periventricular, juxtacortical, infratentorial, spinal cord.

are preventive and treatment measures for these reactions (Table 30-3). Periodic laboratory monitoring for adverse effects is recommended (Table 30-4). At the threshold laboratory values (Table 30-3), interferon should be suspended. When values normalize, interferon may be resumed with gradual dose increases and careful monitoring.³⁴ The α - and γ -interferons are associated with depression. Up to 50% of MS patients experience depression, even without β -interferon treatment.⁹ Because of conflicting data, it is difficult to determine the role of β -interferons in depression.⁹

Tests for Responsiveness Antibodies to β -interferons can reduce clinical benefit.³⁷ **Neutralizing antibodies** develop 18 to 24 months after initiation. Neutralizing antibodies can form against any β -interferon and are cross-reactive, but frequency and route of administration affect development: 28% to 47% for subcutaneous interferon β -1b; 12% to 28% for subcutaneous interferon β -1a; and 2% to 6% for intramuscular interferon β -1a.³⁷

Issues surround neutralizing antibodies: standardization of the assay, testing recommendations, and treatment recommendations for positive tests.³⁷ Neutralizing antibodies may disappear even during continued treatment.³⁷

β -interferons induce the expression of interferon-responsive genes such as myxovirus-resistance-protein A (MxA). Lack of expression to MxA testing is associated with MS relapses.³⁸

Dosing and Administration Dose, frequency, and route of administration differ among the β -interferon products (Table 30-2). **7** *Dose-response curves have been observed with the β -interferons.* However, it is unknown if the total weekly dose or the frequency of administration is more important.³³

► Glatiramer Acetate

Pharmacology and Mechanism of Action The mechanism of action of glatiramer acetate is unknown; the following properties have been observed:

- Binds to MHC class II, blocking the activation of T cells
- Activates Th2 cells, preventing inflammation
- Activated Th2 cells secrete brain-derived neurotrophic factor, which may be neuroprotective.²⁷

Efficacy Glatiramer acetate reduces relapses by 28% each year compared with placebo. Additionally, relapses occur later compared with placebo (322 versus 219 days).³⁹

Table 30–2

Comparison of Disease-Modifying Therapies

Drug	Dose	Route	Frequency	Selected Adverse Effects
Interferon β -1a (Avonex)	30 mcg	IM	Weekly	Flu-like symptoms 61% Anemia 8%
Interferon β -1a (Rebif)	44 mcg	SQ	3 x per week	Flu-like symptoms 28% Injection site reactions 66% Leukopenia 22% Increased aspartate aminotransferase/alanine transaminase 17–27%
Interferon β -1b (Betaseron, Extavia)	0.25 mg	SQ	Every other day	Flu-like symptoms 60–76% Injection site reactions 50–85% Asthenia 49% Menstrual disorder 17% Leukopenia 10–16% Increased aspartate aminotransferase/alanine transaminase 4–19%
Glatiramer acetate (Copaxone)	20 mg	SQ	Daily	Injection site reaction 90% Systemic reaction 15%
Mitoxantrone (Novantrone)	12 mg/m ² up to 140 mg/m ² (maximum lifetime dose)	IV	Every 3 months	Nausea 76% Arrhythmia 3–18% Cardiotoxicity Alopecia 61% Menstrual disorders 61% Urinary tract infection 32% Amenorrhea 25% Leukopenia 19%
Natalizumab (Tysabri)	300 mg	IV	Every 4 weeks	γ -Glutamyl transpeptidase increase 15% Headache 38% Fatigue 27% Arthralgia 19% Urinary tract infection 20% Hypersensitivity reaction less than 1% Progressive multifocal leukoencephalopathy 0.13%
Fingolimod (Gilenya)	0.5 mg	PO	Daily	Headache 25% Increased aspartate aminotransferase/alanine transaminase 14% Influenza viral infections 13% Diarrhea 12% Cough 10% Bradycardia 4% Lymphopenia 4%

From Refs. 19, 25, 26, 34, 35, 36.

Adverse Effects Patients report injection site reactions (Table 30–2). Icing the injection site pre- and postinjection and/or topical anesthetics improve these reactions. Systemic reactions involve flushing, chest tightness, palpitations, anxiety, and shortness of breath. This reaction usually occurs within 30 minutes of the injection; recurrence is infrequent. Doses may be reduced by 75% for the week following the reaction, then increased by 25% per week to the full dose.³⁵

► Issues with Self-Injected Disease-Modifying Therapies

Adherence Adherence to injectable medications is a significant problem, with no significant difference in discontinuation

rates between products (17%–41%). Reasons for discontinuation are adverse effects and lack of efficacy. Realistic therapy expectations, higher educational levels, and higher self-efficacy improve adherence rates; depression and cognitive problems lower adherence.^{40,41}

- **Choosing Therapy** 8 *There is no consensus on the best medication for initial therapy.* Comparative β -interferon trials indicate better efficacy with more frequent and/or higher dosing.³³ This consideration must be balanced with neutralizing antibody development, patient acceptance, and tolerance. Head-to-head trials between β -interferons and glatiramer acetate demonstrated similar efficacy and tolerability.^{42,43}

Patient Education Refer to Table 30–5 for patient education for self-injection.

Table 30-3

Prevention or Treatment Strategies for β -Interferon Adverse Effects

Flu-Like Symptoms	Injection Site Reaction	Laboratory Abnormalities ^a
Inject dose in the evening	Bring medication to room temperature	Hemoglobin less than 9.4 g/dL (94 g/L or 5.8 mmol/L)
Begin at ¼–½ dose for 2 weeks of treatment; then increase to a full dose	Ice injection site before and after injection Rotate injection sites Inject in areas with more subcutaneous fat (buttocks or abdomen)	White blood cells less than $3 \times 10^3/\text{mm}^3$ (less than $3 \times 10^9/\text{L}$) Absolute neutrophil count less than $1.5 \times 10^3/\text{mm}^3$ (less than $1.5 \times 10^9/\text{L}$)
Use ibuprofen 200 mg before and 6 and 12 hours after injection	Use an autoinjection device	Platelets less than $75 \times 10^3/\text{mm}^3$ (less than $75 \times 10^9/\text{L}$)
Alternatives to ibuprofen include acetaminophen, prednisone taper, and pentoxifylline	If severe, use hydrocortisone 1% cream on the site If necrotic: temporarily discontinue; consult dermatologist; do not use topical corticosteroids	Bilirubin more than $2.5 \times$ baseline AST/ALT more than $5 \times$ baseline Alkaline phosphatase more than $5 \times$ baseline

ALT, alanine aminotransferase; AST, aspartate aminotransferase.

^aAt these threshold values, β -interferon should be temporarily discontinued and laboratory values monitored.

From Refs. 34 and 35.

Table 30-4

Monitoring Disease-Modifying Therapies

Therapy	Tests	Frequency
β -Interferons (Avonex, Betaseron, Rebif)	CBC, bilirubin, electrolytes, AST, ALT, γ -glutamyl transferase, alkaline phosphatase Thyroid function tests	Baseline, 1, 3, and 6 months; then every 3 months Baseline and every 6 months in patients with a history of thyroid dysfunction
	EDSS, MSFC, neurologic history and examination	Every 3 months during the first year of therapy; then every 6 months
Glatiramer acetate (Copaxone)	EDSS, MSFC, neurologic history and examination	Every 3 months during the first year of therapy; then every 6 months
Mitoxantrone (Novantrone)	CBC, bilirubin, AST, ALT, alkaline phosphatase, pregnancy test ECG Echocardiogram or MUGA scan	Before each infusion Baseline and prior to each infusion Baseline; prior to each infusion, and yearly after stopping mitoxantrone
Natalizumab (Tysabri)	EDSS, MSFC, neurologic history and examination	Every 3 months during the first year of therapy; then every 6 months
	HIV, CBC, AST, ALT, MRI MRI, CSF examination for JC virus Preinfusion patient checklist Status report and reauthorization questionnaire	Baseline; every 3 months during the first year of therapy; then every 6 months Baseline; repeat MRI at 6 months; then yearly At onset of new neurologic symptoms not suggestive of MS Prior to every infusion
Fingolimod (Gilenya)	EDSS, MSFC, neurologic history and examination	Every 6 months Every 3 months during the first year of therapy; then every 6 months
	Varicella zoster immunity evaluation and/or vaccination and FEV ₁ (full pulmonary function testing if patient has history of asthma or COPD)	Baseline
	CBC, ALT, AST Pulse and blood pressure	Baseline and every 6 months Baseline; observe in clinical area for 6 hours after initial dose with periodic monitoring
	Ophthalmology evaluation Dermatologic evaluation	Baseline; 4 months; then as needed Baseline; then as needed

ALT, alanine aminotransferase; AST, aspartate aminotransferase; CBC, complete blood count; COPD, chronic obstructive pulmonary disease; CSF, cerebrospinal fluid; EDSS, Expanded Disability Status Scale; FEV₁, forced expiratory volume in 1 second; HIV, human immunodeficiency virus; MRI, magnetic resonance imaging; MS, multiple sclerosis; MSFC, Multiple Sclerosis Functional Composite; MUGA, multiple-gated acquisition.

Table 30-5

Patient Education for Self-Injection

Keep all nonrefrigerated supplies together and out of the reach of children and pets
 If refrigerated, allow medication to warm to room temperature
 Wash hands thoroughly
 Choose injection site, rotating among sites
 Ice area to be injected for no more than 15 minutes, if desired
 Clean injection site thoroughly with alcohol or soap and water
 Administer injection
 Ice injection site for no more than 15 minutes after injection, if desired

► Mitoxantrone

Pharmacology and Mechanism of Action Mitoxantrone is an anthracenedione antineoplastic indicated for MS. The mechanisms of action thought to be important for MS include:

- Causes **apoptosis** in T and APCs, preventing initial T-cell activation
- Inhibits DNA and RNA synthesis, decreasing proliferation of T cells, B cells, and macrophages
- Decreases cytokine release, preventing inflammation
- Inhibits macrophages, preventing myelin degradation⁴⁴

Efficacy Mitoxantrone is indicated for secondary progressive MS, progressive relapsing MS, and for patients with worsening relapsing remitting MS. It reduces the relapse rate and attack-related MRI outcome measures. **9** *Because of its potential for significant toxicities, mitoxantrone is reserved for patients with rapidly advancing disease who have failed other therapies.*¹⁹

Adverse Effects Adverse effects are seen regularly in patients given mitoxantrone (Table 30-2). Bluish discoloration of the sclera and the urine lasts 24 hours postinfusion.³⁶ Transient leukopenia and neutropenia are common.⁴⁹ Patients taking mitoxantrone should not receive live virus vaccines; other vaccines should be held for 4 to 6 weeks after a mitoxantrone dose.³⁶ Amenorrhea may be permanent.³⁶

Cardiotoxicity is a serious adverse effect; reduction in left ventricular ejection fraction is not related to dose, sex, or age.^{36,45} Mitoxantrone should not be used in patients with baseline cardiomyopathy, even if asymptomatic. Cyclooxygenase-2 inhibitors should be avoided in patients receiving mitoxantrone because of a potential for worsening cardiac toxicity.³⁶ The maximum lifetime dose of mitoxantrone is 140 mg/m².

Acute myelogenous leukemia occurred in 0.07% of mitoxantrone-treated patients, appearing within 2 to 4 years of initiating mitoxantrone and responsive to standard therapy.³⁶

Dosing and Administration Mitoxantrone is infused intravenously over 30 minutes to reduce the chance of cardiotoxicity.³⁶ Mitoxantrone is administered every

3 months, if cardiac function and laboratory values are normal (Table 30-4).

► Natalizumab

Pharmacology and Mechanism of Action Natalizumab is a α_4 -integrin antagonist indicated for relapsing forms of MS. Its postulated mechanism of action follows:

- Binds to $\alpha_4\beta_1$ and $\alpha_4\beta_7$ integrins, preventing lymphocytes migration into the CNS and inflammation
- Inhibits binding of α_4 -positive leukocytes to fibronectin and osteopontin, decreasing the activation of leukocytes already within the CNS²⁶

Efficacy Treatment with natalizumab reduced relapses by 68% at 1 year and disability by 42% at 2 years compared with placebo.²⁶

Adverse Effects Adverse effects of natalizumab include infection, arthralgia, headache, and fatigue (Table 30-2).²⁶ Hypersensitivity reactions have been observed; symptoms may include itching, dizziness, fever, rash, hypotension, dyspnea, chest pain, and anaphylaxis, usually within 2 hours of administration. If these symptoms occur, natalizumab is discontinued. An infusion reaction consisting of headache, dizziness, fatigue, nausea, sweats, and rigors may occur within 2 hours of dosing.⁴⁶ Histamine 1 and 2 receptor blockers can be used to prevent these symptoms, and discontinuation is not required. A much more serious, but rare, adverse effect is progressive multifocal leukoencephalopathy (PML). PML, caused by the JC polyomavirus virus, is rapidly progressive and usually results in death or permanent disability. Due to this risk, natalizumab is distributed through a restricted program. **9** These concerns lead to the recommendation that *natalizumab be reserved for patients with rapidly advancing disease who have failed other therapies*. Specific recommendations are to avoid in immunocompromised patients; carefully assess for immune compromise in patients previously treated with immunosuppression, radiation therapy, or chemotherapy; and to carefully monitor patients.⁴⁷ Between 2006 and 2010, 31 new cases of natalizumab PML were reported.⁴⁸ Risk of PML increases with increased infusions.⁴⁸ Vigilance is paramount because PML can mimic symptoms associated with MS.⁴⁹

Antinatalizumab antibodies develop in 9% to 12% of patients. If patients are persistently antibody positive, relapse rates and disability increase; antibody development is also associated with hypersensitivity reactions.⁵⁰

Dosing and Administration Natalizumab should be used as monotherapy.⁴⁷ Natalizumab is administered 300 mg in 100 mL normal saline over a 1-hour IV infusion every 4 weeks. Few patients have been treated for more than 3 years with natalizumab.

► Fingolimod

Pharmacology and Mechanism of Action Fingolimod, indicated for relapsing forms of MS, is a sphingosine 1-phosphate

receptor modulator. It retains T cells in lymphoid tissues, thus depleting peripheral blood and CNS lymphocytes.⁵¹

Efficacy Treatment with fingolimod reduced the annualized relapse rate to 0.18 compared with 0.40 for placebo.²⁵

Adverse Effects Fingolimod is generally well-tolerated (Table 30–2), but it has serious adverse effects. Fingolimod reduces circulating lymphocytes by about 75%; thus infections and malignancies are concerns.^{25,52} Sphingosine 1-phosphate receptors elsewhere in the body are associated with first-dose bradycardia, macular edema, and reduced forced vital capacity.⁵³ With the exception of bradycardia, these effects persist for 2 months after medication discontinuation due to the long half-life of fingolimod.⁵⁴

Dosing and Administration Fingolimod is given 0.5 mg orally once daily.

► Outcome Evaluation

- Assess periodically for symptom changes.
- In β -interferon-treated patients with frequent relapses, testing for neutralizing antibodies and/or MxA gene expression may assist in choosing therapy.
- Monitor for medication-specific adverse effects (Tables 30–2 and 30–4).
- Assess adherence with all components of therapy regularly.

► Symptomatic Therapies

The symptoms most unique to MS are fatigue, spasticity, impaired ambulation, and pseudobulbar affect. Other important symptoms such as urinary incontinence, pain, depression, cognitive impairment, and sexual dysfunction are discussed only briefly (refer to other chapters).

Fatigue There are nonpharmacologic and pharmacologic strategies for decreasing the impact of fatigue on the lifestyle of MS patients (Table 30–6). Pharmacologic management of fatigue includes amantadine or stimulants; however, evidence of efficacy from randomized controlled trials is limited.

Spasticity Spasticity treatment goals are patient specific. For ambulatory patients, reducing spasticity may improve mobility. For bed-bound patients, treating spasticity may relieve pain and facilitate care. Physical therapy is a nonpharmacologic treatment for spasticity.⁵

MS patients usually have upper motor neuron spasticity that cannot be treated with muscle relaxants (e.g., carisoprodol).

10 MS patients must be treated with agents specific for upper motor neuron spasticity (Table 30–7).⁵ MS spasticity is classified as focal or generalized. If the spasticity involves only one muscle group, it is focal and may benefit from botulinum toxin administration.⁵ Systemic medications are used for generalized spasticity. No clear conclusion can be reached regarding the efficacy superiority of one agent; medication selection is based on adverse effects (see Table 30–7).⁵

Patient Encounter, Part 2

PMH: Migraine headaches

FH: No history of MS. Both parents and one sister alive and well.

SH: Faculty member in Psychology Department. Single. She does not smoke or use illicit drugs. She does have two to four drinks per week of alcohol.

Allergies: NKDA

Medications: Zolmitriptan 5 mg by mouth as needed for headache. May repeat once in 2 hours, if needed.

ROS: (–) N/V/D, HA, SOB, chest pain, cough

PE:

VS: 126/74, P 70, RR 18, T 38°C (100.4°F)

Skin: warm, dry

HEENT: NC/AT, PERRLA, TMs intact

CV: RRR, normal S₁ and S₂, no m/r/g

Chest: CTA

Abd: Soft, NT/ND

Neuro: A & O \times 3; CN II–XII intact, end point nystagmus on lateral gaze bilaterally

Motor: mild weakness in right arm, poor finger-to-nose left upper extremity

LABS: WNL

Imaging: T-2 weighted MRI shows a gadolinium-enhancing T2-weighted lesion in the left corona radiate (periventricular region), five nonenhancing T2-weighted white matter lesions scattered near the cortex (juxtacortical region), and one nonenhancing T2-weighted lesion in the white matter tracts of the left medial cerebellum (infratentorial region).

Given this additional information, what is your assessment of SN's condition?

Identify your treatment goals for this patient.

What pharmacologic alternatives are available for SN?

What counseling points will you give SN for administration of your chosen therapy?

Impaired Ambulation Gait abnormalities decrease walking speed and endurance and lead to use of assistive devices.

- An extended-release form of dalfampridine is indicated for improvement in walking ability. This potassium channel blocker probably prolongs the action potential and improves conduction in demyelinated neurons.⁵⁸ Not all patients respond to therapy, but in responders, times to complete a 25-foot (7.6-m) timed walk decrease about 25%.⁵⁹ Urinary tract infections, insomnia, dizziness, headache, nausea, asthenia, back pain, and balance disorder all occur relatively frequently with extended-release dalfampridine.⁵⁸ Seizures are an uncommon adverse effect; patients with preexisting seizure disorders should not receive extended-release dalfampridine.⁵⁸

Table 30-6

Pharmacologic and Nonpharmacologic Treatments for Fatigue

Nonpharmacologic	Pharmacologic	Renal Dosing
Appropriate rest-to-activity ratio Use of assistive devices to conserve energy	<i>First-line therapy:</i> Amantadine 100 mg orally every morning and early afternoon	CrCl 30–50 mL/min (0.50–0.84 mL/s): 100 mg/day CrCl 15–29 mL/min (0.25–0.49 mL/s): 100 mg every other day CrCl less than 15 mL/min (less than 0.25 mL/s): 200 mg every 7 days
Environmental modifications to make activities more energy efficient Cooling strategies to avoid fatigue caused by elevations in core body temperature due to heat, exercise-related exertion, and fever Regular aerobic exercise, geared to the person's ability, to promote cardiovascular health, strength, improved mood, and reduce fatigue Progressive resistance training of lower limb muscles Stress management techniques	<i>Second-line therapy:</i> Methylphenidate 10–20 mg every morning and noon	

CrCl, creatinine clearance.

From Refs. 6, 55, 56.

- Pseudobulbar Affect** Ten percent of patients with MS develop pseudobulbar affect, characterized by inappropriate laughing or crying.⁶⁰ These outbursts can cause patients to become socially isolated. Dextromethorphan prevents the release of excitatory neurotransmitters. Low-dose quinine blocks first-pass metabolism of dextromethorphan and increases serum concentrations. A 49% decrease in inappropriate emotional episodes was seen with treatment.⁶⁰
- Other Symptoms** Two types of urinary tract symptoms are commonly seen in MS: incomplete bladder emptying and incontinence. Dyscoordination of the external urethral sphincter and detrusor activity causes incomplete bladder emptying.⁸ Most patients with this condition require urinary catheterization.⁸ Incontinence is usually caused by neurogenic detrusor overactivity. First-line treatments are anticholinergics such as oxybutynin or tolterodine.
- Bowel symptoms in MS patients include fecal incontinence and constipation. Fecal incontinence is difficult to treat; a regular schedule for emptying the bowel with laxative suppositories or enemas may be helpful. Alternatively, antidiarrheal medications such as loperamide can be used.⁸

Table 30-7

Comparison of Antispasticity Agents

Place in Therapy	Medication	Mechanism of Action	Dose
First line	Baclofen	Pre- and postsynaptic γ -aminobutyric acid β -receptor blocker	5 mg orally 3 \times daily; increase by 5 mg/dose every 3 days to a maximum of 80 mg/day <i>Renal dysfunction:</i> Dose reduction may be necessary 4 mg orally daily; increase by 2–4 mg 3–4 \times daily to a maximum of 36 mg/day <i>Hepatic and renal dysfunction:</i> Dose reduction may be necessary
	Tizanidine	Centrally acting α_2 -receptor agonist	25 mg orally daily; increase to 25 mg 3–4 \times daily; then increase by 25 mg every 4–7 days to a maximum of 400 mg/day 2–10 mg orally 3–4 \times daily <i>Cirrhosis:</i> Reduce dose by 50%
Second line	Dantrolene	Direct inhibitor of muscle contraction by decreasing the release of calcium from skeletal muscle sarcoplasmic reticulum	25 mg orally daily; increase to 25 mg 3–4 \times daily; then increase by 25 mg every 4–7 days to a maximum of 400 mg/day
	Diazepam	γ -Aminobutyric acid agonist	2–10 mg orally 3–4 \times daily <i>Cirrhosis:</i> Reduce dose by 50%
Third-line	Intrathecal baclofen	Pre- and postsynaptic γ -aminobutyric acid β -receptor blocker	Titrated individually; usual range: 62–749 mcg/day
Focal spasticity	Botulinum toxin	Prevents release of acetylcholine in the neuromuscular junction	Individualized

Data from Refs. 5 and 57.

Patient Encounter, Part 3

SN begins therapy with interferon β -1b subcutaneously every other day. She does very well with no relapses and minimal adverse effects for 2 years. Then, within the course of 6 months, she experiences two relapses. Her MRI shows several new lesions, and her neurologist orders a neutralizing antibody titer. The laboratory reports the titer as "high" with 160 neutralizing units/mL. SN also complains of fatigue that worsens throughout the day to the point that she says she is unable to get off the couch in the evenings and frequently skips her evening meal.

How will you respond to the neutralizing antibody titer?

What nonpharmacologic and pharmacologic treatments can you recommend for SN's fatigue?

- Pain occurs in up to 86% of patients. Pain may be neuro-pathic, related to spasticity, related to treatment, or unrelated to MS. Correct pain type classification is necessary for effective treatment.⁹
- Desipramine and sertraline are efficacious for MS-related depression.⁹ Discontinuation of β -interferon treatment may be considered.

Patient Care and Monitoring

1. Once diagnosed, work with the patient to select therapy, considering:
 - Route of administration
 - Frequency of administration
 - Adverse-effect profile and other concerns (e.g., neutralizing antibodies and concomitant depression)
2. Obtain the required baseline laboratory studies (Table 30–6).
3. Educate the patient regarding self-injection (Table 30–5).
4. Assess the patient for symptomatic treatment needs.
5. Initiate needed symptomatic treatments.
6. Refer the patient to the National MS Society for information, newsletters, and local support groups (www.nmss.org).
7. Instruct the patient to contact the clinician for any sudden symptom changes that suggest a relapse.
8. Monitor the patient for efficacy and adverse effects of disease-modifying and symptomatic therapies every 3 months for the first year and every 6 months thereafter and as required for selected therapy (Table 30–6).
9. Treat any relapses with methylprednisolone IV or prednisone orally.

- Cognitive impairment and memory dysfunction can be troublesome, affecting 40% to 60% of patients. Treatment with β -interferon or acetylcholinesterase inhibitors has demonstrated improvement.⁶¹

Phosphodiesterase type 5 inhibitors are effective for MS-induced erectile dysfunction.⁸ In women, vaginal dryness or dyspareunia may respond to lubricating jellies.

► Outcome Evaluation

- Assess for improvement/recurrence of symptoms.
- Monitor for adverse effects of medications.
- Monitor for adherence.

Abbreviations Introduced in This Chapter

Abs	Autoantibodies
ALT	Alanine aminotransferase
APC	Antigen-presenting cell
AST	Aspartate aminotransferase
CAM	Cellular adhesion molecule
CNS	Central nervous system
CSF	Cerebrospinal fluid
EDSS	Expanded Disability Status Scale
HHV-6	Human herpes virus 6
IL	Interleukin
LT	Lymphotoxin
MHC	Major histocompatibility complex
MMP	Matrix metalloproteinase
MS	Multiple sclerosis
MSFC	Multiple Sclerosis Functional Composite
MUGA	Multiple-gated acquisition
MxA	Myxovirus-resistance-protein A
NO	Nitric oxide
PML	Progressive multifocal leukoencephalopathy
TCR	T-cell receptor
TGF	Transforming growth factor
Th1	T-helper-1 cells
Th2	T-helper-2 cells
TNF	Tumor necrosis factor

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Epilepsy

Timothy E. Welty and Edward Faught

LEARNING OBJECTIVES

1. Describe the epidemiology and social impact of epilepsy.
2. Define terminology related to epilepsy, including seizure, convulsion, and epilepsy.
3. Describe the basic pathophysiology of seizures.
4. Describe the basic pathophysiology of epilepsy.
5. Differentiate and classify seizure types when provided a description of the clinical presentation of the seizure and electroencephalogram.
6. Identify key therapeutic decision points in the treatment of epilepsy.
7. Establish therapeutic goals for pharmacotherapy in a patient with epilepsy.
8. Discuss nonpharmacologic treatments for epilepsy.
9. Recommend an appropriate pharmacotherapeutic regimen for the treatment of epilepsy.
10. Select appropriate monitoring parameters for a pharmacotherapeutic regimen for epilepsy.
11. Devise a plan for switching a patient from one antiepileptic regimen to a different regimen.
12. Recognize complications of pharmacotherapy for epilepsy.
13. Analyze potential drug interactions with antiepileptic drugs (AEDs).
14. Determine when and how to discontinue AED therapy.
15. Educate a patient or caregiver on epilepsy and pharmacotherapy for this disorder.

KEY CONCEPTS

- 1 A distinction between convulsions, a single seizure, pseudoseizure, and epilepsy should be made in patients presenting with possible seizures.
- 2 Selection of appropriate pharmacotherapy depends on distinguishing, identifying, and understanding different seizure types.
- 3 Prior to starting pharmacologic therapy, it is essential to determine the risk of having a subsequent seizure.
- 4 Mechanisms of action, effectiveness for specific seizure types, common adverse effects, and potential for drug interactions are key elements in selecting a medication for individual patients.
- 5 Antiepileptic drug (AED) therapy should usually be initiated carefully using a titration schedule to minimize adverse events.
- 6 Changes in AED regimens should be done in a stepwise fashion, keeping in mind drug interactions that may be present and may necessitate dosage changes in concomitant drugs.
- 7 Discontinuation of AEDs should be done gradually, only after the patient has been seizure-free for 2 to 5 years, and with careful consideration of factors predictive of seizure recurrence.
- 8 Children and women with epilepsy have unique problems related to the use of AEDs.
- 9 Older adults have the highest incidence of newly diagnosed epilepsy and face unique challenges in treatment.
- 10 Patients receiving AEDs for seizures should have regular monitoring for seizure frequency, seizure patterns, acute adverse effects, chronic adverse effects, and possible drug interactions.

EPIDEMIOLOGY, SOCIAL IMPACT, AND ETIOLOGY

Epidemiology

- **Epilepsy** is a disorder that afflicts approximately 2 million individuals in the United States, with an age-adjusted

prevalence of approximately 4 to 7 cases/1,000 persons.¹ The incidence of epilepsy in the United States is estimated at 35 to 75 cases/100,000 persons per year.^{2,3} In developing countries, the incidence is higher at 100 to 190 cases/100,000 persons per year, possibly related to poor health care and prenatal care, increased risk of neurologic trauma, and increased rates of infections. About 8% of the U.S. population will experience a **seizure** during their lifetime. New-onset seizures occur most frequently in infants younger than 1 year of age and in adults after age 55.⁴ However, the largest number of patients suffering from epilepsy are between the ages of 15 and 64 years.

Social Impact

Epilepsy is a disorder with a profound impact on a patient's life. All states limit driving for individuals who have recently had a seizure with impaired consciousness, and restrictions vary from state to state.⁵ Patients who live in communities without adequate public transportation face major impediments to simple activities of life such as purchasing groceries or getting to a job. Education is also problematic for patients with epilepsy.^{6,7} Fifty percent of patients with epilepsy complain of cognitive difficulties and believe their seizures interfere with learning. Transportation and educational difficulties combine with persistent seizures to cause patients with epilepsy to be unemployed or underemployed. Thus this group of patients faces multiple financial difficulties and often do not have health insurance.

Finally, patients with epilepsy often depend on caregivers to assist with medications, transportation, and ensuring the patient's safety. Caregivers should be informed of the patient's medical needs and how to assist should a seizure occur.

Etiology

For nearly 80% of patients with epilepsy, the underlying etiology is unknown.⁸ The most common recognized causes of epilepsy are head trauma and stroke. Developmental and genetic defects cause about 5% of cases of epilepsy. CNS tumors, CNS infections, and neurodegenerative diseases are other common causes. Human immunodeficiency virus infection or neurocysticercosis infection, primarily occurring in Latin America, are also important causes.

Isolated seizures that are not epilepsy can be caused by stroke, CNS trauma, CNS infections, metabolic disturbances (e.g., hyponatremia, hypoglycemia), and hypoxia. If these underlying causes of seizures are not corrected, they may lead to the development of epilepsy. Medications can also cause seizures. Some drugs that are commonly associated with seizures include tramadol, bupropion, theophylline, some antidepressants, some antipsychotics, amphetamines, cocaine, imipenem, lithium, excessive doses of penicillins or cephalosporins, and sympathomimetics or stimulants.

PATHOPHYSIOLOGY

Seizures

- Regardless of the underlying etiology, all seizures involve a sudden electrical disturbance of the cerebral cortex. A population of neurons fires rapidly and repetitively for seconds to minutes. Cortical electrical discharges become excessively rapid, rhythmic, and synchronous. This phenomenon is presumably related to an excess of excitatory neurotransmitter action, a failure of inhibitory neurotransmitter action, or a combination of the two. In the individual patient, it is usually impossible to identify which neurochemical factors are responsible.

Neurotransmitters

- The major excitatory neurotransmitter in the cerebral cortex is glutamate.⁹ When glutamate is released from a presynaptic neuron, it attaches to one of several receptor types on the postsynaptic neuron. The result is opening of membrane channels to allow sodium or calcium to flow into the postsynaptic neuron, depolarizing it and transmitting the excitatory signal.¹⁰ Many antiepileptic drugs (e.g., phenytoin, carbamazepine, lamotrigine) work by interfering with this mechanism, either by blocking the release of glutamate or by blocking the sodium or calcium channels, thus preventing excessive excitation.¹¹ These drugs typically do not block normal neuronal signaling, only the excessively rapid firing characteristic of a seizure. For this reason, they do not usually affect normal brain function.
 - The major inhibitory neurotransmitter in the cerebral cortex is *γ-aminobutyric acid* (GABA). It attaches to neuronal membranes and opens chloride channels. When chloride flows into the neuron, it becomes hyperpolarized and less excitable. This mechanism is probably critical for shutting off seizure activity by controlling the excessive neuronal firing. Some antiepileptic drugs (AEDs), primarily barbiturates and benzodiazepines, work by enhancing the action of GABA.
- Cortical function is modulated by many other neurotransmitters. However, their role in the pathophysiology of epilepsy and in the action of AEDs is not well understood.

Neuronal Mechanisms

- Seizures originate in a group of neurons that do not have normal electrical behavior.¹² Presumably, this is due to an underlying imbalance of neurotransmitter function as described earlier. At the level of the individual neuron, firing is excessively prolonged and repetitive. Instead of firing a single action potential, these neurons stay depolarized too long, firing a train of many action potentials. This long, abnormal depolarization is called a *paroxysmal depolarizing shift* (PDS).

The excessive electrical discharges can spread to other neurons, either adjacent ones or distant ones connected by fiber tracts. The seizure thus spreads to other areas of the brain, recruiting them into the uncontrolled firing pattern.

The neurons involved may not be abnormal themselves but are diverted from their normal functioning to participate in the wildly excessive discharges. The degree of spread and the location of brain areas involved determine the clinical manifestations of the seizure.

Nearly all seizures stop spontaneously because brain inhibitory mechanisms become strong enough to shut off the abnormal excitation.

Epilepsy

Epilepsy is the tendency to have recurrent, unprovoked seizures. This implies that there is a permanent change in cortical function that renders neurons more likely to participate in a seizure discharge. This process is called epileptogenesis, and the exact way in which it occurs is not known. A process thought to be similar to epileptogenesis in humans occurs after prolonged, intermittent electrical stimulation of animal brains and is known as **kindling**. Epilepsy may develop days, months, or many years after an insult to the cortex. It may be that an originally small group of abnormal neurons causes adjacent or connected neurons to gradually become abnormal as well, by bombarding them over time with frequent, repeated electrical impulses. When the network of abnormal neurons becomes sufficiently large, it becomes capable of sustaining an excessive firing pattern for at least several seconds: a seizure. This hyperexcitable network of neurons is then the seizure focus.

If the change in cortical electrical characteristics is permanent, why do seizures not occur all the time? This is probably because the occurrence of an individual seizure depends on an interplay of environmental and internal brain factors that intermittently result in loss of the normal mechanisms that control abnormal neuronal firing. Some common factors are sleep loss and fatigue, but it is impossible to determine what sets off a particular seizure in most patients.

In some patients, epilepsy worsens over time, with the seizures becoming more frequent as patients grow older. This does not occur in most patients with epilepsy. In those so affected, it is possible that the seizures themselves may cause some damage to the cortex; loss of neurons, especially inhibitory neurons, has been demonstrated in tissue from seizure foci. Other changes occur in brain areas affected by seizures: reorganization of connections between groups of neurons may strengthen excitatory connections and weaken inhibitory connections, making the occurrence of future seizures more likely. Additionally, epilepsy is associated with an increased mortality rate.¹³ For these reasons, an argument can be made for controlling epileptic seizures with medications as early as possible. This may reduce the possibility of permanent changes in brain function, although this hypothesis is unproven.

Genetic Factors

Patients with seizures may be concerned that their children or other family members will inherit epilepsy. This fear is

usually unfounded. Patients with acquired causes of seizures, such as head trauma or stroke, will not transmit the problem. There is a group of patients, however, who apparently have epilepsy on a genetic basis. Most of these individuals have primary generalized epilepsy.^{14,15} Usually these patients develop seizures during childhood. However, the hereditary tendency is not strong. Complex inheritance patterns are usually seen, indicating the likely involvement of several abnormal genes or other factors for seizures to be seen in offspring. Most patients can be reassured that their children and siblings are unlikely to develop epilepsy. Increasing numbers of epilepsy syndromes are being identified as being of genetic origin, and once the specific genes are identified, it may be possible to target drug therapies toward individual biochemical defects.

SEIZURE CLASSIFICATION AND PRESENTATION

General Principles

Careful diagnosis and identification of seizure types is essential to proper treatment of epilepsy. Numerous schemes and descriptions of seizures exist, but the International League Against Epilepsy (ILAE) has established the currently accepted standard for classifying epileptic seizures (**Fig. 31-1**) and epilepsies or epilepsy syndromes (**Table 31-1**).^{16,17} Classification of epileptic seizures is based on **electroencephalographic (EEG)** findings combined with the clinical findings or **semiology** of the seizure events. Clinical presentations of seizures vary widely depending on the region and amount of brain involved in the seizure.

Primary Generalized Seizures

If the entire cerebral cortex is involved in the seizure from the onset of the seizure, the seizure is classified as primary generalized. The following are types of primary generalized seizures:

- **Tonic-clonic:** Characterized by a sudden loss of consciousness accompanied by tonic extension and rhythmic clonic contractions of all major muscle groups. The duration of the seizure is usually 1 to 3 minutes. These seizures are often described as “grand mal.”
- **Absence:** Characterized by sudden and brief (i.e., several seconds in duration) losses of consciousness without muscle movements. These seizures are often described as daydreaming or blanking-out episodes. A common term for these seizures is “petit mal.”
- **Myoclonic:** Characterized by single and very brief jerks of all major muscle groups. Patients with these seizures may not lose consciousness due to the seizure lasting less than 3 to 4 seconds. Patients may describe these seizures as shoulder shrugs or spinal chills. Myoclonic seizures may cluster and build into a generalized tonic-clonic seizure.

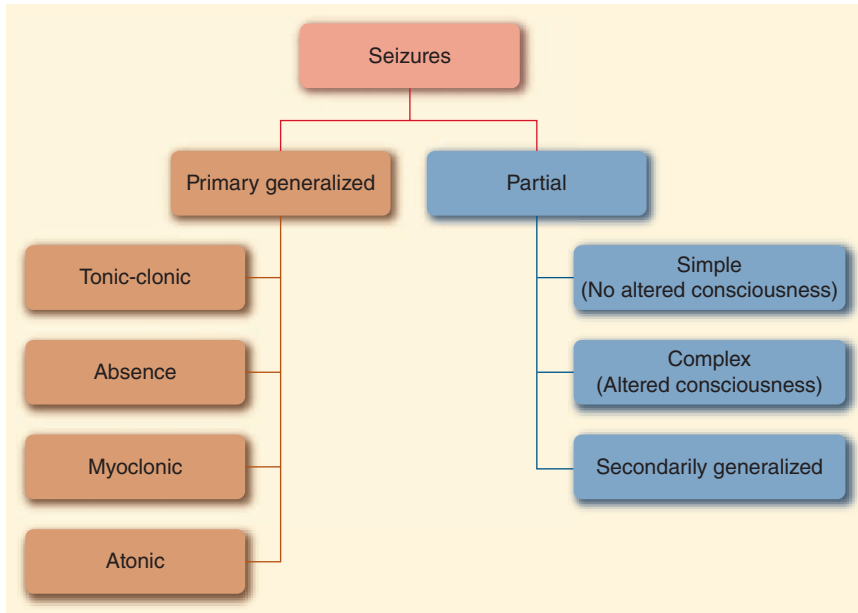

FIGURE 31-1. ILAE classification of epileptic seizures (1981). (From Commission on Classification and Terminology of the International League Against Epilepsy. Proposal for revised clinical and electroencephalographic classification of epileptic seizures. *Epilepsia* 1981;22:489–501.)

- **Atonic:** Characterized by loss of consciousness and muscle tone. No muscle movements are typically noted, and the patient falls if not lying down or sitting in a chair. These seizures may be described as “falling out.”

Partial Seizures

When the seizure begins in a localized area of the brain, it is defined as partial. There are three types of partial seizures in the current classification system (Fig. 31-1):

- **Simple:** The patient has a sensation or uncontrolled muscle movement of a portion of their body without an alteration in consciousness. The type of sensation or movement depends on the location of seizure in the brain.
- **Complex:** Although the seizure is localized in a specific area of the brain, like a simple partial seizure, there is an alteration in the patient’s level of consciousness.
- **Secondarily generalized:** The seizure starts as a simple or complex partial seizure and spreads to the entire brain. Patients may report a warning or aura, and these are actually the start of the seizure.

Table 31-1

ILAE Classification Scheme for Epilepsies and Epilepsy Syndromes

- I. Localization-related (focal, local, partial) epilepsies and epileptic syndromes
 - A. Idiopathic with age-related onset
 1. Benign childhood epilepsy with centrotemporal spikes
 2. Childhood epilepsy with occipital paroxysms
 - B. Symptomatic
- II. Generalized epilepsies and epileptic syndromes
 - A. Idiopathic and age-related onset
 1. Benign neonatal epilepsy
 2. Childhood absence epilepsy (pyknolepsy)
 3. Juvenile myoclonic epilepsy (impulsive petit mal)
 4. Juvenile absence epilepsy with generalized tonic-clonic seizure on awakening
 - B. Secondary (idiopathic or symptomatic)
 1. West’s syndrome (infantile spasms)
 2. Lennox-Gastaut syndrome
 - C. Symptomatic
 1. Nonspecific etiology (early myoclonic encephalopathy)
 2. Specific syndromes (epileptic seizures that may complicate many diseases, e.g., Ramsay-Hunt syndrome, Unverricht’s disease)

Data from Commission on Classification and Terminology of the International League Against Epilepsy. Proposal for revised classification of epilepsies and epileptic syndromes. *Epilepsia* 1989;30:389–399.

Epilepsy Syndromes

Classification of epilepsies and epilepsy syndromes is helpful in determining appropriate pharmacotherapy. This classification scheme is based on the type of seizures a patient has and an attempt to identify the etiology of the epilepsy or epilepsy syndrome:

- **Idiopathic epilepsies:** These syndromes are thought to be due to genetic alterations, but the underlying etiology is not identified. Neurologic functions are completely normal apart from the occurrence of seizures.
- **Symptomatic epilepsies:** There is an identifiable cause for the seizures, such as trauma or hypoxia.
- **Cryptogenic epilepsies:** In these epilepsies the seizures are the result of an underlying neurologic disorder that is often ill defined. Neurologic functions are often abnormal or developmentally delayed in patients with cryptogenic epilepsies.

A complete description of a patient’s epilepsy should include the seizure type with the epilepsy or syndrome type (e.g., idiopathic, symptomatic, cryptogenic).

Commonly encountered epilepsy syndromes are:

- **Juvenile myoclonic epilepsy (JME):** A primary generalized epilepsy syndrome that usually starts in the early to middle teenage years and has a strong familial component. Patients have myoclonic jerks and tonic-clonic seizures and may also have absence seizures.
- **Lennox-Gastaut syndrome (LGS):** Patients with this syndrome have cognitive dysfunction and mental retardation. Their seizures usually consist of a combination of tonic-clonic, absence, atonic, and myoclonic seizures.
- **Mesial temporal lobe epilepsy (MTLE):** A type of epilepsy that consists of partial seizures arising from the mesial temporal lobe of the brain. Often this type of epilepsy is associated with an anatomical change described as hippocampal sclerosis. Patients with this type of epilepsy often have excellent surgical outcomes.
- **Infantile spasms:** A seizure syndrome in infants younger than 1 year of age. It is characterized by a specific EEG pattern and spasms or jitters. Another name is West's syndrome. Infants with infantile spasms often develop other seizure types and epilepsies later in life.

Other Classifications

The ILAE is proposing a new classification system that improves the description of the seizure type and epilepsy.^{18,19} The proposed scheme revolves around five axes:

- Axis 1: Description of the seizure event
- Axis 2: Epileptic seizure type or types
- Axis 3: Any syndrome type
- Axis 4: Etiology when known
- Axis 5: Degree of impairment by the epilepsy

This classification system is undergoing final review and should become the standard in the near future.

DIAGNOSIS

Determining a correct and accurate diagnosis is essential to any consideration of pharmacotherapy. **1** *A distinction between convulsions, a single seizure, pseudoseizure, and epilepsy should be made in patients presenting with possible seizures.* Numerous other disorders, including convulsions,

Clinical Presentation and Diagnosis of Epilepsy

General

Typically, healthcare providers are not able to observe a patient's seizures, and for most types of seizures the patient has no memory of the event. It is important to obtain a careful history from the patient and any individuals who witness the seizures.

Common Descriptions of Seizures

The clinical presentation of seizures varies from patient to patient depending on the portion of brain involved in the seizure. Events tend to be stereotypical for an individual patient.

Patients who experience seizures may complain of paroxysmal spells of

- Blanking-out spells, lapses in memory, periods of altered consciousness
- Warnings or auras consisting of various sensations or automatic, uncontrolled movements
- Daydreaming
- Jerks, shoulder shrugs, sudden chills of spine
- Falling out

Associated Symptoms

- Incontinence, usually of urine
- Tongue biting
- Traumatic injuries, usually associated with falling during a seizure

Diagnosis

Description of events: The patient and any witnesses to the seizures should be carefully interviewed to obtain a full and complete description of typical seizures.

Neurologic examination: Usually, the neurologic physical examination is completely normal. Any neurologic deficits identified should be fully investigated because seizures do not usually cause permanent, detectable neurologic deficits.

Electroencephalogram (EEG): A routine EEG can be helpful if epileptiform discharges are seen. However, the EEG may be normal between seizures, and most routine EEGs are not performed during a seizure. Maneuvers such as sleep deprivation, photic stimulation, hyperventilation, or prolonged monitoring can help expose EEG changes consistent with epilepsy.

Neuroimaging (preferably an MRI of the brain): Imaging of the brain is important to rule out obvious causes of seizures such as stroke or tumors. An MRI scan is also helpful in detecting mesial temporal sclerosis, a finding often associated with mesial temporal epilepsy and predictive of positive surgical outcomes.

Video EEG monitoring: A procedure consisting of continuous video monitoring of the patient with a simultaneous EEG. Usually a patient is monitored in the hospital for 4 to 5 days. This procedure is used to determine if the patient is truly having seizures, to determine the specific type of seizures the patient is having, and to localize the area of the brain that is the origin of the seizures.

syncope, psychogenic nonepileptic events (i.e., pseudoseizures), anxiety attacks, cardiac arrhythmias, hypoglycemia, transient ischemic attacks, tics, and complicated migraine headaches, are often mistaken for seizures by patients and caregivers. Seizures are typically brief spells, lasting no more than 5 minutes. However, seizures can be prolonged and can last for ≥ 15 minutes. In this situation the patient is in status epilepticus and requires immediate medical attention.

A proper diagnostic workup of a patient presenting with seizures should include the following elements:

- Thorough neurologic examination
- EEG
- Laboratory tests (complete blood count [CBC], liver function tests [LFTs], serum chemistry)
- Neuroimaging (preferably magnetic resonance imaging [MRI]).

In patients with epilepsy these laboratory findings may be normal. Many of the tests are done to rule out other causes of seizures (e.g., infection, electrolyte imbalance). Often the EEG appears normal between seizures.²⁰ Sleep deprivation, photic stimulation, prolonged (more than 20 minutes) EEG recording, and 24-hour EEG monitoring with video correlation can be done in an attempt to capture seizure or seizure-like activity on the EEG.

TREATMENT

Desired Outcomes

- The ultimate outcome goal for any patient with epilepsy is elimination of all seizures without any adverse effects of the treatment. An effective treatment plan would allow the patient to pursue a normal lifestyle with complete control of seizures. Specifically, the treatment should enable the patient to drive, perform well in school, hold a reasonable job, and function effectively in the family and community. However, due to the intractability of the seizures or sensitivity to AEDs, many patients are not able to achieve these outcomes. In these cases, the goal of therapy is to provide a tolerable balance between reduced seizure severity and/or frequency and medication adverse effects, enabling the individual to have a lifestyle as nearly normal as possible.

General Approach to Treatment

Once it is concluded that the patient has seizures, the type of seizure and epilepsy syndrome, if any, must be determined.

2 *Selection of appropriate pharmacotherapy depends on distinguishing, identifying, and understanding different seizure types.* Without an accurate classification of the seizure type, it is possible to select a medication that is ineffective or even harmful to the patient.

3 *Prior to starting pharmacologic therapy, it is essential to determine the risk of having a subsequent seizure.* If there is an underlying treatable cause, such as hyponatremia or a CNS infection, the risks of another seizure and the

development of epilepsy are very small. In these cases, the only necessary pharmacotherapy is to correct the underlying problem and possibly short-term use of an AED. Risk factors for repeated seizures in patients without an underlying disorder include:

- Structural CNS lesion
- Abnormal EEG
- Partial seizure type
- Positive family history
- Postictal motor paralysis²¹

If no risk factors are present, the risk of another seizure is 10% to 15%. However, if two or more risk factors are present, the risk of another seizure is 100%.

When sufficient evidence is available to determine the patient has seizures and is at risk for another seizure, pharmacotherapy is usually started (Fig. 31-2). The patient should be in agreement with the plan, be willing to take the medication, and be able to monitor seizure frequency and adverse drug effects. 4 *Mechanisms of action, effectiveness for specific seizure types, common adverse effects, and potential for drug interactions are key elements in selecting a medication for individual patients.* Other patient factors such as gender, concomitant drugs, age, economic factors, and lifestyle also need to be considered.

Nonpharmacologic Therapy

- Several nonpharmacologic treatments for epilepsy are available. For some patients, surgery is the treatment approach with the greatest probability of eliminating seizures.²² The most common surgical approach for epilepsy is temporal lobectomy. When the seizure focus can be localized and it is in a region of the brain that is not too close to critical areas, such as those responsible for speech or muscle control, surgical removal of the focus can result in 80% to 90% of patients becoming seizure free. According to a National Institutes of Health Consensus Conference, three criteria should be met for patients to be candidates for surgery.²³ These criteria are (a) a definite diagnosis of epilepsy, (b) failure of adequate drug therapies, and (c) definition of the electroclinical syndrome (i.e., localization of the seizure focus in the brain). Other surgical procedures that are less likely to make a patient seizure free include corpus callosotomy and extra-temporal lesion removal.
- Vagal nerve stimulation is another nonpharmacologic approach to treating all types of seizures.²⁴ In this treatment, a unit that generates an intermittent electrical current is placed under the skin in the chest. A wire is tunneled under the skin to the left vagus nerve in the neck. The unit generates a small electrical current that stimulates the vagus nerve. Additional stimulations can be initiated by the patient swiping a magnet over the device located in the chest. This treatment approach is essentially equivalent to starting a new medication with regard to efficacy. Approximately 25% to 50% of patients who have a vagal nerve stimulator placed will experience at least a 50% reduction in seizure frequency.

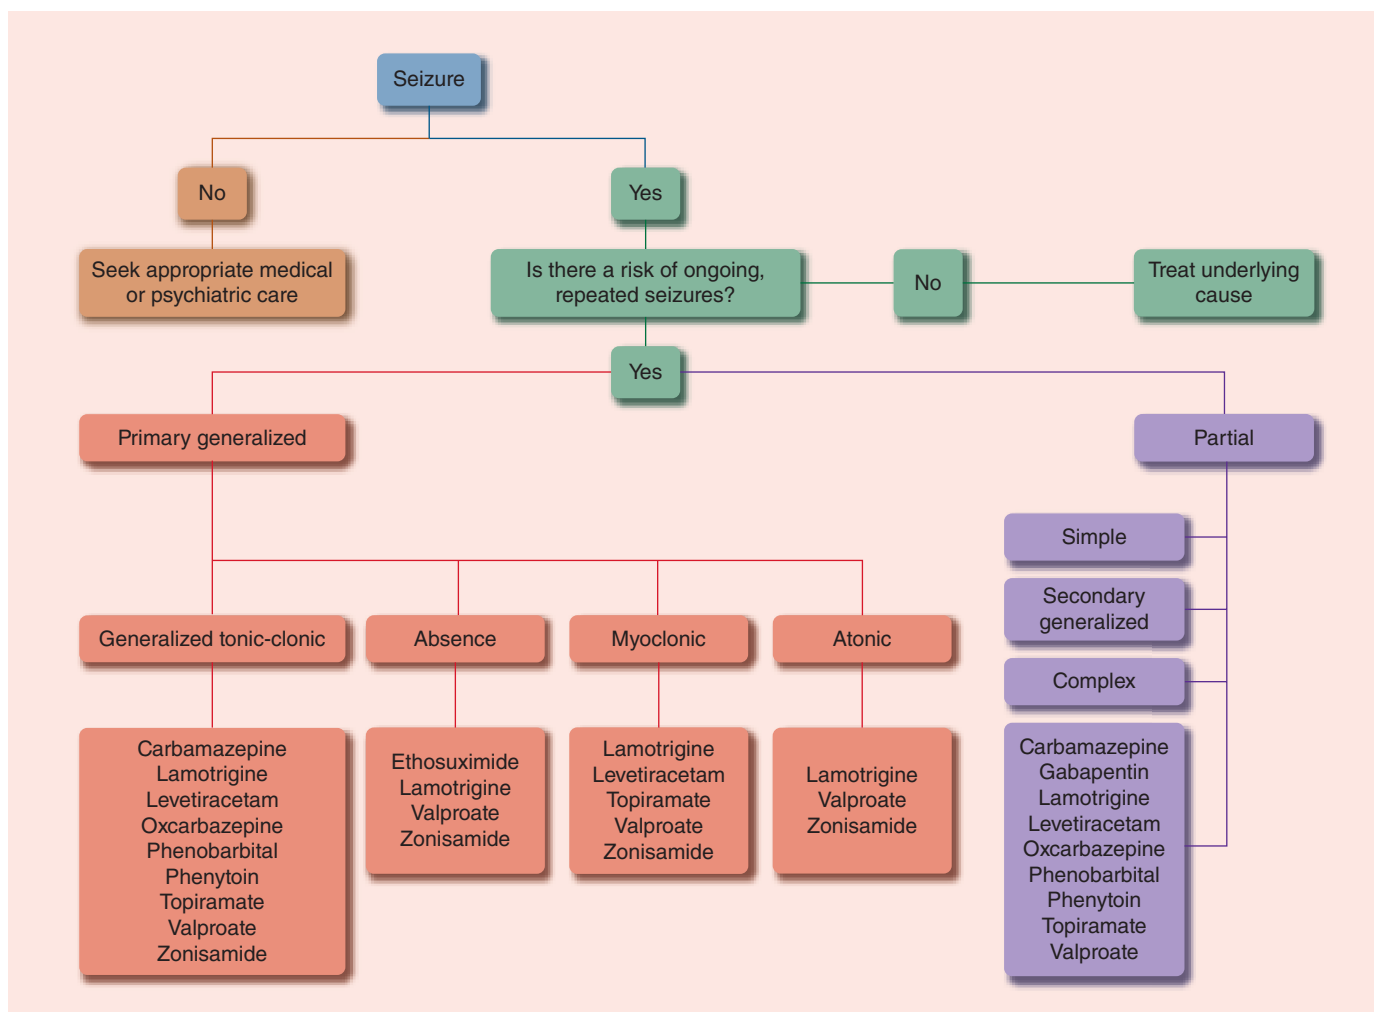

FIGURE 31-2. Treatment algorithm for management of seizure disorders.

However, fewer than 10% become seizure free. Adverse effects include hoarseness, swallowing difficulties, tingling or vibration in the neck, infection or bleeding due to surgery, and, rarely, laryngeal spasms. Vagal nerve stimulation is usually reserved for patients who do not respond to several drugs and are not surgical candidates.

One of the oldest nonpharmacologic treatments is the ketogenic diet.²⁵ Modern use of the diet was started in the 1920s. This diet produces a keto-acidotic state through the elimination of nearly all carbohydrates. To initiate the diet, patients undergo 24 to 48 hours of fasting until ketones are detected in the urine. The diet consisting of dietary fats (e.g., butter, heavy cream, fatty meats) and protein with no added sugar is started. Daily urinalysis for ketones is performed to ensure the patient remains in ketosis. Any inadvertent consumption of sugar results in the diet needing to be reinitiated. Pharmacists have an important role in maintaining the diet, by determining the sugar or carbohydrate content of medications the patient is taking. This diet is typically used only in children with difficult-to-control seizures. In certain patients the diet can be extremely effective, resulting in complete seizure control and reduction of AEDs. However, it is

hard to maintain a ketotic state, and palatability of the diet is a concern. Additionally, there are concerns about growth retardation in children and hypercholesterolemia with prolonged use of the diet.

Pharmacologic Therapy

► Special Considerations

Use of AEDs presents some unique challenges, some of which relate to their pharmacokinetic properties, which need to be clearly understood.²⁶

Michaelis-Menten Metabolism Phenytoin metabolism is capacity limited. Michaelis-Menten metabolism or Michaelis-Menten pharmacokinetics occurs when the maximum capacity of hepatic enzymes to metabolize the drug is reached within the normal dosage range. The clinical significance is that small changes in doses result in disproportionate and large changes in serum concentrations. The patient is at risk of sudden toxicity if too large a dose increase is made, or a breakthrough seizure may occur if too large a reduction in dose is made. Due to individual differences in metabolism,

each patient follows a different curve in the relationship between dose and serum concentrations. These differences can be defined only by careful use of serum concentration and dosing data. There are numerous schemes for determining appropriate dosage adjustments of phenytoin, and these are discussed in pharmacokinetic textbooks. For routine clinical practice, dosage adjustments for adults with normal protein binding of phenytoin and a steady-state serum concentration can be made using the following plan:

- For serum concentrations less than 7 mcg/mL (28 $\mu\text{mol/L}$), the total daily dose is increased by 100 mg.
- For serum concentrations of 7 to 12 mcg/mL (28–48 $\mu\text{mol/L}$), the total daily dose is increased by 50 mg.
- For serum concentrations more than 12 mcg/mL (48 $\mu\text{mol/L}$), the total daily dose is increased by no more than 30 mg.²⁷

Protein Binding Some AEDs, especially phenytoin and valproate, are highly bound to plasma proteins. When interpreting a reported concentration for these drugs, it is important to remember the value represents the total (i.e., bound and unbound) concentration in the blood. Because of differences in the metabolism of these drugs, the clinical effects of altered protein binding are different.

Normally, 88% to 92% of phenytoin is bound to plasma protein, leaving 8% to 12% as unbound. The unbound component is able to leave the blood to produce the clinical effect in the CNS, produce dose-related side effects in the CNS and at other sites, distribute to other peripheral sites, and be metabolized. Certain patient groups are known to have decreased protein binding, resulting in an increased percentage of drug that is unbound. These patient groups include:

- Those with kidney failure
- Those with hypoalbuminemia
- Neonates
- Pregnant women
- Those taking multiple highly protein-bound drugs
- Patients in critical care

Due to the Michaelis-Menten metabolism of phenytoin, alterations in its protein binding will result in increased severity of dose-related adverse effects. In patients with suspected changes in protein binding, it is useful to measure unbound phenytoin concentrations.

When valproate protein binding is altered, the risk for severe dose-related adverse effects is much less compared with phenytoin. Michaelis-Menten metabolism is not a factor with valproate, so hepatic enzymes are able to efficiently metabolize the additional unbound portion.

Autoinduction Carbamazepine is a potent inducer of hepatic microsomal enzymes. Not only does it increase the rate of metabolism for many other drugs, it increases the rate of its own metabolism. Hepatic enzymes become maximally induced over several weeks, necessitating a small initial dose of carbamazepine that is increased over time to compensate for the enzyme induction (Fig. 31-3).

FIGURE 31-3. Serum concentrations of carbamazepine in the presence and absence of appropriate dose titration.

Most dosage regimens for carbamazepine call for a starting dose that is 25% to 30% of the typical maintenance dose of 15 mg/kg/day. The dosage is increased weekly until the target maintenance dose is achieved within 3 to 4 weeks. Titration of the carbamazepine dose lessens the risk for

Patient Encounter 1: New-Onset Seizures

JL, a 17-year-old young woman, is seen by her physician 4 days after a generalized tonic-clonic seizure during a ski trip with friends. The seizure lasted for 1 to 2 minutes. She was confused for several minutes and went to sleep for a few hours after the seizure.

Her physical examination is completely normal, and no focal neurologic deficits were observed. An MRI was ordered and reported as normal. An EEG shows generalized 3- to 4-Hz spike waves.

What additional information is needed to make a decision about pharmacotherapy?

How should this information be used to make choices concerning AED therapy?

During the visit she mentions several previous episodes of brief jerks in the early morning. These started a couple of years ago and now occur 2 to 3 days of the week.

Is pharmacotherapy indicated?

If it is indicated, what drug should be used and how should it be started?

What adverse effects are important to monitor?

Three months later she is doing well. She reports no generalized tonic-clonic seizures and jerks on only a few days a month.

What adjustments in pharmacotherapy should be made at this point?

Is it possible for her to discontinue AED therapy at some time in the future?

severe dose-related adverse effects when carbamazepine is first started.

► Drug Selection and Seizure Type

The key to selecting effective pharmacotherapy is to base the decision on the seizure type. Several consensus treatment guidelines from the Scottish Intercollegiate Guidelines Network (SIGN), the National Institute for Clinical Excellence in the United Kingdom (NICE), the American Academy of Neurology (AAN), and ILAE all use determination of seizure type as the basis for selection of pharmacotherapy (Table 31-2).²⁸⁻³⁰ While the guidelines make recommendations for specific drugs to be used in certain seizure types, the consensus recommendations use only

data available from the medical literature. In many cases, a recommendation is not made because there are no published data on which to make an evidence-based decision. Therefore, a drug may not currently be recommended for a seizure type simply because it has not been studied for that seizure type. Absence of a recommendation should not be taken to mean the drug is ineffective for a specific seizure type. For example, according to the AAN Practice Parameter, topiramate is useful as monotherapy for primary generalized tonic-clonic seizures, and there is insufficient evidence to make any recommendation regarding gabapentin, lamotrigine, oxcarbazepine, tiagabine, levetiracetam, or zonisamide.³¹

Outside of the evidence-based guidelines, other pharmacologic treatments are commonly used or avoided. For

initial treatment of absence seizures, ethosuximide and valproate are commonly used. Zonisamide may be also used for the initial treatment of absence and myoclonic seizures. In absence and myoclonic seizures, carbamazepine, oxcarbazepine, gabapentin, tiagabine, and pregabalin should be avoided because they have been associated with an exacerbation of these types of seizures.

5 Antiepileptic drug therapy should usually be initiated carefully using a titration schedule to minimize adverse events. Usually a moderate target dose is chosen until the patient's response can be further evaluated in the clinic. If seizures continue, the dose should be increased gradually until the patient becomes seizure free or adverse effects appear. For some drugs like lamotrigine, specific titration guidelines are established by the manufacturer.

Refractory seizure (i.e., unresponsive to at least two first-line AEDs) treatment is somewhat different. Combinations of drugs are not addressed by guidelines but may be useful in patients with difficult to control primary generalized seizures. All AEDs, except ethosuximide, are effective in combination therapy for partial seizures.

► Complications of Pharmacotherapy

- Adverse effects of AEDs are frequently dose limiting or can cause a drug to be discontinued. Two types of adverse effects occur with AEDs: serum concentration-related and idiosyncratic (Table 31-3). Concentration-related adverse effects happen with increasing frequency and severity as the dose or serum concentration of a drug is increased. For many AEDs,

Table 31-3

Characteristics of Common AEDs

Drug	Mechanism of Action	Dose	Pharmacokinetic Parameters	Usual Serum Concentration Range	Dose-Related Adverse Effects	Idiosyncratic Adverse Effects
Carbamazepine (Tegretol, Tegretol XR, Carbatrol, generic)	Fast sodium channel inactivation	<i>Loading dose:</i> Not recommended due to excessive dose-related toxicity <i>Maintenance dose:</i> Titrate dosage to target over 3–4 weeks Adults: 10–20 mg/kg/day as a divided dose Children: 20–30 mg/kg/day as a divided dose	<i>Half-life:</i> 10–25 hours with chronic dosing <i>Apparent volume of distribution:</i> 0.8–1.9 L/kg <i>Protein binding:</i> 67–81% <i>Primary elimination route:</i> Hepatic	4–12 mcg/mL (17–51 µmol/L)	Diplopia, drowsiness, nausea, sedation	Aplastic anemia, hyponatremia, leucopenia, osteoporosis, rash
Clobazam (Onfi)	Enhance GABA	Weight less than 30 kg, start 5 mg/day, titrate to 20 mg/day in 2 divided doses Weight more than 30 kg start 10 mg/day, titrate to 40 mg/day in 2 divided doses	<i>Half-life:</i> 10–50 hours <i>Apparent volume of distribution:</i> ~0.9 L/kg <i>Protein binding:</i> ~90% <i>Primary elimination route:</i> Hepatic; metabolized to active metabolite that is further metabolized by CYP 2C19	Not established	Sedation somnolence lethargy pyrexia irritability drooling aggression	
Clonazepam (Klonopin, generic)	Enhance GABA activity	<i>Loading dose:</i> Not recommended due to increased adverse effects <i>Maintenance dose:</i> Initiate at 0.5 mg 1–3 times daily, titrate dose to effectiveness, usually 3–5 mg daily in 2 or 3 divided doses	<i>Half-life:</i> 30–40 hours <i>Apparent volume of distribution:</i> 3.2 L/kg <i>Protein binding:</i> 47–80% <i>Primary elimination route:</i> Hepatic	Not established	Ataxia, memory impairment, sedation, slowed thinking	
Ethosuximide (Zarontin, generic)	Modulate calcium channels	<i>Loading dose:</i> Not recommended due to increased adverse effects <i>Maintenance dose:</i> Initiate at 250 mg twice daily and titrate to 500–1,000 mg twice daily	<i>Half-life:</i> 60 hours <i>Apparent volume of distribution:</i> 0.6–0.7 L/kg <i>Protein binding:</i> None <i>Primary elimination route:</i> Hepatic	40–100 mcg/mL (283–708 µmol/L)	Ataxia, sedation	Hepatotoxicity, neutropenia, rash

(Continued)

Table 31-3

Characteristics of Common AEDs (Continued)

Drug	Mechanism of Action	Dose	Pharmacokinetic Parameters	Usual Serum Concentration Range	Dose-Related Adverse Effects	Idiosyncratic Adverse Effects
Felbamate (Felbatol)	Inhibit glutamate activity	<i>Loading dose:</i> Not recommended due to increased adverse effects <i>Maintenance dose:</i> 1,200–3,600 mg/day in 3 or 4 divided doses	<i>Half-life:</i> Monotherapy: 20 hours Concurrent enzyme inducers: 11–16 hours <i>Apparent volume of distribution:</i> 0.7–0.8 L/kg <i>Protein binding:</i> 25–35% <i>Primary elimination route:</i> Hepatic	Not established	Anxiety, insomnia, nausea	Anorexia, aplastic anemia, headache, hepatotoxicity, weight loss
Gabapentin (Neurontin, generic)	Modulate calcium channels and enhance GABA activity	<i>Loading dose:</i> Not recommended due to short half-life <i>Maintenance dose:</i> 900–3,600 mg/day in 3 or 4 divided doses (doses up to 10,000 mg/day have been tolerated)	<i>Half-life:</i> 5–7 hours (proportional to creatinine clearance) <i>Apparent volume of distribution:</i> 0.6–0.8 L/kg <i>Protein binding:</i> less than 10% <i>Primary elimination route:</i> Renal	Not established	Drowsiness, sedation	Peripheral edema, weight gain
Lacosamide (Vimpat)	Slow sodium channel inactivation; modulate collapsin response; mediator protein-2	<i>Loading dose:</i> Data unavailable <i>Maintenance dose:</i> 200–400 mg/day; Start at 100 mg/day in 2 divided doses and titrate upward according to response	<i>Half-life:</i> Approximately 13 hours <i>Volume of distribution:</i> 0.6 L/kg <i>Protein binding:</i> Less than 15% <i>Primary elimination route:</i> 40% renal 60% hepatic	Not established	Ataxia, dizziness, diplopia, headache, nausea, vomiting	PR interval prolongation
Lamotrigine (Lamictal, Lamictal XR, generic)	Fast sodium channel inactivation	<i>Loading dose:</i> Not recommended due to increased risk of rash <i>Maintenance dose:</i> 150–800 mg/day in 2 or 3 divided doses. Doses should be initiated and titrated according to the manufacturer's recommendations to reduce the risk of rash	<i>Half-life:</i> Monotherapy: 24 hours Concurrent enzyme inducers: 12–15 hours Concurrent enzyme inhibitors: 55–60 hours <i>Apparent volume of distribution:</i> 1.1 L/kg <i>Protein binding:</i> 55% <i>Primary elimination route:</i> Hepatic	Not established	Ataxia, drowsiness, headache, insomnia, sedation	Rash

Levetiracetam (Keppra, Keppra XR, generic)	Modulate synaptic vesicle protein	<i>Loading dose:</i> Not recommended due to excessive adverse effects <i>Maintenance dose:</i> 1,000–3,000 mg/day. Start at 1,000 mg/day and titrated upward as indicated by response	<i>Half-life:</i> 6–8 hours <i>Apparent volume of distribution:</i> 0.5–0.7 L/kg <i>Protein binding:</i> Less than 10% <i>Primary elimination route:</i> 70% renal 30% hepatic	Not established	Somnolence, dizziness	Depression
Oxcarbazepine (Trileptal, generic)	Fast sodium channel inactivation	<i>Loading dose:</i> Not recommended due to excessive adverse effects <i>Maintenance dose:</i> 600–1,200 mg/day. Start at 300 mg twice daily and titrated upward as indicated by response	<i>Half-life:</i> Parent drug Approximately 2 hours; 10-monohydroxy <i>Metabolite</i> Approximately 9 hours <i>Apparent volume of distribution:</i> 0.5–0.7 L/kg <i>Protein binding:</i> 40% <i>Primary elimination route:</i> Hepatic	Not established	Diplopia, dizziness, somnolence	Hyponatremia, 25–30% cross sensitivity in patients with hypersensitivity to carbamazepine
Phenobarbital (Luminal, generic)	Fast sodium channel inactivation	<i>Loading dose:</i> 10–20 mg/kg as single or divided IV infusion or orally in divided doses over 24–48 hours <i>Maintenance dose:</i> Adults: 1–4 mg/kg/day as a single or divided dose Children: 3–6 mg/kg/day as divided dose Neonates: 1–3 mg/kg/day as divided dose	<i>Half-life:</i> Adults: 49–120 hours Children: 37–73 hours Neonates: approximately 115 hours <i>Volume of distribution:</i> 0.7–1 L/kg <i>Protein binding:</i> Approximately 50% <i>Primary elimination route:</i> Hepatic	15–40 mcg/mL (65–172 µmol/L)	Ataxia, drowsiness, sedation	Attention deficit, cognitive impairment, hyperactivity, osteoporosis, passive- aggressive behavior

(Continued)

Table 31-3

Characteristics of Common AEDs (Continued)

Drug	Mechanism of Action	Dose	Pharmacokinetic Parameters	Usual Serum Concentration Range	Dose-Related Adverse Effects	Idiosyncratic Adverse Effects
Phenytoin (Dilantin, generic)	Fast sodium channel inactivation	<i>Loading dose:</i> Adults: 15–20 mg/kg single IV dose or divided oral dose Infants younger than 3 months: 10–15 mg/kg single IV dose Neonates: 15–20 mg/kg single IV dose <i>Maintenance dose:</i> Adults: 5–7 mg/kg/day, as single or divided dose Children: 6–15 mg/kg/day, as divided dose Neonates: 3–8 mg/kg/day, as divided dose	<i>Half-life:</i> Follows capacity-limited or Michaelis-Menten pharmacokinetics. Half-life increases as the dose and serum concentration increases. <i>Volume of distribution:</i> Adults: 0.7 L/kg Children: 0.8 L/kg Neonates: 1.2 L/kg <i>Protein binding:</i> Adults, children: 88–92% Neonates: 65% <i>Primary elimination route:</i> Hepatic	10–20 mcg/mL (40–79 µmol/L) total concentration 1–2 mcg/mL (4–8 µmol/L) unbound concentration	Ataxia, diplopia, drowsiness, sedation	Anemia, gingival hyperplasia, hirsutism, lymphadenopathy, osteoporosis, rash
Pregabalin (Lyrica)	Modulate calcium channels	<i>Loading dose:</i> Not recommended due to increased adverse effects <i>Maintenance dose:</i> Initiate at 150 mg/day in 2 or 3 divided doses and titrate to a maximum dose of 600 mg/day	<i>Half-life:</i> 6.3 hours, proportional to creatinine clearance <i>Apparent volume of distribution:</i> 0.5 L/kg <i>Protein binding:</i> Negligible <i>Primary elimination route:</i> Renal	Not established	Ataxia, blurred vision, dizziness, dry mouth, somnolence	Edema, weight gain
Rufinamide (Banzel)	Unknown, may enhance inactivation of sodium channels	<i>Loading dose:</i> Data unavailable <i>Maintenance dose:</i> Children: 45 mg/kg/day or 3,200 mg/day; start at 10 mg/kg/day in 2 divided doses and titrate upward according to response Adults: 3,200 mg/day; start at 400–800 mg/day in 2 divided doses and titrate upward according to response	<i>Half-life:</i> 6–10 hours <i>Apparent volume of distribution:</i> Approximately 0.7 L/kg, varies with dose <i>Protein binding:</i> 34% (27% to albumin) <i>Primary elimination route:</i> Hepatic	Not established	Dizziness, fatigue, headache, nausea, somnolence, vomiting	

Tiagabine (Gabitril, generic)	Enhance GABA activity	<i>Loading dose:</i> Not recommended due to excessive adverse effects <i>Maintenance dose:</i> 32–56 mg/day in 4 divided doses. Doses should be titrated upward over 6 weeks, starting at 4 mg/day	<i>Half-life:</i> Monotherapy: 7–9 hours Concurrent enzyme inducers: 2.5–4.5 hours <i>Apparent volume of distribution:</i> 0.6–0.8 L/kg <i>Protein binding:</i> 96% <i>Primary elimination route:</i> Hepatic	Not established	Dizziness, somnolence, irritability, slowed thinking	
Topiramate (Topamax, generic)	Fast sodium channel inactivation, inhibit glutamate activity, enhance GABA activity	<i>Loading dose:</i> Not recommended due to excessive adverse effects <i>Maintenance dose:</i> 100–400 mg/day in 2 or 3 divided doses. Doses should be started at 25–50 mg/day and gradually titrated upward over 3–6 weeks to avoid excessive adverse effects	<i>Half-life:</i> Monotherapy: 21 hours Concurrent enzyme inducers: 11–16 hours <i>Apparent volume of distribution:</i> 0.55–0.8 L/kg <i>Protein binding:</i> 13–17% <i>Primary elimination route:</i> 60% renal 40% hepatic	Not established	Ataxia, dizziness, drowsiness, slowed thinking	Acute glaucoma, metabolic acidosis, oligohidrosis, paresthesia, renal calculi, weight loss
Valproic acid/divalproex sodium (Depakene, Depakote, Depakote ER, generic)	Fast sodium channel inactivation	<i>Loading dose:</i> 20–40 mg/kg <i>Maintenance dose:</i> Adults: 15–45 mg/kg/day in 2–4 divided doses Children: 5–60 mg/kg/day in 2–4 divided doses	<i>Half-life:</i> Adults: 8–15 hours Children: 4–15 hours Infants younger than 2 months: 65 hours <i>Volume of distribution:</i> 0.1–0.5 L/kg <i>Protein binding:</i> 90% (decreases with increasing serum concentrations) <i>Primary elimination route:</i> Hepatic	50–100 mcg/mL (346–693 µmol/L). Children may require concentrations up to 150 mcg/mL (1,040 µmol/L)	Drowsiness, nausea, sedation, tremor	Hepatotoxicity, osteoporosis, pancreatitis, weight gain

(Continued)

Table 31-3

Characteristics of Common AEDs (Continued)

Drug	Mechanism of Action	Dose	Pharmacokinetic Parameters	Usual Serum Concentration Range	Dose-Related Adverse Effects	Idiosyncratic Adverse Effects
Vigabatrin (Sabril)	Inhibits GABA transaminase	<i>Children:</i> 1 month–2 years: 50 mg/kg/day in 2 divided doses <i>Adults:</i> Initiate at 1,000 mg/day in 2 divided doses, titrate up to 3,000 mg/day <i>Renal failure:</i> CrCl 50–80 mL/min, decrease dose by 25%; CrCl 30–50 mL/min, decrease dose by 50%; CrCl 10–30 mL/min, decrease dose by 75%	<i>Half-life:</i> 7.5 hours, proportional to creatinine clearance <i>Volume of distribution:</i> 1.1 L/kg <i>Protein binding:</i> negligible <i>Primary route of elimination:</i> Renal	Not established	Convulsion, dizziness, headache, nasopharyngitis, somnolence, weight gain	Vision loss and blindness
Zonisamide (Zonegran, generic)	Modulate sodium and calcium channels	<i>Loading dose:</i> Not recommended due to excessive adverse effects <i>Maintenance dose:</i> 100–600 mg/day; start at 100 mg/day and titrated upward as indicated by response	<i>Half-life:</i> Approximately 63 hours <i>Apparent volume of distribution:</i> 1.45 L/kg <i>Protein binding:</i> 40% <i>Primary elimination route:</i> Hepatic	Not established	Dizziness, somnolence	Metabolic acidosis, oligohidrosis, paresthesia, renal calculi

GABA, γ -aminobutyric acid.

Data from Refs. 25, 35, 38.

common concentration-related adverse effects include sedation, ataxia, and diplopia. These adverse effects should be carefully considered and used as one of the AED selection criteria. For example, if a patient has a job that requires mental alertness, it is best to choose an AED that is less likely to cause sedation (e.g., lamotrigine).

Idiosyncratic adverse effects are not dose or concentration related and will almost always result in the AED being discontinued. Rash, hepatotoxicity, and hematological toxicities are the most common idiosyncratic reactions seen with AED. Because many of these adverse effects are life threatening or potentially life threatening, the AED should be discontinued immediately when the reaction is observed. Carbamazepine, phenytoin, phenobarbital, valproate, lamotrigine, oxcarbazepine, and felbamate are most likely to cause these types of reactions. Many of these reactions are thought to occur primarily on an immunological basis, which raises the possibility of cross-reactivity. This is especially true for carbamazepine, phenytoin, phenobarbital, and oxcarbazepine, where 15% to 25% of patients who have an idiosyncratic reaction to one drug will have a similar reaction to the other drugs.

► Chronic Adverse Effects

Because AEDs are administered for long periods of time, adverse effects due to prolonged drug exposure are of concern. Some chronic adverse effects associated with AEDs include peripheral neuropathy and cerebellar atrophy. Other chronic adverse effects are extensions of acute adverse effects, for example, weight gain.

One chronic adverse effect that is of concern is osteoporosis.^{32,33} Carbamazepine, phenytoin, phenobarbital, oxcarbazepine, and valproate have all been shown to decrease bone mineral density, even after only 6 months of treatment. Data on the relationship between other AEDs and osteoporosis are not currently available. Multiple studies have shown the risk of osteoporosis due to chronic AED use to be similar to the risk with chronic use of glucocorticosteroids. Patients taking carbamazepine, oxcarbazepine, phenytoin, phenobarbital, or valproate more than 6 months should take supplemental

calcium and vitamin D. Additionally, routine monitoring for osteoporosis should be performed every 2 years, and patients should be instructed on ways to protect themselves from fractures.

► Practical Issues

Comorbid Disease States Patients with epilepsy often have comorbid disease states. Disorders such as chronic headaches and asthma are frequent problems. For patients who also have asthma, care must be taken to identify drug interactions between AEDs and medications used for asthma. These interactions necessitate close monitoring for changes in efficacy or increased toxicity, and dosage changes of other drugs may be necessary when an AED is added or removed. Patients with chronic headaches need special attention in the selection of an AED. Agents known to prevent headache (e.g., valproate and topiramate) may be preferred among several choices, and agents associated with increased headaches (e.g., lamotrigine and felbamate) may be a secondary or tertiary alternative.

Depression is a common problem in patients with epilepsy, with approximately 30% having symptoms of major depression at some point.³⁴ Patients with epilepsy should be routinely assessed for signs of depression, and treatment should be initiated if necessary. Certain AEDs may exacerbate depression, for example, levetiracetam and phenytoin. Other AEDs (e.g., lamotrigine, carbamazepine, oxcarbazepine) may be useful in treating depression. Changes in mood can be precipitated by the addition or discontinuation of an AED. If treatment for depression is necessary, caution should be exercised in choosing an agent that does not increase seizure frequency and does not interact with AEDs.

• **Switching Drugs** Changing from one AED to another can be a complex process. If the first drug is stopped too abruptly, breakthrough seizures may occur. **6** *Changes in AED regimens should be done in a stepwise fashion, keeping in mind drug interactions that may be present and may necessitate dosage changes in concomitant drugs.* Typically the new drug is started at a low initial dose and gradually increased over several weeks. Once the new drug is at a minimally effective dose, the drug to be discontinued is gradually tapered while the dose of the new drug continues to be increased to the target dose. During a transition between drugs, patients should be cautioned about the possibility of increased seizures or adverse reactions.

Stopping Therapy Epilepsy is generally considered to be a lifelong disorder that requires ongoing treatment. However, many patients who are seizure free may desire to discontinue their medications.³⁵ Patients who become seizure free following surgery for their epilepsy may have medications slowly tapered starting 1 to 2 years after their surgery. Many patients will choose to stay on at least one medication, following successful surgery, to ensure they remain seizure free. **7** *Discontinuation of AEDs should be done gradually, only after the patient has been seizure free for 2 to 5 years and with careful consideration of factors predictive of seizure recurrence.*³⁶ They are:

Patient Encounter 2: Managing Chronic Adverse Reactions

PL, a 41-year-old man with complex partial seizures, has been treated with carbamazepine 800 mg/day for 20 years. His seizures are well controlled on this regimen, and he works as a dental equipment sales representative. He expresses concern about taking the carbamazepine for so long.

What chronic adverse effects are important to monitor in this patient?

How should monitoring for these adverse effects be done?

What measures can be taken to prevent these adverse effects?

- No seizures for 2 to 5 years
- Normal neurologic examination
- Normal intelligence quotient
- Single type of partial or generalized seizure
- Normal EEG with treatment

Individuals who fulfill all of these criteria have a 61% chance of remaining seizure free after AEDs are discontinued. Additionally, there is a direct relationship between the duration of seizure freedom while taking medications and the chance of being seizure free after medications are withdrawn. Withdrawal of AEDs is done slowly, usually with a tapering dose over at least 1 to 3 months.

► Dosing

Dosing of AEDs is determined by general guidelines and response of the patient. Serum concentrations may be helpful in benchmarking a specific response. Therapeutic ranges that are often quoted are broad guidelines for dosing but should never replace careful evaluation of the patient's response. It is not unusual for a patient to be well managed with serum concentrations or doses outside the typical ranges.

► Drug Interactions

AEDs are associated with many different drug interactions.^{37–39} These interactions are primarily in relation to absorption, metabolism, and protein binding. Tube

feedings and antacids are known to reduce the absorption of phenytoin and carbamazepine. Phenytoin, carbamazepine, and phenobarbital are potent inducers of various CYP 450 isoenzymes, increasing the clearance of other drugs metabolized through these pathways (Table 31–4). In contrast, valproate is a CYP 450 and UDP-glucuronosyltransferase (UGT) isoenzyme inhibitor and reduces the clearance of some drugs. Phenytoin and valproate are highly protein bound and can be displaced when taken concurrently with other highly protein-bound drugs. For example, when phenytoin and valproate are taken together, there may be increased dose-related adverse effects within several hours of dosing. This can be avoided by staggering doses or giving smaller doses more frequently during the day. Whenever a change in a medication regimen occurs, drug interactions should be considered and appropriate adjustments in dose of AEDs made.

► Special Populations

8 *Children and women with epilepsy have unique problems related to the use of AEDs.* In children, developmental changes occur rapidly, and metabolic rates are greater than those seen in adults. When treating a child, it is imperative to control seizures as quickly as possible to avoid interference with development of the brain and cognition. AED doses are increased rapidly, and frequent changes in the regimen are made to maximize control of seizures. Due to the rapid metabolic rates seen in children, doses of AEDs are typically higher on a milligram per kilogram basis compared with

Table 31–4

Patient Encounter 3: Pregnancy

MA is a 28-year-old woman who comes with her husband to clinic. They would like to start a family and have several questions regarding AEDs and pregnancy. She is currently taking lamotrigine 400 mg/day for complex partial seizures. Her seizures are well controlled, except for two seizures in the last year when she missed doses due to not getting refills on time. Otherwise she is in good health.

What is the risk of birth defects if she gets pregnant while taking AEDs?

What can be done to limit the risk of birth defects?

What AEDs should generally be avoided in women of childbearing potential?

How should lamotrigine be managed when she becomes pregnant and after delivery?

adults, and serum concentrations are used more extensively to help ensure an adequate trial of a drug has been given.

For women, the treatment of epilepsy poses challenges, including teratogenicity, interactions between AEDs and hormonal contraceptives, and reduced fertility.^{40,41} Recommendations for managing women of childbearing potential and who are pregnant have been developed (Table 31-5). Several AEDs have been implicated in causing both minor and serious birth defects.⁴² Of special concern are neural tube defects (e.g., spina bifida, microcephaly, anencephaly) associated most commonly with valproate and possibly carbamazepine. Additionally, valproate has been associated with impaired cognitive development in children born to women taking valproate during pregnancy. Use of valproate is not absolutely contraindicated in women who may become pregnant, but it is appropriate to use alternative AEDs, if possible, in women of childbearing potential. All women of childbearing potential who have epilepsy should take 1 to 4 mg daily of supplemental folic acid to reduce the risk of these defects. Many AEDs are excreted in breast milk.

Table 31-5

Management of AEDs During Pregnancy

- Give supplemental folic acid 1–4 mg daily to all women of childbearing potential
- Use monotherapy whenever possible
- Use lowest doses that control seizures
- Continue pharmacotherapy that best controls seizures prior to pregnancy
- Monitor AED serum concentrations at start of pregnancy and monthly thereafter
- Adjust AED doses to maintain baseline serum concentrations
- Administer supplemental vitamin K during eighth month of pregnancy to women receiving enzyme-inducing AEDs
- Monitor postpartum AED serum concentrations to guide adjustments of drug doses

However, infants were exposed to higher concentrations of AED in utero, so it is unclear if drugs in breast milk are harmful to the child. Decisions about breast-feeding should be made on an individual basis.

As noted earlier, many of the AEDs induce hepatic microsomal enzyme systems and thus reduce the effectiveness of hormonal contraceptives. Women taking AEDs that may reduce the effectiveness of hormonal contraceptives should be encouraged to also use other forms of birth control. In contrast to these interactions, hormonal contraceptives induce glucuronidation of lamotrigine and valproate. Oral contraceptives that cycle hormones cause reductions in serum concentrations of lamotrigine or valproate during days of the cycle when hormones are taken; serum concentrations increase during days when hormones are not taken. Due to induction or inhibition of sex hormone metabolism and changes in binding of hormones to sex hormone binding globulin, some AEDs may reduce fertility. For example, valproate has been associated with a drug-induced polycystic ovarian syndrome. Women who experience difficulties with fertility should seek the advice of healthcare professionals with expertise in fertility.

9 *Older adults have the highest incidence of newly diagnosed epilepsy and face unique challenges in treatment.* The highest incidence of seizures and epilepsy is in individuals older than 65 years. Cerebrovascular disease, tumors, trauma, and neurodegenerative diseases are the primary causes of epilepsy in this age group. Diagnosis of epilepsy in older adults is often difficult. This is due to the subtle symptoms of seizures in the elderly, their often compromised memory, and the fact that many elderly live alone. Carbamazepine, lamotrigine, and gabapentin have been studied in this age group, and all are effective in controlling seizures.⁴³⁻⁴⁵ Fewer adverse events occur with lamotrigine and gabapentin. Elderly patients are more sensitive to adverse events, so smaller doses tend to be used in this age group.

Patient Encounter 4: Seizures in Older Adults

SB is a 78-year-old woman with a recent onset of spells where she is briefly confused. Her daughter has observed some of these episodes and reports that her mother has no memory of these events. During the spells she is unable to talk, and she has no memory of the episodes. SB has a history of hypertension and a minor stroke several years ago. Her MRI is consistent with an old stroke and her EEG is reported as normal.

Should pharmacotherapy be started in this patient?

If pharmacotherapy is started, what AED is preferable?

How should the efficacy and toxicity be monitored in this patient?

OUTCOME EVALUATION

10 Patients receiving AEDs for seizures should have regular monitoring for seizure frequency, seizure patterns, acute adverse effects, chronic adverse effects, and possible drug interactions.

Efficacy

- Seizure counts are the only reasonable and standard way to evaluate the efficacy of treatment.
- Encourage patients to keep a seizure calendar that notes the time and day a seizure occurs and the type of seizure. Compare seizure counts on a monthly basis to determine the level of seizure control.

Toxicity

- Monitor acute toxicity of AEDs at every clinic visit.

Patient Care and Monitoring

1. Monitor the patient's seizure frequency and characteristics. The only objective measure of efficacy for AEDs is a count of seizure frequency. Ask patients to keep seizure calendars, noting the numbers and types of seizures that occur, and have them bring the calendars to clinic at every visit for analysis and documentation of seizure frequency.
2. Monitor for acute and chronic adverse effects of AED. Acute adverse effects are best detected by a thorough neurologic examination at clinic visits. Instruct patients to report sedation, ataxia, rash, or other problems immediately. Monitor for chronic adverse effects, including a loss of bone mineral density, which should be measured every 2 years in patients taking phenytoin, phenobarbital, carbamazepine, and valproate.
3. Monitor for comorbid disease states at each clinic visit. Evaluate for depression at every clinic visit. Monitor comorbid disease states when a change in AED therapy is made.
4. Take measures to ensure compliance with medications and access to care. Compliance with medication regimens is a common problem for patients with epilepsy. Ask patients at every visit how they are taking their medications and whether they miss any doses. Identify barriers to care such as financial issues or transportation problems.
5. Instruct patients, family members, and caregivers on first aid for seizures. First aid for seizures consists primarily of keeping patients from hurting themselves. They should be placed on the floor, if possible, and their head cushioned. First responders to a seizure should never attempt to restrain the patient or force an item into their mouth. If a seizure lasts more than 5 to 10 minutes, emergency medical assistance should be called.

- Question patients about common adverse effects of the AEDs they are receiving. Weigh the impact of acute adverse effects against the extent of seizure control achieved from a treatment regimen. If it is determined the adverse effects negatively impact the patient more than the extent of seizure control benefits the patient, adjust the therapeutic regimen. Continuously monitor chronic adverse effects of AEDs.

Abbreviations Introduced in This Chapter

AAN	American Academy of Neurology
AED	Antiepileptic drug
CNS	Central Nervous System
EEG	Electroencephalograph
GABA	Gamma-aminobutyric acid

Status Epilepticus

Gretchen M. Brophy and Eljim P. Tesoro

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of status epilepticus.
2. Explain the urgency of diagnosis and treatment of status epilepticus.
3. Recognize the signs and symptoms of status epilepticus.
4. Identify the treatment options available for termination of status epilepticus.
5. Formulate an initial treatment strategy for a patient in generalized convulsive status epilepticus.
6. Compare the pharmacotherapeutic options for refractory status epilepticus.
7. Describe adverse drug events associated with the pharmacotherapy of status epilepticus.
8. Recommend monitoring parameters for a patient in status epilepticus.

KEY CONCEPTS

- 1 Status epilepticus is a neurologic emergency that can lead to permanent brain damage or death.
- 2 Status epilepticus can be practically defined as continuous seizure activity lasting more than 5 minutes or two or more seizures without complete recovery of consciousness.
- 3 It is important to evaluate possible etiologies of status epilepticus and treat underlying causes to obtain timely and optimal seizure control. A thorough history along with laboratory and diagnostic testing should be conducted.
- 4 The goal of therapy is to terminate physical and electroencephalographic evidence of seizures, prevent their recurrence, and minimize adverse drug events.
- 5 The first-line treatment for status epilepticus is IV benzodiazepines (emergent therapy). Lorazepam is currently considered the first-line agent by most clinicians.
- 6 Urgent therapy with antiepileptic drugs (AEDs) should be used to prevent seizure recurrence. IV phenytoin (or fosphenytoin), valproate sodium, and phenobarbital are options after benzodiazepines.
- 7 Seizure activity that does not respond to benzodiazepines (emergent therapy) and antiepileptics (urgent therapy) or persists beyond 30 to 60 minutes in duration can be considered refractory status epilepticus.

- 8 Midazolam, propofol, and pentobarbital infusions are commonly used for refractory status epilepticus, but intensive monitoring and supportive care are required.

1 **Status epilepticus** (SE) is a neurologic emergency that can lead to permanent brain damage or death. 2 SE can be practically defined as continuous seizure activity lasting more than 5 minutes or two or more seizures without complete recovery of consciousness.¹ Refractory status epilepticus (RSE) can be defined as seizure activity that does not respond to first-line (emergent) or second-line (urgent) antiepileptic therapy.²

SE can present as nonconvulsive status epilepticus (NCSE) or generalized convulsive status epilepticus (GCSE). NCSE is characterized by a persistent state of impaired consciousness without clinical seizure activity. For patients with NCSE, **electroencephalography** (EEG) is essential for diagnosis. GCSE is characterized by full-body motor seizures and involves the entire brain. This chapter focuses on GCSE, the most common type of SE, which is associated with the greatest risk of neurologic and physical damage.

EPIDEMIOLOGY AND ETIOLOGY

There are an estimated 150,000 cases of SE each year in the United States, with approximately 55,000 associated deaths, and an estimated annual direct cost for inpatient admissions of \$4 billion.^{3,4} Status epilepticus occurs more frequently in African Americans, children, and the elderly.

3 It is important to evaluate possible etiologies of SE to obtain timely and optimal seizure control. The causes of SE

Patient Encounter 1, Part 1

SR is a 56-year-old woman with a history of hypertension, diabetes, and arthritis who was admitted with a traumatic subdural hematoma after sustaining a fall down a flight of stairs in her home. She underwent surgery to evacuate the hematoma and is currently recovering in the ICU. Her nurse reports that a few minutes ago SR was alert and awake, but now she is unarousable and is having jerky, convulsive movements on both sides of her body. Her diagnosis is status epilepticus.

Ht 165 cm (5'5"); Wt 100 kg (220 lbs)

What initial assessments should be performed?

What are some possible etiologies for her seizure?

What interventions need to be performed at this time?

- can be categorized as acute or chronic. Acute changes that cause SE include metabolic disturbances (e.g., hyponatremia, hypernatremia, hyperkalemia, hypocalcemia, hypomagnesemia, hypoglycemia); central nervous system (CNS) disorders, infections, or injuries; **hypoxia**; and drug toxicity (e.g., theophylline, isoniazid, cyclosporine, cocaine). Chronic processes that cause SE include preexisting **epilepsy**, chronic alcohol abuse (withdrawal seizures), CNS tumors, and strokes.² In patients with epilepsy, the common causes of SE are anticonvulsant withdrawal or subtherapeutic anticonvulsant levels. Patients with SE due to chronic processes generally respond well to antiepileptic drug therapy.

PATHOPHYSIOLOGY

- Status epilepticus occurs when the brain fails to stop an isolated seizure. The exact reason for this failure is unknown and probably involves multiple mechanisms. A seizure is likely to occur due to a mismatch of excitatory and inhibitory neurotransmitters in the brain. The primary excitatory neurotransmitter is **glutamate**. Glutamate stimulates postsynaptic *N*-methyl-D-aspartate (NMDA) receptors, causing an influx of calcium into the cells and depolarization of the neuron. Sustained depolarization may maintain SE, eventually causing neuronal injury and death.⁵ The primary inhibitory neurotransmitter, **γ-aminobutyric acid** (GABA), opposes the excitatory response by stimulating GABA_A receptors, enhancing chloride inhibitory currents, producing hyperpolarization, and inhibiting the postsynaptic cell membrane. The inhibitory ability of GABA diminishes as the duration of seizures increases, perhaps due to a mechanistic shift in the functional properties of the GABA_A receptors that causes a decrease in response to GABA-receptor agonists.⁶ Seizures lasting more than 30 minutes can cause injury and neuronal loss in the hippocampal, cortical, and thalamic regions. These neurologic sequelae are related to the excessive electrical activity and alterations in cerebral metabolic

- demand. The clinical impact of the GABA_A-receptor changes on treatment response and the worsening degree of neuronal injury with prolongation of seizure activity necessitates rapid control of SE.

Several systemic changes occur in two phases during the course of SE. Phase I occurs during the first 30 minutes of seizure activity, and phase II occurs after 30 to 60 minutes of seizure activity.⁷

Phase I

- During phase I, each seizure causes a sharp increase in autonomic activity with elevated epinephrine, norepinephrine, and steroid plasma concentrations, resulting in hypertension, tachycardia, hyperglycemia, hyperthermia, sweating, and salivation. Cerebral blood flow is also increased to preserve the oxygen supply to the brain during this period of high metabolic demand. Increases in sympathetic and parasympathetic stimulation with muscle hypoxia can lead to ventricular arrhythmias, severe acidosis, and rhabdomyolysis, which could then lead to hypotension, shock, hyperkalemia, and acute tubular necrosis.

Phase II

- After approximately 30 to 60 minutes of continuous seizure activity, phase II begins with loss of cerebral autoregulation, decreased cerebral blood flow, increased intracranial pressure, and systemic hypotension. Metabolic demand is still high; however, the body is no longer able to compensate.
- The systemic changes that may occur include hypoglycemia, hyperthermia, respiratory failure, hypoxia, respiratory and metabolic acidosis, hyperkalemia, hyponatremia, and uremia. It is important to note that motor activity may not be clinically evident during prolonged seizures, but the electrical activity may still exist. This is referred to as nonconvulsive or subclinical seizure activity and needs to be recognized and treated aggressively.

CLINICAL PRESENTATION AND DIAGNOSIS

History

- 3** *When a patient presents with seizures, a thorough history is needed to determine the type and duration of the seizure activity. This will help guide therapy and identify which laboratory and diagnostic tests need to be conducted.* A firm diagnosis of SE can be made when a patient with a history of repeated seizures and impaired consciousness has a seizure witnessed by a healthcare professional. However, emergent treatment should not be delayed if seizure activity is suspected based on reports provided by the patient's family or emergency response personnel.

Physical Examination

Once seizures are controlled, a neurologic examination should be conducted to evaluate the level of consciousness

Clinical Presentation of Status Epilepticus

General

The patient may present with or without clinically noticeable seizure activity.

Symptoms

- Impaired consciousness ranging from lethargy to coma
- Disorientation after cessation of GCSE
- Pain from associated injuries (e.g., tongue lacerations, dislocated shoulder, head trauma, facial trauma)

Signs

Phase I:	Phase II (>30 minutes of SE):
Generalized convulsions	Respiratory failure with pulmonary edema
Hypertension, tachycardia	Cardiac failure (arrhythmias, shock)
Fever and sweating	Hypotension
Muscle contractions, spasms	Hyperthermia
Respiratory compromise	Rhabdomyolysis and multiorgan failure
Incontinence	

Laboratory Tests

- Hyperglycemia (phase I) and hypoglycemia (phase II) can occur
- Hyponatremia, hypernatremia, hyperkalemia, hypocalcemia, hypomagnesemia, and hypoglycemia can cause SE
- The WBC count may slightly increase
- Abnormal ABGs due to hypoxia and respiratory or metabolic acidosis
- Elevated serum creatinine will be present in renal failure patients
- Myoglobinuria can occur in patients with continuous seizures

Diagnostic Tests

EEG to confirm seizure activity
CT or MRI may reveal mass lesions or hemorrhage

(coma, lethargy, or somnolence), motor function and reflexes (rhythmic contractions, rigidity, spasms, or posturing), and pupillary response. A physical examination to identify secondary injuries from SE should also be conducted.

Clinical Symptoms

Patients with SE usually present with generalized, convulsive tonic-clonic seizure activity. They may also be hypertensive, tachycardic, febrile, and diaphoretic; however, these symptoms

will resolve soon after the seizure is terminated. A loss of bowel or bladder function, respiratory compromise, and **nystagmus** may also be observed. When seizure activity is sustained for more than approximately 30 to 60 minutes, muscle contractions may no longer be visible, but the patient remains in SE. Twitching of the face, hands, or feet may be seen in these comatose patients with prolonged seizures. As motor signs diminish, an EEG will be necessary to diagnosis SE.

Laboratory Parameters

3 It is important to obtain a serum chemistry profile to help identify possible underlying causes of SE. Abnormalities that can cause seizures include hypoglycemia, hypo- or hypernatremia, hypomagnesemia, and hypocalcemia; patients with renal and liver failure are at high risk as well. In a febrile patient with an elevated white blood cell (WBC) count, an active infection should be ruled out or treated appropriately. Cultures from the blood, cerebrospinal fluid (CSF), respiratory tract, and urine should be obtained once the seizures are controlled. Computed tomography (CT) or magnetic resonance imaging (MRI) can be done to rule out CNS abscesses, bleeding, or tumors, all of which may be a source of seizure activity. A blood alcohol level and urine toxicology screen for drugs of abuse should also be conducted to determine if alcohol withdrawal, illicit drug use, or a drug overdose could be the underlying cause of SE. Also, drug levels should be obtained in a drug overdose situation to rule out toxicity as a cause of SE. 3 Knowing the source of SE will help guide the initial antiepileptic therapy and increase the probability of halting seizure activity.

In patients with epilepsy who use AEDs, a baseline serum concentration may be useful to determine if the drug concentration is below the desired range and if a loading dose is needed. Albumin levels, renal function tests, and liver function tests can also be used when assessing antiepileptic therapy.

Hypoxia and respiratory or metabolic acidosis are common in patients with SE. Therefore, pulse oximetry and arterial blood gas (ABG) measurements are used to assess respiratory status and determine if airway protection or supplemental oxygen is needed. Metabolic acidosis typically corrects on its own after clinical seizure activity stops, so pharmacologic treatment is not required.

Diagnostic Tests

The only way to determine if a comatose patient has SE is by EEG. Continuous EEG monitoring should be used in patients who remain unconscious after initial antiepileptic treatment and for those who receive long-acting paralytic agents or require prolonged therapy for RSE. Treatment should never be delayed while awaiting EEG results. An electrocardiogram (ECG) should be obtained to rule out cardiac dysfunction when hypotension or an abnormal heart rate is observed.

Patient Encounter 1, Part 2

Physical examination and a review of her chart and recent laboratory studies reveal the following additional information about SR:

PE:

VS: blood pressure 178/92 mm Hg, pulse 109 bpm, respiratory rate 26 breaths/min, temperature 39.0°C (102.2°F)

CNS: Unresponsive, unarousable

CV: Sinus tachycardia; normal S_1 , S_2 ; no murmurs, rubs, gallops

Pulm: Tachypneic; oxygen saturation 88% (0.88) on room air; no rhonchi, wheezes, rales

Abd: Deferred

Exts: Rhythmic tonic-clonic movements of all extremities

GU: Incontinent of urine and stool

HEENT: Persistent upward gaze

Medications

Phenytoin 100 mg IV q 8 h

Famotidine 20 mg IV q 12 h

Metoprolol 50 mg PO q 12 h

Insulin glargine 25 U SQ at bedtime

Insulin aspart 5 U SQ with meals

Acetaminophen/hydrocodone 325 mg/5 mg tablet PO q 4 h as needed for pain

Morphine 2 mg IVP q 2 h as needed for pain

Labs

Sodium 135 mEq/L (135 mmol/L)

Potassium 4.1 mEq/L (4.1 mmol/L)

Phenytoin 8.7 mcg/mL (35 μ mol/L)

Albumin 3.5 g/dL (35 g/L)

Chloride 105 mEq/L (105 mmol/L)

Carbon dioxide 12 mEq/L (12 mmol/L)

Blood urea nitrogen 10 mg/dL (3.6 mmol/L)

Serum creatinine 0.9 mg/dL (80 μ mol/L)

Glucose 54 mg/dL (3.0 mmol/L)

WBC $15 \times 10^3/\text{mm}^3$ ($15 \times 10^9/\text{L}$)

Hemoglobin 9.6 g/dL (96 g/L or 5.96 mmol/L)

Hematocrit 28% (0.28 volume fraction)

Platelets $235 \times 10^3/\text{mm}^3$ ($235 \times 10^9/\text{L}$)

Prothrombin time 12 seconds

International normalized ratio 1.1

Activated partial thromboplastin time 28 seconds

What is your assessment of the cause of this patient's condition?

Identify your goals of therapy for this patient.

What therapies must be instituted next?

TREATMENT

Desired Outcomes

4 *The goal of therapy is to terminate physical and electroencephalographic evidence of seizures, prevent their recurrence, and minimize adverse drug events.* Poor outcomes have been associated with longer duration of SE or the development of refractory SE.⁸ Complications of SE should also be treated.

General Approach

- The initial approach to SE involves first removing the patient from harmful surroundings and ensuring a safe airway to prevent respiratory collapse or aspiration. A benzodiazepine is the first medication administered (emergent therapy) because benzodiazepines are the drugs of choice to stop acute seizure activity, followed by the initiation of an AED (urgent therapy) for continued suppression of seizures. Medications are typically given IV for immediate onset of action, but if no IV access is available, select medications may be given rectally, intramuscularly (IM), buccally, or nasally. Once the seizures stop, clinicians must identify and treat any underlying cause of the seizures, such as toxins, hypoglycemia, or brain injury. Patients with known seizure disorders should be evaluated for abrupt cessation of their medications or for history of noncompliance.

Nonpharmacologic Treatment

Nondrug interventions include administration of oxygen or intubation for mechanical ventilation in cases of hypoxia or body cooling for febrile seizures. Specialists in neurology or epileptology should be consulted as appropriate. Admission to an intensive care unit (ICU) allows appropriate monitoring during the seizure and postictal period.

Pharmacologic Treatment

► Initial Treatment

All patients suspected of having hypoglycemia-induced SE should receive IV dextrose. In patients with a history of alcohol abuse, IV thiamine 100 mg should be given prior to the administration of any dextrose-containing solutions to prevent encephalopathy.

► Benzodiazepines

- 5 *Initial or emergent drug therapy begins with the administration of an IV benzodiazepine, a class of agents that is highly effective in aborting seizure activity.^{9,10} IV bolus doses of diazepam, lorazepam, and midazolam have all been used in SE because of their rapid effects on GABA receptors in the CNS. Lorazepam is now considered the first-line agent by most clinicians.* When treating patients on chronic benzodiazepine therapy, clinicians should consider using higher doses to overcome the effects of tolerance. Diazepam and lorazepam should be diluted with normal saline in a 1:1 ratio before parenteral administration via peripheral veins to avoid venous irritation from the propylene glycol diluent in the formulation.

Diazepam Extremely **lipophilic**, diazepam penetrates quickly into the CNS but rapidly redistributes out into the body fat and muscle. This results in a faster decline in CNS levels and early recurrence of seizures. It is dosed at 5 to 10 mg (or 0.15 mg/kg) and infused no faster than 5 mg/min. Repeated doses can be given every 5 minutes until seizure activity stops or toxicities are seen (e.g., respiratory depression). Diazepam can also be administered as a rectal suppository, making it possible for nonmedical personnel to provide rapid therapy for seizures that develop at home or in public areas.¹¹ The adult dose is 10 mg given rectally, and this dose may be repeated once if necessary. Diazepam is erratically absorbed via the IM route; therefore, IM administration is not recommended.

Lorazepam Less lipophilic than diazepam, lorazepam has a longer redistribution half-life, resulting in longer duration of action and a decrease in the need for repeated doses. Both lorazepam and diazepam are effective in stopping seizures,¹² but lorazepam is currently the preferred agent due to a longer duration of action. Lorazepam is given as a single IV dose of 0.1 mg/kg (up to 4 mg/dose) with a maximum rate of infusion of 2 mg/min. It can be redosed every 5 to 10 minutes (up to a maximum cumulative dose of 8 mg) until seizure activity stops or side effects such as respiratory depression occur. IM administration is not preferred due to slow and unpredictable absorption.

Midazolam Midazolam is water soluble and can be administered IM,¹³ buccally,^{14,15} and nasally.^{16,17} At physiologic pH, it becomes more lipophilic and can diffuse into the CNS. Compared with diazepam and lorazepam, it has fewer effects on the respiratory and cardiovascular systems. Its short half-life requires that it be redosed frequently or administered as a continuous IV infusion. Midazolam is given at a dose of 0.2 mg/kg IM as a single dose, up to a maximum dose of 10 mg. The liquid or injectable formulation can be given buccally or intranasally (0.3 mg/kg) in pediatric patients.

Nasal administration in SE can be hindered by rapid breathing and increased nasal secretions. A recent study in adults and children showed that IM midazolam was as safe and effective as IV lorazepam for prehospital administration for seizure cessation.¹⁷

► Anticonvulsants

6 Once the first dose of benzodiazepine is given, an AED such as phenytoin (or fosphenytoin), valproate sodium, or phenobarbital should be started to prevent further seizures from occurring (urgent therapy). AEDs must not be given as first-line therapy because they are infused relatively slowly to avoid adverse effects, delaying their onset of action. If the underlying cause of the seizures has been corrected (e.g., hypoglycemia) and seizure activity has ceased, an AED may not be necessary. This may be reasonable when patients are completely alert and oriented or if an EEG confirms absence of ongoing seizure activity.

Once the loading dose of the AED is administered, it is important to initiate maintenance doses to ensure that therapeutic levels are sustained. Chronic and idiosyncratic side effects as well as potential drug interactions should be considered if the patient will continue AED therapy indefinitely. All drugs should be adjusted for any hepatic or renal disease states. **Table 32-1** summarizes the drug doses used in SE, and **Table 32-2** provides an example of an algorithm for the treatment of patients in SE.

Phenytoin The most widely used AED for the urgent treatment of SE is phenytoin, which is available in its original form or as a prodrug, fosphenytoin, which is described later. Phenytoin is administered IV as a loading dose (for patients previously not on phenytoin) of 15 to 20 mg/kg. The loading dose must be modified in patients taking phenytoin who have subtherapeutic levels in order to avoid toxic serum concentrations. The loading dose is infused no faster than 50 mg/min due to potential risks of hypotension or arrhythmias. Continuous monitoring of ECG and blood pressure is recommended. Maintenance dosing can be started 12 hours after the loading dose. Phenytoin should not be infused with other medications because of stability concerns (it is soluble in propylene glycol and compatible only in 0.9% sodium chloride solutions). It should not be given via the IM route due to its alkaline nature. **Extravasation** of the drug can cause local tissue discoloration, edema, pain, and sometimes necrosis (purple glove syndrome). Oral loading is not recommended in SE due to the limitations of single-dose absorption (i.e., doses greater than approximately 400 mg are not fully absorbed) and delayed peak concentrations when given by this route.

Fosphenytoin Fosphenytoin is a water-soluble, phospho-ester prodrug that is rapidly converted to phenytoin in the body. It is compatible with most IV solutions. It is dosed in phenytoin equivalents (PEs), and it can be infused three times as fast as phenytoin, up to 150 mg PE/min. The loading dose for patients not taking phenytoin is 15 to 20 mg

Patient Encounter 2, Part 1

DB is a 26-year-old man admitted for intractable headaches for the last 4 weeks. He does not take any medications and has no allergies to medications. The CT scan of his head reveals a large right frontal lobe mass. While the nurse is taking his vital signs, he becomes confused and then unarousable with jerky movements in all of his extremities. His diagnosis is status epilepticus.

VS: blood pressure 102/65 mm Hg, pulse 112 beats/min, respiratory rate 23 breaths/min, temperature 37.0°C (98.6°F), Wt 85 kg (187 lb), Ht 173 cm (5'8")

What is the most likely cause of this patient's SE?

What possible treatment options exist at this time?

How would you optimize this patient's outcome?

Table 32-1

Parenteral Medications Used in Status Epilepticus in Adults

Drug Name (Brand Name)	Loading Dose and RSE Maintenance Dose (If Applicable)	Administration Rate	Therapeutic Level	Side Effects	Comments
Diazepam (Valium)	0.15 mg/kg (up to 10 mg/dose)	5 mg/min (IVP)	N/A	Hypotension, respiratory depression	Rapid redistribution rate; can be given rectally
Lorazepam (Ativan)	0.1 mg/kg (up to 4 mg/dose)	2 mg/min (IVP)	N/A	Hypotension, respiratory depression	May be longer-acting than diazepam
Midazolam (Versed)	0.2 mg/kg IM up to 10 mg/dose RSE: 0.2 mg/kg (2 mg/min) IV then 0.05–2 mg/kg/h		N/A	Sedation, respiratory depression	Can also be given buccally, intranasally; expensive
Phenytoin (Dilantin)	15–20 mg/kg	Up to 50 mg/min	10–20 mcg/mL (40–79.2 μmol/L)	Arrhythmias, hypotension,	Hypotension, especially in elderly
Fosphenytoin (Cerebyx)	15–20 mg PE/kg	Up to 150 mg PE/min	10–20 mcg/mL of phenytoin (40–79.2 μmol/L)	Paresthesias, hypotension	Less CV side effects than phenytoin
Phenobarbital (Luminal)	15–20 mg/kg	50–100 mg/min	15–40 mcg/mL (65–172 μmol/L)	Hypotension, sedation, respiratory depression	Long acting
Valproate sodium (Depacon)	15–20 mg/kg (up to 40 mg/kg)	3–6 mg/kg/min	50–150 mcg/mL (347–1039 μmol/L)		Less CV side effects than phenytoin
Propofol (Diprivan)	1–2 mg/kg RSE: 30–250 mcg/kg/min	Approximately 40 mg q 10 s	N/A (typically titrated to EEG)	Hypotension, respiratory depression	Requires mechanical intubation; high lipid load (increased calories); propofol-related infusion syndrome
Pentobarbital (Nembutal)	10–15 mg/kg RSE: 0.5 – 4 mg/kg/h	Up to 50 mg/min	10–20 mcg/mL (44–89 μmol/L) (typically titrated to EEG)	Hypotension, respiratory depression, cardiac depression, infection, ileus	Requires mechanical intubation, vasopressors, hemodynamic monitoring

CV, cardiovascular; EEG, electroencephalogram; IM, intramuscular; IVP, intravenous push; N/A, not applicable; PE, phenytoin equivalents.

PE/kg. Although it has fewer cardiovascular side effects than phenytoin, clinicians should still continuously monitor blood pressure, ECG, and heart rate. Maintenance doses are begun 12 hours after the loading dose. A common side effect is **paresthesias**, especially around the lips and groin, which typically resolve within a few minutes and should not necessitate stopping the infusion. If a postload serum level is desired, it should be obtained 2 hours after an IV load. Generic fosphenytoin is now available, so increased expense is no longer an issue.

Phenobarbital If phenytoin or fosphenytoin fails to prevent seizure recurrence, phenobarbital can be considered. However, emerging evidence suggests that phenobarbital may not be effective if SE persists after giving benzodiazepines and phenytoin. This may be due to the progressive resistance of the GABA_A receptor, where barbiturates also act.¹⁸ It is dosed as an IV load of 15 to 20 mg/kg with a maximum rate of administration of 100 mg/min. Adverse reactions of phenobarbital include sedation, hypotension, and respiratory depression; therefore, patients who receive a rapid

IV loading dose of phenobarbital should have hemodynamic monitoring and be mechanically ventilated if at high risk of respiratory compromise. Its long half-life makes it a popular agent for both acute treatment and chronic maintenance therapy or as adjunct therapy to prevent withdrawal seizures when weaning refractory SE patients off pentobarbital continuous infusions.

Valproate Sodium Although valproate sodium is not FDA approved for SE, its IV use has been documented in various types of SE including generalized tonic-clonic, myoclonic, and nonconvulsive SE.¹⁹ One study comparing it with phenytoin found similar efficacy (80% cessation of seizure activity) but with less cardiopulmonary side effects.²⁰ Additional studies also support its use for urgent therapy,^{21,22} especially in patients who are not intubated and/or are allergic to phenytoin and phenobarbital.²³ Valproate sodium can be loaded IV at 15 to 20 mg/kg and infused at a rate of up to 6 mg/kg/min. Higher doses (up to 30 to 40 mg/kg) have also been used to attain serum levels of 100 to 150 mcg/mL (693 to 1039 μmol/L) in less responsive cases of SE.²⁴

Table 32-2

Algorithm for Treatment of Status Epilepticus in Adults

Time (minutes)	Assessment/Monitoring	Treatment
0	Vital signs (HR, RR, BP, T) Assess airway Monitor cardiac function (ECG) Pulse oximeter Check blood glucose Check laboratory tests: complete blood count, serum chemistries, liver function tests, arterial blood gas, blood cultures, serum anticonvulsant levels, urine drug/alcohol screen	Stabilize airway (intubate if necessary) Administer oxygen Secure IV access and start fluids Give IV thiamine (100 mg), then IV dextrose (50 mL of 50% solution) if hypoglycemic
0–10	Vital signs Physical examination Patient history including medications (prescription, OTC, and herbals)	Lorazepam 0.1 mg/kg (maximum 4 mg) IVP at 2 mg/min (may repeat in 5–10 minutes to maximum of 8 mg if no response) If no IV access, can give: diazepam 10 mg PR (may repeat in 10 minutes if no response); midazolam 0.2 mg/kg IM (maximum 10 mg; may repeat in 10 minutes if no response) AED may not be necessary if underlying cause is corrected and seizures have ceased
10–20	Vital signs Review laboratory results and correct any underlying abnormalities CT scan (if seizures controlled)	Phenytoin 15–20 mg/kg IV at a maximum rate of 50 mg/min (or fosphenytoin 15–20 mg PE/kg IV at a maximum rate of 150 mg/min) In patients allergic to phenytoin, give valproate sodium 20 mg/kg IV at a maximum rate of 6 mg/kg/min Treat for possible infection
20–30	Vital signs Consult neurologist/epileptologist Consider admission to ICU Consider EEG	If seizures continue: additional phenytoin bolus 5–10 mg/kg (or fosphenytoin 5–10 mg PE/kg) or start phenobarbital at 20 mg/kg IV at a maximum rate of 100 mg/min or start valproate sodium 20 mg/kg IV at a maximum rate of 6 mg/kg/min in patients who are not intubated
Greater than 30–60 refractory status epilepticus	Vital signs Transfer to ICU Obtain EEG Consider MRI when controlled	Midazolam 0.2 mg/kg IV bolus followed by 0.05–2 mg/kg/h CI or propofol 1 mg/kg bolus followed by 30–250 mcg/kg/min CI or pentobarbital 10–15 mg/kg bolus over 1–2 hours followed by 0.5–4 mg/kg/h Consider intubation and/or vasopressor support if needed Optimize AED levels: repeat boluses of phenobarbital 10 mg/kg or valproate sodium 20 mg/kg at 6 mg/kg/min max

BP, blood pressure; CI, continuous infusion; CT, computed tomography; ECG, electrocardiogram; EEG, electroencephalography; HR, heart rate; ICU, intensive care unit; IVP, intravenous push; OTC, over the counter; MRI, magnetic resonance imaging; PE, phenytoin equivalents; PR, per rectum; RR, respiratory rate; T, temperature.

Treatment of Refractory Status Epilepticus

7 Seizure activity that does not respond to benzodiazepines (emergent therapy) and antiepileptics (urgent therapy) or persists beyond 30 to 60 minutes in duration can be considered RSE.²⁵ RSE can occur in up to 30% of patients with SE and has a mortality rate approaching 50%. Patients in RSE are unlikely to return to their baseline state, even if the seizures are eventually controlled. As RSE progresses, clinical signs may become subtle, and in certain patients, an EEG is required to detect ongoing seizure activity. 1 Even SE patients without clinical signs of seizing are at risk for brain damage or even death.

- The optimal therapy for RSE has not been determined.²⁶ Clinicians must aggressively investigate and treat possible causes including infection, tumors, drugs or toxins, metabolic disorders, liver failure, or fever. In general, patients with RSE are managed in an ICU where hemodynamic and respiratory support are available and frequent monitoring

Patient Encounter 2, Part 2

Over the next hour, DB is treated with your recommendations for emergent and urgent treatment as above. His jerky movements have stopped, but he remains comatose. His breathing is shallow and slow, and his oxygen saturation is 90% (0.90).

VS: blood pressure 101/72 mm Hg, pulse 98 beats/min, respiratory rate 10 breaths/min, temperature 37.0°C (98.6°F)

What is your assessment of the patient's condition at this time?

What recommendations for further drug therapy would you make?

How would you optimize his outcome?

can be performed. Continuous EEG monitoring is essential to document cessation of seizure activity and should not be delayed. Any AEDs initiated before treatment for RSE should be continued and their serum levels optimized to minimize any breakthrough or withdrawal seizures. **8** *Treatment of RSE typically consists of intensive monitoring, supportive care, and a continuous IV infusion of midazolam, propofol, or pentobarbital to suppress all clinical and EEG evidence of seizures.*²⁷ These agents are typically titrated to achieve “burst suppression” on the EEG, although no strong evidence exists to support this as the universal goal. Patients should be intubated and mechanically ventilated before initiating these treatment strategies for RSE. Consultation with a neurologist or epileptologist is highly recommended in these cases.

► Midazolam

A loading dose of 0.2 mg/kg IV (repeated up to a maximum of 2 mg/kg) followed by a continuous infusion of 0.05 to 2 mg/kg/h is recommended in RSE.^{28,29} The dose must be adjusted during prolonged infusions, especially in patients with renal impairment, because the active metabolite can accumulate.³⁰ Breakthrough seizures are common with midazolam infusions and usually respond to a bolus and a 20% increase in the infusion rate. Despite this, tachyphylaxis can occur, and the patient should be switched to another agent if seizures continue.

► Propofol

The anesthetic agent propofol can be started with loading doses of 1 to 2 mg/kg repeated every 3 to 5 minutes until a clinical response is achieved, after which the infusion can be initiated at 30 to 60 mcg/kg/min. Propofol can cause hypotension, especially with loading doses; therefore, some clinicians avoid loading doses and go directly to continuous infusion propofol and rapidly titrate it to effect. Long-term, high-dose (>80 mcg/kg/min) propofol infusions are associated with rhabdomyolysis, acidosis, and cardiac arrhythmias (propofol-related infusion syndrome), especially in children.^{31,32} Propofol has a very short serum half-life and should be tapered off slowly to avoid withdrawal seizures. High-dose propofol infusions can also provide a considerable amount of calories (1 kcal/mL) over time, so other sources of nutrition may have to be adjusted accordingly.

► Pentobarbital

Barbiturate infusions have been reported to be highly successful in treating RSE,³³ but their side effects are considerable. They can cause significant hypotension, myocardial and respiratory depression, ileus, and infection (especially gram-positive organisms). As a result, patients require mechanical ventilation and invasive hemodynamic monitoring. In addition, they also often require IV **vasopressor** therapy and total parenteral nutrition while undergoing “barbiturate coma.” However, barbiturates are beneficial in decreasing elevated intracranial pressure (ICP).

Pentobarbital is commonly loaded at a dose of 10 to 15 mg/kg over 1 to 2 hours, followed by a continuous infusion

of 0.5 to 4 mg/kg/h. Therapy can be tapered off after 12 to 24 hours of seizure control as evident on EEG.³⁴ One meta-analysis reported a lower incidence of treatment failure with pentobarbital (3%) when compared with midazolam (21%) or propofol (20%), although the risk of hypotension requiring vasopressor therapy was higher with pentobarbital.³³ This relative efficacy for pentobarbital must be considered together with its complications when determining which agent to use. Patients who fail midazolam and/or propofol infusions should be switched over to pentobarbital therapy.

► Levetiracetam

Although not FDA-approved for SE, levetiracetam is a newer AED that does not have the significant cardiopulmonary, hepatic, and sedative side effects seen with the other agents; nor does it have potentially harmful drug interactions. Both IV³⁵ and oral³⁶ formulations have been used in RSE patients as add-on therapy with some success, although it is unclear if levetiracetam would be effective as a single agent in these cases.³⁷ Loading doses of up to 2000 mg over 15 to 30 minutes in the critically ill have been documented with very little toxicity noted.³⁸

► Other Agents

Ketamine,³⁹ topiramate, and inhaled anesthetics have also been used to treat RSE. Ketamine is an NMDA receptor antagonist that has been given orally⁴⁰ and IV⁴¹ for RSE in children. Topiramate is an oral AED with multiple mechanisms of action that may have some benefit in RSE. The oral dose in adults ranges from 300 to 1600 mg/day.⁴² Children have also been administered topiramate at a starting dose of 2 to 3 mg/kg/day and titrated to a maintenance dose of 5 to 6 mg/kg/day.⁴³ Topiramate can induce metabolic acidosis, which should be monitored carefully. The inhaled anesthetics, desflurane and isoflurane,⁴⁴ are normally delivered in an operating room, and they require special equipment for administration in an ICU. One of the newest agents that have been used in RSE is lacosamide, an enhancer of slow inhibition of sodium channels with limited drug interactions.⁴⁵ It has been used both orally⁴⁶ and IV⁴⁷ in the setting of refractory partial SE. Future studies are needed to determine the place of these agents in therapy.

Special Populations

Certain patient populations require special considerations due to their altered metabolism, unique volume of distribution, or increased risk for side effects.⁴⁸ Although many of these patients are excluded from clinical trials in SE, the standard algorithm for SE still applies in terms of immediate care, assessment, and drugs (see Table 32–2).

► Pediatrics

The treatment approach of SE in children is similar to that in adults with a few exceptions (Table 32–3). The doses are also weight based but are typically higher than those used in adults due to higher clearance by the liver. It may be

Table 32-3

Drugs Used in Pediatric Status Epilepticus

Drug	Dose	Comments
Diazepam (Valium injection, Diastat rectal gel)	IV: 0.2–0.3 mg/kg over 2–5 minutes PR: 2–5 years: 0.5 mg/kg 6–11 years: 0.3 mg/kg More than 12 years: 0.2 mg/kg	Maximum dose in children less than 5 years: 5 mg Maximum dose in children greater than 5 years: 15 mg A second rectal dose can be given 4–12 hours after the first dose if necessary
Lorazepam (Ativan)	0.05–0.1 mg/kg IV over 2–4 minutes	May redose twice in 10–15 minutes if necessary
Midazolam (Versed)	0.2 mg/kg IV bolus followed by 0.05–0.6 mg/kg/h continuous infusion	Bolus dose may also be given intranasally, buccally, or intramuscularly
Phenytoin (Dilantin)	15–20 mg/kg IV at 1–3 mg/kg/min <i>max</i>	
Fosphenytoin (Cerebyx)	15–20 mg PE/kg IV at 3 mg/kg/min <i>max</i>	
Phenobarbital (Luminal)	15–20 mg/kg IV at 100 mg/min <i>max</i>	
Valproate sodium (Depacon)	15–20 mg/kg IV at 1.5–3 mg/kg/min	May have fewer cardiovascular side effects than other agents
Propofol (Diprivan)		Not recommended due to adverse events (e.g., propofol-related infusion syndrome)
Pentobarbital (Nembutal)	10–15 mg/kg IV over 1–2 hours followed by continuous infusion at 1 mg/kg/h	Titrated to EEG

PR, per rectum; EEG, electroencephalograph; PE phenytoin equivalent.

difficult to rapidly obtain IV access in children, so alternative routes of drug administration have been studied, including intranasal, buccal, rectal, and IM. Early administration of benzodiazepines and reduced time to hospital admission are important factors in decreasing the incidence of prolonged seizures.⁴⁹

► Geriatrics

The elderly are prone to injury and toxicity from multiple concomitant disease states and polypharmacy. Seizures in the elderly can easily arise from metabolic disorders, drug interactions, or even incorrect dosing of medications in patients with impaired renal and hepatic function and decreased protein binding. Clinicians treating elderly patients with SE should investigate drug- and disease state-induced causes because treating these etiologies alone may terminate seizures. Acute treatment with benzodiazepines and AEDs is no different in the elderly, but they may have more pronounced reactions to these medications in terms of their sedative and cardiorespiratory side effects. Phenytoin and fosphenytoin loading doses should be carefully calculated in the elderly because their weights may be overestimated, and they may not tolerate high doses. They should also be infused at slower rates to minimize hypotension and arrhythmias. Phenobarbital may cause respiratory depression earlier in the elderly, especially once benzodiazepines are administered. Clinicians should consider using smaller doses and evaluate for renal and hepatic insufficiency if repeated doses are to be given.

► Pregnancy

The main concern in the treatment of pregnant females in SE is the safety of the fetus that is at risk of hypoxia during

periods of prolonged seizures. Although many of the agents used in SE are **teratogenic**, clinicians should still use them as acute measures to stop the seizures and consider alternative agents as maintenance therapy.⁵⁰ The volume of distribution and clearance of many drugs are typically increased during pregnancy, which should be considered when calculating doses.

OUTCOME EVALUATION

4 The success of treatment is measured by the early termination of seizures without adverse drug effects or brain injury. Therefore, start pharmacologic treatment as soon as possible.

- First-line (emergent) treatment for SE should halt seizure activity within minutes of administration.
- In patients who are unarousable following treatment, confirm termination of seizures with an EEG.
- Perform a physical examination and evaluation of the patient's laboratory results to help determine if the cause or complications of seizure activity are being appropriately treated.
- Once seizure activity has ceased and the patient has stabilized, review the patient's therapeutic regimen.
- Evaluate and monitor serum trough concentrations of AEDs with defined target ranges to determine patient-specific therapeutic goals.
- Treat known causes of SE and simplify therapy.
- In patients with RSE on multiple AEDs, slowly decrease the dose of one drug at a time while continuing to evaluate the patient for seizure activity.

- Base the titration schedule on the half-life of the drug and individual patient response.
- Optimize treatment using the fewest medications to prevent seizure recurrence without causing adverse drug reactions.
- Continue to monitor AED serum trough concentrations approximately every 3 to 5 days until the AEDs have reached steady-state concentrations.
- Give additional loading doses or hold doses as needed to maintain target trough concentrations.
- Monitor the patient for signs of drug toxicity and seizures until drug concentrations have stabilized.
- Closely evaluate medication profiles, and change drugs or doses to minimize any drug interactions, if possible.

Patient Care and Monitoring

1. Obtain a seizure history from the patient or family members, including precipitating factors and duration of seizure activity.
2. Identify and correct the underlying cause of the seizures, if possible. Does the patient have any laboratory abnormalities? Is there a positive toxicology screen for alcohol or drugs?
3. Obtain a thorough history of nonprescription, prescription, and alternative drug or herbal use. Determine adherence with the medication regimen and whether barriers to care exist. Does the patient have the financial ability and transportation to obtain the prescriptions?
4. Assess the AED serum concentration and adjust therapy as needed for agents with a defined therapeutic range (e.g., phenytoin, carbamazepine, valproic acid, and phenobarbital). Drug levels can also be used to determine adherence to medication regimens for agents that do not have defined ranges. Monitoring free phenytoin concentrations is recommended in critically ill patients with hypoalbuminemia.⁵¹
5. Evaluate the patient for adverse drug reactions, IV site extravasation, and allergic reactions. What alternative AEDs should be used if a drug allergy is identified?
6. Determine whether there are any drug interactions with the patient's current or home medication regimens. Do you need to adjust the dose of any medications for toxic or subtherapeutic concentrations from the drug interaction?
7. Maintain adequate cardiovascular support, nutrition, and electrolyte and glucose serum concentrations to prevent recurrence of seizure activity.
8. Continue to evaluate the patient for seizure activity and adjust therapy as needed to control seizures and optimize quality of life.

Abbreviations Introduced in This Chapter

ABG	Arterial blood gas
AED	Antiepileptic drug
CSF	Cerebrospinal fluid
CT	Computed tomography
ECG	Electrocardiogram
EEG	Electroencephalography
GABA	γ -Aminobutyric acid
GCSE	Generalized convulsive status epilepticus
ICP	Intracranial pressure
ICU	Intensive care unit
IM	Intramuscular
MRI	Magnetic resonance imaging
NCSE	Nonconvulsive status epilepticus
NMDA	<i>N</i> -methyl- <i>D</i> -aspartate
PE	Phenytoin equivalent
RSE	Refractory status epilepticus
SE	Status epilepticus
WBC	White blood cell

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Parkinson's Disease

Mary L. Wagner and Jamie C. Holmes

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of Parkinson's disease (PD) related to neurotransmitter involvement and targets for drug therapy in the brain.
2. Recognize the cardinal motor symptoms of PD and determine a patient's clinical status and disease progression based on the Unified Parkinson's Disease Rating Scale (UPDRS).
3. For a patient initiating therapy for PD, recommend appropriate drug therapy and construct patient-specific treatment goals.
4. Recognize and recommend appropriate treatment for nonmotor symptoms.
5. Formulate a plan to minimize patient "off-time" and maximize "on-time" including timing, dosage, and frequency of medications.
6. Recognize and treat various motor complications that develop as PD progresses.
7. Construct appropriate patient counseling regarding medications and lifestyle modifications for a patient with PD.
8. Develop a monitoring plan to assess effectiveness and adverse effects of treatment.

KEY CONCEPTS

- 1 Parkinson's disease (PD) is a slow, progressive neurodegenerative disease of the extrapyramidal motor system that features classic motor symptoms of tremor, rigidity, akinesia/bradykinesia, and postural/gait instability (TRAP).
 - 2 The most useful diagnostic tool is the clinical history, including both presenting symptoms and associated risk factors. The Unified Parkinson's Disease Rating Scale (UPDRS) is used to define the degree of disability.
 - 3 The goals of treatment are to maintain patient independence, activities of daily living (ADLs), and quality of life (QOL) by alleviating the patient's symptoms, minimizing the development of response fluctuations, and limiting medication-related adverse effects.
 - 4 The treatment of PD is categorized into three types: (1) lifestyle changes, nutrition, and exercise; (2) pharmacologic intervention, primarily with drugs that enhance dopamine concentrations; and (3) surgical treatments for those who fail pharmacologic interventions.
 - 5 Drug therapy is aimed at enhancing dopaminergic activity in the substantia nigra. The best time to initiate dopaminergic therapy is controversial and patient specific.
 - 6 Medication schedules should be individualized. The doses are divided throughout the day to maximize **on time** and minimize **off time**.
 - 7 The treatment of nonmotor symptoms should be based on whether they are worse during an off state or potentially related to other neurotransmitter dysfunction.
 - 8 As the disease progresses, most patients develop response fluctuations. Treatment is based on optimizing the pharmacokinetic and pharmacodynamic properties of PD medications.
 - 9 Patient monitoring should involve a regular systematic evaluation of efficacy and adverse events, referral to appropriate specialists, and patient education.
- Parkinson's disease (PD) is a slow, progressive neurodegenerative disease of the extrapyramidal motor system. Dopamine neurons in the substantia nigra are primarily affected, and degeneration of these neurons causes a disruption in the ability to generate body movements.
- Cardinal features of PD include tremor at rest, rigidity, akinesia/bradykinesia, and postural instability. There is no cure, and treatment is aimed at controlling symptoms and slowing disease progression.

EPIDEMIOLOGY AND ETIOLOGY

PD affects approximately 1 million Americans, with a lifetime risk of developing the disease of 1.5%. The median age of onset is 60 years of age, but about 10% of people with PD are younger than 45 years. There is an estimated mortality ratio of 2:1 in PD, and the average duration of time from diagnosis to death is about 15 years. About 15% of patients with PD have a first-degree relative with the disease.^{1,2}

The etiology of neuron degeneration in PD remains unknown, but aging has been implicated as a primary risk factor. Other explanations for cell death may include oxidative stress, mitochondrial dysfunction, increased concentrations of excitotoxic amino acids and inflammatory cytokines, immune system disorders, trophic factor deficiency, signal-mediated apoptosis, and environmental toxins. Genetic mutations such as those in *LRRK2* have been linked to the disease.^{2,3} Genetic factors contributing to the development of PD may include mutations in several genes, including glucocerebrosidase, leucine-rich repeat kinase, and *PTEN*-induced putative kinase.¹ These mutations may predict early versus late onset of the disease. It is not certain if genetic mutations alone contribute to the development of PD or if this risk factor is greater when combined with aging, environmental toxins, and oxidative stress, glutamate excitotoxicity, mitochondrial dysfunction, neuroinflammation, and **apoptosis**.² Conditions that may promote oxidative stress include increased monoamine oxidase-B metabolism or decreased glutathione clearance of free radicals.¹⁻⁵

In PD there is a loss of pigmented cells in the **substantia nigra** that make and store dopamine. When patients are diagnosed, they have lost 50% to 60% of their dopamine neurons in the substantia nigra, and the remaining neurons beyond the substantia nigra in the basal ganglia, spinal cord, and neurocortex may not function well. Neurons have lost about 80% of their activity in the striatum at the onset of PD.

There may be cortical **Lewy bodies** along with Lewy neurites seen in microscopic samples from the basal ganglia, cortex, brainstem, spinal cord, sympathetic ganglia, cardiac plexus, and GI system that may explain some of the nonmotor symptoms of PD.^{2,4,5}

PATHOPHYSIOLOGY

The extrapyramidal motor system controls muscle movement through pathways and nerve tracts that connect the cerebral cortex, basal ganglia, thalamus, cerebellum, reticular formation, and spinal neurons. Patients with PD lose dopamine neurons in the substantia nigra, which is located in the midbrain within the brainstem. The substantia nigra sends nerve fibers up to the corpus striatum, which is part of the **basal ganglia** in the cerebrum. The corpus striatum is made up of the caudate nucleus and the lentiform nuclei that consist of the pallidum (globus pallidus) and putamen (**Fig. 33-1**). As dopamine neurons die, dopamine-relayed messages cannot communicate to other motor centers of the brain, and patients develop motor symptoms. A variety of neurotransmitters are active in the basal ganglia including acetylcholine, histamine, glutamate, serotonin, dopamine, norepinephrine, epinephrine, γ -aminobutyric acid (GABA), enkephalins, substance P, and adenosine. Some of these neurotransmitters also decrease in concentration as other brain regions degenerate, resulting in degeneration of norepinephrine neurons in the locus coeruleus and acetylcholine neurons in the nucleus basalis, as well as selected neurons of the dorsal motor nucleus of the vagus, spinal cord, and peripheral autonomic system. Decreases in these neurotransmitters may explain some of the nonmotor symptoms of PD.^{2,5,6} For example, loss of dopamine and norepinephrine neurons in the limbic system is associated with depression and anxiety.⁷ Loss of acetylcholine, dopamine, norepinephrine, and serotonin, in the substantia nigra, locus coeruleus,

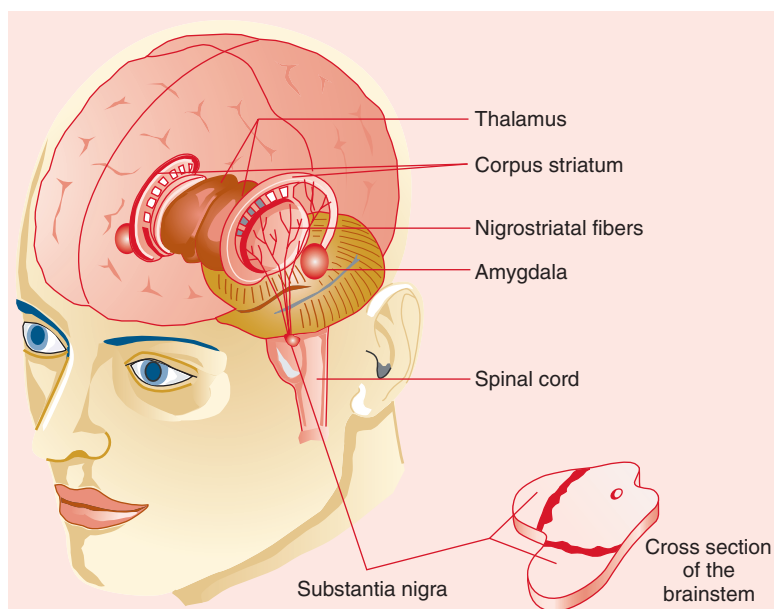

FIGURE 33-1. Anatomy of the extrapyramidal system. The extrapyramidal motor system controls muscle movement through a system of pathways and nerve tracts that connect the cerebral cortex, basal ganglia, thalamus, cerebellum, reticular formation, and spinal neurons. Patients with PD have a loss of dopamine neurons in the substantia nigra in the brainstem that leads to depletion of dopamine in the corpus striatum. The corpus striatum is made up of the caudate nucleus and the lentiform nuclei that are made up of the putamen and the globus pallidus.

Clinical Presentation of PD

Patients with PD display both motor and nonmotor symptoms. The nonmotor symptoms may precede the motor symptoms.

Motor Symptoms (mnemonic TRAP)

T = Tremor at rest (“pill rolling”)

R = Rigidity (stiffness and cogwheel rigidity)

A = Akinesia or bradykinesia

P = Postural instability and gait abnormalities

Nonmotor Symptoms (mnemonic SOAP)

S = Sleep disturbances (insomnia, rapid eye movement sleep behavioral disorder, restless legs syndrome [RLS])

O = Other miscellaneous symptoms (problems with nausea, fatigue, speech, pain, **dysesthesias**, vision, seborrhea)

A = Autonomic symptoms (drooling, constipation, sexual dysfunction, urinary problems, sweating, orthostatic hypotension, dysphagia)

P = Psychological symptoms (anxiety, psychosis, cognitive impairment, depression)

Response Fluctuations (mnemonic MAD)

M = Motor fluctuations (delayed peak, wearing off, random off, freezing)

A = Akathisia

D = Dyskinesias (e.g., chorea, dystonia, diphasic dyskinesia)

Patient Encounter, Part 1: Initial Visit—Medical History

GR, a 60-year-old woman with a 5-year history of PD, comes in for an initial visit at the movement disorder clinic to assess worsening symptoms. She was last seen 6 months ago by her family doctor where her UPDRS score was 35 (while on), and no changes were needed in her medications other than adding a stool softener and fiber laxative for constipation. Since her last visit, she has noticed increased stiffness, slowness, and progression of tremor in both hands instead of one. She tends to have off periods that make it difficult for her to make dinner. She denies any postural problems or falls. She reports some improvement in bowel movements.

Identify this patient's motor and nonmotor symptoms of PD.

What additional information would you collect before creating this patient's treatment plan?

nucleus raphe, and limbic system is associated with cognitive impairment.⁷

Based on patient symptoms, the disease may begin in the autonomic system, olfactory system, or vagus nerve in the lower brainstem and then spread to the upper brainstem and cerebral hemisphere affecting dopamine pathways later in the course of disease progression.² It is essential to rule out drug-induced PD before providing treatment because most cases are reversible. Offending agents include drugs that deplete dopamine such as antipsychotics, metoclopramide, and some antiemetics. Treatment includes removal of the offending agent.⁸

CLINICAL PRESENTATION AND DIAGNOSIS

Motor Symptoms

1 *Parkinson's disease (PD) is a slow, progressive neurodegenerative disease of the extrapyramidal motor system that features classic motor symptoms of tremor, rigidity, **akinesia/bradykinesia**, and postural/gait instability (TRAP).*

A thorough patient history and detailed description of symptom onset is essential in making an accurate diagnosis of PD. The onset is gradual and presents with impairment of movement that may go unnoticed. The tremor of PD occurs during rest and disappears with purposeful movement. The hand tremor can appear as if the patient is rolling a pill between their fingers. Patients usually describe rigidity as stiffness. Muscles display uniform resistance on examination and seem to be in a constant state of increased tone. Cogwheel rigidity is found when the examiner extends or flexes the patient's extremities and feels as if they are rhythmically hitting a series of teeth on the rim of a wheel. Bradykinesia is noted when there is hesitancy in movement initiation, slowness in movement performance, or rapid fatiguing during movement. Patients may have a decrease in automatic movements, such as eye blinking, **hypomimia**, or a decrease in arm swing while walking. Postural instability is a result of the loss of reflexes necessary to maintain balance when ambulating and stooped posture. Patients may report feeling unsteady. Gait abnormalities may be evidenced by slow shuffling, leg dragging, **festination**, propulsion, retropulsion, or freezing. Rigidity and bradykinesia may make handwriting difficult as evidenced by **micrographia**.^{2,9-13}

Nonmotor Symptoms

Nonmotor symptoms associated with PD commonly include sleep disturbances, autonomic impairment in the form of sexual dysfunction or constipation, psychological disturbances such as anxiety or depression, and many miscellaneous symptoms such as **anosmia** or sensory disturbances. Nonmotor symptoms may be a result of PD itself or medications. Nonmotor symptoms may precede the onset of motor symptoms by many years.^{2,6,9,14-20}

Speech problems may manifest as **hypophonia**, slurring, monotone speech, rapid speech, or stammering. Visual problems

such as difficulty reading, double vision, perceptual changes, decreased blink, burning eyes, or itchy eyes are the result of impaired function of the muscles that move the eyeball and decreased retinal dopamine.^{2,6,9,10,14}

Because the autonomic system is disturbed in patients with PD, orthostatic hypotension, GI, urinary, sexual, and dermatologic symptoms are common. Patients with orthostatic hypotension may experience dizziness, lightheadedness, fainting upon standing, or fall-related injuries. GI symptoms include constipation and **dysphagia** due to a slowing of the automatic pattern of contraction and relaxation of the throat muscles. Swallowing difficulties may lead to weight loss, **sialorrhea**, and aspiration.^{14,16} Genitourinary symptoms include incontinence, urgency, and frequency. Symptoms may worsen at night, causing nocturia. Sexual dysfunction includes decreased libido or inability to achieve orgasm in both sexes and erectile or ejaculatory dysfunction in men. Skin symptoms include sweating and intolerance to temperature changes.^{2,6,9,14,16}

Psychological symptoms may occur during the natural course of PD, during symptom exacerbation, or as adverse effects from medications. These symptoms may include psychosis, dementia, impaired **cognitive function**, depression, and anxiety. Psychosis occurs in nearly 30% of PD patients and is exhibited as vivid dreams, hallucinations (usually visual), paranoia, and delusions. Hallucinations may be more common when the patient is in dim light, falling asleep, or upon awakening. Dementia occurs in 20% to 44% of patients. Major depressive disorder occurs in 40% to 50% of PD patients and is likely due to abnormalities in the pathways of the neurotransmitters dopamine and serotonin. Some features of PD, such as the decreased facial expression and bradykinesia, may make the diagnosis of depression more difficult. Anxiety may present as panic attacks, phobia, or generalized anxiety. Anxiety was noted in 66% of patients with motor fluctuations and is often comorbid with depression.^{2,7,14,17–19} Psychosis is rarely found in untreated patients with PD and can subsequently present a difficult clinical situation when treated patients experience symptoms such as psychosis. It is likely that this phenomena results from a complex interaction of neurotransmitters, pathology, hypersensitivity to dopamine receptors, as well as changes in other neurotransmitters and brain pathways.^{14,17}

Sleep disorders may occur commonly. Patients have abnormal polysomnogram findings ranging from decreases in slow-wave sleep, total sleep time, and sleep efficiency. Disturbances may include excessive daytime sleepiness, insomnia, and abnormal sleep events, such as REM behavior disorder (RBD). Possible etiologies include disease progression, sleep-related motor symptoms, depression, and poor sleep hygiene. Medications such as amantadine and selegiline may worsen insomnia, and dopamine agonists may contribute to somnolence. The loss of neuronal functioning in various pathways related to sleep may contribute to sleep problems in PD patients.^{9,14,15}

Motor Complications

Motor complications occur with disease progression, as the patient's dopamine reserves are depleted, and as a complication

of treatment, mainly with levodopa. Motor complications include delayed peak response, early and unpredictable “wearing off,” freezing, and **dyskinesias**. Dyskinesias include **chorea** and **dystonia**. Risk factors for developing motor complications include younger age at diagnosis, high dosage of levodopa, and longer duration and severity of disease. Wearing off can be visualized by imagining the therapeutic window of levodopa narrowing over time. The therapeutic window is defined as the minimum effective concentration of levodopa required to control PD symptoms (“on” without dyskinesia) and the maximum concentration before experiencing side effects from too much levodopa (“on” with dyskinesia). Early in the disease, plasma concentrations following doses of levodopa are supplemented by the brain's supply of dopamine. Thus, although the plasma half-life of levodopa is 1.5 to 2 hours, the therapeutic effect lasts about 5 hours, and the patient experiences no dyskinesias. As the disease progresses, the therapeutic window narrows, and each dose of levodopa acts unpredictably, with the therapeutic effect lasting only 2 to 3 hours and dyskinesias occurring during the on state.^{5,20,21}

② *The most useful diagnostic tool is the clinical history, including both presenting symptoms and associated risk factors. The Unified Parkinson's Disease Rating Scale (UPDRS) is used to define the degree of disability.*

The patient's degree of disability should be evaluated by using the UPDRS, which has six parts. This clinician-rated scale combines patient history and a physical examination that is performed bilaterally because symptoms may initially appear asymmetric. It evaluates mentation, behavior, mood, ADLs, motor symptoms, and complications of therapy. It also includes the modified Hoehn and Yahr stage of disease and Schwab and England ADL.²² The modified Hoehn and Yahr staging scale defines eight stages of PD ranging from asymptomatic to wheelchair or bedbound. A copy of the examination can be obtained at <http://www.mdvu.org/library/ratingscales/pd/updrs.pdf>.

TREATMENT

Desired Outcomes

③ *The goals of treatment are to maintain patient independence, activities of daily living (ADLs), and quality of life (QOL) by alleviating the patient's symptoms, minimizing the development of response fluctuations, and limiting medication-related adverse effects.*

General Approach to Treatment

④ *The treatment of PD is categorized into three types: (1) lifestyle changes, nutrition, and exercise; (2) pharmacologic intervention, primarily with drugs that enhance dopamine concentrations; and (3) surgical treatments for those who fail pharmacologic interventions.*

Initial treatment depends largely on the patient's age, risk of adverse effects, degree of physical impairment, and readiness to initiate therapy. The 2002 American Academy of Neurology guidelines²³ and 2006 European National Institute for Health and Clinical Excellence guidelines suggest that symptomatic

Patient Encounter, Part 2: Initial Visit—Physical Examination and Diagnostic Tests

Chief complaint: Increased tremor, stiffness, and slowness

PMH: Constipation >10 years

SH: Retired. Lives with husband and has no children. Drinks a glass of wine a few times per month. Denies smoking.

Meds:

Carbidopa/levodopa 25 mg/100 mg orally at 7 AM, noon, and 7 PM

Docusate sodium 100 mg 2 caps at bedtime

Psyllium unflavored (Metamucil) 1 rounded teaspoon in 8 oz (~240 mL) of juice three times daily

ROS: (–) agitation, depression, or psychosis; (–) N/V/D, HA, dizziness, or pain

PE:

Gen: Flat affect, looks older than stated age, slow, shuffling gait

VS: BP: sitting 125/80 mm Hg, standing 110/80 mm Hg (with no orthostatic symptoms); P 65 bpm, RR 18/min, weight 59 kg (130 lb), height 165 cm (65 inches)

HEENT: Decreased eye blinking and facial expression, CN II–XII intact, PERLLA, TMs intact

CV: RRR, normal S₁, S₂; no murmurs, rubs, gallop

Abd: Soft, nontender, nondistended; (+) bowel sounds, no hepatosplenomegaly

Skin: Normal

Exts: Mild tremor in both hands and feet. Cogwheel rigidity bilateral elbows, no edema

Neuro: Slow, shuffling gait, sensory function intact, normal muscle strength, normal reflexes, alert, mental status exam normal

Rating Scales:

Mini Mental Status Exam (MMSE) = Normal 30/30

Handwriting sample micrographia

UPDRS = 45 while “on”

Labs: Normal metabolic profile and CBC

Given this additional information, what is your assessment of the patient's condition?

Identify treatment goals for the patient.

Describe nonpharmacologic and pharmacologic treatments that are available for the patient.

treatment should be delayed until the patient experiences functional disability.²⁴ Some data, however, suggest that earlier treatment may delay the progression of disease, possibly by normalizing basal ganglia physiology that supports compensatory mechanisms, limiting the neurotoxic changes that occur as dopamine neurons diminish. In support of this, some note that progression of symptoms occurs most rapidly around the time of diagnosis and in early PD, whereas progression of symptoms slows later in the disease.^{25,26} Although patients receiving rasagiline early in treatment, or potentially other dopamine medications with longer half-lives, may have better outcomes, the studies have design flaws and inconsistent results.^{11,13} Until current clinical practice guidelines are revised, one must consider the pros and cons of delaying pharmacotherapy or starting medications early.²³

Nonpharmacologic Therapy

► Lifestyle Modifications

Nonpharmacologic therapy including education, support, and lifestyle modifications such as exercise should be started early and continued throughout treatment for PD. These treatments may improve ADLs, gait, balance, and mental health. The most common interventions include maintaining good nutrition, physical condition, and social interactions.^{1,27} The multidisciplinary care approach is ideal. Patients should maintain regular visits with their optometrist/ophthalmologist and dentist. PD medications decrease saliva flow, increasing the risk of dental caries.

Dietary modifications improve constipation, nausea, erratic drug absorption, and minimize the risk of aspiration and weight loss. Dietitians help with meal selection, increasing calories, and suggestions for protein intake to maximize medication absorption. Speech therapy may improve swallowing, articulation, and the force of speech.

Physical therapy may improve a patient's strength, activity, and reduce fall risk. An exercise program and activity during the day should minimize daytime sleepiness, possibly improving sleep at night, and may be neuroprotective.^{1,28} Occupational therapists provide information about adaptive equipment for the home, specialized clothing, and personal training that can maximize independence, safety, and ADLs. They can help evaluate driving ability, improve handwriting, and train patients to use communication software.

Social workers help patients and families handle disease progression and arrange for special community assistance programs. Family counseling may help patients engage in family activities and minimize family conflicts.

Surgery

Surgical treatment, for patients with inadequate control of motor symptoms despite medical treatment, may decrease symptoms by 40% to 75%. Symptoms of imbalance, akinesia, speech impairment, and freezing do not improve with surgery. Deep-brain stimulation, the surgery of choice, involves electrical stimulation of the globus pallidus and subthalamic nucleus.^{2,29,30}

Pharmacologic Therapy

- 5 Drug therapy is aimed at enhancing dopaminergic activity in the substantia nigra. The best time to initiate dopaminergic therapy is controversial and patient specific. Medications help minimize motor symptoms, improve QOL and ADLs, but they are not curative (Table 33-1).^{1,2,31-33} PD patients with optimal treatment still have greater mortality and morbidity than the general population.¹
- 6 Choice of pharmacologic agent should be individualized based on patient-specific parameters, and dose frequency should be scheduled based on individual response to maximize “on” and minimize “off” time.

- Pharmacologic options for PD include anticholinergics, amantadine, monoamine oxidase type B inhibitors (MAO-B), dopamine agonists, levodopa/carbidopa, and catechol-O-methyltransferase (COMT) inhibitors. Because most pharmacologic treatments in PD aim to avoid degeneration of the dopaminergic nigrostriatal pathway, it is essential to understand how all drugs may affect dopamine concentrations (Fig. 33-1). The American Academy of Neurology and the Movement Disorder Society determined that it is reasonable to start treatment with either levodopa, a dopamine precursor, or a dopamine agonist.¹⁰⁻¹⁴

Choice of agent varies based on clinical experience and patient preference. Starting with a dopamine agonist rather

Table 33-1

Dosing of Medications to Treat PD

Generic Name (Trade Name)	Dosing
Levodopa with carbidopa (Sinemet)	Start with (Sinemet) ½ tab (100 mg LD, 25 mg CD) twice daily for 1 week, then ½ tab three times daily; then increase by ½ tab daily every week; usual MD is 300–2,000 mg daily; because the duration of LD is 2–3 hours, patients may require doses q 2 h
(Parcopa with phenylalanine) (Sinemet CR)	Rapid-dissolving LD dosed as with Sinemet Start with 1 tab (100 mg LD, 25 mg CD) 2–3 times daily; as symptoms increase, use 200 mg LD tab 2–4 times daily; usual MD is 200–2,200 mg daily
(Duodopa orphan drug on fast track for approval) Apomorphine (Apokyn)	Portable pump that continuously delivers LD 20 mg/mL and carbidopa 5 mg/mL via a duodenal tube Start an antiemetic for 3 days; then give apomorphine 2 mg SC injection (1 mg if outpatient) while monitoring blood pressure; then increase by 1–2 mg every ≥2 hours; usual MD is 2–6 mg 3–5 times daily for off periods. Reduce initial dose to 1 mg SC in mild to moderate renal failure.
Bromocriptine (Parlodel)	Start with 1.25 mg daily at bedtime, then 1.25 mg twice daily; on week 2, increase to 2.5 mg twice daily, then increase by 2.5 mg daily every 2–4 weeks up to 15–45 mg daily divided 2–3 times daily. Dosing adjustments may be necessary with hepatic impairment.
Pramipexole (Mirapex)	Start with 0.125 mg three times daily; increase about weekly by 0.375–0.75 mg/day to an MD of 0.5–1.5 mg three times daily; dosage reduction needed in patients with creatinine clearance less than 60 mL/min (1 mL/s).
(Mirapex ER)	Start with 0.375 mg once daily; may increase up to 0.75 mg/day after a minimum of 5 days. Dose may then be increased in increments of 0.75 mg/day no more frequently than every 5–7 days. Maximum recommended dose is 4.5 mg/day.
Ropinirole (Requip)	Start with 0.25 mg three times daily; increase about weekly by 0.75–1.5 mg daily to a MD dose of 3–8 mg three times daily.
(Requip XL)	Start with 2 mg once daily for 1–2 weeks, increase by 2 mg/day in 1-week intervals; maximum dose is 24 mg/day. When switching from immediate-release form, use dose closest to the total daily dose.
Selegiline (Eldepryl)	Start with 5 mg in the morning; if symptoms continue, add 5 mg at noon; 5 mg daily may be as clinically effective as 10 mg daily with fewer side effects.
(Zelapar with phenylalanine)	Start with 1.25 mg every morning before breakfast; if symptoms continue after 6 weeks, increase dose to 2.5 mg every morning. Avoid food or liquid for 5 minutes before or after the dose.
Rasagiline (Azilect)	Start with 0.5 mg daily. If symptoms continue, increase to 1 mg daily. Patients with mild hepatic impairment (Child-Pugh score 5–6) should be given the dose of 0.5 mg/day as plasma concentration may increase up to twofold. Do not use in moderate to severe liver disease (Child-Pugh score greater than 7) because plasma concentration may exceed sevenfold.
Tolcapone (Tasmar)	Start with 100 mg with first Sinemet dose once daily; if symptoms continue, increase to 2 and then 3 times daily, then to 200 mg each dose; usual MD is 100–200 mg 3 times daily. Do not use in patients with active liver disease or SGPT/ALT or SGOT/AST greater than the upper limit of normal.
Entacapone (Comtan)	200-mg tab with each Sinemet dose up to 8 tabs daily; usual MD is 200 mg 3–4 times daily. Decrease dose by 50% with hepatic impairment because C_{max} may double.
CD/LD/Entacapone (Stalevo)	Usual MD is 300–1,600 mg LD daily; the largest strength tab contains 150 mg LD and 200-mg entacapone; patients requiring larger LD doses will need additional LD medication; titrate as with LD
Amantadine (Symmetrel)	Start with 100 mg daily at breakfast; after 1 week, add 100 mg daily, decrease dose as creatinine clearance decreases less than 80 mL/min (1.3 mL/s); usual MD is 200–300 mg daily with last dose in afternoons.

Ach, acetylcholine; CD, carbidopa; COMT, catechol-O-methyltransferase; D1, a class of dopamine receptors that includes D₁, and D₅ subtypes; D2, a class of dopamine receptors that includes D₂, D₃, and D₄ subtypes; DA, dopamine; LD, levodopa; MAO, monoamine oxidase; MD, maintenance dose; NMDA, N-methyl-D-aspartate.

From Refs. 1, 2, 31–33.

than levodopa may help to delay the onset of dyskinesias and the on and off fluctuations seen with long-term levodopa use. However, initiating therapy with a dopamine agonist instead of levodopa/carbidopa may result in less motor benefit and greater risk of hallucinations or somnolence. Levodopa results in greater motor improvement and should be used as initial therapy in the elderly (older than 75 years) and in those with cognitive impairment.²⁶ There is no preference for using controlled-release over immediate-release levodopa as initial therapy. There are insufficient data to recommend initiating treatment with both levodopa and a dopamine agonist. Initiating treatment with anticholinergic medications, amantadine, or MAO-B inhibitors is only for patients who have mild symptoms because they are not as effective as dopamine agonists.^{1,2,10-14,31-33}

Medications should be started at the lowest dose and increased gradually based on symptoms (Table 33-1). Adjust dose timing, frequency, or both based on the patient's report of "on" time duration and wearing off symptoms. Consider more frequent dosing or long-acting formulations when available. Dyskinesias related to dopamine concentrations can be managed by decreasing the dose, frequency, or use of medications that may enhance dopamine concentrations.

► Anticholinergics

Anticholinergics (ACh) block acetylcholine, decreasing the acetylcholine to dopamine concentration ratio. They minimize resting tremor and drooling, but they are not as effective as other agents in controlling rigidity, bradykinesia, and gait problems. Anticholinergics should be discontinued gradually to avoid withdrawal effects or worsening of symptoms. Side effects of anticholinergics include dry mouth, blurred vision, constipation, cognitive impairment, hallucinations, urinary retention, orthostatic hypotension, temperature sensitivity, and sedation.

They are usually avoided or used with caution in patients older than 70 years because of an increased risk of cognitive impairment.^{1,2,9,31,32} Use of anticholinergics is associated with an increased incidence of amyloid plaques and neurofibrillary tangles in patients with PD that may translate to an increased risk of Alzheimer's disease.³⁴ Anticholinergics decrease gastric motility, which may decrease levodopa drug absorption.²⁷

► Amantadine

Amantadine is a *N*-methyl-D-aspartate (NMDA)-receptor antagonist that blocks glutamate transmission, promotes dopamine release, and blocks acetylcholine. It improves PD symptoms in mildly affected patients and has reduced dyskinesias.²¹ Amantadine may minimize or delay the development of motor complications because levodopa's pulsatile stimulation of dopamine receptors is associated with NMDA receptor changes and resultant motor complications. Patients who develop tolerance to amantadine's effects may benefit from a drug holiday. When stopping amantadine, it should be gradually discontinued to minimize potential withdrawal effects. Side effects include nausea, dizziness, livedo reticularis (purple mottling of the skin), peripheral edema, orthostatic hypotension, hallucinations, restlessness, and anticholinergic

effects. Its stimulant action may worsen insomnia, so amantadine should not be dosed in the evening. It should be avoided in the elderly who cannot tolerate its anticholinergic effects.^{31,32,35} It should be used cautiously with memantine because there may be an increased risk of psychosis and prolonged QT interval.^{27,36}

► MAO-B Inhibitors

Selegiline and rasagiline selectively and irreversibly block MAO-B metabolism of dopamine in the brain. They may provide a mild symptomatic benefit for patients who choose to delay dopaminergic medications, and they reduce off time when added to therapy.^{10-13,37} Combining selegiline or rasagiline with levodopa in early treatment may delay motor complications.^{21,25,37}

Both rasagiline and selegiline are thought to be neuroprotective; however, there is no evidence to fully validate neuroprotection by any agent in PD patients to date. In two large blinded, randomized, controlled trials evaluating rasagiline 1 mg and 2 mg in early PD, significant UPDRS change was inconsistent between studies and cannot be used to support the neuroprotection theories.³⁸

Selegiline is available in a patch formulation that is used in patients with depression but not PD. The orally disintegrating tablet formulation avoids first-pass metabolism that improves bioavailability and decreases serum concentrations of its amphetamine metabolite. Side effects of selegiline are minimal but include nausea, confusion, hallucinations, headache, jitteriness, and orthostatic hypotension. The amphetamine-like metabolite may improve fatigue but cause insomnia. Thus selegiline should not be dosed in the late afternoon or evening. Doses are limited to 10 mg daily in divided doses because MAO-B selectivity may be lost at higher doses increasing the risk of adverse effects and drug interactions. Selegiline may interact with serotonergic agents, increasing the risk of serotonin syndrome.^{1,25-27}

Rasagiline is less likely to cause insomnia because it is not metabolized to amphetamines. Side effects are primarily GI with no increased risk of vasoreactive or psychiatric effects. The approved labeling of rasagiline states that restriction of tyramine-containing foods is not ordinarily required at recommended dosages, but eating certain foods with extremely high levels of tyramine and exceeding recommend dosing of rasagiline may increase the risk of hypertensive crisis. The manufacturer of rasagiline also recommends that serotonergic agents be avoided, and extra monitoring is required if they are prescribed together.³⁷

Dyskinesias can be minimized by decreasing the levodopa dose when adding either of these agents. Patients should avoid or use these medications cautiously with narcotic analgesics, antidepressants, or sympathomimetic amines (cold and weight loss products). Rasagiline is metabolized by the CYP1A2 pathway; thus drugs that inhibit CYP1A2 (e.g., ciprofloxacin or cimetidine) increase rasagiline concentrations, and inducers (e.g., omeprazole) may reduce rasagiline concentrations. Rasagiline does not induce or inhibit enzymes in the P450 system. Selegiline is metabolized by

CYP2B6 and CYP3A4. It does not inhibit P450 enzymes, but CYP3A4 inducers (e.g., phenytoin and carbamazepine) could reduce selegiline concentrations.^{1,27,31–33}

Safinamide is an investigational MAO-B inhibitor and a dopamine reuptake inhibitor.³⁹

► Dopamine Agonists

Dopamine agonists bind to postsynaptic dopamine receptors. They are useful as initial therapy because they can delay starting levodopa and can decrease the risk of developing motor fluctuations by two- to threefold during the first 4 to 5 years of treatment. Eventually, they inadequately control the patient's symptoms, and levodopa needs to be started. In advanced disease, they can be added to levodopa because their longer duration of action can minimize fluctuations in dopamine blood concentrations, decrease off time, improve wearing-off symptoms, allow a reduction in levodopa dose, and improve ADLs.^{1,2,10,12,40} The 2010 Scottish Intercollegiate Guidelines Network suggests using dopamine agonists in early PD.³³

Dopamine agonists include the ergot derivatives (bromocriptine) and the nonergot derivatives (rotigotine, pramipexole, ropinirole, and apomorphine). Generally, all are equally effective. There are five subtypes of dopamine receptors that are divided into two classes called D1 (D₁ and D₅ subtypes) and D2 (D₂, D₃, and D₄ subtypes). Receptor selectivity may result in subtle differences between the products. Rotigotine, a once-daily skin patch, minimizes pulsatile dopaminergic stimulation; however, it contains sodium metabisulfite, that may cause allergic-type reactions in people allergic to sulfites. Rotigotine was withdrawn in the United States due to stability problems in 2008, but it was reformulated to prevent crystallization and remarketed in 2012. If patients fail one dopamine agonist, another can be tried. Although not well established, it appears that bromocriptine 30 mg, ropinirole 15 mg, and pramipexole 4.5 mg are equivalent, and this relationship can be a guide when switching agents.^{1,26,31,32,35}

Common side effects include nausea, vomiting, sedation (highest with apomorphine), pedal edema, orthostatic hypotension (highest with pramipexole and cabergoline), and psychiatric effects that are greater than with levodopa (nightmares, confusion, and hallucinations). Ergot side effects are uncommon but include painful reddish discoloration of the skin over the shins and pleuropulmonary, retroperitoneal, and cardiac fibrosis.^{1,31,32,35} Patients with PD are commonly affected with impulse control disorders (ICDs). Dopamine agonists may cause changes in the striatum, possibly enhancing sensitivity to risky behavior such as gambling or compulsive shopping. Reducing or eliminating the agonist usually resolves these problems.⁴¹

Excessive daytime sleepiness can be caused by dopamine agonists and may occur in 50% of patients with PD. Dopamine agonist-induced sleep attacks can be very dangerous if the patient is performing an activity that requires mental alertness such as driving. However, using agents such as modafinil to promote wakefulness remains controversial.⁴²

All dopamine agonists are metabolized by the liver except pramipexole, which is eliminated unchanged in the urine by

active tubular secretion, and it requires dose reduction when creatinine clearance is less than 60 mL/min (1 mL/s). Drug interactions may occur if it is given concurrently with other agents that are eliminated by active tubular secretion, such as verapamil and cimetidine. Ropinirole is metabolized by cytochrome P450 oxidation in the liver and subject to drug–drug interactions with drugs that induce (i.e., smoking) or inhibit (i.e., ciprofloxacin, fluvoxamine, and mexiletine) CYP1A2.^{31,32,35}

Apomorphine is approved for acute off episodes in patients with advanced stages of PD when rapid rescue therapy is needed. It requires premedication with an antiemetic because it causes nausea and vomiting.^{31,32,35}

Phase III studies are currently underway for partial dopamine agonist pramipexole (SLV308) in the treatment of patients with early PD.⁴³

► Levodopa/Carbidopa

Although levodopa, a dopamine precursor, is the most effective agent for PD, when to initiate therapy remains controversial. Patients experience a 40% to 50% improvement in motor function with levodopa versus 30% with dopamine agonists.^{1,2,26} However, some feel it best to delay starting treatment with levodopa because approximately 70% of patients experience motor complications within 6 years. Others start sooner because it may normalize basal ganglia dysfunction. In support of this idea, patients from the pre-levodopa era who delayed starting levodopa until it became available developed dyskinesias sooner than modern era patients.^{1,20,26,31,32}

Levodopa is absorbed in the small intestine and peaks in the plasma in 30 to 120 minutes. Excess stomach acid, food, or anticholinergic medications delay gastric emptying time and decrease the amount of levodopa absorbed. Antacids decrease stomach acidity and improve levodopa absorption. Levodopa absorption requires active transport by a large neutral amino acid transporter protein (Fig. 33–2). Levodopa competes with other amino acids, such as those contained in food, for this transport mechanism. Thus, in advanced disease, avoidance of protein-rich meals in relationship to levodopa doses may be helpful. Levodopa also binds to iron supplements, and administration of iron products should be spaced by at least 2 hours from the levodopa dose.^{1,26,31,32}

The controlled-release (CR) formulation (labeled as sustained release or extended release depending on brand) is more slowly absorbed and longer acting than immediate-release tablets. With these dosage forms the total daily dose should be increased by 30% because it is not as bioavailable as the immediate-release levodopa/carbidopa. The CR formulation has a delayed onset (45 to 60 minutes) compared with the standard formulation (15 to 30 minutes). Thus patients may also need to take immediate-release tablets or even a liquid formulation when they want a quicker onset of effect, such as with the first morning dose.^{1,26,31,32}

Converting patients from oral formulations to enteral or duodenal levodopa administration reduces motor fluctuations and improves UPDRS scores over oral formulations. The levodopa/carbidopa combination can be administered directly to the duodenum via small tube and is marketed

FIGURE 33-2. Levodopa absorption and metabolism. Levodopa is absorbed in the small intestine and distributed into the plasma and brain compartments by an active transport mechanism. Levodopa is metabolized by dopa decarboxylase, monoamine oxidase, and catechol-*O*-methyltransferase. Carbidopa does not cross the blood–brain barrier. Large neutral amino acids in food compete with levodopa for intestinal absorption (transport across gut endothelium to plasma). They also compete for transport into the brain (plasma compartment to brain compartment). Food and anticholinergics delay gastric emptying resulting in levodopa degradation in the stomach and a decreased amount of levodopa absorbed. If the interaction becomes a problem, administer levodopa 30 minutes before or 60 minutes after meals.

under the trade name Duodopa in the European Union, Norway, Switzerland, and Canada. It is indicated for patients with advanced levodopa-responsive PD with severe motor fluctuations and hyper/dyskinesia when available combinations of PD medications are unsatisfactory. A positive clinical response to Duodopa administered via a temporary nasoduodenal tube is required before a permanent tube is inserted. This delivery system allows direct absorption of the medication through the GI tract, and the dose and frequency of administration is determined by a programmable pump. The patient wears a small cassette outside of the body.³⁹ This system is currently undergoing phase III trials in the United States.

Additional formulations of levodopa in development include a long-acting formulation, IPX066, a levodopa prodrug, XP21279, and an effervescent levodopa prodrug formulation, melevodopa.³⁹

Levodopa is usually administered as a combination product with carbidopa, a dopa-decarboxylase inhibitor, which decreases the peripheral conversion of levodopa to dopamine. Carbidopa does not cross the blood–brain barrier and does not interfere with levodopa conversion in the brain. Concomitant administration of carbidopa and levodopa allows for lower

levodopa doses and minimizes levodopa peripheral side effects such as nausea, vomiting, anorexia, and hypotension. Generally 75 to 100 mg daily of carbidopa is required to adequately block peripheral dopa-decarboxylase. Higher doses of carbidopa may reduce nausea related to initiating levodopa.^{1,26,31,32}

Initial levodopa side effects include orthostatic hypotension, dizziness, anorexia, nausea, vomiting, and discoloration of urine/sweat. Most of these effects can be minimized by taking levodopa with food and using a slow dose titration. Side effects that develop later in therapy include dyskinesias, sleep attacks, impulse control disorders, and psychiatric effects (confusion, hallucinations, nightmares, and altered behavior). Dyskinesias caused by adding other PD drugs to levodopa may be improved by decreasing the levodopa dose.^{1,26,31,32}

Levodopa commonly causes end of dose wearing off periods, and medication adjustments may ameliorate this phenomenon. Patients with severe dyskinesias and off periods may achieve more constant blood concentrations (lower peak and higher trough concentrations) by taking a liquid formulation of levodopa with carbidopa. Levodopa solution is available in a 1 mg/mL concentration, which allows patients to take a precisely adjusted dose more frequently when needed.^{26,31,32,44}

► COMT Inhibitors

- COMT inhibitors are used in conjunction with levodopa/carbidopa. COMT, or catechol-*O*-methyltransferase, is the enzyme responsible for catalyzing levodopa. Inhibitors of COMT, such as entacapone or tolcapone, allow levodopa concentrations to be maximized, extending its half-life and area under the curve. This increase in levodopa concentration may allow for a decrease in daily levodopa doses while increasing on time by 1 to 2 hours and decreasing wearing off time. Some clinicians believe that a COMT inhibitor should be added when levodopa is first introduced in an effort to promote more continuous dopamine stimulation, potentially minimizing long-term complications associated with the more pulsatile effect of intermittent levodopa administration. However, starting multiple drugs at the same time increases the risk of side effects. Side effects include diarrhea (worse with tolcapone), nausea, vomiting, anorexia, dyskinesias, urine discoloration, daytime sleepiness, sleep attacks, orthostatic hypotension, and hallucinations. Dyskinesias should improve with a decrease in the levodopa dose.^{26,31,32}

An analysis of four studies demonstrated that tolcapone was efficacious in reducing off time for about 41 minutes per day when compared with placebo. Tolcapone, however, is reserved for late-stage PD due to its safety profile.^{11,13}

- Tolcapone should be used only in patients who cannot take or do not respond to entacapone due to its hepatic safety profile. Serum liver function tests should be monitored at baseline, then every 2 to 4 weeks for 6 months, and then periodically for the remainder of therapy. Patients who fail to show symptomatic benefit after 3 weeks should discontinue tolcapone.^{26,31-33}

► Adenosine-2 Antagonists

The adenosine-2 antagonist receptors are currently being explored as a nondopaminergic therapy for the treatment of PD. They are proposed to facilitate intrastriatal GABA release, reducing striatopallidal neuronal over activity and restoring balance within the basal ganglia. Currently, several compounds are in development, and the drug preladenant has reached phase II trials.³⁹

► Herbs and Supplements

There is very little support for using creatine, ginkgo, ginseng, green tea, ginger, yohimbine, or St. John's wort in patients with PD. Melatonin and valerian may improve insomnia, but there are insufficient data in PD patients.

Patients should eat a balanced diet and take a multi-vitamin with minerals, but there is generally no need to supplement with specific vitamins. Metabolism of levodopa may elevate homocysteine concentrations. Administering levodopa with a COMT inhibitor may minimize the increase in homocysteine, and patients may have a greater requirement for B vitamins than patients not receiving levodopa. Excess pyridoxine (vitamin B₆) may decrease the effect of levodopa, so limit doses to less than 50 mg per day.^{45,46}

TREATMENT OF NONMOTOR SYMPTOMS

- 7 *The treatment of nonmotor symptoms should be based on whether they are worse during an off state or might be related to other neurotransmitter dysfunction.*

The treatment of nonmotor symptoms, such as psychological conditions, sleep disorders, and autonomic dysfunction, should include both pharmacologic and nonpharmacologic approaches. Patients should be given suggestions for maintaining ADLs, a positive self-image, family communication, and a safe environment.

Psychological Symptoms

Psychological symptoms and psychosis are potential problems in PD patients. When psychological changes are suspected, causes of mental status changes that need to be ruled out include infections, metabolic changes, electrolyte disturbances, or toxic exposures. Confusion may be alleviated by the presence of a night light or correction of vision and hearing deficits. Because off periods can precipitate anxiety, therapy should be adjusted to maximize on periods.

► Depression

Depression is extremely common in patients with PD, with some estimating that ≥40% of patients may have coexisting depression. Experts believe that depression often precedes PD. Brain catecholamine changes and serotonin dysregulation contribute to depression associated with PD. Although the body of evidence supports efficacy of tricyclic antidepressants in patients with both depression and PD, the adverse effect profile of these agents limits its use. Alternatively, selective serotonin reuptake inhibitors may be considered. Pramipexole may also improve depression.¹⁸ Although maximizing on time may help, drug therapy is usually required. Antidepressants may also be useful for the maintenance of anxiety disorders. Electroconvulsive therapy in depressed patients who fail medications should be considered.^{2,6,7,9,14,17}

► Dementia

Dementia occurs in approximately 80% of patients with PD 20 years after disease diagnosis, and it can significantly impair a patient's quality of life. A decrease in cholinergic neurotransmission is implicated in dementia associated with PD. Patients with dementia and PD have an increased risk for falls compared with patients without dementia. Patients must be assessed carefully for fall risk, and appropriate safety measures should be in place to ensure fall prevention. Atypical antipsychotics can be used, but they carry a Boxed Warning for increased risk of death in elderly patients with dementia, and they can worsen symptoms of PD.

- Cholinesterase inhibitor drugs may be effective. The efficacy of memantine in this patient population is unclear.^{2,14,17-19}

► Psychosis

- Low-efficacy PD medications should be gradually decreased and stopped in patients with psychosis. If reducing PD

medication compromises motor control or does not improve psychosis, low-dose quetiapine (12.5 to 200 mg) at bedtime may improve psychosis. However, it should be used with caution due to long-term metabolic side effects. Clozapine is also recommended but requires stringent monitoring.^{2,14,17-19}

Sleep Problems

- Sleep problems and fatigue are common in PD and may be due to medications, uncontrolled PD symptoms, or other causes such as nocturia, depression, RBD, or restless legs syndrome (RLS). Disorders of wakefulness such as sleep attacks may also affect adequate and restful sleep. Patients may benefit from instruction on good sleep hygiene, improvement in nighttime PD symptoms, or cognitive behavioral therapy.^{6,14,15}

Ongoing studies have indicated that the nonergot dopamine agonist rotigotine may improve early morning motor function and overall quality of sleep.⁴⁷

Amantadine and selegiline may worsen insomnia, selegiline and tricyclic antidepressants may worsen REM sleep, and some antidepressants and antipsychotics may worsen

- RLS. Ramelteon may improve circadian sleep disorders (study in progress). Melatonin may improve patient perception of sleep, but this has not been validated using objective measures of sleep. Levodopa/carbidopa reduces nighttime periodic leg movements, but data regarding nonergot dopamine agonists are lacking in patients with PD. When iron is used for RLS, it may decrease the absorption of levodopa and increase constipation. A nighttime dose of a COMT inhibitor may help RLS.^{2,6,15}

Autonomic and Other Problems

- Drooling may be accompanied by speech problems and dysphagia. Anticholinergics, botulinum toxin injections, and sublingual atropine can decrease drooling. Speech therapists can perform swallowing studies to assess the risk of aspiration, and nutritionists can optimize diet. Patients at high risk of aspiration or poor nutrition may require placement of a percutaneous endoscopic gastrostomy tube. Nausea improves if patients take their PD medications with meals, and pharmacologic therapy (e.g., domperidone [or trimethobenzamide]) can also help. Sexual dysfunction or urinary problems may require further evaluation. Adjustment of PD therapy to increase on time, removal of drugs that decrease sexual response, and pharmacologic therapy (e.g., sildenafil) may help treat sexual dysfunction. Studies of sexual dysfunction in women with PD are lacking. Patients with urinary frequency may find a bedside urinal and a decrease in evening fluid intake helpful. Improvement in PD symptom control can improve urinary frequency, but worsening symptoms may require catheterization or pharmacologic measures (e.g., oxybutynin, tolterodine, propantheline, imipramine, hyoscyamine, or nocturnal intranasal desmopressin). Anticholinergic drugs can cause urinary retention and constipation. Constipation can be improved by increased fluid intake, a fiber-rich diet, and physical activity.

Patients should generally avoid cathartic laxatives and use stool softeners, osmotic or bulk-forming laxatives, glycerin suppositories, or enemas. Dyskinesia-related sweating may respond to PD therapy adjustment or β -blockers. Orthostasis may respond to the removal of offending drugs (e.g., tricyclic antidepressants, PD medications, alcohol, and antihypertensives) increasing carbidopa doses, addition of salt or fluids to the diet, compression stockings, fludrocortisone, indomethacin, or midodrine. Seborrhea usually responds to over-the-counter dandruff shampoos or topical steroids.^{2,6,9,16}

Treatment of Response Fluctuations

- **8** *As the disease progresses, most patients develop response fluctuations. Treatment is based on optimizing the pharmacokinetic and pharmacodynamic properties of PD medications.*
- Treatment includes adjusting or adding medications to maximize the patient's on time, minimize the time on with dyskinesia, and minimize off time (**Table 33-2**). Use various dosage plans to minimize suboptimal or delayed peak levodopa concentrations by adding longer acting medications to minimize wearing-off periods, adding or adjusting medications to stop an unpredicted off period, and providing treatments that decrease freezing episodes. It also involves adjusting or adding medications to decrease chorea, dystonia, **diphasic dyskinesias**, or **akathisia**. Patients should schedule activities when they are on. Patients can also keep an extra dose of medication with them when they are away from home in case their medication wears off.^{2,6,11,13,21}

Patient Encounter, Part 3: First Follow-up Visit 3 Months Later

GR comes in for a follow-up visit with complaints of agitation and visual hallucinations. At her last visit 3 months ago, ropinirole was added. Since then, she reports improvement in her ability to get out of bed in the morning. She feels that she has less tremor and stiffness throughout the day. She has no off periods. However, her husband reports that GR has become increasingly frustrated and agitated, and sometimes she claims to see faces in the shadows at night. She also reports vivid dreams. She seems very suspicious of her husband at times and has had an increased interest in Internet shopping, which her husband says is a new behavior. She is more physically active with improved PD symptoms. She is taking polyethylene glycol one time per week with five to seven bowel movements per week.

UPDRS 35 (on)

Create a problem list and provide an assessment of each problem.

Considering the goals of therapy, treatment options, and your assessment of each of the problems, create a care plan for each problem.

Table 33-2

Management of Motor Complications in Advanced PD**I. Motor fluctuations**

- A. Suboptimal or delayed peak response
 1. Take Sinemet on an empty stomach
 2. Decrease dietary protein and fat around the dose that is delayed
 3. Use rapid-dissolving tablet (Parcopa), crush Sinemet, or make liquid Sinemet
 4. Substitute standard Sinemet for some of the Sinemet CR
 5. Minimize constipation
 6. Withdraw drugs with anticholinergic properties
 7. Add intermittent subcutaneous apomorphine
- B. Optimal peak but early wearing off
 1. Decrease dose and increase frequency of standard Sinemet
 2. Substitute Sinemet CR for some of the standard Sinemet
 3. Add other PD medications (dopamine agonist, MAO-B inhibitor, amantadine, or COMT inhibitor)
- C. Optimal peak but unpredictable offs
 1. Adjust time of medications with meals and avoid high-protein meals or redistribute the amount of protein in diet
 2. Substitute or add rapid-dissolving tablet form or liquid form of Sinemet
 3. Add COMT inhibitor
 4. Add or try a different dopamine agonist
 5. Consider continuous infusion of levodopa (Duodopa), apomorphine, or lisuride
 6. Deep-brain stimulation procedure
- D. Freezing
 1. Gait modifications (use visual cues such as walkover lines, tapping, rhythmic commands, rocking; use rolling walker)
 2. Difficult to treat, so adjust current medication up or down based on other PD symptoms
 - a. On freezing, reduce dopamine medications, inject botulinum toxin
 - b. Off freezing, increase Sinemet dose or add dopamine agonists
 3. Treat anxiety if present

II. Dyskinesias

- A. Chorea
 1. Evaluate the value of adjunctive PD medications
 2. Decrease risk by lowering Sinemet dose when adding other PD medications
 3. Adjust levodopa formulation, dose, or frequency
 4. Add amantadine
 5. Add propranolol, fluoxetine, buspirone, or clozapine
 6. Deep-brain stimulation
- B. Off period dystonia in the early morning (e.g., foot cramping)
 1. Add Sinemet CR or dopamine agonist at bedtime if having nighttime offs
 2. Morning Sinemet dose should be immediate-release with or without CR
 3. Selective denervation with botulinum toxin
 4. Add lithium or baclofen
- C. Diphasic dyskinesia
 1. Avoid controlled-release preparations; consider liquid Sinemet
 2. Add dopamine agonist, amantadine, or COMT inhibitor
 3. Increase Sinemet dose and frequency
 4. Deep-brain stimulation

III. Akathisia

1. Benzodiazepine
2. Propranolol
3. Dopamine agonists
4. Gabapentin

COMT, catechol-O-methyltransferase.

From Refs. 2, 11, 20, 21.

OUTCOME EVALUATION

- 9 Patient monitoring should involve a regular systematic evaluation of efficacy and adverse events, referral to appropriate specialists, and patient education.
- Evaluate the clinical outcomes of treatment over time by assessing the change in the UPDRS from baseline and over time. Patients should record daily the amount of on and off time in a diary to guide medication adjustment. A variety of scales can be used to assess QOL, depression, anxiety, and sleep disorders. PD cannot be cured, but treatment is aimed at decreasing symptoms and improving ADLs and QOL.

Patient Encounter, Part 4: Second Follow-up Visit 3 Months Later

GR, a 61-year-old woman with PD, comes in for a follow-up visit with no new complaints. At her last visit 3 months ago, ropinirole was removed, and her daily Sinemet dose was increased to cover the afternoon off period that had previously been treated with ropinirole. Since then, her symptoms have improved, and she is able to prepare dinner. She denies any auditory or visual hallucinations or vivid dreams. Her husband says that she is less agitated, suspicious, and has stopped Internet shopping. She has joined an exercise class at the senior center. She continues to have five to seven bowel movements per week.

UPDRS 35 (on)

Medications

Sinemet 25/100 7 AM, 11:30 AM, 4 PM, 9 PM

Docusate sodium 100 mg 2 caps at bedtime

Psyllium unflavored (Metamucil) 1 rounded teaspoon in 8 oz (~240 mL) of juice three times daily

Polyethylene glycol (MiraLAX) 17 g/scoop. 1 scoop in 4 to 8 oz (~120 to 240 mL) of liquid, 1 to 2 times per week as needed for constipation.

If GR's psychosis had continued and was determined to be a nonmotor symptom of PD rather than an adverse effect of her dopaminergic therapy, what options might you consider?

How would you counsel a patient who has been on PD medications and is initiating an atypical antipsychotic such as quetiapine?

Were therapeutic goals achieved in GR after discontinuation of her dopamine agonist and adjustment of her carbidopa/levodopa?

If a patient was unable to speak due to disease progression, what would be the advantages and disadvantages of having a significant other communicate for the patient?

Patient Care and Monitoring

1. Determine type of symptoms, frequency, and exacerbating factors. Assess for PD treatment-related complications. Assess the patient's symptoms to determine if therapy should be adjusted or maintained, or if referral for more extensive evaluation is needed.
2. Review any available diagnostic data to determine status, motor ability, dyskinesias, and nonmotor symptoms.
3. Obtain a thorough history of prescription, nonprescription, and complementary/alternative medication use. Determine what treatments have been helpful to the patient in the past. Is the patient taking any medications that may increase PD symptoms?
4. Educate the patient about lifestyle modifications that will improve symptoms and sustain independence.
5. Determine whether the patient is taking the appropriate dose of PD medication to maximize on time and minimize adverse effects. If not, why?
6. Determine if polytherapy treatment is necessary and/or adequate.
7. Assess improvement in QOL measures.
8. Evaluate the patient for the presence of drug adverse reactions, allergies, and interactions.
9. Recommend a therapeutic regimen that is easy for the patient to follow. Educate the patient on how to use medications, and allow the patient to adjust medications for fluctuations in response.
10. Educate patient regarding PD, including lifestyle modifications and drug therapy, including:
 - When and how to take medications
 - The potential adverse effects that may occur
 - Which drugs may interact with therapy (give patient a list)
 - Warning signs to report to the physician
 - Where the patient can obtain further information such as books and websites (e.g., <http://www.apdaparkinson.org>; <http://www.parkinson.org>.)
11. Refer patient to a local PD support group to obtain educational materials as well as empathy and social support from fellow PD patients. Support groups that include patients with advanced disease may upset patients with early disease; therefore, the advantages and disadvantages of attending should be explained to the patient.

Abbreviations Introduced in This Chapter

ADLs	Activities of daily living
COMT	Catechol- <i>O</i> -methyltransferase
CR	Controlled-release
DIP	Drug-induced Parkinsonism
GABA	γ -Aminobutyric acid
GI	Gastrointestinal
MAO	Monoamine oxidase
NMDA	<i>N</i> -Methyl- <i>D</i> -aspartate
PD	Parkinson's disease
QOL	Quality of life
RBD	Rapid eye movement sleep behavior disorder
RLS	Restless legs syndrome
UPDRS	Unified Parkinson's Disease Rating Scale

Pain Management

Christine Karabin O'Neil

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Identify characteristics of the types of pain: nociceptive, inflammatory, neuropathic, and functional.
2. Explain the mechanisms involved in pain transmission.
3. Select an appropriate method of pain assessment.
4. Recommend an appropriate choice of analgesic, dose, and monitoring plan for a patient based on type and severity of pain and other patient-specific parameters.
5. Perform calculations involving equianalgesic doses, conversion of one opioid to another, rescue doses, and conversion to a continuous infusion.
6. Educate patients and caregivers about effective pain management, dealing with chronic pain, and the use of nonpharmacologic measures.

KEY CONCEPTS

- 1 Pain is an unpleasant, subjective experience that is the net effect of a complex interaction of the ascending and descending neurons involving biochemical, physiologic, psychological, and neocortical processes.
- 2 Following initial assessment of pain, reassessment should be done as needed based on medication choice and the clinical situation.
- 3 Effective treatment involves an evaluation of the cause, duration, and intensity of the pain and selection of an appropriate treatment modality for the pain situation.
- 4 Whenever possible, the least potent oral analgesic should be selected.
- 5 Equianalgesic doses should be used when converting from one opioid to another.

Pain is defined by the International Association for the Study of Pain (IASP) as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.”¹

1 Pain is an unpleasant subjective experience that is the net effect of a complex interaction of the ascending and descending neurons involving biochemical, physiologic, psychological, and neocortical processes. Pain can affect all areas of a person's life including sleep, thought, emotion, and activities of daily living. Because there are no reliable objective markers for

pain, the patient is the only person who can describe the intensity and quality of their pain.

Pain is the most common symptom prompting patients to seek medical attention and is reported by more than 80% of individuals who visit their primary care provider.² Despite the frequency of pain symptoms, individuals often do not obtain satisfactory relief of pain. This has led to initiatives in healthcare to make pain the fifth vital sign, thus making pain assessment equal in importance to obtaining a patient's temperature, pulse, blood pressure, and respiratory rate.

EPIDEMIOLOGY AND ETIOLOGY

Prevalence of Pain

Most people experience pain at some time in their lives, and pain is a symptom of a variety of diseases. For some, pain might be mild to moderate, intermittent, easily managed, and have minimal effect on daily activities. For others, pain might be chronic, severe, or disabling, all consuming, and treatment resistant. Thus identifying the exact prevalence of pain is a difficult task. According to the American Pain Foundation, more than 76 million people in the United States suffer from chronic pain, and an additional 25 million experience acute pain from injury or surgery.² About 26% of the adults, mostly women and the elderly, experience chronic pain such as back pain, headache, and joint pain.

Prevalence rates for a variety of different types of pain have been described. Approximately one-fourth of U.S. adults

reported having low back pain lasting at least 1 day in the past 3 months.³ Migraine affects more than 28 million Americans, and 78% of Americans experience a tension headache during their lifetime.⁴ Pain resulting from fibromyalgia affects 10 million Americans.⁵ Pain ranges in prevalence from 14% to 100% among cancer patients. Cancer is commonly associated with both acute and chronic pain, and about 50% to 70% of those in active treatment will experience significant pain.⁶

The prevalence of **neuropathic pain** is unknown because of the lack of epidemiologic studies. Current estimates suggest that approximately 1.5% of the population in the United States might be affected by neuropathic pain.⁷ However, this figure is probably an underestimate and will likely increase due to the increase in disorders associated with neuropathic pain in the ever-growing older population. Approximately 25% to 50% of all pain clinic visits are related to neuropathic pain.⁸ Central neuropathic pain is estimated to occur in 2% to 8% of all stroke patients.⁹

The elderly, defined as people 65 years and older, bear a significant burden of pain, and pain continues to be under-recognized and undertreated in this population. The prevalence of pain in people older than 60 years is twice that in those younger than 60 years.¹⁰ Studies suggest that 25% to 50% of community-dwelling elderly suffer pain. Pain is quite common among nursing home residents. It is estimated that pain in 45% to 80% of nursing home patients contributes to functional impairment and a decreased quality of life.¹¹

The financial impact of pain is considered to be significant. Low back pain alone was responsible for direct medical costs of more than \$26 billion annually in 1998 and as much as \$50 billion per year in indirect costs.¹² The American Productivity Audit of the U.S. workforce, conducted from 2001 to 2002, revealed that the cost of lost productivity due to arthritis, back pain, headache, and other musculoskeletal pain was approximately \$61.2 billion per year.¹³

Undertreatment of Pain

Despite the growing emphasis on pain management, pain often remains undertreated and continues to be a problem in hospitals, long-term care facilities, and the community. In one series of reports, 50% of seriously ill hospitalized patients reported pain; however, 15% were dissatisfied with pain control, and some remained in pain after hospitalization.^{14,15}

Misconceptions about pain management, both from patients and healthcare providers, are among the most common causes of analgesic failure. Some clinicians might be hesitant to treat pain because either they do not believe the patient's reports of pain or feel the patient is exaggerating symptoms in order to obtain medications. Inadequate clinical knowledge of available pain management strategies, including pharmacologic, nonpharmacologic, and alternative therapy options, also often leads to suboptimal pain management. In one survey, approximately three-fourths of physicians cited low competence in pain assessment as the major barrier to effective pain management.¹⁶ Concerns about opiate misuse, abuse, and diversion also contribute to less than optimal pain management and cause providers to exercise caution

when prescribing opiates for pain. Misunderstandings about the terms **addiction**, **physical dependence**, **tolerance**, and **pseudoaddiction** are additional obstacles to optimal pain management.

Patients might present barriers to pain management by not reporting pain symptoms because of fear of becoming addicted or because of cultural beliefs. Elderly patients might not report pain for a variety of reasons including belief that pain is something they must live with, fear of consequences (e.g., hospitalization, loss of independence), or fear that the pain might be forecasting impending illness, inability to understand terminology used by healthcare providers, or a belief that showing pain is unacceptable behavior.

PATHOPHYSIOLOGY

Types of Pain

- Several distinct types of pain have been described, for example, nociceptive, inflammatory, neuropathic, and functional.¹⁷ Nociceptive pain is a transient pain in response to a noxious stimulus at **nociceptors** that are located in cutaneous tissue, bone, muscle, connective tissue, vessels, and viscera. Nociceptors are classified as thermal, chemical, or mechanical. The nociceptive system extends from the receptors in the periphery to the spinal cord, brainstem, to the cerebral cortex where pain sensation is perceived. This system is a key physiologic function that prevents further tissue damage due to the body's autonomic withdrawal reflex. When tissue damage occurs despite the nociceptive defense system, inflammatory pain ensues. The body now changes focus from protecting against painful stimuli to protecting the injured tissue. The inflammatory response contributes to pain hypersensitivity that serves to prevent contact or movement of the injured part until healing is complete, thus reducing further damage.
- Neuropathic pain is defined as spontaneous pain and hypersensitivity to pain associated with damage to or pathologic changes in the peripheral nervous system as in painful diabetic peripheral neuropathy (DPN), adult immune deficiency syndrome (AIDS), polyneuropathy, postherpetic neuralgia (PHN), or in the CNS, which occurs with spinal cord injury, multiple sclerosis, and stroke. Functional pain, a relatively newer concept, is pain sensitivity due to an abnormal processing or functioning of the CNS in response to normal stimuli. Several conditions considered to have this abnormal sensitivity or hyperresponsiveness include fibromyalgia and irritable bowel syndrome.

Mechanisms of Pain

► Pain Transmission

- The mechanisms of nociceptive pain are well defined and provide a foundation for the understanding of other types of pain.¹⁸ Following nociceptor stimulation, tissue injury causes the release of substances (bradykinin, serotonin, potassium, histamine, prostaglandins, and substance P) that might

further sensitize and/or activate nociceptors. Nociceptor activation produces action potentials (transduction) that are transmitted along myelinated A δ -fibers and unmyelinated C-fibers to the spinal cord. The A δ -fibers are responsible for first, fast, sharp pain and release excitatory amino acids that activate α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors in the dorsal horn. The C-fibers produce second pain, which is described as dull, aching, burning, and diffuse. These nerve fibers synapse in the dorsal horn of the spinal cord, where several neurotransmitters are released including glutamate, substance P, and calcitonin gene-related peptide. Transmission of pain signals continues along the spinal cord to the thalamus, which serves as the pain relay center, and eventually to the cortical regions of the brain where pain is perceived.

► Pain Modulation

Modulation of pain (inhibition of nociceptive impulses) can occur by a number of processes. Based on the gate-control theory, pain modulation might occur at the level of the dorsal horn.¹⁹ Because the brain can process only a limited number of signals at one time, other sensory stimuli at nociceptors might alter pain perception. This theory supports the effectiveness of counterirritants and transcutaneous electrical nerve stimulation (TENS) in pain management. Pain modulation can occur through several other complex processes. The endogenous opiate system consists of endorphins (enkephalins, dynorphins, and β -endorphins) that interact with μ -, δ -, and κ -receptors throughout the CNS to inhibit pain impulses and alter perception. The CNS also includes inhibitory descending pathways from the brain that can attenuate pain transmission in the dorsal horn. Neurotransmitters involved in this descending system include endogenous opioids, serotonin, norepinephrine, γ -aminobutyric acid (GABA), and neurotensin. The perception of pain involves not only nociceptive stimulation but physiologic and emotional input that contributes to the perception of pain. Consequently, cognitive behavioral treatments such as distraction, relaxation, and guided imagery can reduce pain perception by altering pain processing in the cortex.

► Peripheral Sensitization, Central Sensitization, and Windup

Under normal conditions, a balance generally exists between excitatory and inhibitory neurotransmission. Changes in this balance can occur both peripherally and centrally, resulting in exaggerated responses and sensitization, such as that observed in inflammatory, neuropathic, or functional chronic pain. Pain in these settings might occur spontaneously without any stimulus or might be evoked by a stimulus. Evoked pain might arise from a stimulus that normally does not cause pain (**allodynia**) such as a light touch in neuropathic pain. **Hyperalgesia**, an exaggerated and/or prolonged pain response to a stimulus that normally causes pain, can also occur as a result of increased sensitivity in the CNS.

During normal pain transmission, the AMPA receptors are activated, but the *N*-methyl-D-aspartate (NMDA)

receptor is blocked by magnesium.¹⁶ Repeated nerve depolarization causes release of the magnesium block, allowing the influx of calcium and sodium, and results in excessive excitability and amplification of signals. Continued input from C-fibers and subsequent increases in substance P and glutamate causes the activation of the NMDA receptor, a process referred to as windup. Windup increases the number and responsiveness of neurons in the dorsal horn irrespective of the input from the periphery. Recruitment of neurons not normally involved in pain transmission or spread occurs, leading to allodynia, hyperalgesia, and spread to uninjured tissues.²⁰ The windup phenomenon supports the observation that untreated acute pain can lead to chronic pain and the belief that pain processes are plastic and not static.

CLINICAL PRESENTATION AND DIAGNOSIS

Classification of Pain

Pain has always been described as a symptom. However, recent advances in the understanding of neural mechanisms have demonstrated that unrelieved pain might lead to changes in the nervous system known as neural plasticity. Because these changes reflect a process that influences a physiologic response, pain, particularly chronic pain, might be considered a disease unto itself.

Pain can be divided into two broad categories: acute and chronic pain. Acute pain is also referred to as adaptive pain because it serves to protect the individual from further injury or promote healing.¹⁷ However, chronic pain has been called maladaptive, a pathologic function of the nervous system or pain as a disease.

► Acute Pain

Acute pain is pain that occurs as a result of injury or surgery and is usually self-limited, subsiding when the injury heals. Untreated acute pain can produce physiologic symptoms including tachypnea, tachycardia, and increased sympathetic nervous system activity, such as pallor, diaphoresis, and pupil dilation. Furthermore, poorly treated pain can cause psychological stress and compromise the immune system due to the release of endogenous corticosteroids. Somatic acute pain arises from injury to skin, bone, joint, muscle, and connective tissue, and it is generally localized to the site of injury. Visceral pain involves injury to nerves on internal organs (e.g., intestines, liver) and can present as diffuse, poorly differentiated, and often referred pain. Acute pain should be treated aggressively, even before the diagnosis is established, except in conditions of head or abdominal injury where pain might assist in the differential diagnosis.

► Chronic Pain

Chronic pain persists beyond the expected normal time for healing and serves no useful physiologic purpose. Chronic pain might be nociceptive, inflammatory, neuropathic, or

functional in origin; however, all forms share some common characteristics. Chronic pain can be intermittent or persistent, or both. Physiologic responses observed in acute pain are often absent in chronic pain; however, other symptoms might predominate. The four main effects of chronic pain include (a) effects on the physical function, (b) psychological changes, (c) social consequences, and (d) societal consequences. Effects of chronic pain on physical function include impaired activities of daily living and sleep disturbances. Psychological components of chronic pain might include depression, anxiety, anger, and loss of self-esteem. As a result of physical and psychological changes, social consequences might ensue, such as changes in relationships with friends and family, intimacy, and isolation. On a societal level, chronic pain contributes to increased healthcare costs, disability, and lost productivity. Management of chronic pain should be multimodal and might involve cognitive interventions, physical manipulations, pharmacologic agents, surgical intervention, and regional or spinal anesthesia.

Chronic Malignant Pain Chronic malignant pain is associated with a progressive disease that is usually life threatening such as cancer, AIDS, progressive neurologic diseases, end-stage organ failure, and dementia.²¹ The goal is pain alleviation and prevention, often through a systematic and stepwise approach. Tolerance, dependence, and addiction are often not a concern due to the terminal nature of the illness.

Chronic Nonmalignant Pain Pain not associated with a life-threatening disease and lasting more than 6 months beyond the healing period is referred to as chronic nonmalignant pain. Pain associated with low back pain, osteoarthritis, previous bone fractures, peripheral vascular disease, genitourinary infection, rheumatoid arthritis, and coronary heart disease is considered nonmalignant. The numerous causes of this type of chronic pain make treatment complex and involves a multidisciplinary approach. Treatment is initially conservative but might involve the use of more potent analgesics including opiates in psychologically healthy patients.²²

Neuropathic Pain Neuropathic pain is considered to be a type of chronic nonmalignant pain involving disease of the central and peripheral nervous systems. Neuropathic pain might be broadly categorized as peripheral or central in nature. Examples of neuropathic pain include PHN, which is pain associated with acute herpetic neuralgia or an acute shingles outbreak. Peripheral or polyneuropathic pain is associated with the distal polyneuropathies of diabetes, human immunodeficiency virus (HIV), and chemotherapeutic agents. Types of **central pain** include central stroke pain, trigeminal neuralgia, and a complex of syndromes known as complex regional pain syndrome (CRPS). CRPS includes both reflex sympathetic dystrophy and **causalgia**, both of which are neuropathic pain associated with abnormal functioning of the autonomic nervous system. One of the newest categories of neuropathic pain is neuropathic low back pain.

The symptoms of neuropathic pain are characterized as tingling, burning, shooting, stabbing, electric shock-like quality, or radiating pain. The patient might describe either

Clinical Presentation and Diagnosis of Pain Management

General

Patients may be in acute distress (acute pain) or have no signs or symptoms of suffering (chronic pain).

Symptoms

Pain is described based on the following characteristics: onset, duration, location, quality, severity, and intensity. Other symptoms may include anxiety, depression, fatigue, anger, fear, and insomnia.

Signs

Acute pain may cause hypertension, tachycardia, diaphoresis, mydriasis, and pallor.

Diagnosis

The patient is the only person who can describe the intensity and quality of their pain. There are no laboratory tests that can diagnose pain.

a constant dull throbbing or burning pain, or an intermittent pain that is stabbing or shooting. Damage to the peripheral nerves might frequently be referred to the body region innervated by those nerves.

Pain Assessment

Effective pain management begins with a thorough and accurate assessment of the patient. Even though pain is a common presenting complaint, lack of regular assessment and reassessment of pain remains a problem and contributes to the undertreatment of pain.²³

► Pain Assessment Guidelines/Regulations for Specific Practice Settings

Screening for pain should be a part of a routine assessment, which has led several organizations such as the Veterans Health Administration (VHA) and the American Pain Society (APS) to declare pain as the fifth vital sign. Many states have adopted a bill of rights for patients in pain. In 2001, the Joint Commission on Accreditation of Health Care Organizations (JCAHO) incorporated pain as the fifth vital sign in its accreditation standards.²⁴ According to the JCAHO, patients have a right to appropriate assessment and management of their pain and education regarding their pain.

2 Following initial assessment of pain, reassessment should be done as needed based on medication choice and the clinical situation.

► Methods of Pain Assessment

A patient-oriented approach to pain is essential, and methods do not differ greatly from those used in other medical conditions. A comprehensive history (medical, family, and

psychological) and physical are necessary to evaluate underlying disease processes for the source of pain and other factors contributing to the pain.²⁰ A thorough assessment of the characteristics of the pain should be completed, including questions about the pain (onset, duration, location, quality, severity, and intensity), pain relief efforts, and efficacy and side effects of current and past treatments for pain. A common mnemonic for pain assessment is PQRST (Palliative/precipitating, Quality, Radiation, Severity, and Time).²⁵ Some clinicians have suggested the addition of U (“you”) to this mnemonic.²⁶ During the pain interview, the impact of the pain on the patient’s functional status, behavior, and psychological states should also be assessed. Evaluation of psychological status is especially important in patients with chronic pain because depression and affective disorders might be common comorbid conditions. A history of drug and alcohol use should be elicited due to the potential for addiction in patients who might require opiates or other pain medications with a potential for abuse. Other conditions, such as renal or hepatic dysfunction, diabetes, and conditions that affect bowel function, can influence therapy choices and goals. A discussion of the patient’s expectations and goals with respect to pain management (level of pain relief, functional status, and quality of life) should also be part of any pain interview.

► Pain Assessment Tools

Pain, particularly acute pain, might be accompanied by physiologic signs and symptoms, but there are no reliable objective markers for pain. Many tools have been designed for assessing the severity of pain including rating scales and multidimensional pain assessment tools.

Rating scales provide a simple way to classify the intensity of pain, and they should be selected based on the patient’s ability to communicate (Fig. 34–1).²⁷ Numeric scales are widely used and ask patients to rate their pain on a scale of 0 to 10, with 0 indicating no pain and 10 being the worst pain possible. Using this type of scale, 1 to 3 is considered mild pain, 4 to 6 is moderate pain, and 7 to 10 is severe pain. The visual analog scale (VAS) is similar to the numerical scale in that it requires patients to place a mark on a 10-cm line where one end is no pain, and the worst possible pain is on the other end. For patients who have difficulty assigning a number to their pain, a categorical scale might be an option to communicate the intensity of the pain experience. Examples of this include a simple descriptive list of words and the Wong-Baker FACES of Pain Rating Scale.²⁸

Multidimensional assessment tools obtain information about the pain and impact on quality of life, but they are often more time consuming to complete. Examples of these types of tools include the Initial Pain Assessment Tool, Brief Pain Inventory, McGill Pain Questionnaire, the Neuropathic Pain Scale, and the Oswestry Disability Index.^{29–33}

► Pain Assessment in Challenging Populations

Children Pain interviews can be conducted with children as young as 3 or 4 years of age; however, communication might be limited by vocabulary.³⁴ Terms familiar to children such

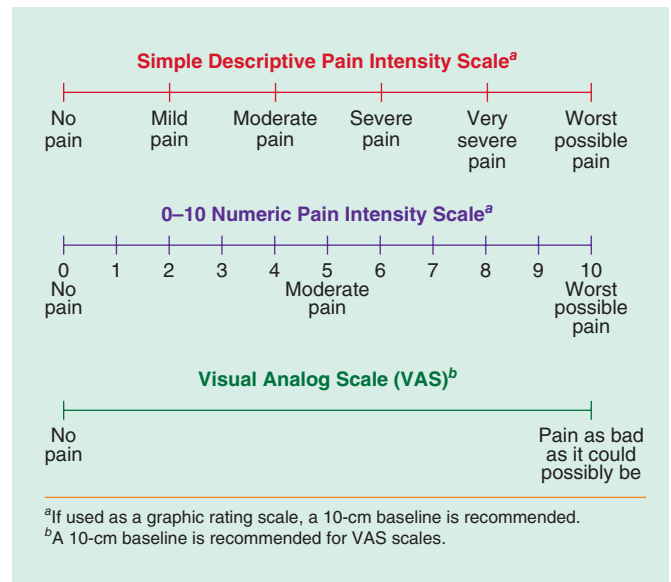

FIGURE 34–1. Pain rating scales. (From U.S. Department of Health and Human Services, Agency for Health Care Policy and Research. Clinical practice guideline, cancer pain management. Rockville, MD: AHCPR; 1994 [cited 2011 Oct 10]. Available from: http://www.ncbi.nlm.nih.gov/books/bookres.fcgi/hstat6/f37_capcf4.gif)

as *hurt*, *owie*, or *boo boo* might be used to describe pain. The VAS is best used with children older than 7 years. Other scales based on numbers of objects (e.g., pokers chips), increasing color intensity, or faces of pain might be helpful for children between 4 and 7 years of age. In children younger than 3 to 4 years, behavioral or physiologic measures, such as pulse or respiratory rate, might be more appropriate. Pain assessment in newborns and infants relies on behavioral observation for such clues as vocalizations (crying and fussing), facial expressions, body movements (flailing of limbs and pulling legs in), withdrawal, and change in eating and sleeping habits.³⁵ Preschool children experiencing pain might become clingy, lose motor and verbal skills, and start to deny pain because treatment might be linked to discomfort or punishment. School-age children might exhibit aggressiveness, nightmares, anxiety, and withdrawal when in pain; adolescents might respond to pain with oppositional behavior and depression.

Elderly Most of the previously discussed pain scales can be used in older persons who are cognitively intact or with mild dementia. The pain thermometer and FACES of pain have been studied in older persons. In persons with moderate to severe dementia or those who are nonverbal, observation of pain behaviors, such as guarding or grimacing, provides an alternative for pain assessment. The Pain Assessment in Advanced Dementia (PAINAD) tool might be used to quantify signs of pain and involves observing the older adult for 15 minutes for breathing, negative vocalizations, facial expression, body language, and consolability.³⁶ Regardless of which pain assessment tool is used, the practitioner should first determine if the patient understands the concept of the scale to ensure reliability of the instrument.

Patient Encounter, Part 1

HPI: MA is a 68-year-old woman who fell while golfing and sustained a hip fracture. She is to undergo an open-reduction and internal fixation.

PMH: Hypertension for 18 years
Diabetes type 2 for 13 years

FH: Mother had osteoporosis; father had diabetes

SH: Lives with husband; has two grown children

Meds: Lisinopril 20 mg daily, metformin 500 mg three times daily

Pain assessment: Patient rates pain as 8 on a scale of 1 to 10

Based on the type of injury, what type of pain is this patient likely to experience?

What type of pain management regimen would you recommend in the postoperative period? Explain your answer.

on the type of pain, treatment might involve pharmacologic and nonpharmacologic therapy or both. General principles for the pharmacologic management of pain are listed in the section “Patient Care and Monitoring.” Two common approaches to the selection of treatment are based on severity of pain and the mechanism responsible for the pain (Fig. 34–2). Clinical practice guidelines for pain management are available from the APS, the Agency for Healthcare Research and Quality (AHRQ), the American Geriatrics Society (AGS), and the American Society of Anesthesiologists (ASA).

► Selection of Agent Based on Severity of Pain

4 *Whenever possible, the least potent oral analgesic should be selected.* Guidelines for the selection of therapeutic agents based on pain intensity are derived from the World Health Organization (WHO) analgesic ladder for the management of cancer pain (Table 34–1).³⁷ Mild to moderate pain is generally treated with nonopioid analgesics. Combinations of medium-potency opioids and acetaminophen (APAP) or nonsteroidal anti-inflammatory drugs (NSAIDs) are often used for moderate pain. Potent opioids are recommended for severe pain. Throughout this progression, adjuvant medications are added, as needed, to manage side effects and to augment analgesia. While these guidelines can be useful for initial therapy, the clinical situation (type of pain), cost and pharmacokinetic profile of available drugs, and patient-specific factors (age, concomitant illnesses, previous response, and other medications) must also be considered. Pain medications might also be used in the absence of pain

TREATMENT

General Approach to Treatment

3 *Effective treatment involves an evaluation of the cause, duration, and intensity of the pain, and selection of an appropriate treatment modality for the pain situation.* Depending

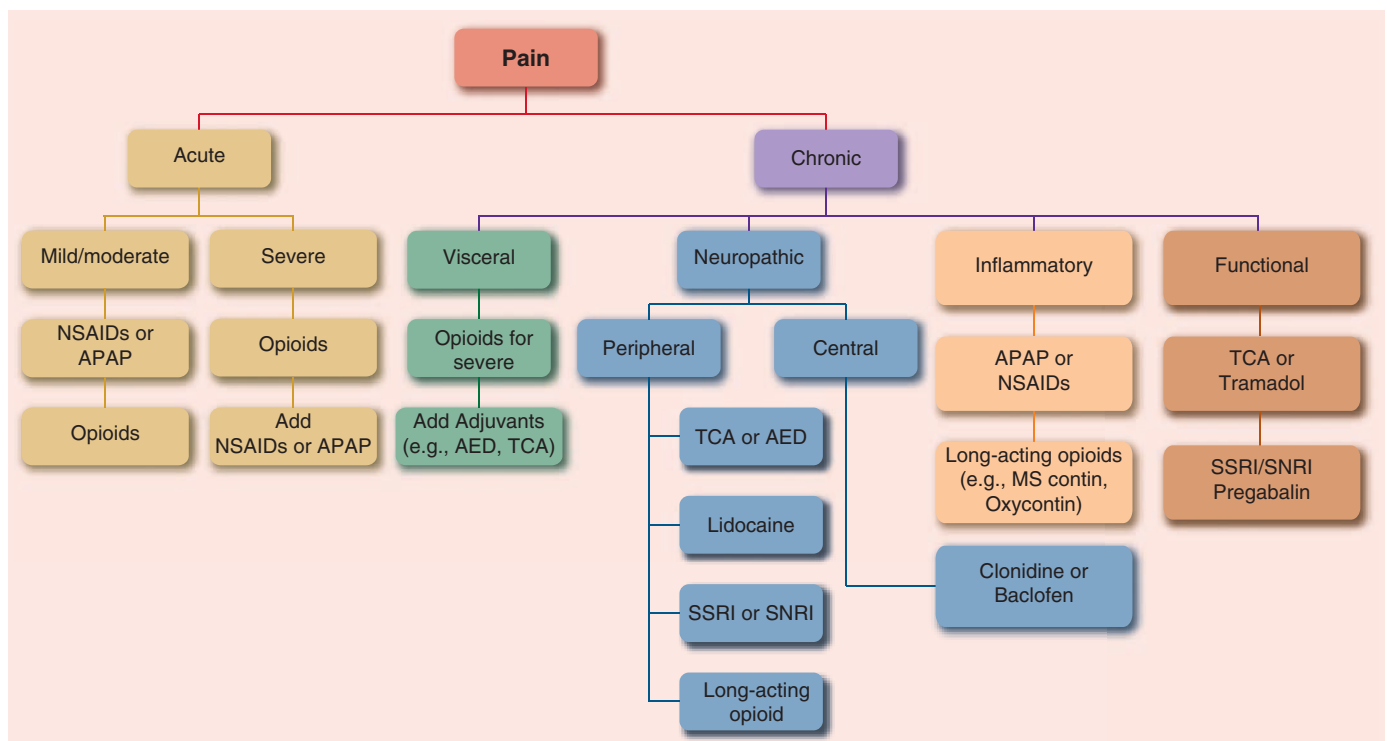

FIGURE 34–2. Pain algorithm. (AED, antiepileptic drugs; APAP, acetaminophen; MS, morphine sulfate; NSAIDs, nonsteroidal anti-inflammatory drugs; SNRI, serotonin norepinephrine reuptake inhibitors; SSRI, selective serotonin reuptake inhibitors; TCA, tricyclic antidepressants.)

Table 34-1

Selection of Analgesics Based on Intensity of Pain

Pain Intensity	Corresponding Numerical Rating	WHO Therapeutic Recommendations	Examples of Initial Therapy	Comments
Mild	1–3/10	Nonopioid analgesic; regular scheduled dosing	Acetaminophen 1,000 mg q 6 h; ibuprofen 600 mg q 6 h	Consider adding an adjunct or using an alternate regimen if pain is not reduced in 1–2 days
Moderate	4–6/10	Add an opioid to the nonopioid for moderate pain; regular scheduled dosing	Acetaminophen 325 mg + codeine 60 mg q 4 h; acetaminophen 325 mg + oxycodone 5 mg q 4 h	Consider step-up therapy if pain is not relieved by two or more different drugs
Severe	7–10/10	Switch to a high-potency opioid; regular scheduled dosing	Morphine 10 mg q 4 h; or hydromorphone 4 mg q 4 h	

Data from Ref. 37, 39, 45.

in anticipation of a painful event such as surgery to minimize peripheral and central sensitization.

► Mechanistic Approach to Therapy

Current analgesic therapy is aimed at controlling or blunting pain symptoms. However, diverse mechanisms contributing to the various types of pain continue to be further elucidated. An understanding of these new mechanisms of pain transmission might lead to improvement in pain management as pharmacologic management of pain becomes more mechanism specific. Use of NSAIDs for inflammatory types of pain is an example of a mechanistic approach. Because several mechanisms of pain often coexist, a polypharmacy approach seems rational to target each mechanism.

Two current foci in pain management are to identify the mechanisms that are responsible for pain hypersensitivity and to prevent this initial hypersensitivity. Therefore, the goal of pain therapy is to reduce peripheral sensitization and subsequent central stimulation and amplification associated with windup, spread, and central sensitization.¹⁷

Nonpharmacologic Therapy

- Nonpharmacologic therapies (psychological interventions and physical therapy) might be used in both acute and chronic pain. Psychological interventions can reduce pain as well as the anxiety, depression, fear, and anger associated with pain. Psychological interventions helpful in management of acute pain are imagery (picturing oneself in a safe, peaceful place) and distraction (listening to music or focusing on breathing). Chronic pain patients might benefit from relaxation, biofeedback, cognitive behavioral therapy, psychotherapy, support groups, and spiritual counseling. Biofeedback teaches patients to control physiologic responses to pain and has been effective in headache and chronic low back pain. Cognitive therapy encourages patients to monitor their perceptions of pain, reducing stress and negativism.

Psychotherapy is very useful for patients with chronic pain; it can also assist in the treatment of psychiatric comorbidities and help patients deal with terminal illness.³⁸ The patient should be educated about what to expect regarding pain and its treatment, whether pain is acute pain (e.g., preoperative explanations of expected postsurgical pain) or chronic (e.g., patient and family education in hospice care).

Physical therapy is an essential part of many types of pain situations. Treatment modalities include heat, cold, water, ultrasound therapy, TENS, massage, and therapeutic exercise. Heat and cold therapy are utilized in a variety of musculoskeletal conditions (muscle spasms, low back pain, fibromyalgia, sprains, and strains). Heating modalities include local hot packs, paraffin wrap, hydrotherapy, and deep-heating methods (ultrasound). Cold treatments might be delivered via cold packs, ice massage, cold water immersion, or coolant sprays. TENS therapy is based on the theory that electrical stimulation of a nerve in a particular area can block pain impulses originating from that area. TENS is also believed to release endogenous endorphins and enkephalins. Massage therapy is used to relieve muscle tension and stiffness and is also felt to increase endogenous endorphins. Therapeutic exercise improves not only strength, endurance, and range of motion but also provides cardiovascular, psychological, and other health benefits.

Pharmacologic Therapy

► Nonopioid Analgesics

- **Acetaminophen** APAP, an analgesic and antipyretic, is often selected as initial therapy for mild to moderate pain and is considered first line in several pain situations such as low back pain and osteoarthritis.³⁹ Mechanistically, APAP is believed to inhibit prostaglandin synthesis in the CNS and block pain impulses in the periphery. APAP is well tolerated at usual doses and has few clinically significant drug interactions except causing increased hypoprothrombinemic response to warfarin in patients receiving APAP doses of

more than 2,000 mg/day. The maximum recommended dose for patients with normal renal and hepatic function is 4,000 mg/day. Hepatotoxicity has been reported with excessive use and overdose, and the risk of this adverse effect increases in those with hepatitis or chronic alcohol use, as well as those who binge drink or are in a fasting state. Regular chronic use of APAP has been associated with chronic renal failure, but reports are conflicting. For these reasons, the maximum dose should be reduced by 50% to 75% in patients with renal dysfunction or hepatic disease and in those who engage in excessive alcohol use. Due to concerns about increasing rates of acetaminophen toxicity, the FDA commissioned a working group within the Center for Drug Evaluation and Research to recommend interventions to reduce APAP induced liver toxicity. An assembly of three advisory panels reviewed the report of the working group and endorsed the following three recommendations including a reduction of the maximum daily dose from 4 g to possibly 3,250 mg daily, a reduction in acetaminophen dose to 325 mg in prescription narcotic-acetaminophen combinations, and a reduction of the maximum single nonprescription dose from 1 g to 650 mg, thus relegating the 500-mg dosage strength to prescription status.⁴⁰

Aspirin and Other Salicylates Aspirin, nonacetylated salicylates, and other NSAIDs have analgesic, antipyretic, and anti-inflammatory actions. These agents inhibit cyclooxygenase (COX-1 and COX-2) enzymes, thereby preventing prostaglandin synthesis, which results in reduced nociceptor sensitization and an increased pain threshold. NSAIDs are the preferred agents for mild to moderate pain in situations that are mediated by prostaglandins (rheumatoid arthritis, menstrual cramps, and postsurgical pain) and in the management of pain from bony metastasis, but they are of minimal use in neuropathic pain.

Aspirin is effective for mild to moderate pain; however, the risk of GI irritation and bleeding limits frequent use of this drug for pain management. Direct effects of aspirin on the GI mucosa and irreversible platelet inhibition contribute to this risk, which can occur even at low doses. Hypersensitivity reactions are also possible and might occur in 25% of patients with coexisting asthma, nasal polyps, or chronic urticaria. Of additional concern is the potential for cross-sensitivity of other NSAIDs in this group of patients. Nonacetylated salicylates (choline magnesium salicylate and sodium salicylate) have a reduced risk of GI effects and platelet inhibition and might be used in aspirin-sensitive patients. Diflunisal, a salicylic acid derivative, is associated with fewer GI complaints compared with aspirin, but platelet inhibition does increase the risk of GI bleeding.

Nonsteroidal Anti-inflammatory Drugs NSAIDs provide analgesia equal to or better than that of aspirin or APAP combined with codeine, and they are very effective for inflammatory pain and pain associated with bone metastasis.¹⁸ These agents are classified by their chemical structures (fenamates, acetic acids, propionic acids, pyranocarboxylic acids, pyrrolizine carboxylic acids, and COX-2 inhibitors). Although only some members of this class have approval for treatment of pain, it is likely that all of them have similar analgesic effects.

All members of this class appear to be equally effective, but there is great inpatient variability in response. After an adequate trial of 2 to 3 weeks with a particular oral agent, it is reasonable to switch to another member of the class. Ketorolac and ibuprofen are available in parenteral and oral dosage forms; unlike other NSAIDs, ketorolac's duration of use is limited to 5 days. NSAIDs demonstrate a flat-dose response curve, with higher doses producing no greater efficacy than moderate doses but resulting in an increased incidence of adverse effects (GI irritation, hepatic dysfunction, renal insufficiency, platelet inhibition, sodium retention, and CNS dysfunction).

Patients at increased risk of NSAID-induced GI adverse effects (e.g., dyspepsia, peptic ulcer formation, and bleeding) include the elderly, those with peptic ulcer disease, coagulopathy, and patients receiving high doses of concurrent corticosteroids. Nephrotoxicity is more common in the elderly, patients with creatinine clearance values less than 50 mL/min (0.84 mL/s), and those with volume depletion or on diuretic therapy. NSAIDs should be used with caution in patients with reduced cardiac output due to sodium retention and in patients receiving antihypertensives, warfarin, and lithium.

NSAIDs are classified as nonselective (they inhibit COX-1 and COX-2) or selective (inhibit only COX-2) based on degree of COX inhibition. COX-2 inhibition is responsible for anti-inflammatory effects, whereas COX-1 inhibition contributes to increased GI and renal toxicity associated with nonselective agents. Because the antiplatelet effect of nonselective NSAIDs is reversible, concurrent use might reduce the cardioprotective effect of aspirin due to competitive inhibition of COX-1. For this reason, administration of aspirin prior to the NSAID is recommended.⁴¹ The cardiovascular safety of the COX-2 inhibitors has been questioned due to increased risk of myocardial infarction (MI) and stroke noted in several trials.⁴²⁻⁴⁴ The FDA Committees on Arthritis and Drug Safety and Risk Management convened in February 2005 to evaluate the published studies and manufacturer information about the cardiovascular-adverse events associated with COX-2 inhibitors. As a follow-up to the committee's recommendations, the FDA took regulatory action in April 2005 announcing that the increased risk of cardiovascular events was likely a class effect of NSAIDs. A Boxed Warning highlighting the potential for increased risk of cardiovascular events and GI bleeding is now required for all prescription nonselective NSAIDs and celecoxib. Stronger warnings about these adverse events are also required on nonprescription NSAIDs. As a result of the data and subsequent events, two members of this class, rofecoxib and valdecoxib, were withdrawn from the market. Future COX-2 inhibitors and nonselective NSAIDs will likely have to undergo cardiovascular safety studies before receiving FDA approval. When a NSAID is needed in a patient with cardiovascular risk, the benefits of therapy must outweigh the risks, and the lowest effective dose of the NSAID is recommended.⁴⁵

► Opioid Analgesics

• Opioids are considered the agents of choice for the treatment of severe acute pain and moderate to severe pain associated with cancer.⁴⁶ For chronic pain, their use was once highly

controversial; however, use of opioids in chronic pain is now gaining acceptance.⁴⁷ Opioids are classified by their activity at the receptor site, usual pain intensity treated, and duration of action (short acting versus long acting).

Selection and Dosing The opioids exert their analgesic efficacy by stimulating opioid receptors (μ , κ , and δ) in the CNS. There is a wide variety of potencies among the opioids, with some used for moderate pain (codeine, hydrocodone, tramadol, and partial agonists) and others reserved for severe pain (morphine and hydromorphone). Pure agonists (morphine) bind to μ -receptors to produce analgesia that increases with dose without a ceiling effect. Pure agonists are divided into three chemical classes: phenanthrenes or morphine-like, phenyl piperidine or meperidine-like, and diphenyl heptane or methadone-like. Partial agonists/antagonists (butorphanol, pentazocine, and nalbuphine) partially stimulate the μ -receptor and antagonize the κ -receptors. This activity results in reduced analgesic efficacy with a ceiling dose, reduced side effects at the μ -receptor, psychotomimetic side effects due to κ -receptor antagonism, and possible withdrawal symptoms in patients who are dependent on pure agonists.

Selection of the agent and route depend on individual patient-related factors including severity of pain, individual perceptions, weight, age, opioid tolerance, and concomitant disease (renal or hepatic dysfunction). Because pure agonists are pharmacologically similar, choice of agent might be also guided by pharmacokinetic parameters and other drug characteristics. Hepatic impairment can decrease the metabolism of most opioids, particularly methadone, meperidine, and pentazocine. Furthermore, the clearance of meperidine and morphine and their metabolites is reduced in renal dysfunction.

Table 34–2 provides a summary of opiate options, but several drugs warrant further discussion. Normeperidine, the active metabolite of meperidine, can produce tremors, myoclonus, delirium, and seizures. Due to the potential for accumulation of normeperidine, meperidine should not be used in the elderly, those with renal impairment, in patients using patient-controlled analgesia (PCA) devices, or for more than 1 to 2 days of intermittent dosing. Methadone is unique among the opiates because it has several mechanisms (μ -agonist, NMDA-receptor antagonist, and inhibition of reuptake of serotonin and norepinephrine) that make it an interesting choice for chronic pain. The long-half of methadone (30 hours) permits extended dosing intervals; however, the potential for accumulation with repeated dosing often results in challenging dose conversion. Tramadol is a synthetic opioid with a dual mechanism of action (μ -agonist and inhibition of serotonin and norepinephrine reuptake) and efficacy and safety similar to that of equianalgesic doses of codeine plus APAP. Tramadol has been evaluated in several types of neuropathic pain and might have a role in the treatment of chronic pain. Tramadol is associated with an increased risk of seizures in patients with a seizure disorder, those at risk for seizures, and those taking medications that can lower the seizure threshold. Doses greater than 500 mg have also been associated with seizures. The use of tramadol with other serotonergic drugs (e.g., selective serotonin

Table 34–2

Equianalgesic Doses of Selected Opioids

Opioid (Brand Name)	Dose Equianalgesic to 10 mg of Parenteral Morphine (mg)	
	Parenteral (mg)	Oral (mg)
Mild to Moderate Pain		
Codeine (generic, various)	120	200
Hydrocodone (Vicodin, Lorcet)	N/A	30
Oxycodone (OxyContin, OxyFAST, Oxy IR)	N/A	20
Meperidine (Demerol)	100	400
Moderate to Severe Pain		
Morphine (Roxanol, MS Contin, Kadian, Avinza)	10	30
Hydromorphone (Dilaudid)	1.5	7.5
Oxymorphone (Opana, Opana SR, Numorphan)	1	N/A
Levorphanol (Levo-Dromoran)	2	4
Fentanyl (Duragesic)	0.1–0.2	N/A ^a
Methadone (Dolophine)	10 ^b	3–5 ^b

^aTransdermal: 100 mcg/h = 2–4 mg/h of IV morphine.

^bDosage calculations when converting from morphine to methadone are not linear. The equianalgesic dose of methadone will decrease progressively as the morphine equivalents increase (Table 34–4).

Data from Refs. 26, 45, 49, 51.

reuptake inhibitors [SSRIs]) might precipitate serotonin syndrome. Although originally thought not to be habit forming, dependence can occur with tramadol.

About 70% of individuals will experience significant analgesia from 10 mg/70 kg of body weight of IV morphine or its equivalent.¹⁸ For severe pain in opiate-naive patients, a usual starting dose is 5 to 10 mg of morphine every 4 hours. In the initial stages of severe pain, medication should be given around the clock. Rescue doses should be made available for breakthrough pain in doses equivalent to 10% to 20% of the total daily opioid requirement and administered every 2 to 6 hours if needed. Alternatively, one-sixth of the total daily dose or one-third of the 12-hourly dose might be used. Scheduled doses should be titrated based on the degree of pain. One method involves adjustment of the maintenance dose based on the total 24-hour rescue dose requirement. Alternatively, utilizing dose escalation, doses could be increased by 50% to 100% or 30% to 50% of the current dose, for those in severe and moderate pain, respectively. Once pain relief is achieved, and if treatment is necessary for more than a few days, conversion to a controlled-release or long-acting opioid should be made with an equal amount of agent. Several sustained-release products are available containing morphine, oxycodone, and fentanyl. Some clinicians will reduce the total daily dose of the long-acting dosage form by 25% when initiating a sustained-release product to reduce the likelihood of oversedation. The dose of a pure agonist is limited only by tolerability to side effects. Tolerance might

develop to analgesic effects, necessitating increasing doses to achieve the same level of pain relief. Physical dependence will also occur with the long-term use of opioids. However, addiction or psychological dependence is unlikely in legitimate pain patients unless there are predisposing risk factors. Pain patients who are undertreated might appear to be drug seeking (pseudoaddiction); however, effective pain management resolves the behaviors. When opioids are used for chronic pain, use of informed consent for chronic opioid therapy, medication management agreements, or pain contracts might be appropriate to monitor the use (prescribing and dispensing) of controlled substances.

Opioids are administered by a variety of routes, including oral (tablet and liquid), sublingual, rectal, transdermal, transmucosal, IV, subcutaneous, and intraspinal. Although the oral and transdermal routes are most common, the method of administration is based on patient needs (severity of pain) and characteristics (swallowing difficulty and preference). Oral opioids have an onset of effect of 45 minutes, so IV or subcutaneous administration might be preferred if more rapid relief is desired. Intramuscular (IM) injections are not recommended because of pain at the injection site and wide fluctuations in drug absorption and peak plasma concentrations achieved. More invasive routes of administration such as PCA and intraspinal (epidural and intrathecal) are primarily used postoperatively but might also be used in refractory chronic pain situations. PCA delivers a self-administered dose via an infusion pump with a preprogrammed dose, minimum dosing interval, and a maximum hourly dose. Morphine, fentanyl, and hydromorphone are commonly administered via PCA pumps by the IV route but less frequently by the subcutaneous or epidural route.

Epidural analgesia is frequently used for lower extremity procedures and pain (e.g., knee surgery, labor pain, and some abdominal procedures). Intermittent bolus or continuous infusion of preservative-free opioids (morphine, hydromorphone, or fentanyl) and local anesthetics (bupivacaine) might be used for epidural analgesia. Opiates given by this route might cause pruritus that is relieved by naloxone. Adverse effects including respiratory depression, hypotension, and urinary retention might occur. When epidural routes are used in narcotic-dependent patients, systemic analgesics must also be used to prevent withdrawal because the opioid is not absorbed and remains in the epidural space. Doses of opioids used in epidural analgesia are 10 times less than IV doses, and intrathecal doses are 10 times less than epidural doses (i.e., 10 mg of IV morphine is equivalent to 1 mg epidural morphine and 0.1 mg of intrathecally administered morphine).⁴⁵

Combination Analgesics Combinations of opioids and nonopioids often result in enhanced analgesia and lower dose of each. Combination analgesics are frequently used in moderate pain. However, in severe pain, the nonopioid component reaches maximum dosage, and thus the usefulness of nonopioids in this situation is limited. Additionally, the combination products are short acting and often not suitable for chronic therapy. Single agents offer greater dosing flexibility than combination products.

Opioid Allergy True narcotic allergies are rare and should not be confused with pruritus associated with opiate use. Cross-sensitivity between morphine-like, meperidine-like, and methadone-like agents is unlikely. Therefore, when an individual is allergic to one drug in a chemical class of opioids, it is reasonable to select an agent in another chemical class. For the purpose of drug selection in patients with allergies, mixed agonists/antagonists should be treated as morphine-like agents.

Tapering of Opioids Tapering of opioids might be necessary once the painful situation has resolved in patients receiving doses greater than 160 mg/day of oral morphine (or the equivalent) or in those with prolonged opioid use. In these situations the dose should be reduced by 15% to 20% each day to avoid withdrawal symptoms.

Managing Opioid Side Effects and Drug Interactions Side effects common to all opioids include sedation, hallucinations, constipation, nausea and vomiting, urinary retention, myoclonus, and respiratory depression. **Table 34-3** shows management strategies for side effects. In terms of medication management, the most frequent are sedation, nausea, and constipation. Sedation and nausea are common when initiating therapy and when increasing doses. Nausea

Table 34-3

Managing Opioid Side Effects

Adverse Effects	Drug Treatment/Management
Excessive sedation	Reduce dose by 25% or increase dosing interval
Constipation	Casanthranol-docusate 1 cap at bedtime or twice daily; senna 1–2 tabs at bedtime or twice daily; bisacodyl 5–10 mg daily plus docusate 100 mg twice daily
Nausea and vomiting	Prevention: Hydroxyzine 25–100 mg (PO/IM) every 4–6 hours as needed; diphenhydramine 25–50 mg (PO/IM) q 6 h as needed; ondansetron 4 mg IV or 16 mg PO Treatment: Prochlorperazine 5–10 mg (PO/IM) q 3–4 h as needed or 25 mg PR twice daily; ondansetron 4–8 mg IV q 8 h as needed
Gastroparesis	Metoclopramide 10 mg (PO/IV) q 6–8 h
Vertigo	Meclizine 12.5–25 mg PO q 6 h as needed
Urticaria/itching	Hydroxyzine 25–100 mg (PO/IM) q 4–6 h as needed; diphenhydramine 25–50 mg (PO/IM) q 6 h as needed
Respiratory depression	Mild: Reduce dose by 25% Moderate to severe: Naloxone 0.4–2 mg IV q 2–3 min (up to 10 mg) for complete reversal; 0.1–0.2 mg IV q 2–3 min until desired reversal for partial reversal; may need to repeat in 1–2 hours depending on narcotic half-life
CNS irritability	Discontinue opioid; treat with benzodiazepine

IM, intramuscular; PO, orally; PR, per rectum.

Data from Refs. 27, 45, 49.

can be prevented with a centrally acting antiemetic. Sedation usually improves with continued therapy but might become intractable at high doses, and stimulants such as methylphenidate might be needed. Respiratory depression is a serious adverse effect and usually occurs after acute administration in opioid-naïve patients. Tolerance to respiratory depression develops rapidly with repeated doses, and respiratory depression is rarely a clinically significant problem in pain patients even those with respiratory impairment. Constipation is a significant adverse effect to which tolerance does develop, and prophylaxis with stimulant laxatives (e.g., senna or bisacodyl) and stool softeners such as docusate is recommended.

Codeine, hydrocodone, morphine, methadone, and oxycodone are substrates of the cytochrome P450 (CYP) enzyme: CYP2D6.⁴⁸ Inhibition of CYP2D6 results in decreased analgesia of codeine and hydrocodone due to decreased conversion to the active metabolites (e.g., morphine and hydromorphone, respectively) and increased effects of morphine, methadone, and oxycodone. Methadone is also a substrate of CYP3A4, and its metabolism is increased by phenytoin and decreased by cimetidine. CNS depressants might potentiate the sedative effects of opiates.

Opioid Rotation Opioid rotation is the switch from one opioid to another to achieve a better balance between analgesia and treatment-limiting adverse effects. This practice is often used when escalating doses (more than 1 g morphine/day) become ineffective. In some settings, opioid rotation is used routinely to prevent the development of analgesic tolerance.⁴⁹

Equianalgesic Dosing of Opioid Analgesics Conversion from one dosage form to another or from one opioid to another might be necessary in situations such as ineffective pain control, emergence of side effects, change in patient

status, and in formulary restrictions. **5** *Equianalgesic doses should be used when converting from one opioid to another.*

Clinicians should be familiar with the equianalgesic dosing and conversion strategies to avoid analgesic failure. Equianalgesic tables serve as a guide for selection of the dosage of the new opioid, but they have limitations because they are often based on single-dose studies and clinical observations.⁵⁰ Opioid potency is compared using a reference standard of 10 mg parenteral morphine. Switching from one dosage form to another of the same opioid (i.e., IV to oral) is relatively simple. The current total daily dose is calculated and the total of the new dosage form is determined using a ratio of the equianalgesic doses. This result is then adjusted based on the usual dosing frequency of the new form. When converting to a sustained-release form of the same opioid, dosage may be reduced by 25% to avoid initial sedation; however, the specific product literature should also be consulted.

The first step in an opioid rotation is to calculate the patient's total daily dose of opioid based on the regularly scheduled dose and the total amount of rescue dose needed in 24 hours. This total is then converted to morphine-dosing equivalents using equianalgesic doses (Table 34–2). The total daily morphine dose is then used to calculate the daily dose of the new opioid using dosing equivalents from an equianalgesic table. Because cross-tolerance may not be complete between opioids, some references suggest that the calculated equianalgesic dose be reduced by 25% to 50%.⁵⁰ If the opioid switch is due to uncontrolled pain, a dosage reduction may not be needed. The calculated equianalgesic dose may need to be reduced more in the medically frail and when converting to methadone.^{51,52} Methadone appears to be much more potent than once believed, and morphine-to-methadone ratios vary according to the total dose of morphine taken at the time of making the conversion to methadone (Table 34–4).^{53,54} Conversion to methadone is a complex process, and several different strategies have been proposed including a switch of the entire dose in 1 day or a gradual conversion over 3 days.

► Adjuvant Agents for Chronic Pain

The role of NSAIDs and opioids in chronic nonmalignant pain has been discussed; however, a review of adjuvant agents

Patient Encounter, Part 2

Following surgery MA was placed on morphine patient-controlled analgesia (PCA). She has been using 80 mg of morphine/24 hours with adequate pain control; however, she has developed redness and itching on her neck that was believed to be due to the morphine.

Current medications: Morphine PCA, lisinopril 20 mg daily, metformin 500 mg three times daily, Lovenox 30 mg subcutaneously daily, until ambulating. She will be discharged to a skilled nursing facility for rehabilitation therapy.

The physician would like to convert her to a combination preparation of oxycodone and APAP.

What dosing regimen would you suggest?

Recommend a monitoring plan for this patient.

How would you assess pain response?

The patient is concerned about the redness and itching she developed while on morphine. What other interventions or education may be necessary at this time?

Table 34–4

Methadone Dose Conversions

Total Daily Dose of Oral Morphine	Morphine:Methadone Factor
Less than 100 mg	3:1 3 mg morphine:1 mg methadone
101–300 mg	5:1
301–600 mg	10:1
601–800 mg	12:1
801–1,000 mg	15:1
More than 1,000 mg	20:1

Data from Ripamonti C, Bianchi M. The use of methadone for cancer pain. *Hematol Oncol Clin North Am* 2002;16:543–555.

Patient Encounter, Part 3

MA was discharged to a skilled nursing facility and is receiving physical therapy and occupational therapy 6 days each week.

Current medications: Lisinopril 20 mg daily; metformin 500 mg three times daily; Lovenox 30 mg subcutaneously daily, until ambulating; hydrocodone/acetaminophen 5/325 mg q 6 h as needed for pain.

Pain Assessment: Patient reports pain of 7 out of 10; worse with movement.

Physical therapy notes indicate patient is unable to complete therapy goals due to complaints of pain.

Based on this information, what would you recommend as the consultant pharmacist to optimize pain control?

for chronic pain, particularly neuropathic pain, is warranted. Adjuvant analgesics are drugs that have indications other than pain but are useful as monotherapy or in combination with nonopioids and opioids. Common adjuvants include antiepileptic drugs (AEDs), antidepressants, antiarrhythmic drugs, local anesthetics, topical agents (e.g., capsaicin), and a variety of other drugs (e.g., NMDA antagonists, clonidine, and muscle relaxants).

There is little consensus on the optimal management of neuropathic pain because much of the evidence for treatment effectiveness consists of anecdotal reports or poorly designed trials. Published guidelines have been suggested for the general management of neuropathic pain.⁵⁵ Suggestions for first-line therapy include gabapentin or pregabalin, transdermal lidocaine, or tricyclic antidepressants (TCAs) (Table 34–5).^{55–59} Newer antidepressants, such as the SSRIs, have fewer side effects but appear to be less effective than the TCAs for neuropathic pain. However, serotonin-norepinephrine reuptake inhibitors (SNRIs), (e.g., duloxetine and venlafaxine) have been used successfully for painful DPN. A stepwise approach is suggested for managing the patient with neuropathic pain beginning with the least invasive, effective therapeutic choice and proceeding to the rational use of multiple drug regimens. To guide the choice of pharmacologic agents, patients might be identified as candidates for AEDs, TCAs, or opioids based on the presence of peripheral or central nerve pain and description of symptoms (Fig. 34–2). Choice of agent might also depend on dosing frequency and comorbidities. Data on combination therapy are lacking, and the use of combined treatment is empirical based on the additive therapeutic benefit. Scheduled medication regimens instead of “as-needed” dosing should be used when treating chronic pain, and the effectiveness of therapy should be reassessed regularly. If patients are managed on a multiple drug regimen and changes are indicated, changing only one drug at a time is suggested. Topical agents (e.g., capsaicin) might be added to a regimen to reduce the oral medication load, particularly if adverse effects are a problem or if pain is not relieved.

Table 34–5

Selected Adjuvant Analgesics and Suggested Dosing

Agent	Dosing Guidelines	FDA-Approved Indication
Amitriptyline (Elavil)	10–25 mg at bedtime with weekly increments to a target dose of 25–150 mg of amitriptyline or an equivalent dose of another TCA	
Duloxetine (Cymbalta)	DPN: 60 mg daily Fibromyalgia: 30 mg daily, may be increased by 30 mg increments to a maximum of 120 mg daily	DPN, fibromyalgia
Gabapentin (Neurontin)	Initially, 300 mg three times a day up to a maximum of 3,600 mg daily, in divided doses ^a	PHN
Pregabalin (Lyrica)	DPN: Initially, 50 mg three times a day; may be increased to 100 mg three times a day within 1 week based on efficacy and tolerability ^a PHN: Initially 75 mg twice a day or 50 mg three times a day; may be increased to 100 mg three times a day within 1 week based on efficacy and tolerability ^a Fibromyalgia: Initially 75 mg twice a day, increase to 300 mg daily over 7 days	DPN, PHN, and fibromyalgia
Lidocaine 5% (Lidoderm patch)	Up to 3 patches may be applied directly over the painful site once daily; patches are applied using a regimen of 12 hours on and 12 hours off	PHN

DPN, diabetic peripheral neuropathy; PHN, postherpetic neuralgia; TCA, tricyclic antidepressant.

^aDosing for creatinine clearance of ≥ 60 mL/min (1.0 mL/s).

Data from Refs. 54–58.

► Complementary and Alternative Medicine

Complementary and alternative medicine (CAM) is a term used to encompass a variety of therapies (e.g., acupuncture, chiropractic, botanical, and nonbotanical dietary supplements, and homeopathy). Painful conditions are among the most common reasons individuals seek relief from CAM. In a recent survey, neck pain, joint pain, arthritis, and headache were among the top 10 reasons for use of CAM, and low back pain ranked the number-one reason for CAM therapies. Of the CAM therapies, chiropractic and acupuncture are the most accepted and used modalities. A variety of dietary supplements have been suggested for painful conditions such as S-adenosylmethionine (SAM-e), ginger, fish oil, feverfew,

Patient Encounter, Part 4

MA has been at the skilled nursing facility for 3 weeks and is making progress toward rehabilitation goals. She is walking with a walker almost 200 feet (61 m); however, she complains that her feet feel “very heavy” and feel like pins and needles. As a result, she requests to rest several times during her therapy sessions. During unit rounds, her therapist inquires whether her previous pain medication should be reordered.

Pain Assessment: 0 out of 10

Current Medications: Lisinopril 20 mg daily; metformin 500 mg three times daily; Lovenox 30 mg subcutaneously daily, until ambulating

What additional recommendations would you have at this time regarding pain management?

Are there any other therapeutic issues that should be addressed?

γ -linoleic acid, glucosamine, and chondroitin. Of these, glucosamine and chondroitin are the most popular and have the most evidence supporting their efficacy. Glucosamine in doses of 1,500 mg/day has been shown to be effective in reducing the pain of osteoarthritis by fostering repair of cartilage, and it is recommended by the Osteoarthritis Research Society International (OARSI).³⁹

Patient Care and Monitoring

1. Identify the source of pain.
2. Assess the level of pain using a pain intensity scale.
3. Base the initial choice of analgesic on the severity and type of pain, as well as on the patient's medical condition and concurrent medications.
4. Use the least potent oral analgesic that provides adequate pain relief and causes the fewest side effects.
5. Titrate the dose to one that achieves an adequate level of pain control.
6. Use a dosing schedule versus as-needed dosing.
7. Assess the patient for analgesic effectiveness and for side effects at each visit or more frequently, depending on the acuity of the patient's condition.
8. Avoid excessive sedation.
9. Adjust the route of administration if the patient is unable to take oral medications.
10. Use equianalgesic doses as a guide when switching opioids.

OUTCOME EVALUATION

Individualize the treatment goals at the beginning of treatment. Use information obtained during the pain interview to create goals that are consistent with the patient's expectations. Prevention, reduction, and/or elimination of pain are important goals for the treatment of acute pain. With chronic pain, elimination of pain might not be possible, and goals might focus on improvement or maintenance of functional capacity and quality of life. Thus, for example, pain goals might include “pain scale less than 3,” or “be able to play a game with grandchildren,” or “be able to knit again.” Assess patients periodically, depending on the method of analgesia and pain condition, for achievement of pain goals. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.

Abbreviations Introduced in This Chapter

AED	Antiepileptic drug
AGS	American Geriatrics Society
AHRQ	Agency for Healthcare Research and Quality
AMPA	α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid
APAP	Acetaminophen
APS	American Pain Society
ASA	American Society of Anesthesiologists
CAM	Complementary and alternative medicine
CHF	Congestive heart failure
COX	Cyclooxygenase
CRPS	Complex regional pain syndrome
CYP	Cytochrome P450 enzyme
DPN	Cytochrome P450 enzyme
GABA	γ -Aminobutyric acid
HIV	Human immunodeficiency virus
HTN	Hypertension
IASP	International Association for the Study of Pain
IM	Intramuscular
JCAHO	Joint Commission on Accreditation of Healthcare Organizations
MI	Myocardial infarction
NMDA	<i>N</i> -methyl- <i>D</i> -aspartate
NSAID	Nonsteroidal anti-inflammatory drug
OARSI	Osteoarthritis Research Society International
PAINAD	Pain Assessment in Advanced Dementia (tool)
PCA	Patient-controlled analgesia
PHN	Postherpetic neuralgia
PQRST	Palliative/precipitating, Quality, Radiation, Severity, and Time
SAM-e	<i>S</i> -adenosylmethionine
SNRI	Serotonin-norepinephrine reuptake inhibitor
SSRI	Selective serotonin reuptake inhibitor
TCA	Tricyclic antidepressant
TENS	Transcutaneous electrical nerve stimulation
VAS	Visual analog scale
VHA	Veterans Health Administration
WHO	World Health Organization

Headache

Leigh Ann Ross and Brendan S. Ross

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Differentiate types of headache syndromes based on clinical features.
2. Recommend nonpharmacologic measures for headache treatment and prevention.
3. Determine when the pharmacologic treatment of headache is indicated.
4. Construct individualized treatment regimens for the acute and chronic management of headache syndromes.
5. Monitor headache treatment to ensure its safety, tolerability, and efficacy.

KEY CONCEPTS

- 1 Headache may be a primary condition or a secondary one arising from an underlying medical disorder.
- 2 Most primary headache syndromes are benign and can be classified as migraine, tension-type, or cluster.
- 3 Tension-type headache is the most prevalent and can be episodic or chronic.
- 4 Migraine headache can be further classified as with or without aura.
- 5 The short-term goal of headache treatment is pain relief; the long-term goal is preventing recurrence.
- 6 The pharmacologic treatment of headache should be provided promptly to improve response to therapy.
- 7 Several clinical markers, so-called red flags, have been identified that warrant urgent physician referral and further diagnostic evaluation.
- 8 Prophylactic treatment is indicated if headaches are frequent, severe, or require the use of pain relievers two or more times per week.
- 9 Treatment regimens should be individualized: based on the pattern of occurrence, response to therapy, medication tolerability, and comorbid medical conditions.

INTRODUCTION

Headache is a common medical complaint associated with significant quality of life and economic issues. 1 *Even when persistent or recurrent, headaches are usually a benign primary condition; secondary headaches are caused by an*

underlying medical disorder and may be medical emergencies. Primary headache syndromes are the focus of this chapter. Patients may seek headache care from multiple providers. All clinicians should be familiar with the various types of headache, clinical indicators suggesting the need for urgent medical attention or specialist referral, and nonpharmacologic and pharmacologic options for treatment. 2 *The International Headache Society (IHS) classifies primary headaches as migraine, tension-type, or cluster and other trigeminal autonomic cephalalgias.*¹ Tension-type headaches (TTHs) are more common than migraine, and both are more common in women than men. Cluster headache is a much less common chronic headache syndrome that affects predominantly men.

EPIDEMIOLOGY OF HEADACHE DISORDERS

Migraine Headache

Migraine is a primary headache disorder that is estimated to affect 10% to 15% of adults in the United States.² Less than one-half of headaches meeting the diagnostic criteria for migraine are appropriately diagnosed. Migraine runs in families, and its prevalence depends on age and gender. In children younger than 12 years of age, migraines are more prevalent in males. At puberty, this prevalence shifts markedly to women. This change in gender distribution is thought to be due to the hormonal changes of menarche.³ Onset typically occurs between the ages of 10 and 30 years, but the prevalence is greatest between the ages of 35 to 45 years.⁴ Migraines can significantly impact function; more than one-half of patients report symptoms necessitating bed rest during an attack.

Migraines are the leading cause of employee absenteeism and decreased workplace productivity.⁵

Tension-Type Headache

3 *TTH is the most common primary headache disorder and can be further divided into episodic or chronic.* TTHs are underrepresented in clinical practice because most patients do not present for care.⁶ The term *TTH* is used to describe all headache syndromes in which sensitization to pericranial **nociception**, noxious stimuli, is the most significant factor in the pathogenesis of pain. The 1-year prevalence of TTH in the United States ranges from 30% to 90%.⁶ Such headaches are more common in adult females. Environmental factors, as opposed to genetic predisposition, play a central role in the development of TTH. The mean frequency of attacks is 3 days per month in episodic disorders; chronic TTH is defined as 15 or more attacks in a 1-month period.⁷ The estimated prevalence of chronic TTH is less than 5%.⁶ Some researchers believe that chronic TTH represents a continuum of headache severity with migraine headache.⁸ When severe headaches are difficult to differentiate clinically, treatment should initially target TTH.

Cluster Headache and Other Trigeminal Autonomic Cephalgias

Cluster headache disorders are the most uncommon and severe primary headache syndromes.⁹ The estimated point prevalence is less than 0.5% to 1%. Unlike migraine and TTH, cluster headaches are more frequently found in men. Onset most commonly occurs prior to age 30 years.⁶ A genetic predisposition is apparent, although affected individuals often provide the additional history of tobacco use and alcohol abuse.⁶ Attacks consist of debilitating, unilateral head pains that occur in series lasting up to months at a time but remit over months to years between occurrences. In rare instances, cluster headache can be a chronic disorder without remission.⁴

ETIOLOGY AND PATHOPHYSIOLOGY OF HEADACHE DISORDERS

Migraine Headache

The exact mechanism by which migraines produce headache remains obscure, but the belief that only vascular changes are responsible for the pain is no longer accepted.¹⁰ The vascular hypothesis suggested that intracerebral vasoconstriction led to neural ischemia, which was followed by reflex extracranial vasodilation and pain. Negative neuroimaging evidence for such vascular changes and the effectiveness of medications with no vascular properties make this contention untenable.⁶ A neuronal etiology has emerged as the leading mechanism for the development of migraine pain.¹¹ It is believed that depressed neuronal electrical activity spreads across the brain, producing transitory neural dysfunction.¹² Headache pain is likely due to compensatory overactivity in the trigeminovascular system of the brain. Activation of trigeminal sensory

nerves leads to the release of vasoactive neuropeptides (e.g., calcitonin gene-related peptide [CGRP], neurokinin A, substance P) that produce a sterile inflammatory response around vascular structures in the brain, provoking the sensation of pain.¹¹ Continued sensitization of CNS sensory neurons can potentiate and intensify headache pain as an attack progresses.¹² Bioamine pathways projecting from the brainstem regulate activity within the trigeminovascular system. The pathogenesis of migraine is most likely due to an imbalance in the modulation of nociception and blood vessel tone by serotonergic and noradrenergic neurons.¹³

Tension-Type Headache

The pathophysiologic mechanisms producing TTHs are not clearly understood and are likely multifactorial. However, central sensitization to peripheral nociceptive input arising from the pericranial myofascia is the leading hypothesis. The belief that sustained muscle contraction is solely responsible for generating the pain cannot be supported. Muscle tenderness is prominent in this syndrome, but it only reflects a heightened sensitivity to pain. TTH pain is believed to arise by disturbances in the muscles and tissues of the head being misinterpreted due to disordered CNS pain processing.¹⁴ Repetitive pain transmission from peripheral structures may be responsible for the evolution from episodic to chronic TTH.¹⁵

Clinical Presentation and Diagnosis of Migraine Without Aura

Patients experiencing “migraine without aura” may display the following headache symptoms and characteristics:

Two or more of the following are present:

1. Pain interrupts or worsens with physical activity
2. Unilateral pain
3. Pulsating pain
4. Moderate to severe pain intensity

Two or more of the following are present during headache:

1. Nausea
2. Vomiting
3. **Photophobia**
4. **Phonophobia**
5. **Osmophobia**

Duration: 4 to 72 hours (treated or not treated)

Criteria for diagnosis: Five or more attacks fulfilling above criteria are necessary

Laboratory assessments that may be helpful in excluding medical comorbidities: Complete blood count (CBC), chemistry panel, thyroid function tests (TFTs), erythrocyte sedimentation rate (ESR)

Clinical Presentation and Diagnosis of Migraine With Aura

Patients experiencing “migraine with aura” may display the following headache symptoms and characteristics:

One or more of the following present with no motor weakness:

1. Visual symptoms (positive and/or negative; reversible)
2. Sensory symptoms (positive and/or negative; reversible)
3. Dysphasic speech (reversible)
4. Moderate or severe pain intensity

Two or more of the following:

1. Homonymous visual symptoms and/or unilateral sensory symptoms
2. One aura symptom develops at least 5 minutes prior and/or a second aura symptom develops in 5 minutes or more after headache starts
3. Duration of each symptom 5 to 60 minutes

Criteria for diagnosis: Two or more attacks fulfilling above criteria are necessary

Clinical Presentation and Diagnosis of Tension-Type Headache

Patients experiencing TTH may display the following headache symptoms and characteristics:

Two or more of the following present:

1. Bilateral pain
2. Nonpulsating pain
3. Mild or moderate pain intensity

Both of the following:

1. No nausea or vomiting (anorexia possible)
2. Either photophobia or phonophobia (not both)

Duration: 30 minutes to 7 days

Criteria for diagnosis: 10 or more attacks fulfilling above criteria occurring on average less than 1 day per month are necessary

Clinical Presentation and Diagnosis of Cluster Headache

Patients experiencing “cluster headache” may display the following headache symptoms and characteristics:

1. Unilateral pain
2. Orbital, supraorbital, or temporal pain
3. Sharp and stabbing pain

One or more of the following present:

1. Conjunctival injection and/or lacrimation
2. Nasal congestion and/or rhinorrhea
3. Eyelid edema

Duration of pain: 2 seconds to 10 minutes

Frequency of attacks: One or more per day more than half of the time

Criteria for diagnosis: 20 or more attacks fulfilling above criteria are necessary

to be the result of vasoactive neuropeptide release and neurogenic inflammation. The exact cause of trigeminal activation in this intermittently manifest syndrome is unclear.⁹ One hypothesis is that hypothalamic dysfunction, occasioned by diurnal or seasonal changes in neurohumoral balance, are responsible for headache periodicity.⁶ Serotonin affects neuronal activity in the hypothalamus and trigeminal system and may play a role in the pathophysiology of cluster headache. The precipitation of cluster headache by high-altitude exposure also implicates hypoxemia in the pathogenesis of trigeminal autonomic cephalalgias.¹⁷

CLINICAL PRESENTATION OF HEADACHES

Migraine Headache

Migraine presents as a recurrent headache that is severe enough to interfere with daily functioning. **4** *Migraine headaches are classified as migraine with aura and migraine without aura.*⁶ The correlative terms of “classic” and “common” migraine are no longer used. Aura is defined as a transient focal neurologic symptom that can be positive or negative and can occur prior to or during an attack.¹⁸ Examples of positive symptoms include the visual perception of flickering lights, spots, or wavy lines; the partial loss of vision, called a **scotoma**, is considered a negative finding. The IHS outlines diagnostic criteria that differentiate migraine with and without aura. The pain of a migraine headache is typically described as moderate to severe, throbbing, unilateral, and retroorbital in location.⁶ The pain can be accompanied by nausea, sensitivity to light and sound, and difficulty concentrating.¹⁹ Migraines can be triggered by hormonal, emotional, or environmental factors. Menstrual migraines,

Cluster Headache and Other Trigeminal Autonomic Cephalalgias

Cluster headache is one of a group of disorders referred to as trigeminal autonomic cephalalgias.¹⁶ This autonomic nervous system dysfunction is characterized by sympathetic underactivity coupled with parasympathetic activation. Similar to migraine, the pain of a cluster headache is believed

headaches precipitated by stress or sleep disorders, and pain due to exposures to noxious odors or extremes of weather are well recognized. Untreated migraines can last from 4 to 72 hours. Migraines occurring 15 or more days per month for a 3-month period or longer, without the overuse of analgesic medications, are classified as chronic migraines.⁶ Severe and debilitating migraine pain lasting more than 72 hours is termed status migrainosus.¹⁹ Even in the absence of neurologic focality, brain imaging is mandated in patients with frequent, severe, and prolonged attacks or attacks that are atypical for a migraine patient's stereotyped presentation.²⁰

Tension-Type Headache

- TTH pain differs from migraine pain in that it is usually reported to be mild to moderate in severity, nonpulsating, and bilateral.⁶ The pain is described by sufferers as a band-like tightness or pressure around the head. No transient neurologic deficits are noted, and systemic symptoms are rare.⁴ TTHs infrequently disrupt normal activity. Muscle tenderness in the frontotemporal and parietooccipital regions is a common finding on physical examination.⁴ Neuroimaging and laboratory testing are unrevealing, and such tests are usually unnecessary if the presentation and clinical history is classic for TTHs.

Cluster Headache

- Pain associated with cluster headache differs from migraine and TTH in that it is severe, intermittent, and short in duration.⁶ Headaches typically occur at night, but attacks may occur multiple times per day.⁹ The pain is usually unilateral, but, unlike migraine, it is not described as pulsatile.⁶ Aura is not a feature, and pain intensity peaks early after onset, although it may persist for hours.⁶ The headache is described as explosive and excruciating. A constellation of

features, ascribed to parasympathetic overactivity, can be seen, such as ipsilateral conjunctival injection and lacrimation, rhinorrhea, and sweating.⁹ Cluster headache patients tend to become excited and restless during attacks, rather than seeking quiet and solitude as in migraine.¹⁶

TREATMENT OF HEADACHE DISORDERS

Desired Outcomes

- **5** *The short-term treatment goal of migraine is to achieve rapid pain relief to allow the patient to resume normal activities.²¹ The long-term goal of therapy is to prevent headache recurrences and to diminish headache severity.* Similarly, the goal of TTH care is to lessen headache pain, whereas the long-term goal is to avoid analgesic overuse and dependence.²² The short-term therapeutic goal in cluster headache is to achieve rapid pain relief. Prophylactic therapy may be necessary to obtain the intermediate-term outcome of reducing the frequency and severity of headaches within a periodic cluster series, as well as to achieve the long-term goal of delaying or eliminating recurrent periods.²³

General Approach to Treatment

The most important goal of acute headache management is pain relief. First-line pharmacologic agents include nonsteroidal and opiate analgesics, and serotonin-receptor agonists (triptans).²⁴ Despite the availability of targeted prescription therapies, most headache patients rely on over-the-counter (OTC) products for pain relief and so are not treated adequately.²⁵ **6** *Pharmacologic treatment of acute headache should be started early to abort the intensification of pain and to improve response to therapy.* The long-term management of headache syndromes focuses on lifestyle modification and other nonpharmacologic therapeutic options; if headaches are severe and frequent, then prophylactic pharmacologic therapy is needed.²⁶ **7** *Several clinical markers, so-called red flags, have been identified that warrant urgent physician referral and further diagnostic evaluation (Table 35-1).*

Patient Encounter, Part 1

A 48-year-old man complains of "almost daily" headaches that make it difficult to work. He describes his pain as dull, bilateral, and steady, "like a tight cap." His headaches are not associated with visual changes or GI distress. Previously, his pain had responded to OTC analgesics. Lately, he has had to take acetaminophen or aspirin in combination with daily caffeine to obtain relief.

What type of headache is the patient most likely experiencing?

What characteristics of the headache support this diagnosis?

What are possible causes or triggers of headache in this patient?

What additional information is needed to formulate a treatment plan?

Table 35-1

Headache "Red Flags" Indicating Need for Urgent Medical Evaluation

- New-onset sudden and/or severe pain
- Onset after 40 years of age
- Stereotyped pain pattern worsens
- Systemic signs (e.g., fever, weight loss, or accelerated hypertension)
- Focal neurologic symptoms (i.e., other than typical visual or sensory aura)
- Papilledema
- Cough-, exertion-, or Valsalva-triggered headache
- Pregnancy or postpartum state
- Patients with cancer, human immunodeficiency virus (HIV), and other infectious and immunodeficiency disorders
- Seizures

Nonpharmacologic Therapy

The successful management of headache disorders depends on comprehensive patient education. Recording headache frequency, duration, and severity in a “headache diary” provides beneficial information for the patient regarding headache precipitants and useful insights for the clinician selecting appropriate management strategies.²⁷ To prevent future occurrences, exposure to headache triggers (Table 35–2) should be limited. In the acute setting, environmental control can lessen the severity of an attack, so patients may benefit from resting in a dark, quiet area.²⁸ Behavioral interventions, such as biofeedback, relaxation therapy, and cognitive-behavioral training, are effective and can be recommended for headache prevention.¹⁷ Headache sufferers may also benefit from stress management training.¹⁷ Acupuncture has yielded inconsistent benefits in clinical trials.²² Although the response is variable, headache patients should be advised to moderate alcohol use and curtail tobacco abuse.²³ Emotional distress may compound headache pain through the outward displacement of inner conflicts: somatization. Psychological interventions

Table 35–2

Migraine Triggers

Behavioral:

Fatigue
Menstruation or menopause
Sleep excess or deficit
Stress
Vigorous physical activity

Environmental:

Flickering lights
High altitude
Loud noises
Strong smells
Tobacco smoke
Weather changes

Food:

Alcohol
Caffeine intake or withdrawal
Chocolate
Citrus fruits, bananas, figs, raisins
Dairy products
Fermented or pickled products

Food containing:

Monosodium glutamate (MSG): Asian food, seasoned salt
Nitrites: processed meats
Saccharin/aspartame: diet soda or diet food
Sulfites: shrimp
Tyramine: cheese, wine, organ meats
Yeast: breads

Medications:

Cimetidine
Estrogen or oral contraceptives
Indomethacin
Nifedipine
Nitrates
Reserpine
Theophylline
Withdrawal due to overuse of analgesics, benzodiazepines, decongestants, or ergotamines

Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH: Hypertension (HTN); gastroesophageal reflux disease (GERD); dyslipidemia

FH: Father living, age 77 years: HTN, diabetes mellitus; mother living, age 72 years: “sinus” headaches; two sisters in good health

SH: Recently divorced; general contractor; smoker; “social” alcohol intake (one to two beers per day, more on weekends), four to six cups of coffee per day

Med: Hydrochlorothiazide/triamterene 50/25 mg orally per day; esomeprazole 20 mg orally twice daily; rosuvastatin 20 mg orally once daily; naproxen 220 mg, two tablets orally twice daily as needed for headache, or OTC headache “powders”

ROS: Headache, moderate intensity, no sensitivity to light or sound; no dizziness; no chest pain or palpitations; no shortness of breath with exertion; pyrosis without dysphagia; no weakness or joint discomfort

PE:

VS: BP 154/72, P 85, RR 18, T 37.0°C (98.6°F) oral

HEENT: No papilledema, neck tender without stiffness, bitemporal muscle tenderness

CV: RRR, normal S1, S2, S4 gallop, no MR

Chest: CTA

Abd: Benign, bowel sounds positive

Neuro: Nonfocal

Labs: CBC and chemistry panel within normal limits

What is your assessment of this patient's condition?

What medical comorbidities or drug therapies may be contributing to his distress?

Identify treatment goals for this patient.

What nonpharmacologic options are needed at present, and what options are appropriate in the long term?

What pharmacologic therapy would you recommend in the acute setting?

Does this patient require long-term pharmacologic prophylaxis against recurrent headaches?

are urged in such instances and should be considered in all headache sufferers resistant to standard medication treatments.²⁹ All such nonpharmacologic therapies may be useful in augmenting pharmacologic response.

Pharmacologic Therapy

► Migraine

Analgesics, such as nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen, with or without an opioid,

are the initial pharmacologic option for the acute management of migraine headache. If these analgesics prove to be ineffective, then migraine-specific medications, such as triptans, are administered.³⁰ Early, abortive treatment should be the rule. If the orally administered route is selected for medication administration, then larger doses than otherwise required to produce pain relief may need to be provided, due to the enteric stasis and poor drug absorption accompanying migraine attacks.²⁰ Intranasal, parenteral, and rectal administration can circumvent this complication.

Clinical trial evidence supports many NSAID medications in the acute treatment of migraines with and without aura.³⁰ Acetaminophen alone or in proprietary combinations with aspirin, opioids, caffeine, or the barbiturate butalbital is also effective.²⁸ Although deemed to have a benign adverse effect profile on gastric mucosal integrity and renal blood flow, overwhelming clinical experience supports the observation that the overuse of acetaminophen may lead to tolerance or dependence clinically manifested as acute withdrawal headaches.³¹ These so-called “rebound” headaches are the result of poor attention to prevention therapies and thus the chronic use of daily short-acting analgesics.³² Proprietary fixed-dose combinations of anti-inflammatories with oral triptans may facilitate proper care.

The triptans are considered specific therapies in that they target the pathophysiology underlying migraine.³³ They abort headache through beneficial effects on neuronal imbalances.¹¹ Triptans inhibit neurotransmission in the trigeminal complex and activate serotonin 1B/1D pathways in the brainstem, which modulate nociception. They also decrease the release of vasoactive neuropeptides leading to vascular

reactivity and pain.³⁴ The triptans are available in intranasal, subcutaneous, and oral dosage forms. The available agents differ in their dosing and pharmacokinetic properties, but all are effective treatments to abort or diminish migraine headache (Table 35-3).⁴³ Patient responses can be variable; if a patient does not respond to one agent, then another is selected before a patient is prematurely labeled as triptan-unresponsive.⁴⁴ The initial severity of headache correlates with symptomatic response; thus administration should be prompt. Relief is usually experienced within 2 to 4 hours. Treatment delay may lead to decreased analgesia through the development of refractory central pain sensitization. Efficacy tends to be dose related, although adverse effects are less so.⁴⁵ These medications are well tolerated; the most common side effects are dizziness, a sensation of warmth, chest fullness, and nausea. Rarely, ischemic vascular events may be precipitated by the potential vasoconstrictive nature of these drugs.³⁴ An initial dose under direct practitioner supervision is indicated for patients at increased cardiovascular risk. Triptans are avoided in patients with migraine associated with neurologic focality, a history of previous stroke, poorly controlled hypertension, or unstable angina. Triptans are relatively contraindicated for routine use in pregnancy.³⁰ Triptans should not be used with concurrent ergotamine administration.³⁴

Ergotamine derivatives produce salutary effects on serotonin receptors similar to triptans. They also impact adrenergic and dopaminergic receptors. Ergotamine tartrate and dihydroergotamine (DHE) are the most commonly used agents.²⁰ The latter is not available in an oral dosage form. Analgesic onset is within 4 hours, although additional dosing is required if an

Table 35-3

Comparison of Serotonin Receptor Agonists (Triptans)

Medication (Brand Name)	Dosage Forms	Strength (mg)	Usual Dosage (mg)	May Repeat in (hours)	Potential Drug Interactions
Almotriptan (Axert)	Oral tablets	6.25 12.5	6.25–12.5		Ergot derivatives
Eletriptan (Relpax)	Oral tablets	20 40	20–40		Substrate: CYP 3A4, CYP 2D6; ergot derivatives
Frovatriptan (Frova)	Oral tablets	2.5	2.5	2	Substrate: CYP 1A2; ergot derivatives

CYP, cytochrome P450 enzyme; MAO-A, monoamine oxidase type A.

Data from Refs. 35–42.

acceptable response is not achieved. When dosed parenterally, these drugs are usually provided with an antiemetic, due to their potential to worsen the nausea associated with migraine. Metoclopramide and chlorpromazine are the drugs of choice in such instances. Intranasal DHE can be self-administered to abort an attack.²⁰ The outpatient use of subcutaneous ergotamines is limited by the lack of a prefilled syringe form. The same cautions associated with triptan use are also applicable to ergot use in patients at risk for vascular events.

The choice of initial therapy for acute migraine attacks is a subject of debate among specialists.⁴⁶ Some believe that nonspecific analgesics should be used first-line, whereas others believe migraine-specific drugs should be the choice for patients with severe pain or a history of significant disability.⁴⁷ A stepped-care approach within attacks from less to more specific drugs is usually recommended. Once a history of headache refractory to common analgesics is established, triptans should be used as initial therapy. In patients who present to the hospital with intractable pain, IV metoclopramide supplemented with DHE may be needed. Oral medications in this setting are not used because nausea and vomiting limit their bioavailability. Migraine patients with frequent and severe attacks are candidates for prophylactic treatment.

► Tension-Type Headache

Most individuals who experience episodic TTHs will not seek medical attention.²² Instead, they will find relief with the use of widely available OTC analgesics. Acetaminophen products and NSAIDs are commonly utilized. An individual patient may benefit from topical analgesics (e.g., ice packs) or physical manipulation (e.g., massage) during an acute attack, but the evidence supporting nonpharmacologic therapies is inconsistent.⁶

Relaxation techniques can often reduce headache frequency and severity. When pain is unrelieved, prescription-strength NSAID use is required, or the combination of acetaminophen with an opioid analgesic may be necessary. The frequent use of these more potent analgesics should be limited, so that the development of dependency is prevented. Use for more than 2 days per week suggests the need for prophylactic therapy.⁴⁸ In sufferers who do not seek medical attention but rely on the frequent use of unprescribed analgesics, medication-overuse headache (MOH) may supervene. This secondary syndrome of chronic daily headaches requires physician referral to desensitize patient-initiated analgesic tolerance and dependence; weaning analgesics through the use of tricyclic antidepressant (TCA) coprescribing is usually helpful.⁴⁹

► Cluster Headache

Cluster headache responds to many of the treatment modalities used in acute migraine; however, initial prophylactic therapy is required to limit the frequency of recurrent headaches within a periodic series. A therapy specific to cluster headaches is the administration of high-flow-rate oxygen: 100% at 5 to 10 L/min by nonrebreather face mask for approximately 15 minutes.⁵⁰ If the pain is not aborted, retreatment is indicated. No long-term side effects are seen with short-term

oxygen use. If oxygen therapy is not wholly effective, then drugs are useful adjunctive therapy. Drug therapy is also used when supplemental oxygen is not readily available. The triptan class is safe and effective. Intranasal or subcutaneous sumatriptan has demonstrated efficacy in decreasing cluster headache pain.⁵¹ Oral triptans are also effective, but their delayed onset of action may limit their applicability in acute cluster headache treatment.⁵² Cluster headache is rapid in onset and achieves peak intensity quickly, but it can be of short duration. Oral agents may have utility in limiting the recurrence of cluster attacks. Intranasal, intramuscular, or IV ergotamine agents are an alternative to triptan use.⁶ Repeated dosing may break a cluster series. For those patients in whom triptans and ergotamine derivatives are contraindicated due to ischemic vascular disease, octreotide may be helpful to relieve pain.⁵³ Octreotide is a somatostatin analogue that has a short half-life and may be administered subcutaneously. Unlike the other abortive agents, it has no vasoconstrictive effects; the most prominent treatment emergent adverse effect is GI upset. Glucocorticoids, provided IV and later tapered orally, are effective when cluster headache attacks are not satisfactorily controlled.⁹

Pharmacologic Therapy for Headache Prophylaxis

8 *Prophylaxis for headache disorders is indicated if headaches are frequent or severe, if significant disability occurs, or if pain-relieving medications are used two or more times per week.*

► Migraine Prophylaxis

Migraine headaches that are severe, frequent, or lead to significant disability require long-term medication therapy. Prophylactic therapy is also recommended for migraines associated with neurologic focality because it may prevent permanent disability. Although multiple medication classes have garnered FDA labeling for migraine prevention, there is no consensus on the best initial therapy (Table 35-4).

9 *The choice of pharmacologic agent is individually tailored to patient tolerability and medical comorbidities.*

The β -blockers propranolol and timolol are FDA approved for migraine prophylaxis, but others in the class are also as effective.⁵⁷ Cautious dosage titration is advised for those patients who do not have other indications for β -blocker use. Rizatriptan interacts with propranolol, and thus dosages must be downward titrated, or another triptan should be chosen for abortive therapy.⁴⁴ Comorbid reactive airway disease is a relative contraindication to β -blocker prophylaxis, and patients with cardiac conduction disturbances should be closely monitored. Calcium channel antagonists are often used when patients cannot tolerate β -blockers. They are purported to beneficially impact aura as well as pain. The different calcium-blocker drugs are variably effective, and none carries an FDA indication. Moreover, even in responsive patients, tachyphylaxis may develop. Renin-angiotensin

Table 35-4

Medications for Prophylaxis of Migraines

Medication (Brand Name)	Usual Dosage (mg/day)	Main Adverse Effects
Antiepileptics:		
Gabapentin (Neurontin)	1,200–2,400	Paresthesias, dizziness, fatigue, nausea
Lamotrigine (Lamictal)	50–200	
Topiramate ^a (Topamax)	50–200	
Valproic acid (Depakene)	500–1,500	
Divalproex sodium ^a (Depakote)	500–1,500	
β-Blockers:		
Atenolol (Tenormin)	50–200	Fatigue, exercise intolerance
Metoprolol (Lopressor)	50–200	
Nadolol (Corgard)	20–160	
Propranolol ^a (Inderal)	80–240	
Timolol ^a (Blocadren)	20–30	
Calcium channel blockers:		
Amlodipine (Norvasc)	2.5–10	Constipation
Verapamil (Calan)	120–320	
Tricyclic antidepressants:		
Amitriptyline (Elavil)	10–150	Weight gain, dry mouth, sedation
Nortriptyline (Pamelor)	10–150	
Ergot alkaloids:		
Ergotamine tartrate (Cafergot)	1	2–6
Methysergide (Sansert)	2–6	
Others:		
Hormones (various)	Varies per agent	25–150
Muscle relaxants (various)	Varies per agent	
Trazodone (Desyrel)	25–150	

^aFDA approved for migraine prophylaxis.

Data from Refs. 54–56.

antagonists have also been noted to decrease headache frequency and severity in migraine sufferers.⁵⁸ Consensus recommendations for hypertension treatment often advocate multidrug regimens to achieve tight control.⁵⁹ Combination therapies with the antihypertensive agents noted earlier are ideal combinations for migraine patients.

Low-dose amitriptyline or other TCAs are of proven efficacy in migraine prevention.²⁷ Due to sedation, these medications are commonly administered at night. The use of later generation tricyclic medications (e.g., nortriptyline) or heterocyclic compounds (e.g., trazodone) decreases the dose-limiting adverse effects of TCAs, especially those attributable to their anticholinergic properties (e.g., dry mouth, constipation, and urinary retention). Whether the various selective serotonin reuptake inhibitors (SSRIs) can yield consistent efficacy in the majority of migraineurs is questionable.²¹ Although they affect serotonin balance in the brain, their utility may be derived from their beneficial impact on mood and anxiety, rather than through serotonergic effects on migraine generation. Concurrent TCA and triptan administration may rarely precipitate the serotonin syndrome, a

serious and potentially life-threatening drug–drug interaction that presents clinically with confusion, GI upset, symptomatic blood pressure (BP) changes, and muscle rigidity.²⁰

The antiepileptics valproic acid and topiramate are approved for migraine prophylaxis. Gabapentin and lamotrigine are anecdotally reported to be efficacious as well. In patients whose migraine headaches are believed to be related to trigeminal neuralgia, carbamazepine is used as prevention for both disorders. The precise mechanism of benefit of these agents is unclear, but enhancement of γ -aminobutyric acid (GABA) neuroinhibition and modulation of the neuroexcitatory amino acid glutamate is likely.⁶⁰ Divalproex sodium doses are gradually titrated to 1,000 mg/day; topiramate is titrated to a maximum of 100 mg twice per day. At these doses, serum drug level monitoring is infrequently needed. These medications are as effective as propranolol at reducing the frequency and severity of migraines and are preferred for prevention in patients intolerant to β -blockers.⁶¹ Topiramate is especially useful in metabolic syndrome, diabetes, and dyslipidemic patients because it is unlikely to lead to the weight gain often seen with valproic acid. Patients prescribed topiramate should be advised to stay well hydrated to prevent dysgeusia, disordered taste, and, more seriously, hyperthermia.

Methysergide is an ergotamine derivative that impacts central serotonin balance. Inflammatory fibrosis is a rare but serious, adverse reaction associated with the prolonged use of methysergide. Retroperitoneal fibrosis, pulmonary fibrosis, or fibrosis in cardiac tissue can occur. These conditions may resolve upon drug withdrawal, but cardiac valvular damage can be irreversible. Some experts believe it is the best choice for refractory migraine with frequent attacks, but due to its significant adverse effect profile, it is not marketed in the United States.⁶²

► Tension-Type Headache Prophylaxis

The prevention of chronic TTHs uses the same pharmacologic strategies as for migraine prophylaxis. TCAs are a mainstay of chronic therapy. The efficacy of serotonergic agonists remains in question. Although there is little need for muscle relaxants (e.g., methocarbamol) in the treatment of acute TTH, they are often provided as a preventive intervention.⁶ Combination prophylactic therapies may be needed to wean patients from daily analgesic abuse. Stress reduction techniques may be particularly effective in this setting. The injection of botulinum toxin into cranial muscles has demonstrated prophylactic efficacy for severe TTHs.⁴⁹

► Cluster Headache Prophylaxis

The calcium channel blocker verapamil is the mainstay of cluster attack prevention and chronic prophylaxis.⁶ Within an attack period, it is dosed at 240 to 360 mg/day. Higher doses may be necessary to stave off recurrent cluster periods. Beneficial effects may be appreciated after 1 week of treatment, but 4 to 6 weeks is usually needed. Adverse effects

Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for the acute and chronic management of this patient's headache. Your plan should include:

1. A statement of the drug-related needs and/or problems
2. The goals of therapy
3. A detailed, patient-specific therapeutic plan
4. A monitoring plan to determine whether the goals have been achieved and adverse effects avoided

include smooth muscle relaxation with the subsequent exacerbation of gastroesophageal reflux and the development of constipation. Caution should be exercised in patients with myocardial disease because verapamil is an inotropic and chronotropic cardiac suppressant. Pharmacokinetic drug-drug interactions must be considered, as verapamil is a potent inhibitor of oxidative metabolism through cytochrome P450 (CYP) enzyme 3A4. Eletriptan is a CYP 3A4 substrate and should not be administered concurrently with verapamil.⁴⁴ Lithium is another effective therapy to reduce headache frequency in a cluster series and to limit recurrences.⁹ The dose administered should be individualized to achieve a low serum concentration (0.4–0.8 mEq/L [mmol/L]). Dose adjustments in the setting of renal disease or congestive heart failure are required.⁶ Lithium is contraindicated in patients concurrently prescribed thiazide diuretics and angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs). Patient persistence with long-term lithium therapy may be hindered by the emergence of tremor, GI distress, and lethargy. Verapamil and lithium doses can be lowered when used in combination with ergotamine. If possible, bedtime dosing is recommended, given the nocturnal predilection of cluster headache attacks.¹⁶

SPECIAL POPULATIONS

Migraine Headache in Children and Adolescents

Migraine headaches are common in children, and their prevalence increases in the adolescent years.^{2,3} The diagnosis and evaluation of headaches is especially difficult in children, given their decreased ability to articulate symptoms. Treatment presents another challenge to the practitioner because medications used for headache management in adults have not been fully evaluated for efficacy and safety in children. Consensus panel recommendations identify ibuprofen as effective and acetaminophen as probably effective in the acute treatment of headache in patients older than 6 years.²⁶ Aspirin use is avoided due to the risk of precipitating Reye's syndrome. Antiemetic therapy can be used alone

or in combination with analgesics; promethazine is usually prescribed, as it is less prone to cause extrapyramidal reactions than other antiemetics. For adolescents older than 12, triptans are effective and are beneficial for abortive migraine therapy.²⁶ Medication prophylaxis for migraines in children and adolescents is understudied. The data are conflicting, and no consensus recommendation for the use of preventive drug therapy exists.²⁶ Nonpharmacologic interventions and trigger identification and avoidance are advised.

Pregnancy

Headaches are more common in women than in men. Fluctuations in estrogen levels are believed to account for this gender discrepancy.⁶³ Hence headaches are common in pregnancy. TTHs predominate; migraine attacks may increase in frequency, but more usually they decrease during pregnancy.⁶⁴ Recommendations for headache care during pregnancy are based on a limited evidence base and largely anecdotal. Because headaches are not associated with fetal harm, reflexive pharmacologic therapy should be avoided and drug treatment choices considered carefully. Standard nonpharmacologic therapies are often sufficient. Acetaminophen is safe for the pregnant woman and her fetus.⁶⁵ NSAIDs are avoided late in the third trimester to prevent detrimental prostaglandin alterations leading to premature ductus arteriosus closure. Opioids are second-line agents and should not be used chronically because they can lead to dependence in the mother and to acute withdrawal in the infant after birth. Centrally acting antiemetic agents are safe and may be useful as adjunctive agents. Corticosteroids may be needed for intractable headache relief. Prednisone and methylprednisone are preferred, as they are metabolized in the placenta and do not expose the fetus. In pregnant women with migraine, vasoconstrictive agents such as triptans are relatively contraindicated, even though maternal registry data reveal little teratogenicity.⁶⁶ Ergot compounds are strictly avoided because they may precipitate uterine contractions and placental ischemia leading to hypoxemia in the fetus. Migraine prophylaxis is considered cautiously because β -blockers and calcium-channel antagonists may lead to maternal hypotension and diminished placental blood flow or fetal bradycardia. Anti-epileptic drug use in this setting has not been sufficiently studied to allow definitive recommendations.

Some headache disorders are specific to the pregnant state. These include postprocedure headache and those associated with preeclampsia. The former are the result of dural puncture with cerebrospinal fluid (CSF) leak after spinal anesthesia and generally respond to bed rest in the supine position.⁶⁷ The latter are seen in the third trimester accompanied by the clinical triad of hypertension, edema, and proteinuria. Preeclamptic headache is believed to result from alterations in cerebral blood flow.⁶⁸ Headaches experienced in preeclamptic women herald eclampsia, and urgent delivery is indicated.⁶⁹ Antihypertensives are administered to prevent intracranial hemorrhage, and prophylactic anticonvulsants are provided to prevent eclamptic seizures.

Patient Care and Monitoring

9 Treatment regimens for headache disorders should be individualized: based on headache type, pattern of occurrence, response to therapy, medication tolerability, and comorbid medical conditions.

1. Assess the patient complaint to yield a detailed description of the headache and to determine if immediate referral for emergency or specialist care is necessary.
2. Obtain a complete medical and social history to identify any potential drug–disease interactions or social factors that may influence treatment choices.
3. Obtain a family medical history, focusing on headache or mental health disorders in first-degree relatives.
4. Complete a review of systems and physical examination to identify causes or complications of headache.
5. Identify medication allergies, and obtain a thorough history of nonprescription and prescription drug use to identify potential drug–drug interactions that may arise when selecting acute and prophylactic headache treatment.
6. Determine the type of headache disorder and rule out acute complications.
7. Recommend appropriate pharmacologic therapy to abort headache based on type, patient characteristics, current medication profile, and comorbid conditions.
8. Educate the patient on the administration, maximum dosage, and anticipated adverse effects of the prescribed medication, and advise the patient when to seek emergency medical attention.
9. Recommend appropriate nonpharmacologic therapy to abort headache and to prevent headache recurrence.
10. Determine if the patient is a candidate for prophylactic pharmacologic therapy, and if not, instruct the patient to keep a headache diary to assess therapeutic response.

Abbreviations Introduced in This Chapter

ACEI	Angiotensin-converting enzyme inhibitor
AMI	Acute myocardial infarction
ARB	Angiotensin receptor blocker
CCU	Coronary care unit
CGRP	Calcitonin gene-related peptide
CHF	Congestive heart failure
CSF	Cerebrospinal fluid
CT	Computed tomography
CTA	Clear to auscultation
CYP	Cytochrome P450 isoenzyme system
DHE	Dihydroergotamine
ESR	Erythrocyte sedimentation rate
GABA	γ -Aminobutyric acid
GERD	Gastroesophageal reflux disease
IHS	International Headache Society
MAO-A	Monoamine oxidase type A
MOH	Medication overuse headache
MRG	Murmur, rub, gallop
NSAID	Nonsteroidal anti-inflammatory drug
OTC	Over the counter
RR	Respiratory rate
SNRI	Serotonin-norepinephrine reuptake inhibitor
SSRI	Selective serotonin reuptake inhibitors
TCA	Tricyclic antidepressant
TTH	Tension-type headache

36 Substance-Related Disorders

Christian J. Teter

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Identify the prevalence of abuse for commonly used substances (i.e., alcohol, opioids, central nervous system [CNS] stimulants, and nicotine) in the U.S. population.
2. Explain the commonalities of action of abused substances on the reward system in the brain.
3. Identify the typical signs and symptoms of intoxication and withdrawal associated with the use of alcohol, opioids, CNS stimulants, and nicotine.
4. Determine the appropriate treatment measures to produce a desired outcome after episodes of intoxication and withdrawal.
5. Determine when a patient meets criteria for substance dependence.
6. Choose specific pharmacotherapeutic options based on patient-specific factors.
7. Recommend a comprehensive medication treatment and monitoring program to help maintain recovery and prevent relapse to substance abuse.

KEY CONCEPTS

- 1 Pharmacotherapy has been shown to have a role in treatment of some substance-related disorders, including intoxication, withdrawal, and long-term relapse prevention. These substances include alcohol, opioids, CNS stimulants, and nicotine.
- 2 Virtually all abused substances appear to activate the same brain reward pathway, which is highlighted by dopaminergic neurotransmission arising in the ventral tegmental area and projecting to the nucleus accumbens and prefrontal cortex.
- 3 Although activation of the reward pathways explains the pleasurable sensations associated with acute substance use, chronic use of abused substances, which may result in addiction and withdrawal, may be related to neuroadaptive effects occurring within the brain.
- 4 Individuals with a pattern of chronic use of commonly abused substances should be assessed to determine if they meet the *Diagnostic and Statistical Manual*, fourth edition, text revision, criteria for substance dependence or withdrawal.
- 5 The treatment goals for acute intoxication of ethanol, CNS stimulants, and opioids include (a) management of psychological and psychiatric manifestations of intoxication, such as aggression, hostility, and psychosis and (b) management of medical manifestations of intoxication, such as respiratory depression, hyperthermia, hypertension, cardiac arrhythmias, and stroke.
- 6 The treatment goals for withdrawal from ethanol, CNS stimulants, and opioids include (a) a determination if pharmacologic treatment of withdrawal symptoms is necessary, (b) management of other medical manifestations, and (c) referral to the appropriate program for long-term substance abuse treatment.
- 7 A multimodal and comprehensive approach is usually preferred when treating individuals with substance use disorders given the heterogeneous nature of addiction. Pharmacologic treatment is always adjunctive to psychosocial therapy.
- 8 Certain pharmacologic agents have been shown to be helpful for long-term maintenance in patients with substance dependence. Typically, these medications exert their effects by one of the following theorized mechanisms: (a) drug substitution therapy with an agonist, (b) blocking drug effects with an antagonist, and (c) miscellaneous relapse prevention medications with indirect mechanisms of action.
- 9 A major component of successful treatment of addiction is to continue monitoring the use of medications and to identify a mechanism for long-term support of sobriety that might be appropriate, such as

Alcoholics Anonymous (AA) or recovery programs for professionals such as doctors, nurses, or pharmacists.

- 10 Clinicians must be familiar with “essential” resources, many of which are in the public domain.

Substance abuse and dependence are highly prevalent problems in the United States and worldwide. In the United States, the use of all substances of abuse has undergone a series of periodic cycles of societal tolerance or condemnation. As an example, cocaine was first isolated from coca leaves in 1860 by a chemistry graduate student in Germany. Its use was advocated by many in the medical establishment until around the mid-1890s when it became evident that chronic use of cocaine might be addictive in some individuals and could be associated with deleterious physiologic effects. Its use decreased after restriction of prescribing and dispensing of cocaine in the early 20th century, but it continued to be abused by a small segment of the population. Unfortunately, in the 1980s, a smokeable formulation of cocaine (i.e., crack) became available, and cocaine use again became an epidemic. This historically cyclic nature of substance abuse is common to many substances of abuse.

1 Pharmacotherapy has been shown to have a role in treatment of some substance-related disorders, including intoxication, withdrawal, and/or long-term relapse prevention. These substances include alcohol, opioids, central nervous system (CNS) stimulants, and nicotine. This chapter focuses on efficacious pharmacotherapy for these common substance-related disorders. Although many more substances can be and have been abused, these drugs are among the most popular and are treatable with medication.

EPIDEMIOLOGY

In the United States, the federal government annually conducts the National Survey on Drug Use and Health (NSDUH) using a representative sample of persons who are 12 years of age or older to determine the prevalence of licit and illicit drug use.¹ In 2010, more than half (51.8%; 131.3 million) of Americans reported being a current (i.e., past month) alcohol drinker; about one quarter (23.1%; 58.6 million) reported binge drinking (i.e., 5+ drinks) at least once in the 30 days before the survey; and heavy drinking (i.e., binge drinking on 5+ occasions in past 30 days) was reported by 6.7% (16.9 million) of Americans in 2010. In 2010, approximately one-quarter (27.4%; 69.6 million Americans) were current users of tobacco products, with young adults aged 18 to 25 reporting the highest rates of current tobacco product use (40.8%). Regarding illicit drug use, 8.9% of the U.S. population (22.6 million) reported current illicit drug use, with nonmedical psychotherapeutics being second only to marijuana (Fig. 36-1). In 2010, there were 3.0 million illicit drug initiates, with marijuana being the first drug in a majority of cases (61.8%). However, approximately one-quarter (26.2%) nonmedically used a psychotherapeutic as their first illicit drug (i.e., 17.3% with pain relievers, 4.6%

FIGURE 36-1. Past-month illicit drug use among the U.S. population in 2010. ^aIllicit drug use includes a wide variety of substances such as marijuana or hashish, cocaine (including crack), heroin, hallucinogens, inhalants, or prescription-type psychotherapeutics used nonmedically. (Data from Substance Abuse and Mental Health Services Administration (SAMHSA). Results from the 2010 National Survey on Drug Use and Health: Summary of National Findings, NSDUH Series H-41, HHS Publication No. (SMA) 11-4658. Rockville, MD: Substance Abuse and Mental Health Services Administration; 2011.)

with tranquilizers, 2.5% with stimulants, and 1.9% with sedatives).¹ The results of NSDUH (a gold-standard, national U.S. survey) indicate that substance use is wide ranging; peaks in the age range of 18 to 25 years; and consists of a significant number of individuals reporting the nonmedical use of prescription medications, which is a relatively new and growing public health concern.

PATHOPHYSIOLOGY

Reward Pathway

2 Virtually all abused substances appear to activate the same brain reward pathway, which is highlighted by dopaminergic neurotransmission arising in the **ventral tegmental area (VTA)** and projecting to the **nucleus accumbens (NA)** and **prefrontal cortex (PFC)**.

- Figure 36-2 shows a depiction of the **mesocorticolimbic dopamine pathway**. Key components are dopamine (DA) projections from the VTA to the NA and to the PFC.^{2,3} It appears clear from many studies, using a variety of

FIGURE 36-2. The mesocorticolimbic dopaminergic pathway (i.e., the “reward pathway”). VTA, ventral tegmental area. (Data from *The Neurobiology of Drug Addiction* [Internet]. Available at: <http://www.drugabuse.gov/pubs/teaching/Teaching2/Teaching.html>.)

techniques, that this mesolimbic DA system is involved in natural rewards and drug reinforcement⁴; however, there is also evidence that dopamine-independent reinforcement exists.⁵ In any case, abused drugs generally produce pleasant effects that are desired by the user. The initial hedonic experiences secondary to use of drugs appear to be primarily attributable to their ability to activate the primary reward circuits in the brain. These same reward circuits operate under normal circumstances to reinforce certain activities that promote survival, such as food and water, social affiliation, or sexual activity. However, these systems appear to be disrupted after drug use in susceptible individuals.

However, although most individuals will experience pleasant effects, not everyone abuses these drugs, and not everyone who abuses them becomes dependent on them. Why some persons abuse drugs while most people do not is a complex area of research. It appears that genetic, environmental, and cultural factors may all interact to predispose some individuals to substance abuse and subsequent dependence.

Neuronal Adaptation

3 Although activation of the reward pathways explains the pleasurable sensations associated with acute substance use, chronic use of abused substances, which may result in addiction and withdrawal, may be related to neuroadaptive effects occurring within the brain.

A recent review by two of the preeminent researchers in the addiction sciences thoroughly describes the addiction cycle moving past the acute rewarding effects of substances of abuse and into other important processes.⁵ In their review, they describe three phases of the addiction cycle: (a) binge/intoxication, (b) withdrawal/negative affect, and (c) preoccupation/anticipation. The first phase of binge/intoxication refers to the acute rewarding effects of drugs of abuse and the corresponding CNS circuitry. However, chronic use of substances leads to alterations in the brain and associated symptoms. For example, in phase 2 proposed

by Koob and Volkow, chronic drug exposure leads to neuroadaptations such as decreased activity in the brain circuits involved in the acute rewarding phase. More specifically, chronic use of drugs of abuse appears to cause a generalized decrease in DA neurotransmission, probably in response to the intermittent increases in DA induced by the frequent use of these drugs. Additionally, with chronic drug use, release of corticotropin-releasing factor (CRF) is increased, indicating an activation of central stress pathways. In phase 3 of the framework, other neurotransmitter systems (i.e., beyond DA) are postulated to be involved. For example, elevated CRF, norepinephrine, and glutamate may exist in the “extended amygdala” during prolonged abstinence. Perhaps these changes lead to a long-term need to use substances to relieve unpleasant symptoms, such as stress.⁵ Multiple factors are associated with an increased risk of relapse, including the availability of the abused drug, an increase in psychological stressors, and a triggering of conditioning factors (cues) such as seeing a white powder or going to a location where drugs were often previously used or obtained. These factors may be acting to trigger residual adaptive changes (e.g., elevated glutamatergic activity) that occurred in the brain during the period of drug addiction.

OVERALL THEORY OF USE OF PHARMACOLOGIC AGENTS TO TREAT SUBSTANCE-RELATED DISORDERS

Unfortunately, unlike some medical diseases, substance dependence cannot be cured with medications alone. However, we can sometimes alleviate the effects of drug intoxication, attenuate the adverse effects of withdrawal, or use agents that may somewhat decrease craving for and relapse to abused substances. For example, the pleasurable and intoxicating effects of opioids appear to be caused by their action as agonists on μ -receptors of the opioid neurotransmitter system. Competitive μ -opioid antagonists such as naloxone and naltrexone acutely reverse many of the effects of opioids. To date, we do not have specific antagonists for most other abused substances, so rapid pharmacologic reversal of intoxication is usually not possible. Similarly, reversal of withdrawal syndromes caused by abused substances is not always possible. One pharmacologic solution for reversing a drug withdrawal syndrome, most commonly used by substance dependent individuals, is to readminister the drug that caused the physiologic dependence. The more commonly used treatment method is to administer a medication that has some cross-dependence with the abused drug but also has fewer of the reinforcing effects and a more predictable pharmacokinetic profile. A good example is the use of benzodiazepines for the withdrawal of ethanol. Although benzodiazepines can cause dependence, they are rated as less desirable than ethanol by substance abusers, cause fewer of the long-term adverse health effects of ethanol, and are easier to manage medically. Regarding longer term dependence, an example is maintaining an opioid-addicted individual on a regimen of medically managed, orally administered opioids

(referred to as substitution therapy) compared with more dangerous illicit opioid use. Regardless of the specific pharmacotherapy chosen for each symptom presentation, medications should always be used as adjuncts to a comprehensive psychosocial approach.

CLINICAL PRESENTATION AND DIAGNOSIS

4 *Individuals with a pattern of chronic use of commonly abused substances should be assessed to determine if they meet the Diagnostic and Statistical Manual, fourth edition, text revision (DSM-IV-TR) criteria for substance dependence or withdrawal.*⁶ Criteria are not defined for each separate abused substance; rather, a pattern of behavior common to the abuse or dependence of all drugs of abuse is established. The criteria for abuse indicate an established pattern of using a substance that has resulted in undesirable family, job, or legal consequences, such as recurrent instances of neglecting school, work, or family responsibilities, or being arrested for driving under the influence. However, abuse becomes dependence when tolerance to the drug, withdrawal from the drug, or an inability to discontinue use of the drug is apparent. Most notably, in cases of addiction, there is a loss of control over its use or the use has become compulsive. The criteria for substance dependence from the *DSM-IV-TR* are listed in [Table 36–1](#).⁶

In addition to formal diagnostic criteria, a variety of standardized instruments are available to screen for and assess the various stages of substance use and its consequences,

Patient Encounter 1

GC, a 43-year-old man with a history of diabetes, presents to your clinic for follow-up evaluation of his diabetes. You notice that he admits to drinking a pint of Scotch whiskey per day despite his unstable diabetes. He states that his drinking has “crept up” on him over the years and that he finds a pint to be “just the right amount.” When you question him about his drinking, he says it is not a problem because he can still “mountain bike with the best of them.” He does, however, admit his wife is concerned with his drinking. The only times his drinking bothers him are when he is too hung over to mountain bike on the Saturday morning group rides (patient notes that riding is his favorite part of the day) and when he occasionally “messes up his sugar control” because he is intoxicated. Other than that, GC truly feels that his drinking is under his control.

What information would suggest this patient might be alcohol dependent?

Are there any standardized instruments that you can recommend to assess the impact of drinking on the patient’s overall functioning?

Table 36–1

DSM-IV-TR Criteria for Diagnosis of Substance Dependence

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

- (1) Tolerance, as defined by either of the following:
 - (a) a need for markedly increased amounts of the substance to achieve intoxication or desired effect
 - (b) a markedly diminished effect with continued use of the same amount of the substance
- (2) Withdrawal, as manifested by either of the following:
 - (a) the characteristic withdrawal syndrome for the substance
 - (b) the same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms
- (3) The substance is often taken in larger amounts or over a longer period than was intended
- (4) There is a persistent desire or unsuccessful efforts to cut down or control substance use
- (5) A great deal of time is spent in obtaining the substance (e.g., visiting multiple doctors or driving long distances), using the substance (e.g., chain-smoking), or recovering from its effects
- (6) Important social, occupational, or recreational activities are given up or reduced because of substance use
- (7) The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression, or continued drinking despite recognition that an ulcer was made worse by alcohol consumption)

Specify if:

- With physiologic dependence: Evidence of tolerance or withdrawal (i.e., either Item 1 or 2 is present)
- Without physiologic dependence: No evidence of tolerance or withdrawal (i.e., neither Item 1 nor 2 is present)

Data from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders. 4th ed, text rev. Washington, DC: American Psychiatric Association; 2000; with permission.

such as withdrawal symptoms and functional impairment (see [Table 36–2](#)).^{7–10} Some instruments are specific to a particular substance (e.g., Clinical Institute Withdrawal Assessment Scale for Alcohol—Revised [CIWA-Ar]), and others cover a wide range of substances. For example, the Addiction Severity Index (ASI) is a gold-standard instrument that assesses seven problem areas associated with substance use, such as medical status and psychiatric status, in addition to measures of alcohol and drug use.⁸

Intoxication Signs and Symptoms

Intoxication caused by most substances of abuse is described in the *DSM-IV* as clinically significant, **maladaptive** behavioral, physiologic, or psychological changes to the user. These changes are seen during or shortly after use of the substance.

- Euphoria or the experience of a pleasurable sensation are common effects of most drugs of abuse.¹¹ Other signs and symptoms are specific to the particular drug or class of drugs

Table 36-2

Commonly Used Instruments for Substance Use Disorders

Instrument	Purpose	Values and Interpretation
Addiction Severity Index (ASI) Assessment tool (past 30 days or lifetime) for various substances	Semi-structured interview that addresses seven problem areas: medical status, employment and support, alcohol use, drug use, legal status, family and social status, and psychiatric status Questions include frequency, duration, and severity of problems	Patient and interviewer ratings included Interviewer severity ratings of the “need for additional treatment” + composite scores to measure problem severity Scoring completed by a technician or computerized scoring and interpretation Composite score normative data from a nationally representative sample of treatment programs is available for those seeking to compare a patient’s ASI data with national data (available at http://www.tresearch.org); otherwise, comparisons with previous (e.g., baseline) composite scores are useful
Alcohol Use Disorders Identification Test (AUDIT)	Evaluates quantity and frequency of drinking; physiologic dependence on alcohol; and harmful use	10 items (scores 0–40) Score of 8 or above identifies heavy drinkers and those with alcohol use disorders
Screening tool	Clinician administered	“Zones” of interventions based on scores
CAGE C = Cut down A = Angry or annoyed G = Guilty E = Eye opener Screening tool	Clinician or self-administered Used to identify the presence of problematic drinking No training is necessary	Four items Score of 2 or more is positive and suggests problem drinking Positive screen prompts the need for further assessment
Clinical Institute for Withdrawal Assessment—Alcohol, Revised (CIWA-Ar) Assessment tool	Gold standard alcohol withdrawal assessment; used as part of symptom-triggered approach Clinician administered	10 items; maximum score = 67 Less than 10: mild withdrawal; likely does not require medication 10–18: moderate withdrawal Greater than 18: severe withdrawal Monitor scores over time; lower score implies less withdrawal severity; higher scores (e.g., 8 to 10 or greater, depending on institutional protocols or co-occurring conditions) indicate need for medication
Clinical Opiate Withdrawal Scale (COWS) Assessment tool	Used to follow the course of withdrawal symptoms and the effectiveness of medication regimens Clinician administered	11 items; scoring is 0 (asymptomatic) to 4 or 5 (severely symptomatic); scale for each item based on intensity of signs and symptoms Total score (sum of all 11 items): 5–12: Mild 13–24: Moderate 25–36: Moderately severe Greater than 36: Severe withdrawal Monitor scores over time (lower score implies less opioid withdrawal severity); higher scores (i.e., scores of 5 or greater represent increasing levels of withdrawal symptoms) may indicate the need for medication, although no standard cut-off exists for this indication
Fagerstrom Test for Nicotine Dependence	Assesses extent of nicotine tolerance, dependence, and craving; contains six questions (tolerance, withdrawal symptoms, and craving); higher scores may predict greater difficulty in quitting	Total scoring for dependence: 0–2: Very low 3–4: Low 5: Moderate 6–7: High 8–10: Very high

Data from Refs. 7–10.

Table 36-3

Signs and Symptoms of Drug Intoxication for Select Substances

Drug	Behavioral Effects	Physiologic Effects
Ethanol	Changes in mood and behavior, inappropriate aggressive or sexual behavior, giddiness or verbally loud, impaired judgment; possibly progressing to somnolence and coma as the blood level increases	At blood levels of 0.02–0.1% (20–100 mg/dL or 4.34–21.7 mmol/L): Euphoria, feeling of well-being, disinhibition, slight impairment (e.g., reaction time) At blood levels from 0.1% to 0.2% (100–200 mg/dL or 21.7–43.4 mmol/L): Significant impairment (e.g., balance, speech, vision and hearing, reaction times), dysphoria At blood levels from 0.2% to 0.3% (200–300 mg/dL or 43.4–65.1 mmol/L): Marked ataxia, mental confusion, and possible nausea and vomiting At blood levels from 0.3% to 0.4% (300–400 mg/dL or 65.1–86.8 mmol/L): Severe dysarthria, amnesia, hypothermia At blood levels greater than 0.4% (400 mg/dL or 86.8 mmol/L): Alcoholic coma, decreased respiration or respiratory arrest; aspiration of gastric contents or airway obstruction caused by flaccid tongue, drop in blood pressure and body temperature
Opioids	Drowsiness or sedation, slurred speech, impaired memory and attention, psychomotor retardation	Nausea and vomiting, respiratory depression (dose-related), stupor, coma, constipation very common in chronic users, itching, miosis (pinpoint pupils), hypothermia, bradycardia
CNS stimulants	Initially, most prominent effect is elated mood, hypervigilance, anxiety or panic, impairment of judgment, violence to others or self, paranoia or psychosis with delusions and hallucinations (hallucinations are generally tactile or auditory, rarely visual), an increase in motor activity, compulsive or stereotyped behavior (e.g., skin picking)	Neurologic: Pupillary dilation, headache, tremor, hyperreflexia, muscle twitching, flushing, hyperthermia or cold sweats, seizures, coma Cardiovascular: Increased pulse and blood pressure, peripheral vasoconstriction, arrhythmias, myocardial infarction, cerebral hemorrhage GI: Nausea and vomiting, weight loss Neuromuscular: Rhabdomyolysis, possibly resulting in renal failure, muscular weakness, dyskinesias

CNS, central nervous system; GI, gastrointestinal.

Data from Refs. 6, 12–15.

involved. **Table 36-3** lists the psychological/behavioral and physiologic effects of intoxication with ethanol, opioids, and CNS stimulants.^{6,12-15}

Withdrawal Signs and Symptoms

Although most abused drugs can cause some degree of physiologic dependence, the severity of withdrawal varies considerably among these drugs. **Table 36-4** lists the common withdrawal symptoms seen upon abstinence from drug use.^{6,12-16} It is typical that withdrawal symptoms appear opposite to the acute effects of drug use. For example, although alcohol is a CNS depressant, many of the signs and symptoms of withdrawal signify a hyper-alert physiologic response.

TREATMENT OF INTOXICATION SYNDROMES

5 *The treatment goals for acute intoxication of ethanol, CNS stimulants, and opioids include (a) management of psychological/psychiatric manifestations of intoxication, such as aggression, hostility, and psychosis and (b) management of medical manifestations of intoxication, such as respiratory depression, hyperthermia, hypertension, cardiac arrhythmias, and stroke. In all cases of intoxication associated with a substance use disorder (abuse or dependence), referral to and participation in substance abuse treatment after acute treatment for intoxication is desirable.*

Patient Encounter 2

CD, a 27-year-old woman, was admitted to the cardiology unit from the emergency department (ED) after she called 911 claiming that she had severe chest pain and that her heart was racing. Upon arrival in the ED, it was noted that her blood pressure was slightly elevated at 143/92 mm Hg and that she was diaphoretic. She was in otherwise good physical condition with no previous cardiac history. After a urine toxicology screen was positive for cocaine, she admitted that she had snorted several large lines of cocaine before having the chest pain. She said she almost never uses cocaine, but that it helps her chronic depression (diagnosed at age 19 years), which has worsened since she lost her job approximately 3 weeks ago. The treatment plan is to address the patient's stimulant use and major depressive disorder (MDD) after the cardiac issues are resolved.

What are the possible physical signs and symptoms of CD's cocaine use that are consistent with cocaine intoxication?

What is the most appropriate pharmacotherapy for this patient's acute condition?

What is the most appropriate long-term pharmacotherapy for this patient?

Table 36–4

Signs and Symptoms of Drug Withdrawal for Select Substances

Drug	Timeline	Symptoms
Ethanol	As ethanol level decreases (especially after last drink): Early symptoms Peak at 24 hours 72 to 96 hours Onset at any time	Tremor, nausea and vomiting, tachycardia (greater than 110 bpm), hypertension (greater than 140/90 mm Hg), headache, vivid dreams, insomnia Convulsions (usually one or two of grand mal type but can be numerous and possibly fatal) Delirium tremens Hallucinations, usually visual
Opioids	For shorter acting opioids (e.g., heroin, morphine, hydrocodone, oxycodone) withdrawal may begin within 6–24 hours after the last dose and last for about 1 week; with longer acting opioids (e.g., methadone) it may take up to 2–4 days for withdrawal to emerge, and it will last longer	GI: Nausea and vomiting, diarrhea, and dehydration Neurologic or psychological: Irritability, restlessness, yawning, tremulousness, and twitching Cardiovascular: Increase in heart rate and blood pressure Musculoskeletal: Chills, increased body temperature, piloerection, and rhinorrhea Ocular: Lacrimation and dilated pupils
Nicotine	Begins within 24 hours of cessation of use; may persist	The severity of symptoms reflects the degree and duration of nicotine use; symptoms include anxiety, irritability, frustration, anger, craving, difficulty concentrating, decreased heart rate, and increased appetite
CNS stimulants	Immediately after binge Within 1–4 hours Days 3–4	Stimulant craving, accompanied by intense dysphoria, depression, anxiety, and agitation Desire for sleep, dysphoria continues Hypersomnia, increased appetite, craving may dissipate slightly but returns strongly later

CNS, central nervous system; GI, gastrointestinal.

Data from Refs. 6, 12–16.

Alcohol Intoxication

Most cases of mild to moderate intoxication with alcohol, as well as cases in which blood alcohol concentrations (BACs) are at the lower limits of legal intoxication, do not require formal treatment. Such intoxications are characterized by **mood lability**, loud or inappropriate behavior, slurred speech, incoordination, or an unsteady gait. Providing a safe environment and supportive reassurance until the effects of alcohol have worn off is sufficient in most cases. At more severe levels of intoxication, confusion, stupor, coma, and death may be observed. As shown in Table 36–3, in nontolerant individuals, confusion, impaired consciousness, and vomiting are observed at BACs of 200 to 300 mg/dL (0.2% to 0.3% or 43.4 to 65.1 mmol/L); stupor and coma are seen with BACs exceeding 300 to 400 mg/dL (0.3% to 0.4% or 65.1 to 86.8 mmol/L). Death may occur at levels of 400 mg/dL (0.4% or 86.8 mmol/L) or higher from cardiac arrhythmias or respiratory depression. Thus, the most important physiologic goal of treating high levels of intoxication is maintaining cardiopulmonary functioning, including the prevention of aspiration. Accordingly, vital signs must be monitored regularly. Serial BACs at least hourly are strongly recommended, and patients should not be allowed to leave the treatment setting on their own while legally intoxicated (greater than or equal to 80 mg/dL [0.08% or 17.4 mmol/L]). Initially, BACs

may continue to rise if gastrointestinal (GI) absorption is still occurring. Otherwise, the BAC generally decreases at a rate of 15 to 20 mg/dL (0.015% to 0.02% or 3.3 to 4.3 mmol/L) per hour. Although more tolerant individuals may not show the same level of symptoms for a given BAC as nontolerant individuals, behavioral tolerance and tolerance for vital physiologic functions may differ. Thus, alcoholic patients who are awake and alert at a BAC greater than or equal to 400 mg/dL (0.4% or 86.8 mmol/L) may still be at risk for cardiopulmonary instability and collapse.

Other causes of confusion, stupor, or coma must be ruled out because alcohol-intoxicated individuals commonly combine alcohol with other substances, sustain head and other injuries, and have vitamin deficiencies and electrolyte abnormalities. If consciousness is impaired, then thiamine should be given intravenously (IV) or intramuscularly (IM) at 100 mg/day for at least 3 days. If hypoglycemia is suspected, then thiamine administration should precede administration of glucose-containing fluids to prevent precipitation of an acute **Wernicke's encephalopathy**. Thiamine administration will be discussed in further detail below in the Alcohol Withdrawal section. Patients may also develop adverse interactions between alcohol and medications that have been prescribed including disulfiram. See Table 36–5 for a listing of drug–drug interactions with abused substances.^{17,18}

Table 36-5

Clinically Relevant Drug Interactions With Abused Drugs or Medications Used to Treat Substance Use Disorders

Drug	Interacting Drug	Type of Interaction and Appropriate Action
Amphetamines (including dextro- and methamphetamine)	MAOIs (phenelzine, selegiline, tranylcypromine, possibly linezolid)	Pharmacodynamic interaction resulting in an increase in blood pressure; possibly resulting in a hypertensive emergency or stroke; AVOID this drug combination
	Sodium bicarbonate	Sodium bicarbonate increases renal tubular reabsorption of amphetamine, resulting in a prolonged amphetamine elimination half-life; closely monitor this combination
Bupropion	MAOIs	Neurotoxicity; AVOID this drug combination
Buprenorphine	Substances that lower seizure threshold	Alcohol (<i>withdrawal</i>); AVOID bupropion use in patients at risk for experiencing alcohol withdrawal
	Atazanavir	Combination of buprenorphine + atazanavir (without ritonavir) results in both lower atazanavir levels and greater buprenorphine exposure; AVOID this bidirection-interacting drug combination
	Conivaptan	Conivaptan is a potent inhibitor of CYP3A4, and the manufacturer recommends that its use be avoided with medications metabolized by CYP3A4
Cigarette smoking	CYP3A4 inhibitors (in addition to the specific medications listed above)	May raise buprenorphine levels; monitor for greater than expected buprenorphine effects
	Clozapine and olanzapine	Cigarette smoking induces CYP1A2, increasing the metabolism of clozapine; may need to increase usual clozapine dose when a patient begins to smoke or decrease clozapine dose if smoking is stopped or nicotine replacement is used instead of smoking
	Theophylline	Theophylline is also a CYP1A2 substrate; may need to increase the usual theophylline dose when a patient begins to smoke or decrease the theophylline dose if smoking is stopped or nicotine replacement is used instead of smoking
Disulfiram	Alcohol-containing solutions (variety of medications)	Disulfiram reaction; AVOID this combination
	Metronidazole	The combination of disulfiram and metronidazole has lead to CNS effects (e.g., psychosis); AVOID this combination
	Benzodiazepines (including alprazolam, chlordiazepoxide, diazepam, flurazepam, triazolam)	Disulfiram (weakly) inhibits CYP enzymes 1A2, 2C9, and 3A4; many benzodiazepines are metabolized via these pathways; lorazepam, temazepam, and oxazepam are primarily conjugated to inactive products and are reasonable alternatives Otherwise, if benzodiazepines are combined with disulfiram, the pharmacologic effect may be greater than expected, and the dose of benzodiazepine may need to be lowered
	Cocaine	Disulfiram decreases the clearance of cocaine from the body; may see increased or prolonged cocaine effects with this combination
	Phenytoin	Disulfiram decreases the metabolism of phenytoin, resulting in higher phenytoin levels; dose of phenytoin will need to be reduced; because phenytoin undergoes nonlinear metabolism, it is difficult to predict the magnitude of increase in blood levels that could be seen; it is best to avoid this interaction if possible
Ethanol (alcohol)	Acetaminophen	Chronic ethanol use increases the risk of hepatotoxicity when acetaminophen is used in high doses
	Bupropion	Abrupt <i>discontinuation</i> of alcohol with continued bupropion use may lower seizure threshold; this combination should be avoided in those at risk for seizure activity (e.g., alcoholics with co-occurring depressive symptoms)
	Cefamandole, cefoperazone, cefotetan, and moxalactam, metronidazole	A disulfiram-type reaction may occur when these anti-infectives are combined with alcohol; the reaction includes flushing, diaphoresis, tachycardia, headache, and increases in blood pressure; avoid alcohol if these drugs are used
	Cycloserine	Neurotoxicity (specifically seizure risk) may be enhanced with the combination of alcohol and cycloserine; AVOID combination
	Didanosine	The risk for pancreatitis may be increased with the combination of alcohol and didanosine; AVOID combination
	Methotrexate	Hepatotoxicity is a higher risk when methotrexate is given to those who chronically drink large amounts of alcohol; avoid methotrexate in this group if possible; otherwise monitor LFTs

(Continued)

Table 36-5

Clinically Relevant Drug Interactions With Abused Drugs or Medications Used to Treat Substance Use Disorders (Continued)

Drug	Interacting Drug	Type of Interaction and Appropriate Action
Methadone	MAOIs	Ethanol DOES NOT interact with MAOIs; however, tyramine may be a component of some aged alcoholic drinks, such as red wines or tap beers; if a reaction occurs, hypertension and a pounding headache are the most likely symptoms; usually white wine is tolerable (in moderation) and most widely available domestic canned beers do not contain significant amounts of tyramine
	Tapentadol	The combination of alcohol and <i>extended-release</i> tapentadol may result in increased maximum serum concentrations of tapentadol; AVOID this drug combination
	Carbamazepine	Carbamazepine is a potent inducer of CYP3A4 and methadone is primarily metabolized via CYP3A4; if carbamazepine is added to a drug regimen containing methadone, the methadone dose will probably need to be adjusted upward to avoid withdrawal
	Conivaptan	Conivaptan is a potent inhibitor of CYP3A4, and the manufacturer recommends that its use be avoided in medications metabolized by CYP3A4
	CYP3A4 inhibitors (in addition to the specific medications listed)	Methadone serum concentrations may be increased when combined with potent CYP3A4 inhibitors; adjustment of methadone dose should be based on clinical judgment, but a decrease of dose may be necessary
	Didanosine	Methadone decreases the amount of didanosine that is orally absorbed; therapeutic monitoring of didanosine effects are recommended, and doses may need to be increased
	Efavirenz	This HIV drug is a CYP3A4 inducer; efavirenz decreases methadone blood levels and has precipitated withdrawal in opioid-dependent individuals; may need to increase methadone dose
	MAOIs	Potential serotonin syndrome when MAOIs are combined with methadone; transdermal selegiline lists co-treatment with methadone as a CONTRAINDICATION
	Nevirapine	Nevirapine is an HIV drug that is a CYP3A4 inducer; in a small sample, nevirapine caused a 50% reduction in methadone blood levels, resulting in complaints of methadone withdrawal symptoms in patients receiving methadone maintenance; may need to increase methadone dose in patients who have nevirapine added to their drug regimen
	QTc-prolonging drugs or medications	Medications that prolong the QT interval (e.g., ziprasidone) should be AVOIDED with methadone co-administration when possible because of potential additive QT-prolonging effects
	Stavudine	Methadone decreases the amount of stavudine (a reverse transcriptase inhibitor) by about 25%. Although this may not be clinically significant in some cases, the clinician should be aware of the possibility of this interaction
	St. John's wort	This herbal remedy may induce CYP3A4; the certainty of an interaction probably rests on the specific preparation being used, but caution dictates that this herbal product should be avoided in those receiving methadone treatment; withdrawal symptoms have been noted in patients taking methadone maintenance who have added St. John's wort to their drug regimen
	Tamoxifen	Methadone may inhibit the formation of important active tamoxifen metabolites (e.g., endoxifen), and therapeutic monitoring is recommended
Zidovudine	Methadone increases the blood level of this anti-HIV drug, probably via methadone inhibition of both metabolic and renal clearance of zidovudine; may need to decrease zidovudine dose to avoid toxicity	

CYP, cytochrome P450 isoenzyme; LFT, liver function test; MAOI, monoamine oxidase inhibitor.

Data from Refs. 17 and 18.

Behaviorally, patients may insist on driving, become physically aggressive and agitated, or otherwise become a danger to themselves or others. Indeed, most suicidal behaviors among alcohol-dependent individuals occur while they are intoxicated. In such cases, the desired outcomes are

appropriate management of medical problems, prevention of harmful behaviors, and stabilization of mood. Antipsychotics may lower the seizure threshold and are best avoided. However, in some instances, agitation may require treatment with haloperidol such as 5 to 10 mg by mouth every 2 to 4 hours

or 5 mg either IV or IM every 1 to 2 hours. Sedation with benzodiazepines has been used in some cases, but the risk of respiratory depression when mixed with the alcohol already in the patient's system can be dangerous if not fatal.

There are no available medications that can fully reverse the effects of alcohol intoxication. Caffeine and other stimulants can induce arousal and alertness, but they are less effective at reversing poor judgment and motor incoordination, which are vital for complex tasks such as driving. Thus, stimulants are neither indicated nor considered a viable option to make driving safe.

Opioid Intoxication

The word *opioid* is used in this chapter to refer to the overall class of medications and substances that exert their mechanism of action through the body's opioid system. Opioids encompass a wide range of substances, including naturally occurring (e.g., morphine) and synthetic (e.g., oxycodone) substances.

Patients who are acutely intoxicated with an opioid usually present with miosis, euphoria, slow breathing, slow heart rate, low blood pressure, and constipation. Seizures may occur with certain agents, such as meperidine (Demerol).

It is critically important to monitor patients carefully to avoid cardiac and respiratory depression and death from an excessive dose of opioids. One strategy is to reverse the intoxication by using naloxone (Narcan) 0.4 to 2 mg IV every 2 to 3 minutes up to 10 mg. Alternatively, the IM or subcutaneous (SC) route may be used if an IV access is not available. Because naloxone is shorter acting than most abused opioids, it may need to be readministered at periodic intervals; otherwise, patients could lapse into cardiopulmonary arrest after a symptom-free interval of reversed intoxication. In addition, naloxone can induce withdrawal symptoms in opioid-dependent patients, so patients may awaken feeling quite distressed and agitated. The other critical issue is to secure the airway and breathing. In some cases, intubation and manual or mechanical ventilation might be required to avoid oxygen desaturation leading to brain hypoxia or anoxia that may cause brain damage or death.

Stimulant (Cocaine and Amphetamines) Intoxication

The desired outcomes of stimulant intoxication are appropriate management of medical and psychiatric problems. Medical problems include hyperthermia, hypertension, cardiac arrhythmias, stroke, and seizures. Some medical problems are related to route of administration such as nosebleeds with intranasal administration and infections with IV administration. Psychiatric effects include anxiety, irritability and aggression, and psychosis.

Notably, stimulant intoxication is the only stimulant use disorder for which specific pharmacotherapy has been shown to be effective. Current guidelines from the American Heart Association indicate that acute use of β -blockers may lead to worsening cocaine-related chest pain (caused by coronary

vasoconstriction) and hypertension secondary to unopposed alpha activity; they are not recommended for acute use. Recommended medication options in the acute setting include benzodiazepines, aspirin, nitroglycerin, nitroprusside, and phentolamine.¹⁹

Cocaine is short acting, and a single dose of a benzodiazepine sedative-hypnotic may be sufficient treatment for anxiety reactions. Depending on the half-life of the benzodiazepine, one or more sequential doses may be required for longer acting amphetamine intoxication. Antipsychotics are indicated when psychosis is present, and the psychosis usually responds quite rapidly in the absence of other co-occurring psychiatric disorders.

TREATMENT OF WITHDRAWAL SYNDROMES

6 The treatment goals for withdrawal from ethanol, CNS stimulants, and opioids include (a) a determination if pharmacologic treatment of withdrawal symptoms is necessary, (b) management of other medical manifestations, and (c) referral to the appropriate program for long-term substance abuse treatment. The desired outcomes in the treatment of withdrawal syndromes are to ensure patient safety, comfort, and successful transition from treatment of withdrawal to treatment of dependence. Referral to specialized treatment for substance dependence is strongly recommended after treatment for withdrawal syndromes because treatment of withdrawal is not sufficient treatment to prevent relapse to problematic substance use. Achieving a drug-free state by detoxification and then rehabilitation with a focus on total abstinence is the ideal outcome.

Alcohol Withdrawal

There are four different alcohol withdrawal syndromes, which differ in terms of their pharmacologic treatment and need for hospitalization.

► Uncomplicated Alcohol Withdrawal

This is the most commonly observed syndrome, and as the name denotes, is not complicated by seizures, **delirium tremens** (DTs), or hallucinosis. Symptoms are typically rated using a validated scale such as the CIWA-Ar (Table 36-2). The recommended CIWA-Ar threshold score for treating uncomplicated alcohol withdrawal with medications on an outpatient basis is between 8 and 10. For patients who score greater than or equal to 15, inpatient treatment should be strongly considered. Patients who score 20 or higher on the CIWA-Ar should always be treated with medications. The risks of not treating high-scoring patients with medications are seizures and DTs, and those with a prior history of seizures or DTs have an increased risk for subsequent episodes. Therefore, when a history of seizures or DTs is positive, the lower threshold of 8 is recommended, and hospitalization is safer than outpatient detoxification. There is some evidence for "kindling" during successive episodes of

alcohol withdrawal, such that symptom severity and complications increase with additional withdrawal episodes. Thus, it may be advisable to use medications when the CIWA-Ar score is in the 8 to 10 range.

Benzodiazepines are the treatment of choice for uncomplicated alcohol withdrawal.^{10,12} Some of the anticonvulsants have also been used to treat uncomplicated withdrawal (particularly carbamazepine and sodium valproate). Although anticonvulsants provide an alternative to benzodiazepines, they are not as well studied and are less commonly used. The most commonly used benzodiazepines are lorazepam, oxazepam, diazepam, and chlordiazepoxide. They differ in three major ways: (a) their pharmacokinetic properties, (b) the available routes for their administration, and (c) the rapidity of their onset of action due to the rate of GI absorption and rate of crossing the blood–brain barrier.

Benzodiazepines can be administered using a symptom-triggered approach when withdrawal signs and symptoms are already present.²⁰ In this approach, medication is administered every hour when the CIWA-Ar is greater than or equal to eight. For the shorter acting agents, oxazepam (15 to 60 mg orally) or lorazepam (1 to 4 mg orally), the CIWA-Ar is repeated hourly after each administration during the first 24 hours until the patient is comfortably sedated. Because of their short half-life, dosing of lorazepam or oxazepam on subsequent days may be needed, and the risk of seizures may possibly (although not definitively proven) be higher. For the longer acting agents, chlordiazepoxide and diazepam, the symptom-triggered approach is used in combination with another technique known as loading. With the loading technique, chlordiazepoxide at doses of 50 to 100 mg or diazepam (10 to 20 mg) is administered orally at 1-hour intervals during the first 24 hours until the patient is comfortably sedated and the CIWA-Ar score is lower than 4. Then loading is stopped, and for the next 24 hours, the benzodiazepine is used as needed only if the CIWA-Ar score is greater than or equal to eight, although the long half-lives of these drugs and their active metabolites usually provide a natural taper without further drug administration. The loading technique is especially useful in the hospital, where patients can be medically monitored throughout the day.

In contrast to chlordiazepoxide and diazepam, lorazepam and oxazepam are not metabolized into active compounds in the liver. Instead, they are excreted by the kidneys after glucuronidation. This is important because many alcohol-dependent patients have compromised liver function. Therefore, when treatment is initiated before the results of blood tests for liver function are known, as is often the case in outpatient clinics, lorazepam and oxazepam may be preferred. Patients with liver disease may still be treated with diazepam or chlordiazepoxide but at lower doses. This can be accommodated with the loading technique, although hourly dosing with 5 mg of diazepam or 25 mg of chlordiazepoxide may be sufficient.

Oxazepam is available in oral form only, so it is useful only for uncomplicated withdrawal. Other benzodiazepines are available in injectable form and are further described below. Diazepam is more lipophilic than lorazepam, chlordiazepoxide,

and oxazepam, resulting in quicker GI absorption and passage across the blood–brain barrier, which makes it valuable in an inpatient setting, especially to prevent seizures. However, a faster onset of action may be associated with feeling high (i.e., “euphoria”), which can be a treatment disadvantage.

The American Psychiatric Association (APA) Guidelines recommend that thiamine be given routinely to patients being treated for moderate to severe alcohol use disorders to treat or prevent adverse neurologic symptoms.¹² However, according to a recent Cochrane Review, there are inadequate data from randomized controlled trials regarding the most efficacious thiamine dose, frequency, and route of administration to prevent or treat Wernicke’s encephalopathy associated with alcohol use disorders.²¹ The APA Guidelines recommend thiamine 50 to 100 mg per day given IV or IM, although some guidelines recommend higher doses.²² Regardless of the dose chosen, it is particularly important that administration of thiamine (essential for proper energy utilization by the CNS) precedes administration of any glucose-containing IV fluids, which can help prevent an acute exacerbation of Wernicke’s encephalopathy.

► Alcohol Withdrawal Seizures

- Alcohol withdrawal seizures are a medical emergency and should be treated in an inpatient setting. Withdrawal seizures are usually few in number and generalized. The occurrence of focal seizures or status epilepticus may suggest another etiology. Management consists of keeping the airway open and preventing self-injury during convulsions. Benzodiazepines are the treatment of choice. IV diazepam 5 to 10 mg is preferred to terminate a seizure in progress if IV access is available. The dose may be repeated in 5 minutes if seizures persist. Alternatively, lorazepam 4 mg may be given IM followed by insertion of an IV line when convulsive movements have subsided. In the event of a recurrent seizure, lorazepam 2 mg IV may be administered if the patient already received IM lorazepam. IM use of diazepam or chlordiazepoxide should be avoided because of erratic absorption that complicates the timing of subsequent doses and can result in delayed oversedation. IV benzodiazepines may depress respiration, so they should be administered only when and where advanced cardiopulmonary support is readily available. When the patient becomes conscious enough to take medication orally, then treatment may continue using the loading procedure for diazepam or the symptom-triggered technique for lorazepam as described above. Electrolyte imbalances can contribute to seizures and should be corrected if they exist. For example, it may be advisable to administer magnesium in addition to benzodiazepine treatment.

► Alcohol Withdrawal Delirium (Delirium Tremens)

- Delirium tremens is another medical emergency that requires hospitalization in order to prevent mortality. Parenterally administered benzodiazepines are the treatment of choice.²³ DTs are characterized by hallucinations, delirium, severe agitation, fever, elevations of blood pressure and heart rate,

and possible cardiac arrhythmias. A sample regimen consists of diazepam 5 mg IV (at 2.5 mg/min) every 5 to 10 minutes until “light somnolence” is achieved, referring to a tendency to fall asleep without stimulation or a light stage of sleep from which the patient is easily awakened. If the first two doses of diazepam are not effective, then 10 mg IV every 5 to 10 minutes can be administered for the third and fourth doses. If still not effective, then up to 20 mg IV may be used thereafter. When a state of light somnolence is induced, then it should be maintained with diazepam 5 to 20 mg IV every 1 hour as needed. Similarly, lorazepam 1 to 4 mg IV every 5 to 10 minutes or lorazepam 1 to 4 mg IM every 30 to 60 minutes may be given to achieve light somnolence, which is then maintained by similar doses every hour as needed. The antipsychotic haloperidol is given only for severe agitation that is unresponsive to benzodiazepine therapy. The evidence does not support the use of an antipsychotic as a single agent.²³ Furthermore, newer generation antipsychotic agents have not been studied yet for the treatment of DTs. Lastly, thiamine should be given according to the same guidelines described above.

► Alcohol Hallucinosi

Alcohol hallucinosis refers to hallucinations that occur during a clear sensorium, which distinguishes it from DTs, during which hallucinations are associated with a reduced clarity of awareness of the environment. Alcohol hallucinosis is generally treated with oral antipsychotics at usual therapeutic dosages for psychosis.

Opioid Withdrawal

Although it is rare to die from opioid withdrawal per se, underlying medical complications (e.g., hypertension) and recent myocardial infarction increase the risk of complications and death. Therefore, it is important to manage and stabilize any medical issues (e.g., uncontrolled blood pressure, diabetes) and then determine if hospitalization is appropriate. Patients with underlying medical problems should be evaluated for possible triage to an inpatient detoxification program to be followed up with substance abuse treatment in either the inpatient or outpatient setting. Rapid referral for substance abuse treatment will help “seize the moment” and introduce patients to the concept of recovery while they still vividly remember the negative consequences from using substances. Withdrawal from opioids is commonly described by patients as resembling “a bad case of the flu,” and symptoms include nausea; vomiting; diarrhea; anxiety; headaches; mydriasis; rhinorrhea; lacrimation; muscle, bone, and joint pain; piloerection; yawning; fever; increased heart rate; and hypertension.

The use of clinical withdrawal scales, such as Clinical Opiate Withdrawal Scale (COWS), provides high interrater reliability and clinical utility because it is an objective measurement of withdrawal severity. The full items contained in the COWS instrument (*along with many other substance use disorder [SUD] instruments*) can be obtained free-of-charge from the Substance Abuse and Mental Health Services Administration (SAMHSA).⁹ Furthermore, a brief overview

is provided in Table 36–2. The baseline score helps to make the decision to treat pharmacologically or to observe. As the scores become higher, the indication for either opioid substitution or a “symptoms-based approach” may be indicated. In severe withdrawal, either buprenorphine (i.e., partial μ -opioid agonist) or methadone (i.e., full μ -opioid agonist) are recommended for detoxification. Methadone is the gold-standard full μ -agonist, but under current U.S. law, methadone detoxification requires referral to a federally approved methadone detoxification program. The two possible options for the treatment of opioid withdrawal in regular clinical settings are opioid substitution with buprenorphine and symptomatic treatment, which is discussed in the following paragraphs.

► Opioid Substitution

Treatment with a μ -opioid agonist is accomplished with either buprenorphine or methadone. Methadone can be used for opioid detoxification and long-term relapse prevention. However, in the United States, this can be done only at a federally approved opioid treatment program (OTP). Because this drug cannot legally be used for opioid detoxification by general clinicians, methadone detoxification regimens are not covered here because they are readily available elsewhere.

Buprenorphine is a partial agonist at the μ -opioid receptors that can be used sublingually. It is available in three formulations in the United States, two of which are indicated for the treatment of addiction. Buprenorphine plus naloxone (Suboxone) in ratio of 4:1 (2 mg:0.5 mg or 8 mg:2 mg) is the recommended formulation unless the patient is pregnant or hypersensitive to naloxone, in which case buprenorphine without naloxone (Subutex) is recommended. Naloxone was added to the Suboxone formulation to secure Food and Drug Administration (FDA) approval in the United States. Because naloxone is poorly absorbed when used sublingually but blocks opioid receptors if injected, this combination is designed to minimize diversion of the drug to the street for IV use. Only 10% of buprenorphine is bioavailable if it is swallowed, but 50% is bioavailable via the sublingual route.

To initiate a buprenorphine induction, a patient has to be experiencing moderate or severe withdrawal, and the last opioid use should be at least 12 to 24 hours earlier, depending on the half-life of the particular opioid (the longer the half-life, the longer a clinician should wait before initiating buprenorphine induction). The score on the COWS should be greater than or equal to 5 (i.e., suggesting some level of opioid withdrawal); otherwise, buprenorphine likely will induce withdrawal because it has high affinity for μ -receptors, and it will displace any other full μ -opioid agonist that is present. When withdrawal is established, buprenorphine can be initiated, and protocols such as the example provided in Table 36–6 can be used to titrate the dosing and administration.⁹ When a final dose is established, there are generally two treatment approaches, depending on many factors (e.g., patient preference). A maintenance dose can be prescribed or the dose can be tapered down gradually to zero within 1 to 2 weeks (a 25% reduction per day is a general rule of thumb).

Table 36–6

Sample Regimen^a for Buprenorphine Induction Treatment of Opioid Withdrawal and Long-Term Relapse Prevention

Day	Buprenorphine Oral Dosage
1	2 mg every 2 hours (maximum, 8 mg on first day)
2	Start with total dose of day 1 with additional 2–4 mg every 2 hours (maximum, 16 mg)
3+	Start with total dose of day 2, with additional 2–4 mg every 2 hours (maximum, 32 mg)
4–5	Maintain on dose required to alleviate withdrawal symptoms ^b

^aFor withdrawal from any long-acting opioid.

^bPatient will likely be transitioned to long-term maintenance dose indefinitely.

Data from Center for Substance Abuse Treatment. Clinical Guidelines for the Use of Buprenorphine in the Treatment of Opioid Addiction. Treatment Improvement Protocol (TIP) Series 40. DHHS Publication no. (SMA) 04–3939. Rockville, MD: Substance Abuse and Mental Health Services Administration; 2004.

► Symptoms-Based Treatment

- Symptomatic treatment focuses on minimizing the withdrawal symptoms to help patients be as comfortable as possible. Symptom-specific medications, as shown in Table 36–7, are often used as adjunct medication with opioid substitution.^{9,12} Clonidine is one of the primary non-opioid medications used during withdrawal to decrease the excessive noradrenergic symptoms (e.g., sweating) of opioid withdrawal. However, the use of clonidine requires close monitoring of blood pressure; it should be held if systolic blood pressure is below 90 mm Hg or diastolic blood pressure is below 60 mm Hg. Compared with opioid substitution, clonidine does not help other withdrawal symptoms, such as craving or distress.¹²

Table 36–7

A “Symptoms-Based” Treatment Approach for Opioid Withdrawal

The following medications are used for symptoms that cause distress. This approach includes the use of any single or a combination of two or more of the following agents, depending on the symptoms reported:

1. Insomnia: Diphenhydramine 50–100 mg, trazodone 75–200 mg, or hydroxyzine 25–50 mg at bedtime
2. Headache, muscle aches, and pain: Acetaminophen 500 mg–1 g every 6 hours, ibuprofen 600 mg by mouth every 8 hours, or naproxen 600 mg by mouth every 12 hours
3. Noradrenergic hyperactivity: Clonidine (Catapres) 0.1–0.2 mg every 6–8 hours; maximum dosage not to exceed 1.2 mg in 24 hours
4. Abdominal cramps: Dicyclomine 10–20 mg every 6 hours
5. Constipation: Milk of magnesia at 30 mL daily
6. Diarrhea: Bismuth subcarbonate 30 mL can be given every 2 to 3 hours

Data from Refs. 9 and 12.

► General Patient Guidelines for Outpatient Opioid Detoxification

When treating opioid withdrawal with pharmacologic agents, patient safety is the highest priority. The first step is to educate patients about the course of withdrawal. Symptoms peak at around 5 to 7 days and may last up to 2 weeks, depending on the half-life of the opioid that was being used before detoxification. Patients also should be advised regarding the side effects of the drugs used to detoxify. For instance, clonidine causes dizziness from low blood pressure, sedation (which may impair driving or operating heavy machinery), and dry mouth. There is also an overdose potential if clonidine is mixed with opioids or other CNS sedatives or antihypertensives. The risk of these adverse events needs to be balanced with potential benefits. The side effects of buprenorphine include constipation, sedation, and headaches. It should also be noted that there is a potential for serious overdose when buprenorphine is mixed with benzodiazepines or other sedative-hypnotics. The risk of developing physiologic tolerance to buprenorphine is high if it is used for prolonged periods. In this case, buprenorphine should be slowly tapered to discontinuation. However, withdrawal from buprenorphine is easier and less severe than withdrawal from a pure agonist, such as methadone.

- Successful transition from treatment of withdrawal to treatment of opioid dependence in a rehabilitation setting is the most important challenge for a clinician. Patients often think that all they need is detoxification, but this is not the case because a successful outcome is tied to successful rehabilitation and acquiring recovery skills after detoxification. This goal can be accomplished by either achieving detoxification on site during rehabilitation or by quick and seamless transition of the patient from detoxification to a rehabilitation program. The more time that elapses between the two modalities, the greater the likelihood of treatment failure and return to drug use.

Central Nervous System Stimulant (Cocaine, Amphetamines) Withdrawal

Cocaine and amphetamine withdrawal are grouped together because their symptom profiles as described in *DSM-IV-TR*⁶ are identical, and the physiologic basis of their withdrawal syndromes involves the DA neurotransmitter system. Stimulants of this group also include methylphenidate but not nicotine and caffeine, which have different neurophysiologic mechanisms of action. Although neurophysiologic alterations underlie the syndrome of stimulant withdrawal, its symptoms are manifested psychologically for the most part as a depressed or dysphoric mood. Consequently, the major adverse complication of stimulant withdrawal is profound depression with suicidal thoughts, and the major goal of treatment is to prevent suicide. Therefore, unless suicidality warrants hospitalization, stimulant withdrawal can be treated on an outpatient basis with psychological support and reassurance with an emphasis on patient safety. A number of medications have been studied to alleviate symptoms of stimulant withdrawal and the intense craving that may accompany it, but inconsistent results across controlled trials

preclude any recommendations for their routine use. Patients with stimulant use disorders should be referred for substance abuse treatment because of the high risk for continued use either during or immediately following stimulant withdrawal.

Treatment referral (after intoxication or withdrawal): Overall, intoxication or withdrawal with any of the substances discussed above is evidence of substance abuse and is strongly suggestive of substance dependence. In all cases, it is important to strongly emphasize to the patient that this is an issue that needs to be addressed and that treatment may be beneficial depending on how frequent and severe the intoxication or withdrawal symptoms present.

GENERAL APPROACH TO THE TREATMENT OF SUBSTANCE DEPENDENCE

7 A multimodal and comprehensive approach is usually preferred when treating individuals with substance use disorders given the heterogeneous nature of addiction. Pharmacologic treatment is always adjunctive to *psychosocial therapy*. The overall goals in recovery from addiction are the same for all substances, and they consist of the following components:¹²

- Assessment includes (a) patient history (e.g., past and present substance use, including the effect of substance use on the patient's functioning), (b) medical and psychiatric history and examination, (c) treatments and associated outcomes, (d) family and social history, (e) alcohol and drug testing (e.g., urine drug testing), (f) laboratory tests (e.g., liver function tests), and (g) corroborating evidence
- Psychiatric management: includes (a) motivating the patient to change, (b) establishing a therapeutic alliance, (c) ensuring patient safety and monitoring clinical status, (d) managing intoxication and withdrawal, (e) monitoring and ensuring treatment adherence, (f) preventing relapse, (g) educating patients, and (h) reducing negative consequences of substance use
- Treatment:
 - Pharmacotherapy: intoxication, withdrawal, long-term maintenance
 - Psychosocial: examples include cognitive-behavioral therapies (CBTs), motivational enhancement therapy (MET), behavioral therapies
- Treatment plan: patient specific (i.e., individualized) aims and outcomes of treatment
- Treatment setting: least restrictive while maintaining patient safety

Using the above steps, the overarching aims (i.e., outcomes) that are desired include:

- Achieve abstinence or reduce substance use
- Reduce negative consequences associated with use
- Reduction in the frequency or severity of relapse to substance use
- Improve psychological and social functioning

It is important to remember that mere treatment of withdrawal is not sufficient treatment of *DSM-IV-TR* dependence and that medications are always adjunctive to psychosocial therapy. Comorbid psychiatric conditions such as anxiety, depression, insomnia, pain, and continued smoking should be addressed. All of these conditions increase the risk of relapse to use of drugs. Additionally, although complete abstinence may be desirable in many patients, decreasing substance use and negative consequences may be sufficient in certain cases. The latter concept is also known as “harm reduction.” For example, if a patient relapses to alcohol consumption, at least ensure the patient is not driving and is in a safe environment.

Nonpharmacologic Therapy

Although pharmacologic agents may help prevent relapse, psychotherapy should be the core therapeutic intervention. Psychotherapy encompasses widely different approaches. However, they typically address one or more of the following tasks:

- Motivation enhancement to stop or reduce drug use
- Coping skills education
- Providing alternative reinforcement
- Managing painful affect
- Enhancing social support and interpersonal functioning

There are many examples of psychosocial approaches, and a thorough review of these approaches is beyond the scope of this chapter and are available elsewhere.¹² However, a few of the commonly used techniques are CBT, MET, and behavioral therapies (e.g., community reinforcement).

Pharmacologic Therapy

► Maintenance Treatment

8 Certain pharmacologic agents have been shown to be helpful for long-term maintenance in patients with substance dependence. Typically, these medications exert their effects by one of the following theorized mechanisms: (a) drug substitution therapy with an agonist, (b) blocking drug effects with an antagonist, and (c) miscellaneous relapse prevention medications with indirect mechanisms of action. Medications from each of these categories are discussed in greater detail in the following paragraphs for alcohol, opioid, stimulant, and nicotine dependence.

► Alcohol Dependence

- Currently, the three FDA-approved medications that are indicated to treat alcohol dependence are disulfiram, naltrexone (oral and depot), and acamprosate. Among the three agents, naltrexone and acamprosate are generally considered first-line agents as evidenced by their “grade A” efficacy rating in the seminal paper by Garbutt et al.²⁴ However, in motivated patients, disulfiram is another reasonable option.²⁵

Disulfiram First marketed in the United States in the 1950s, disulfiram works by irreversibly blocking the enzyme aldehyde dehydrogenase (ALDH), a step in the metabolism of alcohol. The result of inhibiting ALDH is increased blood levels of the toxic metabolite acetaldehyde. As levels of acetaldehyde increase, the patient experiences decreased blood pressure, increased heart rate, chest pain, palpitations, dizziness, flushing, sweating, weakness, nausea and vomiting, headache, shortness of breath, blurred vision, and syncope. These effects are commonly referred to as the disulfiram–ethanol reaction. Their severity increases with the amount of alcohol that is consumed, and they may warrant emergency treatment. Psychologically, disulfiram works through aversion, and drinking is avoided to prevent the aversive disulfiram–ethanol reaction. The efficacy of disulfiram has always been found to be directly dependent on medication adherence,²⁶ and more recent reports advocate that disulfiram can be highly effective when procedures for enhancing adherence are used, such as supervised administration.²⁵

The usual starting dose of disulfiram is 250 mg/day orally (appropriate to be started at 500 mg/day for the first 1 to 2 weeks), and the range is 125 to 500 mg/day. Compared with 250 mg/day, the larger dose is recommended if a patient does not experience a disulfiram–ethanol reaction after alcohol consumption, and the smaller dose is given when intolerable side effects are experienced at higher doses. Dosing begins only after the BAC is zero (usually 12 to 24 hours after the last drink) and after the patient understands the consequences of the disulfiram–ethanol reaction.

Disulfiram is contraindicated in patients who have cardiovascular or cerebrovascular disease or in combination with antihypertensive medications because the cardiovascular effects of the disulfiram–alcohol reaction could be fatal in such patients. The most common side effects are rash, drowsiness, a metallic or garlic-like taste, and headache. If drowsiness occurs, the dose may be lowered or given at night. Other less common but concerning adverse effects include neuropathies and hepatotoxicity. Given the serious nature of these adverse effects, baseline and periodic monitoring is recommended. If serum levels of alanine aminotransferase (ALT) or aspartate aminotransferase (AST) are greater than three times the upper limit of normal values, then disulfiram should be withheld and the tests repeated every 1 to 2 weeks until they are normal. When liver function tests (LFTs) return to the normal range, they may be repeated every 1 to 6 months. It is advisable to follow LFTs and clinical symptoms until resolution has been confirmed.²⁷ Although elevated LFTs may signal disulfiram-induced hepatotoxicity, it is also likely the patient was nonadherent to treatment and resumed drinking, ultimately leading to hepatotoxicity. Another uncommon side effect of disulfiram is psychosis, which has been reported in doses exceeding 500 mg/day, especially in predisposed patients. This may be related to disulfiram's ability to inhibit dopamine β -hydroxylase, resulting in increased dopamine activity. Nevertheless, alcohol-dependent patients with schizophrenia and other co-occurring mental disorders have received disulfiram at usual therapeutic doses without difficulties.²⁸

Drug Interactions. The disulfiram–ethanol interaction is described above and is the intended interaction that serves as disulfiram's mechanism of action. Depending on the dose of disulfiram, sensitivity to disulfiram, amount of alcohol consumed, and metabolism, patients may be at risk for an adverse interaction with alcohol for 2 to 14 days after stopping disulfiram (5 days on average) and should be warned accordingly. See Table 36–5 for additional relevant interactions that occur with disulfiram (particularly with metronidazole).

Naltrexone Naltrexone is a competitive opioid antagonist that decreases alcohol intake in both animals and humans.

There is evidence that it works by decreasing both craving for alcohol and alcohol-induced euphoria (i.e., reduces **positive reinforcement** associated with drinking). Numerous controlled trials and meta-analyses have demonstrated that naltrexone is more efficacious than placebo for a variety of drinking measures.¹² For example, one meta-analysis that included more than 20 controlled trials demonstrated naltrexone significantly decreased risk of relapse compared with placebo.²⁹ Reported predictors of naltrexone efficacy include a family history of alcoholism, genetic differences in opioid alleles, drinking problems at an early age, and high levels of craving.^{12,30} In a landmark study assessing the efficacy of behavioral treatment, medication management, and their combinations for the treatment of alcohol dependence, naltrexone was associated with high rates of percent days abstinence.³¹ The trial design was very complex, and the details of the study are beyond the scope of this chapter. However, an oversimplification of the findings suggests that naltrexone was effective (e.g., percent days abstinent), but acamprostate (discussed in greater detail below) was not associated with any treatment advantage.³¹

Naltrexone is available in both oral and sustained-release injections. The usual therapeutic dose of oral naltrexone is 50 mg/day, with a range from 25 to 100 mg. The 25-mg dose is commonly given initially as a test dose to minimize side effects, especially nausea, and then increased to 50 mg/day as tolerated. Adherence to daily doses of naltrexone strongly affects drinking outcomes. Therefore, a sustained-release IM injection of naltrexone, designed to be given once monthly, has been marketed. A 380-mg monthly injection of naltrexone (Vivitrol) resulted in a significantly greater reduction in heavy drinking days compared with placebo injection.³²

The most common side effects are GI complaints, headache, insomnia, and nervousness. Injectable naltrexone is also associated with injection site pain or reactions. Because naltrexone can precipitate withdrawal in patients dependent on opioids, the first dose should be withheld for 7 to 10 days after the last use of opioids and given only when the urine drug screen result for opioids is negative. Also, naltrexone can be hepatotoxic, albeit typically not at oral doses less than 250 mg/day or at the recommended injectable dose of 380 mg per month. Nevertheless, baseline and periodic monitoring of LFTs is recommended.

It is important for patients to carry a pocket warning card or wear a warning bracelet because, in the event that

emergency treatment is needed, they will be insensitive to opioid analgesia unless usually toxic doses are administered. Patients need to be warned of the potential for an opioid overdose under two different conditions. First, dosing with opioids to reverse opioid insensitivity (i.e., naltrexone's competitive blockade of opioid receptors) requires very high doses of opioids that can cause respiratory depression and death. Second, chronic antagonist therapy with naltrexone may cause patients to become hypersensitive to opioid drugs after stopping naltrexone, thereby facilitating respiratory depression and death when opioids are used.

Drug Interactions. Naltrexone can block the effects of opioid receptor agonists, rendering them therapeutically ineffective. Given that opioid agonists are a mainstay of pain management, alternative pain treatment options (e.g., conscious sedation) may be required in a patient receiving naltrexone maintenance for alcoholism.

Acamprosate Acamprosate appears to be a glutamatergic antagonist and may also have GABA-ergic effects.³ Alcohol use acutely inhibits glutamatergic function and chronically causes upregulation of glutamate receptors. During alcohol withdrawal and postacute alcohol withdrawal, increased activity of the glutamate system is caused by upregulation of receptors and the absence of alcohol-related inhibition. Thus, it has been postulated that acamprosate may restore the glutamate/GABA imbalance that occurs after chronic alcohol dependence (e.g., reduces **negative reinforcement** associated with postacute withdrawal and craving).

• Generally, trials assessing the efficacy of acamprosate have shown mixed results. However, this may be partly attributable to differences in research methodologies, such as varying levels of abstinence required in trials before acamprosate initiation.¹² Notably, in the landmark Combining Medications and Behavioral Interventions for Alcoholism (COMBINE) study described earlier, acamprosate appeared to offer no treatment advantage,³¹ but a relatively recent meta-analysis of randomized control trials suggests that it is more efficacious than placebo.³³ Another recent meta-analysis suggests that acamprosate may be more effective at maintaining abstinence, but naltrexone may more effectively prevent full relapse to heavy drinking in non-abstinent individuals.³⁴ Despite the availability of mixed findings (and study methodologies) in the literature, there appears to be sufficient evidence that acamprosate is more effective than placebo, although differences may be modest.

The therapeutic dose of acamprosate is 666 mg orally three times daily, and it is supplied as a 333-mg tablet. It is not metabolized by the liver and is excreted unchanged by the kidneys. Consequently, it is contraindicated in patients with severe renal impairment (creatinine clearance less than or equal to 30 mL/min [0.50 mL/sec]), and a dose reduction is necessary when the creatinine clearance is between 30 and 50 mL/min (0.50 and 0.83 mL/sec). The most common side effects are GI and include nausea and diarrhea. CNS adverse effects include insomnia, anxiety, and depressive symptoms.

• **Medication Selection** Please refer to **Table 36–8** for patient-specific factors that can be used to guide medication

Table 36–8

Alcohol Use Disorder Medication Decision Grid

Pretreatment Indicator	Acamprosate (Campral)	Disulfiram (Antabuse)	Oral Naltrexone (ReVia)	Injectable Naltrexone (Vivitrol)
Renal failure	X	A	A	A
Significant liver disease	A	C	C	C
Coronary artery disease	A	C	A	A
Chronic pain	A	A	C	C
Current opioid use	A	A	X	X
Psychosis	A	C	A	A
Unwilling or unable to sustain total abstinence	A	X	A	A
Risk factors for poor medication adherence	C	C	C	A
Diabetes	A	C	A	A
Obesity that precludes IM injection	A	A	A	X
Family history of AUDs	A	A	+	+
Bleeding or other coagulation disorders	A	A	A	C
High level of craving	A	A	+	+
Opioid dependence in remission	A	A	+	+
History of postacute withdrawal syndrome	+	A	A	A
Cognitive impairment	A	X	A	A

+ = particularly appropriate; A = appropriate to use; C = use with caution; X = contraindicated.

AUD, alcohol use disorder; IM, intramuscular.

Patient Encounter 3

A 29-year-old man is being seen for long-term addiction to oxycodone. The patient last took oxycodone (orally) approximately 10 hours ago. Recently, he has come to realize that he has no legal means of earning a living, and he is reluctant to return home because all of his roommates are actively using substances. He feels he is worthless and has wasted his life up to now. However, he states that he is committed to finally “shaking his habit.”

What is the most immediate action to be taken regarding this young man’s treatment?

After acute detoxification, how can he be helped to maintain abstinence, and is there a medication that offers advantages over other first-line options?

management for alcohol dependence.²⁷ Given the lack of universally accepted treatment algorithms for the treatment of alcohol dependence, this table may help guide medication selection.

► Opioid Dependence

After the conclusion of withdrawal, some patients still do not feel their usual selves for a long time and may relapse to using opioids again, just to “feel normal.” Long-term use of opioids results in changes in the brain, and the brain might not readily return to its prior homeostasis. Because the goal of treatment is to encourage stability, both in the body and in the patient’s life, if an individual is not successful in tapering off of opioids because of a reemergence of severe withdrawal or a return to opioid use, then maintenance treatment should be considered.

- **Opioid Agonists** The time-honored opioid agonist treatment for opioid dependence is methadone maintenance. However, methadone maintenance can be provided only in federally approved OTPs, which is beyond the scope of this chapter. The other first-line agent, which will be the focus of this chapter, is buprenorphine maintenance.

The more widely available office-based opioid treatment (OBOT) exclusively uses buprenorphine, a partial μ -agonist.⁹ The effective maintenance dose of buprenorphine (+/- naloxone) is usually between 8 and 16 mg/day, with maximum reported efficacy at 64 mg/day. Patients receiving buprenorphine maintenance should sign a treatment contract requiring full compliance, financial responsibility for treatment, adherence to office policies, respectful behavior to staff, and agreement to provide random urine samples for drug screens, and patients should bring their bottles for pill counts at every visit. In the event of failure of OBOT, the alternative to buprenorphine maintenance is a referral to an OTP for methadone administration. Under the provisions of the Drug

Addiction Treatment Act of 2000, physicians may prescribe buprenorphine (Suboxone or Subutex) in their office if they meet the predetermined requirements (e.g., training) and become qualified providers. When these criteria are met, they obtain an “X” on their Drug Enforcement Administration (DEA) number.⁹

- Although there are no treatment algorithms to guide medication selection, there are protocols for some medications that assist with dosing and titration. For example, the extensive buprenorphine treatment protocol available from SAMHSA provides guidelines on how to dose buprenorphine from induction to maintenance treatment.⁹ Furthermore, findings from a recent Cochrane meta-analysis indicate that methadone may offer an advantage over buprenorphine for select treatment outcomes (e.g., retention in treatment).³⁵ Therefore, there may be circumstances for which methadone remains the best medication option.

► Stimulant Dependence

There are no proven pharmacotherapies for treatment of CNS stimulant dependence at this time. However, the APA Practice Guidelines mention three medications as possible treatment options for CNS stimulant dependence when combined with psychosocial approaches (i.e., after psychosocial approaches alone have failed). These medications include topiramate, disulfiram, and modafinil. For example, disulfiram shows some promise in randomized, controlled trials possibly due to its inhibition of the dopamine β -hydroxylase enzyme that converts DA to NE in the brain. The resulting increase in DA levels may counter the DA deficiency state that is believed to underlie cocaine withdrawal and craving.¹²

► Tobacco Cessation

Nonpharmacologic Behavioral treatment delivered by a variety of clinicians (e.g., physician, psychologist, nurse, pharmacist, and dentist) increases abstinence rates. The five As should be applied by all clinicians.¹⁶

- Ask if they smoke.
- Advise to quit.
- Assess motivation for change.
- Assist if willing to change.
- Arrange for follow-up.

Smoking cessation counseling should be provided to all smokers, and those interested should be assisted to achieve cessation. Furthermore, it is now a standard of practice for clinicians to screen for smoking and provide all smokers with brief advice and assistance with appropriate medications to quit or provide referral to specialized services when needed.

Pharmacologic According to the seminal tobacco use clinical practice guideline,¹⁶ there are seven first-line medications available to treat nicotine use disorders. **Table 36–9** provides product-specific overviews and recommendations, such as dosing, for each of these medications.³⁶

Table 36–9

First-Line Medications for Treatment of Nicotine Dependence

Medication	Dosing and Administration	Adverse Effects
Nicotine patch (7, 14, and 21 mg)	One patch per day on a hairless area of body between the waist and neck; rotate patch site More than or equal to 10 cigarettes/day: 21 mg × 4 weeks, 14 mg × 2–4 weeks, 7 mg × 2–4 weeks Less than 10 cigarettes /day: 14 mg × 4 weeks, 7 mg × 4 weeks Duration: 8–12 weeks	Local skin reactions, insomnia, vivid dreams, headache May apply hydrocortisone or triamcinolone to ameliorate skin reactions Warnings and Precautions: Pregnancy category D CV risks: Recent (less than 2 weeks) MI, arrhythmias, unstable angina
Nicotine gum (2 or 4 mg)	One piece every 1–2 hours (maximum, 24 pieces/day); chew and “park” Use 2-mg dose if 25 cigarettes/day or less and the 4-mg dose if 25 cigarettes/day or more or chewing tobacco Do not eat or drink (except water) 15 minutes before or during use Duration: 12 weeks (or as needed)	Sore mouth, hiccups, stomachache, dyspepsia, insomnia Avoid chewing (i.e., should “park” the gum in cheek) and limit swallowing excess saliva to avoid GI problems Warnings and Precautions: Pregnancy category D CV risks: Recent (less than 2 weeks) MI, arrhythmias, unstable angina
Nicotine lozenge (2 or 4 mg)	Use 2-mg dose for first cigarette 30 minutes or more after waking or 4-mg dose for first cigarette less than 30 minutes after waking Weeks 1–6: 1 every 1–2 h; weeks 7–9: 1 every 2–4 h, weeks 10–12: 1 every 4–8 h Do not eat or drink 15 minutes before or during use Maximum is 20 lozenges per day; use one lozenge at a time Duration: 3 to 6 months	Hiccups, cough, heartburn, nausea, headache, insomnia Avoid chewing (i.e., should “park” the lozenge in cheek) and limit swallowing excess saliva to avoid GI problems Warnings and Precautions: Pregnancy category (not evaluated) CV risks: Recent (less than 2 weeks) MI, arrhythmias, unstable angina
Nicotine nasal spray (0.5 mg delivered to each nostril)	One “dose” = 1 squirt/nostril 1 to 2 doses/h (8–40 doses per day; maximum, 5 doses/h) Do not inhale Duration: 3 to 6 months; taper (see dependence risk)	Nasal irritation, nasal congestion, changes in smell Warnings and Precautions: Pregnancy category D CV risks: Recent (less than 2 weeks) MI, arrhythmias, unstable angina Avoid in persons with reactive airway disease Dependence (risk is higher)
Nicotine inhaler (4 mg in each cartridge)	Use 6–16 cartridges per day Inhale (i.e., “puff”) 80 times/cartridge Do not eat or drink 15 minutes before or during use; puff lightly and do not inhale into lungs (avoid coughing); avoid cold temperatures Duration: Up to 6 months; taper	Mouth and throat irritation (improves with use), cough, rhinitis, sneezing, headache Warnings and Precautions: Pregnancy category D CV risks: Recent (less than 2 weeks) MI, arrhythmias, unstable angina
Bupropion	Initial dosing: 150 mg once daily × 3 days Maintenance dosing: 150 mg twice daily Should initiate at least 1 week before target quit date; efficacy of maintenance at 300 mg/day has been shown up to 6 months May be combined with NRT	U.S. Boxed Warning(s): Serious neuropsychiatric events (e.g., mood disturbances) when used for smoking cessation
Varenicline	Initial dosing: Days 1–3: 0.5 mg once daily Days 4–7: 0.5 mg twice daily Maintenance dosing: Day 8 and after: 1 mg twice daily Renal dosing (CrCl less than 30 mL/min [less than 0.50 mL/s]): Requires lower doses; 0.5 mg once daily with a maximum of 0.5 mg twice daily Initiate varenicline at least 1 week before target quit date or begin varenicline dosing and then quit smoking between days 8 and 35	CNS: Insomnia, headache, abnormal dreams GI: Dose-related nausea U.S. Boxed Warning: Serious neuropsychiatric events (depression, suicidal thoughts, and suicide) have been reported with varenicline use

CNS, central nervous system; CrCl, creatinine clearance; CV, cardiovascular; GI, gastrointestinal; NRT, nicotine replacement therapy; MI, myocardial infarction.

Data from Teter CJ. Substance Use Disorders. 2012 Board Certified Psychiatric Pharmacist (BCPP) Examination Review and Recertification Course. Lincoln, NE: College of Psychiatric & Neurologic Pharmacists; 2012.

Symptomatic detoxification and maintenance for nicotine dependence is achieved with any single or combination of the currently available nicotine replacement therapies (NRTs).¹⁶ Similar to opioid agonists, these nicotine replacement therapies act as substitution therapy using a safer alternative. NRT is generally considered safe with one notable exception: Given the pregnancy category D assigned to NRT, the decision to use NRT for pregnant women must be made on a case-by-case basis. According to the clinical practice guidelines, pregnant smokers should be encouraged to quit smoking without the use of medication.¹⁶ Given there are various NRT products that are efficacious at treating tobacco dependence, the choice of specific NRT depends on other factors, such as patient preference.¹²

First-line non-nicotine medications that have proven beneficial for treating nicotine dependence are bupropion and varenicline. The sustained-release form of the antidepressant bupropion was approved by the FDA with a new brand name (Zyban) for the treatment of tobacco dependence. Bupropion blocks reuptake of DA and NE, and it appears that one of its metabolites is a nicotinic antagonist.³ These mechanisms may help explain how bupropion acts to reduce nicotine reinforcement, withdrawal, and craving.

The FDA has approved varenicline (Chantix), which is a $\alpha_4\beta_2$ nicotinic acetylcholine (nACh) partial agonist.³ Varenicline decreases withdrawal and craving and prevents reinforcing effects of nicotine if the patient relapses and is at least as effective as bupropion in clinical trials. Caution must be taken with both bupropion and varenicline because both have been associated with severe psychiatric disturbances when used for smoking cessation.³⁷⁻³⁸

As shown in **Table 36-10**, various NRTs, bupropion, and varenicline increase abstinence rates at 6 months relative to placebo.¹⁶ Furthermore, combining the nicotine patch with ad libitum nicotine gum provides the highest likelihood of abstinence at 6 months. The single agent (i.e., monotherapy) with the highest odds of maintaining abstinence is varenicline (2 mg/day dose).

OUTCOME EVALUATION

9 A major component of successful treatment of addiction is to continue monitoring the use of medications and to identify a mechanism for long-term support of sobriety that might be appropriate for a specific individual such as AA, or recovery programs for professionals such as doctors, nurses, or pharmacists.

To determine immediate treatment outcomes for patients with intoxication and withdrawal syndromes, evaluate parameters such as blood pressure, heart rate, respirations, and body temperature, as well as mental state. Choose from a number of validated and standardized rating scales to monitor the responsiveness of withdrawal syndromes to medical treatment. To determine the overall effectiveness

Table 36-10

Six-Month Post-Quit Abstinence Rates and Associated Odds Ratios^a

Medication	Abstinence Rate (%)	Odds Ratio (95% CI)
Placebo	13.8	1.0
NRTs		
Nicotine gum (6–14 weeks)	19.0	1.5 (1.2–1.7)
Nicotine patch (6–14 weeks)	23.4	1.9 (1.7–2.2)
Nicotine gum (more than 14 weeks)	26.1	2.2 (1.5–3.2)
Nicotine patch (more than 14 weeks)	23.7	1.9 (1.7–2.3)
Non-NRTs		
Bupropion SR	24.2	2.0 (1.8–2.2)
Varenicline (1 mg/day)	25.4	2.1 (1.5–3.0)
Varenicline (2 mg/day)	33.2	3.1 (2.5–3.8)
Combination Strategies		
Patch (more than 14 weeks) + ad lib gum or spray	36.5	3.6 (2.5–5.2)
Patch + bupropion SR	28.9	2.5 (1.9–3.4)

^aMeta-analysis; 83 studies included.

Data from Refs. 16 and 36.

of your health system for the treatment of substance abuse and dependence, you could monitor outcomes using sentinel events such as the rates of cardiopulmonary arrest, seizures, discharges against medical advice, patient violence, and use of physical restraints. The ultimate goal should be to enable the transition of patients to formal substance abuse treatment when indicated.

Important outcome indicators to evaluate postintoxication and/or postwithdrawal treatment can be divided into three major groups: decreased consumption of substances, decreased problems associated with substance use, and improved psychosocial functioning. When complete abstinence has not been achieved, quantify the consumption of substances using quantity–frequency measures, rates of abstinence, and time to first relapse as determined by interviews and self-report and by biological markers such as urine and blood tests. The Addiction Severity Index (see **Table 36-2**) is a gold-standard instrument that can be used to assess alcohol and drug-related problems in various domains and provides a more comprehensive picture of the substance user's life.

10 Clinicians must be familiar with “essential” resources, many of which are in the public domain. **Table 36-11** provides a list of these resources along with their website address. These websites provide information useful for clinical management, research, teaching, and policy development purposes.

National Institute on Drug Abuse (NIDA)	www.drugabuse.gov	Education Resources (<i>downloadable teaching slides; see Fig. 36–2 for an example</i>)
Substance Abuse and Mental Health Services Administration (SAMHSA)	www.samhsa.gov	National Survey on Drug Use and Health (NSDUH) (<i>national, representative alcohol and drug use survey</i>) Treatment Improvement Protocols (TIPs) (<i>evidence-based treatment recommendations</i>)

^aThere is a great deal of information from these resources that is available in the public domain and may be used without permission. For example, the Treatment Improvement Protocols are comprehensive documents that can be accessed (free of charge) via the internet.

Patient Care and Monitoring

- By evaluating the patient's history and symptoms, determine if substance intoxication, or withdrawal are likely.
- If drug intoxication is the likely scenario:
 - Conduct a physical examination and measure blood pressure, heart and respiratory rate, and body temperature.
 - In most cases, management of intoxication is supportive. The most important goal is to maintain cardiopulmonary function. If consciousness is impaired, obtain blood chemistries and administer thiamine (100 to 250 mg) followed by IV glucose. Thiamine must be administered before glucose.
 - Cocaine or stimulant intoxication may require administration of a small dose of a short-acting benzodiazepine (e.g., lorazepam 1 to 2 mg) for agitation or severe anxiety. Avoid β -blocker monotherapy because of unopposed alpha adrenergic activity. If hyperthermia is present, initiate cooling measures.
 - Observe the patient until the intoxication has resolved (if alcohol, the BAC should be less than 80 mg/dL [0.08% or 17.4 mmol/L]) for the patient's safety and the safety of others. Encourage the patient to consider treatment for substance abuse, especially if this is not the first episode of intoxication.
- If substance withdrawal is the likely scenario:
 - Determine from which substance or substances the patient is withdrawing.
 - Conduct a physical examination to help determine if medical problems are present.
 - Select the appropriate standardized withdrawal severity instrument to determine the degree of drug withdrawal and to help guide medication use and dosing. Refer to the correct scoring procedure for each instrument.
 - More severe symptoms, such as alcohol withdrawal seizures and DTs, should be treated in the inpatient setting with benzodiazepines. These conditions can be fatal if left untreated.
 - Withdrawal from opioids and CNS stimulants is uncomfortable but unlikely to be fatal unless the patient has underlying medical problems.
- Withdrawal from nicotine is treated in the outpatient setting. Symptomatic detoxification from nicotine is achieved with any single or combination of NRTs. Additional non-nicotine first-line medications, such as bupropion or varenicline, may be helpful to reduce craving and various other withdrawal symptoms.
- The overall goals in recovery from addiction are the same for all substances and include improved coping skills and relapse prevention.
 - To achieve long-term recovery, consider medication management as an adjunct to psychosocial approaches. The combination of medication and psychosocial support provides the greatest likelihood of recovery for many individuals who struggle with substance-related disorders.

Abbreviations Introduced in This Chapter

AA	Alcoholics Anonymous
ALDH	Aldehyde dehydrogenase
ALT	Alanine aminotransferase
ASI	Addiction Severity Index
AST	Aspartate aminotransferase
AUDIT	Alcohol Use Disorders Identification Test
BAC	Blood alcohol concentration
CBT	Cognitive-behavioral therapy
CIWA-Ar	Clinical Institute Withdrawal Assessment for Alcohol—Revised
CNS	Central Nervous System
COWS	Clinical Opiate Withdrawal Scale
CRF	Corticotropin-releasing factor
DA	Dopamine
DEA	Drug Enforcement Administration
DSM-IV-TR	<i>Diagnostic and Statistical Manual of Mental Disorders</i> , 4th ed, text revision
DTs	Delirium tremens
ED	Emergency department
GABA	γ -aminobutyric acid
5-HT	Serotonin
IM	Intramuscular
IV	Intravenous
LFT	Liver function test
MET	Motivational enhancement therapy
NA	Nucleus accumbens
nACh	Nicotinic acetylcholine
NE	Norepinephrine
NMDA	<i>N</i> -Methyl- <i>D</i> -aspartate
NRT	Nicotine replacement therapy
NSDUH	National Survey on Drug Use and Health
OBOT	Office-Based Opioid Treatment
OTP	Opioid Treatment Program
PFC	Prefrontal cortex
SAMHSA	Substance Abuse and Mental Health Services Administration
SC	Subcutaneous
SUD	Substance use disorder
VTA	Ventral tegmental area

Schizophrenia

Deanna L. Kelly, Elaine Weiner, and
Heidi J. Wehring

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Recognize the signs and symptoms of schizophrenia and be able to distinguish among positive, negative, and cognitive symptoms of the illness.
2. Explain the pathophysiologic mechanisms that are thought to underlie schizophrenia.
3. Identify the treatment goals for a patient with schizophrenia.
4. Recommend appropriate antipsychotic medications based on patient-specific data.
5. Compare the side effect profiles of individual antipsychotics.
6. Educate patients and families about schizophrenia, treatments, and the importance of adherence to antipsychotic treatment.
7. Describe the components of a monitoring plan to assess the effectiveness and safety of antipsychotic medications.

KEY CONCEPTS

- 1 A diagnosis of schizophrenia is made clinically because there are no psychological assessments, brain imaging, or laboratory examinations that confirm the diagnosis.
- 2 Patients presenting with odd behaviors, illogical thought processes, bizarre beliefs, and hallucinations should be assessed for schizophrenia.
- 3 The goals of treatment are to reduce symptomatology, decrease psychotic relapses, and improve patient functioning and social outcomes.
- 4 The cornerstone of treatment is antipsychotic medications. Because most patients with schizophrenia relapse when not medicated, long-term treatment is usually necessary.
- 5 Psychosocial support is needed to help improve functional outcomes.
- 6 Compared with the older antipsychotics (first-generation antipsychotics [FGAs], typical antipsychotics), the more recently developed second-generation antipsychotics (SGAs, atypical antipsychotics) are associated with a lower risk of motor side effects (tremor, stiffness, restlessness, and dyskinesia); may offer greater benefits for affective, negative, and cognitive symptoms; and may prolong the time to psychotic relapse.
- 7 SGAs as a class are heterogeneous with regard to side effect profiles. Many SGAs carry an increased risk for

weight gain and for the development of glucose and lipid abnormalities; therefore, careful monitoring is essential.

- 8 Education of the patient and family regarding the benefits and risks of antipsychotic medications and the importance of adherence to their therapeutic regimens must be integrated into pharmacologic management.

● In most cases, schizophrenia is a devastating, chronically debilitating disorder. Conceptually, it may be thought of as a clinical syndrome, comprising several disease entities that manifest with psychotic symptoms, including hallucinations, delusions, and disordered thinking. Commonly, these more flagrant symptoms are accompanied by more insidious ones, including cognitive impairment (abnormalities in thinking, reasoning, attention, memory, and perception), impaired insight and judgment, loss of motivation (avolition), loss of emotional range (restricted affect), and a decrease in spontaneous speech (poverty of speech). The latter three symptoms are termed negative symptoms and collectively are frequently called the deficit syndrome. Cognitive impairments and negative symptoms account for much of the poor social and functional outcomes observed in schizophrenia. Schizophrenia is the fourth leading cause of disability among adults and is associated with substantially lower rates of employment, marriage, and independent living compared with population norms. However, earlier diagnosis and treatment, as well as advances in research and newer

Patient Encounter, Part 1

KH is a 24-year-old single woman with an approximately 1-year history of paranoia, continuously hearing voices of “spirits” advising her daily activities, and social withdrawal. KH withdrew from college 2 years ago after having difficulty concentrating, and she was employed up until 6 months ago as a cashier at a local fast food restaurant. She eventually left her job because of missing too many shifts secondary to her beliefs that others could read her mind. KH lives with her parents, who have become increasingly worried about her throughout the past year. When she lost her job, she began to “go downhill fast,” her father says. She is spending more and more time in her room, which she says is the only place in the house where she feels comfortable. The voices, which she calls “spirits,” have been advising her that she needs to limit time outside her room. She also has stopped doing activities she used to enjoy, such as listening to music and going to movies. She states she “doesn’t really miss” doing these things. KH has also become irritable and complains she is sleeping poorly. When her mother asked that she leave her room to join the family for dinner, KH recently became angry and so agitated that she threw a vase at her mother. Although her parents are supportive, they are worried about her symptoms and frustrated about her recent behavior and withdrawal.

What diagnoses are suggested by this presentation?

What additional information would help to clarify the diagnosis?

treatment developments, have led to better outcomes for people who have this complex and challenging illness.

EPIDEMIOLOGY AND ETIOLOGY

One percent of the world’s population suffers from schizophrenia, and symptoms usually first present in late adolescence or early adulthood.¹ Although equally prevalent between the genders, symptoms generally appear earlier in men, and men have a younger age at first hospitalization (15 to 24 years) compared with women (25 to 34 years).

The etiology of schizophrenia remains largely unknown, although the evidence strongly supports a genetic basis for the disorder. First-degree relatives of patients with schizophrenia carry a 10% risk of developing the disorder. When both parents have the diagnosis, the risk to their offspring is 40%. For monozygotic twins, the likelihood of one twin developing the illness if the other twin has schizophrenia is about 50%. Many genes have been weakly associated with the development of schizophrenia; however, no clear association exists for any one gene. There is probably no single “schizophrenia gene,” but research continues in the hopes of more fully exploring candidate genes, loci, and copy number variants.² Environmental stimuli or triggers along

with genetic liability may contribute to the expression of the illness. Some data suggest intrauterine exposure to viral or bacterial infections may be a risk factor; however, more research is needed.

PATHOPHYSIOLOGY

- The oldest theory associated with the pathophysiology of schizophrenia is the dopamine hypothesis, which proposes that psychosis is caused by excessive dopamine in the brain. This hypothesis dates from the late 1950s after the discovery that chlorpromazine, the first antipsychotic, acted as a postsynaptic dopamine antagonist. Drugs that cause an increase in dopamine (e.g., cocaine and amphetamines) increase psychotic symptoms, and drugs that decrease dopamine (e.g., all current antipsychotic medications) decrease psychotic symptoms. However, data over the past several decades revealed a more complicated picture with both hyperdopaminergic and hypodopaminergic brain regions in schizophrenia. Hypodopaminergic activity observed in the prefrontal lobe is thought to relate to the core negative symptoms associated with schizophrenia. Thus, a more modern reworking of the dopamine hypothesis is the “dysregulation hypothesis,” which takes these findings into account.³ It is possible, however, that the dopamine abnormalities hypothesized to underlie the etiology of schizophrenia may represent compensatory changes that occur secondary to other pathophysiologic abnormalities intrinsic to the illness. Other neurotransmitter systems have also been implicated
- in schizophrenia. Some investigators have suggested that a combined dysfunction of the dopamine and glutamate transmitter systems may better explain the disorder.⁴ In particular, it is hypothesized that glutamate, possibly through malfunctioning *N*-methyl-D-aspartate (NMDA) receptors, impacts dopaminergic activity in brain areas such as the mesolimbic and **mesocortical** pathways. NMDA antagonists such as phencyclidine (PCP) and ketamine can elicit a state resembling psychotic symptoms of schizophrenia, including positive, negative, and cognitive symptoms. There has also been a great deal of speculation regarding a role for serotonin receptor antagonism in antipsychotic efficacy⁵ because many second-generation antipsychotics (SGAs) are active at serotonin receptors. Serotonin receptor binding may be important to drug action, possibly by modulating dopamine activity in mesocortical pathways. However, a compelling pathophysiologic theory relating to dopamine and serotonin receptor affinities does not yet exist. It is important to note that to date, antipsychotics without any primary or secondary dopamine-modulating properties have been ineffective for the treatment of positive symptoms of schizophrenia.

CLINICAL PRESENTATION AND DIAGNOSIS

- People with schizophrenia may appear uncooperative, suspicious, hostile, anxious, or aggressive because of their misinterpretation of reality. They may have poor

Clinical Presentation of Schizophrenia

General

Schizophrenia is a chronic disorder of thought and affect, causing a significant disturbance in the individual's ability to function vocationally and interpersonally. The onset of symptoms in most cases is insidious, usually preceded by a prodromal phase characterized by gradual social withdrawal, diminished interests, changes in appearance and hygiene, changes in cognition, and bizarre or odd behaviors. Despite the tendency of the media to portray a stereotype, the clinical presentation of a person with schizophrenia is extremely varied. Hallmark symptoms include psychotic symptoms, negative symptoms, and cognitive impairments that last for at least 6 months.

Symptoms

Psychotic symptoms: These symptoms are sometimes called positive symptoms because they are “added on to” a person's normal experience. They may include hallucinations (distortions or exaggeration of perception), delusions (fixed false beliefs), and thought disorder (illogical thought and speech). Hallucinations, most frequently auditory, can also be visual, olfactory, gustatory, and tactile. Auditory hallucinations may be experienced as voices or as thoughts that feel distinct from the person's own thoughts. The content of the hallucinations is variable, but often they are threatening or commanding (e.g., commanding the person to perform a particular action). Patients may feel compelled to perform the commanded task or may experience much anxiety when they do not. Delusions frequently involve fixed false beliefs despite invalidating evidence and may be bizarre in nature. Often they have

paranoid themes, which may make the patient suspicious of others. The characteristic thought disorder of schizophrenia includes loosening of associations, **tangentiality, thought blocking, concreteness**, circumstantiality, and perseveration. Thinking and speech may be incomprehensible and illogical. Subtle disturbances in associative thinking may develop years before disorganized thinking (formal thought disorder).

Negative symptoms: So called because they are qualities “taken away” from the personality, include impoverished speech and thinking, lack of social drive, flatness of emotional expression, and apathy. Although quite ubiquitous, these symptoms are difficult to evaluate because they occur in a continuum with normality and can be attributable to secondary causes, including medication side effects, mood disorder, environmental understimulation, or demoralization. When caused by schizophrenia itself, they are termed *primary negative symptoms* or *deficit symptoms*. The best strategy for differentiating primary from secondary negative symptoms is to observe for their persistence over time despite efforts at resolving the other causes. Approximately 10% to 15% of people with schizophrenia may present primarily with negative symptoms; these people may be referred to as having a deficit syndrome.

Cognitive symptoms: Neuropsychological research shows that patients with schizophrenia show abnormalities in the areas of attention, processing speed, verbal and visual memory, working memory, and problem solving. There is a loss of, on average, 1 standard deviation of pre-illness IQ, with the average IQ between 80 and 84.

hygiene and appear unkempt because both psychotic and depressive symptoms may lead to impaired self-care. Sleep and appetite are often disturbed. People with schizophrenia often have difficulty living independently and forming close relationships with others. Additionally, they have problems initiating or maintaining employment. Comorbid medical disorders, such as type 2 diabetes and chronic obstructive pulmonary disease, are prevalent in people with schizophrenia because of sedentary lifestyles, poor dietary habits, obesity, or cigarette smoking. Approximately 60% of people with schizophrenia smoke, and approximately 50% use drugs and alcohol, rates much higher than the general population.⁶

1 A diagnosis of schizophrenia is made clinically because there are no psychological assessments, brain imaging, or laboratory examinations that confirm the diagnosis.

Although biological markers are being investigated, currently the diagnosis is made by ruling out other causes of psychosis and meeting specified diagnostic criteria that are based on symptoms and functioning. A family

history of psychiatric disorders is helpful in supporting the diagnosis. The commonly accepted diagnostic criteria for schizophrenia are from the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (DSM-IV-TR)⁷ (Table 37-1).

2 Patients presenting with odd behaviors, illogical thought processes, bizarre beliefs, and hallucinations should be assessed for schizophrenia.

A person presenting with an initial episode of psychosis requires a comprehensive assessment and careful diagnosis because psychosis is not pathognomonic for schizophrenia. Often, people present with a short history of psychopathology and cannot recall historical information accurately. This lack of information, along with frequent comorbid substance abuse, medical illnesses, and psychosocial stressors, often confounds the diagnosis. Patients presenting with psychotic symptoms, particularly those in their initial episode, should have a thorough medical and laboratory evaluation (electrolytes, blood urea nitrogen, serum creatinine, urinalysis, liver and thyroid function profile, syphilis serology, serum

Table 37-1

Diagnostic Criteria for Schizophrenia

- A. *Characteristic symptoms*: Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated):^a
- Delusions
 - Hallucinations
 - Disorganized speech (e.g., frequent derailment or incoherence)
 - Grossly disorganized or catatonic behavior
 - Negative symptoms (e.g., flat affect, alogia, avolition)
- B. *Social or occupational dysfunction*: For a significant portion of the time since the onset of the disturbance, one or more major areas of functioning such as work, interpersonal relations, or self-care are markedly below the level achieved before onset (or when onset is in childhood or adolescence, failure to achieve the expected level of interpersonal, academic, or occupational achievement)
- C. *Duration*: Continuous signs of disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meets criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of disturbance may be manifested by only negative symptoms or by two or more symptoms listed in category A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences)
- D. *Ruling out other disorders*:
- Schizoaffective and mood disorder exclusion: Schizoaffective disorder and mood disorder with psychotic features have been ruled out because either (a) no major depressive, manic, or mixed episodes have occurred concurrently with the active-phase symptoms or (b) if mood episodes have occurred during active-phase symptoms, their total duration has been brief relative to the duration of the active and residual periods
 - Substance and general medical condition exclusion: The disturbance is not attributable to the direct physiologic effects of a substance (e.g., drug of abuse or medication) or a general medical condition
 - Pervasive developmental disorder: If the patient has a history of autistic disorder or another pervasive developmental disorder, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations are also present for at least 1 month (or less if successfully treated)

^aOnly one symptom from category A is required if delusions are bizarre or hallucinations consist of a voice maintaining a running commentary on the person's behavior or thoughts or two or more voices conversing.

Adapted from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders. 4th ed, text rev. Washington, DC: American Psychiatric Association; 2000.

pregnancy test, and urine toxicology), including a careful review of systems and a physical examination, including a neurologic evaluation. At the minimum, in accordance with the American Psychiatric Association (APA) Practice Guidelines⁸ and the Expert Consensus Guideline Series for Schizophrenia,⁹ patients with psychosis should have a medical workup at the time of admission to rule out other diagnoses or contributing factors.

COURSE AND PROGNOSIS

The onset of psychosis, whether insidious or acute, is marked by difficulties for patients, families, and clinicians. Patients may keep symptoms hidden from family and friends; they may also isolate themselves from social support networks. The gradual development of psychosis and the frequent misunderstanding of symptoms generally lead to a substantial time period between symptom onset and diagnosis and treatment. Recent data suggest that people treated early in their illness may have a better prognosis. Therefore, the first challenge of optimal therapy is to move treatment initiation closer to the onset of psychosis.

Although the course of schizophrenia is variable, the long-term prognosis for independent function is often poor. The course of illness is marked by intermittent acute psychotic episodes with a downward decline in psychosocial functioning. Over time, a patient may become

more withdrawn, bizarre, and nonfunctional. Many of the more dramatic and acute symptoms fade with time, but severe residual symptoms may persist. Family and friends often find this illness difficult to interpret and understand. Involvement with the law is fairly common for misdemeanors such as vagrancy, loitering, and disturbing the peace. The overall life expectancy is shortened primarily because of suicide, accidents, and the inability of self-care. The lifetime risk of suicide for people with schizophrenia is 5% to 10%.¹⁰ Persistent compliance with a tolerable drug regimen improves prognosis, although relapse without medication exceeds 50% annually.

TREATMENT

Desired Outcomes

- 3 *The goals of treatment are to reduce symptomatology and psychotic relapses and to improve functional and social outcomes.*⁹ Patients should receive, as early in their course as possible, comprehensive treatment designed to achieve functional outcomes. Although in the past, the primary treatment goal was to decrease positive symptoms and the associated hostile and aggressive behaviors, newer approaches to treatment have a wider focus, including positive, negative, depressive, and anxious symptoms, as well as preserving cognition. Combativeness, hostility, sleep

Patient Encounter, Part 2

Past Psychiatric History: KH has not had any extensive psychiatric treatment. When she withdrew from college 2 years ago, she cited concentration difficulties as the main factor. However, when referred for a psychological evaluation, she did not follow through with the referral.

Past Medical History: She has no history of medical illness, head trauma, or seizure disorder. KH is 160 cm (63 in) tall and weighs 66 kg (145 lb). Toxicology screen results are negative for alcohol and drugs of abuse.

Social History: KH grew up in a middle class family, completed high school, and entered college. Initially, she was very involved in coursework, but she withdrew 2 years ago citing concentration difficulties. Her GPA dropped dramatically from her first to her third year of college. KH periodically drinks alcohol and smokes marijuana, by her estimation, once a month. She has never been diagnosed with any substance use disorder. KH has held several part time jobs from the ages of 18 to 23 years, the last of which was as a cashier at a fast food restaurant. She has no health insurance.

Family History: KH's grandfather had an alcohol problem, and her great uncle has a history of depression. KH's mother and aunt both have type 2 diabetes.

Mental Status Exam

Appearance: Appears somewhat disheveled, dressed in dirty clothes, and hair looks like it has not been washed or brushed for several days. No abnormal movements. Poor eye contact

Speech: Quiet and somewhat monotonous

Mood: Nervous

Affect: Guarded and mildly anxious with restricted range
Thought content: She is an adequate historian but with a tendency to leave out detail. Hears the voices of "spirits" daily, which give her advice, and she feels like others can read her thoughts. KH denies suicidal or homicidal thoughts.

Thought processes: Vague and sometimes illogical

Cognition: Grossly intact

Insight and judgment: Impaired at this time. She does not feel like anything is wrong with her, and does not recognize that some of her recent behaviors are inappropriate (throwing vase) or that her experiences may be symptoms (paranoia, hallucinations, etc.) of an illness

Given this additional information, how has your differential diagnosis changed?

What are the goals of acute treatment?

What medications would you recommend as first-line options for KH, and why?

disturbances, appetite, and hallucinations may be some of the first symptoms to improve. Improvements in negative symptoms, cognitive functioning, social skills, and judgment generally require a longer period to improve.

General Approach to Treatment

Over the past few years, partial recovery and remission have become an increasingly prominent paradigm for treatment of schizophrenia. A range of interventions must be incorporated into long-term treatment strategies, including pharmacologic interventions and psychosocial therapies. Current treatment planning is increasingly focused on functional outcomes by providing treatment and recovery-oriented services to people with schizophrenia. Also, implementation of evidence-based practice, whereby new information from the published literature gets incorporated into clinicians' prescribing behavior, has led to the use of interventions that promote a remission or recovery attitude.¹⁰⁻¹² Moreover, recent attempts have been made to address and measure patient satisfaction with treatments and instill hope and optimism in order to empower patients. Unfortunately, despite these advances and recent treatment improvements, long-term outcomes currently remain poor, and many patients fail to receive comprehensive care.

4 The cornerstone of treatment is antipsychotic medications. Because most patients with schizophrenia relapse

when not medicated, long-term treatment is usually necessary. Because early detection and intervention in schizophrenia is important for maximizing outcomes, treatment with antipsychotic medications should begin as soon as psychotic symptoms are recognized. Antipsychotic medications are the cornerstone of therapy for people with schizophrenia, and most patients are on lifelong therapy because nonadherence and discontinuation of antipsychotics are associated with high relapse rates. If other symptoms are present such as depression and anxiety, these symptoms should also be aggressively treated. Additionally, psychosocial treatments should be used concomitantly to improve patient outcomes.

Nonpharmacologic Therapy

5 Psychosocial support is needed to help improve functional outcomes. Only 30% of patients respond robustly to antipsychotics, another 30% respond partially, and another 30% have a minimal response. Responding patients often continue to have residual symptoms such as **amotivation**, isolation, and impaired social functioning, thus limiting their participation in social, vocational, and educational endeavors. Psychosocial interventions are based on the premise that increased psychosocial functioning will lead to improvements in subjective feelings of self-esteem and life satisfaction. A few of the best-supported and most promising approaches to psychosocial rehabilitation are social skills

training (SST), cognitive-behavioral therapy (CBT), and cognitive remediation (CR). These treatments are mainly used as targeted treatments for social and cognitive impairments and as adjuncts to pharmacotherapy for psychotic symptoms.¹³ Most psychosocial studies have been carried out in the United Kingdom, and findings are not yet widely used in the United States. Nonetheless, there are substantial data to support that family education and vocational support help to improve long-term functional outcomes. In addition, Assertive Community Treatment (ACT), programming designed to provide direct service provision and high frequency of patient contact by a multidisciplinary team, has been found to reduce hospitalizations and homelessness in persons with schizophrenia.¹³

Pharmacologic Therapy

Generally, along with antipsychotic medications, adjunctive medications should be used when necessary for specific symptoms or comorbid diagnoses. Because each schizophrenic patient presents differently, each treatment regimen should be individually tailored. For years, only first-generation antipsychotics (FGAs; typical antipsychotics) were available, but since 1990, nine new antipsychotics have been marketed in the United States. These agents, known as SGAs (atypical antipsychotics), include risperidone (Risperdal), olanzapine (Zyprexa), quetiapine (Seroquel), ziprasidone (Geodon), aripiprazole (Abilify), paliperidone (Invega), iloperidone (Fanapt), asenapine (Saphris), lurasidone (Latuda), and clozapine (Clozaril). Clozapine, the prototype of this class of medications, is reserved as second-line therapy because of its unusual side effect profile (see below).

6 Compared with the older FGAs, the more recently developed SGAs are associated with a lower risk of motor side effects (tremor, stiffness, restlessness, and dyskinesia); may offer greater benefits for affective, negative, and cognitive symptoms; and may prolong the time to psychotic relapse.

Since the introduction of SGAs, the use of FGAs has progressively decreased, and the current market share for FGAs in treatment of schizophrenia is less than 10%. This decline occurred because of the touted lower side effect profile and other benefits of SGAs in several domains of illness. Early comparative studies used high-dose, high-potency FGAs such as haloperidol and concluded that SGAs were more effective in some domains. More recently, a large multisite clinical trial ($n =$ more than 1,400 patients) examined the effectiveness of SGAs relative to a midpotency FGA, perphenazine (the Clinical Antipsychotics Trials of Intervention Effectiveness; CATIE trial). Findings were that FGAs may be as effective as SGAs when using the primary endpoint of time to discontinuation of medication.¹⁴ Thus, although these results suggest that midpotency FGAs may be similar in efficacy to SGAs, the CATIE trial had several limitations, and other evidence suggests SGAs may be more effective in some illness domains, such as relapse prevention, affective and negative symptoms, and cognitive function. The SGAs have historically been much more expensive than the FGAs; however risperidone, olanzapine,

and clozapine are now available in generic formulations, and other SGAs will lose patent protection in the next 5 years. In conclusion, when selecting among the various agents, the risk-to-benefit profile becomes fundamental, and all the antipsychotics are associated with somewhat different side effect profiles.

Second-Generation (Atypical) Antipsychotics

Although the FGAs exert most of their effects through dopamine-receptor blockade at the dopamine₂ (D₂) receptor, the SGAs may work through a more complicated mechanism. The SGAs have greater affinity for serotonin receptors than for dopamine receptors. Despite being heterogeneous with regard to receptor binding, the overall efficacy among the SGAs is similar.¹⁴ Recent comparative data among SGAs and FGAs (lower doses) have reported that overall efficacy is similar between groups, which suggests a reevaluation of the place of FGAs in therapy is needed.¹⁴ Only clozapine, however, has demonstrated superior efficacy for some patients (see Treatment-Resistant Patients). An important distinction of the SGAs as a class is their lower propensity to cause **extrapyramidal symptoms** (EPS) and **tardive dyskinesia** (TD). The annual risk of TD is considered to be less than 1.5% per year in adults (younger than 54 years old) taking SGAs compared to approximately a 5% per year risk in those taking FGAs.¹⁵ Pharmacologic profiles and side effect profiles, however, are very different among the agents.

7 The SGAs as a class are heterogeneous with regard to side effect profiles. Many SGAs carry an increased risk for weight gain and for the development of glucose and lipid abnormalities; therefore, careful monitoring is essential. **Table 37-2** lists the SGA agents, recommended dosing, and dosage forms available. **Table 37-3** lists the side effect profiles of the SGAs and haloperidol.

► Risperidone

Risperidone, a benzisoxazole derivative, was the first SGA to be marketed after the release of clozapine and was the initial first-line oral SGA to become available generically. It has high binding affinity to both serotonin 2_A (5-HT_{2A}) and D₂ receptors and binds to α_1 and α_2 receptors, with very little blockade of cholinergic receptors.¹⁶ Multicenter registry trials found 6 to 16 mg of risperidone at least equal in efficacy to haloperidol (20 mg), but 6 mg of risperidone produced EPS at a rate no different than placebo.¹⁷ Risperidone is also approved for relapse prevention and is associated with significantly lower relapse rates than long-term haloperidol treatment.¹⁸ At clinically effective doses (less than or equal to 6 mg/day), EPSs are low, although higher doses are clearly associated with a greater incidence of EPS. Risperidone is associated with serum prolactin elevations that are similar to or greater than those seen with the FGAs. Elevated prolactin levels can, but do not always, lead to clinical symptoms such as hormonal problems (e.g., amenorrhea, galactorrhea, and gynecomastia) or sexual dysfunction. Risperidone is associated with mild

Table 37-2

Second-Generation (Atypical) Antipsychotics

Second-Generation Antipsychotic	Usual Target Dose (mg/day)	Maximal Dose Likely to Be Beneficial (mg/day)	Available Dosage Forms
Aripiprazole (Abilify)	15–30	30	<ul style="list-style-type: none"> • 2-, 5-, 10-, 15-, 20-, and 30-mg tablets • 1-mg/mL oral solution • 10- and 15-mg discmelt orally disintegrating tablets • IM 9.75 mg/1.3 mL

to moderate weight gain, and mild elevations in lipid and glucose may occur. However, patients chronically treated with other antipsychotics such as olanzapine may experience a decline in cholesterol and triglyceride levels when changed to risperidone monotherapy.¹⁴

► Olanzapine

Olanzapine has greater affinity for 5-HT_{2A} than for D₂ receptors. In addition, the compound has affinity at the binding sites of D₄, D₃, 5-HT₃, 5-HT₆, α₁-adrenergic, muscarinic₁₋₅ (M₁₋₅), and histamine₁ (H₁) receptors.¹⁹

Olanzapine has recently become available in generic form. Multicenter clinical trials have reported that the effectiveness of olanzapine is at least equal to that of haloperidol for the treatment of positive symptoms^{20,21} and equal or superior to haloperidol for the treatment of negative symptoms. The premarketing clinical trials reported no significant differences in efficacy among dosage groups. However, the higher dose range appeared to offer the greatest benefits for both positive and negative symptoms when compared with haloperidol (20 mg). In one study, olanzapine (16.3 mg/day) was superior to haloperidol (16.4 mg/day) for the treatment of negative symptoms,²⁰ but another study found that 13.2 mg olanzapine was superior for both positive and negative symptoms compared with 11.8 mg haloperidol.²¹ Among the first-line agents, olanzapine is associated with the longest time to treatment discontinuation,¹⁴ a finding that suggests that olanzapine may somewhat differ from the other SGAs in effectiveness. Olanzapine has a low rate of EPS and causes slight, transient prolactin elevations. Clinically significant weight gain occurs with olanzapine across the dosage range. The degree of weight gain is similar to that seen with clozapine and greater than that observed with the other SGAs. Olanzapine is also associated with hypertriglyceridemia, increased fasting glucose, and new-onset type 2 diabetes (i.e., metabolic syndrome), and among the first-line SGAs, it is associated with the greatest elevations in these metabolic parameters.¹⁴

► Quetiapine

Structurally quetiapine is related to clozapine and olanzapine. Quetiapine has high affinity for 5-HT_{2A} receptors and lower affinity for D₂ and D₁ receptors. This drug has some affinity for α_1 , α_2 , and H₁ receptors, and very little for muscarinic receptors. The efficacy of quetiapine for psychosis was established in two controlled trials, which found that maximum benefits occurred at 300 mg/day or greater.^{22,23} The most effective doses of quetiapine may be higher than 500 mg/day. Quetiapine may have beneficial effects for anxious and depressive symptoms. Because of its low D₂ occupancy, motor side effects and prolactin elevations are usually not seen with quetiapine. Orthostasis occurred in 4% of subjects in clinical trials. Sedation may occur but is generally transient. Mild weight gain and minor elevations in triglycerides can occur. The use of agents that can prolong the QT interval corrected for heart rate (QTc interval) should be avoided during quetiapine treatment, and quetiapine should not be used in circumstances that may increase risk of torsades de pointes (congenital long QT syndrome, arrhythmia, hypokalemia, or hypomagnesemia).

► Ziprasidone

Ziprasidone was developed specifically to block D₂ receptors but also bind with even greater affinity to central 5-HT_{2A} receptors. As a result, ziprasidone has a binding affinity ratio of 11:1 for 5-HT_{2A}:D₂ receptors. Ziprasidone also has a relatively high affinity for 5-HT_{2C}, 5-HT_{1D}, α_1 -adrenergic, and D₁ receptors.²⁴ Several short-term, placebo-controlled,

premarketing clinical trials led to the recommended dose range of 40 to 160 mg/day with food,²⁵ but current practice suggests that efficacy may be greater at doses over 200 mg/day. Liability for EPS, weight gain, and lipid elevations were very low in the clinical trials. Ziprasidone is associated with some prolongation of the QTc interval in adults. However, drug overdose data and studies of pharmacokinetic interactions have thus far shown little evidence that significant QTc prolongation occurs. Use caution, however, when using medications affecting ziprasidone metabolism or when prescribed along with other medications known to prolong QTc. Please see the Pharmacokinetics section of this chapter for further discussion. Caution should also be used when prescribing ziprasidone in situations that have increased risk for prolongation of QTc including comorbid diabetes, electrolyte disturbances (e.g., low serum sodium and potassium concentrations), heavy alcohol consumption, female gender, and congenital QTc disorder.

► Aripiprazole

Aripiprazole was formulated to function as a potential dopamine modulator, with both antagonist and agonist activity at the D₂ receptor. It is the first D₂ partial agonist available for the treatment of schizophrenia. This antipsychotic functions as an antagonist in a hyperdopaminergic state and as an agonist when in a hypodopaminergic state. Aripiprazole is also a partial agonist at 5-HT_{1A} receptors, an antagonist at 5-HT_{2A} receptors, and also has affinity for D₃ receptors. Additionally, it has a moderate affinity for α_1 and H₁ receptors with no appreciable affinity for the M₁ receptor.²⁶ In short- and long-term studies, aripiprazole has been shown to improve positive and negative symptoms of schizophrenia compared with placebo.²⁷ The recommended starting dose is 10 to 15 mg/day. No titration is required because the starting dose is an effective dose. The recommended dosing range is 10 to 30 mg/day; doses greater than 30 mg have not been systematically evaluated. Doses should be adjusted in persons who are CYP2D6-poor metabolizers by starting with one-half the usual dose and then adjusting to clinical efficacy, and by giving one-quarter the usual dose if given concomitantly with a CYP3A4 inhibitor. Side effects are low with sedation, nausea, and vomiting occurring most frequently. Elevations in weight, lipids, and glucose are generally negligible, and because of its partial dopamine receptor agonism, it does not usually cause elevations in prolactin. In fact, patients switched to aripiprazole from other antipsychotic agents may experience decreases in prolactin levels.

► Paliperidone

Paliperidone is the separately marketed 9-hydroxy metabolite of risperidone. The effects of risperidone and paliperidone in the body are expected to be similar because the effects of risperidone are thought to be a result of both the parent drug and the 9-hydroxy metabolite. The neurotransmitter receptor binding affinity is also similar between the two agents, with paliperidone having a greater affinity at 5-HT_{2A} compared with D₂ receptors. Unlike many other antipsychotic

medications, paliperidone is mostly excreted unchanged. Patients may be told to expect to see the shell of the tablet in the stool because it does not dissolve in the digestive tract. Short- and long-term studies have established the efficacy of paliperidone compared with placebo.²⁸ For adults with schizophrenia, the recommended oral dose is 6 mg every morning. No dose titration is required; however, if needed, the dose can be adjusted at 5-day intervals to doses of 3 to 12 mg once daily. Side effects of paliperidone are expected to be similar to those of risperidone, including the potential for dose-related EPS and prolactin elevation.²⁹

► Iloperidone

Iloperidone is indicated for acute treatment of adults with schizophrenia. Iloperidone exhibits high affinity for 5HT_{2A} and dopamine D₂ and D₃ receptors and acts as an antagonist at these receptors, as well as the 5HT_{1A} and norepinephrine α_1/α_{2C} receptors. Efficacy for short-term treatment of schizophrenia has been established for positive and negative symptoms of schizophrenia.³⁰ Doses must be titrated because of the risk of orthostatic hypotension and start at 1 mg twice daily, titrating daily up to the recommended dose of 12 to 24 mg (total daily dose). The maximum dose recommendation is 24 mg total daily dose (12 mg twice daily). Dosing should be reduced by half in persons who are poor metabolizers at CYP2D6. Iloperidone has the potential to prolong the QT interval, so clinicians should consider using other drugs first. Common adverse reactions include dizziness, dry mouth, fatigue, orthostatic hypotension, tachycardia, and weight gain. Dizziness, tachycardia, and weight gain were at least two times as common with higher dose (20 to 24 mg total daily dose) iloperidone compared with lower doses (10 to 16 mg total daily dose) in clinical trials.³¹

► Asenapine

Asenapine is indicated for the acute treatment of schizophrenia in adults. Its mechanism of action is thought to be associated with antagonistic activity at 5HT_{2A} and D₂ receptors. Asenapine also exhibits a high affinity for other serotonergic and dopaminergic receptors, as well as α_1 - and α_2 -adrenergic receptors and H₁-receptors. Asenapine's efficacy for short-term and maintenance treatment of schizophrenia has been established.³¹ The recommended starting and target dose for the treatment of symptoms of schizophrenia is 5 mg sublingually twice a day, which is lower than the maximum dose recommended for bipolar disorder. Tablets must be placed under the tongue and allowed to dissolve completely; the tablets should not be chewed or swallowed. Patients should refrain from drinking or eating for 10 minutes after administration. In controlled trials, no added benefit was seen with doses above 10 mg twice daily, but there was an increase in adverse effects. Adverse effects commonly seen with asenapine may include somnolence, dizziness, and akathisia. Somnolence is the most commonly occurring side effect. Asenapine has shown little effect on metabolic parameters and weight change. Recently, labeling for asenapine was modified to alert clinicians regarding

the occurrence of hypersensitivity reactions, including anaphylaxis and angioedema.³¹

► Lurasidone

Lurasidone is indicated for the treatment of adults with schizophrenia. Lurasidone's effectiveness for longer term use (greater than 6 weeks) has not yet been established, so healthcare professionals prescribing lurasidone for extended periods of time should periodically evaluate long-term usefulness for each individual patient. Lurasidone's mechanism of action, like most SGA, is thought to be D₂ and 5HT_{2A} receptors. Lurasidone also has moderate affinity as antagonist at α_{2C} and is a partial agonist at 5HT_{1A} and antagonist at α_{2A} -receptors. Lurasidone's efficacy for the short-term treatment of acute schizophrenia has been established. Prescribing information recommends starting lurasidone at a dose of 40-mg tablet once daily, and initial dose titration is not required. The maximum recommended dose of lurasidone is 80 mg once daily; doses greater than 80 mg/day do not appear to add great benefit, and may be associated with an increase in certain side effects. Lurasidone should be taken with food. Adverse reactions reported in at least 5% of patients (and at least twice the placebo rate) include somnolence, akathisia, nausea, parkinsonism, and agitation. Lurasidone has shown only small effect on weight, and minimal changes in other metabolic parameters.³¹

Patient Encounter, Part 3

KH is hospitalized and prescribed risperidone, titrated to 6 mg/day. After 6 weeks, her sleep pattern has normalized, her irritability and agitation have decreased, she is less preoccupied by the feeling that others can read her thoughts, and her auditory hallucinations of the "spirits" have decreased significantly, so that she is able to ignore them and no longer follows their advice. She is discharged from the hospital and returns home with her parents. Unfortunately, KH misses her first follow-up appointment at the outpatient clinic, and she is not seen again until 2 months after discharge. When she comes in for this appointment, it is apparent that KH is having trouble. She's pacing around the room, stating that she is so restless that she cannot sit still, which started happening a few days ago. Apparently, KH started skipping doses of risperidone last month, after another patient told her it could "mess with my reproduction." Her symptoms started getting worse last week, and her mother, after finding out about the skipped doses, made KH start doubling the prescribed dose of risperidone. It is thought that she's been taking 12 mg of risperidone for the past 5 days.

How would a clinician address KH's ideas that risperidone could "mess with her reproduction?"

What is the basis for this information told to her by another patient?

What side effect is KH currently experiencing, and why?

First-Generation (Typical) Antipsychotics

The FGAs are high-affinity D₂-receptor antagonists. During chronic treatment, these agents block 65% to 80% of D₂ receptors in the striatum and block dopamine receptors in the other dopamine tracts in the brain as well.³² Clinical response is generally associated with 60% D₂-receptor blockade, but 70% and 80% are associated with hyperprolactinemia and EPS, respectively. This group of antipsychotics was widely used from the 1950s to the 1990s, when the SGAs began to replace these agents as first-line therapy.

Dosages for these agents are frequently given as **chlorpromazine equivalent** dosages, which are defined as the dosage of any of the FGAs equipotent with 100 mg of chlorpromazine. The target dose recommendation for acute psychosis is 400 to 600 chlorpromazine equivalents unless the patient's history indicates that this dose may result in intolerable side effects. Generally, maintenance therapy should provide a dose of 300 to 600 chlorpromazine equivalents for maximum efficacy. Information on dosing and available dosage forms is provided in [Table 37-4](#). All FGAs are equally efficacious in groups of patients when used in equipotent doses. However, individual variation does occur, such that a patient may not respond equally to each antipsychotic. Selection of a particular antipsychotic should be based on patient variables, such as the need to avoid certain side effects or drug–drug interactions or previous patient or family history of response.

► Decanoates

Long-acting, depot preparations are available for two FGAs (fluphenazine decanoate and haloperidol decanoate) in the United States. These compounds are esterified antipsychotics formulated in sesame seed oil for deep intramuscular (IM) injection. Because these are long-acting preparations, patients should be exposed to the oral form of the drug first to ensure tolerability. With initial dosing of haloperidol

decanoate, oral supplementation may temporarily be necessary because the drug accumulates over many weeks, not reaching steady state until 4 to 5 dosing intervals have elapsed. The pharmacokinetic profiles of the depot agents are useful parameters for strategic dosing. Patients may be dosed with fluphenazine decanoate on a 1- to 3-week interval, but haloperidol decanoate is usually dosed once a month. Conversion from oral to depot and maintenance dosing recommendations are shown in [Table 37-5](#). Based on these recommendations, a reasonable estimate is that 12.5 mg (0.5 mL) of fluphenazine decanoate given every 2 weeks is approximately equivalent to 10 mg/day of fluphenazine orally. A maintenance haloperidol decanoate dose of 150 mg every 4 weeks is approximately equivalent to 10 mg/day of oral haloperidol. Initial decanoate injections should be preceded by a small test dose.

Side Effects of the First-Generation Antipsychotics

The FGAs are associated with a host of side effects that largely differ between high- and low-potency agents. In general, the low-potency agents are less likely to cause EPS than the high-potency agents. Of note, lower equivalent doses and midpotency agents may be associated with less EPS than once believed and similar to SGAs in clinical trials.¹⁴

The FGAs are associated with EPS, including akathisia (motor or subjective restlessness), dystonia (muscle spasm), and pseudoparkinsonism (akinesia, tremor, and rigidity). These fairly common motor side effects are caused by dopamine antagonism in the nigrostriatal pathways. Akathisia is the most frequently occurring motor side effect, with approximately 20% to 40% of people treated with FGA drugs experiencing it. Roughly half of the cases of akathisia present within 1 month of antipsychotic initiation, although the onset of akathisia many times may be within 5 to 10 days after the first dose or increase in dosage. Younger people

Table 37-4

First-Generation (Typical) Antipsychotics^a

Class	Agent (Brand Name)	Dosage Range (mg/day)	Chlorpromazine Equivalents (mg)	Available Formulations
Butyrophenone	Haloperidol (Haldol)	5–30	2	T, LC, I
Dibenzoxazepine	Loxapine (Loxitane)	25–100	10	C
Diphenylbutylpiperidine	Pimozide (Orap)	1–10	1–2	T
Indole	Molindone (Moban)	25–100	10	T
Phenothiazines	Chlorpromazine (Thorazine)	300–800	100	T, LC, I, R
	Fluphenazine (Prolixin)	2–40	2	T, L, I
	Perphenazine (Trilafon)	8–64	10	T, LC
	Thioridazine (Mellaril)	300–800	100	T, LC
	Trifluoperazine (Stelazine)	15–30	5	T
Thioxanthenes	Thiothixene (Navane)	5–40	4	C

^aLow-potency antipsychotics include thioridazine, mesoridazine, and chlorpromazine. High-potency antipsychotics include haloperidol, fluphenazine, thiothixene, and pimozide.

Table 37-5

Antipsychotic Dosing of Long-Acting Preparations

Drug	Starting Dose	Maintenance Dose	Comments
Haloperidol decanoate	20 × oral haloperidol daily dose; in the elderly use 10–15 × oral haloperidol daily dose Generally 100–450 mg/mo Initial dose should not exceed 100 mg regardless of previous dose requirements (if more than 100 mg, give 3–7 days apart)	10–15 × oral haloperidol daily dose, generally 50–300 mg/mo	With initial dosing, oral supplementation may temporarily be necessary; deep IM injection generally with 21-gauge needle; maximum volume per injection site should not exceed 3 mL Available in 50 and 100 mg/mL (5-mL vials and 1-mL ampules)
Fluphenazine decanoate	1.2 × oral fluphenazine daily dose; generally 12.5-mg/2–3 weeks	Based on starting dose and clinical response Generally 12.5–25 mg dosed at 2–4-wk intervals (may be up to 6 weeks in some cases)	Can be administered IM or SC; 21-gauge needle, must be dry Should not exceed 100 mg; when dosing above 50 mg, should increase in increments of 12.5 mg Available in 25 mg/mL (5-mL vials)
Olanzapine (Zyprexa Relprevv)	To target oral 10 mg/day dose: Either 210 mg/2 wk or 405 mg/4 wk during first 8 wk To target oral 15 mg/day dose: 300 mg/2 wk for first 8 wk To target 20 mg/day oral dose: 300 mg/2 wk	To target oral 10 mg/day dose: after 8 wk, give 150 mg/2 wk or 300 mg/4 wk To target oral 15 mg/day dose: after 8 wk, 210 mg/2 wk or 405 mg/4 wk To target 20 mg/day oral dose: continue with 300 mg/2 wk	Gluteal injection, 19-gauge needle Do not confuse with rapid-acting IM injection Must reconstitute with included diluent Measure amount to inject from vial (there will be remaining suspension in vial) 3-hour observation period; patient must be accompanied to destination No refrigeration needed
Paliperidone (Invega Sustenna)	Initiate with 234 mg on day 1 and 156 mg 1 wk later, both in deltoid muscle	Recommended monthly maintenance dose is 117 mg (range, 39–234 mg)	First two doses must be given in the deltoid muscle; after that, monthly doses given in either the deltoid or gluteal muscle; available as 39-, 78-, 117-, 156-, and 234-mg prefilled syringes
Risperidone long-acting injection (Risperdal Consta)	25 mg every 2 wk	25–50 mg every 2 wk	Previous antipsychotics should be continued for 3 wk after initial dose of risperidone long-acting injection Recommended to establish tolerability with oral risperidone prior to initiation of long-acting injection Available in 12.5-, 25-, 37.5-, and 50-mg vial/kit; must use needle supplied with kit, administer IM

IM, intramuscular; SC, subcutaneous.

and those taking high doses of high-potency antipsychotics are at greater risk for the development of akathisia. Acute dystonic reactions are abrupt in onset and are usually seen within 24 to 96 hours after a first dose or increase in dosage. Characteristic signs and symptoms include abnormal positioning or spasm of the muscles of the head, neck, limbs, or trunk. Dystonia may occur in 10% to 20% of patients. There is higher risk for dystonia in young male patients and those taking high-potency FGAs. Pseudoparkinsonism resembles idiopathic Parkinson's disease, and features may be present in up to 30% to 60% of people treated with FGAs. The onset of symptoms is usually seen within 1 to 2 weeks after initiation of dosing or a dose increase. Risk factors include older age, female gender, high doses, and possibly those with depressive symptoms.³³

Tardive dyskinesia is a movement disorder characterized by abnormal choreiform (rapid, objectively purposeless, irregular, and spontaneous movement) and athetoid (slow and irregular) movements occurring late in onset in relation

to initiation of antipsychotic therapy. This adverse effect usually develops over several months or after at least 3 months of cumulative exposure to antipsychotic medications. The severity of TD can range from mild and barely noticeable to severe, with interference with ambulation. TD may stigmatize persons taking antipsychotics if symptoms are visible to others. The estimated average prevalence of TD is 20% with a range of 13% to 36%. The incidence of new cases per treatment year with FGAs is approximately 5%.³⁴ TD is reversible in one-third to half of cases with the cessation of the antipsychotic.³⁵ When the antipsychotic is tapered or discontinued, there is typically an initial worsening of abnormal movements. Risk factors for TD include older age; longer duration of antipsychotic treatment; and presence of EPS, substance abuse, and mood disorders. SGAs carry a lower risk of TD than FGAs. A pooled analysis of studies indicated that new-onset TD incidence was 0.8% per year with SGA treatment versus 5.4% per year for FGAs.¹⁵ A more recent review of studies published from 2004 to

2008 reported a smaller difference in incidence of TD between agents at 3.9% for SGAs and 5.5% for FGAs.³⁶

Neuroleptic malignant syndrome (NMS), a life-threatening emergency characterized by severe muscular rigidity, autonomic instability, and altered consciousness, can occur uncommonly with all the FGAs and may also occur with SGAs. Rapid dose escalation, the use of high-potency FGAs at higher doses, and younger patients are associated with a higher risk of NMS. When NMS is diagnosed or suspected, antipsychotics should be discontinued and supportive and symptomatic treatment begun (e.g., antipyretics, cooling blanket, intravenous fluids, oxygen, monitoring of liver enzymes, and complete blood cell count). Dopamine agonists (e.g., bromocriptine) should be considered in moderate to severe cases.

Additionally, dermatologic side effects, photosensitivity, and cataracts may occur with the phenothiazine agents. Sedation is mediated by H₁-receptor antagonism; anticholinergic side effects (constipation, blurred vision, dry mouth, and urinary retention) are caused from M₁-receptor antagonism; and α_1 -receptor blockade is associated with orthostatic hypotension and tachycardia (Table 37-6). QTc prolongation may occur with the lower potency FGAs, and thioridazine has a black box warning for QTc prolongation.

Treatment Guidelines and Algorithms

- Because of the plethora of choices and the rising costs of SGAs, algorithms and treatment and consensus guidelines have been developed for the treatment of schizophrenia. One widely accepted algorithm in the United States was developed as part of the Texas Implementation of Medication Algorithms (TIMA). A national panel of experts developed this algorithm, most recently updated in 2006.³⁷ Algorithms go beyond guidelines, providing a framework for clinical decision making at critical decision points. According to the TIMA schizophrenia algorithm, the SGAs (except clozapine) should be used as first-line treatment. The choice of SGA is guided by consideration of the side effect profiles and the clinical characteristics of the patient. Treatment with a given drug should be continued for 4 to 6 weeks to assess

response. If only partial response or nonresponse is noted, a trial of a second SGA should be initiated (Fig. 37-1). Other similar guidelines include the APA Practice Guidelines for schizophrenia,⁸ the Expert Consensus Guideline Series,⁹ and the 2009 Schizophrenia Patient Outcomes Research Team (PORT) Treatment Recommendations.³⁸ In contrast to the TIMA guidelines, the PORT recommends either the use of FGAs or SGAs as first-line therapy.

Treatment Adherence

Medication nonadherence in schizophrenia is common and often associated with symptom relapse.³⁹ Estimates of nonadherence to antipsychotics range from approximately 24% to 88% with a mean of approximately 50%. Subjects who are nonadherent have approximately a fourfold greater risk of a relapse than those who are adherent. Adherence to antipsychotic regimens is problematic for many reasons. Neurocognitive deficits and paranoid symptoms may hamper adherence, and identification of nonadherence by caretakers and providers can be challenging. Frequently, there is no obvious connection between nonadherence and symptom exacerbation because there may be no immediate consequences of missing a dose, and patients may relapse suddenly after several weeks or months of nonadherence. The antipsychotic side effects such as EPS, weight gain, and sexual dysfunction are also a major contributing factor to treatment nonadherence. Several other factors associated with nonadherence include delusions, substance abuse, and deficit symptoms.⁴⁰ For patients who have relapsed several times because of nonadherence, have a history of dangerous behavior, or risk a significant loss of social or vocational gains when relapsed, treatment with long-acting formulations should be encouraged. Risperidone, paliperidone, and olanzapine are all available as long-acting formulations (Table 37-5).

Special Populations

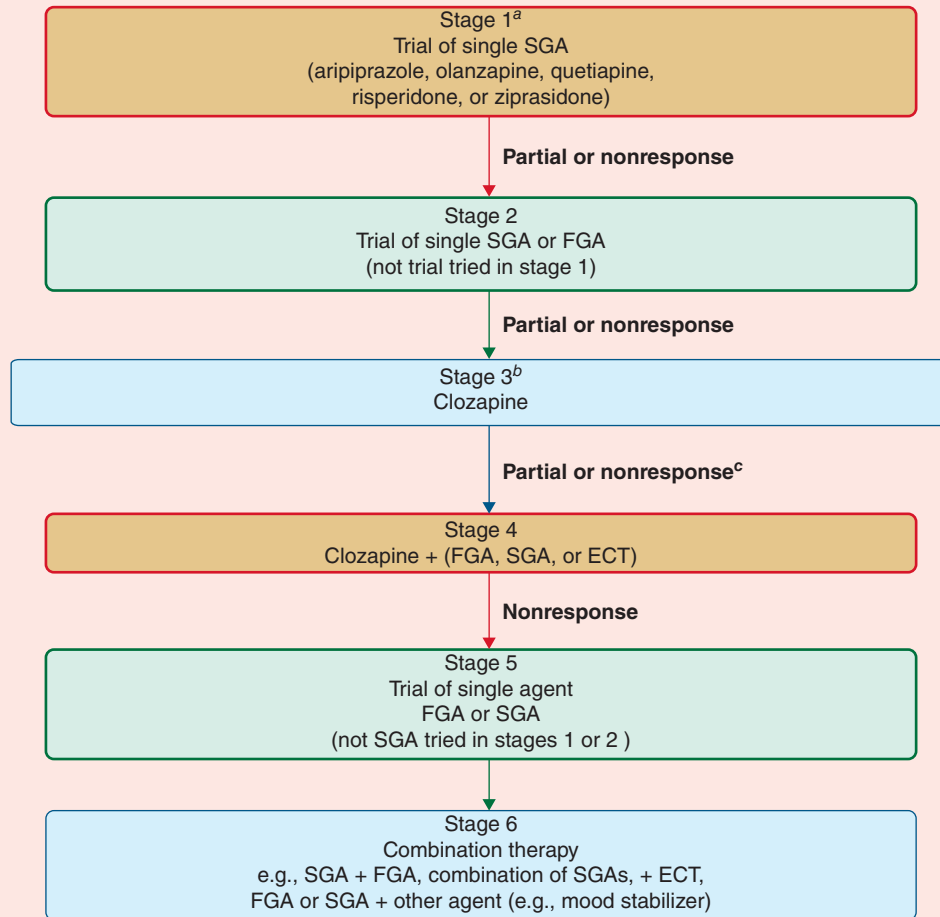

► Dosing in Renal and Hepatic Impairment

See Table 37-7 for dosing guidance on specific antipsychotic medications.

Choice of antipsychotic should be guided by considering the clinical characteristics of the patient and the efficacy and side effect profiles of the medication.

Stages may be skipped depending on the clinical picture or history of antipsychotic failures.

First episode or never before treated with an SGA

^aif patient is nonadherent to medication, the clinician may use risperidone microspheres, haloperidol, or fluphenazine decanoate at any stage, but should carefully assess side effects.

^bMay consider earlier trial of clozapine if history of recurrent suicidality, violence, comorbid substance abuse, or persistent positive symptoms >2 years. If persistent positive symptoms >5 years, clozapine trial independent of number of preceding trials.

^cEvaluate patient for other underlying or concomitant factors; consider adding cognitive behavioral therapy and other psychosocial interventions.

FIGURE 37-1. Texas Implementation of Medication Algorithms (TIMA) algorithm for antipsychotic treatment in schizophrenia. Choice of antipsychotic should be guided by considering the clinical characteristics of the patient and the efficacy and side effect profiles of the medication. Any stage may be skipped depending on the clinical picture or history of antipsychotic failures. (ECT, electroconvulsive therapy; FGA, first-generation antipsychotic; SGA, second-generation antipsychotic.) (Adapted from the Texas Department of State Health Services.)

► Children and Adolescents

Epidemiologic data show that 10% to 30% of patients with schizophrenia develop their first psychotic symptoms before their 18th birthday. The diagnosis of schizophrenia in children and adolescents is often difficult to make, and the differential diagnosis includes pervasive developmental disorders, attention-deficit hyperactivity disorder, and language or communication disorders. The existence of prominent hallucinations or delusions, however, helps make

the diagnosis because they are not a prominent part of the other disorders. Fifty-four percent to 90% of patients developing schizophrenia before age 18 years have premorbid abnormalities such as withdrawal, odd traits, and isolation.⁴¹

Treatment for psychotic children and adolescents ideally involves an intensive and comprehensive program with a highly structured environment that includes special education and psychoeducation. Day treatment, hospitalization, or long-term residential treatment may be necessary. Pharmacologic treatment is indicated if psychotic symptoms

Table 37-7

Second-Generation Antipsychotic Dosing Recommendations for Special Populations

Medication	Pediatric	Geriatric	Renal Impairment	Hepatic
Aripiprazole	Ages 13–17 years (schizophrenia): Initiate 2 mg every day, increasing to target of 10 mg gradually over several days; maximum, 30 mg/day	No adjustment necessary	No adjustment necessary in renal impairment	No adjustment necessary in hepatic dysfunction
Asenapine	No pediatric FDA indication	No adjustment necessary	No adjustments necessary in renal impairment	No adjustment necessary for mild to moderate hepatic impairment, but use not recommended in severe hepatic impairment
Iloperidone	No pediatric FDA indication	No adjustment necessary	No adjustment necessary in renal impairment	Not recommended for use in hepatic impairment
Lurasidone	No pediatric FDA indication	No adjustment required	In moderate to severe renal impairment, do not exceed 40 mg/day	In moderate and severe hepatic impairment, do not exceed 40 mg/day
Olanzapine	Oral: Ages 13–17 years (schizophrenia): Initial dose, 2.5–5 mg orally every day with target dose of 10 mg/day; maximum dose, 20 mg/day Long-acting injection: Not approved in children	Oral: 5 mg/day, if escalation needed use caution Long-acting injection: No information given	Oral: In renal impairment, no adjustment usually necessary; however, consider a lower initial dose of 5 mg/day Long-acting injection: No information given	Oral: No change needed in Childs Pugh Classification A and B Long-acting injection: No information given
Paliperidone	Oral: Ages 12–17 years (schizophrenia): Oral: Dose by body weight: less than 51 kg, initiate 3 mg/day oral, increase at increments of more than 5 days; maximum, 6 mg/day At least 51 kg/day, initiate at 3 mg/day, increase at increments of more than 5 days, maximum of 12 mg/day	Oral: For patients with normal renal function, no adjustment is required, but if renal impairment guidance is available	Long-acting injection: CrCl 50–79 mL/min (0.83–1.32 mL/s): initiate with 156 mg IM day 1, 117 mg IM 1 week later, with maintenance at 78 mg IM monthly CrCl less than 50 mL/min (0.83 mL/s): Use not recommended Oral: CrCl 50–79 mL/min (0.83–1.32 mL/s): 3 mg once daily initiation, maximum 6 mg/day CrCl between 10 and 49 mL/min (0.17–0.82 mL/s): 1.5 mg once daily initiation; maximum, 3 mg/day CrCl less than 10 mL/min (0.17 mL/s): Use is not recommended	Long-acting injection: No dosage adjustment needed for mild or moderate impairment Oral: For Child-Pugh Class A and B, no dose adjustment is required
Quetiapine	Regular-release tablets ONLY: Indicated for schizophrenia (ages 13–17 years): Initiate 50 mg/day on day 1; may increase to 400 mg gradually by day 5 administered as 2–3 doses; recommended 400–800 mg/day; maximum, 800 mg/day	Regular-release tablets: Slower dose escalation and a lower target dose Extended-release tablets: Initiate at 50 mg/day and increase at 50-mg/day increments based on response or tolerance	No dosing recommendations for renal dysfunction	Regular-release tablets: Initiate at 25 mg/day, increasing daily in amounts of 25–50 mg/day to effective dose Extended-release tablets: Should be initiated with 50 mg/day, increasing in 50-mg/day increments

(Continued)

Table 37-7

Second-Generation Antipsychotic Dosing Recommendations for Special Populations (Continued)

Medication	Pediatric	Geriatric	Renal Impairment	Hepatic
Risperidone	Oral: Pediatric ages 13 years and older (schizophrenia): Initiate at 0.5 mg orally daily, adjusting at intervals of at least 24 hours and in increments of 0.5–1 mg/day as tolerated Recommended target dose, 3 mg/day	Long-acting IM: Initial dose, 25 mg IM every 2 wk with a 3-week oral crossover Oral: Initiate at 0.5 mg twice daily; may increase by 0.5 mg twice daily, increases above 1.5 mg twice daily done at intervals of at least 1 week	Long-acting IM: Patients with renal impairment should receive titrated doses of oral risperidone before initiation of IM (more detail in prescribing information) Oral: Recommended initial dose in severe renal impairment, 0.5 mg twice daily; dose may be increased by 0.5 mg twice daily, but increases above 1.5 mg twice daily should be done at intervals of at least 1 week	Long-acting IM: Titrate with oral risperidone (see renal dosing) Oral: Recommended initiation in severe hepatic impairment (see renal dosing)
Ziprasidone	No pediatric indication	No official adjustment recommended	Oral doses: No adjustment necessary for mild to moderate renal impairment IM doses: Use with caution because of cyclodextrin sodium excipient	No adjustment necessary for mild to moderate hepatic impairment

CrCl, creatinine clearance; FDA, Food and Drug Administration; IM, intramuscular.

cause significant impairments or interfere with other interventions. Children and adolescents are more vulnerable to EPS, particularly dystonias, than are adults. Because of concerns about EPS and TD, it has been recommended that pharmacotherapy in children and adolescents should be initiated with SGAs. Aripiprazole, risperidone, quetiapine, and paliperidone are indicated by the Food and Drug Administration (FDA) for the treatment of schizophrenia in varying ages of pediatric populations. Recommended initiation and target dosing is lower for adolescents than adults.

Agents with significant sedation and anticholinergic side effects are not preferred because they can cause attention difficulties and cognitive dulling that may interfere with optimal school performance. Compared with adults, children and adolescents tend to gain more weight when taking these agents. Young patients should be started on lower doses than adults and should be titrated at a slower rate. Side effects should be monitored closely during initiation and throughout maintenance therapy. Informed consent, addressing the rationale for treatment and potential risks and benefits of therapy, should be obtained from the parents or guardians before treatment with any antipsychotic medication, and assent should be obtained from the child as well.

► Elderly

Psychotic symptoms in late life (after 65 years of age) are generally a result of an ongoing chronic illness carried over from younger life; however, a small percentage of patients develop psychotic symptoms de novo, defined as late-life schizophrenia. However, other illnesses presenting with psychotic symptoms are common in this population; approximately one-third of patients with Alzheimer's disease, Parkinson's disease,

and vascular dementia experience psychotic symptoms. The majority of data for antipsychotic use in the elderly comes from experience treating these other disease states.

Antipsychotics can be safe and effective for the treatment of psychosis in the elderly, if used at lower doses than those commonly used in younger adults. Older adults are particularly vulnerable to the side effects of the FGAs. Parkinsonian symptoms reportedly occur in more than 50% of all elderly patients receiving these agents, and the cumulative annual incidence of TD in middle-aged and elderly patients is greater than 25%. With the SGAs, the risk of TD appears to be approximately 4%. However, these numbers are based on limited data, and future investigations are likely to yield more specific information regarding TD risk with the SGAs.⁴² The likelihood of reversing this potentially debilitating condition diminishes with age.

Orthostasis, estimated to occur in 5% to 30% of geriatric patients, is a major contributing factor to falls that often leads to fractures, injuries, and loss of independence.

Low-potency antipsychotics and clozapine are more likely to cause significant drops in orthostatic blood pressure. Antipsychotics may cause or worsen anticholinergic effects, including constipation, dry mouth, urinary retention, and cognitive impairment. Cognitive impairment may lead to decreased independence, and a more rapid decline in cognitive functioning may occur in the elderly treated with antipsychotics than in the younger adult population. As a result of data showing a statistically significant increase in mortality rate in elderly dementia patients who are treated with SGAs, a warning was added in 2005, and this warning was extended to include all antipsychotics, FGA and SGA, as of 2008, when the results of two epidemiological studies suggested that the risk for FGA was comparable to or higher

than those for SGA. Because all antipsychotics now carry a warning, patients and families should be informed of this risk before treatment with these agents in patients with dementia. Dosing in the elderly is initiated lower, and titration is slower than in younger adults. Maximum doses are often half of adult doses. See Table 37-7 for specific dosing information for certain antipsychotics.

► *Dually Diagnosed Patients*

The prevalence of substance dependence and abuse among persons with schizophrenia is significantly higher than in the general population. Estimates of the proportion of schizophrenic patients abusing alcohol and/or illicit drugs range from 40% to 60%.⁴³ The most common drugs of abuse are cannabis, cocaine, and alcohol. Unfortunately, substance use often worsens the course and complicates the treatment of schizophrenia. Dually diagnosed patients are more likely to be nonadherent with treatment. Characteristically, they have a poorer response rate to the FGAs, have more severe psychosis, and have higher rates of relapse and rehospitalization than patients who are not abusing substances. EPS may occur more frequently in substance-abusing patients, and alcohol use is a risk factor for developing TD. A growing body of literature indicates that the SGAs are effective in this population, and some studies have shown a reduction in the use of drugs and alcohol with the SGAs.⁴⁴

► *Treatment-Resistant Patients*

For approximately 20% to 30% of people with schizophrenia, drug treatment is ineffective. A standard definition of treatment resistance is persistent positive symptoms despite treatment with at least two different antipsychotics given at adequate doses (a dose equivalent to at least 600 mg of chlorpromazine) for an adequate duration (4 to 6 weeks). In addition, patients must have a moderately severe illness as defined by rating instruments, and have a persistence of illness for at least 5 years.⁴⁵ These patients are often highly symptomatic and require extensive periods of hospital care.

● **Clozapine** To date, clozapine remains the only drug with proven and superior efficacy in treatment-resistant patients, and it is currently the only drug approved for treatment-resistant schizophrenia. Studies have shown a response of approximately 30% to 50% in treatment-resistant patients. Clinical trials have consistently found clozapine superior to traditional antipsychotics for treatment-refractory patients, and it is efficacious even after nonresponse to other SGAs and in partially responsive patients. It is often effective even in those who have had a poor response to other medication for years. Recent studies have demonstrated that it has a beneficial effect for aggression and suicidality, which led to the FDA approval for the treatment of suicidal behavior in people with psychosis.⁴⁶

To date, it has not been elucidated what pharmacologic properties of clozapine contribute to its superior efficacy. Clozapine has a low affinity for D₂ receptors, blocks

D₁ receptors, and is a 5-HT_{2A} antagonist. Its unsurpassed efficacy suggests that there is a neuropharmacologic effect associated with clozapine that to date is unique to this agent.

Clozapine's use is limited by its association with the rare but life-threatening risk of agranulocytosis. Other side effects include seizures, as well as common unpleasant side effects, including sedation, enuresis, anticholinergic effects, weight gain, and hypersalivation. The long-term hematologic monitoring (see monitoring section) required for prevention of agranulocytosis can be a barrier for both patients and care providers. The optimal plasma level of clozapine is a minimum trough level of 300 to 350 ng/mL (300 to 350 mcg/L or 0.92 to 1.07 μmol/L or 918 to 1,071 nmol/L), usually corresponding to a daily dose of 200 to 400 mg, although dosage must be individualized. According to published guidelines and recommendations, clozapine should be considered after two failed antipsychotic trials but may be considered sooner if the individual patient situation warrants.³⁷

Other Strategies Approximately 30% of patients treated with clozapine will not respond, and another 30% will have only a partial response to the drug. Treatment options with other medications are limited after clozapine nonresponse. For these patients, the best evidence points to augmentation using an FGA, SGA, or **electroconvulsive therapy** (ECT). The only available data support the combination of clozapine with risperidone, clozapine with lamotrigine, or clozapine with aripiprazole; however, controlled trial results are mixed. Other potential strategies include combining antipsychotics with mood stabilizers (e.g., lithium, valproate, and topiramate) or antidepressants (mirtazapine).³⁷

► *Acutely Psychotic Patients*

Psychiatric emergencies occur in a variety of settings, including emergency departments, psychiatric units, medical facilities, and outpatient settings. Although verbal interventions are recommended as initial interventions, most psychiatric emergencies require both pharmacologic and psychological interventions. Often, the psychiatrist must make decisions based on limited information and history. IM formulations are available for a number of FGAs and three SGAs (aripiprazole, ziprasidone, and olanzapine). These formulations are safe and effective in treating patients with acute psychosis. These SGAs are now recommended as first-line therapy in agitated schizophrenia patients; however, IM lorazepam with or without concomitant oral (tablets, liquid, or disintegrating tablets) SGAs are also used. Concomitant olanzapine and benzodiazepines may cause orthostasis. High doses of FGAs, termed *rapid neuroleptization*, is no longer recommended.

► *Pregnancy and Lactation*

When to use antipsychotics in pregnancy and during lactation remains a complicated decision based on a careful analysis of risks and benefits. Women with schizophrenia,

even those who are unmedicated, have a significantly greater risk for stillbirth, infant death, preterm delivery, low infant birth weight, and infants who are small for gestational age. A labeling change for antipsychotic medications has been implemented by the FDA in order to address the potential risk for EPS and symptoms of withdrawal in newborns whose mothers were treated with antipsychotics in the third trimester of pregnancy. Symptoms may include agitation, abnormal muscle tone, tremor (increased or decreased), sleepiness, and difficulty in breathing or feeding, and they may last for hours to days after delivery. In some newborns, symptoms do not require specific treatment, but in other situations, longer hospital stays may be required.

Women who experience a relapse in psychotic symptoms during pregnancy are at the greatest risk for birth complications.⁴⁷ Because risks related to psychotic relapse may be more detrimental than antipsychotic treatment to both the mother and baby, antipsychotics are often continued during this period. Women treated with antipsychotics who become pregnant should not discontinue use of these agents without consulting their healthcare professionals.

Essentially all antipsychotic medications pass through the placenta. Both FGAs and SGAs may be associated with an increased risk of neonatal complications. High-potency FGAs are associated with a low risk for congenital abnormalities; however, limb defects and dyskinesias have been reported.⁴⁸ Low-potency phenothiazine antipsychotics may increase the risk of congenital abnormalities when used in the first trimester. According to the relevant literature published to date, there appears to be little risk associated with the first-line SGAs.⁴⁹ Long-term neurobehavioral studies of children

exposed to SGAs in utero have not yet been done, however, and certain FGA agents may be preferred in drug-naïve pregnant patients because of a larger reproductive safety profile and cumulative exposure data. If pregnancy occurs during antipsychotic treatment, however, continuation of previous therapy should be considered preferential. On the basis of available data, generalization is impossible, and each case and specific antipsychotic should be weighed on an individual basis. Although SGAs are excreted in breast milk, most case reports have reported a low frequency of deleterious effects on the infant. Women taking SGAs may have enhanced fertility compared with women taking FGAs because the SGAs (except risperidone and paliperidone) are less likely to cause prolactin elevations leading to anovulation. Therefore, careful discussion with patients, including education about birth control, must occur.

Pharmacokinetics

Pharmacokinetic and pharmacodynamic issues are not generally a major concern with antipsychotic treatment; however, additive side effects may occur with combined treatment, and a few clinically significant drug interactions are notable (Table 37-8). In addition, cigarette smoking can cause significant interactions with the metabolism of certain antipsychotics by induction of CYP1A2 (clozapine, olanzapine). All of the antipsychotics are highly protein bound; however, protein-binding interactions are generally not clinically significant. Absorption of most antipsychotics is not affected by food, with the exception of lurasidone and ziprasidone. The mean maximum concentration of

Table 37-8

Metabolism and Drug Interactions With Antipsychotics

Antipsychotic	Major CYP450 Metabolic Enzyme	Other CYP450 Metabolic Pathways	Increase Antipsychotic Concentrations	Decrease Antipsychotic Concentrations
Aripiprazole	3A3/4	2D6	Fluvoxamine, ketoconazole	Carbamazepine
Asenapine	Glucuronidation by UGT1A4 and CYP 1A2	3A4, 2D6	Fluvoxamine	
Clozapine	1A2	3A3/4, 2D6, 2C19	Fluvoxamine, ciprofloxacin, paroxetine	Cigarette smoking
Haloperidol	2D6, 3A3/4		Fluvoxamine, fluoxetine, ketoconazole	Carbamazepine
Iloperidone	2D6, 3A4		Ketoconazole, fluoxetine, paroxetine	
Lurasidone	3A4		Ketoconazole, diltiazem	Rifampin
Olanzapine	1A2	2D6	Fluvoxamine, ciprofloxacin, paroxetine	Cigarette smoking
Paliperidone	2D6, 3A4 (in vitro, but limited role in vivo)		Divalproex sodium, paroxetine	Carbamazepine (via increased renal elimination)
Perphenazine	2D6		Fluvoxamine, fluoxetine, paroxetine	
Quetiapine	3A3/4	2D6	Fluvoxamine, ketoconazole	Carbamazepine
Risperidone	2D6	3A3/4	Fluoxetine, paroxetine	Carbamazepine
Thioridazine	2D6	1A2	Fluvoxamine	Cigarette smoking
Ziprasidone	3A3/4		Fluvoxamine, ketoconazole	Carbamazepine

CYP450, cytochrome P-450 isoenzyme.

lurasidone increases threefold when administered with food, and ziprasidone's absorption is increased by 60% to 70% when given with meals.

All antipsychotics are, at least to some extent, metabolized by hepatic microsomal enzymes to water-soluble compounds that are excreted by the kidneys. Table 37–8 lists the primary metabolic enzymes and some potential drug interactions for the antipsychotic medications. Clinicians should assess the clinical impact of the addition or discontinuation of these drugs in individual patients and should make appropriate adjustments when necessary. Unlike the other antipsychotics, ziprasidone is mostly metabolized by aldehyde oxidase, a metabolic system independent of the CYP450 system. Paliperidone, the 9-hydroxy metabolite of risperidone, is mostly excreted unchanged in the urine, although up to one-third may be metabolized. Another recent discovery in metabolism of antipsychotics and their distribution involves the transmembrane energy-dependent efflux transporter, P-glycoprotein. This may limit the ability of a number of drugs to penetrate the blood–brain barrier and therefore impact pharmacologic activity in the brain.⁵⁰ Antipsychotics currently known to use this pathway include perphenazine, haloperidol, fluphenazine, quetiapine, risperidone, and olanzapine.⁵¹

Because of its propensity to cause prolongation of the QTc interval, the use of ziprasidone with other agents that prolong the QTc interval should be avoided. These other agents include, but are not limited to, antiarrhythmic medications such as quinidine and sotalol, certain FGAs (chlorpromazine, droperidol, mesoridazine, pimozide, and thioridazine), and certain antibiotics (e.g., gatifloxacin, halofantrine, mefloquine, moxifloxacin, and pentamidine). Ziprasidone has not been shown to have clinically significant drug interactions with the CYP450A3/4 inhibitors regarding increasing the QTc; however, higher doses, especially given with inhibitors of CYP450A3/4 (e.g., ketoconazole and erythromycin), should be used cautiously. The use of quetiapine with other agents that prolong the QTc interval should also be avoided. Clinicians should also be vigilant to avoid pharmacodynamic interactions with any of the antipsychotics involving additive side effects from combination therapies. Side effects that may be worsened with combination therapies include sedation, hypotension, anticholinergic symptoms, and weight gain or metabolic abnormalities.

Adjunct Pharmacologic Treatments

The judicious use of pharmacologic therapies other than antipsychotics is often necessary in the treatment of patients with schizophrenia. Concomitant medications may be indicated for the treatment of motor side effects, anxiety, depression, mood elevation, and possibly refractory psychotic symptoms. Anticholinergic medications (e.g., benztropine, 1 to 2 mg two times daily; trihexyphenidyl, 1 to 3 mg three times daily; and diphenhydramine, 25 to 50 mg two times daily) are used to effectively treat EPS, thereby improving the tolerability of these medications. They may be prescribed prophylactically with high-D₂-binding agents or in patients at risk for EPS or for treatment of EPS. Beta-blockers (e.g., propranolol 30 to 120 mg/day) are sometimes effective for

patients who develop akathisia. In some situations, such as on an inpatient unit, the concomitant use of benzodiazepines (e.g., lorazepam 1 to 3 mg/day) with the SGAs may be necessary for agitation and insomnia.

Antidepressants may be useful for patients with depressive symptoms. Because suicide and depression are linked, aggressive treatment is necessary when depression is present. The selective serotonin reuptake inhibitors (SSRIs) are the preferred agents, but may inhibit the CYP450 enzymes, thus raising plasma concentrations of clozapine, olanzapine, and haloperidol. The mood stabilizers, such as lithium and the anticonvulsants, have long been used adjunctively with the antipsychotics to treat the affective component of schizoaffective disorder. Last, much research is currently underway to develop better treatments for primary negative symptoms and cognitive impairment; however, no approved treatments are yet available.

OUTCOME EVALUATION

Patient Education

8 *Education of the patient and family regarding the benefits and risks of antipsychotic medications and the importance of adherence to their therapeutic regimens must be integrated into pharmacologic management.* Meetings for purposes of medication management offer an opportunity to provide some education on the general illness. Discuss the nature and course of schizophrenia and be prepared to accept that the patient might have a different understanding of the nature of his or her illness. Key points to cover include:

- Involve families in the education and treatment plans because family psychoeducation may decrease relapse, improve symptomatology, and enhance psychosocial and family outcomes.⁵²
- Be clear that there is no cure for schizophrenia and that medications only help to decrease the symptoms.
- Explain common and rare but dangerous side effects.
- Stress the importance of medication and treatment adherence for improving long-term outcomes in schizophrenia.

Symptom Monitoring

Develop a good working alliance with the patient. In the absence of a solid therapeutic foundation, patients are frequently reluctant to share their psychotic experiences. When a solid working relationship and some knowledge of the patient's psychotic experiences exist, perform a more structured interview. Many assessments are available to objectively rate positive and negative symptoms, level of function, and life satisfaction. The most commonly used scales include:

- Positive and Negative Symptom Scale (PANSS)
- Brief Psychiatric Rating Scale (BPRS)
- Clinical Global Impression (CGI) Scale

Using these scales on a regular basis, particularly when switching medications or changing doses, is a more reliable

means of monitoring for improvement. Certainly, symptom assessments cannot capture the full range of possible improvements a patient may experience, but they can be useful in deciding whether a medication is having substantial benefit.

Side Effect Monitoring

7 Regularly monitor patients for side effects and overall health status while taking antipsychotic medications.^{53,54} Perform orthostatic blood pressure measurements before initiating antipsychotics and throughout treatment. Ask about impaired menstruation, libido, and sexual performance regularly. Encourage patients to have annual eye examinations

because several antipsychotic medications have been associated with the premature development of cataracts. Check body weight, fasting glucose, glycosylated hemoglobin, and lipid profile at baseline, at 4 months after initiation of medication, and then yearly.⁵⁵ For patients at higher risk of developing diabetes and those who gain weight, check body weight more often (Table 37-9). Encourage patients to act proactively against weight gain through healthier eating and exercise. Perform baseline electrocardiography for patients with preexisting cardiovascular disease or risk for arrhythmia. With clozapine therapy, there is a risk for the development of agranulocytosis, which is greatest in the first 6 months of treatment. Current guidelines require the monitoring of white blood cell counts before drug dispensing (Table 37-10).

Table 37-9

Monitoring Protocol for Patients on Second-Generation Antipsychotics

	Baseline	4 Weeks	8 Weeks	12 Weeks	Quarterly	Annually	Every 5 Years
Personal or family history ^a	X					X	
Weight	X	X	X	X	X		
Waist circumference	X					X	
Blood pressure	X			X		X	
Fasting plasma glucose	X			X		X	
Fasting plasma lipids	X			X			X

^aOf obesity, diabetes, dyslipidemia, hypertension, or cardiovascular disease.

Data from Love RC, Mackowick M, Carpenter D, Burks EJ. Expert consensus-based medication-use evaluation criteria for atypical antipsychotic drugs. *Am J Health Syst Pharm* 2003;60:2455–2470.⁵⁶

Table 37-10

Monitoring of White Blood Cell Count and Absolute Neutrophil Count During Clozapine Treatment

	Hematologic Values ^a	Frequency of WBC and ANC Monitoring
Before clozapine initiation	Recommended levels: WBC $\geq 3.5 \times 10^3/\text{mm}^3$ ($3.5 \times 10^9/\text{L}$) and ANC $\geq 2 \times 10^3/\text{mm}^3$ ($2 \times 10^9/\text{L}$) No history of a myeloproliferative disorder or clozapine-induced agranulocytosis	
Initiation to 6 months	WBC $\geq 3.5 \times 10^3/\text{mm}^3$ ($3.5 \times 10^9/\text{L}$) and ANC $\geq 2 \times 10^3/\text{mm}^3$ ($2 \times 10^9/\text{L}$)	Weekly for 6 months
6–12 months	WBC $\geq 3.5 \times 10^3/\text{mm}^3$ ($3.5 \times 10^9/\text{L}$) and ANC $\geq 2 \times 10^3/\text{mm}^3$ ($2 \times 10^9/\text{L}$)	Every 2 weeks for 6 months
After 12 months of therapy	WBC $\geq 3.5 \times 10^3/\text{mm}^3$ ($3.5 \times 10^9/\text{L}$) and ANC $\geq 2 \times 10^3/\text{mm}^3$ ($2 \times 10^9/\text{L}$)	Every 4 weeks
Whenever clozapine is discontinued		Weekly for at least 4 weeks from day of discontinuation
Mild leukopenia or granulocytopenia	WBC value lies between $3 \times 10^3/\text{mm}^3$ ($3 \times 10^9/\text{L}$) and $3.5 \times 10^3/\text{mm}^3$ ($3.5 \times 10^9/\text{L}$) or ANC lies between $1.5 \times 10^3/\text{mm}^3$ ($1.5 \times 10^9/\text{L}$) and $2 \times 10^3/\text{mm}^3$ ($2 \times 10^9/\text{L}$)	Twice weekly until returned to recommended levels
Moderate leukopenia or granulocytopenia	WBC value lies between $2 \times 10^3/\text{mm}^3$ ($2 \times 10^9/\text{L}$) and $3 \times 10^3/\text{mm}^3$ ($3 \times 10^9/\text{L}$) or ANC value lies between $1 \times 10^3/\text{mm}^3$ ($1 \times 10^9/\text{L}$) and $1.5 \times 10^3/\text{mm}^3$ ($1.5 \times 10^9/\text{L}$)	Interrupt therapy; monitor daily until WBC $> 3 \times 10^3/\text{mm}^3$ ($3 \times 10^9/\text{L}$) and ANC $> 1.5 \times 10^3/\text{mm}^3$ ($1.5 \times 10^9/\text{L}$); then twice weekly until back to recommended levels
Severe leukopenia or granulocytopenia or agranulocytosis	WBC $< 2 \times 10^3/\text{mm}^3$ ($2 \times 10^9/\text{L}$) or ANC $< 1 \times 10^3/\text{mm}^3$ ($1 \times 10^9/\text{L}$) ANC $\leq 0.5 \times 10^3/\text{mm}^3$ ($0.5 \times 10^9/\text{L}$) (agranulocytosis)	Discontinue treatment and do not rechallenge; monitor daily until WBC $> 3 \times 10^3/\text{mm}^3$ ($3 \times 10^9/\text{L}$) and ANC $> 1.5 \times 10^3/\text{mm}^3$ ($1.5 \times 10^9/\text{L}$); then twice weekly until back to recommended levels

^a $3.5 \times 10^3/\text{mm}^3 = 3.5 \times 10^9/\text{L}$; $3 \times 10^3/\text{mm}^3 = 3 \times 10^9/\text{L}$; $2 \times 10^3/\text{mm}^3 = 2 \times 10^9/\text{L}$; $1.5 \times 10^3/\text{mm}^3 = 1.5 \times 10^9/\text{L}$; $1 \times 10^3/\text{mm}^3 = 1 \times 10^9/\text{L}$; $0.5 \times 10^3/\text{mm}^3 = 0.5 \times 10^9/\text{L}$.

ANC, absolute neutrophil count; WBC, white blood cell count.

Commonly used rating scales to monitor for EPS include the Simpson Angus Scale (SAS) and the Extrapyramidal Symptom Rating Scale (ESRS). Akathisia is commonly monitored by the Barnes Akathisia Scale (BAS). The emergence of dyskinesias (writhing or involuntary

movements) could represent the emergence of TD. Monitor for TD at least annually, and if FGAs are used, patients should be evaluated at each visit. The most commonly used instrument to measure these symptoms is the Abnormal Involuntary Movement Scale (AIMS).

Patient Encounter, Part 4

KH is restarted on risperidone 6 mg/day. She is seen weekly to monitor for EPS or akathisia. After 18 months of treatment, however, KH has gained 20 lb (9.1 kg). In addition, she and her clinician began noticing slight mouth movements that could have been associated with preliminary TD movements. KH became unwilling to continue risperidone, and with her history of nonadherence in the past, discussed different treatment options with her healthcare providers. She recently started treatment with aripiprazole and was stabilized at 10 mg/day 2 weeks ago. She started volunteering at the

local library restocking book shelves 5 hours a week and continues to live with her parents. She hopes to return to college someday and to increase her interactions with family and make friends.

Based on the information above, create a care plan for this patient's treatment. Your plan should include (a) a statement of the drug-related concerns or problems, (b) the goals of therapy, and (c) a plan for monitoring and follow-up to determine whether the goals have been achieved and adverse effects minimized.

Patient Care and Monitoring

1. Assess the patient's symptoms, review the patient and family history, and obtain initial medical evaluation to rule out other causes of psychosis.
2. Periodically review patient data for consistency with diagnostic criteria, and regularly monitor changes in symptomatology.
3. Obtain a thorough history of prescription medication use, and determine what treatments have been helpful in the past, which treatments the patient is currently receiving, and previous side effects experienced.
4. Determine whether the patient is taking an appropriate antipsychotic drug and dose and whether the patient has other symptoms that may need to be treated.
5. Educate the patient and the family, if possible, about the disease state, medication treatments, possible side effects, and goals of treatment.
6. Develop a plan to assess the effectiveness of the current treatment regimen. Also, consider alternative treatments if current treatment is ineffective.
7. Encourage a healthy lifestyle, including eliminating or decreasing substance abuse and cigarette use, as well as appropriate nutritional counseling and exercise suggestions.
8. Determine the role of psychosocial treatments.
9. Evaluate the patient for the presence of adverse drug reactions, drug interactions, and allergies.
10. Monitor the appropriate laboratory measures to prevent or minimize metabolic abnormalities and other side effects.
11. Stress the importance of adherence with the treatment regimen and maintaining treatment even if the patient is feeling well.

Abbreviations Introduced in This Chapter

5-HT	Serotonin
ACT	Assertive Community Treatment
AIMS	Abnormal Involuntary Movement Scale
ANC	Absolute neutrophil count
BAS	Barnes Akathisia Scale
BPRS	Brief Psychiatric Rating Scale
CATIE	Clinical Antipsychotics Trials of Intervention Effectiveness
CBT	Cognitive-behavioral therapy
CGI	Clinical Global Impression Scale
CR	Cognitive remediation
CYP450	Cytochrome P-450 isoenzyme
D	Dopamine
DSM-IV-TR	<i>Diagnostic and Statistical Manual of Mental Disorders</i> , 4th edition, text revision
ECT	Electroconvulsive therapy
EPS	Extrapyramidal side effects
ESRS	Extrapyramidal Symptom Rating Scale
FGA	First-generation antipsychotic
H	Histamine
IM	Intramuscular
M	Muscarinic
NMDA	N-methyl-D-aspartate
NMS	Neuroleptic malignant syndrome
PCP	Phencyclidine
PANSS	Positive and Negative Symptom Scale
PORT	Schizophrenia Patient Research Outcomes Team
QTc	Corrected QT interval
SAS	Simpson Angus Scale
SGA	Second-generation antipsychotic
SNP	Single nucleotide polymorphism
SSRI	Selective serotonin reuptake inhibitor
SST	Social skills training
TD	Tardive dyskinesia
TIMA	Texas Implementation of Medication Algorithms
WBC	White blood cell

Major Depressive Disorder

Cherry W. Jackson and Marshall E. Cates

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Explain the etiology and pathophysiology of major depressive disorder (MDD).
2. Identify symptoms and clinical features of MDD.
3. Differentiate antidepressants according to pharmacologic properties, adverse effect profiles, pharmacokinetic profiles, drug interaction profiles, and dosing features.
4. Predict adverse effect profiles of antidepressants based on pharmacology.
5. State the goals of pharmacotherapy in MDD.
6. Educate patients and caregivers on the proper use of antidepressants.

KEY CONCEPTS

- 1 Classic views as to the cause of major depressive disorder (MDD) focus on the monoamine neurotransmitters norepinephrine (NE); serotonin (5-HT); and to a lesser extent, dopamine (DA) in terms of both synaptic concentrations and receptor functioning.
- 2 It is not uncommon for a patient to experience only a single major depressive episode, but most patients with MDD experience multiple episodes.
- 3 One extremely important goal in the treatment of MDD is the prevention of suicide attempts.
- 4 Sexual dysfunction, common and challenging to manage, often leads to noncompliance with serotonergic medications.
- 5 Each antidepressant has a response rate of approximately 60% to 80%, and no antidepressant medication or class has been reliably shown to be more efficacious than another.
- 6 It is widely accepted that approximately 2 to 4 weeks of treatment is required before improvement is seen in emotional symptoms of depression, such as sadness and anhedonia. Furthermore, as long as 6 to 8 weeks of treatment may be required to see the full effects of antidepressant therapy.
- 7 Because the typical major depressive episode lasts 6 months or longer, if antidepressant therapy is interrupted for any reason after the acute phase of treatment, the patient may relapse into the depressive episode. When treating the first depressive episode, antidepressants must be given for an additional 4 to

9 months in the continuation phase for the purpose of preventing relapse.

- 8 Pediatric patients and young adults should be observed closely for suicidality, worsened depression, agitation, irritability, and unusual changes in behavior, especially during the initial few months of therapy and at times of dosage changes. Furthermore, families and caregivers should be advised to monitor patients for such symptoms.
- 9 Lack of patient understanding concerning optimal antidepressant drug therapy frequently leads to partial compliance or noncompliance with therapy; thus, the primary purpose of antidepressant counseling is to enhance compliance and improve outcomes.

My spirit is broken, my days are cut short, the grave awaits me.

—Job 17:1

Contrary to popular belief, major depression is not a fleeting “bad day,” is not the result of personal weaknesses or character flaws, and does not respond to volitional efforts simply to feel better. Major depressive disorder (MDD) is a serious medical condition with a biological foundation, and it responds to biological and psychological treatments. Individuals with MDD experience significant and pervasive symptoms that can affect mood, thinking, physical health, work, and relationships. Unfortunately, suicide is often the result of MDD that has not been diagnosed and treated adequately.

Patient Encounter, Part 1

LM, a 40-year-old white woman, presents to the inpatient psychiatric service after being referred from the mental health center. She is admitted secondary to stress over the holidays resulting in exacerbation of long-standing psychiatric illness. She complains of depressed mood, difficulty falling asleep, middle of the night awakening, early morning awakening, poor energy, poor concentration, recent weight loss of 15 lb (6.8 kg) over a 6-week period, nervousness, and frequent thoughts of death.

What information is suggestive of MDD?

What medical or psychiatric issues could be contributing to her symptoms?

Does she have risk factors for depression?

What additional information do you need to know before creating a treatment plan for this patient?

The past 2 decades have seen improvements in the screening, diagnosis, and treatment of MDD. The willingness of general practitioners to involve themselves in the identification and treatment of MDD is noteworthy. To that end, antidepressants have become some of the most commonly prescribed drugs, and they account for 10 of the top 200 prescription drugs dispensed in the United States.¹ Inadequate treatment remains a serious concern.²

EPIDEMIOLOGY AND ETIOLOGY

- Major depressive disorder is quite common; lifetime and 12-month prevalence estimates are 13.2% and 5.2%, respectively.² Women are approximately twice as likely as men to experience MDD.² The average age at onset is the midtwenties.³ Interestingly, MDD appears to occur earlier in life in people born in more recent decades.² Most patients with MDD also have comorbid psychiatric disorders, especially anxiety disorders and substance use disorders.²

According to the World Health Organization (WHO), depression is the leading cause of disability (based on years lived with disability) and the fourth leading contributor to the global burden of disease (based on disability-adjusted life years).⁴

PATHOPHYSIOLOGY

- The exact cause of MDD remains unknown, but it is probably multifactorial. Biological, psychological, and social theories abound, and many practitioners suggest that the development of depression often is predicated on the complex synthesis of genetic predisposition, psychological stressors, and biological pathophysiology. At present, there are currently no accepted unifying theories that explain these various factors adequately.

Genetics

- First-degree relatives of MDD patients are about three times more likely to develop MDD compared with first-degree relatives of normal control individuals. Adoption studies and twin studies reveal that the familial aggregation of MDD is due to genetic influences.⁵

Life Stress

- Depression can occur in the absence of major life stressors, and conversely, major life stressors do not invariably cause depression. Nevertheless, there is an undeniable association between life stressors and depression, and there appears to be a significant interaction between life stressors and genetic liability in causing depression.⁶ Although acute stressors may precipitate depression, chronic stressors have a longer risk period, cause longer episodes, and are more likely to lead to **relapse** and **recurrence**.⁶

Monoamine Neurotransmitter and Receptor Hypotheses

- 1** Classic views as to the cause of MDD focus on the monoamine neurotransmitters norepinephrine (NE); serotonin (5-HT); and to a lesser extent, dopamine (DA) in terms of both synaptic concentrations and receptor functioning. The monoamine hypothesis asserts that depression is attributable to a deficiency of monoamine neurotransmitters. The major supporting evidence for this hypothesis is that existing antidepressants increase synaptic monoamine concentrations through various mechanisms (see Pharmacologic Therapy). One argument against the monoamine hypothesis is that depressed patients do not consistently exhibit decreased monoamine concentrations. In addition, monoamine levels are altered within hours of the initiation of antidepressant therapy, but there is a latency period of weeks before the actual antidepressant effect is typically evident.⁷⁻⁹

The neurotransmitter receptor hypothesis suggests that depression is related to abnormal functioning of neurotransmitter receptors. In this model, antidepressants presumably exert therapeutic effects by altering receptor sensitivity. In fact, chronic administration of antidepressants has been shown to cause desensitization, or down-regulation, of β -adrenergic receptors and various 5-HT receptors. Importantly, the time required for changes in receptor sensitivity corresponds to the onset of antidepressant effects.⁷⁻⁹

Such models of the pathophysiology of depression are assuredly an oversimplification. Depression probably involves a complex dysregulation of monoamine systems, and these systems in turn modulate and are modulated by other neurobiological systems.¹⁰

Other Neurobiological Hypotheses

- Various other pathophysiologic hypotheses have been proposed. These hypotheses include the role of nonmonoamine

Clinical Presentation of Major Depressive Disorder

Patients typically present with a combination of emotional, physical, and cognitive symptoms:

- Emotional
 - Sadness
 - **Anhedonia**
 - Pessimism
 - Feeling of emptiness
 - Irritability
 - Anxiety
 - Worthlessness
 - Thoughts of death or suicidal ideation
- Physical
 - Disturbed sleep
 - Change in appetite or weight
 - Psychomotor changes
 - Decreased energy
 - Fatigue
 - Bodily aches and pain

- Cognitive
 - Impaired concentration
 - Indecisiveness
 - Poor memory

Occasionally, severely depressed patients also will present with psychotic symptoms:

- Hallucinations
- Delusions

Some patients present with “atypical features” of depression:

- Reactive mood (i.e., mood improves in response to positive events)
- Significant increase in appetite/weight gain
- Hypersomnia
- Heavy feelings in arms or legs
- Sensitivity to interpersonal rejection

neurotransmitters (e.g., glutamate and γ -aminobutyric acid), neuroendocrine systems (e.g., the hypothalamic–pituitary–adrenal axis), neurosteroids (e.g., allopregnanolone), neuronal plasticity (e.g., brain-derived neurotrophic factor),¹¹ messenger cascades, and gene expression.¹²

CLINICAL PRESENTATION AND DIAGNOSIS

The diagnosis of a major depressive episode requires the presence of a certain number of depressive symptoms (five) for a minimum specified duration (2 weeks) that cause clinically significant effects (Table 38–1).³

HINT: To remember the nine diagnostic symptoms for a major depressive episode, learn the following mnemonic: Depression = SIG E CAPS (depression equals sleep, interest, guilt, energy, concentration, appetite, psychomotor, suicide).

In turn, the diagnosis of MDD is based on the presence of one or more major depressive episodes during a person’s lifetime.³

Differential Diagnosis

Major depressive episodes also occur in patients with bipolar disorder. Persons with bipolar disorder also experience manic, hypomanic, or mixed episodes (see Chapter 39) during the course of their illness, but persons with MDD do not.³

The presence of a significant medical disorder can produce depressive symptoms via either psychological or

Table 38–1

Diagnostic Criteria for Major Depressive Episode

At least five of the following symptoms have been present during the same 2-week period and represent a change from previous functioning:

- Depressed mood^a
- Markedly diminished interest or pleasure in usual activities^a
- Increase or decrease in appetite or weight
- Increase or decrease in amount of sleep
- Increase or decrease in psychomotor activity
- Fatigue or loss of energy
- Feelings of worthlessness or guilt
- Diminished ability to think, concentrate, or make decisions
- Recurrent thoughts of death, suicidal ideation, or suicide attempt

The symptoms cause clinically significant distress or impairment in functioning

The symptoms are not due to the direct physiologic effects of a substance or medical condition

^aOne of these two symptoms must be present.

Data from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders. 4th ed, text revision. Washington, DC: American Psychiatric Association; 2000:356.

physiologic mechanisms. Examples include hypothyroidism, neoplasms, anemia, infections, electrolyte disturbances, folate deficiency, cardiovascular diseases, neurologic disorders, and many others.⁹ Various psychiatric conditions, such as substance use disorders and anxiety disorders, have been associated with depression as well.⁹ The use

of central nervous system (CNS) depressants, such as benzodiazepines and narcotics, is associated with an increased propensity for depression.¹³ Drugs that reportedly cause depressive symptoms or depressive-like side effects include corticosteroids, contraceptives, gonadotropin-releasing hormone agonists, interferon- α , interleukin-2, mefloquine, isotretinoin, propranolol, and sotalol.¹⁴

Dysthymia is a condition that must be differentiated from MDD. Many of the symptoms of dysthymia are similar to those of MDD, but in dysthymia, the symptoms are chronic and milder. Symptoms of dysthymia must be present for at least 2 years and may include sleep and appetite disturbances, a loss of energy, a lack of interest in things that would usually be enjoyable, and poor self-image. Patients with dysthymia often have family members with a history of depression or dysthymia. It occurs more frequently in women, and patients with dysthymia are more likely to develop major depression than the general population.³

COURSE AND PROGNOSIS

- Symptoms of a major depressive episode usually develop over days to weeks, but mild depressive and anxiety symptoms may last for weeks to months before the onset of the full syndrome. Left untreated, major depressive episodes typically last 6 months or more, but a minority of patients experience chronic episodes that last at least 2 years. Approximately two-thirds of patients recover fully from major depressive episodes and return to normal mood and full functioning, but the other one-third have only partial remission.³

The course of MDD varies markedly from patient to patient. ② *It is not uncommon for a patient to experience only a single major depressive episode, but most patients with MDD experience multiple episodes.* Some patients experience isolated episodes separated by many years, others have clusters of episodes, and still others have more frequent episodes as they age. Some experience seasonal affective disorder (SAD) in which symptoms occur certain times of the year, usually in the winter. The number of prior episodes predicts the likelihood of developing subsequent episodes. A patient experiencing a third major depressive episode has about a 90% chance of having a fourth one. MDD is associated with a high mortality rate because about 15% of patients ultimately commit suicide.³

TREATMENT

Desired Outcomes

- The goals of therapy for depressed patients are the resolution of depressive symptoms, a return to **euthymia**, and prevention of relapse and recurrence of depressive symptoms. ③ *One extremely important goal in the treatment of MDD is the prevention of suicide attempts.* Other desired outcomes include improvement of the patient's quality of life, normalization of functioning in areas such as work and relationships, avoidance or minimization of adverse effects, and reduction of health care costs.¹⁵

Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Tests

The workup on LM reveals:

PMH: She has multiple medical problems, including insulin-dependent diabetes mellitus, hypertension, congestive heart failure, hypothyroidism, endometrial cancer by history, status post hysterectomy, and obesity. She is followed by a local internist.

PPH: Patient has multiple psychiatric hospitalizations with the last being 2 years before this admission. She has a diagnosis of major depressive episode (MDE).

FH: Mother with diabetes mellitus and MDD; father is alive and well with no medical problems; brother is a recovered alcoholic.

SH: Worked for a mortgage company, but job ended 2 months ago. For the past several months, she has been drinking three to four beers per night. She denies smoking cigarettes and using illicit substances.

Current Meds: Sertraline 100 mg/day, trazodone 150 mg at bedtime, nifedipine 20 mg four times daily, furosemide 100 mg/day, albuterol inhaler 2 puffs every 6 hours, levothyroxine 0.05 mg every morning, Novulin 70/30 56 units in the morning and 15 units in the evening.

ROS: Decreased energy; decreased sleep; decreased concentration; nervousness; all others noncontributory

PE:

Ht: 5 ft, 3 in (160 cm); wt, 83 kg (183 lb); weight loss of 6.8 kg (15 lb) over past 6 weeks

MSE: Depressed mood; decreased concentration; nervousness; positive suicidal ideation without plan

Labs: Within normal limits

Given this additional information, what is your assessment of the patient's condition?

Identify your treatment goals for the patient.

What nonpharmacologic and pharmacologic alternatives are available for this patient?

Nonpharmacologic Therapy

Interpersonal therapy and cognitive-behavioral therapy are psychotherapies that have well-documented efficacy for the treatment of MDD. Psychotherapy alone is an initial treatment option for mild to moderate depression, and it may be useful when combined with pharmacotherapy in the treatment of more severe cases. The combination of psychotherapy and pharmacotherapy can be more effective than either treatment modality alone in severe or recurrent MDD. It may be especially helpful for patients with significant psychosocial stressors, interpersonal difficulties, or comorbid personality disorders.¹⁶

Electroconvulsive therapy (ECT) is a highly efficacious treatment for MDD. The **response** rate is about 80% to 90%, and it exceeds 50% for patients who have failed pharmacotherapy.^{16,17} ECT may be particularly beneficial for MDD that is complicated by psychotic features, severe suicidality, refusal to eat, pregnancy, or contraindication or nonresponse to pharmacotherapy.^{16,17} Around 6 to 12 treatments are typically necessary with response occurring in 10 to 14 days. When ECT is discontinued, antidepressants are initiated to help maintain the response. ECT is typically a very safe treatment alternative, but various cautions do exist. Side effects include confusion and retrograde and anterograde amnesia.¹⁶

Light therapy is an alternative treatment for depression associated with seasonal (e.g., winter) exacerbations. Side effects include eye strain, headache, insomnia, and hypomania.^{16,17} Potentially vulnerable patients, such as those with photosensitivity or a history of skin cancer, should be evaluated carefully before therapy.^{16,17}

Vagus nerve stimulation (VNS), which was approved by the Food and Drug Administration (FDA) in 2005, may be used for adult patients with treatment-resistant depression. A pulse generator is surgically implanted under the skin of the left chest, and an electrical lead connects the generator to the left vagus nerve. Stimulation of this nerve sends signals to the brain. This therapy is used along with traditional therapies such as pharmacotherapy and ECT.¹⁸ Adverse effects of VNS include alterations in patients' voice, coughing, pharyngitis, sore throat, hoarseness, headache, nausea, vomiting, dyspnea, and paresthesias.¹⁸

Transcranial magnetic stimulation is a noninvasive and well-tolerated procedure that is FDA approved for use after one failed trial of an antidepressant.¹⁹ Some data suggest that physical exercise may reduce depressive symptoms, but well-controlled studies are needed to document efficacy.²⁰

Pharmacologic Therapy

- Each antidepressant has its unique blend of characteristics, and in fact, even individual drugs within the same class have important differences.²¹ **Table 38–2** demonstrates the differing pharmacologic properties of the antidepressant medications,^{7–9} and **Table 38–3** delineates the results of those pharmacologic actions.^{7,8} Monoamine oxidase inhibitors (MAOIs) inhibit the enzyme responsible for the intraneuronal breakdown of 5-HT, NE, and DA. There are two main forms of MAO, MAO-A and MAO-B; inhibition of MAO-A impacts the breakdown of 5-HT, epinephrine, and NE, and MAO-B is primarily involved in the inhibition of dopamine and phenethylamine. Dietary restrictions are necessary for MAO-A but not usually for MAO-B inhibitors. The tricyclic antidepressants (TCAs) possess both 5-HT (serotonin) reuptake inhibition (SRI) and NE reuptake inhibition (NRI) properties but unfortunately also block the so-called “dirty receptors,” including α_1 -adrenergic, histamine-1, and muscarinic cholinergic receptors, which contribute to side effects but not efficacy. The selective serotonin reuptake inhibitors (SSRIs) are classified as such because SRI is the predominant effect. Bupropion is an NE and DA reuptake inhibitor (NDRI). Venlafaxine, desvenlafaxine, and duloxetine are 5-HT and NE reuptake inhibitors (SNRIs)

Table 38–2

Primary Pharmacologic Actions of Antidepressants^a

MAOI, monoamine oxidase inhibitor; SNRI, serotonin norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

Data from Refs. 7–9.

Table 38-3

Efficacy and Adverse Effect Profiles Based on Pharmacology

Pharmacologic Action	Result
SRI	Antidepressant and antianxiety efficacy (via interaction of 5-HT at 5-HT _{1A} receptors) Anxiety, insomnia, sexual dysfunction (via interaction of 5-HT at 5-HT _{2A} receptors) Anxiety, anorexia (via interaction of 5-HT at 5-HT _{2C} receptors) Nausea, GI problems (via interaction of 5-HT at 5-HT ₃ receptors)
NRI	Antidepressant efficacy Tremor, tachycardia, sweating, jitteriness, increased blood pressure
Dopamine reuptake inhibition	Antidepressant efficacy Euphoria, psychomotor activation, aggravation of psychosis
α_2 -Adrenergic receptor blockade	Increase in serotonergic and noradrenergic activity—see actions of SRI and NRI above
Serotonin _{1A} partial agonism	Antianxiety, antidepressant augmentation, decreased blood pressure, decreased heart rate
Serotonin _{2A} receptor blockade	Antianxiety efficacy Increased REM sleep; decreased sexual dysfunction
Serotonin _{2C} receptor blockade	Antianxiety efficacy Increased appetite or weight gain
Serotonin ₃ receptor blockade	Antinauseant, decreased GI problems
α_1 -Adrenergic receptor blockade	Orthostatic hypotension, dizziness, reflex tachycardia
Histamine-1 receptor blockade	Sedation, weight gain
Muscarinic cholinergic receptor blockade	Dry mouth, blurred vision, constipation, urinary hesitancy, sinus tachycardia, memory problems

GI, gastrointestinal; NRI, norepinephrine reuptake inhibition; REM, rapid eye movement; SRI, serotonin reuptake inhibition.

Data from Refs. 7 and 8.

but are also weak inhibitors of DA reuptake. Compared with venlafaxine and desvenlafaxine, which have primarily SRI activity, duloxetine has more balanced SRI and NRI activities and has a higher affinity for the reuptake sites. Nefazodone and trazodone are 5-HT antagonists/reuptake inhibitors. Their SRI activity is not as pronounced as that of the SSRIs, but they potently block 5-HT_{2A} receptors, which allow more 5-HT to interact at postsynaptic 5-HT_{1A} sites. In addition, trazodone blocks histaminergic and α -adrenergic receptors, and nefazodone possesses weak NRI and α -adrenergic blocking properties. Vilazodone is a combination of an SRI and a partial agonist at the 5-HT_{1A} receptor. Partial agonist activity at the 5-HT_{1A} receptor is thought to reduce negative feedback on endogenous serotonin receptors which is thought to improve the medications antidepressant effect.²² Finally, mirtazapine is a noradrenergic and specific serotonergic antidepressant. It blocks presynaptic α_2 receptors, both autoreceptors on noradrenergic neurons and heteroreceptors on serotonergic neurons, with resulting increases in NE and 5-HT synaptic concentrations, respectively. Mirtazapine also blocks various postsynaptic serotonergic receptors and histamine-1 receptors.⁷⁻⁹

► Complementary and Alternative Treatments

St. John's wort (*Hypericum perforatum*) is a herbal medication that has shown some efficacy in mild to moderate depression but minimal efficacy for moderate to severe depression.²⁰ It has some mild MAO-inhibiting properties. Many patients believe that herbal medications, being "natural" products, are devoid of adverse effects and drug interactions; however,

St. John's wort can cause gastrointestinal (GI) irritation, headache, fatigue, and nervousness,¹⁷ and it triggers drug interactions through induction of CYP3A4 enzymes, as well as other potential mechanisms.²² The safety and efficacy of St. John's wort combined with standard antidepressant medications remains unknown.¹⁶

S-adenosyl methionine (SAM-e) is a naturally occurring compound that tends to be lower in people with major depression. Treatment with SAM-e increases blood levels of both S-adenosyl methionine and hydroxyindoleacetic acid. It is sold as a nutritional supplement and lacks the standardization of medications that are FDA approved.²⁰

Low folate levels have been associated with a greater risk of depression or with a lack of response to antidepressants. Because folic acid prevents neural tube defects in pregnancy and causes few to no adverse effects, it can be used in doses of 0.4 to 1 mg/day to improve the efficacy of antidepressants.²⁰

Omega-3 fatty acids (eicosapentaenoic acid, docosahexaenoic acid, or both) have been used adjunctively for major depression. Doses typically at the lower end of 1 to 9 g/day appear useful for the treatment of major depression, but more study needs to be completed to establish their role.²⁰

► Adverse Effects

The important adverse effects of the various antidepressants are often a function of their underlying pharmacologic profiles^{7,8} (Table 38-3). The TCAs cause problematic sedative, anticholinergic, and cardiovascular adverse effects owing to their interaction with "dirty receptors." Although these adverse effects generally are considered to be common

and bothersome, they can be quite serious in some cases. For example, constipation in its extreme form can lead to paralytic ileus. The tertiary amines (e.g., amitriptyline, imipramine) are more sedative and anticholinergic than the secondary amines (e.g., desipramine, nortriptyline). The TCAs have a quinidine-like effect on the heart, which makes them quite toxic on overdose. The average lethal dose in a young adult is only 30 mg/kg, which is typically less than a 1 month's supply.^{7,9,21,23}

The adverse effect profile of the SSRIs includes sexual dysfunction (e.g., delayed or absent orgasms), CNS stimulation (e.g., nervousness and insomnia), and GI disturbances (e.g., nausea and diarrhea).^{7,9,21,23} **4** *Sexual dysfunction, common and challenging to manage, often leads to noncompliance.*²⁴ Various strategies to deal with antidepressant-induced sexual dysfunction include waiting for symptoms to subside, reducing the dosage, permitting periodic “drug holidays,” prescribing adjunctive therapy, and switching antidepressants.²⁵ However, waiting for symptoms to subside usually does not work because sexual dysfunction may very well persist throughout the duration of therapy. Reducing the dose and using drug holidays may weaken the antidepressant effects. Thus, clinicians often prescribe adjunctive therapy such as dopaminergic drugs (e.g., bupropion or amantadine), 5-HT₂ antagonists (e.g., cyproheptadine or nefazodone), and phosphodiesterase inhibitors (e.g., sildenafil) or simply switch to antidepressants with less likelihood of causing these effects, such as bupropion, mirtazapine, or nefazodone, which may rarely cause liver failure.^{24,25}

Bupropion causes insomnia, nightmares, decreased appetite, anxiety, and tremors, but the most concerning adverse effect is seizures. Because of the risk for seizures, patients with a CNS lesion, history of seizures, head trauma, or bulimia should not receive the drug. The daily dose of bupropion should not exceed 450 mg/day (immediate release and extended release), and any single dose of the immediate-release formulation should not exceed 150 mg. The maximum

dose of sustained release is 200 mg twice daily. Occurrences of insomnia and/or nightmares often respond to moving the last daily dose from bedtime to late afternoon.^{7,9,21,23}

The adverse effects of the SNRIs are similar to those of the SSRIs. Nausea can be particularly troublesome with venlafaxine and desvenlafaxine, which sometimes necessitates using lower starting dosages than usual and giving the medication with food. A dose-related elevation in blood pressure can occur at higher doses, probably owing to the NRI effects. Blood pressure monitoring should be conducted for patients receiving venlafaxine and desvenlafaxine therapy. As a rule, duloxetine should not be prescribed to patients with extensive alcohol use or evidence of chronic liver disease owing to the potential for hepatic injury.^{9,21,26,27}

Trazodone routinely causes sedation, which is why it is used far more often as an adjunct with other antidepressants for sleep than as an antidepressant. Priapism is a rare but serious adverse effect in men who take trazodone. In addition, orthostatic hypotension and dizziness are more common with trazodone than with nefazodone because the latter agent has a weaker effect at α -adrenergic receptors and also has a balancing of adrenergic effects owing to weak NRI activity. Unfortunately, nefazodone has been associated with development of hepatotoxicity, which has led to a black-box warning and a great reduction in its use. It has been discontinued in some countries.^{7,9,21,23}

Mirtazapine can cause sedation and weight gain by virtue of blocking histamine-1 receptors. Despite being partially a serotonergic drug, it rarely causes serotonergic-related adverse effects because it blocks the various postsynaptic 5-HT receptors. Although it carries a bolded warning for neutropenia owing to a handful of cases reported during clinical trials, it is questionable whether neutropenia is any more problematic with this agent than other antidepressants.^{9,21,23}

The relative incidences of adverse effects among some of the newer antidepressant agents are shown in [Table 38–4](#).^{9,13,28}

Table 38–4

Relative Incidence of Adverse Effects of Various Newer Antidepressants

Drug	Sedation	Activation	Weight Gain	Weight Loss	GI Upset	Sexual Dysfunction
Bupropion	+	++++	+	++	+++	+
Citalopram	+	+	+	+	++++	++++
Desvenlafaxine	++	+++	+	+	++++	++++
Fluoxetine	+	++++	+	+	++++	++++
Mirtazapine	+++	+	++	+	+	+
Nefazodone	++	+	+	+	++	+

Venlafaxine	++	+++	+	+	++++	++++
Vilazodone	+	+	+	+	++++	+

+, minimal; ++, low; +++, moderate; +++++, high; GI, gastrointestinal.

Data from Refs. 9, 13, and 28.

Table 38-5

Pharmacokinetic Parameters of Newer Antidepressants

Drug	Protein Binding (%)	Elimination Half-Life (hours)	Active Metabolite(s)
Bupropion	84	10–21	Yes
Citalopram	80	33	Yes
Desvenlafaxine	30	7.5	No
Duloxetine	90	9–19	No
Escitalopram	56	27–32	No
Fluoxetine	94	4–6 days with chronic dosing; 4–16 days (active metabolite)	Yes
Fluvoxamine	77	15–26	No
Mirtazapine	85	20–40	No
Nefazodone	99	2–4	Yes
Paroxetine	95	21	No
Selegiline	99	1.2–2	Yes
Sertraline	98	27	Yes
Venlafaxine	27	5	Yes
Vilazodone	99	25	No

Data from Refs. 9 and 29.

► Pharmacokinetic Parameters

- Pharmacokinetic parameters of the newer antidepressants are shown in [Table 38-5](#).^{9,29} Several antidepressants are not highly protein bound, and the most notable of these are venlafaxine and desvenlafaxine. The elimination half-lives

of nefazodone and venlafaxine are relatively short compared with those of the other agents. Conversely, fluoxetine has a very long half-life (i.e., 5 to 9 days) with chronic dosing, and its active metabolite (norfluoxetine) has an even longer half-life. Owing to the extremely long half-life of fluoxetine and its active metabolite, a 5-week washout of fluoxetine is required before starting an MAOI. A 2-week washout is generally considered sufficient for other SSRIs. Sertraline and citalopram are the other SSRIs with active metabolites, but these metabolites (desmethylsertraline and desmethylcitalopram, respectively) are only about one-eighth as potent as the parent compounds in terms of SRI activity.

► Drug Interactions

- The major drug interactions of the antidepressants are shown in [Table 38-6](#).^{9,22,30} The usual pharmacodynamic drug interactions involve the “dirty receptors” blocked by some antidepressants. Hence, TCAs especially can cause significant additive effects with drugs that cause sedation, hypotension, or anticholinergic effects. Similarly, trazodone and mirtazapine can interact with other drugs that cause hypotensive and sedative effects, respectively. By far, the most concerning pharmacodynamic interactions are hypertensive crisis and 5-HT syndrome, which are both potentially life threatening when they occur. Hypertensive crisis is characterized by sharply elevated blood pressure, occipital headache, stiff or sore neck, nausea, vomiting, and sweating. It may result during MAOI therapy if the patient takes a sympathomimetic drug, such as ephedrine, pseudoephedrine, phenylephrine, or phenylpropanolamine

Table 38-6

Drug Interactions of Antidepressants^a

Antidepressants	Type of Interaction	Examples of Interacting Drugs
TCAs, trazodone, mirtazapine	Pharmacodynamic—additive sedation	Benzodiazepines, alcohol, antihistamines
TCAs, trazodone	Pharmacodynamic—additive hypotensive effects	Prazosin, antipsychotics
TCAs	Pharmacodynamic—additive anticholinergic effects	Phenothiazines, benzotropine
TCAs	Pharmacodynamic—additive cardiac toxicity	Thioridazine, quinidine
TCAs	Pharmacodynamic—decreased antihypertensive effect	Guanethidine, clonidine, methyl dopa
Bupropion	Pharmacodynamic—increased seizure risk	TCAs, phenothiazines
MAOIs	Pharmacodynamic—hypertensive crisis	Tyramine-rich foods, sympathomimetics
MAOIs, TCAs, SSRIs, SNRIs, SARIs	Pharmacodynamic—5-HT syndrome	Serotonergic antidepressants, meperidine, dextromethorphan, tramadol
Fluvoxamine	Pharmacokinetic—CYP1A2 inhibition	TCAs, clozapine, theophylline
Fluoxetine, fluvoxamine, sertraline	Pharmacokinetic—CYP2C inhibition	TCAs, phenytoin, warfarin, tolbutamide
Fluoxetine, paroxetine, duloxetine, sertraline, bupropion	Pharmacokinetic—CYP2D6 inhibition	TCAs, haloperidol, risperidone, codeine, propranolol, propafenone
Nefazodone, fluoxetine, fluvoxamine	Pharmacokinetic—CYP3A4 inhibition	TCAs, alprazolam, verapamil, carbamazepine, lovastatin

^aNot an all-inclusive list.

5-HT, serotonin; MAOI, monoamine oxidase inhibitor; SARI, serotonin antagonist and reuptake inhibitor; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

Data from Refs. 9, 22, and 30.

or stimulants such as amphetamines or methylphenidate or if the patient consumes foods rich in tyramine, such as tap beers, aged cheeses, fava beans, yeast extracts, liver, dry sausage, sauerkraut, or tofu.²³ There are extensive lists of foods and drinks that are permitted and not permitted during therapy with MAOIs, and these always should be provided to patients. Because many over-the-counter products contain sympathomimetics, patients always should be told to consult with their clinician and/or pharmacist before using these drugs. 5-HT syndrome is characterized by confusion, restlessness, fever, abnormal muscle movements, hyperreflexia, sweating, diarrhea, and shivering.³¹ It may result when a serotonergic agent is added to any serotonergic antidepressant, but the MAOIs are strongly associated with severe cases of 5-HT syndrome.³¹ 5-HT syndrome is complicated by (a) an unawareness by clinicians of the diagnosis³¹ and (b) the fact that many implicated drugs are not obviously serotonergic in nature, such as dextromethorphan, meperidine, tramadol, linezolid, and triptans.

Several antidepressants, including most of the SSRIs, bupropion, nefazodone, and duloxetine, are known to inhibit various cytochrome P450 isoenzymes, thereby elevating plasma levels of substrates for those isoenzymes and thus potentially leading to increased adverse effects or toxicity. The propensity to cause these drug interactions will vary with the particular antidepressant and the precise isoenzyme^{9,22,30} (Table 38–6).

► Dosing

- Dosing is summarized in [Table 38–7](#).^{13,16,17,20,29,32} The extended-release formulations of venlafaxine and bupropion allow for once-daily dosing. The delayed-release capsule of fluoxetine can be given once weekly, which can be started 7 days after the last regular-release capsule or tablet. Selegiline is available as a transdermal patch, and a dose of 6 mg/24 hours can be used without the usual dietary restrictions associated with MAOI use, although patients on the higher doses (9 and 12 mg/24 hours) should follow the usual dietary restrictions. Liquid dosage forms and disintegrating tablets of various antidepressants are ideal for patients who have difficulty swallowing tablets or capsules and those who otherwise may attempt to “cheek” their medication.

The starting dose is the usual therapeutic dose for most of the SSRIs, desvenlafaxine, duloxetine, and mirtazapine, but there is usually need for at least some upward titration of venlafaxine, vilazodone, bupropion, and nefazodone. A particular disadvantage of TCAs is that the customary way of dosing them involves meticulous upward titration from a small starting dose to a wide usual therapeutic dosage range. On the contrary, one advantage of some TCAs is that plasma levels may be used to help guide dosing, especially for those that have well-defined therapeutic plasma level ranges, including nortriptyline (50 to 150 ng/mL or mcg/L, or 190 to 570 nmol/L), desipramine (100 to 160 ng/mL or mcg/L, or

375 to 600 nmol/L), amitriptyline (75 to 175 ng/mL or mcg/L, 270 to 631 nmol/L), and imipramine (200 to 300 ng/mL or mcg/L, or 714 to 1,071 nmol/L).²⁸

► Efficacy of Pharmacotherapy

- **5** Each antidepressant has a response rate of approximately 60% to 80%, and no antidepressant medication or class has been reliably shown to be more efficacious than another.^{7,21} MAOIs may be the most effective therapy for atypical depression, but MAOI use continues to wane because of problematic adverse effects, dietary and drug restrictions, and the possibility of fatal drug interactions.^{21,28} There is some evidence that dual-action antidepressants, such as TCAs and SNRIs, may be more effective for inpatients with severe depression than are the single-action drugs such as SSRIs,^{21,28} but the more general assertion that multiple mechanisms of action confer efficacy advantages is quite controversial.³³

► Selection of Medication

Figure 38–1 depicts a well-known algorithm for the pharmacologic treatment of nonpsychotic MDD—the Texas Medication Algorithm Project.³⁴ Notable aspects of this algorithm include the preferential use of newer antidepressants in the earlier stages of treatment and sequential trials of antidepressant monotherapy prior to the use of combination therapy (see Managing Partial Response or Nonresponse). It has been shown that patients undergoing treatment guided by this algorithm fared better than those who received treatment not guided by the algorithm during a 1-year period, as measured by clinician-rated symptoms, self-reported symptoms, and overall mental functioning.³⁵ Antipsychotic medication should be combined with antidepressant medication in cases of depression with psychotic features.¹⁶

Various factors must be taken into account when selecting antidepressant therapy for a particular patient. The most reliable predictor of response is the patient’s history of response (e.g., efficacy, side effects, and overall satisfaction) to antidepressants. To a lesser extent, the history of a first-degree relative’s response to antidepressants may be used to predict a patient’s response. Adverse effect profiles should be considered because compliance is influenced greatly by tolerability. In this regard, a frank discussion should occur with the patient in order to determine which adverse effects are acceptable and which are not and how to deal with side effects (e.g., using chewing gum, hard candy, or ice chips for dry mouth). The clinician must be careful to contemplate potential drug–drug interactions and disease–state interactions. For instance, a patient with seizure disorder would be an inappropriate candidate for bupropion therapy. The presence of comorbid psychiatric conditions can help the clinician to determine the best antidepressant to choose for a patient. For example, an SSRI can treat both MDD and panic disorder, obviating the need for separate

Table 38-7

Dosing of Antidepressants in Adult Patients

Generic Name	Brand Name	Generic	Initial Dose (mg/day)	Usual Dosing Range (mg/day)	Usual Dosage Schedule	Renal Dosing Adjustment	Hepatic Dosing Adjustment ^d
MAOIs							
Phenelzine	Nardil	No	15–30	15–90	Twice daily	None	None
Selegiline	Emsam	No	6	6–12	Once daily	None	None
Tranylcypromine	Parnate	No	10–20	30–60	Twice daily	None	None
TCAs and Tetracyclics							
Amitriptyline	Elavil ^a	Yes	25–50	100–300	Once daily	Nondialyzable	Use with caution
Amoxapine	Asendin ^a	Yes	25–50	100–400	Once to twice daily	None	None
Clomipramine	Anafranil	Yes	25	100–250	Once daily	Use with caution	None
Desipramine	Nortriptyline	Yes	25–50	100–300	Once daily	None	Use with caution
Doxepin	Sinequan ^a	Yes	25–50	100–300	Once daily	Use with caution	Use a lower dose
Imipramine	Tofranil	Yes	25–50	100–300	Once daily	Use with caution	None
Maprotiline	Ludiomil ^a	Yes	50–75	100–225	Once to twice daily	None	None
Nortriptyline	Pamelor	Yes	25	50–150	Once daily	Use with caution	Use a lower dose
Protriptyline	Vivactil	No	5–10	15–60	Once daily	Use with caution	Use with caution
Trimipramine	Surmontil	No	25–50	100–300	Once daily	Use with caution	Use with caution
SSRIs							
Citalopram	Celexa	Yes	20	20–40 ^b	Once daily	No adjustment for clcr greater than 20; for clcr less than 20, use with caution	20 mg/day maximum; may increase to 40 mg in nonresponders
Escitalopram	Lexapro	Yes	10	10–20	Once daily	No adjustment for clcr greater than 20; for clcr less than 20, use with caution	10 mg/day
Fluoxetine	Prozac	Yes	10–20	20–80	Once daily	None	Use lower or less frequent dosing
	Prozac weekly	Yes	90	90	Once weekly	None	Use lower or less frequent dosing
Fluvoxamine	Luvox	Yes	50	50–300	Twice daily	None	Reduce dose
	Luvox CR	No	100	100–300	Once daily	None	Reduce dose
Paroxetine	Paxil	Yes	10–20	20–50	Once daily	In ClCr less than 30, 10 mg/day increase weekly to a dose of 40 mg/day	Severe impairment, 10 mg daily; increase weekly to dose of 40 mg/day
	Paxil CR	Yes	12.5–25	25–62.5	Once daily	In ClCr less than 30, 12.5 mg daily increase weekly daily, to a dose of 50 mg/day	Severe impairment, 12.5 mg daily, increase weekly to dose of 40 mg/day
Sertraline	Zoloft	Yes	25–50	50–200	Once daily	None	Use a lower dose
NDRI							
Bupropion	Wellbutrin	Yes	150–200	300–450 ^c	Twice to thrice daily	Consider lower dose	75 mg/day
	Wellbutrin SR	Yes	150	300–400 ^c	Twice daily	Consider lower dose	100 mg/day or 150 mg every other day
	Wellbutrin XL	Yes	150	300–450 ^c	Once daily	Consider lower dose	150 mg every other day
SNRIs							
Desvenlafaxine	Pristiq	No	50	50–100	Once daily	ClCr 30–50 50 mg maximum daily, ClCr 50 mg every other day	50 mg/day, 100 mg/day maximum
Duloxetine	Cymbalta	Yes	40–60	40–60	Once to twice daily	Use lower dose, not recommended For ClCr less than 30	Not recommended
Venlafaxine	Effexor	Yes	37.5–75	75–225	Once daily	Reduce dose 25%–50%	Reduce dose by 50%
	Effexor XR	Yes	37.5–75	75–225	Once daily	Reduce dose 25%–50%	Reduce dose by 50%

Dosing of Antidepressants in Adult Patients (Continued)

Generic Name	Brand Name	Generic	Initial Dose Range (mg/day)	Usual Dosing Range (mg/day)	Usual Dosage Schedule	Renal Dosing Adjustment	Hepatic Dosing Adjustment ^d
SARIs							
Nefazodone	Serzone ^a	Yes	100–200	300–600	Twice daily	Use with caution	Discontinue if ALT/AST is more than 3 times normal
Trazodone	Desyrel ^a	Yes	50–150	200–600	Twice daily	Use with caution	Use with caution
	Olpetro	No	150	150–375	Daily	Use with caution	Use with caution
NaSSA							
Mirtazapine	Remeron	Yes	15	15–45	Once daily	CICr less than 40, 30% decreased clearance CICr less than 10, 50% decreased clearance	Clearance decreased by 30% Clearance decreased by 30%
SRI/5-HT_{2A}							
Vilazodone	Viibryd	No	10	40	Once daily	None	Use with caution

^aBrand no longer available in the United States.

^bMaximum dose is 40 mg/day.

^cUpper limit of this range is the maximum dose.

^dAll creatinine clearances (CICrs) are stated in terms of milliliters per minute.

ALT, alanine aminotransferase; AST, aspartate aminotransferase; MAOI, monoamine oxidase inhibitor; NaSSA, noradrenergic and specific serotonergic antidepressant; NDRI, norepinephrine and dopamine reuptake inhibitor; SARI, serotonin antagonist and reuptake inhibitor; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; SRI/5-HT_{2A}, partial agonist-serotonin reuptake inhibitor/serotonin_{2A} partial agonist; TCA, tricyclic antidepressant.

Data from Refs. 13, 16, 17, 20, 22, 29, and 32.

medication therapy. Fluvoxamine, an SSRI, is marketed for obsessive compulsive disorder, although it also treats depression. The patient must be willing and able to comply with dosing schedules (e.g., upward titration of TCAs or twice-daily dosing of nefazodone) and special instructions (e.g., dietary restrictions with MAOI therapy) associated with certain antidepressants. Another patient-specific factor is the potential for accidental or intentional overdosing because certain antidepressants (e.g., TCAs) are quite toxic and potentially lethal in overdose situations. Finally, the patient should be able to comfortably afford the chosen medication or else compliance is at risk.²¹

Time Course of Response

Unfortunately, the antidepressants do not produce a clinical response immediately. Improvement in physical symptoms, such as sleep, appetite, and energy, can occur within the first week or so of treatment. Although a recent meta-analysis suggests earlier effects of antidepressant treatment,³⁶ **6** *it is widely accepted that approximately 2 to 4 weeks of treatment is required before improvement is seen in emotional symptoms of depression, such as sadness and anhedonia. Furthermore, as long as 6 to 8 weeks of treatment may be required to see the full effects of antidepressant therapy.*^{7,21,23}

Managing Partial Response or Nonresponse

Approximately one-third of patients with MDD do not respond satisfactorily to their first antidepressant medication.³⁷ In such cases, the clinician must evaluate the adequacy of antidepressant therapy, including dosage, duration, and patient compliance.¹⁷ Treatment reappraisal should also include verification of the patient's diagnosis and reconsideration of clinical factors that could be impeding successful therapy, such as concurrent medical conditions (e.g., thyroid disorder), comorbid psychiatric conditions (e.g., alcohol abuse), and psychosocial issues (e.g., marital stress).¹⁶

A series of reports from the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial revealed that remission is associated with a better overall prognosis for patients than is improvement alone. STAR*D also established that in patients with a greater level of resistance, clinicians are less likely to push the patient to achieve remission, and in addition, those patients with the greatest levels of resistance had the highest rates of relapse. In these cases, STAR*D established some successful treatment recommendations.³⁷

For patients who have experienced a partial response, extending the medication trial and/or using higher doses within the recommended dosage range of the antidepressant may be helpful.¹⁶ Another option is to use augmentation

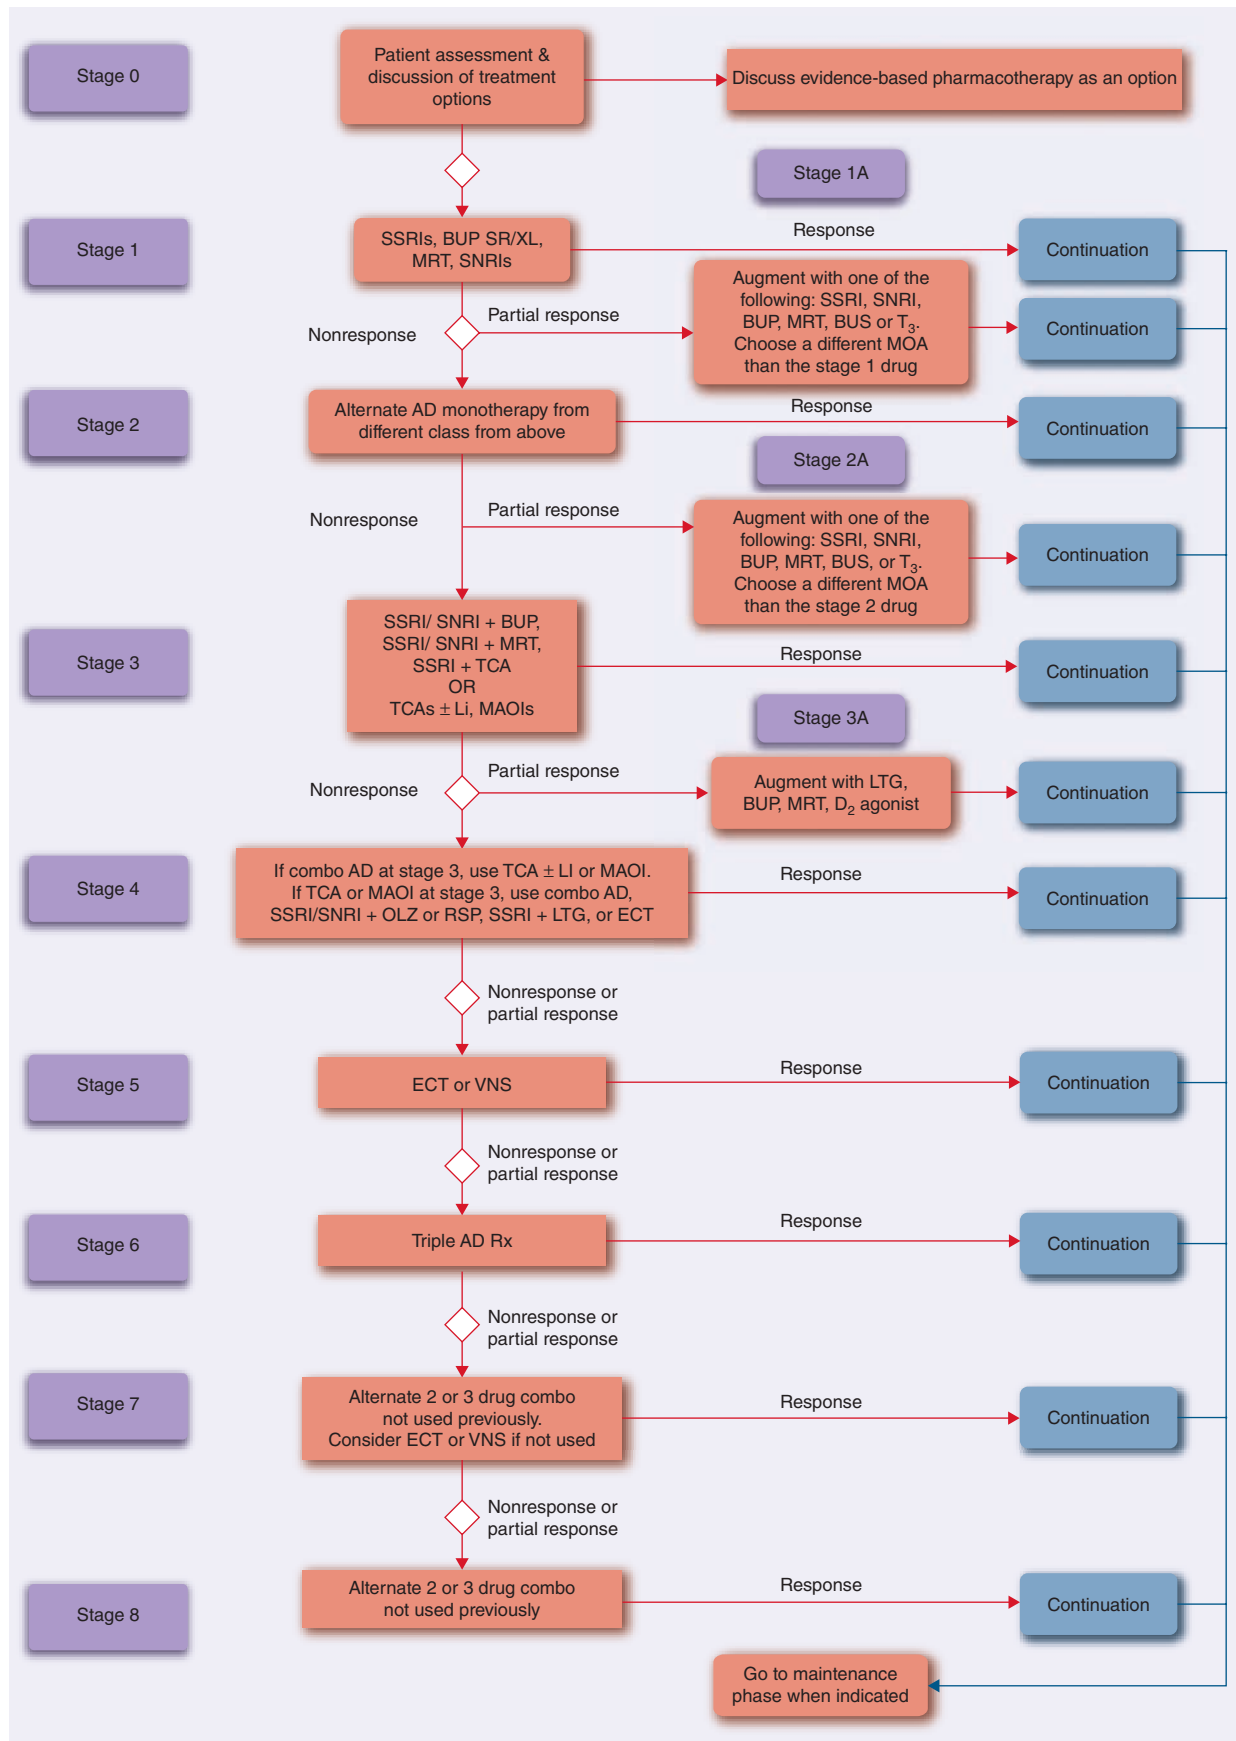

FIGURE 38-1. Strategies for the treatment of nonpsychotic major depression. (AD, antidepressant; BUP, bupropion; BUS, buspirone; ECT, electroconvulsive therapy; Li, lithium; T₃, liothyronine; LTG, lamotrigine; MAOI, monoamine oxidase inhibitor; MOA, mechanism of action; MRT, mirtazapine; OLZ, olanzapine; RSP, risperidone; Rx, prescription; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant; VNS, vagus nerve stimulation.) (Redrawn with permission from the Texas Medication Algorithm Project.³⁴)

therapy, that is, adding another medication that generally is not used as an antidepressant.³⁸ Augmenting agents with clear efficacy include lithium, buspirone, and triiodothyronine.³⁹ Aripiprazole and the extended-release formulation of quetiapine, second-generation antipsychotics, were recently approved by the FDA for augmenting partial response to antidepressants. Whereas efficacy has been suggested for dopaminergic drugs (e.g., pramipexole) and psychostimulants (e.g., methylphenidate), various other medications such as anticonvulsants (e.g., valproic acid), modafanil, and estrogen have anecdotal evidence to support their use as augmenting agents.³⁹ A third option is to make use of combination therapy, whereby another antidepressant, typically from a different pharmacologic class, is added to the first antidepressant medication. Examples include combining bupropion and SSRIs and combining TCAs and SSRIs.^{39,40}

Switching to a different antidepressant is a common strategy for patients who have had no response to initial antidepressant therapy but also is acceptable in cases of partial response.¹⁶ Relative to augmentation or combination, advantages of switching include improved compliance, decreased costs, and less concern over drug–drug interactions. Disadvantages include loss of time (“reset the clock”) and loss of any improvement seen with the initial drug.⁴⁰ When switching from one antidepressant to another, clinicians may choose to stay within the same class (e.g., sertraline to fluoxetine) or go outside of the class (e.g., paroxetine to venlafaxine).^{38,40} The olanzapine–fluoxetine combination medication Symbyax has been approved for treatment-resistant depression.²⁰

Nonpharmacologic interventions in cases of treatment nonresponse include adding or changing to psychotherapy or initiating ECT.¹⁶

Duration of Therapy

Treatment of MDD can be conceptualized as a series of three phases: acute, continuation, and maintenance^{7,8,16} (Fig. 38–2). During a major depressive episode, a clinician will initiate antidepressant therapy for the purpose of

attaining **remission** of symptoms. This acute phase of treatment typically lasts 6 to 12 weeks. **7** *Because the typical major depressive episode lasts 6 months or longer, if antidepressant therapy is interrupted for any reason after the acute phase, the patient may relapse into the depressive episode. When treating the first depressive episode, antidepressants must be given for an additional 4 to 9 months in the continuation phase for the purpose of preventing relapse.* Maintenance treatment takes place after the normal course of a major depressive episode to prevent recurrence, which is the development of future episodes. This phase can last for years, if not for a lifetime. Although all patients who have a major depressive episode should receive both acute and continuation treatment, not all of them will require maintenance treatment. The reason for this is because not all patients experience multiple major depressive episodes, and even in many cases in which they do, many years may separate the episodes. Therefore, the clinician must consider various factors in determining whether an individual patient requires maintenance treatment. A major factor is the number of prior episodes experienced by the patient. As discussed earlier, the more episodes experienced, the more likely future episodes will occur. This has led many clinicians to adopt the “three strikes and you’re on” approach, whereby a patient with a history of three or more major depressive episodes is given lifelong maintenance treatment because of the very high (i.e., 90%) chance of experiencing additional episodes. Other factors to consider are the severity of previous episodes, especially if suicide attempts were made or psychotic features were present, and patient preference.¹⁶ In general, the dose of the antidepressant required in the acute phase of treatment should be sustained during the continuation and maintenance phases.¹⁶

Discontinuation of Therapy

When the clinician and patient are ready to attempt discontinuation of therapy, whether at the end of the continuation phase or during the maintenance phase, it is best to do so via gradual taper of the antidepressant. This is done for two reasons. First, almost all antidepressants can

FIGURE 38–2. The course of depression and phases of treatment. (From Refs. 7 and 8).

produce withdrawal syndromes if discontinued abruptly or tapered too rapidly, especially antidepressants with shorter half-lives (e.g., venlafaxine, paroxetine, and fluvoxamine).¹⁷ These withdrawal syndromes can cause sleep disturbances, anxiety, fatigue, mood changes, malaise, GI disturbances, and a host of other symptoms¹⁷ and often are confused with depressive relapse or recurrence.¹⁶ In general, a tapering schedule involving a small dosage decrement (e.g., paroxetine 5 mg) every 3 to 5 days should prevent significant withdrawal symptoms.¹⁷ Second, depressive symptoms may return on taper or discontinuation of the antidepressant. If antidepressant therapy is discontinued abruptly and depressive symptoms return weeks later, then the lag time to onset of action must be observed when the antidepressant is restarted (“reset the clock”); however, if gradual tapering is carried out, then early signs of depression can be countered with a return to the original dosage and a potentially quicker response.¹⁶ Depending on the patient’s illness and the clinical circumstances, tapering of the antidepressant can be extended for weeks or even months because of the concern over relapse or recurrence.

Special Considerations

► *Pregnant or Breastfeeding Patients*

It is a common misconception that pregnancy protects against depression. Depression actually is quite common in pregnancy, especially for women with a history of recurrent depression. Both maternal and fetal well-being must be considered when weighing the benefits and risks of using antidepressant therapy during pregnancy. The prescribing information for paroxetine was changed to reflect the findings of epidemiological studies showing an increased risk of congenital malformations, particularly atrial and ventricular septal defects, in infants born to women taking the drug during the first trimester of pregnancy.⁴¹ Sertraline and citalopram have also been associated with causing septal heart defects when taken during the first trimester. In addition, the incidence of having a baby with a septal heart defect was four times higher for mothers taking more than one SSRI in the first trimester.⁴² Antidepressants have been reported occasionally to cause perinatal sequelae, such as poor neonatal adaptation, respiratory distress, feeding problems, and jitteriness.⁴³ Data concerning the long-term neurobehavioral effects of in utero antidepressant exposure remain quite limited.⁴³ Fluoxetine, citalopram, and the TCAs have the greatest reproductive safety data and should be considered first-line treatments when pharmacotherapy is indicated.⁴³

There will be at least some drug exposure to the infant from nursing mothers taking antidepressant medications. Although there have been rare anecdotal reports of adverse effects (i.e., respiratory depression and seizure-like episodes) in infants exposed to antidepressants through breast milk, no rigorous study has confirmed adverse effects of these drugs, and it is generally accepted that the benefits of breastfeeding outweigh the risks to the infant of antidepressant exposure.

Patient Encounter, Part 3: Creating a Care Plan

On the basis of information presented, create a care plan for LM. Your plan should include:

- (a) A statement of the drug-related needs and/or problems*
- (b) The goals of therapy*
- (c) A patient-specific detailed therapeutic plan*
- (d) A plan for follow-up to determine whether the goals have been achieved*

However, the decision needs to be made on an individual basis.⁴⁴

► *Geriatric Patients*

It is generally agreed that depression in older adults is underrecognized and undertreated.⁴⁵ Although not uncommon in community samples, MDD is particularly prevalent among those living in long-term care facilities.^{15,45} Barriers to recognition of geriatric depression include the tendency toward “masked” presentations, that is, complaints of physical symptoms (e.g., pain and GI problems) instead of mood symptoms, the frequent presence of medical illnesses, and the overlap of mood and cognitive symptoms with those of dementia.^{15,45} Age-related pharmacokinetic and pharmacodynamic changes cause geriatric patients to be more sensitive to the effects of antidepressant medications.¹⁵ Thus, lower starting doses of antidepressants with slow upward titrations as tolerated are recommended for geriatric patients.^{13,16,45} The SSRIs are chosen frequently to treat geriatric depression because of their overall favorable adverse effect profiles and low toxicity; most TCAs are avoided owing to problematic anticholinergic, cardiovascular, and sedative properties.⁴⁵ Desipramine and nortriptyline are two TCAs that are more tolerable in terms of these adverse effects and thus may be used in geriatric depression.⁴⁵ Other newer antidepressants, such as bupropion, venlafaxine, nefazodone, and mirtazapine, are alternatives for the treatment of geriatric patients as well.⁴⁵

► *Pediatric Patients*

Antidepressant medications appear to be useful for certain children and adolescents, particularly those who have severe or psychotic depression, fail psychotherapeutic measures, or experience chronic or recurrent depression. Fluoxetine and escitalopram are the only antidepressants FDA approved to treat depression in children younger than the age of 18 years. The SSRIs generally are considered the initial antidepressants of choice, although comorbid conditions may favor alternative agents. Clinicians should be aware of the possibility of “behavioral activation” with the SSRIs, including such symptoms as impulsivity,

Table 38–8

Patient Counseling

Counseling Point

Mechanism of action—The medication works by affecting certain chemicals in the brain
 Lack of addiction potential—Although the medication affects certain chemicals in the brain, it is not addicting
 Need for routine use—The medication will only work if it is taken as prescribed every day
 Delayed onset of action—It may take several weeks to see significant improvement in symptoms
 Prolonged duration of therapy—The medication should be taken for at least 6–12 months; do not discontinue it without consulting with the prescriber
 Adverse effects—Mention common and expected adverse effects as well as what to do if they occur
 Avoidance of alcohol and CNS depressants—Use of alcohol or other CNS depressants could cause worsened depression and additive adverse effects with the medicine
 Risk of suicidality—Be alert to symptoms of worsening depression and suicidality

Clinical Rationale

Patient may feel that depression is a character weakness or personality flaw instead of a biological disorder
 Patient may worry that because the antidepressant is psychoactive, it must be addicting
 Patient may try taking the medication on an as-needed basis
 Patient may prematurely discontinue therapy before the onset of beneficial effects
 Patient may prematurely discontinue therapy after symptoms have remitted, which could lead to relapse or recurrence
 Patient may be more likely to discontinue therapy and distrust the prescriber if adverse effects occur without forewarning
 Patient may be unaware of the possible consequences of drinking alcohol or taking other drugs with antidepressants
 Patient may become suicidal or have suicidal thinking while taking the antidepressant

CNS, central nervous system.

From Refs. 28 and 49.

silliness, daring conduct, and agitation.⁴⁶ Desipramine should be used with caution in this population because of several reports of sudden death, and a baseline and follow-up electrocardiography may be warranted when this medication is used to treat pediatric patients.⁹

The FDA has warned that antidepressants increase the risk of suicidality (i.e., suicidal thinking and behavior) in children and young adults. A large analysis of clinical trials revealed that the risk of such events was 4% for antidepressant medications versus 2% for placebo, although no completed suicides occurred in the trials. Because of this increased risk, antidepressants have black-box warnings concerning the matter, and patient medication guides are required to be distributed with each prescription or refill of antidepressant medications. **8** *Pediatric patients and young adults should be observed closely for suicidality, worsened depression, agitation, irritability, and unusual changes in behavior, especially during the initial few months of therapy and at times of dosage changes. Furthermore, families and caregivers should be advised to monitor patients for such symptoms.*⁴⁷

► Suicidal Patients

The FDA has determined that in addition to children and adolescents, there is an increased risk of suicidality in patients between the ages of 18 and 24 years, with no increased risk after the age of 24 years. Similar monitoring for suicidality and clinical worsening that is mandated for pediatric patients should also be followed for young adult patients.⁴⁸

Clinicians should bear in mind the toxic potential for the various antidepressant medications when patients already have or develop suicidality. Whereas the TCAs and

MAOIs have narrow therapeutic indices, the SSRIs, SNRIs, nefazodone, and mirtazapine have wide therapeutic indices.²¹

Patient Counseling

- Major counseling points and the clinical rationales behind them are outlined in **Table 38–8**.^{28,49} **9** *Lack of patient understanding concerning optimal antidepressant drug therapy frequently leads to partial compliance or noncompliance with therapy; thus, the primary purpose of antidepressant counseling is to enhance compliance and improve outcomes.*⁴⁹

OUTCOME EVALUATION

- Review the patient's medication profile to ensure that there are no potential or actual pharmacotherapy problems related to dosing, disease-state precautions or contraindications, drug–drug interactions, or unnecessary therapeutic duplication.
- Verify the extent of compliance with pharmacotherapy.
- Assess the response to pharmacotherapy, especially with regard to suicidality and symptoms that cause significant subjective distress and/or functional impairment.
- Determine whether the patient is experiencing any adverse effects of pharmacotherapy. Although general questioning (e.g., “Are you having any side effects?”) may reveal some problems with therapy, it is better to use direct questioning concerning adverse effects that are most common and/or most problematic (e.g., “Have you noticed any change in your sexual functioning?”).
- Provide counseling to enhance patient understanding of MDD and its pharmacotherapy.

Patient Care and Monitoring

1. Assess the patient's severity of symptoms to determine if self-care is appropriate or whether a psychiatrist should evaluate the patient.
2. Obtain a thorough history of prescription, nonprescription, natural, and illicit drug use. Rule out medications or medical disorders that may cause or mimic depressive symptoms.
3. Review the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision (*DSM-IV-TR*) criteria to determine an appropriate diagnosis.
4. Determine appropriate pharmacologic and psychological treatments (e.g., cognitive-behavioral therapy), including what has been helpful to the patient in the past.
5. Educate the patient and/or caretaker about the disease state, lifestyle modifications, and medication therapy.
 - What risk factors are present that could contribute to depression?
 - What lifestyle modifications could be made to improve the condition (e.g., exercise)?
 - How the medication should be taken?
 - What potential adverse effects may occur?
 - Which drugs may interact with their therapy?
 - Warning signs and prevention of suicidal and/or homicidal ideation.
6. Develop a plan to assess effectiveness of pharmacologic therapy after 4 weeks of being on a clinically effective dose.
7. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
8. Assess improvement in quality-of-life measures such as physical, psychological, and social functioning and well-being.
9. If the patient does not respond, determine if the patient is taking the appropriate medication and dose.
10. Recommend changes in therapy if the patient does not respond.
11. Assess the need for long-term maintenance therapy.

Abbreviations Introduced in This Chapter

DA	Dopamine
DRI	Dopamine reuptake inhibitor
<i>DSM-IV-TR</i>	<i>Diagnostic and Statistical Manual of Mental Disorders</i> , 4th ed, text revision
ECT	Electroconvulsive therapy
GI	Gastrointestinal
5-HT	Serotonin

MAOI	Monoamine oxidase inhibitor
MDD	Major depressive disorder
NaSSA	Noradrenergic and specific serotonergic antidepressant
NDRI	Norepinephrine and dopamine reuptake inhibitor
NE	Norepinephrine
NRI	Norepinephrine reuptake inhibitor
SAD	Seasonal affective disorder
SARI	Serotonin antagonist and reuptake inhibitor
SI	Suicidal ideation
SNRI	Serotonin and norepinephrine reuptake inhibitor
SRI	Serotonin reuptake inhibition
SSRI	Selective serotonin reuptake inhibitor
STAR*D	Sequenced Treatment Alternatives to Relieve Depression
TCA	Tricyclic antidepressant
VNS	Vagus nerve stimulation
WHO	World Health Organization

Bipolar Disorder

Brian L. Crabtree and Lydia E. Weisser

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiologic mechanisms underlying bipolar disorder.
2. Recognize the symptoms of a manic episode and depressive episode in patients with bipolar disorder.
3. Identify common comorbidities of bipolar disorder.
4. Recognize the *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed, text revision, criteria for bipolar disorder as well as the subtypes of bipolar I disorder, bipolar II disorder, and cyclothymic disorder.
5. List the desired therapeutic outcomes for patients with bipolar disorder.
6. Explain the use of drugs as first-line therapy in bipolar disorder, including appropriate dosing, expected therapeutic effects, potential adverse effects, and important drug–drug interactions.
7. Recommend individualized drug therapy for acute treatment and relapse prevention based on patient-specific data.
8. Recommend monitoring methods for assessment of therapeutic and adverse effects of drugs used in the treatment of bipolar disorder.
9. Recommend treatment approaches for special populations of patients with bipolar disorder, including pediatric patients, geriatric patients, and pregnant patients.
10. Educate patients with bipolar disorder about their illness, drug therapy required for effective treatment, and the importance of adherence.

KEY CONCEPTS

- 1 Patients presenting with depressive or elevated mood features and a history of abnormal or unusual mood swings should be assessed for bipolar disorder.
- 2 The diagnosis of bipolar disorder is made based on clinical presentation, a careful diagnostic interview, and a review of the history. There are no laboratory examinations, brain imaging studies, or other procedures that confirm the diagnosis.
- 3 Goals of treatment are to reduce symptoms, induce remission, prevent relapse, improve patient functioning, and minimize adverse effects of drug therapy.
- 4 Psychotherapy improves functional outcomes and may help treat or prevent mood episodes.
- 5 The primary treatment modality for manic episodes is mood stabilizing agents or antipsychotic drugs, often in combination.
- 6 The primary treatment for depressive episodes in bipolar disorder is mood stabilizing agents or certain

antipsychotic drugs, sometimes combined with antidepressant drugs.

- 7 The primary treatment for relapse prevention is mood stabilizing agents, often combined with antipsychotic drugs.
- 8 Education of the patient regarding benefits and risks of drug therapy and the importance of adherence to treatment must be integrated into pharmacologic management.

INTRODUCTION

Bipolar disorder is a mood disorder characterized by one or more episodes of mania or **hypomania**, often with a history of one or more major depressive episodes.¹ It is a chronic illness with relapses and improvements or remissions. Mood episodes can be manic, depressed, or mixed. They can be separated by long periods of stability or can cycle rapidly. They occur with or without psychosis. Disability and other consequences (e.g., increased risk of suicide) of bipolar

Patient Encounter, Part 1

Chief Complaint: “My family doctor made me come here. I’m not crazy.”

History of Present Illness:

Roger is a 28-year-old attorney with a local law firm. He presents somewhat reluctantly after being told by his supervisor that he needed to seek help for some unusual behavior. Roger initially presented to his family physician, who performed a physical examination and some screening to include CBC, metabolic profile, thyroid function, and ECG. All results were unremarkable. He was then referred to a psychiatric clinician for further evaluation.

Roger is an unmarried, well-nourished, well-developed white man appearing his stated age. He is wearing a suit and is well-groomed; however, his speech is somewhat rapid, and you find it difficult to interrupt him to get him to answer your questions. He paces around your office while speaking and is quite distractible. Roger says he has been experiencing decreased sleep, getting only 2 or 3 hours per night without feeling fatigued the next day. In fact, he says he feels, “more energetic than ever.” His appetite is decreased, and he has lost about 10 lb (4.5 kg) over the past few weeks. He has been working hard on a project for the firm and, to his annoyance, his boss and coworkers told him his work is less than up to standard and full of mistakes. He admits to some recent financial problems as well.

What diagnoses are suggested by this patient’s presentation?

What additional information is needed to clarify the diagnosis?

disorder can be devastating to patients and their families. Correct diagnosis and treatment are essential as early as possible in the course of the illness to prevent complications and maximize response to treatment.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

Bipolar disorders are categorized into bipolar I disorder, bipolar II disorder, and bipolar disorder not otherwise specified (NOS). Bipolar I disorder is characterized by one or more manic or **mixed mood episodes**. Bipolar II disorder is characterized by one or more major depressive episodes and at least one hypomanic episode. Hypomania is an abnormally and persistently elevated, expansive, or irritable mood but not of sufficient severity to cause significant impairment in social or occupational function and does not require hospitalization. The lifetime prevalence of bipolar I disorder is estimated to be between 0.3% and 2.4%. The lifetime prevalence of bipolar II disorder ranges from 0.2% to 5%. When including the entire spectrum of bipolar disorder diagnoses, the lifetime prevalence is between 3% and 6.5%.¹

Bipolar I disorder affects men and women equally. Bipolar II is more common in women. Rapid cycling and mixed mood episodes occur more often in women. In all, 78% to 85% of individuals with bipolar disorder report having another *Diagnostic and Statistical Manual*, 4th edition, text revision (DSM-IV-TR), diagnosis during their lifetime. The most common comorbid conditions include anxiety, substance abuse, and impulse control disorders. Nonpsychiatric medical comorbidities are also common.²

The mean age of onset of bipolar disorder is 20 years, although onset may occur in early childhood to the mid-40s.¹ If the onset of symptoms occurs after age 60, the condition is probably secondary to medical causes. An early onset of bipolar disorder is associated with greater comorbidities, more mood episodes, a greater proportion of days depressed, and greater lifetime risk of suicide attempts compared with bipolar disorder with a later onset. Substance abuse and anxiety disorders are more common in patients with an early onset. Patients with bipolar disorder also have higher rates of suicidal thinking, suicide attempts, and completed suicides than the general population.

Etiology

The precise etiology is unknown. Thought to be genetically based, bipolar disorder is influenced by a variety of factors that may enhance gene expression. These include trauma, environmental factors, anatomical abnormalities, exposure to chemicals or drugs, and others.³⁻⁵ Neurochemical abnormalities in bipolar disorder may be caused by these factors, which are discussed further in the pathophysiology section.

● PATHOPHYSIOLOGY

Neurochemical

The pathophysiology remains incompletely understood. Imaging techniques such as positron emission tomography (PET) scans and functional magnetic resonance imaging (fMRI) are being used to elucidate the cause. Research in the 1970s focused on neurotransmitters such as norepinephrine (NE), dopamine (DA), and serotonin. One hypothesis was that bipolar disorder is caused by an imbalance of cholinergic and catecholaminergic neuronal activity. Serotonin (5-HT) has been suggested to modulate catecholamine activity. Dysregulation of this relationship could cause a mood disturbance. Early theories included that an elevation of NE and DA caused mania and a reduction caused depression, but these theories are now considered overly simplistic.³ Other neurotransmitters are involved and interact with multiple neurochemical and neuroanatomic mechanisms and pathways.⁶ The pathophysiology has also been hypothesized from the mechanisms of action of lithium and other mood stabilizers. Lithium, valproate, and carbamazepine all have similar effects on neuronal growth that are reversible by inositol, supporting the hypothesis that bipolar disorder is related to inositol disturbance.⁷ Evidence has shown that brain-derived neurotrophic factor (BDNF) may also play a role

in bipolar disorder. Serum BDNF is low in mania and improves with response to treatment.⁸

Genetic

Results of family and twin studies suggest a genetic basis for bipolar disorder.⁴ The lifetime risk of bipolar disorder in relatives of a bipolar patient is 40% to 70% for a monozygotic twin and 5% to 10% for another first-degree relative.

CLINICAL PRESENTATION AND DIAGNOSIS

Diagnosis of Bipolar Disorder

1 *Patients presenting with depressive or elevated mood features and a history of abnormal or unusual mood swings should be assessed for bipolar disorder.* Bipolar disorder is categorized into four subtypes: bipolar I (periods of major depressive, manic, and/or mixed episodes); bipolar II (periods of major depression and hypomania), cyclothymic disorder (periods of

hypomanic episodes and depressive episodes that do not meet all criteria for diagnosis of a major depressive episode), and bipolar disorder NOS. The defining feature of bipolar disorders is one or more manic or hypomanic episodes in addition to depressive episodes that are not caused by a medical condition, substance abuse, or other psychiatric disorder.¹

Initial and subsequent episodes of bipolar disorder are mostly depressive.⁹ Studies that followed patients with bipolar disorder over an average of about 13 years show that bipolar I patients spend about 32% of weeks with depressive symptoms compared with 9% of weeks with manic or hypomanic symptoms.¹⁰ Patients with bipolar II disorder spend 50% of weeks symptomatic for depression and only 1% with hypomanic symptoms.¹¹ Because patients may present with depression and spend more time depressed than with mood elevation, bipolar disorder is often misdiagnosed or underdiagnosed. It is helpful to use a screening tool such as the mood disorder questionnaire.¹²

DSM-IV-TR criteria for the diagnosis of bipolar disorder are summarized in [Table 39-1](#).

Patient Encounter, Part 2: Medical History, Physical Examination, and Laboratory Examination

Your interview reveals the following information:

Past Medical History: No known medical problems except a history of mildly elevated blood pressure, controlled by hydrochlorothiazide 25 mg/day. One episode of gonorrhea in his early 20s.

Past Psychiatric History: Noncontributory

Family History: Parents alive and well. A paternal uncle committed suicide several years ago. A maternal aunt has history of alcohol, opiate, and benzodiazepine abuse. The patient's paternal grandfather reportedly had episodes of "moodiness" and bizarre behavior at times but was never treated. Two sisters in good health, although older sister has been treated for depression in the past.

Social History: The patient is bisexual with a history of multiple casual partners of both genders whom he meets at parties and bars. He graduated from college with honors and a degree in political science. He subsequently graduated from law school and has worked at his current job for 1 year. He began work at one law firm immediately upon graduation but was terminated because of frequent absences. He quit his previous job because he "wants to rise to the top" of his field as quickly as possible and thought his current firm was more prestigious. He lives alone but has an active sexual life and enjoys gambling at casinos. He reports a similar episode in college when he felt naturally energetic and, on a dare, jumped on a plane to go to Washington to tell the president some of his ideas about Homeland Security.

Substance Use History: Denies use of tobacco products; cocaine; hallucinogens; intravenous drugs; amphetamines;

and overuse of prescription medications, such as opiates and benzodiazepines. However, he admits to smoking marijuana "to calm myself down" at times and tends to binge drink on the weekend when at casinos or at parties. He also drinks several mixed drinks each night to help get to sleep. He drinks one cup of coffee each morning and denies use of vitamins and herbal supplements.

Medications: Hydrochlorothiazide 25 mg po daily.

ROS: Increased energy, racing thoughts, decreased need for sleep, decreased appetite.

PE:

VS: BP 135/80, P 90, RR 20, T 98.6°F (37.0°C)

HEENT: PERRLA. Extraocular movements intact. Nares patent. Ear canals patent and eardrums easily visualized. Neck supple without JVD, bruits, or adenopathy. Thyroid smooth, symmetric, and nontender.

CV: Regular rate and rhythm without murmurs, gallops, or rubs.

Abd: Soft, nontender, no organomegaly or masses. Positive bowel sounds.

Exts: Without clubbing, cyanosis, or edema. Peripheral pulses full and equal bilaterally.

CN: II–XII intact.

Labs: Urine drug screen + for THC. HIV negative

Considering this additional information, what is the most likely diagnosis?

What are the key pieces of information leading you to this conclusion?

Table 39-1

Evaluation and Diagnostic Criteria of Mood Episodes

Diagnostic workup depends on clinical presentation and findings		<ul style="list-style-type: none"> • Mental status examination • Psychiatric, medical, and medication history • Physical and neurologic examination • Basic laboratory tests: CBC, blood chemistry screen, thyroid function, urinalysis, urine drug screen • Psychological testing • Brain imaging: MRI and fMRI; alternative: CT, PET • Lumbar puncture • Electroencephalogram
Diagnosis episode	Impairment of functioning or need for hospitalization ^a	<i>DSM-IV-TR</i> criteria ^b
Major depressive	Yes	<p>Greater than or equal to 2-week period of either depressed mood or loss of interest or pleasure in normal activities, associated with at least five of the following symptoms:</p> <ul style="list-style-type: none"> • Depressed, sad mood (adults); can be irritable mood in children • Decreased interest and pleasure in normal activities • Decreased appetite, weight loss • Insomnia or hypersomnia • Psychomotor retardation or agitation • Decreased energy or fatigue • Feelings of guilt or worthlessness • Impaired concentration and decision making • Suicidal thoughts or attempts
Manic	Yes	<p>Greater than or equal to 1-week period of abnormal and persistent elevated mood (expansive or irritable), associated with at least three of the following symptoms (four if the mood is only irritable):</p> <ul style="list-style-type: none"> • Inflated self-esteem (grandiosity) • Racing thoughts (FOI) • Distractible (poor attention) • Increased activity (either socially, at work, or sexually) or increased motor activity or agitation • Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures)
Hypomanic	No	<p>At least 4 days of abnormal and persistent elevated mood (expansive or irritable); associated with at least three of the following symptoms (four if the mood is only irritable):</p> <ul style="list-style-type: none"> • Inflated self-esteem (grandiosity) • Decreased need for sleep • Increased talking (pressure of speech) • Racing thoughts (FOI) • Increased activity (either socially, at work, or sexually) or increased motor activity or agitation • Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures)
Mixed	Yes	Criteria for both a major depressive episode and manic episode (except for duration) occur nearly every day for at least a 1-week period
Rapid cycling	Yes	More than three major depressive or manic episodes (manic, mixed, or hypomanic) in 12 months

^aImpairment in social or occupational functioning; need for hospitalization because of potential self-harm, harm to others, or psychotic symptoms.

^bThe disorder is not caused by a medical condition (e.g., hypothyroidism) or substance-induced disorder (e.g., antidepressant treatment, medications, electroconvulsive therapy).

Data from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders. 4th ed, text rev. Washington, DC: American Psychiatric Press; 2000 and Drayton SJ. Bipolar disorder. In: DiPiro JT, Talbert RL, Yee GC, Matzke GR, Wells BG, Posey LM, eds. Pharmacotherapy: A Pathophysiologic Approach. 8th ed. New York, NY: McGraw-Hill. 2010; 1191–1208. With permission.

► **Bipolar I Disorder**

- The diagnosis of bipolar I disorder requires at least one episode of mania for at least 1 week or longer with a persistently elevated, expansive, or irritable mood with related symptoms of decreased need for sleep, excessive energy, racing thoughts, a propensity to be involved in high-risk activities, and excessive talkativeness.¹ Bipolar I depression can be misdiagnosed as major depressive disorder (MDD); therefore, it is essential to rule out past episodes of hypomania or mania. If bipolar depression is mistaken for MDD and the patient is treated with antidepressants, it can precipitate a manic episode or induce rapid cycling of depression and mania.

► **Bipolar II Disorder**

- The distinguishing feature of bipolar II disorder is depression with past hypomanic episodes that often are not recalled by the individual as being unusual. Irritability and anger episodes are also common. There cannot have been a prior full-manic episode.¹

► **Cyclothymic Disorder**

- Cyclothymic disorder is a chronic mood disturbance generally lasting at least 2 years (1 year in children and adolescents) and characterized by mood swings that include periods of hypomania and depressive symptoms. Hypomanic symptoms include inflated self-esteem or **grandiosity** (nondelusional), decreased need for sleep, pressure of speech, **flight of ideas (FOI)**, distractibility, and increased involvement in goal-directed activities, not causing severe impairment in social or occupational functioning or requiring hospitalization. Psychotic features are not present in cyclothymic disorder.¹

► **Suicide**

Patients with bipolar disorder have a high risk of suicide. Factors that increase that risk are early age at disease onset, high number of depressive episodes, comorbid alcohol abuse, personal history of antidepressant-induced mania, and family history of suicidal behavior. About one-third of individuals

1 Clinical Presentation and Diagnosis

General

The patient may present in a hypomanic, manic, depressed, or mixed state and may or may not be in acute distress.

Symptoms

Mood and Affect:

- Mood elevation
- Expansive mood
- Irritable mood
- Depression
- Hopelessness
- Suicidality

Physical and Behavioral:

- Agitation
- Impulsivity
- Aggression
- Rapid, pressured speech
- Decreased need for sleep
- Insomnia (sometimes for days or weeks)
- Hypersexuality
- Increased physical energy
- Inflated self-esteem, boasting, grandiosity
- Heightened interest in pleasurable activities with a high risk of negative consequences (e.g., spending sprees, promiscuity)
- Fatigue
- Hypersomnia

Thought Processes, Content, and Perceptions:

- Racing thoughts, FOI, distractibility
- Delusions of grandeur, ideas of reference, persecution, wealth, religion

Psychosocial

- Substance use
- Disrupted relationships
- Job loss

Laboratory and Other Diagnostic Assessments

2 *There are no objective laboratory tests or procedures to diagnose bipolar disorder, but such testing can be done to rule out other medical diagnoses.*

- Urinalysis, urine toxicology, thyroid function, and white blood cell count in elderly patients to rule out urinary tract infection
- Mood disorder questionnaire, completed by the patient, asks about common symptoms of bipolar disorder, problems caused by the symptoms, and family history in a “yes” or “no” answer format. It is then scored by the clinician

Suicidality risk is increased in the presence of:

- Substance abuse
- Prior suicide attempts and lethality of attempts
- Access to a means of suicide
- Command hallucinations or psychosis
- Severe anxiety
- Family history of attempted or completed suicide

Data from Refs. 1, 3, and 16.

with bipolar disorder report a previous suicide attempt.¹³ One of five suicide attempts is fatal in contrast to one of 10 to one of 20 in the general population.

► Differential Diagnosis

Schizophrenia and bipolar disorder share certain symptoms, including psychosis in some patients. The prominence of mood symptoms and the history of mood episodes distinguish bipolar disorder and schizophrenia. In addition, the psychosis of schizophrenia occurs in the absence of prominent mood symptoms.

Schizoaffective disorder may also be considered when developing a differential diagnosis for bipolar disorder. Schizoaffective disorder is characterized by an uninterrupted period of illness during which there is either a major depressive episode, a manic episode, or a mixed episode concurrent with symptoms that meet criterion A for schizophrenia (e.g., delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and/or negative symptoms such as affective flattening, alogia, or avolition). The major depressive episode must include depressed mood. During the same period of illness, there have been delusions or hallucinations for at least 2 weeks in the absence of prominent mood symptoms. Schizoaffective Disorder may be of two different types. The bipolar type includes a manic or mixed episode or a manic or mixed episode and major depressive episodes. The depressive type includes only major depressive episodes.¹

Personality disorders are inflexible and maladaptive patterns of behavior that deviate markedly from expectations of society beginning in adolescence or early adulthood.¹ Personality disorders and bipolar disorder may be comorbid, and patients with personality disorders may have mood symptoms. The two diagnoses are distinguished by the predominance of mood symptoms and the episodic course of bipolar disorder in contrast to the stability and persistence of the behavioral patterns of personality disorders.

► Comorbid Psychiatric and Medical Conditions

Lifetime prevalence rates of psychiatric comorbidity with bipolar disorder are up to 58%.¹⁴ Comorbidities, especially substance abuse, make establishing a definitive diagnosis more difficult and complicate the treatment. Comorbidities also place the patient at risk for a poorer outcome, high rates of suicidality, onset of depression, and higher costs of treatment.^{2,13} Psychiatric comorbidities include:

- Personality disorders
- Alcohol and substance abuse or dependence
- Anxiety disorders
- Panic disorder
- Obsessive-compulsive disorder
- Social phobia
- Eating disorders
- Attention-deficit hyperactivity disorder

Patient Encounter, Part 3: Creating a Care Plan

Based on all information presented, create a care plan for this patient's bipolar disorder. Your plan should include (a) a statement of the drug-related needs or problems, (b) the goals of therapy, (c) a patient-specific therapeutic plan, and (d) a plan for follow-up to assess therapeutic response and adverse effects.

Medical comorbidities include:

- Migraine
- Multiple sclerosis
- Cushing's syndrome
- Brain tumor
- Head trauma

TREATMENT

Desired Outcomes

- 3 Goals of treatment are to reduce symptoms, induce remission, prevent relapse, improve patient functioning, and minimize adverse effects of drug therapy.

General Approach to Treatment

- Treatment guidelines for manic and depressive episodes of bipolar disorder are included in [Table 39–2](#).

Although not all patients achieve remission, this is a goal of treatment. The mainstay of drug therapy has been mood-stabilizing drug but new research based on multiple-treatments meta-analysis indicates antipsychotic drugs, both first-generation antipsychotics (FGAs) and second-generation antipsychotics (SGAs), may be more effective for acute mania.¹⁵ Antipsychotic drugs may be used as monotherapy or adjunctively with mood-stabilizing drugs. A person entering treatment for a first mood episode in bipolar disorder must have a complete assessment and careful diagnosis to rule out nonpsychiatric causes. A variety of conditions can cause similar symptoms ([Table 39–3](#)). Because early and accurate diagnosis is essential to maximizing response to treatment, pharmacologic and nonpharmacologic therapy should begin as soon as possible. Treatment is often lifelong. Comorbid conditions should also be addressed aggressively.

► Suicidality Risk

Patients should be assessed for their potential for violence and harm to others. Friends or family can be asked to remove from home guns, caustic chemicals, medications, and objects that patients might use to harm themselves or others. Risk factors for suicide include severity of depression, feelings of

Table 39–2

Guidelines for the Acute Treatment of Mood Episodes in Patients With Bipolar I Disorder

Acute Manic or Mixed Episode		Acute Depressive Episode	
General guidelines		General guidelines	
Assess for secondary causes of mania or mixed states (e.g., alcohol or drug use)		Assess for secondary causes of depression (e.g., alcohol or drug use)	
Taper off antidepressants, stimulants, and caffeine if possible		Taper off antipsychotics, benzodiazepines or sedative-hypnotic agents if possible	
Treat substance abuse		Treat substance abuse	
Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy		Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy	
Optimize the dose of mood stabilizing medication(s) before adding on benzodiazepines; if psychotic features are present, add on antipsychotic; ECT used for severe or treatment-resistant manic/mixed episodes or features		Optimize the dose of mood stabilizing medication(s) before adding on lithium lamotrigine, or antidepressant (e.g., bupropion or an SSRI); if psychotic features are present, add on antipsychotic; ECT used for severe or treatment-resistant depressive episodes or for psychotic catatonia	
Hypomania	Mania	Mild to Moderate Depressive Episode	Severe Depressive Episode
First, optimize current mood stabilizer or initiate mood-stabilizing medication: lithium, ^a valproate, ^a or carbamazepine. ^a Consider adding a benzodiazepine (lorazepam or clonazepam) for short-term adjunctive treatment of agitation or insomnia if needed	First, two- or three-drug combinations: lithium or valproate plus a benzodiazepine (lorazepam or clonazepam) for short-term adjunctive treatment of agitation or insomnia; lorazepam is recommended for catatonia. If psychosis is present, initiate atypical antipsychotic in combination with above	First, initiate and/or optimize mood-stabilizing medication: lithium ^a or lamotrigine ^b	First, two- or three-drug combinations: lithium ^a or lamotrigine ^b plus an antidepressant ^c ; lithium plus lamotrigine. If psychosis is present, initiate atypical antipsychotic in combination with above
Alternative medication treatment options: carbamazepine ^a ; if patient does not respond or tolerate, consider atypical antipsychotic (e.g., olanzapine, quetiapine, risperidone) or oxcarbazepine	Alternative medication treatment options: carbamazepine ^a ; if patient does not respond or tolerate, consider oxcarbazepine	Alternative anticonvulsants: valproate, ^a carbamazepine, ^a or oxcarbazepine	Alternative anticonvulsants: valproate, ^a carbamazepine, ^a or oxcarbazepine. Second, if response is inadequate, consider adding an atypical antipsychotic (quetiapine). Third, if response is inadequate, consider a three-drug combination:
Second, if response is inadequate, consider a two-drug combination:	Second, if response is inadequate, consider a three-drug combination:		• Lamotrigine ^b plus an anticonvulsant plus an antidepressant
• Lithium ^a plus an anticonvulsant or an atypical antipsychotic	• Lithium ^a plus an anticonvulsant plus an atypical antipsychotic		• Lamotrigine ^b plus lithium ^a plus an antidepressant
• Anticonvulsant plus an anticonvulsant or atypical antipsychotic	• Anticonvulsant plus an anticonvulsant plus an atypical antipsychotic		Fourth, if response is inadequate, consider ECT for treatment-refractory illness and depression with psychosis or catatonia ^d
	Third, if response is inadequate consider ECT for mania with psychosis or catatonia ^a ; or add clozapine for treatment-refractory illness		

ECT, electroconvulsive therapy; MAOI, monoamine oxidase inhibitor, SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

^aUse standard therapeutic serum concentration ranges if clinically indicated; if partial response or breakthrough episode, adjust dose to achieve higher serum concentrations without causing intolerable adverse effects; valproate is preferred over lithium for mixed episodes and rapid cycling; lithium and/or lamotrigine is preferred over valproate for bipolar depression.

^bLamotrigine is not approved for the acute treatment of depression, and the dose must be started low and slowly titrated to decrease adverse effects if used for maintenance therapy of bipolar I disorder. A drug interaction and a severe dermatologic rash can occur when lamotrigine is combined with valproate (i.e., lamotrigine doses must be halved from standard dosing titration).

^cAntidepressant monotherapy is not recommended for bipolar depression. Bupropion, SSRIs (e.g., citalopram, escitalopram, or sertraline), and SNRIs (e.g., venlafaxine) have shown good efficacy and fewer adverse effects in the treatment of unipolar depression; MAOIs and TCAs have more adverse effects (e.g., weight gain) and can have a higher risk of causing antidepressant-induced mania; fluoxetine, fluvoxamine, nefazodone, and paroxetine inhibit liver metabolism and should be used with caution in patients on concomitant medications that require cytochrome P450 clearance; paroxetine and venlafaxine have a higher risk for a discontinuation syndrome.

^dECT is used for severe mania or depression during pregnancy and for mixed episodes; prior to treatment, anticonvulsants, lithium, benzodiazepines should be tapered off to maximize therapy and minimize adverse effects.

Data from Refs. 32, 47 (with permission), 48, and 49.

Table 39–3

Secondary Causes of Mania**General Medical Conditions**

Alzheimer's disease
 Cerebral infarction
 Cerebral tumors
 Closed head injury
 Cushing's syndrome
 Hemodialysis

hopelessness, comorbid personality disorder, and a history of a previous suicide attempt.¹³

► Nonpharmacologic Therapy

4 *Interpersonal, family, or group psychotherapy with a qualified therapist or clinician assists individuals with bipolar disorder to improve functional outcomes and may help treat or prevent mood episodes, establish and maintain a daily routine and sleep schedule, and improve interpersonal relationships.*^{17,18}

Cognitive-behavioral therapy (CBT) is a type of psychotherapy that combines cognitive and behavioral theories. It stresses the importance of recognizing patterns of cognition (thought) and how thoughts influence subsequent feelings and behaviors. Other people, situations, and events external to the individual are not seen as the sources of thoughts and behaviors. With CBT, patients are taught self-management skills to change their negative thoughts even if external circumstances do not change.

Electroconvulsive therapy (ECT) is the application of prescribed electrical impulses to the brain for the treatment of severe depression, mixed states, psychotic depression, and treatment refractory mania. It also may be used in pregnant

women who cannot take carbamazepine, lithium, or divalproex (DVP).

Psychoeducation for patients, their families, and groups regarding the chronicity of bipolar disorders and self-management through sleep hygiene, nutrition, exercise, stress reduction, and abstinence from alcohol or drugs is critical to the success of supporting the individual in managing bipolar disorder. The development of a crisis intervention plan is essential.

► Pharmacologic Therapy

5 *Pharmacotherapy is the primary treatment modality of acute and maintenance treatment of bipolar disorder. Mood-stabilizing drugs are first-line treatments and include lithium, DVP, carbamazepine, and lamotrigine. The SGAs, including risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, and asenapine, are also approved for treatment of acute mania. Lithium, lamotrigine, aripiprazole, olanzapine, and quetiapine are approved for maintenance therapy. Quetiapine's maintenance therapy indication is adjunctive with lithium or DVP. Drugs used with less research support and without Food and Drug Administration (FDA) approval include topiramate and oxcarbazepine. Benzodiazepines are used adjunctively for mania.*

6 *Mood-stabilizing drugs are the primary treatment for bipolar depression. Among antipsychotic drugs, quetiapine as monotherapy and olanzapine in combination with fluoxetine are approved for bipolar depression. Antidepressants can be used but along with a mood stabilizing agent to reduce risk of a mood switch to mania and after the patient has failed to respond adequately to optimal mood stabilizing therapy. Evidence of efficacy of antidepressant drugs in bipolar depression is considered less robust than evidence for mood-stabilizing drugs quetiapine, and the olanzapine–fluoxetine combination.^{19,20} Combinations of two mood-stabilizing drugs or a mood-stabilizing drug and either an antipsychotic or antidepressant drug are common, especially in acute mood episodes.*

7 *Mood-stabilizing drugs are considered the primary pharmacotherapy for relapse prevention, and they are often combined with antipsychotic drugs. Aripiprazole, olanzapine, and quetiapine are approved for maintenance therapy.*

Table 39–4 includes a summary of current drug therapy for bipolar disorder. An algorithm for treatment of bipolar mania is shown in Table 39–2.

► Mood-Stabilizing Drugs

The optimal mood-stabilizing drug would be effective in treatment of acute mania and acute bipolar depression and in prevention of manic relapse and bipolar depression relapse. All currently approved mood-stabilizing drugs have demonstrated efficacy over placebo for one or more of these

Table 39-4

Product Formulation, Dose, and Clinical Use of Agents Used in the Treatment of Bipolar Disorder

Generic Name	Brand Names	Formulations	Dosages	Clinical Use	Dosage Adjustment in Renal or Hepatic Impairment
Lithium salts					
FDA approved in bipolar disorder					
Lithium carbonate	Lithobid	ER tablets: 300 mg	900–2400 mg/day once daily or in 2–4 divided doses, preferably with meals. There is wide variation in the dosage needed to achieve therapeutic response and 12-hour serum lithium concentration (i.e., 0.6–1.2 mEq/L (mmol/L) for maintenance therapy and 1.0–1.5 mEq/L (mmol/L) for acute mood episodes taken 12 hours after last dose). Single daily dosing is effective and causes fewer renal effects	Monotherapy or in combination with other drugs for the acute treatment of mania and for maintenance treatment	Reduce starting dosage by at least 50% in renal impairment
	Generic	ER tablets: 450 mg			
	Generic	ER tablets: 300 mg			
	Generic	Tablet: 300 mg			
Lithium citrate	Generic	Capsules: 150, 300, 600 mg			
		300 mg (8 mmol)/5 mL			
Anticonvulsants					
FDA approved for use in bipolar disorder					
Carbamazepine	Equetro (only the Equetro brand is FDA approved for bipolar disorder)	Capsules: 100 mg, 200 mg, 300 mg SR; may open capsule but do not crush or chew beads; take with food	Start at 100–200 mg bid; increase by 200 mg every 3–4 days to 200–1,800 mg/day in 2–4 divided doses Target serum concentration is 4–12 mcg/mL (17–51 μmol/L)	Monotherapy or in combination with other drugs for the acute treatment of mania or mixed episodes for bipolar I disorder	Reduce starting dosage by at least half or avoid in hepatic impairment
		Tablets: 200 mg			
		Tegretol, generic			
		Tegretol XR			
		Carbatrol			
Divalproex sodium	Depakote, generic Depakote ER	Enteric-coated, delayed-release tablets: 125, 250, 500 mg	750–3,000 mg/day (20–60 mg/kg per day) in 2–3 divided doses for delayed-release divalproex or valproic acid ER divalproex may be given once daily. A loading dose of 20–30 mg/kg per day can be given, then 20 mg/kg per day and titrated to a serum concentration of 50–125 mcg/mL (347–866 μmol/L)	Monotherapy or in combination with other drugs for the acute treatment of mania. Although commonly used for relapse prevention, maintenance treatment is not FDA approved	Reduce starting dosage by half or avoid in hepatic impairment
		Sprinkles: 125 mg			
		ER tablets: 250, 500 mg			
Valproic acid	Depakene, generic	Capsules: 250 mg			
Valproic acid syrup	Depakene, generic	250 mg/5 mL			
Lamotrigine	Lamictal, generic	Tablets: 25, 100, 150, 200 mg	50–400 mg/day in divided doses. Dosage should be slowly increased by following prescribing information. If divalproex is added to lamotrigine dosage should be reduced by half	Monotherapy or in combination with other drugs for maintenance treatment	
		Chewable tablets: 2, 5, 25 mg			
	Lamictal XR (not FDA approved for bipolar disorder)	Orally disintegrating tablets: 25, 50, 100, 200 mg ER tablets: 25, 50, 100, 200 mg			

(Continued)

Table 39-4

Product Formulation, Dose, and Clinical Use of Agents Used in the Treatment of Bipolar Disorder (Continued)

Generic Name	Brand Names	Formulations	Dosages	Clinical Use	Dosage Adjustment in Renal or Hepatic Impairment
Anticonvulsants and Other Drugs Not FDA Approved for Use in Bipolar Disorder					
Clonazepam	Klonopin, generic	Tablets: 0.5, 1, 2 mg Wafers: 0.125, 0.25, 0.5, 1, 2 mg	0.5–20 mg/day in divided doses or one dose at bedtime Dosage should be slowly adjusted up and down according to response and adverse effects	Use in combination with other drugs for the acute treatment of mania or mixed episodes	
Lorazepam	Ativan, generic	Tablets: 0.5, 1, 2 mg Oral solution: 2 mg/mL Injection: 2, 4 mg/mL	2–10 mg/day in divided doses or one dose at bedtime Dosage should be slowly adjusted up and down according to response and adverse effects		
Oxcarbazepine	Trileptal, generic	Tablets: 150, 300, 600 mg Suspension: 300 mg/5 mL	300–1200 mg/day in two divided doses Doses should be slowly adjusted up and down according to response and adverse effects (e.g., 150–300 mg twice daily and increase by 300–600 mg/day at weekly intervals)		
Atypical Antipsychotics					
FDA approved for bipolar disorder					
Aripiprazole	Abilify Abilify Discmelt	Tablets: 2, 5, 10, 15, 20, 30 mg Oral solution: 5 mg/5 mL Tablets, orally disintegrating: 10, 15 mg	10–30 mg/day once daily	Use as monotherapy or in combination with lithium or valproate for the acute treatment of mania or mixed states for bipolar I disorder and prevention of manic relapse	
Asenapine	Saphris	Sublingual tablets: 5, 10 mg	5–20 mg/day in two divided doses. Must be held under the tongue until dissolved completely, not chewed or swallowed, with no food or liquid for 10 minutes after administering		
Olanzapine	Zyprexa, generic	Tablets: 2.5, 5, 7.5, 10, 15, 20 mg	5–20 mg/day in 1 or 2 doses	Used as monotherapy or in combination with lithium or valproate for acute treatment of mania or mixed states for bipolar I disorder and prevention of manic relapse. Used in combination with fluoxetine (OFC) for treatment of bipolar depression	
Olanzapine/ Fluoxetine combination (OFC)	Zyprexa Zydis Symbyax	Tablets, orally disintegrating: 5, 10, 15, 20 mg Capsules: 3/25, 6/25, 6/50, 12/25, 12/50 mg			
Quetiapine	Seroquel Seroquel XR	Tablets: 25, 50, 100, 200, 300, 400 mg ER tablets: 50, 150, 200, 300, 400 mg	50–800 mg/day in divided doses or once daily when stabilized		
Risperidone	Risperdal, generic Risperdal M-Tabs Risperdal Consta	Tablets: 0.25, 0.5, 1, 2, 3, 4 mg Oral solution: 1 mg/mL Tablets, orally disintegrating: 0.5, 1, 2, 3, 4 mg Long-acting injectable: 12.5, 25, 37.5, 50 mg	0.5 – 6 mg/day in 1 or 2 doses	Used as monotherapy or adjunctively with lithium or divalproex for acute mania or mixed episodes of bipolar I disorder	
Ziprasidone	Geodon	Capsules: 20, 40, 60, 80 mg	40–160 mg/day in divided doses

Data from Ref. 15, 26, 28–32, and 36–38.

areas, but there are differences among them with regard to specific patient populations. The choice of treatment is dictated by individual patient characteristics and history. Few studies have compared mood-stabilizing drugs with each other in systematic clinical trials. Effect sizes across placebo-controlled trials of individual agents are generally similar.

Lithium and DVP are first-choice drugs for the classic presentation of bipolar disorder. Treatment of childhood bipolar disorder is less well researched. Lithium is FDA approved in children and adolescents as young as age 12 years. Among the antipsychotic drugs, aripiprazole, olanzapine, quetiapine, and risperidone are FDA approved in children and adolescents as young as age 10 years. Treatment of bipolar disorder during pregnancy and during breastfeeding is a challenge because of the risks of drug exposure in utero and transmission of drugs via breast milk.

Lithium Lithium was the first approved mood-stabilizing drug. It remains a first-line agent and sets the standard for efficacy against which other drugs are usually measured. It has antimanic efficacy, prevents bipolar disorder relapse, and has more modest efficacy for acute bipolar depression. One of the oldest drugs used for psychiatric illness, research continues to strongly support its use and place in therapy.²¹ In most studies, lithium's efficacy is equivalent to that of anticonvulsant mood stabilizers and SGAs, although recent data regarding antipsychotic drugs make a conclusive statement about lithium's efficacy less clear.¹⁵ It is most effective for patients with few previous episodes, symptom-free interepisode remission, and a family history of bipolar disorder with good response to lithium. Increasing evidence suggests genetic phenotypes that are more responsive to lithium.²² However, patients with rapid cycling bipolar disorder are less responsive to lithium than to other mood-stabilizing drugs such as DVP.²³ Additionally, its efficacy for bipolar depression is less robust than for mania.¹⁹ It may also be less effective in patients with mixed mood episodes (symptoms of mania and depression occurring simultaneously) and in mania secondary to nonpsychiatric illness.

Evidence shows lithium's effect on suicidal behavior is superior to that of other mood-stabilizing drugs.²⁴ Lithium reduces the risk of deliberate self-harm or suicide by about 70%.

Mechanism of Action. Lithium's pharmacologic mechanism of action is not well understood and involves multiple effects. Possibilities include altered ion transport, effects on neurotransmitter signaling, blocking adenylyl cyclase systems, effects on inositol, neuroprotection or increased BDNF, and inhibition of second messenger systems.²⁵

Dosing and Monitoring. Lithium is usually initiated at a dosage of 600 to 900 mg/day. Although it is most commonly given in a divided dosage, once-daily dosing is acceptable, especially with sustained-release formulations. Once-daily dosing can improve patient adherence and reduce some side effects. Lithium has a narrow therapeutic index, meaning the toxic dosage is not much greater than the therapeutic dosage. Lithium requires regular serum concentration monitoring as a guide to dosage titration and to minimize adverse effects.

At least weekly monitoring is recommended until the patient is stabilized; then the frequency can be decreased. Well-maintained patients who tolerate lithium without difficulty can be monitored by serum concentration as infrequently as twice yearly. The dosage is titrated to achieve a serum lithium concentration of 0.6 to 1.4 mEq/L (mmol/L). Higher serum concentrations are usually required to treat an acute episode than to prevent relapse. Serum lithium maintained above 0.8 mEq/L (mmol/L) may be more effective at preventing relapse, however, than lower serum concentrations. The suggested therapeutic serum concentration range is based on a 12-hour postdose sample collection, usually a morning trough in patients taking more than one dose per day. At least 2 weeks at a suggested therapeutic serum concentration is required for an adequate trial of lithium. **Table 39-5** shows pharmacokinetic parameters and desired serum concentrations of mood-stabilizing drugs used for bipolar disorder. It is common for lithium to be combined with other mood-stabilizing drugs or antipsychotic drugs to achieve more complete remission of symptoms.

Adverse Effects. The most common adverse effects are gastrointestinal (GI) upset, tremor, and polyuria,²⁶ which are dose related. Nausea, dyspepsia, and diarrhea can be minimized by coadministration with food, use of the sustained-release formulation, and giving smaller doses more frequently to reduce the amount of drug in the GI tract at a given time. Tremor is present in up to 50% of patients. In addition to the approaches above, low-dose β -blocker therapy, such as propranolol 20 to 60 mg/day, often reduces the tremor.

Lithium impairs the kidney's ability to concentrate urine because of its inhibitory effect on vasopressin. This causes an increase in urine volume and urinary frequency and a consequent increase in thirst. Polyuria and polydipsia occur in up to 70% of patients. A severe form of polyuria, when urine volume exceeds 3 L/day, is known as lithium-induced nephrogenic **diabetes insipidus**. It can be treated with hydrochlorothiazide or amiloride. If the former is used, the lithium dosage should be reduced by 33% to 50% to account for the drug-drug interaction that could increase serum lithium concentrations and cause toxicity. Long-term lithium therapy has been associated with structural kidney changes, such as glomerular sclerosis or tubular atrophy. Once-daily dosing of lithium is less likely to cause renal adverse effects than divided-daily dosing.

Lithium is concentrated in the thyroid gland and can impair thyroid hormone synthesis. Although goiter is uncommon, as many as 30% of patients develop at least transiently elevated thyroid-stimulating hormone values. Lithium-induced hypothyroidism is not usually an indication to discontinue the drug. Patients can be supplemented with levothyroxine if continuation of lithium is desired.²⁶

Other common adverse effects include poor concentration, acneiform rash, alopecia, worsening of psoriasis, weight gain, metallic taste, and impaired glucose regulation. Lithium causes a flattening of the T wave of the electrocardiogram (ECG), which is generally considered benign and not clinically significant. Less commonly, it can cause or worsen

Table 39-5

Pharmacokinetics and Therapeutic Serum Concentrations of Lithium and Anticonvulsants Used in the Treatment of Bipolar Disorder

	Lithium	Carbamazepine	Oxcarbazepine	Divalproex (DVP) Sodium/Valproic Acid (VPA)	Lamotrigine
Gastrointestinal Absorption					
Regular release	Rapid: 95%–100% within 1–6 hours	Slow and erratic: 85%–90%	Slow and complete: 100%	Rapid and complete (VPA)	Rapid: 98%
Syrup, suspension, solution	Faster rate of absorption: 100%	Faster rate of absorption	Unknown	Faster rate of absorption than tablets	NA
ER/enteric-coated tablets	Delayed absorption: 60%–90%	Delayed absorption: 89% of the suspension; and less than regular-release tablets	NA	Delayed absorption with delayed-release tablets; valproate is rapidly converted to VPA in the intestine and then is rapidly and almost completely absorbed from the GI tract ER bioavailability is approximately 15% less than delayed release	Delayed absorption but not significantly different from regular release
Delay in absorption by food	Yes	No; reports of increased rate of absorption with fatty meals (ER capsule)	No	Yes; food slows the rate of absorption but not the extent for DVP	Bioavailability not affected by food
Time to reach peak serum concentrations	0.5–3 hours (regular-release) 4–12 hours (ER) 0.25–1 hour (oral solution)	4–5 hours (regular-release); 1.5 hours (suspension); 3–12 hours (ER tablets); 4.1–7.7 hours (ER capsules); higher peak concentrations with chewable tablets	4.5 hours (range of 3–13 hours)	1–4 hours (VPA) 3–5 hours (DVP single dose) 7–14 hours (DVP ER multiple dosing)	1–4 hours (regular release), 4–6 hours (ER)
Distribution					
Volume of distribution	Initial: 0.3–0.4 L/kg Steady state: 0.7–1 L/kg	0.6–2 L/kg (adults)	10-monohydroxy metabolite: 49 L/kg	11 L/1.73 m ² (total valproate); 92 L/1.73 m ² (free valproate)	0.9–1.3 L/kg
Crosses the placenta	Yes; pregnancy risk category: D Risk of cardiac defects: 0.1%–0.5%	Yes; pregnancy risk category: D	Yes; pregnancy risk category: C	Yes; pregnancy risk category: D Risk of neural tube defects: 1%–5%	Yes; pregnancy risk category: C
Crosses into breast milk	Yes; 35%–50% of mother's serum concentration; breastfeeding not recommended	Yes; ratio of concentration in breast milk to plasma is 0.4 for drug and 0.5 for epoxide metabolite; considered compatible with breastfeeding	Yes; both drug and active metabolite; breastfeeding not recommended	Yes; considered compatible with breastfeeding	Yes; breastfeeding not recommended
Protein binding	No	75%–90%	40% of active metabolite	80%–90% (dose dependent)	55%
Renal clearance	Yes; 10–40 mL/min with 90%–98% of dose excreted in urine; 80% of lithium that is filtered by the renal glomeruli is reabsorbed	Yes; 1%–3% excreted unchanged in urine	Yes; 95% excreted in the urine; less than 1% excreted unchanged	Yes; 30%–50% excreted as glucuronide conjugate; less than 3% excreted unchanged	Yes; 94% excreted as glucuronide conjugate

Pharmacokinetics and Therapeutic Serum Concentrations of Lithium and Anticonvulsants Used in the Treatment of Bipolar Disorder (Continued)
Metabolism

Hepatic metabolism	No	Yes; oxidation and hydroxylation; induces liver enzymes to increase its own metabolism and metabolism of other drugs	Yes; oxidation and conjugation	Yes; oxidation and glucuronide conjugation	Yes; glucuronic acid conjugation induces its own metabolism in normal volunteers
Metabolites	No	Yes; 10, 11-epoxide (active)	Yes; 10-monohydroxy metabolite (active)	Yes (not active)	No
Kinetics	First-order	First-order after initial enzyme induction phase	First-order	First-order	First-order
Half-life ($t_{1/2}$)	18-27 hours (adult); greater than 36 hours (elderly or patients with renal impairment)	Half-life decreases over time due to autoinduction: 25-65 hours (initial) 12-17 hours (adult multiple dosing) 8-14 hours (children multiple dosing)	2 hours (parent) 9 hours (metabolite)	5-20 hours (adults)	25 hours; increases to 59 hours with concomitant VPA therapy

Cytochrome P-450 (CYP450) isoenzyme

CYP450 substrate	No	2C8 and 3A3/4	Unknown	2C19	Unknown
CYP450 inhibitor	No	No	2C19	2C9, 2D6, and 3A3/4	Unknown
CYP450 inducer	No	1A2, 2C9/10, and 3A3/4	3A3/4	No	Unknown

Therapeutic Serum/Plasma Concentrations

1-1.5 mEq/L (mmol/L): for adult, acute mania	4-12 mcg/mL (17-51 μ mol/L): for adult, acute mania and maintenance	No established therapeutic range; 12-30 mcg/mL (47-118 μ mol/L) for 10-hydroxy metabolite based on epilepsy trials	50-125 mcg/mL (347-866 μ mol/L): adult, acute mania and maintenance	No established therapeutic range: 4-20 mcg/mL (16-80 μ mol/L) based on epilepsy trials
0.4-0.6 mEq/L (mmol/L): for elderly or medically ill patients	4-8 mcg/mL (17-34 μ mol/L): for elderly or medically ill		40-75 mcg/mL (277-520 μ mol/L): elderly or medically ill	
0.6-1.2 mEq/L (mmol/L): for adult, maintenance; ranges based on 12-hour postdose sample collection				

ER, extended release; GI, gastrointestinal; NA, not applicable.

Data from Refs. 26 and 28-31.

arrhythmias. Cardiology consultation is recommended for patients with preexisting cardiac disease who are candidates for lithium therapy. A benign leukocytosis is also common.²⁶

Lithium and other mood-stabilizing drugs require baseline and routine laboratory monitoring to help determine medical appropriateness for initiation of therapy and monitoring of potential adverse effects. Guidelines for such monitoring are outlined in [Table 39-6](#).

Acute lithium toxicity, which can occur at serum concentrations over 2 mEq/L (mmol/L), can be severe and life threatening, necessitating emergency medical treatment.

Symptoms include worsening of GI distress to include severe vomiting and diarrhea; deterioration in motor coordination, including a coarse tremor, ataxia, and dysarthria; and impaired cognition. In its most severe form, seizures, cardiac arrhythmias, coma, and kidney damage have been reported. Treatment includes discontinuation of lithium, IV fluids to correct fluid and electrolyte imbalance, and osmotic diuresis or hemodialysis. In case of overdose, gastric lavage is indicated. Clinical symptoms can continue well after the serum concentration is lowered because clearance from the central nervous system (CNS) is slower than from the serum. Factors

Guidelines for Baseline and Routine Laboratory Tests and Monitoring for Agents Used in the Treatment of Bipolar Disorder

	Baseline: Physical Examination and General Chemistry ^d	Hematologic Tests ^b		Metabolic Tests ^c		Liver Function Tests ^d		Renal Function Tests ^e		Thyroid Function Tests ^f		Serum Electrolytes ^g		Dermatologic ^h	
	Baseline	Baseline	6–12 Months	Baseline	6–12 Months	Baseline	6–12 Months	Baseline	6–12 Months	Baseline	6–12 Months	Baseline	6–12 Months	Baseline	3–6 Months
Atypical antipsychotics ⁱ	X			X	X										
Carbamazepine ^j	X	X	X			X	X	X				X	X	X	X
Lamotrigine ^k	X													X	X
Lithium ^l	X	X	X	X	X			X	X	X	X	X	X	X	X
Oxcarbazepine ^m	X											X	X		
Valproate ⁿ	X	X	X	X	X	X	X							X	X

^aScreen for drug abuse and serum pregnancy.

^bCBC with differential and platelets.

^cFasting glucose, serum lipids, weight.

^dLactate dehydrogenase, aspartate aminotransferase, alanine aminotransferase, total bilirubin, alkaline phosphatase.

^eSerum creatinine, blood urea nitrogen, urinalysis, urine osmolality, specific gravity.

^fTriiodothyronine, total thyroxine, thyroxine uptake, and thyroid-stimulating hormone.

^gSerum sodium.

^hRashes, hair thinning, alopecia.

ⁱAtypical antipsychotic: Monitor for increased appetite with weight gain (primarily in patients with initial low or normal body mass index); monitor closely if rapid or significant weight gain occurs during early therapy; cases of hyperlipidemia and diabetes reported.

^jCarbamazepine: Manufacturer recommends CBC and platelets (and possibly reticulocyte counts and serum iron) at baseline, and that subsequent monitoring be individualized by the clinician (e.g., CBC, platelet counts, and liver function tests every 2 weeks during the first 2 months of treatment, then every 3 months if normal). Monitor more closely if patient exhibits hematologic or hepatic abnormalities or if the patient is receiving a myelotoxic drug; discontinue if platelets are less than 100,000/mm³, if WBC is less than 3,000/mm³ or if there is evidence of bone marrow suppression or liver dysfunction. Serum electrolyte levels should be monitored in the elderly or those at risk for hyponatremia. Carbamazepine interferes with some pregnancy tests.

^kLamotrigine: If renal or hepatic impairment, monitor closely and adjust dosage according to manufacturer's guidelines. Serious dermatologic reactions have occurred within 2 to 8 weeks of initiating treatment and are more likely to occur in patients receiving concomitant valproate, with rapid dose escalation, or using doses exceeding the recommended titration schedule.

^lLithium: Obtain baseline ECG for patients older than 40 years or if pre-existing cardiac disease (benign, reversible T-wave depression can occur). Renal function tests should be obtained every 2 to 3 months during the first 6 months, then every 6 to 12 months; if impaired renal function, monitor 24-hour urine volume and creatinine every 3 months; if urine volume more than 3 L/day, monitor urinalysis, osmolality, and specific gravity every 3 months. Thyroid function tests should be obtained once or twice during the first 6 months, then every 6 to 12 months; monitor for signs and symptoms of hypothyroidism; if supplemental thyroid therapy is required, monitor thyroid function tests and adjust thyroid dose every 1 to 2 months until thyroid function indices are within normal range, then monitor every 3 to 6 months.

^mOxcarbazepine: Hyponatremia (serum sodium concentrations less than 125 mEq/L) has been reported and occurs more frequently during the first 3 months of therapy; serum sodium concentrations should be monitored in patients receiving drugs that lower serum sodium concentrations (e.g., diuretics or drugs that cause inappropriate antidiuretic hormone secretion) or in patients with symptoms of hyponatremia (e.g., confusion, headache, lethargy, and malaise). Hypersensitivity reactions have occurred in approximately 25% to 30% of patients with a history of carbamazepine hypersensitivity and requires immediate discontinuation.

ⁿValproate: Weight gain reported in patients with low or normal body mass index. Monitor platelets and liver function during first 3 to 6 months if evidence of increased bruising or bleeding. Monitor closely if patients exhibit hematologic or hepatic abnormalities or in patients receiving drugs that affect coagulation, such as aspirin or warfarin; discontinue if platelets are less than 100,000/mm³/L or if prolonged bleeding time. Pancreatitis, hyperammonemic encephalopathy, polycystic ovary syndrome, increased testosterone, and menstrual irregularities have been reported; not recommended during first trimester of pregnancy due to risk of neural tube defects.

Data from Refs. 47 (with permission), 48, and 50–56.

predisposing to lithium toxicity include fluid and sodium loss from hot weather or exercise or drug interactions that increase serum lithium.²⁶

Drug Interactions. Drug interactions involving lithium are common. Because lithium is not metabolized or protein bound, it is not associated with metabolic drug interactions that occur with other mood-stabilizing drugs. Common and significant drug interactions involve thiazide diuretics, nonsteroidal anti-inflammatory drugs, and angiotensin-converting enzyme (ACE) inhibitor drugs. If a diuretic must be used with lithium and a thiazide is not required, loop diuretics such as furosemide are less likely to increase lithium retention. The ACE inhibitors and by extension, angiotensin receptor blockers (ARB), can abruptly increase serum lithium with the potential of acute and fatal toxicity, even after months of no change in the serum lithium concentration. This combination is strongly discouraged.²⁷

Divalproex Sodium and Valproic Acid Divalproex sodium is composed of sodium valproate and valproic acid (VPA). The delayed-release and extended-release formulations are converted in the small intestine into VPA, which is the systemically absorbed form. It was developed as an anti-convulsant but also has efficacy for mood stabilization and migraine headaches. It is FDA approved for the treatment of the manic phase of bipolar disorder. It is generally equal in efficacy to lithium and some other drugs for bipolar mania. It has particular utility in bipolar disorder patients with rapid cycling, mixed mood features, and substance abuse comorbidity. Although not FDA approved for relapse prevention, studies support this use, and it is widely prescribed for maintenance therapy. DVP can be used as monotherapy or in combination with lithium or an antipsychotic drug.²⁸

Mechanism of Action. The mechanism of action of DVP is not well understood. It is known to affect ion transport and enhances the activity of γ -aminobutyric acid (GABA). Similar to lithium, it has possible neuroprotective effects through enhancement of BDNF.⁸

Dosing and Monitoring. DVP is usually initiated at 500 to 1,000 mg/day, but studies indicate a therapeutic serum VPA concentration can be reached more quickly through a loading dose approach of 20 to 30 mg/kg/day. Using this approach, patients may respond with a significant reduction in symptoms within the first few days of treatment. The dosage is then titrated according to response, tolerability, and serum concentration. The most often referenced desired VPA serum concentration is 50 to 125 mcg/mL (347 to 866 μ moles/L), but it is not unusual for patients to require more than 100 mcg/mL (693 μ moles/L) for optimal efficacy. Some patients require high milligram dosages in order to reach a desired serum concentration. The suggested serum concentration range is based on trough values. Serum concentration monitoring is recommended at least every 2 weeks until stabilized, then less frequently, sometimes as infrequently as twice yearly. The extended-release formulation can be taken once daily (see Table 39-4). If the extended-release formulation is administered at night, a morning blood sampling is a

peak, not a trough. The drug should be given in the morning so that blood sampling the following morning would be a trough value and more easily interpreted if the typical blood sampling time is in the morning. The systemic bioavailability of extended-release DVP is about 15% less than that of the delayed-release formulation. Patients who have difficulty swallowing large tablets can use the sprinkle formulation. The immediate-release formulation, either capsules or syrup, is generally given three or four times per day.²⁸

Adverse Effects. The most common adverse effects of DVP are GI (loss of appetite, nausea, dyspepsia, diarrhea), tremor, and drowsiness. GI distress can be reduced by coadministration with food. The delayed-release and extended-release formulations are less likely to cause gastric distress than immediate-release VPA. This is an advantage for DVP, along with fewer daily doses, which can improve patient adherence to treatment. Dosage reduction can reduce all of the common DVP side effects. As with lithium, a low-dose β -blocker may alleviate the tremor. Weight gain is also common, occurring in up to 50% of patients on maintenance therapy.²⁸

Other adverse effects that are less common include alopecia or a change in hair color or texture. Hair loss can be minimized by supplementation with a vitamin containing selenium and zinc. Polycystic ovarian syndrome associated with increased androgen production has been reported. Thrombocytopenia is not uncommon, and the platelet count should be monitored periodically. It is a dose-related adverse effect and usually asymptomatic, but the drug is usually stopped if the platelet count decreases to less than $100 \times 10^3/\text{mm}^3$ ($100 \times 10^9/\text{L}$). More rare are hepatic toxicity and pancreatitis, which are not always dose related. Severe GI symptoms of hepatic or pancreatic toxicity include vomiting, pain, and loss of appetite. When these occur, the patient should be evaluated for possible hepatitis or pancreatitis. DVP has a wide therapeutic index. Acute toxicity for high dosages or overdose is not life threatening.²⁸

Drug Interactions. Drug interactions involving DVP are common. It is a weak inhibitor of some of the drug metabolizing liver enzymes and can affect the metabolism of other drugs. These include other anticonvulsants and tricyclic antidepressants. The interaction between DVP and lamotrigine is particularly important. The risk of a dangerous rash caused by lamotrigine is increased when given concurrently with DVP. When lamotrigine is added to DVP, the initial lamotrigine dosage should be one-half the typical starting dosage, and lamotrigine should be titrated more slowly than usual. When DVP is added to lamotrigine, the lamotrigine dosage should be reduced by 50%. Conversely, the metabolism of DVP can be increased by enzyme-inducing drugs such as carbamazepine and phenytoin, but DVP may simultaneously slow metabolism of the other agents.²⁷

Carbamazepine Although long used as a mood-stabilizing drug, only the extended-release formulation of carbamazepine has received FDA approval for treatment of bipolar disorder. Similar to DVP, it has efficacy for mood stabilization, but it is considered possibly less desirable as a first-line

agent because of safety and drug interactions. It is sometimes reserved for patients who fail to respond to lithium or for patients with rapid cycling or mixed bipolar disorder. Carbamazepine can be used as monotherapy or in combination with lithium or an antipsychotic drug.²⁹

Mechanism of Action. The mechanism of action of carbamazepine is not well understood. It blocks ion channels and inhibits sustained repetitive neuronal excitation, but whether this explains its efficacy as a mood-stabilizing drug is not known.²⁹

- **Dosing and Monitoring.** Carbamazepine is usually initiated at 400 to 600 mg/day. The sustained-release formulation can be given in two divided doses. In addition to a formulation that is completely sustained release, an additional extended-release formulation contains a matrix of 25% immediate-release, 40% extended-release, and 35% enteric-release beads.²⁹ The suggested therapeutic serum concentration is 4 to 12 mcg/mL (17 to 51 μmol/L). As with DVP, some patients require high milligram dosages to achieve a desired serum concentration and therapeutic effect. The dosage can be increased by 200 to 400 mg/day as often as every 2 to 4 days to achieve the desired effect. Serum concentration monitoring is suggested at least every 2 weeks until stabilized and then less frequently.²⁹
- **Adverse Effects.** The most common adverse effects are drowsiness, dizziness, ataxia, lethargy, and confusion. At mildly toxic serum concentrations, it also causes diplopia and dysarthria. These effects can be minimized through dosage adjustments, use of sustained-release formulations, and giving more of the drug late in the day. GI upset is also common. Carbamazepine has an antidiuretic effect similar to the syndrome of inappropriate antidiuretic hormone secretion and can cause hyponatremia. Mild elevations in liver enzymes can occur, but hepatitis is less common. Mild, dose-related leukopenia is not unusual and not usually an indication for stopping the drug. More serious blood count abnormalities such as aplastic anemia and agranulocytosis are rare but life threatening.²⁹ Suggested baseline and routine laboratory monitoring is reviewed in Table 39–6.
- **Drug Interactions.** Carbamazepine induces the hepatic metabolism of many drugs, including other anticonvulsants, antipsychotics, some antidepressants, oral contraceptives, and antiretroviral agents. Carbamazepine is also an autoinducer (i.e., it induces its own metabolism). The dosage may require an increase after 1 month or so of therapy because of this effect. Conversely, the metabolism of carbamazepine can be slowed by enzyme inhibiting drugs such as some antidepressants; macrolide antibiotics, including erythromycin and clarithromycin;azole antifungal drugs, including ketoconazole and itraconazole; and grapefruit juice. Carbamazepine should not be given concurrently with clozapine because of the additive risk of agranulocytosis.²⁷
- **Lamotrigine** Lamotrigine is effective for the maintenance treatment of bipolar disorder. It is more effective for depression relapse prevention than for mania relapse prevention. Its primary limitation as an acute treatment is the time required for titration to an effective dosage. In addition to maintenance monotherapy, it is sometimes used in combination with lithium

or DVP, although combination with DVP increases the risk of rash, and lamotrigine dosage adjustment is required.³⁰

Mechanism of Action. The mechanism of action of lamotrigine appears to involve blockage of ion channels and effects on glutamate transmission, although the precise mechanism in bipolar disorder is not clear.³⁰

- **Dosing and Monitoring.** Lamotrigine is usually initiated at 25 mg/day for the first 1 to 2 weeks, then increasing in a dose-doubling fashion every 1 to 2 weeks to a target dosage of 200 to 400 mg/day. If lamotrigine is added to DVP, the starting dosage is 25 mg every other day with a slower titration to reduce the risk of rash. If DVP is added to lamotrigine, the lamotrigine dosage should be reduced by 50% for the same reason. If lamotrigine therapy is interrupted for more than a few days, it should be restarted at the initial dosage and retitrated. Serum concentration monitoring is not routinely recommended for patients with bipolar disorder.³⁰
- **Adverse Effects.** The lamotrigine adverse effect of greatest significance is a maculopapular rash, occurring in up to 10% of patients.³⁰ Although usually benign and temporary, some rashes can progress to life-threatening Stevens-Johnson syndrome. The risk of rash is greater with a rapid dosage titration and when given concurrently with DVP or other metabolic enzyme inhibitors. The risk is minimal when the dosage titration schedule is slow. Other side effects include dizziness, drowsiness, headache, blurred vision, and nausea. In contrast to other mood-stabilizing drugs such as lithium and DVP, lamotrigine does not significantly influence body weight.
- **Drug Interactions.** The mechanisms of drug–drug interactions involving lamotrigine are unclear. Lamotrigine’s primary route of metabolism is conjugative glucuronidation, although it is known to exhibit metabolic autoinduction. It is not significantly metabolized by the CYP P450 enzyme system. It does not affect drug metabolizing hepatic enzymes on its own. In particular, DVP slows the rate of elimination of lamotrigine by about half, necessitating dosage reduction. Conversely, carbamazepine increases the rate of lamotrigine metabolism, which would appear to indicate an effect on oxidative metabolism. Upward adjustment in the lamotrigine dosage may be needed as a result.²⁷
- **Oxcarbazepine** Oxcarbazepine is an analogue of carbamazepine, developed as an anticonvulsant. An advantage over carbamazepine is that routine monitoring of hematology profiles and serum concentrations are not indicated because the drug is less likely to cause hematologic abnormalities.³¹ Additionally, drug interactions are less significant, although it is at least a mild inducer of certain metabolic pathways. Vigilance for drug interactions is needed, especially with oral contraceptives. Oxcarbazepine appears in the most recent treatment algorithms for bipolar disorder,³² but clinical trial data are limited. A systematic review concluded that there are insufficient data from well-designed clinical trials to provide guidance on its use.³³
- **Adverse Effects.** Adverse effects from oxcarbazepine include drowsiness, dizziness, GI upset, and hyponatremia, the latter two of which may be more likely than with carbamazepine.³¹

Others High-potency benzodiazepine agents such as clonazepam and lorazepam have been used as adjunctive therapy, especially during acute mania episodes, to reduce anxiety and improve sleep.³⁴ As complementary or alternative medicines gain wider usage, omega-3 fatty acids have been used in mood disorders. Insufficient well-designed studies exist to support a recommendation of routine use or to establish a place in therapy relative to usual therapies.³⁵

► Antipsychotic Drugs

First-generation antipsychotic drugs such as chlorpromazine and haloperidol have long been used in the treatment of acute mania. SGA drugs, including aripiprazole, asenapine, olanzapine, quetiapine, risperidone, and ziprasidone, are approved for the treatment of bipolar mania or mixed mood episodes as monotherapy or in combination with mood-stabilizing drugs.¹⁵ Aripiprazole, olanzapine, and quetiapine are also approved for maintenance therapy for prevention of manic relapse. The combination of olanzapine and fluoxetine is approved for treatment of acute bipolar depression. Quetiapine is approved as monotherapy for acute bipolar depression and as adjunctive therapy with lithium or DVP for prevention of bipolar depression relapse. Approval of antipsychotic drugs in patients with bipolar disorder applies without regard to the presence of psychotic symptoms. In comparative studies, the SGAs are equivalent or better in efficacy to lithium and DVP for treatment of acute mania. Treatment guidelines include antipsychotic drugs as first-line therapy.^{14,32} Of interest is evidence that the combination of mood-stabilizing drugs and antipsychotic drugs is more likely to achieve remission of acute manic episodes than monotherapy with either.³² The quetiapine data in relapse prevention of both manic and bipolar depression episodes favored combination therapy over mood-stabilizing drug monotherapy.³⁶

The mechanisms of action, usual dosages, pharmacokinetics, adverse effects, and drug interactions involving antipsychotic drugs are discussed in detail in the chapter on schizophrenia. Dosages in bipolar disorder are similar to those used in schizophrenia. Higher dosages are often required to treat an acute episode than to prevent relapse. The recommended dosage of aripiprazole for bipolar disorder is 20 to 30 mg/day, somewhat higher than the average dosage used in schizophrenia.³⁷ The recommended dosage for quetiapine in treatment of acute bipolar depression is 300 mg/day, less than the 600 mg/day recommended in acute mania.³⁸

The SGAs are less likely than the FGAs to cause neurologic side effects, especially movement abnormalities. As a group, however, the SGAs are more likely to cause metabolic side effects, such as weight gain, glucose dysregulation, and dyslipidemia.³⁹ Among the SGAs approved for treatment of bipolar disorder, olanzapine is most likely to cause metabolic side effects. Asenapine, quetiapine, and risperidone cause less metabolic effects than olanzapine. Aripiprazole and ziprasidone are least associated with effects on weight, glucose, and lipids, although asenapine has not been compared directly with aripiprazole and ziprasidone. Paliperidone, iloperidone, and lurasidone are not FDA approved for bipolar disorder at

present. The chapter on schizophrenia discusses the adverse effects of antipsychotic drugs in more detail.

► Antidepressants

Treatment of depressive episodes in patients with bipolar disorder presents a particular challenge because of the risk of a drug-induced mood switch to mania, although there is not complete agreement about such risk. The FDA requires the product label of all antidepressant drugs to contain language about the potential risk of inducing a mood switch to mania. Most research shows no advantage for adjunctive antidepressant use compared with mood stabilizer therapy alone.^{19,20} Treatment guidelines and current FDA approvals indicate lithium or quetiapine as first-line therapy.^{32,38} When usual treatment fails, evidence supports use of antidepressants.^{19,20}

Guidelines agree that when antidepressants must be used, they should be combined with a mood-stabilizing drug to reduce the risk of mood switch to hypomania or mania. The question of which antidepressant drugs are less likely to cause a mood switch is not resolved, but the tricyclic antidepressants are thought to carry a greater risk of treatment-emergent mania. A randomized comparison of venlafaxine, sertraline, and bupropion as adjunctive therapy to a mood stabilizer showed venlafaxine with the highest risk of a mood switch to mania or hypomania and bupropion with the least.⁴⁰

Special Populations

- Assessment and management by appropriate psychiatric specialists is important for special populations, such as pediatric, geriatric, and pregnant patients.

► Pediatrics

Evidence regarding treatment of bipolar disorder in children and adolescents is more limited than in adults. Children and adolescents are particularly sensitive to medication side effects, including metabolic side effects of the SGAs. With these caveats, evidence supports the use of mood-stabilizing drugs and the SGAs in children and adolescents with bipolar disorder.

- Lithium is FDA approved for treatment of bipolar disorder in children and adolescents as young as age 12 years. Aripiprazole, olanzapine, quetiapine, and risperidone are FDA approved in children and adolescents as young as age 10 years.^{41,42}

Initial dosages of drug therapy in the pediatric population are lower than in adults. Metabolic elimination rates of many drugs are increased in children, however, so they may actually require higher dosages on a weight-adjusted basis. Dosages are titrated carefully according to response and tolerability. For lithium, DVP, and carbamazepine, serum concentration monitoring is recommended as a guide to dosage adjustment and minimizing adverse effects.

- Children and adolescent patients are often more sensitive to drug side effects than adults. In particular, they are likely to experience significant weight gain from atypical antipsychotic drugs.⁴³ Cognitive toxicity, manifested as confusion, memory or concentration impairment, or impaired learning, is often difficult to detect and is a special consideration in

the pediatric population so that intellectual and educational development is not hindered by drug therapy.

Comorbid conditions must be addressed to maximize desired outcomes. For comorbid bipolar disorder and attention-deficit hyperactivity disorder when stimulant therapy is indicated, treatment of mania is recommended before starting the stimulant to avoid exacerbation of mood symptoms by the stimulant.

► Geriatrics

Treatment of elderly patients with bipolar disorder requires special care because of increased risks associated with concurrent medical conditions and drug–drug interactions. General medical conditions, including endocrine, metabolic, or infectious diseases, can mimic mood disorders. Patients should be evaluated for such medical illnesses that may cause or worsen mood symptoms. As physiologic systems change with aging, elimination of drugs is often slowed. Examples are slowed renal elimination of lithium and slowed hepatic metabolism of carbamazepine and VPA. As a result, dosages of drugs required for therapeutic effect are generally lower in geriatric patients. Also, changes in membrane permeability with aging increase the risk of CNS side effects. An increased frequency of patient monitoring is often required, including serum drug concentration monitoring.

Vigilance for drug–drug interactions is required because of the greater number of medications prescribed to elderly patients and enhanced sensitivity to adverse effects. Pharmacokinetic interactions include metabolic enzyme induction or inhibition and protein binding displacement interactions (e.g., DVP and warfarin). Pharmacodynamic interactions include additive sedation and cognitive toxicity, which increase the risk of falls and other impairments.

► Pregnancy and Postpartum

Treatment of bipolar disorder during pregnancy is fraught with controversy and conflicting recommendations. The key issue is the relative risk of teratogenicity with drug use during pregnancy versus risk of bipolar relapse without treatment with consequent potential harm to both the pregnant patient and the fetus. Therapeutic judgments depend on the history of the patient and whether the pregnancy is planned or unplanned. Treatment is best managed when the pregnancy is planned. Clinicians should discuss the issue with every patient with bipolar disorder who is of childbearing potential. A pregnancy test should be obtained before initiating drug therapy. For a patient with severe bipolar disorder, a history of multiple mood episodes, rapid cycling, or suicide attempts, discontinuing treatment, even for a planned pregnancy, is unwise. For a patient with a remote history of a single mood episode with subsequent long stability and who is contemplating pregnancy, the answer is less clear. Patients should be provided clear and reliable information about the risks versus the benefits of stopping or continuing therapy so they can make an informed decision. Patients who decide to discontinue drug therapy before pregnancy should taper medications slowly to reduce the risk of relapse.^{44,45}

Lithium administration during the first trimester is associated with Ebstein's anomaly in the infant, a downward displacement of the tricuspid valve into the right ventricle. Although more likely to occur in children of patients who took lithium during pregnancy, the absolute risk is considered small, around 0.1%. Pharmacokinetic handling of lithium changes as pregnancy progresses. Renal lithium clearance increases, which requires a dosage increase to maintain a therapeutic serum concentration. It may be advisable to decrease or discontinue lithium at term or the onset of labor to avoid toxicity postpartum when there is a large reduction in fluid volume.⁴⁵

Lithium can cause hypotonicity and cyanosis in the neonate, termed the “floppy baby” syndrome. Most data indicate normal neurobehavioral development when these symptoms resolve. Lithium is readily transferred via breast milk. Breast-feeding is not advised for patients who are taking lithium.²⁶

Valproic acid and carbamazepine are human teratogens. Neural tube defects such as spina bifida occur in up to 9% of infants exposed during the first trimester. The risk of neural tube defects is related to exposure during the third and fourth weeks after conception. As such, women with unplanned pregnancies may not know they are pregnant until after the risk of exposure has occurred. Carbamazepine can cause fetal vitamin K deficiency. Vitamin K is important for facial growth and for clotting factors. The risk of facial abnormalities is increased with carbamazepine and VPA, and neonatal bleeding is increased in infants of mothers who are treated with carbamazepine during pregnancy.^{44,45}

Patient Encounter, Part 4: Outcome Evaluation

After an initial assessment, including evaluation of potential suicidality, support systems, and need for inpatient versus outpatient treatment, Roger was hospitalized briefly and then followed in the community on medication along with psychotherapy. He has cut back significantly on his intake of alcohol, is considering attending Alcoholics Anonymous meetings, and has stopped using marijuana. His job performance has returned to normal. He has responded well to treatment with sustained-release lithium carbonate 1200 mg po once daily at bedtime with a snack. Steady-state 12-hour serum lithium concentrations have stabilized at approximately 1.0 mEq/L (mmol/L). He now returns to clinic for routine follow-up. He has tolerated the lithium except for a slight weight gain of 5 lb (2.3 kg) and some facial acne, which he is willing to accept for now. However, he asks how long he must take this medication because he is now feeling well.

How would you assess therapeutic and adverse effects of treatment for this patient?

How would you educate the patient regarding the need for continued maintenance treatment?

Fewer data are available on other anticonvulsant mood-stabilizing drugs. Lamotrigine may be associated with an increased risk of oral clefts in association with first trimester exposure.^{44,45}

The FGAs have been available for many years, and more data are available on their use in pregnancy compared with the SGAs, but treatment guidelines for bipolar disorder do not otherwise support the FGAs as an initial choice in treatment.

Use of antidepressant drugs during pregnancy is discussed in the chapter on depression.

OUTCOME EVALUATION

Assessment of Therapeutic Effects

Effective interviewing skills and a therapeutic relationship with the patient are essential to assessing response to treatment. Understand the particular symptom profile and needs of individual patients. These become the primary therapeutic monitoring parameters. In addition to the clinical interview, some clinicians use symptom rating scales such as the Young Mania Rating Scale (YMRS) for mania and the Hamilton Depression Rating Scale (Ham-D, discussed in the chapter on depression). The YMRS is composed of 11 items based on a patient's perception of his or her clinical condition over the preceding 48 hours. Adjunctive information is obtained from clinical observations made by the clinician during the patient interview. Items are chosen based on published descriptions of core symptoms of mania. Four items are scored on a scale of 0 to 8 (irritability, speech, thought content, and disruptive/aggressive behavior), and the other seven are graded on a 0 to 4 scale. These initial four items are given twice the weight of the remaining items to compensate for an inability to cooperate by severely ill patients. The YMRS's popularity stems from its ease of administration, widely accepted use, and brief format. The scale takes approximately 15 to 30 minutes to complete.⁴⁶

Check serum concentrations of mood-stabilizing drugs as a guide to dosage adjustment for optimal efficacy. The frequency of follow-up visits depends on response, tolerability, adherence, and other factors.

Assessment of Adverse Effects

Adverse effects cause more nonadherence to prescribed therapy than any other factor. Monitor patients regularly for adverse effects and health status, especially because mood-stabilizing drugs and antipsychotic drugs commonly cause metabolic side effects such as weight gain. Repeat laboratory tests for renal and thyroid function for patients taking lithium and hematology and liver function for patients taking carbamazepine or DVP. Annual measurement of serum lipase may be advisable for patients taking DVP. More specific discussion of metabolic side effect monitoring of patients taking SGAs is provided in the chapter on schizophrenia.

Patient Education

8 Patient education regarding benefits and risks of drug therapy and the importance of adherence to treatment must

be integrated into management. This is especially important because responsiveness to treatment declines as the number of mood episodes increases. Discuss the nature and chronic course of bipolar disorder and the risks of repeated relapses. Help patients understand that treatment of bipolar disorder is not a cure but that many patients can enjoy symptom-free or nearly symptom-free function. Make it clear that long-term recovery is dependent on adherence to both pharmacologic and nonpharmacologic treatment. Explain the purpose of medication, common side effects to expect, and how to respond to side effects. Provide the patient and family with written information about medication indications, benefits, risks, and side effects. Discuss less frequent but more dangerous side effects of drugs and give written instructions on seeking medical attention immediately should they occur.

Patient Care and Monitoring

1. Assess the patient's symptoms and review the history. Review the family history, including the history of response to treatment by family members.
2. Obtain an initial medical evaluation to rule out other causes of mood episodes.
3. Obtain a thorough medication use history, including present and past drugs, prescription and nonprescription drugs, the patient's self-assessment of response and side effect problems, alcohol, tobacco, caffeine, illicit substances, herbal products, dietary supplements, allergies, and adherence.
4. Assess potential drug–disease, drug–drug, and drug–food interactions.
5. Evaluate physiologic parameters that may influence pharmacokinetics.
6. Develop a plan for monitoring therapeutic outcomes, focusing on the individual symptom profile and level of function of the patient. Include a plan for dosage adjustments or alternate therapy if the patient fails to respond adequately. Include serum drug concentration monitoring as appropriate.
7. Develop a monitoring plan for drug side effects. Include measures to prevent side effects as well as management if they occur. Include appropriate laboratory measures.
8. Determine the role of nonpharmacologic therapy and how it is to be integrated with drug therapy.
9. Educate the patient on the nature of bipolar disorder, its treatment, and what to expect with regard to response and side effects, and stress the need for adherence to treatment even when feeling well.
10. Encourage a healthy lifestyle, including eliminating or stopping substance abuse, smoking cessation, and encouraging proper nutrition and exercise.

Abbreviations Introduced in This Chapter

5-HT	5-hydroxytryptamine
Abd	Abdomen
ACE	Angiotensin-converting enzyme
ARB	Angiotensin receptor blocker
BDNF	Brain-derived neurotrophic factor
BP	Blood pressure
CBC	Complete blood count
CBT	Cognitive-behavioral therapy
CN	Cranial nerve
CNS	Central nervous system
DA	Dopamine
DSM-IV-TR	<i>Diagnostic and Statistical Manual of Mental Disorders</i> , 4th edition, text revision
DVP	Divalproex
ECG	Electrocardiogram
ECT	Electroconvulsive therapy
Exts	Extremities
FDA	Food and Drug Administration
FGA	First-generation antipsychotic
fMRI	Functional magnetic resonance imaging
FOI	Flight of ideas
GABA	γ -aminobutyric acid
GI	Gastrointestinal
Ham-D	Hamilton Depression Rating Scale
HIV	Human immunodeficiency virus
JVD	Jugular venous distention
MDD	Major depressive disorder
MRI	Magnetic resonance imaging
NE	Norepinephrine
NOS	Not otherwise specified
P	Pulse
PERRLA	Pupils equal round and reactive to light and accommodation
PET	Positron emission tomography
RR	Respiration rate
SGA	Second-generation antipsychotic
T	Temperature
THC	Tetrahydrocannabinol, psychoactive substance in marijuana
VPA	Valproic acid
YMRS	Young Mania Rating Scale

Generalized Anxiety Disorder, Panic Disorder, and Social Anxiety Disorder

Sheila Botts, Sallie Charles, and Douglas Newton

LEARNING OBJECTIVES

● **Upon completion of the chapter, the reader will be able to:**

1. Describe pathophysiologic findings in patients with generalized anxiety, panic, and social anxiety disorder.
2. List common presenting symptoms of generalized anxiety, panic, and social anxiety disorders.
3. Identify the desired therapeutic outcomes for patients with generalized anxiety, panic, and social anxiety disorders.
4. Discuss appropriate lifestyle modifications and over-the-counter medication use in these patients.
5. Recommend psychotherapy and pharmacotherapy interventions for patients with generalized anxiety, panic, and social anxiety disorders.
6. Develop a monitoring plan for anxiety patients placed on specific medications.
7. Educate patients about their disease state and appropriate lifestyle modifications, as well as psychotherapy and pharmacotherapy for effective treatment.

KEY CONCEPTS

- 1 The goals of therapy for generalized anxiety disorder (GAD) are to acutely reduce the severity and duration of anxiety symptoms and restore overall functioning. The long-term goal in GAD is to achieve and maintain remission.
- 2 Antidepressants are considered first-line agents in the management of chronic GAD.
- 3 Benzodiazepines are recommended for acute treatment of GAD when short-term relief is needed, as an adjunct during initiation of antidepressant therapy, or to improve sleep.
- 4 The acute phase of panic disorder (PD) treatment lasts about 12 weeks and should result in marked reduction in panic attacks, ideally total elimination, and minimal anticipatory anxiety and phobic avoidance. Treatment should be continued to prevent relapse for an additional 12 to 18 months before attempting discontinuation.
- 5 Patients with PD are more likely to experience stimulant-like side effects of antidepressants than patients with major depression. Antidepressants should be initiated at lower doses in patients with PD than in depressed patients and those with other anxiety disorders.
- 6 Antidepressants should be tapered when treatment is discontinued to avoid withdrawal symptoms, including irritability, dizziness, headache, and dysphoria.
- 7 The dose of benzodiazepine required for improvement in PD generally is higher than that used in other anxiety disorders.
- 8 Based on their tolerability and efficacy, selective serotonin reuptake inhibitors are considered the drugs of choice for social anxiety disorder (SAD).
- 9 The onset of response to antidepressants in SAD is delayed and may be as long as 8 to 12 weeks. Patients responding to medication should be continued on treatment for at least 1 year.
- 10 Pharmacotherapy for patients with SAD should lead to improvement in physiologic symptoms of anxiety and fear, functionality, and overall well-being.

Anxiety is a normal response to stressful or fearful circumstances. Most people experience some degree of anxiety in reaction to stressful situations, such as final exams or giving a speech. This allows an individual to adapt to or manage the stressful or threatening situation. Anxiety symptoms generally are short lived and do not necessarily impair function. Anxiety that becomes excessive, causes irrational thinking or behavior, and impairs a person's functioning is considered an anxiety disorder.

Anxiety disorders are among the most frequent mental disorders encountered by clinicians. They often are missed or attributed incorrectly to other medical illnesses, and

most patients are treated inadequately.¹ The burden of detection and diagnosis most often falls to primary care clinicians, to whom most patients present in the context of other complaints. Untreated anxiety disorders may result in increased health care utilization, morbidity and mortality, and a poorer quality of life.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

► Prevalence

With a lifetime prevalence of 28.8%, anxiety disorders collectively represent the most prevalent psychiatric disorders,² with specific phobia (12.5%) and social anxiety disorder (SAD) (12.1%) being the most common.³ Recent reports from the National Comorbidity Survey Revised (NCS-R) estimate the lifetime prevalence of generalized anxiety disorder (GAD) for those 18 years of age and older to be 5.7%.^{3,4} Rates for panic disorder (PD) are slightly lower, with an estimated lifetime prevalence of 4.7%.

Most studies report higher rates of anxiety disorders among women (2:1 female:male ratio) and older adults.² Prevalence rates across the anxiety spectrum increase from the younger age group (18 to 29 years) to older age groups (30 to 44 and 45 to 59 years); however, rates are substantially lower for those older than age 59 years.³

► Course of Illness

PD and GAD have a median age of onset of 24 and 31 years, respectively, whereas specific phobia and SAD tend to develop much earlier (median age of onset, 7 and 13 years, respectively).³ Although GAD and PD may not manifest fully until adulthood, as many as half of adult anxiety patients report subthreshold symptoms during childhood.⁵

Anxiety disorders are chronic, and symptoms tend to wax and wane, with fewer than one-third of patients experiencing spontaneous symptom remission.⁶ The risk for relapse and recurrence of symptoms is also high for anxiety disorders. In a 12-year follow-up study of anxiety disorder patients, recurrence rates ranged from 58% of PD and GAD patients to 39% of SAD patients.⁷

Remission, if achieved with treatment, is most likely to occur within the first 2 years of an index episode.⁶ Similarly, the highest rates of relapse are seen within the same timeframe. This suggests that many patients need ongoing maintenance treatment. Rates of remission do not appear to vary by sex.⁶ Likewise, relapse rates do not appear to differ by sex; however, one study reported that women with PD without agoraphobia were three times more likely than men to experience a relapse of symptoms. Patients with anxiety disorders spend a significant portion of time “being ill” during a particular episode, ranging from 41% to 80% of the time.⁷ Expectedly, anxiety disorders are associated with impaired psychosocial functioning and a compromised quality of life.⁸ Appropriate treatment has been shown to improve the patient’s overall quality of life and psychosocial functioning.⁸

► Comorbidity

More than 90% of individuals with an anxiety disorder have a lifetime history of one or more other psychiatric disorders.⁹ Depression is the most common lifetime comorbid illness, followed by alcohol and substance use disorders, as well as other co-occurring anxiety disorders, especially GAD and PD.⁹ Generally speaking, the onset of SAD and GAD symptoms precedes major depressive disorder (MDD), but there is an equal chance of PD onset before, during, or after MDD. Comorbid psychiatric illness is associated with lower rates of remission and higher rates of relapse. It is essential that both disorders are treated appropriately.

Etiology

Both genetic and psychosocial factors appear to play a role in the initiation and expression of anxiety disorders.¹⁰ Documentation of moderate genetic risk has been identified for all anxiety disorders, although some conflicting data do exist. Currently, no definitive gene or set of genes has been identified as being the causative factor for a specific anxiety disorder. Additionally, it is unclear if anxiety disorders share common genetic risk factors. Genetic overlap may exist between GAD and PD and, to a lesser extent, SAD.¹⁰

Genetics may create a vulnerable phenotype for an anxiety disorder, and an individual’s life stressors and means of coping with the stress may also play a role in precipitation and continued expression of the anxiety disorder.¹¹ In fact, some researchers believe that stressful life events may play a strong role in the onset of anxiety disorders, especially in GAD and PD.¹⁰ It has been reported that those experiencing one or more negative life events have a threefold increased chance of developing GAD.² Similar findings have been reported with PD.¹¹

PATHOPHYSIOLOGY

- The thalamus and amygdala are important in the generation of a normal fear response and play a central role in most anxiety disorders. The nervous system requires a mechanism to detect a potential threat, evaluate, and respond in a defensive or evasive manner. The thalamus provides the first real processing region to organize sensory data obtained from the environment. It passes information to higher cortical centers for finer processing and to the amygdala for rapid assessment of highly charged emotional information. The amygdala provides emotional valence or the emotional importance of the information. This helps the organism to act quickly on ambiguous but vital events. The cortex then performs a more detailed analysis and sends updates to the amygdala for comparison and any needed course corrections, thus enabling a decision on a course of action.

Anxiety becomes an anxiety disorder when the fear-response system leads to maladaptive behavior or distress. Anxiety can become independent of stimuli as in PD, be associated with benign stimuli as in phobias, or continue beyond the stimulus duration as in GAD. The precise

FIGURE 40-1. Neurocircuitry and key neurotransmitters involved in mediating anxiety disorders. (ACTH, adrenocorticotrophic hormone; CRH, corticotropin-releasing hormone; DA, dopamine; 5-HT, serotonin; NE, norepinephrine; RAS, reticular activating system.)

mechanism by which these changes occur is unknown, but much has been discovered regarding how this may be regulated by treatment (Fig. 40-1).

Direct and indirect connections to the reticular activating system (RAS), a region spanning the medulla, pons, and midbrain, help to regulate arousal, vigilance, and fear. These connections are modulated by serotonin and norepinephrine (NE), which have their primary origins in the RAS.¹² The amygdala sends projections to the hypothalamus, thus influencing the autonomic nervous system to affect heart rate, blood pressure, and stress-associated changes. It also influences the **hypothalamic-pituitary-adrenal (HPA) axis**, leading to a cascade of stress hormones.¹³ One such hormone is cortisol, which, if elevated for prolonged periods, can damage the brain and other organs. These are important targets in our understanding of how the amygdala regulates the fear response.

Noradrenergic System

- Norepinephrine-producing cells reside primarily in a region of the brain called the **locus ceruleus (LC)**. Increased activity in this region is associated with an increase in arousal, anxiety, and panic. Whereas drugs such as yohimbine that increase activity in the LC can be anxiogenic, drugs that decrease activity in the LC appear to improve anxiety. Furthermore, dysregulation of this region is implicated by elevated levels of NE or its metabolites in subjects with GAD, PD, and specific phobias.¹³

Serotonergic System

- The **raphe nuclei** and the resident cell bodies of serotonin (5-HT)-producing neurons have a complicated role related to anxiety symptoms. Activity of 5-HT cells in the raphe nuclei over time inhibits firing of noradrenergic cells in the LC. Other influences include their ability to regulate cells in

the prefrontal cortex and amygdala. Perhaps the strongest evidence for the involvement of the serotonergic system is the success of serotonin reuptake inhibitors in treatment of anxiety disorders.¹³

γ-Aminobutyric Acid

- γ-aminobutyric acid (GABA) plays an important role as an inhibitory neurotransmitter. The effects of GABA are nonspecific, and its role is complex. GABA-ergic drugs are used for acute anxiety reduction, but the lack of a specific target for their effect leads to multiple undesirable effects. Current research is focused on defining receptor subtypes that may allow for greater specificity in targeting anxiety symptoms.¹⁴

Hypothalamic-Pituitary-Adrenal Axis

- The HPA axis provides a critical mechanism for regulation of the stress response and its effects on the brain and other organ systems. Several important hormones, including corticotropin-releasing hormone and cortisol, are involved in this pathway. These hormones regulate the effects of anxiety on the body and provide positive feedback to the brain.¹³ A cycle of anxiety and sensitization by such feedback could, if unchecked, result in escalation of symptoms. Neuropeptides may provide one mechanism to balance positive and negative feedback, helping to minimize such escalation.

Neuropeptides

- Several neuropeptides are under current investigation for their role in anxiety disorders. Important neuropeptides include neuropeptide Y (NPY), substance P, and cholecystokinin. NPY appears to have a role in reducing the effect of stress hormones and inhibiting activity of the LC. Both mechanisms may contribute to the anxiolytic properties seen experimentally. Substance P may have anxiolytic and

Clinical Presentation and Diagnosis of GAD

General

Onset is typically in early adulthood. Anxiety emerges and dissipates more gradually than in PD. Laboratory evaluation usually is reserved for later onset, atypical presentation, or poor response to treatment.

Symptoms²

Excessive anxiety or worry involving multiple events or activities occurring more days than not for at least 6 months and associated with at least three of the following:

- Restlessness
- Easily fatigued
- Poor concentration
- Irritability
- Muscle tension
- Insomnia or unsatisfying sleep

Differential Diagnosis

Rule out underlying medical or psychiatric disorders and medications that may cause anxiety (Tables 40–1 and 40–2)

Laboratory Evaluation

- Basic metabolic panel
- Thyroid-stimulating hormone
- Polysomnogram

Table 40–1

Medical Conditions That Can Cause Anxiety

Psychiatric Disorders

Mood disorders, hypochondriasis, personality disorders, alcohol or substance abuse, alcohol or substance withdrawal, other anxiety disorders

Neurologic Disorders

CVA, seizure disorders, dementia, stroke, migraine, encephalitis, vestibular dysfunction

Cardiovascular Disorders

Angina, arrhythmias, congestive heart failure, mitral valve prolapse, myocardial infarction

Endocrine and Metabolic Disorders

Hypo- or hyperthyroidism, hypoglycemia, Cushing's disease, Addison's disease, pheochromocytoma, hyperadrenocorticism, hyponatremia, hyperkalemia, vitamin B₁₂ deficiency

Respiratory Disorders

Asthma, COPD, pulmonary embolism, pneumonia, hyperventilation

Other

Carcinoid syndrome, anemias, SLE

COPD, chronic obstructive pulmonary disease; CVA, cerebrovascular accident; SLE, systemic lupus erythematosus.

Data from Refs. 2 and 16.

Table 40–2

Medications Associated with Anxiety Symptoms

Category	Examples
Anticonvulsants	Carbamazepine, ethosuximide
Antidepressants	Bupropion, SSRIs, SNRIs, TCAs
Antihypertensives	Felodipine
Antimicrobials	Cephalosporins, ofloxacin, isoniazid
Antiparkinson drugs	Levodopa
Bronchodilators	Albuterol, isoproterenol, theophylline
Corticosteroids	Prednisone, methylprednisolone
Decongestants	Pseudoephedrine, phenylephrine
Herbals	Ma huang, St. John's wort, ginseng, guarana, belladonna
NSAIDs	Ibuprofen, indomethacin
Stimulants	Amphetamines, caffeine, cocaine, methylphenidate
Thyroid hormones	Levothyroxine
Toxicity	Anticholinergics, antihistamines, digoxin
Withdrawal of CNS depressants (abrupt)	Alcohol, barbiturates, benzodiazepines

CNS, central nervous system; SNRI serotonin norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant; NSAID, non-steroidal anti-inflammatory drug.

Data from Refs. 2, 16, and 17.

Patient Encounter 1, Part 1

JK is 32-year-old Hispanic woman who presents to the primary care clinic with complaints of fatigue, insomnia, and increasing irritability. She admits to “worrying” about everything, including her job; her two sons; and her father, who recently had a “heart attack.” She is tearful during the interview and states that she feels “overwhelmed.”

Her medical history is positive for migraine headaches and asthma.

Medications: Salmeterol inhalation, valproate 500 mg

What manifestations described above are suggestive of an anxiety disorder?

What additional information do you need to establish a diagnosis and develop a treatment plan?

What other diagnoses should be considered in your differential diagnosis?

Could her medications be contributing to her symptoms?

antidepressant properties partly because of its effects on corticotropin-releasing hormone.¹⁵

TREATMENT: GENERALIZED ANXIETY DISORDER

Desired Outcomes

- 1 The goals of therapy for GAD are to acutely reduce the severity and duration of anxiety symptoms and restore overall

functioning. The long-term goal in GAD is to achieve and maintain remission. With a positive response to treatment, patients with GAD and comorbid depression should have minimal depressive symptoms.

General Approach to Treatment

Patients with GAD may be managed with psychotherapy, pharmacotherapy, or both. The treatment plan should be individualized based on symptom severity, comorbid illnesses, medical status, age, and patient preference. Patients with severe symptoms resulting in functional impairment should receive antianxiety medication.

Nonpharmacologic Therapy

Nonpharmacologic therapy includes psychoeducation, exercise, stress management, and psychotherapy. Psychoeducation should address pertinent information on GAD and its management. Patients should be instructed to avoid stimulating agents such as caffeine, decongestants, diet pills, and excessive alcohol use. Regular exercise is also recommended. Cognitive-behavioral therapy (CBT) is the most effective psychological therapy for GAD patients. It helps patients to recognize and alter patterns of distorted thinking and dysfunctional behavior. Some trials suggest that treatment gains with CBT may be maintained for up to 1 year.¹⁸ CBT may be delivered in individual or group therapy and should often include families (children with anxiety).¹⁹ Computerized CBT offered over the Internet is effective and may offer an alternative to face-to-face therapy for patients with access barriers.²⁰ The effect sizes of trials with CBT are comparable to those of pharmacologic therapies. Although there are limited data evaluating the benefit of combined CBT and medication, a recent trial in children with GAD suggests the combination was superior to either treatment alone.²¹

Patient Encounter 1, Part 2

After a medical workup, JK was diagnosed with GAD and depression NOS.

PMH: Migraine, asthma

FH: Mother treated for depression; father, alcohol dependence

SH: Drinks alcohol occasionally; lives independently with spouse and two children

Meds: Salmeterol inhalation; Valproate 500 mg/day

What are first-line treatment options for this patient?

What factors should be considered in selecting the patient's treatment?

What is the role of benzodiazepines for this patient?

How should the patient be monitored when receiving an antidepressant?

Pharmacologic Therapy

- Antidepressants, benzodiazepines, pregabalin, buspirone, hydroxyzine, and the second-generation (SGA) antipsychotics have controlled clinical trial data supporting their use in GAD. Antidepressants have replaced benzodiazepines as the drugs of choice for chronic GAD owing to a tolerable side effect profile; no risk for dependency; and efficacy in common comorbid conditions, including depression, panic, obsessive-compulsive disorder (OCD), and SAD. Benzodiazepines remain the most effective and commonly used treatment for short-term management of anxiety when immediate relief of symptoms is desired. They are also recommended for intermittent or adjunctive use during GAD exacerbation or for sleep disturbance during the initiation of antidepressant treatment.¹⁸ Buspirone and pregabalin are alternative agents for patients with GAD without depression. Hydroxyzine is usually adjunctive and is less desirable for long-term treatment owing to side effects that include sedation and anticholinergic effects.

Patients with GAD should be treated to remission of symptoms. Although data are lacking on the optimal duration of pharmacotherapy, recent guidelines recommend continuing treatment for 1 year.^{18,19,22,23} Continuation of antidepressant therapy after acute response significantly decreases the risk of relapse (odds ratio, 0.2 [0.15 to 0.26]; number needed to treat [NNT], 3.23 [2.86 to 3.85]).²² An algorithm for the pharmacologic management of GAD is shown in **Figure 40-2**.

► Antidepressants

- 2** Antidepressants (**Table 40-3**) are considered first-line agents in the management of chronic GAD. These agents reduce the psychic symptoms (e.g., worry and apprehension) of anxiety with a modest effect on autonomic or somatic symptoms (e.g., tremor, rapid heart rate, and/or sweating). All antidepressants evaluated provide a similar degree of anxiety reduction. The onset of antianxiety effect is delayed 2 to 4 weeks. Selective serotonin reuptake inhibitors (SSRIs) or serotonin-norepinephrine reuptake inhibitors (SNRIs) are usually preferred over tricyclic antidepressants (TCAs) such as imipramine owing to improved safety and tolerability. Selection of a specific antidepressant generally is based on history of prior response, side effect profile, drug interaction profile (see Chapter 38), cost, or formulary availability.

Antidepressants modulate synaptic 5-HT, NE, and/or dopamine (DA) reuptake and receptor-activated neuronal signal transduction. These intracellular changes ultimately modify the expression of genes and proteins important in stress response (e.g., increase messenger RNA for glucocorticoid receptors and brain-derived neurotrophic factor and decrease mRNA expression for corticotropin-releasing hormone).²⁴ Activation of these “stress-adapting” pathways is thought to improve both somatic and psychic symptoms of anxiety.²⁴

- Serotonin Norepinephrine Reuptake Inhibitors** Venlafaxine and duloxetine are SNRIs approved by the Food and Drug Administration (FDA) for the treatment of GAD.

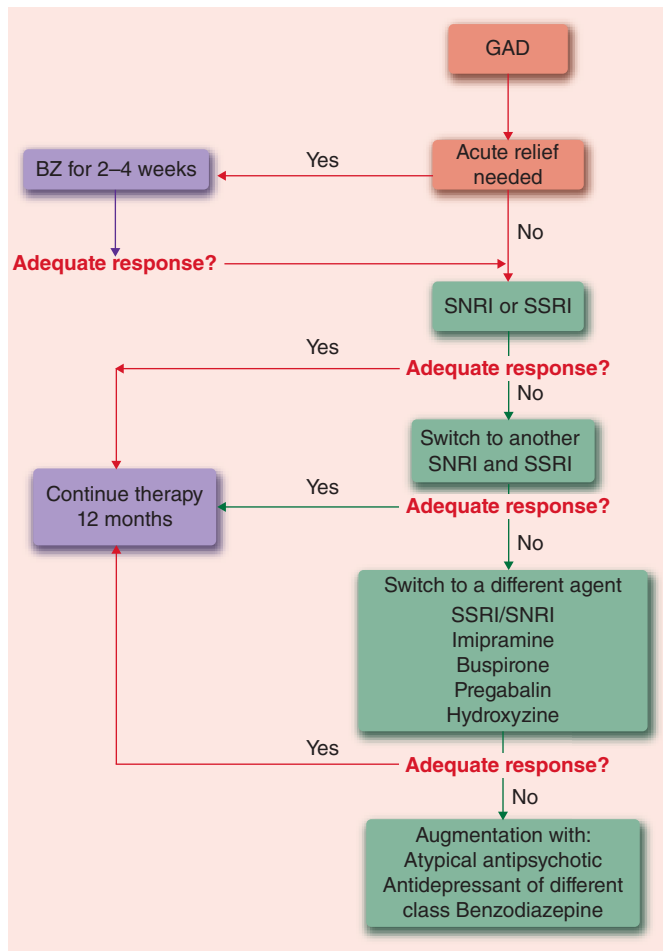

FIGURE 40-2. Treatment algorithm for generalized anxiety disorder. (BZ, benzodiazepine; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.) (Adapted from Kirkwood CK, Melton ST. Anxiety disorders: I. Generalized anxiety, panic and social anxiety disorders. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*. 7th ed. New York: McGraw-Hill; 2008:1166; With permission.)

They alleviate anxiety in GAD patients with and without depression. Venlafaxine is effective at doses 75 to 225 mg/day and maintains response with extended treatment.¹⁸ Venlafaxine is also effective for the management of GAD in children and adolescents.¹⁹ Venlafaxine has more favorable tolerability profile than TCAs. The most common side effects reported by patients with GAD are nausea, somnolence, dry mouth, dizziness, sweating, constipation, and anorexia.^{18,25}

Duloxetine is effective for the treatment of GAD as well, but long-term efficacy has not yet been established. At 60 to 120 mg/day, its efficacy is noninferior to venlafaxine, and tolerability is similar.²⁵ For patients with concurrent pain syndromes, duloxetine has been found to improve anxiety, pain, and functional impairment more than placebo.²⁶

Selective Serotonin Reuptake Inhibitors The SSRIs paroxetine, escitalopram, and sertraline have been shown to be significantly more effective than placebo in reducing anxiety symptoms in adults with GAD. Paroxetine at doses

of 20 and 40 mg/day achieved response in 62% and 68% of patients, respectively, over 8 weeks of treatment.²⁷ Remission occurred in 30% and 36%, respectively. In a 24-week relapse-prevention study, paroxetine was more effective than placebo at maintaining response, and patients were more likely to achieve remission with continued treatment (42.5% at 8 weeks vs. 73% at 24 weeks).²⁸ In GAD trials, paroxetine was associated with a high rate of somnolence, nausea, abnormal ejaculation, dry mouth, decreased libido, and asthenia compared with placebo.²⁷

Escitalopram, in a dose range of 10 to 20 mg/day, was more effective than placebo in patients with GAD without depression. Fifty-eight percent of patients taking escitalopram achieved response versus 38% on placebo over the 8 weeks of treatment.²⁹ Side effects included headache, nausea, somnolence, upper respiratory tract infection, decreased libido, ejaculation disorder, and anorgasmia.²⁹

Sertraline was more efficacious than placebo in patients with GAD being treated for 12 weeks. Sertraline treatment resulted in 56% of patients achieving response; 31% achieved remission.³⁰ Side effects included increased rates of nausea, insomnia, sweating, decreased libido, diarrhea, fatigue, and ejaculation disorder.³⁰

Limited comparative trial data suggest comparable outcomes among these SSRIs.^{31,32} SSRI therapy is better tolerated than TCAs, and tolerability is similar to that with venlafaxine. Citalopram has been shown to be efficacious in the treatment of GAD in the elderly.³³ The SSRIs, sertraline, fluoxetine, and fluvoxamine have demonstrated benefits in children and adolescents with GAD and are the preferred pharmacologic treatment in this population.¹⁹

Tricyclic Antidepressants Imipramine provided a higher rate of remission of anxiety symptoms than trazodone, diazepam, or placebo (e.g., 73% vs. 69% vs. 66% vs. 47%, respectively) in an 8-week controlled trial of GAD patients.¹⁸

- Antidepressants were more effective than diazepam or placebo in reducing psychic symptoms of anxiety. The use of TCAs generally is limited by bothersome adverse effects (e.g., sedation, orthostatic hypotension, anticholinergic effects, and weight gain). TCAs have a narrow therapeutic index and are lethal in overdose because of atrioventricular heart block.

- **Novel Antidepressants** Mirtazapine, an alpha-2 adrenergic antagonist and postsynaptic serotonin (5-HT₂, 5-HT₃) receptor antagonist, is an effective antidepressant but has not been extensively evaluated in anxiety disorders. One open-label study found treatment of GAD for 12 weeks with mirtazapine 30 mg to be efficacious and well tolerated.¹⁸ Mirtazapine is not associated with sexual dysfunction, a common antidepressant side effect, but does have a greater propensity to cause sedation and weight gain. Bupropion, a dopamine and norepinephrine reuptake-inhibitor, lacks the common antidepressant side effects of weight gain and sexual dysfunction. Bupropion has not been studied or used extensively in anxiety disorders owing to its stimulating effects that would be expected to worsen anxiety symptoms.
- However, a pilot controlled trial comparing bupropion XL with escitalopram found bupropion to have comparable anxiolytic efficacy and tolerability.¹⁸

Table 40-3

Antidepressants Used in the Treatment of Generalized Anxiety Disorder

Medication Class	Recommended Starting Dose (mg/day)	Usual Therapeutic Dosage Range (mg/day)	Hepatic Insufficiency	Renal Insufficiency
SSRIs				
Citalopram (Celexa)	20	20–40	Maximum, 40 mg/day	
Escitalopram ^a (Lexapro)	10	10–20	Maximum, 10 mg/day	
Fluoxetine (Prozac)	20	20–80	Titrate with caution	
Fluvoxamine (Luvox)	50	100–300	Titrate with caution	
Paroxetine	20	20–50	Titrate with caution	
Paroxetine CR (Paxil, Paxil CR)	25	25–62.5	Maximum, 50 mg/day	Maximum, 50 mg/day
Sertraline (Zoloft)	50–100	50–200	Reduce dose	
SNRIs				
Venlafaxine XR ^a (Effexor XR)	75	75–300	Reduce dose by 50%	Reduce dose 25%–50%
Duloxetine (Cymbalta)	30	60–120	Use not recommended	Use not recommended ^b
TCA s				
Imipramine (Tofranil)	50–75	75–200	Titrate with caution	

^aFood and Drug Administration approved for use in generalized anxiety disorder.

^bDuloxetine use is not recommended in severe renal impairment (creatinine clearance less than 30 mL/min [less than 0.50 mL/s])

SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

Data from Refs. 17 and 34.

► Benzodiazepines

3 Benzodiazepines are recommended for acute treatment of GAD when short-term relief is needed, as an adjunct during initiation of antidepressant therapy, or to improve sleep.¹⁸

Benzodiazepine treatment results in a significant improvement in 65% to 75% of GAD patients, with most of the improvement occurring in the initial 2 weeks of therapy.¹⁸ They are more effective in reducing somatic symptoms of anxiety than psychic symptoms. The major disadvantages of benzodiazepines are their lack of effectiveness in treating depression; the risk for dependency and abuse; and potential interdose rebound anxiety, especially with short-acting formulations. They should be avoided in patients with chemical dependency.

Benzodiazepines exert their effects by enhancing transmission of the inhibitory neurotransmitter GABA through interaction with the GABA_A-receptor complex.^{17,18} Although all benzodiazepines possess anxiolytic properties, only 7 of the 13 currently marketed agents are approved by the FDA for the treatment of anxiety disorders (Table 40-4). All benzodiazepines are expected to provide equivalent benefit when given in comparable doses. Benzodiazepines differ substantially in their pharmacokinetic properties and potency for the GABA_A-receptor site.

Benzodiazepines are metabolized by hepatic oxidation (cytochrome P-450 3A4) and glucuronide conjugation. Because lorazepam and oxazepam bypass hepatic oxidation and are conjugated only, they are preferred agents for patients with reduced hepatic function secondary to aging or disease (e.g., cirrhosis commonly seen in patients abusing alcohol or with hepatitis B or C from intravenous drug use). Many benzodiazepines are metabolized to long-acting metabolites (see Table 40-4) that provide long-lasting anxiety relief. Drugs that either inhibit or induce CYP450 isozymes or

glucuronidation are the major source of drug interactions (Table 40-5).

The most common side effects associated with benzodiazepine therapy include central nervous system (CNS) depressive effects (e.g., drowsiness, sedation, psychomotor impairment, and ataxia) and cognitive effects (e.g., poor recall and anterograde amnesia). Anterograde amnesia is more likely to occur with high-potency benzodiazepines such as lorazepam or alprazolam.³⁷ Some patients also may be disinhibited with benzodiazepine treatment and experience confusion, irritability, aggression, and excitement.^{17,18} Discontinuation of benzodiazepines may be associated with withdrawal, rebound anxiety, and a high rate of relapse. Higher doses of benzodiazepines and a longer duration of therapy increase the severity of withdrawal and risk of seizures after abrupt or rapid discontinuation. Patients should be tapered rather than discontinued abruptly from benzodiazepine therapy to avoid withdrawal symptoms. The duration of the taper should increase with extended duration of benzodiazepine therapy.^{17,18} For example, patients on benzodiazepine therapy over 2 to 6 months should be tapered over 2 to 8 weeks, but patients receiving 12 months of treatment should be tapered over 2 to 4 months. A general approach to the taper is to reduce the dose by 25% every 5 to 7 days until reaching half the original dose and then decreasing by 10% to 12% per week until discontinued. Patients should expect minor withdrawal symptoms and discomfort even when tapering. Rebound symptoms (e.g., return of original symptoms at increased intensity) are transient. The patient should be counseled so that rebound anxiety is not interpreted as a relapse. Relapse or recurrence of anxiety may occur in as many as 50% of patients discontinuing benzodiazepine treatment.^{17,18} It is unclear if this relapse rate represents

Table 40-4

Comparison of the Benzodiazepines

Drug Name (Brand Name) Active Metabolites	Time to Peak Concentration (hours)	Half-Life Range (hours)	Approved Dosage Range (mg/day)	Dose Equivalent (mg)
Alprazolam ^{a,b} (Xanax)	1-2	12-15	1-4 (GAD) 1-10 (PD)	0.5
Chlordiazepoxide ^a (Librium)	1-4	5-30	25-100	10
Desmethylochlordiazepoxide		18		
Demoxepam		14-95		
Desmethyldiazepam		40-120		
Oxazepam		5-15		
Clonazepam ^b (Klonopin)	1-4	18-50	1-4	0.25
Clorazepate ^a (Tranzene)	1-2		7.5-60	7.5
Desmethyldiazepam		40-120		
Oxazepam		5-15		
Diazepam ^a (Valium)	0.5-2	20-80	2-40	5
Desmethyldiazepam		40-120 ^c		
Temazepam		8-15		
Oxazepam		5-15

^aFood and Drug Administration (FDA) approved for use in generalized anxiety disorder.

^bFDA approved for use in panic disorder.

^cCYP2C19 genetic polymorphisms resulting in little or no enzyme activity are present in 15% to 20% of Asians and 3% to 5% of blacks and whites, resulting in reduced clearance of desmethyldiazepam.³⁶

GAD, generalized anxiety disorder; PD, panic disorder.

Data from Refs. 34 and 35.

Table 40-5

Pharmacokinetic Drug Interactions With Benzodiazepines

Drug	Effect
Alcohol (chronic)	Increased CL of BZs
Carbamazepine	Increased CL of alprazolam
Cimetidine	Decreased CL of alprazolam, diazepam, chlordiazepoxide, and clorazepate and increased $t_{1/2}$
Disulfiram	Decreased CL of alprazolam and diazepam
Erythromycin	Decreased CL of alprazolam
Fluoxetine	Decreased CL of alprazolam and diazepam
Fluvoxamine	Decreased CL of alprazolam and prolonged $t_{1/2}$
Itraconazole	Potentially decreased CL of alprazolam and diazepam
Ketoconazole	Potentially decreased CL of alprazolam
Nefazodone	Decreased CL of alprazolam, AUC doubled, and $t_{1/2}$ prolonged
Omeprazole	Decreased CL of diazepam
Oral contraceptives	Increased free concentration of chlordiazepoxide and slightly decreased CL; decreased CL and increased $t_{1/2}$ of diazepam and alprazolam
Paroxetine	Decreased CL of alprazolam
Phenobarbital	Increased CL of clonazepam and reduced $t_{1/2}$
Phenytoin	Increased CL of clonazepam and reduced $t_{1/2}$
Probenecid	Decreased CL of lorazepam and prolonged $t_{1/2}$
Propranolol	Decreased CL of diazepam and prolonged $t_{1/2}$
Ranitidine	Decreased absorption of diazepam
Rifampin	Increased metabolism of diazepam
Theophylline	Decreased alprazolam concentrations
Valproate	Decreased CL of lorazepam

AUC, area under the plasma concentration time curve; BZ, benzodiazepine; CL, clearance; $t_{1/2}$, elimination half-life.

Adapted from Kirkwood CK, Melton ST. Anxiety disorders: I. Generalized anxiety, panic and social anxiety disorders. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach. 7th ed. New York: McGraw-Hill, 2008:1169; With permission.

an inferiority of benzodiazepines or supports the chronic nature of GAD.

► Pregabalin

Pregabalin is a calcium channel modulator, and its anxiolytic properties are attributed to its selective binding to the $\alpha_2\text{-}\delta$ subunit of voltage-gated calcium channels. In a 4-week controlled trial versus alprazolam and placebo, pregabalin was effective for both somatic and psychic symptoms of anxiety with an onset of effect similar to that of alprazolam.³⁸ Compared with venlafaxine and placebo, pregabalin was found to be safe, well tolerated, and efficacious in GAD, and results were seen 1 week sooner than with venlafaxine.³⁹ Pregabalin reduced the risk of relapse versus placebo in a 26-week relapse prevention trial.⁴⁰ Pregabalin has short elimination half-life and must be dosed two to three times daily. It is excreted renally with a low risk of drug–drug interactions. Pregabalin is a schedule V controlled substance owing to a propensity to cause euphoria, and it has a risk of withdrawal symptoms when discontinued abruptly. It should be used cautiously in patients with a current or past history of substance abuse. It is not beneficial for depression or other anxiety disorders.

► Alternative Agents

Hydroxyzine, buspirone, and SGAs are alternative agents. Hydroxyzine may be effective for acute reduction of somatic symptoms of anxiety.¹⁸ It does not improve psychic features of anxiety and does not treat depression or other common comorbid anxiety disorders.

Buspirone, a 5-HT_{1A} partial agonist, is thought to exert its anxiolytic effects by reducing presynaptic 5-HT firing.⁴¹ Unlike benzodiazepines, it does not have abuse potential, cause withdrawal reactions, or potentiate alcohol and sedative–hypnotic effects. It has a gradual onset of action (i.e., 2 weeks) and does not provide immediate anxiety relief.

Buspirone's inconsistent data regarding its efficacy in chronic GAD or GAD with comorbid depression limit its usefulness.¹⁸ Some research suggests that buspirone is less effective in patients who have been treated previously (4 weeks to 5 years) with benzodiazepines.¹⁸

Buspirone should be initiated at a dose of 7.5 mg twice daily and titrated in 5-mg/day increments (every 2 to 3 days) to a usual target dose of 20 to 30 mg/day.^{18,41} The maximum daily dose is considered to be 60 mg/day.

Buspirone generally is well tolerated and does not cause sedation. The most common side effects include dizziness, nausea, and headaches. Drugs that inhibit CYP3A4 (e.g., verapamil, diltiazem, itraconazole, fluvoxamine, and erythromycin) can increase buspirone levels. Likewise, enzyme inducers such as rifampin can reduce buspirone levels significantly. Buspirone may increase blood pressure when coadministered with a monoamine oxidase inhibitor (MAOI).

The SGAs, quetiapine, olanzapine, and risperidone have demonstrated benefit in GAD. In three large placebo controlled trials, quetiapine in daily doses of 50 to 300 mg resulted in 26% greater likelihood of treatment response (effect size, ~0.3).⁴² In comparative trials, quetiapine has

similar outcomes to paroxetine 20 mg/day and escitalopram 10 mg/day.⁴² Risperidone and olanzapine may improve treatment outcomes in patients with inadequate response to initial pharmacotherapy.¹⁸ SGAs are associated with an increased risk of weight gain, sedation, fatigue, and extrapyramidal symptoms in anxiety patients.

Outcome Evaluation

- Assess patients for improvement of anxiety symptoms and return to baseline occupational, social, and interpersonal functioning. With effective treatment, the patient should have no or minimal symptoms of anxiety or depression. While drug therapy is being initiated, evaluate patients more frequently to ensure tolerability and response. Monitoring

Clinical Presentation and Diagnosis of PD

General

Typically presents in late adolescence or early adulthood. Onset in older adults increases suspicion of relationship to medical disorders or substance use. Laboratory evaluation must be driven by history and physical examination.

Symptoms²

Recurrent, discrete episodes that typically develop rapidly and peak within 10 minutes involving at least four of the following symptoms:

- Palpitations or rapid heart rate
- Sweating
- Trembling or shaking
- Sensation of shortness of breath or smothering
- Feeling of choking
- Chest pain or discomfort
- Feeling dizzy or lightheaded
- Feelings of unreality or being detached from oneself
- Fear of dying
- Numbness or tingling sensation
- Chills or hot flushes

Differential Diagnosis

Rule out underlying medical or psychiatric disorders and medications that may cause anxiety (Tables 40–1 and 40–2).

Laboratory Evaluation

- Urine drug screen
- Basic metabolic panel
- Thyroid-stimulating hormone
- Electrocardiogram
- Holter monitor
- Electroencephalogram
- Urine vanillylmandelic acid (VMA)

should include suicidal ideation and behaviors for children, adolescents, and young adults (24 years of age or younger) initiated on antidepressants.⁴³ Increase the dose in patients exhibiting a partial response after 2 to 4 weeks on an antidepressant or 2 weeks on a benzodiazepine. Individualize the duration of treatment because some patients require up to 1 year of treatment.¹⁸

TREATMENT: PANIC DISORDER

Desired Outcomes

- The main objectives of treatment are to reduce the severity and frequency of panic attacks, reduce anticipatory anxiety and agoraphobic behavior, and minimize symptoms of depression or other comorbid disorders.⁴⁴ The long-term goal is to achieve and sustain remission.

General Approach to Treatment

- Treatment options include medication, psychotherapy (e.g., CBT preferred), or a combination of both. In some cases, pharmacotherapy will follow psychotherapy treatments when full response is not realized. Patients with panic symptoms without agoraphobia may respond to pharmacotherapy alone. Agoraphobic symptoms generally take longer to respond than panic symptoms. 4 *The acute phase of PD treatment lasts about 12 weeks and should result in marked reduction in*

*panic attacks (ideally total elimination), minimal anticipatory anxiety, and phobic avoidance. Treatment should be continued to prevent relapse for an additional 12 to 18 months before attempting discontinuation.*⁴⁴ Patients who relapse after discontinuation of medication should have therapy resumed.⁴⁴

Nonpharmacologic Therapy

- Patients with PD should be counseled to avoid stimulant agents (e.g., decongestants, diet pills, and caffeine) that may precipitate a panic attack. CBT generally includes psychoeducation, self-monitoring, countering anxious beliefs, exposure to fear cues, and modification of anxiety-maintaining behaviors.^{18,44} Exposure therapy is useful
- for patients with phobic avoidance. CBT is considered a first-line treatment of PD, with efficacy similar to that of pharmacotherapy. Some studies suggest lower risk of relapse after CBT versus drug therapy.⁴⁴ The benefit of combination treatment is unclear; however, in a recent trial of PD with or without agoraphobia, SSRI plus CBT therapy was more effective than SSRI or CBT monotherapy after 9 months of treatment.⁴⁵ Panic-focused psychodynamic psychotherapy may be effective for some patients.⁴⁴

Pharmacologic Therapy

- Patients with PD may be treated successfully with TCAs, SSRIs, SNRIs, or MAOIs, as well as benzodiazepines^{18,44} (Table 40–6). Although all of these agents are similarly

Table 40–6

Antidepressants Used in the Treatment of Panic Disorder^{18,23,42}

Medication Class	Recommended Starting Dose (mg/day)	Usual Therapeutic Dosage Range (mg/day)	Advantages	Disadvantages
SSRIs/SNRIs				
Citalopram	10	20–60	SSRIs (in general) Antidepressant activity; antianxiety activity; single daily dosing (all but fluvoxamine); low toxicity; some available in generic	SSRIs (in general) Activation; delayed onset of action; may precipitate mania; sexual side effects; GI side effects
Escitalopram	5–10	10–20		
Fluoxetine ^a	5–10	20–60		
Fluvoxamine	25	100–300		
Paroxetine ^a	10	20–60		
Sertraline ^a	25	50–200		
Venlafaxine XR ^a	37.5	75–225		
TCAs				
Clomipramine	25 mg (twice a day)	75–250	TCAs (in general) Established efficacy; available in generic	TCAs (in general) Activation; sedation; anticholinergic effects; cardiovascular effects; delayed onset of action; may precipitate mania; sexual side effects; toxic in overdose; weight gain
Imipramine ^a	10–25	75–250		
MAOI				
Phenelzine	15	45–90	Antidepressant effects; available in generic	Dietary restrictions; drug interactions; weight gain; orthostasis; may precipitate mania

^aFood and Drug Administration approved for use in panic disorder.

GI, gastrointestinal; MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

Data from Refs. 18, 23, and 42.

effective, SSRIs have become the treatment of choice in PD. Benzodiazepines often are used concomitantly with antidepressants, especially early in treatment, or as monotherapy to acutely reduce panic symptoms. Benzodiazepines are not preferred for long-term treatment but may be used when patients fail several antidepressant trials.^{18,44} PD patients with comorbid depression should be treated with an antidepressant. An algorithm for pharmacologic management of PD appears in **Figure 40–3**.

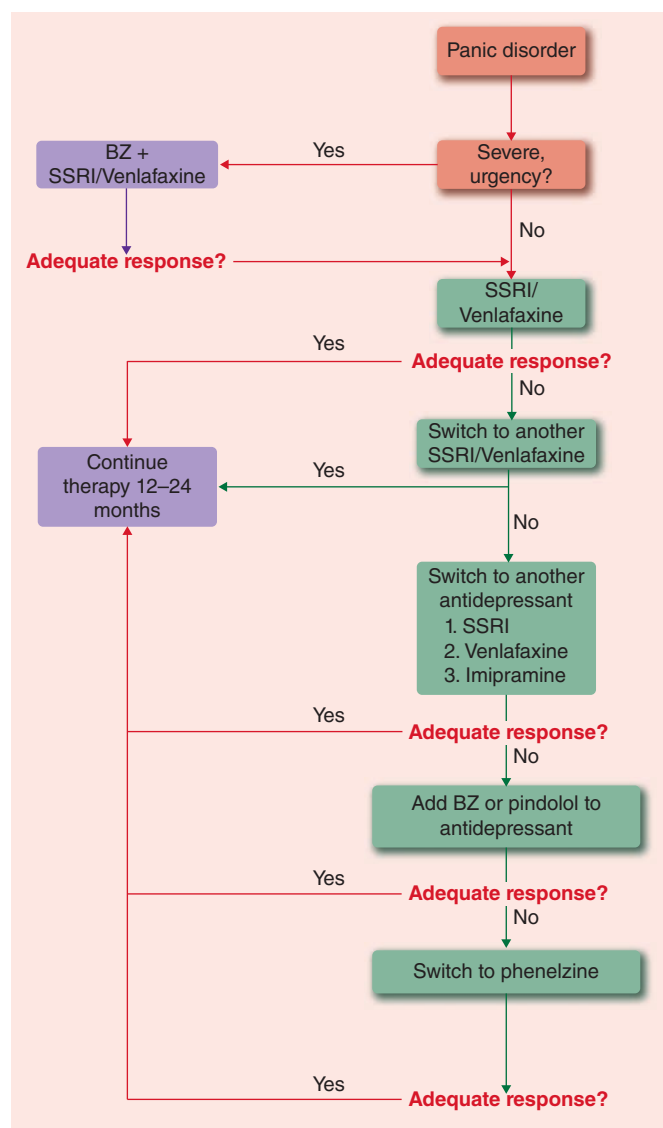

FIGURE 40–3. Algorithm for the pharmacotherapy of panic disorder. BZ, benzodiazepine; SSRI, selective serotonin reuptake inhibitor. (Adapted from Young AS, Klap R, Sherbourne CD, Wells KB. The quality of care for depressive and anxiety disorders in the United States. *Arch Gen Psychiatry* 2001;58:55–61 and Bruce SE, Yonkers SE, Otto MW, et al. Influence of psychiatric comorbidity on recovery and recurrence in generalized anxiety disorder, social phobia, and panic disorder: A 12-year prospective study. *Am J Psychiatry* 2005;162:1179–1187; With permission.)

► Antidepressants

Antidepressants have a delayed onset of anti-panic effect, typically 4 weeks, with optimal response at 6 to 12 weeks. Reduction of anticipatory anxiety and phobic avoidance generally follows improvement in panic symptoms. **5** *PD patients are more likely to experience stimulant-like side effects of antidepressants than patients with major depression. Antidepressants should be initiated at lower doses (Table 40–6) in PD patients than in depressed patients or those with other anxiety disorders.* Target doses are similar to those used for depression. **6** *Antidepressants should be tapered when treatment is discontinued to avoid withdrawal symptoms, including irritability, dizziness, headache, and dysphoria.*

Tricyclic Antidepressants Treatment with imipramine, the most studied TCA, leaves 45% to 70% of patients panic free. Both desipramine and clomipramine have demonstrated effectiveness in PD as well. Despite their efficacy, TCAs are considered second- or third-line pharmacotherapy because of poorer tolerability and toxicity on overdose.^{18,44} TCAs are associated with a greater rate of treatment discontinuation than SSRIs.⁴⁴ PD patients taking TCAs may experience anticholinergic effects, orthostatic hypotension, sweating, sleep disturbances, dizziness, fatigue, sexual dysfunction, and weight gain. Stimulant-like side effects occur in up to 40% of patients.⁴⁴

Selective Serotonin Reuptake Inhibitors SSRIs are the drugs of choice for patients with PD. All SSRIs have demonstrated effectiveness in controlled trials, with 60% to 80% of patients achieving a panic-free state.^{18,42} With similar efficacy reported and no trials comparing different SSRIs, drug selection generally is based on pharmacokinetics, drug interactions, side effects, and cost differences (see Chapter 38). The most common side effects of SSRIs include headaches, irritability, nausea and other gastrointestinal complaints, insomnia, sexual dysfunction, increased anxiety, drowsiness, and tremor.⁴⁴

Serotonin Norepinephrine Reuptake Inhibitors Venlafaxine, in dosages of 75 to 225 mg/day, reduced panic and anticipatory anxiety in short-term controlled trials and prevented relapse with extended treatment over 6 months.^{44,46} The most common side effects include anorexia, dry mouth, constipation, somnolence, tremor, abnormal ejaculation, and sweating.

Monoamine Oxidase Inhibitors MAOIs have not been evaluated systematically for treatment of PD under the current diagnostic classification and generally are reserved for patients who are refractory to other treatments.⁴⁴ They have significant side effects that limit adherence. Additionally, patients must adhere to dietary restriction of tyramine and avoid sympathomimetic drugs to avoid hypertensive crisis (see Chapter 38).

The reversible inhibitors of monoamine oxidase (RIMAs) (brofaromine and meclobemide) have been studied with mixed results.^{18,44} Neither is approved for use in the United States, but they are available in Canada.

Others There is insufficient evidence to recommend the use of bupropion, trazodone, nefazodone, or mirtazapine for treatment of PD.^{18,44}

► Benzodiazepines

Benzodiazepines are effective antipanic agents with significant effects on anticipatory anxiety and phobic behaviors. Alprazolam, the benzodiazepine most studied, is associated with significant panic reduction after 1 week of therapy (e.g., 55% to 75% panic free).^{44,47} Benzodiazepines achieve outcomes similar to antidepressants over extended treatment, but benzodiazepine-treated patients are more likely to relapse when the drugs are discontinued.⁴⁴ The risk for dependence and withdrawal and lack of efficacy for depression are significant concerns for long-term treatment of patients with PD. There is no evidence that tolerance to therapeutic effect occurs. In fact, patients do not require dose escalation during extended treatment. Patients with PD do experience greater rebound anxiety and relapse when discontinuing benzodiazepines than do patients with GAD. Tapering should be done at a slower rate and over a more extended period of time than with other anxiety disorders.^{18,44}

7 *The dose of benzodiazepine required for improvement generally is higher than that used in other anxiety disorders, and this may explain why high-potency agents such as alprazolam and clonazepam generally are preferred. Lorazepam and diazepam, when given in equivalent doses, produce similar treatment benefits.^{18,44} Doses should be titrated to response (see Table 40–4). The use of extended-release alprazolam or clonazepam may minimize breakthrough panic symptoms that are sometimes observed with immediate-release alprazolam.⁴⁷*

Side effects associated with benzodiazepines in PD patients are similar to those observed in other disorders. Sedation, fatigue, and cognitive impairment are the most commonly reported side effects.⁴⁴ Benzodiazepines should be avoided in patients with current or past substance abuse or dependence or sleep apnea. Additionally, caution should be used in older adults because they have more pronounced psychomotor and cognitive side effects.

► β -Blockers

Pindolol 25 mg three times a day has been shown effective as an adjunctive treatment for PD when used with an SSRI.⁴⁴ Propranolol 120 to 240 mg/day has been found equivalent to alprazolam in reduction of panic attacks.⁴⁴ β -blockers are not expected to reduce psychic anxiety or avoidance behavior. Additionally, heart rate and blood pressure reduction are dose-related adverse events that may limit use.

Outcome Evaluation

Assess patients for symptom improvement frequently (e.g., weekly) during the first 4 weeks of therapy. With effective therapy, patients should experience significant reductions in the frequency and intensity of panic attacks, anticipatory

Clinical Presentation and Diagnosis of SAD

General

Often occurs in context of other anxiety disorders. The feared social or performance situation can be limited to a specific social interaction (e.g., public speaking) or generalized to most any social interaction. Differs from specific phobia, in which the fear and anxiety are limited to a particular object or situation (e.g., insects, heights, public transportation).

Symptoms²

- Persistent fear of social interactions, during which time the individual is concerned about being embarrassed or being under scrutiny.
- Engaging in the feared activities can lead to extreme anxiety and panic.
- The fear leads to distress or avoidance of the situation sufficient enough to cause trouble in the patient's life.

Differential Diagnosis

Rule out underlying medical or psychiatric disorders and medications that may cause anxiety (Tables 40–1 and 40–2).

Laboratory Evaluation

Laboratory investigation is of limited value and should be pursued only in context of other history or physical examination findings.

anxiety, and phobic avoidance with resumption of normal activities. Alter the therapy of patients who do not achieve a significant reduction in panic symptoms after 6 to 8 weeks of an adequate dose of antidepressant or 3 weeks of a benzodiazepine. Regularly evaluate patients for adverse effects, medication adherence and educate them about appropriate expectations of drug therapy.

When the patient has achieved a significant response, continue therapy for at least 1 year. Evaluate for symptom relapse and adverse effects that may emerge with continued treatment (e.g., weight gain and sexual dysfunction). During drug discontinuation, monitor frequently for withdrawal, rebound anxiety, and relapse.

TREATMENT: SOCIAL ANXIETY DISORDER

Desired Outcomes

Social anxiety disorder is a chronic disorder that begins in adolescence and occurs with significant functional impairment and high rates of comorbidity. The goal of acute treatment is to reduce physiologic symptoms of anxiety, fear of social situations, and phobic behaviors. Patients with comorbid depression should have a significant reduction in depressive symptoms. The long-term goal is to restore social functioning and improve the patient's quality of life.

Patient Encounter 2

SA is an 18-year-old white woman presenting to the pediatric clinic with complaints of nausea, bloating, and stomach pain. She reports significant anxiety around school performance and social activities. She has missed 10 days of school in the past 6 weeks because of feeling ill. Her mother relates this to her avoidance of presentations and school functions. Her mother states that SA has been treated for anxiety for 15 years with Xanax 0.5 twice daily. She has considered giving her daughter a dose to get her to go to school.

Patient's medical workup is noncontributory, and she is diagnosed with generalized SAD.

What treatment options should be considered for SA?

What are the benefits of using pharmacotherapy versus psychotherapy versus both?

General Approach to Treatment

- Patients with SAD may be managed with pharmacotherapy or psychotherapy. There is insufficient evidence to recommend one treatment over the other, and data are lacking on the benefits of combining treatment modalities. Pharmacotherapy often is the first choice of treatment owing to relative greater access and reduced cost compared with psychotherapy.⁴⁸ Patients with SAD generally respond slowly to treatment, and many will not achieve a full response. Relapse is common when patients are discontinued after effective short-term treatment. Patients generally are continued on treatment for at least 1 year before attempting discontinuation.

Nonpharmacologic Therapy

- Patient education on disease course, treatment options, and expectations is essential, given the chronic nature and functional impairment of SAD. Support groups may be beneficial for some patients. CBT targets avoidance-learning and negative-thinking patterns associated with social anxiety by exposing the patient to a feared situation. CBT is effective for reducing anxiety and phobic avoidance and leads to a greater likelihood of maintaining response after treatment discontinuation than does pharmacotherapy.⁴⁸

Pharmacologic Therapy

- Several pharmacologic agents have demonstrated effectiveness in SAD, including the SSRIs, venlafaxine, phenelzine, RIMAs, benzodiazepines, gabapentin, and pregabalin.
 - 8 SSRIs are considered the drugs of choice based on their tolerability and efficacy for SAD and comorbid depression if present.
 - 9 The onset of response for antidepressants may be as long as 8 to 12 weeks.^{18,49} Patients responding to medication should be continued on treatment for at least 1 year. Many patients relapse when medication is discontinued, and

there are no clear predictive factors for who will maintain response.⁴⁹ Some patients may elect more long-term treatment owing to fear of relapse. A suggested treatment algorithm is shown in [Figure 40-4](#).

▶ Selective Serotonin Reuptake Inhibitors and Venlafaxine

- The efficacy of paroxetine, sertraline, escitalopram, fluvoxamine, and venlafaxine was established in large controlled trials.^{18,49} SSRIs and SNRIs improve social anxiety and phobic avoidance and reduce overall disability. Approximately 50% of patients achieve response during acute treatment. Limited data support the effectiveness of citalopram and fluoxetine in SAD.^{49,50}

The initial dose of SSRI is similar to that used in depression. Patients should be titrated as tolerated to response. Many patients will require maximum recommended daily doses. Patients with comorbid PD should be started on lower doses (see [Table 40-6](#)). When discontinuing SSRIs, the dose should be tapered slowly to avoid withdrawal symptoms. Relapse rates may be as high as 50%, and patients should be monitored closely for several weeks.^{48,49} Side effects of SSRIs in SAD patients are similar to those seen in depression and include nausea, sexual dysfunction, somnolence, and sweating.

Venlafaxine extended release, in doses of 75 to 225 mg/day, has similar efficacy to SSRIs.¹⁸ As with SSRIs, doses should be tapered slowly when discontinuing therapy. Tolerability is similar to that observed in depression trials with venlafaxine extended release. Common side effects are anorexia, dry mouth, nausea, insomnia, and sexual dysfunction.

▶ Monoamine Oxidase Inhibitors and Reversible Inhibitors of Monoamine Oxidase

- Phenelzine is effective in 64% to 69% of SAD patients.⁴⁹ It is generally reserved for treatment-refractory patients owing to dietary restrictions,⁵¹ drug interactions, and side effects. The RIMAs brofaridine and meclobemide are effective in SAD.

▶ Alternative Agents

- **Benzodiazepines** Benzodiazepines are used commonly in SAD; however, limited data support their use. Clonazepam has been effective for social anxiety, fear, and phobic avoidance, and it reduced social and work disability during acute treatment.⁴⁹ Long-term treatment is not desirable for many SAD patients owing to the risk of withdrawal and difficulty with discontinuation, cognitive side effects, and lack of effect on depressive symptoms. Benzodiazepines may be useful for acute relief of physiologic symptoms of anxiety when used concomitantly with antidepressants or psychotherapy. Benzodiazepines are contraindicated in SAD patients with alcohol or substance abuse or history of such.
- **Anticonvulsants** Gabapentin and pregabalin, structurally similar anticonvulsant medications, have each demonstrated modest benefit in a randomized placebo controlled trial.^{18,52} Gabapentin was titrated to a maximum dose of 3,600 mg/day and pregabalin to 600 mg/day. While both medications have good tolerability profiles, they should be considered for patients who have an inadequate response to SSRI/SNRIs.

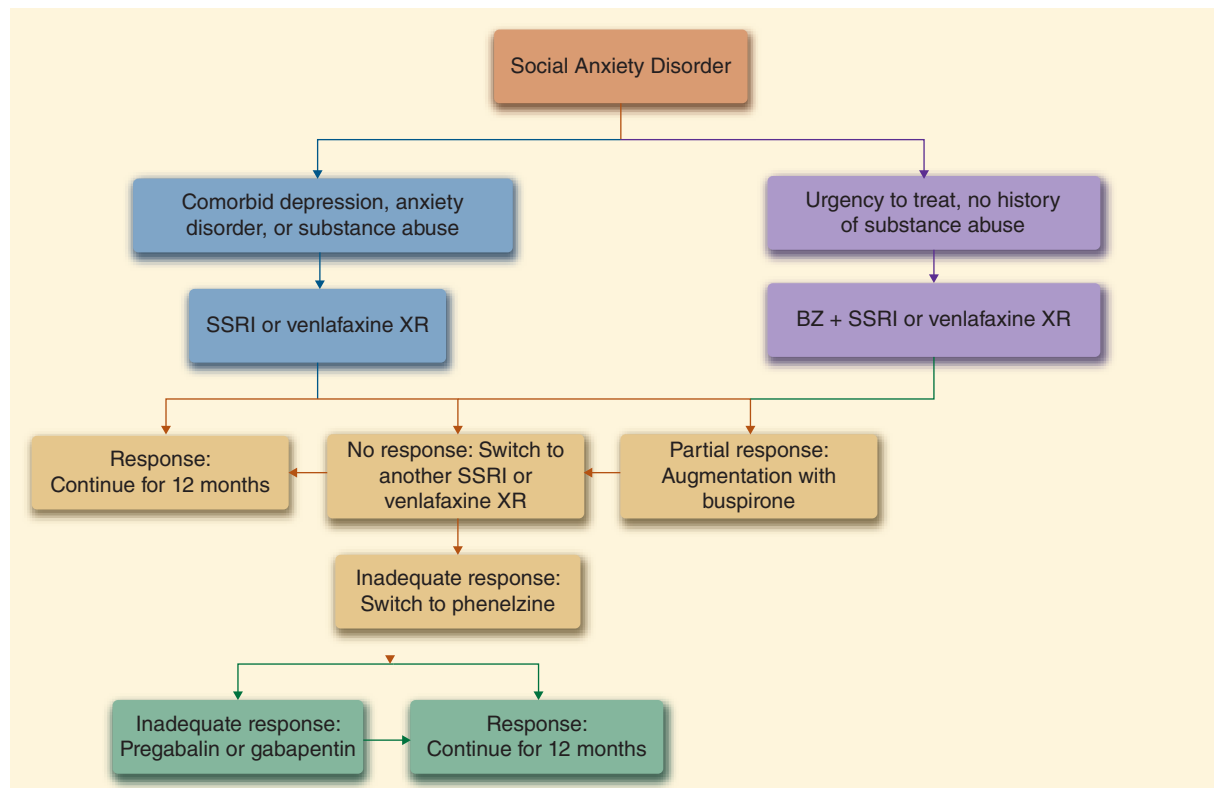

FIGURE 40–4. Algorithm for the pharmacotherapy of social anxiety disorder. BZ, benzodiazepine; SSRI, selective serotonin reuptake inhibitor. (Adapted from Melton ST, Kirkwood CK. Anxiety disorders I: Generalized anxiety, panic and social anxiety disorders. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. *Pharmacotherapy: A Pathophysiologic Approach*. 8th ed. New York: McGraw-Hill; 2011:1209–1227; With permission.)

Patient Care and Monitoring

1. Review medical and laboratory data to rule out contributing causes of anxiety.
2. Obtain a thorough history of prescription, nonprescription, and natural product use.
3. Determine what treatments have been tried or were useful in the past. Is the patient taking medication that may cause anxiety?
4. Assess the patient's symptoms and level of functional impairment to determine if pharmacotherapy is appropriate for the anxiety disorder.
5. Provide patient education regarding disease state, lifestyle modifications, and pharmacotherapy.
 - Lifestyle changes include adequate sleep and exercise, stress management, meditation, and coping skills.
 - Potential complications of an untreated anxiety disorder
 - Potential adverse effects and risk of dependence
 - Drug interactions
6. Inform patients of treatment options for anxiety disorders and the expected benefits of each (e.g., pharmacotherapy, psychotherapy, and combination treatment).
7. Develop a plan to assess the effectiveness of drug therapy during the first 12 weeks.
8. Determine an appropriate duration of treatment. Is long-term maintenance treatment needed?
9. Assess improvement in academic, social, interpersonal, and occupational functioning; quality of life; and well-being.
10. Evaluate the patient for the presence of adverse drug effects, drug–drug interactions, and drug allergies.
11. Stress the importance of adherence to medications to achieve and maintain response.

β -Blockers β -blockers decrease the physiologic symptoms of anxiety and are useful for reducing performance anxiety. Propranolol or atenolol should be administered 1 hour before a performance situation. β -blockers are not useful in generalized SAD.⁴⁹

Outcome Evaluation

10 *Pharmacotherapy for patients with SAD should lead to improvement in physiologic symptoms of anxiety and fear, functionality, and overall well-being.*¹⁸ With effective therapy, many patients will experience significant improvement in symptoms but may not achieve full remission. Monitor patients weekly during acute treatment (e.g., initiation and titration of pharmacotherapy). When patients are stabilized, monitor monthly. Inquire about adverse effects and SAD symptoms at each visit. To aid in assessing improvement, ask patients to keep a diary to record fears, anxiety levels, and behaviors in social situations.¹⁸ Administer the Liebowitz Social Anxiety Scale (LSAS) to rate SAD severity and change, and the Social Phobia Inventory can be used as a “self-assessment” tool for patients with SAD. Last, counsel patients on appropriate expectations of pharmacotherapy in SAD, including the gradual onset of effect and the need for extended treatment of at least 1 year.

Abbreviations Introduced in This Chapter

CBT	Cognitive-behavioral therapy
CNS	Central nervous system
DA	Dopamine
FDA	Food and Drug Administration
GABA	γ -Aminobutyric acid
HPA	Hypothalamic–pituitary–adrenal
GAD	Generalized anxiety disorder
5-HT	Serotonin
LC	Locus ceruleus
LSAS	Liebowitz Social Anxiety Scale
MAOI	Monoamine oxidase inhibitor
MDD	Major depressive disorder
NCS-R	National Comorbidity Survey, Revised
NE	Norepinephrine
NPY	Neuropeptide Y
OCD	Obsessive-compulsive disorder
PD	Panic disorder
RAS	Reticular activating system
RIMA	Reversible inhibitors of monoamine oxidase A
SAD	Social anxiety disorder
SGA	Second-generation antipsychotic
SNRI	Serotonin-norepinephrine reuptake inhibitor
SSRI	Selective serotonin reuptake inhibitor
TCA	Tricyclic antidepressant
VMA	Vanillylmandelic acid

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Sleep Disorders

John M. Dopp and Bradley G. Phillips

LEARNING OBJECTIVES

● **Upon completion of the chapter, the reader will be able to:**

1. List the sequelae of undiagnosed or untreated sleep disorders and appreciate the importance of successful treatment of sleep disorders.
2. Articulate the incidence and prevalence of sleep disorders.
3. Describe the pathophysiology and characteristic features of the sleep disorders covered in this chapter, including insomnia, narcolepsy, restless legs syndrome (RLS), obstructive sleep apnea (OSA), and parasomnias.
4. Assess patient sleep complaints, conduct sleep histories, and evaluate sleep studies to recognize daytime and nighttime symptoms and characteristics of common sleep disorders.
5. Recommend and optimize appropriate sleep hygiene and nonpharmacologic therapies for the management and prevention of sleep disorders.
6. Recommend and optimize appropriate pharmacotherapy for sleep disorders.
7. Describe the components of a monitoring plan to assess safety and efficacy of pharmacotherapy for common sleep disorders.
8. Educate patients about preventive behavior, appropriate lifestyle modifications, and drug therapy required for effective treatment and control of sleep disorders.

KEY CONCEPTS

- 1 Insomnia is most frequently a symptom or manifestation of an underlying disorder (comorbid or secondary insomnia) but may occur in the absence of contributing factors (primary insomnia).
- 2 Patients with sleep complaints should have a careful sleep history performed to assess for possible sleep disorders and to guide diagnostic and therapeutic decisions.
- 3 Although the clinical history guides diagnosis and therapy, only overnight polysomnography and multiple sleep latency tests (MSLTs) can definitively diagnose and/or guide therapy for OSA, narcolepsy, and periodic limb movements of sleep (PLMS).
- 4 Treatment goals vary among different sleep disorders but generally include restoration of normal sleep patterns, elimination of daytime sequelae, improvement in quality of life, and prevention of complications and adverse effects from therapy.
- 5 Early treatment of insomnia may prevent the development of persistent psychophysiologic insomnia.
- 6 Benzodiazepine receptor agonists (including traditional benzodiazepines, zolpidem, zaleplon, and eszopiclone) and ramelteon are approved by the Food and Drug Administration for the treatment of insomnia and are first-line therapies.
- 7 Treatment of excessive daytime sleepiness in narcolepsy and other sleep disorders may require the use of sustained- and immediate-release stimulants to effectively promote wakefulness throughout the day and at key times that require alertness.
- 8 RLS treatment involves suppression of abnormal sensations and leg movements and consolidation of sleep. Dopaminergic and sedative-hypnotic medications are commonly prescribed.
- 9 The primary therapy for OSA is nasal continuous positive airway pressure therapy because of its effectiveness.
- 10 It is important to review patient medication profiles for drugs that may aggravate sleep disorders. Patients should be monitored for adverse drug reactions, potential drug-drug interactions, and adherence to their therapeutic regimens.

Normal humans sleep up to one-third of their lives and spend more time sleeping compared with any other single activity. Despite this, our understanding of the full purpose of sleep and the mechanisms regulating sleep homeostasis remains incomplete. Sleep is necessary to maintain wakefulness, health, and welfare. Unfortunately, disruption of normal sleep is prevalent and represents a major cause of societal morbidity, lost productivity, and reduced quality of life.¹ The link between adequate sleep and optimal health is becoming increasingly apparent, and sleep disturbances may contribute to the development and progression of comorbid medical conditions.¹

Sleep is governed and paced by the suprachiasmatic nucleus in the brain that regulates **circadian rhythm**. Environmental cues and amount of previous sleep also influence sleep on a daily basis. There are two main types of sleep: **rapid eye movement (REM) sleep**, during which eye movements and dreaming occur but the body is mostly paralyzed, and **non-REM sleep**, which consists of four substages (stages 1 to 4). Stage 1 serves as a transition between wake and sleep. Most of the time asleep is spent in stage 2 non-REM sleep. Stage 3 and stage 4 sleep often are grouped together and referred to as *deep sleep*, or *delta sleep*, because prominent delta waves are seen on the electroencephalogram (EEG) during these sleep stages.

EPIDEMIOLOGY AND ETIOLOGY

Sleep disorders are common. Approximately 50% of adults will report a sleep complaint over the course of their lives.² In general, sleep disturbances increase with age, and each disorder may have gender differences. The full extent and impact of disordered sleep on our society are not known because many patients' sleep disorders remain undiagnosed. Normal sleep, by definition, is "a reversible behavioral state of perceptual disengagement from and unresponsiveness to the environment."³ Individuals with sleep disorders exhibit or complain about consequent symptoms (e.g., daytime sleepiness) or a bed partner will observe hallmark characteristics of the sleep disorder. Insomnia, RLS, and sleep-related breathing disorders are the most common sleep disorders.

Insomnia

The prevalence of insomnia increases with age and is nearly 1.5 times greater in women than in men. Approximately one-third of patients older than age 65 years have persistent insomnia.^{4,5} In the adult population, about 10% experience chronic insomnia, and slightly more experience short-term insomnia. **1** *Insomnia is most frequently a symptom or manifestation of an underlying disorder (comorbid or secondary insomnia) but may occur in the absence of contributing factors (primary insomnia).* Forty percent of patients with psychiatric conditions have accompanying insomnia.⁶ Secondary insomnia may be triggered by acute stress and resolve when the stress resolves. Numerous coexisting medical conditions, such as pain, thyroid abnormalities, asthma, and gastroesophageal reflux, and medications, including selective serotonin reuptake

inhibitors (SSRIs), steroids, stimulants, and β -agonists, can interfere with sleep and cause insomnia. In cases of secondary insomnia, the clinician should treat the underlying cause along with insomnia symptoms.

Narcolepsy

- Although difficult to estimate, the prevalence of narcolepsy is between 0.03% and 0.06%.⁷ Significant differences have been reported for various ethnic groups. Narcolepsy has a higher prevalence in Japanese and a lower prevalence in Israeli populations.^{8,9} **Cataplexy** is not required for diagnosis; however, between 50% and 80% of patients with narcolepsy have accompanying cataplexy.¹⁰

Restless Legs Syndrome

- Restless legs syndrome occurs in 6% to 12% of the population, making it a common sleep disorder.^{11,12} The prevalence of RLS increases with age and in various medical conditions such as end-stage renal disease, pregnancy, and iron deficiency.¹³ RLS appears to be more common in women than in men and has a genetic link. The majority of patients (63% to 92%) report a positive family history for RLS.¹⁴

Obstructive Sleep Apnea

- Obstructive sleep apnea is a common disorder, affecting 4% of middle-aged white men and 2% of middle-aged white women.¹⁵ In women, the frequency of OSA increases after menopause. OSA is as common or more common in African Americans and less common in Asian populations. The risk of OSA increases with age and obesity. Individuals with OSA experience repetitive upper airway collapse during sleep, which decreases or stops airflow, with subsequent arousal from sleep to resume breathing. The severity is determined by **nocturnal polysomnography (NPSG)** and is graded by the number of episodes of apnea (total cessation of airflow) and hypopnea (partial airway closure with blood oxygen desaturation) experienced during sleep. The severity is expressed as the **respiratory disturbance index (RDI)**, quantified in events per hour. People with mild sleep apnea have an RDI between 5 and 15 episodes per hour; those with moderate sleep apnea have 15 and 30; and individuals with severe OSA can exhibit more than 30 episodes per hour.

Parasomnias

- Non-REM **parasomnias** have variable prevalence rates depending on patient age and comorbid diagnoses. Sleep talking, bruxism, sleepwalking, sleep terrors, and enuresis occur more frequently in childhood than in adulthood. Nightmares appear to occur with similar frequency in adults and children.
- REM behavior disorder (RBD), an REM-sleep parasomnia, has a reported prevalence of 0.5% and frequently is associated with concomitant neurologic conditions.¹⁶ Chronic RBD is more common in elderly men and may have a familial disposition.

PATHOPHYSIOLOGY

Although the neurophysiology of sleep is complex, certain neurotransmitters promote sleep and wakefulness in different areas of the central nervous system (CNS). Whereas serotonin is thought to control non-REM sleep, cholinergic and adrenergic transmitters mediate REM sleep. Dopamine, norepinephrine, **hypocretin**, substance P, and histamine all play a role in wakefulness. Perturbations of various neurotransmitters are responsible for some sleep disorders and explain why various treatment modalities are beneficial.

Insomnia

Because insomnia is a complex and multifaceted disorder, there is no single pathophysiologic explanation for its various manifestations. Current hypotheses focus on a combination of possible models that incorporate physiologic, cognitive, and cortical arousal. Most insomnia models focus on hyperarousal and its interference with the initiation or maintenance of sleep.

Narcolepsy

The onset of narcolepsy–cataplexy is typically in adolescence and not at birth, suggesting that the disease may require environmental influence to develop. Currently, it is believed that narcolepsy results from autoimmune insult to the CNS because it is associated with human leukocyte antigen (major histocompatibility complex) DQB1*0602 and DQA1*0102.^{17,18} Concentrations of hypocretin (a wake-promoting neuropeptide) in the cerebrospinal fluid of patients with narcolepsy are reduced significantly, suggesting that the autoimmune attack is against hypocretin-producing cells in the hypothalamus.¹⁹ Intact hypocretin neurons normally stimulate arousal and wake-promoting neurons to stimulate cortical activation and behavioral arousal.

Restless Legs Syndrome and Periodic Limb Movements of Sleep

Restless legs syndrome is a neurologic medical condition characterized by an irresistible desire to move the limbs. It is thought that these abnormal sensations are a result of iron deficiency in the brain and iron-handling abnormalities in the CNS. Iron and H-ferritin concentrations, along with transferrin receptor and iron transporter numbers, are reduced in the substantia nigra of patients with RLS.²⁰ These iron abnormalities lead to dysfunction of dopaminergic transmission in the substantia nigra.

Obstructive Sleep Apnea

At least 20 muscles and soft tissue structures control patency of the upper airway. Patients with OSA may have differences in upper airway muscle activity during sleep and may have smaller airways, predisposing them to upper airway collapse and consequent apneic episodes during sleep. The inability of the upper airway to contend with factors that promote collapse,

including fat deposition in the neck, negative pressure in the airway during inspiration, and a smaller lower jawbone, also may play a role in the pathogenesis of OSA. Hallmarks of OSA include witnessed apneas, gasping, or both.

Poor sleep architecture and fragmented sleep secondary to OSA can cause excessive daytime sleepiness (EDS) and neurocognitive deficits. These sequelae can affect quality of life and work performance and may be linked to occupational and motor vehicle accidents. OSA is also associated with systemic disease such as hypertension, heart failure, and stroke.^{21,22} OSA is likely an independent risk factor for the development of hypertension.²³ Furthermore, when hypertension is present, it is often resistant to antihypertensive therapy. Fatal and nonfatal cardiovascular events are two- to threefold higher in male patients with severe OSA.²⁴ OSA is associated with or aggravates biomarkers for cardiovascular disease, including C-reactive protein and leptin.^{25,26} Patients with sleep apnea often are obese and may be predisposed to weight gain. Hence, obesity may further contribute to cardiovascular disease in this patient population.

Several factors suggest an association between OSA and systemic disease. Breathing against a closed upper airway during sleep causes intermittent and repetitive episodes of hypoxemia and hypercapnia, dramatic changes in intrathoracic pressure, and activation of the sympathetic nervous system. These responses can produce acute hemodynamic and humoral responses. Blood pressure can increase to 220/120 mm Hg with each apneic episode.²⁷ Concentrations of circulating vasoconstrictors, such as endothelin-1 and norepinephrine, are increased during OSA.²⁸ These acute responses to OSA may acutely impair vascular function²⁹ and predispose to and enhance the progression of vascular disease in the longer term.

Parasomnias

The pathogenesis of parasomnias (e.g., sleepwalking, enuresis, sleep talking) is variable and not well described and involves

Patient Encounter, Part 1

MC, a 53-year-old woman with a history of hypertension, depression, and anxiety, comes to your clinic complaining of difficulty initiating sleep, frequent nighttime awakenings, and sleepiness in the daytime. She reports that she falls asleep relatively easily during the day if given a chance. The sleep problems have been gradually worsening over the past weeks and occur nightly. She has been taking sertraline 150 mg/day for anxiety and depression for 4 months.

What sleep disorders do her symptoms suggest?

What additional information do you need to know in your assessment of this patient?

What are some possible contributing factors to MC's sleep complaints?

Clinical Presentation and Diagnosis

Patients with sleep disorders may complain about daytime symptoms. A bed partner may witness hallmark characteristics of the sleep disorder. 2 *Patients with sleep complaints should have a careful sleep history performed to assess their possible sleep disorder in order to guide diagnostic and therapeutic decisions.*

Daytime symptoms and associated characteristics:

EDS is the primary symptom described by patients with sleep disorders. It is usually described as not waking up refreshed in the morning or falling asleep or fighting the urge to sleep during the day despite a night of sleep.

Other daytime characteristics of sleep disorders include:

- Irritability, fatigue, or depression
- Confusion or impaired performance at work or school
- Cataplexy
- Hypertension

Nighttime sleep complaints: Depending on the sleep disorder, patients may exhibit or experience various nocturnal complaints during sleep hours. Some of these complaints can be uncovered by clinical history alone (e.g., hallucinations, RLS, snoring), but others can be diagnosed during sleep studies (e.g., OSA, nighttime awakenings, somnambulism, PLMS, etc.). Frequent complaints include:

- Inability to fall asleep, nighttime awakenings
- Sleep walking (somnambulism), sleep talking (somniloquy)
- Cessation of breathing (apnea), snoring
- Sleep paralysis or hallucinations when waking or falling asleep
- Restlessness (PLMS or RLS)

state dissociation, whereby two states of being overlap simultaneously. For example, abnormal activation of the central pattern generator of the spinal cord that produces motor movements is hypothesized to underlie sleepwalking behavior. In RBD, active inhibition of motor activity in the perilocus coeruleus region is lost, resulting in loss of paralysis and dream enactment.

CLINICAL PRESENTATION AND DIAGNOSIS

3 *Although the clinical history guides diagnosis and therapy, only overnight polysomnography and/or multiple sleep latency tests (MSLTs) can definitively diagnose and guide therapy for OSA, narcolepsy, and periodic limb movements of sleep (PLMS). All patients presenting with sleep complaints should have a thorough inventory of their sleep habits and sleep hygiene investigated during the interview and history taking.*

Insomnia (Difficulty Initiating or Maintaining Sleep)

Insomnia is often characterized by difficulty falling asleep, frequent nocturnal awakenings, early morning awakenings, and nonrestorative sleep, which may result in daytime impairments in concentration and school or work performance. In comorbid (secondary) insomnia, social factors (e.g., family difficulties, bereavement), medications (e.g., antidepressants, β -agonists, corticosteroids, decongestants), and coexisting medical or psychiatric conditions (e.g., depression, bipolar disorder) may help to explain difficulties in initiating and maintaining sleep. Insomnia may be described as transient (less than 1 week), acute (1 to 4 weeks), or chronic (more than 1 month) in duration.

Narcolepsy

The hallmark of narcolepsy is EDS and the need for unwanted episodes of sleep during the day. Patients with narcolepsy may experience repeated nighttime awakenings and terrifying dreams along with difficulty falling asleep. Patients with narcolepsy frequently experience abnormal manifestations of REM sleep, including hallucinations and sleep paralysis that occur on falling asleep and/or awakening. Cataplexy is a weakness or loss of skeletal muscle tone in the jaw, legs, or arms that is elicited by emotion (e.g., anger, surprise, laughter, or sadness).

Obstructive Sleep Apnea

Common characteristics of OSA include snoring, choking, gasping for air, nocturnal reflux symptoms, and morning headaches. A bed partner or roommate may observe these characteristics and witness episodes where the patient stops breathing during sleep. Patients with large neck sizes (more than 45 cm [\sim 18 in] neck circumference) and a body mass index (BMI) of 30 kg/m² or greater are at higher risk for OSA. Hypertension, depression, and hypothyroidism are found frequently in patients with OSA.

Periodic Limb Movements of Sleep and Restless Legs Syndrome

Although RLS symptoms can vary, patients commonly report creepy-crawly, burning, tingling, or achy feelings in the legs or arms. These sensations create a desire to move the limbs and may produce motor restlessness. Symptoms are worse in the evening and are worse or exclusively present at rest, with temporary relief with movement. Symptoms also can occur during sleep and often lead to semirhythmic PLMS. PLMS are objective findings during overnight polysomnography recorded by leg electrodes. PLMS are present in most patients with RLS but can occur independently. PLMS frequently are described by a bed partner as restlessness or repeated kicking of legs or thrashing of the arms during sleep.

Parasomnias

Parasomnias are characterized by undesirable physical or behavioral phenomena that occur during sleep (e.g., sleepwalking,

sleep eating, sleep talking, bruxism [grinding of teeth], enuresis, night terrors, and RBD). People with RBD act out their dreams during sleep, often in a violent manner.

Circadian Rhythm Disorders

The most common circadian rhythm disorders (CRDs) include jet lag, shift-work sleep disruption, delayed sleep-phase disorder, and advanced sleep-phase disorder. Jet lag occurs when a person travels across time zones and the external environmental time is mismatched with the internal circadian clock. Delayed and advanced sleep-phase disorders occur when bed and wake times are delayed or advanced (by 3 or more hours) compared with socially prescribed bed and wake times.

Sleep Diagnostics

Complete overnight polysomnography is the “gold standard” for diagnosing and identifying sleep-disordered breathing, PLMS, parasomnias, and nocturnal sleep irregularities related to narcolepsy. Sleep is observed and monitored in a controlled setting using an EEG, electro-oculography, electromyography, electrocardiography, air thermistors, abdominal and thoracic strain belts, and an oxygen saturation monitor. This setup assesses and records sleep onset, arousals, sleep stages, eye movements, leg and jaw movements, heart rhythm, arrhythmias, airflow during sleep, respiratory effort, and oxygen desaturations.

Evaluations of Daytime Sleepiness

The two most commonly performed objective evaluations to assess daytime sleepiness are the MSLT and the maintenance of wakefulness test (MWT). During the MSLT, the patient attempts to take a 20-minute nap every 2 hours during the day beginning 2 hours after morning awakening (after a normal night’s sleep) to evaluate physiologic sleepiness. The patient is instructed not to resist the urge to fall asleep. **Sleep latency** of less than 5 or 6 minutes is considered pathologically sleepy. The occurrence of a REM onset period during two naps is indicative of a diagnosis of narcolepsy. The MWT is performed to assess the patient’s ability to avoid succumbing to sleepiness (manifest sleepiness). Similar nap opportunities are set up for the MWT, with the exception that the patient is instructed to lie down in bed and attempt to stay awake. A subjective assessment of sleepiness can be obtained using the Epworth Sleepiness Scale (ESS). The ESS is a validated questionnaire that is easy to use and reliably predicts subjective sleepiness. The maximum score is 24, and any patient with a score greater than 10 is considered sleepy.

TREATMENT

4 *Treatment goals vary among different sleep disorders but generally include restoration of normal sleep patterns, elimination of daytime sequelae, improved quality of life, and prevention of complications and adverse effects from therapy.*

Table 41–1

Nonpharmacologic Therapies for Insomnia

Sleep Hygiene

- Keep a regular sleep schedule.
- Exercise frequently but not immediately before bedtime.
- Avoid alcohol and stimulants (caffeine, nicotine) in the late afternoon and evening.
- Maintain a comfortable sleeping environment that is dark, quiet, and free of intrusions.
- Avoid consuming large quantities of food or liquids immediately before bedtime.

Stimulus Control

- Go to bed only when sleepy.
- Avoid daytime naps.
- If you cannot sleep, get out of bed and go to another room—only return to your bed when you feel the need to sleep.
- Bed is for sleep and intimacy only (no eating or watching TV in bed).
- Always wake up at the same time each day.

Relaxation Training

- Reduce somatic arousal (muscle relaxation).
- Reduce mental arousal (e.g., attention-focusing procedures, imagery training, meditation).
- Use biofeedback (visual or auditory feedback to reduce tension).

Cognitive Therapy

- Alter beliefs, attitudes, and expectations about sleep.

- Nonpharmacologic interventions for insomnia are outlined in **Table 41–1**. Sleep hygiene should be reinforced in all patients, and behavioral, cognitive, and stimulus-control interventions are used mainly for patients with insomnia-type complaints. Both pharmacologic and nonpharmacologic therapies are effective at improving sleep and reducing insomnia complaints. An algorithm for the initial assessment and first treatment step of EDS is provided in **Figure 41–1**.

Insomnia

5 *Early treatment of insomnia may prevent the development of persistent psychophysiological insomnia.* The ideal hypnotic drug would be effective at reducing sleep latency and increasing total sleep time and would be free of unwanted side effects. **6** *Benzodiazepine receptor agonists (including traditional benzodiazepines, zolpidem, zaleplon, and eszopiclone) and ramelteon are approved by the Food and Drug Administration (FDA) for the treatment of insomnia and are first-line therapies.^{2,30,31}* Not all products are available in all countries. Pharmacologic treatment of insomnia is recommended for transient and acute insomnia. Long-term use of hypnotics is not contraindicated unless the patient has another contraindication to their use. Eszopiclone is the only sedative hypnotic approved by the FDA for chronic use up to 6 months.³² Although not first-line agents for insomnia, sedating antidepressants are also commonly prescribed.

► Benzodiazepine Receptor Agonists

There are currently eight benzodiazepine receptor agonists (BZDRAs) approved for insomnia, and the pharmacokinetic

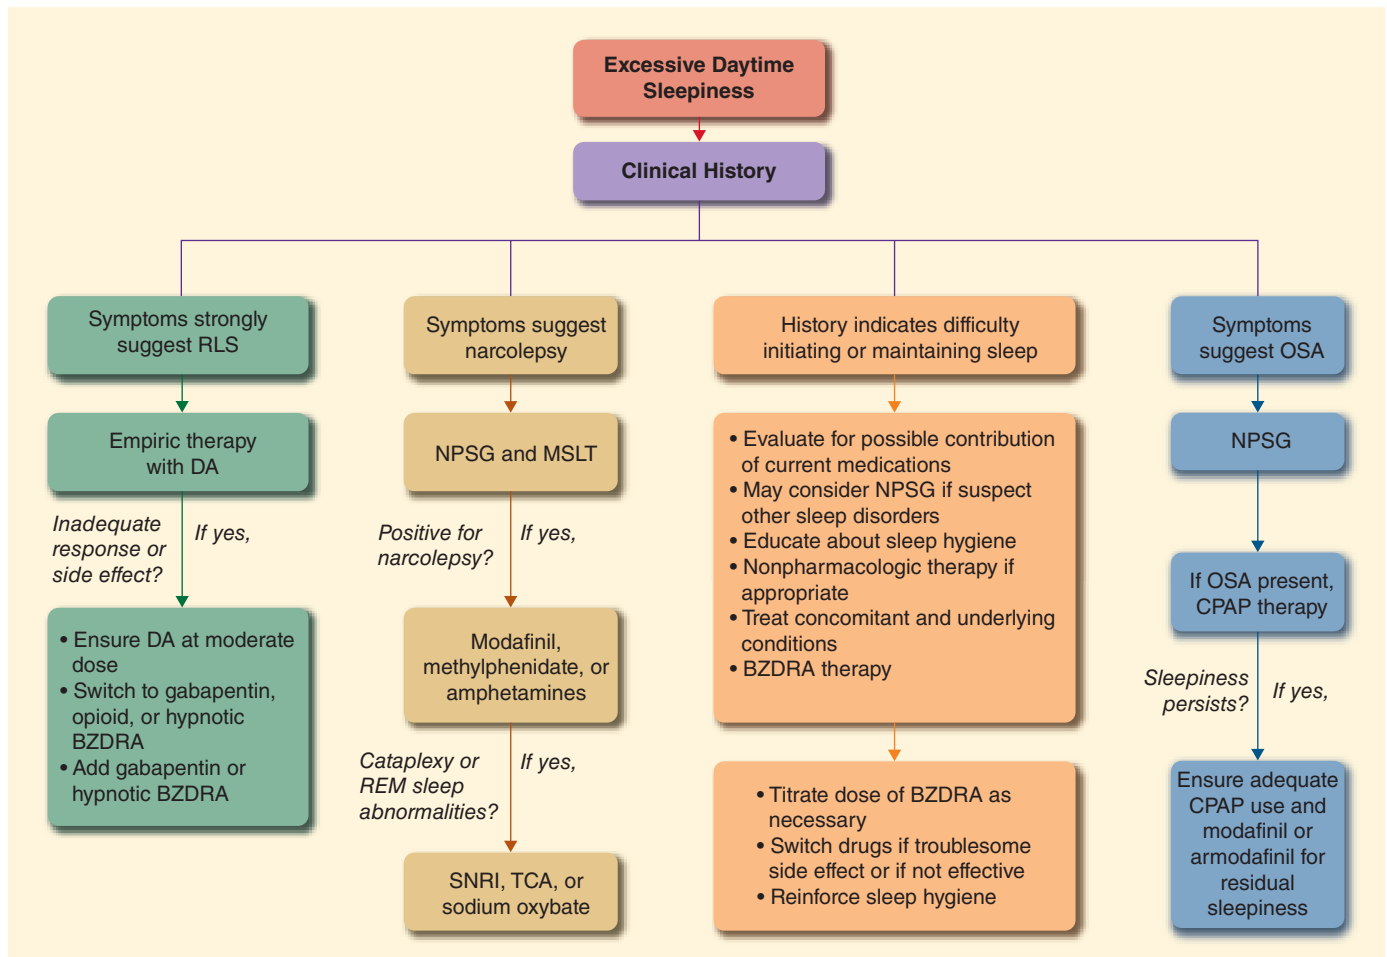

FIGURE 41-1. Primary assessment and initial treatment for complaint of excessive daytime sleepiness. BZDRA, benzodiazepine receptor agonist; CPAP, continuous positive airway pressure; DA, dopamine agonist; MSLT, multiple sleep latency test; OSA, obstructive sleep apnea; RLS, restless legs syndrome; SNRI, serotonin and norepinephrine reuptake inhibitor; NPSG, nocturnal polysomnography; TCA, tricyclic antidepressant.

differences between these agents help to guide selection depending on patient considerations and specific sleep complaints (Table 41-2). These agents occupy the benzodiazepine site on the gamma-aminobutyric acid (GABA) type A receptor complex, resulting in opening of chloride channels that facilitate GABA inhibition and promote sleepiness.³³ BZDRAs have become the first-line agents for treating insomnia and sleep-maintenance problems because they are all efficacious, have wide therapeutic indices, and in clinical use have a low incidence of abuse.^{30,33}

Patients should be instructed to take BZDRAs at bedtime and to avoid engaging in activities requiring alertness after ingestion. Although BZDRAs generally are well tolerated and have good safety profiles, mild to moderate side effects can occur, and precautions are warranted, especially in high-risk populations.

Precautions and Safety The most common side effects associated with BZDRAs include residual sedation (a prolongation of the sedative effects into the waking hours after sleep), grogginess, and psychomotor impairment.³⁴ Careful

selection of a hypnotic agent with a duration of action matching the patient's budgeted sleep time can help minimize the risk of residual sedation. BZDRAs should be initiated at low doses, and agents with active metabolites (see Table 41-2) should be avoided in elderly patients. BZDRAs may cause anterograde amnesia, defined as memory loss of activities and interactions after ingestion of the drug. All sedatives can cause anterograde amnesia, and higher doses increase the extent of amnesia.^{35,36}

On discontinuation of hypnotic BZDRAs, patients may experience rebound effects, specifically rebound insomnia that may last for one to two nights. Rebound insomnia occurs more frequently after discontinuation of shorter duration BZDRAs compared with long-duration BZDRAs. Intermittent hypnotic therapy with the lowest dose possible reduces the likelihood of tolerance, dependence, and withdrawal when therapy is stopped. Patients should be counseled that rebound insomnia is not necessarily a return of their original symptoms, and it may take a few nights for rebound symptoms to subside. In general, eszopiclone, zaleplon, and zolpidem

Table 41-2

Pharmacokinetics and Dosing of Prescription Medications^a Approved to Treat Insomnia

Generic Name	Parent $t_{1/2}$ (hours)	Duration of Action (hours)	Daily Dose Range (mg)	Recommended Daily Dose in Elderly (mg) ^b	Dose or Action in Hepatic Impairment	Comments
Doxepin (Silenor)	15.3	Unpublished ^c	3–6	3	3 mg	Effective for sleep maintenance difficulties only
Estazolam (Prosom)	2	12–15	1–2	0.5	Dose ↓ may be needed	Moderate duration
Eszopiclone (Lunesta)	6	8	2–3	1–2	1 mg in severe impairment	Can be used up to 6 months for chronic insomnia
Flurazepam (Dalmane)	8	10–30	15–30	15	No change necessary	High risk of hangover and residual effects
Quazepam (Doral)	2	25–41	7.5–15	7.5–15	Dose ↓ may be needed	High risk of hangover and residual effects
Ramelteon (Rozerem)	1–2.6	Unpublished ^c	8	No specific recommendations	Do not use in severe hepatic impairment	Noncontrolled substance; may be useful in patients with a history of substance abuse
Temazepam (Restoril)	10–15	7	7.5–30	7.5	No change necessary	Moderate duration, well tolerated, inexpensive
Triazolam (Halcion)	2	6–7	0.125–0.25	0.125	0.125 mg	Short acting; little residual hangover
Zaleplon (Sonata)	1	6	5–10	5	5 mg	Short acting; only for difficulty falling asleep
Zolpidem (Ambien)	2–2.6	6–8	5–10	5	5 mg	Short to moderate duration; no effects on sleep architecture
Zolpidem CR (AmbienCR)	2.8	7–8	6.25–12.5	6.25	6.25 mg	Longer duration of action than regular release zolpidem
Zolpidem sublingual (Intermezzo)	2.5	Less than 4	1.75–3.5	1.75	1.75 mg	Approved for middle-of-the-night insomnia taken more than 4 hours before awakening

^aIn 2007, the Food and Drug Administration required additional information added to the safety labeling of sedative–hypnotic drugs concerning potential risks, including severe allergic reactions and complex sleep-related behaviors, which may include sleep driving. Sleep driving is defined as driving while not fully awake after ingestion of a sedative–hypnotic product with no memory of the event.

^bIf a dosing range is displayed, the first dose listed should be the starting dose.

^cData not available.

appear to be associated with lower risk of tolerance, rebound insomnia, and withdrawal than traditional benzodiazepines.

► Sedating Antidepressants

Sedating antidepressants, including trazodone, amitriptyline, mirtazapine, nefazodone, and doxepin are commonly used for the treatment of insomnia and may be an appealing option for insomnia in patients with concomitant depression. However, at the doses frequently used for sleep, only mirtazapine exhibits significant antidepressant activity. Furthermore, quality clinical studies demonstrating efficacy for treating insomnia are lacking. Side effects from antidepressants can be frequent and often are unpleasant, including carryover sedation, grogginess, anticholinergic effects, and weight gain. Tricyclic antidepressants (TCAs) should be used with

caution in the elderly and patients with cardiovascular and hepatic impairment. Mirtazapine can cause daytime sedation, dizziness, and weight gain, and trazodone can cause hypotension and dizziness and should be used with caution in patients with heart disease or hypertension and those taking cardiovascular agents.^{37,38} Doxepin was recently approved for treatment of sleep maintenance insomnia in low doses (3 to 6 mg).

► Over-the-Counter and Other Miscellaneous Agents

Over-the-counter antihistamines such as diphenhydramine are frequently used (usual doses, 25 to 50 mg) for difficulty sleeping. Diphenhydramine is approved by the FDA for the treatment of insomnia and can be effective at reducing

sleep latency and increasing sleep time.³⁹ However, diphenhydramine produces undesirable anticholinergic effects and carryover sedation that limit its use. As with TCAs and BZDRAs, diphenhydramine should be used with caution in the elderly. Valerian root is an herbal sleep remedy that has inconsistent effects on sleep but may reduce sleep latency and efficiency at commonly used doses of 400 to 900 mg valerian extract. Ramelteon, a melatonin receptor agonist, is indicated for insomnia characterized by difficulty with sleep onset. The recommended dose is 8 mg at bedtime. Ramelteon is not a controlled substance and can be a viable option for patients with a history of substance abuse, and it has documented efficacy treating sleep onset difficulties in those with mild to moderate chronic obstructive pulmonary disease and OSA.⁴⁰⁻⁴²

Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Test

MC undergoes further workup for her sleep complaint, and because she is also at risk for sleep apnea, it is determined she should have an overnight sleep study performed.

PMH: Hypertension × 10 years. Anxiety and depression diagnosed and treated 4 months ago but symptoms present for 1 to 2 years

FH: Father had a history of heart disease and died of a myocardial infarction at age 76 years; mother alive and well with heart disease and years of anxiety treatment

SH: Married, works as an engineer, has never smoked, drinks two or three alcoholic drinks each night

Meds: Sertraline 150 mg taken with dinner; lisinopril 20 mg/day

ROS: (+) daytime sleepiness (Epworth sleepiness score: 13 of 24); (–) symptoms of RLS

PE:

VS: BP 142/74, P 86, RR 18, T 37°C (98.6°F); BMI 29 kg/m²

Mouth: Airway crowded with large tonsils and prominent uvula

Labs: TSH 1.6 μIU/mL (mIU/L)

Overnight polysomnogram: Bedtime at 10 PM; awake at 6 AM. Frequent snoring but very infrequent hypopneas, prolonged sleep latency (75 minutes), frequent awakenings (13), 63 minutes awake after sleep onset. Awakenings occur between 11 PM and 3 AM

- RDI 3 events/h
- No significant leg movements

Given this additional information, summarize the patient's diagnosis.

Identify your treatment goals and recommendations for the patient.

What nonpharmacologic and pharmacologic alternatives are available for this patient if the prescribed therapy is not successful or not tolerated?

Narcolepsy

Therapy for narcolepsy involves two key principles: (a) treatment of EDS with scheduled naps and CNS stimulants and (b) suppression of cataplexy and REM-sleep abnormalities with aminergic signaling drugs. Modafinil (Provigil), armodafinil (Nuvigil), methylphenidate, and amphetamines are effective FDA-approved drugs for the treatment of EDS with narcolepsy.⁴³ Modafinil and armodafinil (the active R-isomer of modafinil) are potentially advantageous in part because they are schedule IV medications in contrast to CNS stimulants, which are schedule II. Modafinil and armodafinil prescriptions are renewable for 6 months, and these drugs may have fewer peripheral and cardiovascular effects than traditional stimulants. Selegiline, a selective monoamine oxidase B enzyme inhibitor, is metabolized to amphetamines and can be successful at reducing daytime sleepiness. In an individual patient, one wake-promoting agent may work better than another, and if the first drug selected is not successful at adequate doses, a trial with another agent should be attempted. **7** *Treatment of EDS in narcolepsy and other sleep disorders may require the use of sustained- and immediate-release stimulants to effectively promote wakefulness throughout the day and at key times that require alertness.* One potential treatment regimen includes a sustained-release preparation first thing in the morning and again at noon followed by an immediate-release preparation as needed in the late afternoon or before driving to maintain wakefulness. One advantage of traditional CNS stimulants over modafinil is their ability to help control cataplexy and REM-sleep abnormalities.

Traditional CNS stimulants have the potential to increase blood pressure and heart rate when used long term. In addition, excessive CNS stimulation can cause tremors and tics and can carry over into evening hours, when initiation of normal nighttime sleep can be disrupted. Caution should be used in patients with underlying cardiovascular or cerebrovascular disease and in patients with a history of seizures because stimulants may lower the seizure threshold.

► Cataplexy

Traditionally, aminergic signaling antidepressants have been used effectively to control symptoms of cataplexy, sleep paralysis, and other REM-sleep manifestations of narcolepsy.⁴³ These include TCAs and certain selective serotonin and serotonin/norepinephrine reuptake inhibitors (SSRIs and SNRIs). Clomipramine, protriptyline, imipramine, venlafaxine, and fluoxetine are the agents that have been used most frequently. In addition, low-dose selegiline may be effective at reducing cataplexy. Although not approved by the FDA for treatment of cataplexy, these drugs effectively suppress REM sleep and have been the mainstay of anticataplectic therapy for years. Sodium oxybate, a potent sedative with a very short duration of action, is FDA approved for the treatment of narcolepsy with cataplexy. The mechanism whereby it reduces sleepiness and cataplexy is not entirely known. Two doses per night are taken, one at bedtime and one follow-up dose taken 2½ to

4 hours later. Sodium oxybate is tightly regulated and is only available from one central pharmacy owing to the high abuse potential of its active ingredient (*γ*-hydroxybutyrate).

Restless Legs Syndrome

8 *RLS treatment involves suppression of abnormal sensations and leg movements and consolidation of sleep. Dopaminergic and sedative-hypnotic medications are prescribed commonly.* In the past few years, dopamine agonists (DAs) have become the therapy of choice for the treatment of RLS, replacing levodopa-carbidopa as first-line agents. The DAs offer many advantages over levodopa-carbidopa, including longer half-lives to cover overnight symptoms, flexible dosing, and a reduced incidence of symptom augmentation. Up to 80% of patients who take levodopa-carbidopa eventually will experience symptom augmentation: RLS symptoms appear earlier in the day, previously unaffected body parts become involved, there is a shorter duration of relief from treatment, and higher doses of medication are required to control symptoms.⁴⁴ Ropinirole (Requip) and pramipexole (Mirapex) are FDA approved for the treatment of RLS and are available in sustained-release products.⁴⁵ Gabapentin is an effective treatment for RLS, particularly in patients with painful symptoms.⁴⁶ A new gabapentin prodrug (gabapentin enacarbil) is now FDA approved for RLS at a recommended dose of 600 mg taken with food at about 5:00 PM.⁴⁷ BZDRAs such as temazepam, clonazepam, zolpidem, and zaleplon

effectively reduce arousals associated with PLMS in patients with RLS.⁴⁸ Their main benefit is derived from improving sleep continuity in patients with RLS, particularly as adjunct treatment with other pharmacologic therapies. Opioids are effective for some patients' RLS symptoms, with oxycodone, hydrocodone, and codeine being used most frequently. For both BZDRAs and opioids, caution should be used in the elderly, in patients who snore and are at risk for sleep apnea, and in patients with a history of substance abuse. Low iron levels frequently exacerbate RLS symptoms. Iron supplementation should be prescribed in patients who are iron deficient. Iron supplementation in patients with serum ferritin concentrations of less than 50 to 75 mcg/L improves RLS symptoms. Medications frequently used for RLS are shown in [Table 41-3](#).

Obstructive Sleep Apnea

9 *The main therapy for OSA is nasal continuous positive airway pressure (CPAP) therapy.* CPAP alleviates sleep-disordered breathing by producing a positive pressure column in the upper airway using room air. The CPAP machine is small enough to be transportable and sits at the bedside. A flexible tube connects the CPAP machine to a mask that covers the nose. During overnight polysomnography, the pressure setting is increased until sleep-disordered breathing is eliminated. CPAP therapy has been shown to have a favorable

Table 41-3

Frequently Used Medications for Restless Legs Syndrome

Generic Name (Brand Name)	Half-Life (hours)	Dose Range (mg/day) ^a	Potential Side Effect or Disadvantage
Dopaminergic Agents^b			
Levodopa-carbidopa (Sinemet)	1.5–2	100–200 of levodopa	Nausea or vomiting; high incidence of symptom augmentation
Pramipexole (Mirapex)	8–12 ^c	0.125–1.5	Nausea or vomiting; risk of compulsive behaviors ^d
Ropinirole (Requip)	6 ^e	0.25–3	Nausea or vomiting; risk of compulsive behaviors ^d
Anticonvulsants			
Gabapentin (Neurontin, Horizant)	5–7 ^c	300–3600	Dizziness, ataxia
Hypnotic Agents			
Clonazepam (Klonopin)	30–40	0.5–2	Tolerance, carryover sedation
Temazepam (Restoril)	10–15	7.5–30	Tolerance, carryover sedation
Zolpidem (Ambien)	2–2.6 ^e	5–10	Tolerance
Zaleplon (Sonata)	1 ^e	5–10	Tolerance; may not last entire night
Opioids			
Hydrocodone	3.8–4.5 ^e	5–10	Constipation, nausea, sedation
Codeine	2.5–3.5 ^e	30–60	Constipation, nausea, sedation
Methadone	22 ^e	5–20	Constipation, nausea, sedation
Oxycodone	3.2–12 ^e	5–30	Constipation, nausea, sedation

^aUsual range; all medications (other than dopaminergic agents) are dosed at bedtime.

^bDopaminergic agents are frequently given at bedtime or 2 hours before bedtime or the anticipated onset of RLS symptoms.

^cMay be longer in patients with renal dysfunction.

^dCompulsive behaviors such as gambling, shopping, sexual behaviors, and eating have been reported in patients taking dopamine agonists.

^eMay be longer in patients with hepatic dysfunction.

Data from Earley CJ. Restless legs syndrome. *N Engl J Med* 2003;348:2103–2109.

impact on blood pressure and to attenuate some of the potential hemodynamic and neurohumoral responses that may link OSA to systemic disease.

Not all individuals tolerate CPAP therapy in part because it requires wearing a mask during sleep, and therapy can dry and irritate the upper airway. In some individuals, these barriers for adherence may be lessened or eliminated by properly fitting the mask, adding humidity or heat to therapy, or using bilevel positive airway pressure (BiPAP) therapy. BiPAP therapy applies a variable pressure into the airway during the inspiratory phase of respiration but, unlike CPAP, reduces the applied pressure during the expiratory phase of respiration.

There are other therapies for OSA. Obesity can worsen sleep apnea, and weight management should be implemented for all overweight patients with OSA. In obese patients with mild OSA, weight loss alone can be effective, and studies have reported improvement in the severity of OSA with gastric stapling. For patients who cannot tolerate CPAP, oral appliances can be used to advance the lower jawbone and to keep the tongue forward to enlarge the upper airway. For individuals who have OSA only during certain positions (e.g., when on their backs) during sleep, positional therapies may be effective. Surgical therapy (uvulopalatopharyngoplasty) opens the upper airway by removing the tonsils, trimming and reorienting the posterior and anterior tonsillar pillars, and removing the uvula and posterior portion of the palate. This is not a first-line option because of its invasiveness. In very severe cases, tracheostomy may be necessary. This procedure may be indicated in selected individuals who are morbidly obese, have severe facial skeletal deformity, experience severe drops in oxygen saturation (e.g., SpO_2 less than 70% [0.70]), or have significant cardiac arrhythmias associated with their OSA.

There is no drug therapy for OSA. Drug therapy for symptoms of OSA may be considered in selected patients. Modafinil and armodafinil are wake-promoting medications that are approved by the FDA to treat residual daytime sleepiness despite CPAP therapy. Initiation of these medications should be attempted only after patients are using optimal CPAP therapy to alleviate sleep-disordered breathing. The need for treating residual sleepiness in this population is not clear because it may not be related to the OSA and is similar to sleepiness in the general population.⁴⁹ Untreated or inadequately treated sleep apnea hinders achieving blood pressure control in hypertensive patients. OSA should always be considered and evaluated in hypertensive patients who are resistant to therapy.

Parasomnias

Non-REM parasomnias usually do not require treatment. If needed, low-dose BZDRAs such as clonazepam can be prescribed for bothersome episodes. Clonazepam reduces the amount of sleep time spent in stages 3 and 4 of non-REM sleep, when most non-REM parasomnias occur. For treating RBD, clonazepam 0.5 to 2 mg at bedtime is the drug of choice, although melatonin 3 to 12 mg at bedtime also may be effective.

Patients with RBD also should have dangerous objects removed from the bedroom and cushions placed on the floor to reduce the chance of injury from breakthrough episodes.

Circadian Rhythm Disorders

Melatonin at doses of 0.5 to 5 mg taken at appropriate target bedtimes for east or west travel is becoming the drug of choice for jet lag. Melatonin significantly reduces jet lag and shortens sleep latency in travelers.⁵⁰ Hypnotic agents with relatively short durations of action (3 to 5 hours) may also be used to sustain sleep during the initial adaptation to the new time zone.

Drug–Disease and Drug–Drug Interactions

10 *It is important to review patient medication profiles for drugs that may aggravate sleep disorders. Patients should be monitored for adverse drug reactions and potential drug–drug interactions. They should be assessed for adherence to their therapeutic regimens.* Pharmacotherapy for sleep disorders should be individualized. Medications can be used commonly to treat several concomitant sleep disorders. Conversely, drug therapy may be effective for one sleep disorder and exacerbate another. For example, antidepressants may alleviate depressive symptoms but exacerbate the symptoms of RLS. Medications that block dopaminergic transmission may worsen RLS symptoms. Smoking can worsen OSA, presumably by increasing upper airway edema. Alcohol and CNS depressants, including opiate analgesics, sedatives, and muscle relaxants, can worsen OSA, even in small doses, by reducing respiratory drive and relaxing the upper airway muscles responsible for maintaining patency. CNS depressants should be avoided, and if they are necessary, they should not be administered before sleep. Drug therapy for sleep disorders should be patient specific, and careful consideration

Patient Encounter, Part 3: Modifying the Treatment Plan

MC returns to the clinic 3 months later. The physician previously diagnosed her with sleep initiation and sleep maintenance insomnia. She received a prescription for temazepam 15 mg taken at bedtime and was instructed to take sertraline in the morning instead of evening. She reports today that the temazepam helps her sleep, but she feels groggy and hungover in the morning. Her Epworth Sleepiness Scale score today is 10 of 24.

Based on the information presented, recommend therapy suggestions for the patient.

What medications would you not want to use for MC's sleep issues?

What precautions would you want to counsel the patient on about her therapy?

Patient Care and Monitoring

Insomnia

1. Ideally limit hypnotic therapy to short-term use, and reevaluate after 2 to 3 weeks of therapy.
2. Evaluate improvement in the specific sleep complaint (e.g., how has therapy affected sleep latency or sleep maintenance?).
3. Inquire about carryover sedation and other side effects associated with the selected agent. Use a lower dose, or select a drug with a shorter duration of action if the patient experiences carryover sedation.
4. Address other psychiatric and medical conditions that frequently coexist with insomnia and medications which can worsen symptoms.

Narcolepsy

1. Administer the ESS at each visit to monitor progress with modafinil or stimulant therapy. Unfortunately, EDS in narcolepsy patients rarely is fully reversed.
2. Evaluate how sleepiness changes throughout the day to best determine how to use sustained- and immediate-release stimulants to maintain wakefulness. If the patient complains of sleep disruption from stimulant therapy, move the dosing time a few hours earlier until sleep disruption is avoided.
3. Review the patient's sleep diaries to track the number of cataplexy, sleep paralysis, and hallucinatory events and when they occur.

RLS

1. Carefully assess both the patient's and bed partner's reports of the patient's nighttime limb movements.
2. Measure sleepiness (via ESS) and RLS symptoms at each visit to track progress with therapy.

3. Evaluate potential side effects of therapy, including nausea, drowsiness, sleep attacks, compulsive behaviors, and headaches for the DA agents.
4. Review the sleep diaries and timing of RLS symptoms to screen for possible symptom augmentation.
5. If symptoms are not resolved, increase the dose of DA agent or add another agent such as gabapentin or a short- to moderate-duration sedative-hypnotic.

OSA

1. Evaluate CPAP therapy annually or at any time individuals experience symptoms (e.g., daytime sleepiness) despite CPAP therapy. For example, a change in pressure settings to alleviate OSA may be needed if weight gain occurs.
2. Monitor compliance with CPAP therapy. CPAP machines have a built-in compliance meter to measure the hours used at effective pressure. Patients should use CPAP therapy for at least 5 hours each night. In addition to alleviating sleep-disordered breathing, CPAP therapy may improve cardiovascular outcomes.

Parasomnias

1. Ask patients and family members about any bothersome or dangerous sleepwalking episodes since the last visit and if therapy has reduced the frequency of these events.
2. For RBD, review the sleep diaries and interview bed partners to determine the number and nature of episodes.
3. Inquire about carryover sedation and anterograde amnesia from therapy.

should be given to coexisting diseases, concomitant medications, and potential drug–drug and drug–disease interactions to optimize patient care and treatment.

OUTCOME EVALUATION

To determine the success of treatment, evaluate whether the treatment plan restored normal sleep patterns, reduced daytime sequelae, and improved quality of life without causing adverse effects. Schedule patients for follow-up within 3 weeks for insomnia and within 3 months for other sleep disorders. Perform a detailed clinical history to determine the patient's perception of treatment progress and symptoms along with medication effectiveness and side effects.

Instruct patients to keep sleep diaries of nightly sleep (number of hours, number of awakenings, and worsening or improved sleep) and daytime symptoms, along with documentation of episodes such as cataplexy or RBD. Increase

medication to effective doses, and if necessary, start additional therapy to control symptoms. Patients with sleep disorders should experience relief of symptoms the first night of drug therapy but may not receive maximal benefit (effect on daytime symptoms) for a few weeks. Perform a detailed history of prescription, nonprescription, and complementary or alternative medications and review the patient's sleep diary, daytime symptoms, and nonpharmacologic therapies on a regular basis.

Abbreviations Introduced in This Chapter

BiPAP	Bilevel positive airway pressure
BMI	Body mass index
BZDRA	Benzodiazepine receptor agonist
CNS	Central nervous system
CPAP	Continuous positive airway pressure

CRD	Circadian rhythm disorder
DA	Dopamine agonist
EDS	Excessive daytime sleepiness
ESS	Epworth Sleepiness Scale
GABA	γ -Aminobutyric acid
MSLT	Multiple sleep latency test
MWT	Maintenance of wakefulness test
NPSG	Nocturnal polysomnography
NREM	Non-rapid eye movement
OSA	Obstructive sleep apnea
PLMS	Periodic limb movements of sleep
RBD	REM-sleep behavior disorder
RDI	Respiratory disturbance index
RLS	Restless legs syndrome
REM	Rapid eye movement
SNRI	Serotonin/norepinephrine reuptake inhibitor
TCA	Tricyclic antidepressant

Attention-Deficit Hyperactivity Disorder

Kevin W. Cleveland and John Erramouspe

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Explain accepted criteria necessary for the diagnosis of attention-deficit hyperactivity disorder (ADHD).
2. Recommend a therapeutic plan, including initial doses, dosage forms, and monitoring parameters, for a patient with ADHD.
3. Differentiate among the available pharmacotherapy used for ADHD with respect to pharmacology and pharmaceutical formulation.
4. Recommend second-line and/or adjunctive agents that can be effective alternatives in the treatment of ADHD when stimulant therapy is less than adequate.
5. Address potential cost–benefit issues associated with pharmacotherapy of ADHD.
6. Recommend strategies for minimizing adverse effects of ADHD medications.

KEY CONCEPTS

- 1 To meet current attention-deficit hyperactivity disorder (ADHD) diagnostic criteria, patients need to display hyperactivity, impulsivity, and/or inattentiveness before 7 years of age.
- 2 The exact cause of ADHD is unknown, but dysfunction in **neurotransmitters** norepinephrine and dopamine has been implicated as a key component.
- 3 ADHD is rarely encountered without comorbid conditions.
- 4 Treatment goals for ADHD are to improve behavior, increase attention or **response inhibition**, and minimize side effects associated with pharmacotherapy.
- 5 Pharmacotherapy is superior to behavioral therapy in the treatment of ADHD, but both should be emphasized in order to maximize outcomes.
- 6 **Stimulants** are first-line agents for the treatment of ADHD. If the initial trial of a stimulant fails, then a trial of an alternative stimulant should be tried. On failure of the second stimulant, it is rational to attempt a third trial with a different stimulant formulation or select a nonstimulant agent such as bupropion, atomoxetine, guanfacine, or clonidine.

ADHD is characterized by a core triad of symptoms: hyperactivity, impulsivity, and inattention. It can have a severe impact on a patient's ability to function

in both academic and social environments. Early diagnosis and appropriate treatment are essential to compensate for areas of deficit.

EPIDEMIOLOGY AND ETIOLOGY

1 *This disorder usually begins by 3 years of age but must occur before 7 years of age to meet current diagnostic criteria.* In the United States, ADHD is the most common neurobehavioral disorder that affects children.^{1–4} ADHD has been estimated to occur in 4.3% to 12% of school-aged children.^{4,5} ADHD occurs more in boys than girls by a factor of approximately 3:1 in school-aged children.⁶

Although ADHD generally is considered a childhood disorder, symptoms can persist into adolescence and adulthood. The prevalence of adult ADHD is estimated to be 4%; however, 60% of adults with ADHD have symptoms that manifested in childhood.^{6,7} Furthermore, problems associated with ADHD (e.g., social, marital, academic, career, anxiety, depression, smoking, and substance abuse problems) increase with the transition of patients into adulthood.

PATHOPHYSIOLOGY

2 *The exact pathologic cause of ADHD has not been identified.* ADHD is generally thought of as a disorder of self-regulation or response inhibition. Patients who meet the criteria for ADHD have difficulty maintaining self-control, resisting

distractions, and concentrating on ideas.^{4,8} Furthermore, children with ADHD often alternate between inattentiveness to monotonous tasks and overexcitement. Multiple brain studies have failed to elucidate any pathophysiological basis for ADHD.

2 *Dysfunction of the neurotransmitters norepinephrine and dopamine is thought to be key in the pathology of ADHD.* Whereas norepinephrine is responsible for maintaining alertness and attention, dopamine is responsible for regulating learning, motivation, goal setting, and memory. Both of these neurotransmitters predominate in the frontal subcortical system, an area of the brain responsible for maintaining attention and memory. Genetics appears to play a role because a child who has a parent with ADHD has a 50% chance of developing ADHD. An association has been made between the development of ADHD and fetal alcohol syndrome, lead poisoning, maternal smoking, and hypoxia.^{4,8}

CLINICAL PRESENTATION AND DIAGNOSIS

3 *ADHD is rarely encountered without comorbid conditions and often is undiagnosed.* Between 50% and 60% of patients with ADHD will have one or more comorbidities (e.g., learning disabilities, oppositional defiant, conduct, anxiety, or depressive disorders).² It is important to identify coexisting conditions in patients with ADHD and to select appropriate treatment.

According to newer diagnostic and treatment guidelines, all patients 4 to 18 years of age presenting with inattention, hyperactivity, impulsivity, academic, and/or behavioral problems should be evaluated for ADHD. Additional information about behavior in various settings should be gathered from the patient, family, and teachers or supervisors. The age of onset, frequency, severity, and duration of symptoms should be documented.^{9,10}

The most useful diagnostic criteria for ADHD is the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision (*DSM-IV-TR*) (**Table 42-1**).¹⁰ The *DSM-IV-TR* defines three subtypes of ADHD: (a) predominantly inattentive; (b) predominantly hyperactive or impulsive; and (c) combined, in which both inattentive and hyperactive or impulsive symptoms are evident.¹¹ Neuroimaging, electroencephalograms, and continuous performance examinations are investigational and not used clinically for diagnosis. It is recommended that parents and teachers complete a standardized rating scale based on the *DSM-IV-TR* criteria that measures various behaviors of ADHD.¹² These rating scales do not by themselves diagnose ADHD but are diagnostic aids when added to a careful history and interview.¹²

Although ADHD is considered a childhood disorder, signs and symptoms persist into adolescence in 40% to 80% of cases and into adulthood in approximately 60% of cases.^{1,7} Adult ADHD is difficult to assess, and diagnosis is always suspect in patients failing to display clear symptoms before 7 years of age.⁹ Untreated adults with ADHD have

Table 42-1

DSM-IV-TR Diagnostic Criteria for ADHD

- I. Either A or B:
 - A. *Inattention.* Must have at least six or more of the following symptoms of inattention for at least 6 months:
 1. Does not pay close attention to details in schoolwork, work, or other activities
 2. Has trouble maintaining attention to tasks or activities
 3. Has trouble actively listening when directly spoken to
 4. Has difficulty following instructions and fails to finish important daily tasks (i.e., homework, chores, and responsibilities at work)
 5. Demonstrates difficulty in organizing tasks or activities
 6. Tends to avoid or put off activities that require concentration
 7. Tends to misplace items needed to complete tasks or activities
 8. Is easily distracted from current tasks or activities
 9. Forgetful
 - B. *Hyperactivity or impulsivity.* Must have at least six or more of the following symptoms of hyperactivity or impulsivity for at least 6 months:

Hyperactivity

 1. Fidgets and is restless in a sitting position
 2. Cannot sit still for extended periods
 3. Runs around when it is not appropriate
 4. Cannot play quietly
 5. Often "on the move"
 6. Talks excessively

Impulsivity

 1. Answers questions prematurely
 2. Has difficulty waiting one's turn
 3. Interruptive or intrudes on others
 - II. Above symptoms were present before 7 years of age
 - III. Above symptoms are present in two or more settings
 - IV. Impairment is clearly evident in social, school, or work functioning
 - V. Symptoms cannot be attributed to another mental disorder (e.g., anxiety, depression, autism, or a personality disorder)
- Based on the above criteria, ADHD can be divided into three types:*
1. ADHD combined type: Both 1A and 1B
 2. ADHD inattentive type: 1A criteria are met
 3. ADHD hyperactive-impulsive type: 1B criteria are met

From American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 4th ed, text rev. Washington, DC: American Psychiatric Press; 2000:39–134; With permission.

higher rates of psychopathology, substance abuse, social dysfunction, and occupational underachievement than adults without ADHD.

TREATMENT

Desired Outcomes

4 *The primary therapeutic objectives in ADHD are to improve behavior and increase attention or response inhibition; secondary goals of treatment are to:*

- Improve relationships with family, teachers, and peers
- Decrease disruptive behavior in academic and social settings
- Improve academic performance

Clinical Presentation and Diagnosis of ADHD

General

Patients with ADHD can present with inattention, hyperactivity–impulsivity, or both. ADHD is rarely encountered without comorbid conditions.

Symptoms

- Inattention; difficulty paying attention to details in school, work, and social activities; difficulty completing tasks that require a lot of mental effort; easily distracted; forgetful
- Hyperactivity–impulsivity; difficulty sitting still, fidgets; has trouble playing quietly and waiting turns; frequently interrupts
- Combined; exhibits both inattention and hyperactivity–impulsivity

Diagnostic Criteria

- Must exhibit symptoms before 7 years of age that persist for at least 6 months
- Symptoms must be present in two or more settings and adversely affect functioning in social situations, school, or work
- Must meet the diagnostic criteria in *DSM-IV-TR* (Table 41–1)
- Symptoms cannot be better explained by another mental disorder (e.g., autism)

- Increase independence in activities
- Minimize undesirable adverse effects of therapy

Nonpharmacologic (Behavioral) Therapy

Behavioral therapy can be used to treat patients with ADHD; however, it is generally not recommended as first-line monotherapy except in preschool-aged children (4 to 5 years of age).^{6,10} **5** *Several studies have demonstrated that treatment with medication alone is superior to behavioral intervention alone in improving attention. However, behavioral therapy in combination with stimulant therapy is better at improving oppositional and aggressive behaviors.*¹³ Behavioral modification involves training parents, teachers, and caregivers to change the physical and social environment and establish a reward or consequence system.^{9,10} Success of behavioral modifications depends on the cooperation and involvement of the patient's parents and teachers.

Pharmacologic Therapy

The proposed mechanism of ADHD pharmacotherapy is to modulate neurotransmitter function in order to improve academic and social functioning. Pharmacologic

Patient Encounter, Part 1

The parents and their high-spirited 8-year-old boy, HA, come to your clinic. The parents are concerned because his teacher has complained about problems he is causing in her classroom. HA has difficulty finishing his classroom work, frequently disrupts his neighbor to talk, and has sudden outbursts during lessons. During recess, HA refuses to wait for his turn in games and frequently pushes others to get his way. Also, HA is not completing his homework on time. His first grade teacher also documented these problems, but the parents were told he would “grow out” of his behavior. In the after-school program, HA cannot pay attention during math tutoring. This is very distressing to HA's parents, who are barely providing for their family; the father is a full-time student, and the mother works at the local grocery store for minimum wage. They do not qualify for medical assistance. They cannot afford a more structured professional care for HA other than the free after-school program.

Which of the patient's symptoms are suggestive of ADHD?

What other comorbid conditions should the child be evaluated for before starting therapy for ADHD?

What other information do you need to assess for ADHD?

What help or suggestions could you offer to HA's parents?

therapy can be divided into two categories, stimulants and nonstimulants. Stimulant medications include methylphenidate, dexamethylphenidate, dextroamphetamine–amphetamine (amphetamine salts), dextroamphetamine and lisdexamfetamine, and nonstimulant medications include atomoxetine, bupropion, clonidine, and guanfacine.

► Stimulants

6 *Psychostimulants (e.g., methylphenidate and dextroamphetamine with or without amphetamine) are the most effective agents in treating ADHD. Once the diagnosis of ADHD has been made, a stimulant medication should be considered first-line in treating ADHD in patients 6 years of age or older (Fig. 42–1).* In preschool-aged children, methylphenidate can be added to the patient's treatment if behavioral modification monotherapy is not sufficient in managing ADHD symptoms.¹⁰ Stimulants are safe and effective and have a response rate of 70% to 90% in patients with ADHD.^{3,9,14} Generally, a trial of at least 3 months on a stimulant is appropriate, and this includes dose titration to response while balancing side effects.^{7,9} **6** *If treatment with the first stimulant formulation fails, it is recommended to switch to a different stimulant formulation.*^{9,10} For example, if the patient was started on methylphenidate but could not tolerate the side effects, switching to dextroamphetamine with or without amphetamine is appropriate. The majority of patients who fail one stimulant will respond to an alternative

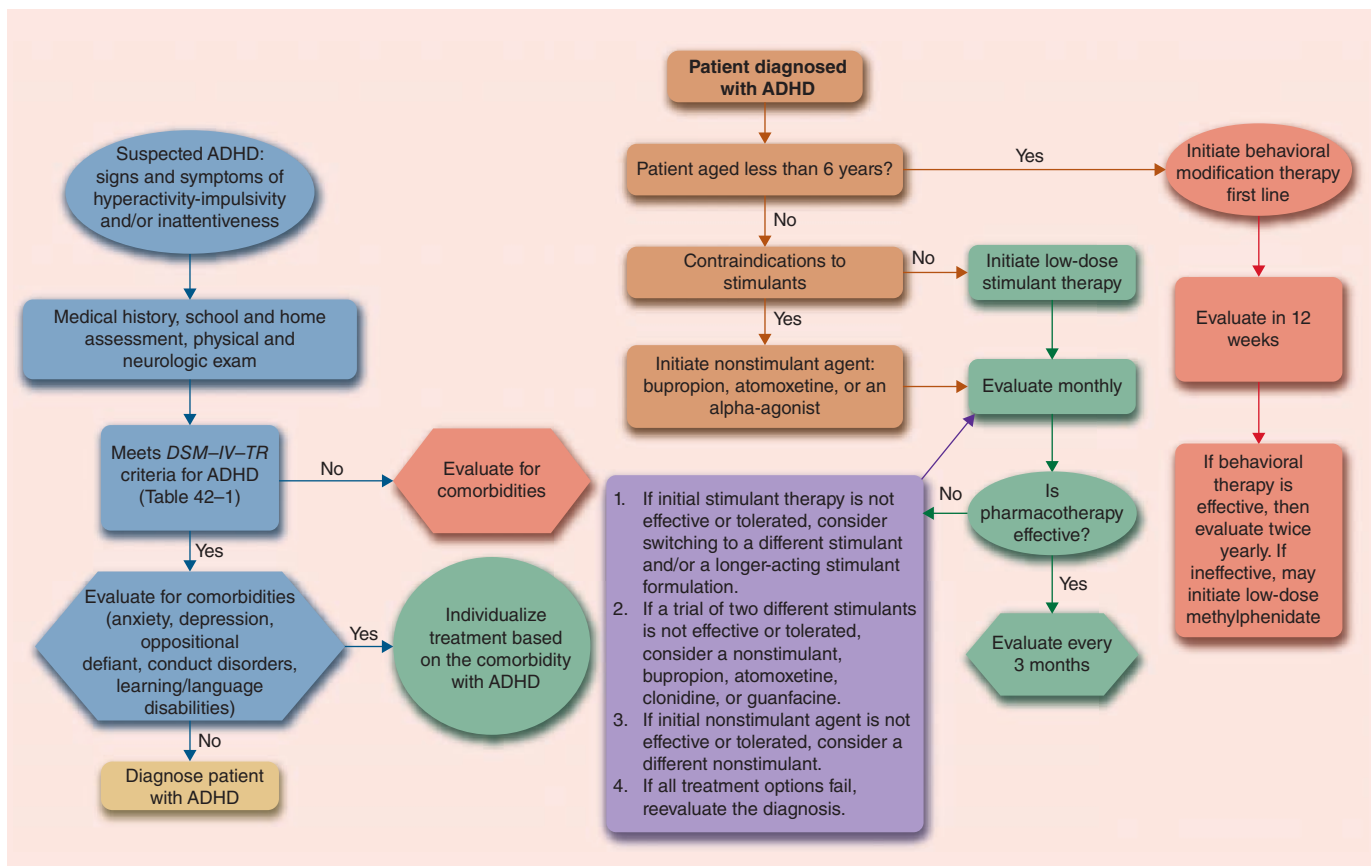

FIGURE 42-1. ADHD diagnosis and treatment algorithm. (Data from Refs. 6, 9, 10, and 16.)

stimulant.^{9,10} **6** *If the patient fails two appropriate trials of different stimulant medications, a third stimulant formulation or second-line nonstimulant such as bupropion, atomoxetine, guanfacine, or clonidine can be considered.* The diagnosis of ADHD should be revalidated as well.

Stimulants theoretically exert their primary effect by blocking the reuptake of dopamine and norepinephrine. Stimulants have been shown to decrease fidgeting and finger tapping, increase on-task classroom behavior and positive interactions at home and in social environments, and ameliorate conduct and anxiety disorders.¹⁴

Stimulants should be initiated at recommended starting doses and titrated up with a consistent dosing schedule to the appropriate response while minimizing side effects (Table 42-2). Generally, stimulants should not be used in patients who have glaucoma, severe hypertension or cardiovascular disease, hyperthyroidism, severe anxiety, or previous illicit or stimulant drug abuse. Furthermore, stimulants can be used, albeit cautiously, in patients with seizure disorders, Tourette's syndrome, and **motor tics**.¹⁴

Stimulant drug formulations can be divided into short-, intermediate-, and extended-acting preparations (Table 42-2). Initial response to short-acting stimulant formulations (e.g., methylphenidate and dextroamphetamine) is seen within 30 minutes and can last for 4 to 6 hours.^{9,10,14} This short duration of effect frequently requires that short-acting stimulant formulations be dosed at least twice daily, thus

increasing the chance of missed doses and noncompliance. Furthermore, patients using any stimulant formulation, but especially short-acting formulations, can experience a **rebound effect** of ADHD symptoms as the stimulant wears off.¹⁴

- Most intermediate-acting stimulants release the medication in a slow, continuous fashion without any early release (except Dexedrine Spansules). The onset of action for this category of stimulants (typically 60 to 90 minutes) may be inadequate for some patients. Some practitioners prescribe a short-acting stimulant concurrently with an intermediate-acting stimulant to curtail the delay in onset of action of the intermediate-acting stimulant. However, this practice can increase copay costs to the patient.

- To minimize rebound problems associated with short-acting formulations and still maintain early stimulant release, extended-acting formulations with rapid onsets have been developed. These formulations have an early release of medication and deliver a delayed release of stimulant in either a pulsed (Adderall XR, Focalin XR, Metadate CD, and Ritalin LA) or continuous manner (Concerta). Formulations available as capsules contain coated beads that can be opened and sprinkled on semisolid food. Concerta tablets have an immediate-release overcoat and an oral osmotic controlled-release that delivers methylphenidate in an extended manner. Furthermore, patients should be counseled that the empty tablet shell of Concerta can be detected in the stool.

Table 42-2

Selected Medications for ADHD^a

Drug, Generic (Brand Name)	Initial Dose	Titration Schedule Increments	Typical Dosing Range (Maximum Dose)
Stimulants			
<i>Short Acting</i>			
Methylphenidate ^b (Methylin, Ritalin)	5 mg 2 × daily	5–10 mg/day in weekly intervals	5–20 mg 2–3 × daily (60 mg/day)
Dexmethylphenidate ^b (Focalin)	2.5 mg 2 × daily	2.5–5 mg/day in weekly intervals	5–10 mg twice daily (20 mg/day)
Dextroamphetamine ^b (Dexedrine)	2.5–5 mg every morning	2.5–5 mg/day in weekly intervals	5–20 mg twice daily (40 mg/day)
<i>Intermediate Acting</i>			
Methylphenidate ^b (Ritalin SR, Metadate ER, Methylin ER)	10 mg once daily	10 mg/day in weekly intervals	20–40 mg daily in the morning (60 mg/day)
Dextroamphetamine–amphetamine ^b (Adderall)	2.5–5 mg once to twice daily	2.5–5 mg/day in weekly intervals	10–30 mg every morning or 5–20 mg twice daily (40 mg/day)
Dextroamphetamine ^b (Dexedrine Spansule)	5 mg every morning	5 mg/day in weekly intervals	5–30 mg daily or 5–15 mg twice daily (40 mg/day)
<i>Extended Acting</i>			
Methylphenidate ^b (Concerta)	18 mg every morning	9–18 mg/day in weekly intervals	18–54 mg every morning (54 mg/day in children)
(Metadate CD)	20 mg every morning	10–20 mg/day in weekly intervals	20–40 mg daily in the morning (60 mg/day)
(Ritalin LA)	20 mg every morning	10 mg/day in weekly intervals	20–40 mg daily in the morning (60 mg/day)
Dextroamphetamine/amphetamine ^b (Adderall XR)	5–10 mg every morning (children); 20 mg once daily (adults)	5–10 mg/day in weekly intervals	10–30 mg every morning or 5–15 mg twice daily (30 mg/day, children) (60 mg/day, adult)
Dexmethylphenidate ^b (Focalin XR)	5 mg every morning (children); 10 mg every morning (adults)	5 mg/day in weekly intervals	10–20 mg daily in the morning (20 mg/day)
Lisdexamfetamine ^b (Vyvanse)	30 mg every morning (children and adults)	10–20 mg/day in weekly intervals	30–70 mg daily in the morning (70 mg/day)
Nonstimulants			
Atomoxetine ^{b,c} (Strattera)	Less than or equal to 70 kg: 0.5 mg/kg/day divided once to twice daily Greater than 70 kg: 40 mg once daily	To target dose of 1.2 mg/kg/day after 3 days 40 mg/day after 3 days (may ↑ to total of 100 mg/day after 2–3 weeks)	40–60 mg/day (1.4 mg/kg or 100 mg/day, whichever is less) 40–80 mg/day divided once to twice daily (100 mg/day)
Clonidine (Catapres)	0.05 mg once daily	0.05 mg/day every 3–7 days	0.1 mg 1 to 4 times daily (0.4 mg/day)
(Kapvay) ^b	0.1 mg at bedtime	0.1 mg/day in weekly intervals	0.1–0.2 mg twice daily (0.4 mg/day)
Guanfacine (Tenex)	0.5 mg at bedtime	0.5 mg every 3–14 days	1.5–3 mg/day divided into 2–3 × daily (4 mg/day)
(Intuniv) ^b	1 mg once daily	No more than 1 mg/week	1–4 mg daily (4 mg/day)
Bupropion (Wellbutrin, Wellbutrin SR, Wellbutrin XL)	3 mg/kg/day for 7 days (children); 150 mg once daily of SR or XL (adults)	3 mg/kg/day in weekly intervals (children); increase 150–300 mg/day in weekly intervals (adults)	6 mg/kg/day or 400 mg/day—whichever is smaller (children); 150–450 mg/day (400 mg/day SR; 450 mg/day XL—adults)

^aPediatric dosing except when adult dosing specified.

^bApproved by the U.S. Food and Drug Administration for the treatment of ADHD.

^cDose adjustment required in patients with hepatic insufficiency.

CD, extended release (biphasic immediate release with extended release); ER, extended release; LA, long acting; SR, sustained release; XL, extended release.

Two extended-acting stimulants, Daytrana and Vyvanse, have slower onsets of action than the other extended-acting stimulants with a rapid release. Daytrana transdermal patches are to be applied for only 9 hours per day and have a delayed onset of 2 hours, and their effects persist for 3 hours

after being removed. Skin sensitization and irritation have been reported in some patients. Vyvanse is a prodrug that is hydrolyzed to its active form, dextroamphetamine, after oral ingestion. Inhalation or injection abuse potential is minimized because of impeded hydrolysis by these routes.

Onset of action for Vyvanse has been reported as soon as 2 hours.¹⁵

Adverse effects of stimulants can be generalized to the whole class (Table 42-3). Most of these side effects can be managed by changing the dosing routine (i.e., giving with food, dividing daily dose, or giving the dose earlier in the day). Serious side effects such as hallucinations and abnormal movements require discontinuation of medication.^{9,10,14} To avoid potential drug–food interactions and absorption issues, stimulants should be given 30 to 60 minutes before eating.

Growth suppression or delay is a major concern for parents of children taking stimulants. However, the evidence of this side effect is not clear. At present, growth delay appears to be transient and to resolve by midadolescence, but more data are needed to firmly resolve this issue. Another concern is the risk of substance abuse with stimulant use. A diagnosis of ADHD alone increases the risk of substance abuse in adolescents and adults. However, stimulant use has not been shown to further increase this risk but actually may decrease this risk, provided ADHD is treated adequately.¹⁶

Table 42-3

ADHD Medication Side-Effect Profiles, Management, and Monitoring

Drug	Side Effects	Management	Monitoring
Stimulants			
Methylphenidate, dextroamphetamine, dextroamphetamine–amphetamine (mixed-salts amphetamine, dexamethylphenidate, lisdexamfetamine)	GI upset, nausea, decreased appetite, potential growth delay Sleep disturbance Rebound symptoms Moodiness Irritability Increased blood pressure and pulse Tics	Administer after meals Encourage high-calorie meals Divide dose Give snacks in the evening Change to shorter acting stimulant Use drug holiday or different medication if severe growth delay Move dose(s) earlier in the day and discontinue later day dose if problem persists Give clonidine or guanfacine at bedtime Change to a shorter acting stimulant Change to longer acting stimulant Overlap stimulant dosing Decrease dose or change to longer acting stimulant Verify diagnosis and comorbidity Evaluate time of occurrence Early onset: Decrease dose or change to longer acting stimulant Late onset: Switch to longer acting stimulant Evaluate for comorbidity Decrease dose or change to longer acting stimulant Discontinue or change to a different stimulant Give clonidine or guanfacine	Height, weight, blood pressure, pulse ECG if warranted Eating and sleeping patterns Evaluate every 2–4 weeks until stable dose is achieved; then evaluate every 3 months
Nonstimulants			
Atomoxetine	Increased blood pressure and pulse, nausea, vomiting, fatigue, and insomnia Hepatotoxicity, suicidal thoughts	Decrease dose or change to another medication Discontinue or change to a another medication	Same as stimulants but with baseline and routine liver function tests for hepatotoxicity
Clonidine and guanfacine	Sedation, arrhythmia, constipation, dizziness (decreased blood pressure)	Sedation: administer later in the day Decrease dose or change medication	Same as stimulants
Bupropion	GI upset, restlessness, sleep disturbances, rash, tics, risk of seizures, tremor	Decrease dose or change medication Tics, rash, and seizures: discontinue medication	Height, weight, blood pressure, pulse every month Eating and sleeping patterns

ECG, electrocardiography; GI, gastrointestinal.

The choice of ADHD medication should be made based on the patient's condition, the prescriber's familiarity with the medications, the ease of administration, and the cost. Stimulants should be used as first-line agents in most ADHD patients, although studies in groups of patients have shown no clear advantage of using one stimulant over another.¹⁷

► Nonstimulants

Atomoxetine Atomoxetine is approved for the treatment of ADHD in both children and adults. In clinical studies, atomoxetine has demonstrated superior efficacy over placebo and either equivalent or inferior efficacy compared with a suboptimal immediate-release methylphenidate dose or Concerta (18 to 54 mg given once daily), respectively.^{18–23}

6 Atomoxetine may be used as a second- or third-line medication for ADHD.

Atomoxetine selectively inhibits the reuptake of adrenergic neurotransmitters, principally norepinephrine.^{18–21} Atomoxetine is metabolized through the cytochrome P450 (CYP) 2D6 pathway. Concurrent use of certain antidepressants (i.e., fluoxetine, paroxetine) may inhibit this enzyme and necessitate slower dose titration of atomoxetine. Approximately 5% to 10% of the population are CYP2D6 poor metabolizers, and atomoxetine's half-life is increased significantly in this population.²⁴ The recommended dosing for atomoxetine depends on the weight of the patient and is given daily in either a single or two divided doses²⁴ (Table 42–2). In poor metabolizers, atomoxetine should be dosed once daily at 25% to 50% of the dose typically used in normal metabolizers.²⁴ The maximum therapeutic effect of atomoxetine may take up to 4 weeks to be seen, which is significantly longer than what is required with stimulants. Common side effects of atomoxetine are similar to those of stimulants and include dyspepsia, nausea, vomiting, somnolence, and decreased appetite. Some studies have reported an increase in blood pressure and heart rate.^{19–21} Evidence shows that atomoxetine can slow growth rate and cause weight loss; thus, height and weight should be monitored routinely in pediatric patients^{19–21} (Table 42–3). Furthermore, atomoxetine's labeling includes strong warnings about severe hepatotoxicity and increased association with suicidal thinking.

Atomoxetine is similar to extended-acting stimulants in that it can be given once daily in many patients. It appears to lack any abuse potential and is not a controlled substance.²⁵ One big disadvantage of atomoxetine is cost compared with other ADHD medications (Table 42–4).

Because of the high cost, lack of long-term efficacy data, and few comparison studies with stimulants, atomoxetine should be advocated only if the patient has failed or is intolerant to stimulant therapy (Fig. 42–1).

Bupropion Bupropion is a monocyclic antidepressant that weakly inhibits the reuptake of norepinephrine and dopamine. Bupropion is effective for relieving symptoms of ADHD in children but is not as effective as stimulants.^{26,27} Similar results have been shown in adults.²⁶ Specific dosing recommendations are outlined in Table 42–2. Bupropion is well tolerated with minimal side effects (e.g., insomnia,

headache, nausea, and tremor). Side effects typically disappear with continuation of therapy and are minimized with slow titration of dose. Bupropion can worsen tics and movement disorders. It is a rational choice in an ADHD patient with comorbid depression.²⁶ However, seizures have been associated with bupropion doses greater than 6 mg/kg/day.²⁸ Seizures related to high doses can be minimized by reducing the dose or switching to a longer acting formulation. Owing to the propensity of seizures with bupropion, its use is contraindicated in patients with seizure and eating disorders.

Clonidine and Guanfacine Clonidine and guanfacine are central α_2 -adrenergic agonists that inhibit the release of norepinephrine presynaptically. Both of these agents are less effective than stimulants in treating symptoms of ADHD but typically are used as adjuncts to stimulants to control disruptive or aggressive behavior and alleviate insomnia.³⁰ The effects of immediate-release guanfacine typically will last 3 to 4 hours longer than immediate-release clonidine, and the drug requires less frequent dosing. Extended-release formulations of guanfacine (Intuniv) and clonidine (Kapvay) have been developed to minimize dosing frequency and improve treatment of oppositional conditions (anger, hostility, irritability) in patients with ADHD. Similar to other nonstimulant medications, these two dosage forms can also be used in patients who are intolerant to stimulants. However, use of these dosage forms is limited because of a lack of comparative trials to stimulants and high cost. Common side effects with clonidine and guanfacine are low blood pressure and sedation. Sedation is transient and generally subsides after 2 to 3 weeks of therapy.^{29,30} Rarely, severe side effects such as bradycardia, rebound hypertension, irregular heart beats, and sudden death have been reported.

Pharmacoeconomic and Treatment Adherence Considerations

Proper ADHD treatment is a substantial financial burden.^{31,32}

Annual healthcare costs of patients with ADHD are more than double those of patients without ADHD (\$1,343 vs. \$503, respectively).³¹ The financial burden of ADHD can be attributed to the direct cost of pharmacotherapy, office visits, diagnostic measurements, therapy monitoring, and indirect costs (e.g., lost work time and productivity). When selecting a treatment for an ADHD patient, the cost burden to the patient's family should be considered. Short-acting stimulants may be more cost effective in many patients compared with longer acting stimulant formulations (Table 42–4), but in certain circumstances, longer acting stimulant formulations may provide a greater benefit owing to increased adherence to the medication and prolonged control of symptoms of ADHD. All intermediate- and three extended-acting (Concerta, Ritalin LA, and Adderall XR) stimulant formulations are now available as generic products, making them potentially a more affordable current or future option for patients. In addition, some nonstimulant ADHD medications (e.g., bupropion and immediate-release α_2 -adrenergic agonists) appear to be less costly than many stimulant

Table 42-4

Day Cost^a of Selected ADHD Medication Regimens

Generic (Brand)	Regimen (Brand)	Cost ^a
Short-Acting Rapid-Onset Stimulants		
Methylphenidate		
Generic	5-, 10-, or 20-mg tablet twice daily	\$
Methylin	5 mg/5 mL solution twice daily	\$\$\$\$
Dexmethylphenidate		
Generic	2.5-mg tablet twice daily	\$
Generic	5- or 10-mg tablet twice daily	\$\$
Dextroamphetamine		
Generic	5- or 10-mg tablet twice daily	\$
Intermediate-Acting Slower-Onset Stimulants		
Methylphenidate		
Methylin ER	10- or 20-mg ER tablet daily	\$
Dextroamphetamine ^b		
Generic	5-, 10-, or 15-mg capsule daily	\$\$
Dextroamphetamine/amphetamine		
Generic	5-, 7.5-, 10-, 12.5-, 15-, 20-, or 30-mg tablet daily	\$
Extended-Acting Rapid-Onset Stimulants		
Methylphenidate		
Concerta (brand & generics) ^b	18-, 27-, 36-, or 54-mg tablet daily	\$\$\$\$
Metadate CD ^c	10-, 20-, or 30-mg capsule daily	\$\$\$\$
Ritalin LA ^c	10-, 20-mg capsule daily	\$\$\$\$
Dextroamphetamine/amphetamine		
Generic ER	5-, 10-, 15-, 20-, 25-, or 30-mg capsule daily	\$\$\$\$
Dexmethylphenidate		
Focalin XR ^c	5-, 10-, 15-, or 20-mg capsule daily	\$\$\$\$
Extended-Acting Slower-Onset Stimulants		
Lisdexamfetamine		
Vyvanse	20-, 30-, 40-, 50-, 60-, or 70-mg capsule daily	\$\$\$\$
Methylphenidate		
Daytrana transdermal patch	10-, 15-, 20-, or 30-mg patch daily	\$\$\$\$
Nonstimulants		
Atomoxetine		
Strattera	10-, 18-, 25-, 40-, 60-, 80-, or 100-mg capsule daily	\$\$\$\$
Clonidine		
Generic	0.1-, 0.2-, or 0.3-mg tablet twice daily	\$
Kapvay	0.1- or 0.2-mg tablet twice daily	\$\$\$\$
Guanfacine		
Generic	1- or 2-mg tablet twice daily	\$
Intuniv	1-, 2-, 3-, or 4-mg tablet daily	\$\$\$\$
Bupropion		
Generic	75- or 100-mg tablet twice daily	\$
Generic	100- or 150-mg SR tablet twice daily	\$
Generic	200-mg SR tablet twice daily	\$\$
Generic	150-mg or 300-mg XL tablet daily	\$

^aCost based on brand regimen specified without a dispensing fee or discount for a 30-day supply. (From: Drug Topics Red Book. Montvale, NJ: Thomson Reuters Healthcare; 2010)

\$, less than \$40; \$\$, \$40–\$79; \$\$\$, \$80–\$120; \$\$\$\$\$, greater than \$120.

^bAscending release (early and then gradual or continuous).

^cBimodal release (early and then late; mimics twice-daily dosing of shorter acting stimulant counterpart).

CD, extended release (biphasic immediate release with extended release); ER, extended release; LA, long acting; SR, sustained release; XL, extended release.

formulations; however, these agents have not been proven to have superior efficacy over stimulants in treating ADHD. Decisions on selection of specific ADHD medications should not be based solely on cost but also on efficacy and safety along with adherence to the prescribed regimen.

OUTCOME EVALUATION

It is important to carefully document core ADHD symptoms at baseline to provide a reference point from which to evaluate effectiveness of treatment. Improvement in individualized

patient outcomes are desired, such as (a) family and social relationships, (b) disruptive behavior, (c) completing required tasks, (d) self-motivation, (e) appearance, and (f) self-esteem. It is very important to elicit evaluations of the patient's behavior from family, school, and social environments in order to assess these outcomes. Using standardized rating scales (e.g., Conners Rating Scales—Revised, Brown Attention-Deficit Disorder Scale, and Inattentive-Overactive With Aggression [IOWA] Conners Scale) in both children and adults with ADHD helps to minimize variability in evaluation.³³ After initiation of pharmacotherapy, evaluate every 2 to 4 weeks to determine efficacy of treatment and potential effects on height, weight, pulse, and blood pressure. Use physical examinations or liver function tests as appropriate to monitor for adverse effects. In children being considered for ADHD pharmacotherapy, obtain baseline electrocardiograms (ECGs) when known or suspected cardiac disease exists or the clinician judges it necessary.^{34–36} Typically, therapeutic benefits will be seen within days of initiating stimulants and within 1 or 2 months of starting bupropion and atomoxetine. When a maintenance dose has been achieved, schedule follow-up visits every 3 months. At these visits, assess height and weight, and screen for possible adverse drug effects. If a patient has failed to respond to multiple agents, reevaluate for other possible causes of behavior dysfunction. Counsel patients and their families that treatment generally is long term. Typically, appropriately treated patients learn to better control their ADHD symptoms as adults.

Patient Encounter, Part 2: Medical History, Physical Examination, and ADHD Evaluation

HA's baseline physical examination is unremarkable. The family history is positive for cardiovascular disease (father had heart attack at age 40 years), and there is no documented history of ADHD in the family.

Wt: 29.1 kg (64 lb)

Allergies: None known

Ht: 51 in (130 cm)

BP: 100/65 mm Hg

P: 91 beats/min

HA's family does not qualify for medical assistance, and they can hardly afford their monthly expenses.

What stimulants and nonstimulants are available that might control HA's symptoms? Which ADHD medications should you be concerned about using?

Which medications will maximize efficacy, facilitate adherence, minimize potential side effects, and offer an acceptable cost?

What baseline assessment do you need before starting stimulant therapy?

What are important counseling points to discuss with HA's parents before starting any ADHD medication?

Patient Care and Monitoring

1. Assess the patient's symptoms and parent–teacher evaluations to determine whether they meet the *DSM-IV-TR* diagnostic criteria for ADHD. Evaluate whether the symptoms can be explained by another disorder.
2. Interview the patient and/or caregivers to obtain a complete medical history, which should include family medical history, current and past prescription and nonprescription medications, and dietary intake. Determine whether the patient is taking medications or supplements that could interfere with the therapy.
3. Educate the patient's parents and/or caregivers that behavioral therapy is not as effective as stimulant therapy. Educate them regarding the issues of growth delay and substance abuse risks with stimulants.
4. Perform a baseline physical examination before starting stimulant therapy. Include blood pressure, pulse, and height and weight measurements. In patients taking stimulants, perform a general physical examination yearly and monitor blood pressure quarterly in adults. In children, baseline ECGs may be obtained when known or strongly suspected cardiac disease exists.
5. Start patients on a low initial dose of a stimulant, and titrate up to the desired response in order to minimize side effects and costs.
6. If the patient is not responding to therapy after an adequate trial, assess compliance with the prescribed regimen. If the patient is not compliant, counsel the patient and caregivers, and explore reasons for noncompliance. In some cases, switching to another stimulant formulation may improve compliance.
7. Important counseling points to convey to the patient and/or caregivers:
 - What is ADHD?
 - What are the complications of untreated ADHD?
 - When to take medications and what to expect with therapy.
 - What side effects to expect and what to do if these occur.
 - Controversy over substance abuse and growth delay with stimulant therapy.
 - What prescription and nonprescription medications to avoid.

Abbreviations Introduced in This Chapter

ADHD	Attention-deficit hyperactivity disorder
CYP	Cytochrome P450
DSM-IV-TR	<i>Diagnostic and Statistical Manual of Mental Disorders</i> , Fourth Edition, Text Revision
IOWA	Inattentive-Overactive With Aggression

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Diabetes Mellitus

Julie Sease, Susan Cornell, Kayce Shealy, and
Tommy Johnson

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Discuss the incidence and economic impact of diabetes.
2. Distinguish clinical differences in type 1, type 2, and gestational diabetes.
3. List screening and diagnostic criteria for diabetes.
4. Discuss therapeutic goals for blood glucose, blood pressure, and lipids for a patient with diabetes.
5. Recommend nonpharmacologic therapies, including meal planning and physical activity, for patients with diabetes.
6. Compare oral agents used in treating diabetes by their mechanisms of action, time of action, side effects, contraindications, and effectiveness.
7. Select appropriate insulin therapy based on onset, peak, and duration of action.
8. Discuss the signs, symptoms, and treatment of hypoglycemia.
9. Define *diabetic ketoacidosis* and discuss treatment goals.
10. Develop a comprehensive therapeutic monitoring plan for a patient with diabetes based on patient-specific factors.

KEY CONCEPTS

- 1 Diabetes mellitus (DM) describes a group of chronic metabolic disorders characterized by hyperglycemia that may result in long-term microvascular, macrovascular, and neuropathic complications.
- 2 Type 1 DM (T1DM) is usually diagnosed before age 30 years but can develop at any age. Autoimmune destruction of the β cells causes insulin deficiency.
- 3 Type 2 DM (T2DM) accounts for approximately 90% to 95% of all diagnosed cases of DM, is progressive in its development, and is often preceded by an increased risk for diabetes (previously known as prediabetes). A combination of insulin deficiency, insulin resistance, and other hormonal irregularities, primarily involving glucagon, are key problems with T2DM. The majority of people with T2DM are overweight, and an increasing number of cases in children have been observed.
- 4 DM treatment goals include reducing, controlling, and managing long-term microvascular, macrovascular, and neuropathic complications; preserving β -cell function; preventing acute complications from high blood glucose levels; minimizing hypoglycemic episodes; and maintaining the patient's overall quality of life.
- 5 To achieve the majority of these goals, near-normal blood glucose levels are fundamental; thus, glycemic control remains a primary objective in diabetes management.
- 6 Patients and clinicians can evaluate disease state control by monitoring daily blood glucose values, hemoglobin A1c or estimated average blood glucose values, blood pressure, and lipid levels.
- 7 Oral and injectable agents are available to treat patients with T2DM who are unable to achieve glycemic control through meal planning and physical activity.
- 8 Insulin is the primary treatment to lower blood glucose levels for patients with T1DM, and the addition of injected amylin may decrease fluctuations in blood glucose levels.
- 9 Uncontrolled blood pressure plays a major role in the development of macrovascular events as well as microvascular complications, including retinopathy and nephropathy, in patients with DM. The American Diabetes Association (ADA) recommends that systolic blood pressure goals for patients with DM be individualized but generally set at less than 130 mm Hg. The diastolic blood pressure goal for patients with DM is less than 80 mm Hg.

- 9 Peripheral neuropathy is a common complication reported in T2DM. This complication generally presents as pain, tingling, or numbness in the extremities.
- 10 Lower extremity amputations are one of the most feared and disabling sequelae of long-term uncontrolled DM. A foot ulcer is an open sore that develops and penetrates to the subcutaneous tissues. Complications of the feet develop primarily as a result of peripheral vascular disease, neuropathies, and foot deformations.

INTRODUCTION

1 *Diabetes mellitus (DM) describes a group of chronic metabolic disorders characterized by hyperglycemia that may result in long-term **microvascular**, **macrovascular**, and neuropathic complications.* These complications contribute to diabetes being the leading cause of (a) new cases of blindness among adults, (b) end-stage renal disease, and (c) nontraumatic lower limb amputations. Although prevention and treatment of DM remain challenges, several studies have shown that complications associated with DM such as **retinopathy** and **neuropathy** can be delayed or prevented through proper blood glucose management.^{1,2}

The increased cardiovascular risk associated with DM contributes to its being the seventh leading cause of death in the United States.³ In 2007, diabetes was the underlying cause of death or a contributing factor of death in approximately 284,000 decedents. The total financial impact of DM in 2007 was approximately \$174 billion, with direct medical costs equaling \$116 billion (2.3 times higher than what expenditures would be in the absence of diabetes) and indirect costs secondary to disability, work loss, and premature mortality equaling \$58 billion.

EPIDEMIOLOGY AND ETIOLOGY

Diabetes mellitus is characterized by a complete lack of insulin, a relative lack of insulin, or **insulin resistance** as well as disorders of other hormones. These defects result in an inability to use glucose for energy. DM affects an estimated 25.8 million persons in the United States, or 8.3% of the population. Although an estimated 18.8 million persons have been diagnosed, another 7 million people have DM but are unaware they have the disease. The increasing prevalence of DM is partly caused by three influences: lifestyle, ethnicity, and age.

Lifestyle

A sedentary lifestyle coupled with greater consumption of high-fat, high-carbohydrate foods, and larger portion sizes have resulted in increasing rates of persons being overweight or obese. Current estimates indicate that 68% of the U.S. population is overweight, with 33.8% of this population being obese.⁴ In the United States, *overweight* is defined as a body mass index (BMI) of greater than 25 kg/m², and a BMI of greater than 30 kg/m² constitutes obesity. The Centers for Disease Control and Prevention (CDC) estimates that 25.1% of Americans in 36 states engage in no leisure-time physical activity.⁵

Ethnicity

In addition to current lifestyle trends and increased body weight, certain ethnic groups are at a disproportionately high risk for developing DM. The risk of diabetes is 18% higher among Asian Americans, 66% higher among Hispanics, and 77% higher among non-Hispanic blacks compared with non-Hispanic white adults.³ In addition, African American and Hispanic or Latino American populations are growing at a faster rate than the general U.S. population. This is a contributing factor to the rising U.S. population that has DM.

Age

The third factor contributing to the increased prevalence of type 2 DM (T2DM) is age. In 2010, 10.9 million people in the United States who were 65 years of age or older had diabetes compared with only 215,000 younger than age 20 years. As the population ages, the incidence of T2DM is expected to increase.

2 *Type 1 DM (T1DM) is usually diagnosed before age 30 years but can develop at any age. Autoimmune destruction of the β cells causes insulin deficiency.* 3 *T2DM accounts for approximately 90% to 95% of all diagnosed cases of DM, is progressive in its development, and is often preceded by an increased risk for diabetes (previously known as **prediabetes**).* A combination of insulin deficiency, insulin resistance, and other hormonal irregularities, primarily involving **glucagon**, are key problems with T2DM. The majority of people with T2DM are overweight, and an increasing number of cases in children have been observed.

T1DM is an autoimmune disease in which insulin-producing β cells in the pancreas are destroyed, leaving the individual insulin deficient.⁶ This is usually precipitated through genetic susceptibility and/or an environmental trigger, or both. Certain genetic markers can be measured to determine if a person is at risk of T1DM. The presence of human leukocyte antigens (HLAs), especially HLA-DR and HLA-DQ, is strongly associated with the development of T1DM. In addition, these individuals often develop islet cell antibodies, insulin autoantibodies, or glutamic acid decarboxylase autoantibodies. As more β cells are destroyed, glucose metabolism becomes compromised because of reduced insulin release after a glucose load. At the time of diagnosis of T1DM, it is commonly believed that most patients have an 80% to 95% loss of β -cell function.⁷ The remaining β -cell function at diagnosis creates a “honeymoon period” during which blood glucose levels are easier to control and smaller amounts of insulin are required.⁶ After this remaining β -cell function is lost, and patients become completely insulin deficient and require more exogenous insulin. Diagnosis occurs before age 16 to 18 years in 50% to 60% of those with T1DM.

Latent autoimmune diabetes in adults (LADA), slow-onset type 1, or type 1.5 DM, is a form of autoimmune T1DM that occurs in individuals older than the usual age of T1DM onset.⁸ Patients often are mistakenly thought to have T2DM because the person is older and may respond initially to treatment with oral blood glucose-lowering agents. These patients

do not have insulin resistance, but antibodies are present in the blood that are known to destroy pancreatic β cells.

C-peptide is the abbreviation for “connecting peptide.” C-peptide is made when proinsulin is split into insulin and C-peptide. They split before proinsulin is released from endocytic vesicles within the pancreas—one C-peptide for each insulin molecule. Routine measurement of **C-peptide levels**, insulin levels, and proinsulin are not recommended in most patients.⁹ However, C-peptide measurements can be used to distinguish between T1DM and T2DM. People with T1DM have C-peptide levels below 1 ng/mL (0.33 nmol/L), whereas those with T2DM will have values greater than 1 ng/mL (0.33 nmol/L).

Categories of increased risk for diabetes (commonly referred to as prediabetes) include impaired fasting glucose (IFG), impaired glucose tolerance (IGT), or hemoglobin A1c (A1c) between 5.7% and 6.4% (0.057 and 0.064; 39 and 46 mmol/mol hemoglobin [Hb]).¹⁰ IFG is defined as having a fasting blood glucose (FBG) level between 100 and 125 mg/dL (5.6 and 6.9 mmol/L). IGT is defined by a postprandial blood glucose level between 140 and 199 mg/dL (7.8 and 11.0 mmol/L). It is currently estimated that 70 million persons in the United States have prediabetes.³ The development of IFG, IGT, or A1c between 5.7% and 6.4% (0.057 and 0.064; 39 and 46 mmol/mol) places the individual at high risk of eventually developing diabetes. Because progression to diabetes is not predictable, early interventions are gaining popularity.

T2DM is usually slow and progressive in its development. Risk factors for T2DM include:

- First-degree family history of DM (i.e., parents or siblings)
- Overweight or obese
- Habitual physical inactivity
- Race or ethnicity (Native American, Latino or Hispanic American, Asian American, African American, and Pacific Islanders)

- Previously identified IFG, IGT, or A1c between 5.7% and 6.4% (0.057 and 0.064 or 39 and 46 mmol/mol Hb)
- Hypertension (greater than or equal to 140/90 mm Hg or on therapy for hypertension)
- High-density lipoprotein (HDL) less than 35 mg/dL (0.91 mmol/L) and/or a triglyceride level greater than 250 mg/dL (2.83 mmol/L)
- History of gestational diabetes or delivery of a baby weighing greater than 4 kg (9 lb)
- History of cardiovascular disease
- History of polycystic ovarian syndrome
- Other conditions associated with insulin resistance (e.g., **acanthosis nigricans**)¹⁰

Gestational diabetes mellitus (GDM) is defined as glucose intolerance in women during pregnancy. This complication develops in between 2% and 10% of all pregnancies.³ Women who have GDM have a 35% to 60% chance of developing T2DM. Clinical detection of and therapy for GDM are important because blood sugar control produces significant reductions in perinatal morbidity and mortality. New diagnostic criteria call for all pregnant women not previously known to have diabetes to undergo screening for GDM between 24 and 28 weeks of gestation.¹¹ Use of these criteria resulted in an 18% GDM diagnosis rate in one multinational epidemiologic study that enrolled 25,000 pregnant women.¹²

Diabetes from other causes includes genetic defects in β -cell function, genetic defects in insulin action, diseases of the exocrine pancreas such as cystic fibrosis, and drug- or chemical-induced diabetes.¹⁰ **Table 43–1** contains a list of medications that may affect glycemic control.¹³ Although the use of these medications is not contraindicated in persons with DM, caution and awareness of the effects on blood glucose should be taken into account when managing these patients.

Table 43–1

Medications That May Affect Glycemic Control¹³

Drug	Effect on Glucose	Mechanism or Comment
Angiotensin-converting enzyme inhibitors	Slight reduction	Improves insulin sensitivity
Alcohol	Reduction	Reduces hepatic glucose production
α -Interferon	Increase	Unclear
Diuretics	Increase	May increase insulin resistance
Glucocorticoids	Increase	Impair insulin action
Nicotinic acid	Increase	Impairs insulin action, increases insulin resistance
Oral contraceptives	Increase	Unclear
Pentamidine	Decrease, then increase	Toxic to β cells; initial release of stored insulin, then depletion
Phenytoin	Increase	Decreases insulin secretion
β -blockers	May increase	Decreases insulin secretion
Salicylates	Decrease	Inhibition of I-kappa-B kinase- β (IKK- β) (only high doses, e.g., 4–6 g/day)
Sympathomimetics	Slight increase	Increased glycogenolysis and gluconeogenesis
Clozapine and olanzapine	Increase	Decreases insulin sensitivity; weight gain

This list is not inclusive of all medications reported to cause glucose changes.

PATHOPHYSIOLOGY

Normal Carbohydrate Metabolism

The body's main fuel source is glucose. Cells metabolize glucose completely through glycolysis and the Krebs cycle, producing adenosine triphosphate (ATP) as energy.¹⁴ Glucose is stored in the liver and muscles as glycogen. When energy is required, **glycogenolysis** converts stored glycogen back to glucose.¹⁵ Excess glucose also may be stored in adipose tissue, which may subsequently undergo lipolysis, yielding free fatty acids.¹⁴ In the fasting state, free fatty acids supply much of the energy needs for the body except for the central nervous system, which requires glucose to function normally.¹⁵ Although usually reserved for other functions, proteins also can be converted to glucose through **gluconeogenesis**.¹⁴ Normal homeostasis is achieved through a balance of the metabolism of glucose, free fatty acids, and amino acids to maintain a blood glucose level sufficient to provide an uninterrupted supply of glucose to the brain.¹⁵

Insulin and glucagon are produced in the pancreas by cells in the islets of Langerhans. β cells make up 70% to 90% of the islets and produce insulin and **amylin**, whereas α cells produce glucagon.¹⁴ The main function of insulin is to decrease blood glucose levels. Glucagon, along with other counterregulatory hormones such as growth factor, cortisol, and epinephrine, increases blood glucose levels.¹⁵ Although blood glucose levels vary, the opposing actions of insulin and glucagon, along with the counterregulatory hormones, normally maintain fasting values between 79 and 99 mg/dL (4.4 to 5.5 mmol/L).

► Normal Insulin Action

Fasting insulin levels in the circulation average from 43 to 186 pmol/L (6 to 26 μ IU/mL).¹⁴ After food is consumed, blood glucose levels rise, and the insulin-secretion response occurs in two phases. An initial burst, known as *first phase insulin response*, lasts approximately 5 to 10 minutes and serves to suppress hepatic glucose production and cause insulin-mediated glucose disposal in adipose tissue. This bolus of insulin minimizes hyperglycemia during meals and during the postprandial period. The *second phase of insulin response* is characterized by a gradual increase in insulin secretion, which lasts 60 to 120 minutes and stimulates glucose uptake by peripheral insulin-dependent tissues. Approximately 80% to 85% of glucose metabolism during this time occurs in muscle.¹³ Slower release of insulin allows the body to respond to the new glucose entering from digestion while maintaining blood glucose levels.

Amylin is a naturally occurring hormone that is cosecreted from β cells with insulin.¹⁴ People with diabetes have either a relative or complete lack of amylin. Amylin has three major mechanisms of action: suppression of postmeal glucagon secretion; regulation of the rate of gastric emptying from the stomach to the small intestine, which increases satiety; and regulation of plasma glucose concentrations in the bloodstream.

► Impaired Insulin Secretion

A pancreas with normal β -cell function is able to adjust insulin production to maintain normal blood glucose levels.¹⁵ Hyperinsulinemia, or high blood levels of insulin, is an early finding in the development of T2DM.¹⁶ More insulin is secreted to maintain normal blood glucose levels until eventually the pancreas can no longer produce sufficient insulin.¹⁴ The resulting hyperglycemia is enhanced by extremely high insulin resistance, pancreatic burnout in which β cells lose functional capacity, or both. Impaired β -cell function results in a reduced ability to produce a first-phase insulin response sufficient to signal the liver to stop producing glucose after a meal.¹⁶ As DM progresses, large numbers of patients with T2DM eventually lose all β -cell function and require exogenous insulin to maintain blood glucose control.

► Insulin Resistance

Insulin resistance is the primary factor that differentiates T2DM from other forms of diabetes. Insulin resistance may be present for several years prior to the diagnosis of DM and can continue to progress throughout the course of the disease.¹⁴ Resistance to insulin occurs most significantly in skeletal muscle and the liver.¹³ Insulin resistance in the liver poses a double threat because the liver becomes nonresponsive to insulin for glucose uptake, and hepatic production of glucose after a meal does not cease, which leads to elevated fasting and postmeal blood glucose levels.

► Impaired Glucagon Secretion

Glucagon is a counterregulatory hormone released by the α cells that raises blood glucose levels.¹⁴ The release of insulin and the inhibition of glucagon is glucose stimulated, meaning that as glucose is consumed, the release of insulin increases and the release of glucagon decreases in people without diabetes.¹⁷ Most patients with a 10- to 20-year history of T1DM have lost their ability to release glucagon, which increases their risk for hypoglycemic unawareness. People with T2DM have impaired phase 1 and phase 2 insulin release, and some have impaired glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP) release, which further reduces the release of insulin. This leads to the liver's producing and releasing glucose even in the postprandial state.¹⁸

► Metabolic Syndrome

Insulin resistance has been associated with a number of other cardiovascular risks, including abdominal obesity, hypertension, dyslipidemia, hypercoagulation, and hyperinsulinemia. The clustering of these risk factors has been termed **metabolic syndrome**. It is estimated that 50% of the U.S. population older than 60 years of age has metabolic syndrome. The most widely used criteria to define metabolic syndrome were established by the National Cholesterol Education Program Adult Treatment Panel III Guidelines¹⁹ (summarized in [Table 43-2](#)). Patients having these additional

Table 43–2

Five Components of Metabolic Syndrome¹⁹

Risk Factor	Defining Level
1. Abdominal obesity <ul style="list-style-type: none"> • Men • Women 	Waist circumference greater than 102 cm (40 in) Waist circumference greater than 89 cm (35 in)
2. Triglycerides	Greater than or equal to 150 mg/dL (1.70 mmol/L)
3. HDL cholesterol <ul style="list-style-type: none"> • Men • Women 	Less than 40 mg/dL (1.03 mmol/L) Less than 50 mg/dL (1.29 mmol/L)
4. Blood pressure	Greater than or equal to 130/85 mm Hg
5. Fasting glucose	Greater than or equal to 100 mg/dL (5.6 mmol/L)

Individuals having at least three of the five above criteria meet the diagnostic criteria for metabolic syndrome.

risk factors have been found to be at a much higher cardiovascular risk than would be expected from the individual components of the syndrome. Therefore, it is important to assume a more aggressive treatment plan for each of the individual abnormal components. As a result, a patient with prediabetes or DM having a convergence of other risk factors should be treated more aggressively than a patient having prediabetes or DM alone.

► Incretin Effect

A great deal of research is occurring today to develop compounds that enhance the **incretin effect**, either by mimicking its action or by enabling incretin hormones to remain physiologically active for longer periods of time.^{18,20–22} As early as the late 1960s, Perley and others observed that insulin's response to oral glucose exceeded that of intravenous (IV) glucose administration.²² It was concluded that factors in the gut, or incretins, affected the release of insulin after a meal is consumed.

When nutrients enter the stomach and intestines, incretin hormones are released, which stimulates insulin secretion. This was validated by measuring C-peptide and insulin response to the IV and oral glucose loads. GLP-1 and GIP are the two major incretin hormones, with GLP-1 being studied the most. GLP-1 is secreted by the L cells of the ileum and colon primarily, and GIP is secreted by the K cells.

GLP-1 was identified in the early 1980s. It is a 30/31 amino acid peptide that is a product of the glucagon gene. GLP-1 secretion is caused by endocrine and neural signals started when nutrients enter the gastrointestinal (GI) tract. Within minutes of food ingestion, GLP-1 levels rise rapidly. A glucose-dependent release of insulin occurs, and the dipeptidyl peptidase-4 (DPP-4) enzyme cleaves GLP-1 rapidly to an inactive metabolite. Much of the research on glucose-lowering products involves prolonging the action of GLP-1. Other glucose-lowering effects of GLP-1 include suppression of glucagon, slowing gastric emptying, and increasing satiety.^{18,20–22}

Clinical Presentation and Diagnosis of Diabetes Mellitus

Characteristic	Type 1 Diabetes Mellitus	Type 2 Diabetes Mellitus
Usual age of onset	Childhood or adolescence	Adult
Speed of onset	Abrupt	Gradual
Family history	Negative	Positive
Body type	Thin	Obese or history of obesity
Metabolic syndrome	No	Often
Autoantibodies	Present	Rare
Symptoms	Polyuria, polydipsia, polyphagia , rapid weight loss	Asymptomatic
Ketones at diagnosis	Present	Uncommon
Acute complications	Diabetic ketoacidosis	Rare
Microvascular complications at diagnosis	Rare	Common
Macrovascular complications at or before diagnosis	Rare	Common

CLINICAL PRESENTATION AND DIAGNOSIS

Screening

- Currently, the American Diabetes Association (ADA) recommends routine screening for T2DM every 3 years in all adults starting at 45 years of age.¹⁰ Testing for T2DM should be considered in any adult, regardless of their age, who have a BMI greater than or equal to 25 kg/m². The ADA does not currently recommend widespread screening for T1DM because of the relatively low incidence in the general population, although measurement of islet autoantibodies may be appropriate for high-risk individuals, including those with transient hyperglycemia or who have relatives with T1DM. See [Table 43–3](#)¹⁰ for complete screening guidelines.

Gestational Diabetes

- All pregnant women who have risk factors for T2DM should be screened for undiagnosed T2DM at their first prenatal visit using standard diagnostic criteria. Any woman found to have diabetes at that early point in pregnancy is considered to have T2DM, not GDM. All other pregnant women, not

Table 43-3

American Diabetes Association Screening Recommendations for Diabetes¹⁰**Asymptomatic type 1**

The ADA does not recommend screening for T1DM because of the low incidence in the general population and due to the acute presentation of symptoms

Asymptomatic type 2

- The ADA recommends screening for T2DM every 3 years in all adults beginning at 45 years of age, particularly in those with a BMI greater than or equal to 25 kg/m²
- Testing should be considered for persons younger than 45 years of age or more frequently in individuals who are overweight (BMI greater than or equal to 25 kg/m²) and have additional risk factors:
 - Habitually inactive
 - First-degree relative with diabetes
 - Member of a high-risk ethnic population (e.g., African American, Latino, Native American, Asian American, Pacific Islander)
 - Delivered a baby weighing greater than 4.1 kg (9 lb) or previous diagnosis of GDM
 - Hypertensive (greater than or equal to 140/90 mm Hg)
 - HDL cholesterol level less than 35 mg/dL (0.91 mmol/L) and/or triglyceride level greater than 250 mg/dL (2.83 mmol/L)
 - Polycystic ovary syndrome
 - Previous IGT or IFG
 - Other clinical conditions associated with insulin resistance (e.g., acanthosis nigricans)
 - History of cardiovascular disease

Type 2 in children and adolescents

Criteria:

- Overweight (BMI greater than 85th percentile for age and sex, weight for height greater than 85th percentile, or weight greater than 120% of ideal for height)

Plus any two of the following risk factors:

- Family history of T2DM in first- or second-degree relatives
- Race or ethnicity (Native American, African American, Latino or Hispanic American, Asian American, Pacific Islander)
- Signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, or polycystic ovary disease)
- Maternal history of diabetes or GDM during child's gestation

Age of initiation:

Age 10 years or at onset of puberty, if puberty occurs at a younger age

Frequency of testing:

Every 2 years

Test method: FPG preferred

Clinical judgment should be used to test for diabetes in high-risk patients who do not meet these criteria

Gestational diabetes

- Screen for undiagnosed T2DM at first prenatal visit in those with risk factors using standard criteria
- All women should be screened with an OGTT between weeks 24 and 28 of gestation

ADA, American Diabetes Association; BMI, body mass index; FPG, fasting plasma glucose; GDM, gestational diabetes mellitus; HDL, high-density lipoprotein; IFG, impaired fasting glucose; IGT, impaired fasting glucose; OGTT, oral glucose tolerance test; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus.

currently known to have DM should be screened for GDM with a 75-g oral glucose tolerance test (OGTT) between weeks 24 and 28 of gestation. The diagnostic criteria for OGTT are listed in [Table 43-4](#).¹⁰

Table 43-4

Diagnosis of Gestational Diabetes Mellitus With a 75-g Glucose Load¹⁰

Time	Plasma Glucose	
	mg/dL	mmol/L
75-g glucose load		
Fasting	92 or more	5.1 or more
1 hour	180 or more	10.0 or more
2 hours	153 or more	8.5 more

A positive diagnosis of diabetes is made when any of the listed glucose values are exceeded. The test should be done in the morning after an 8-hour fast.

- Any woman diagnosed with GDM should be retested at 6 to 12 weeks postpartum. If screening results are normal at that point, then reassessment for DM should occur every 3 years. Family planning for subsequent pregnancies should be discussed, and monitoring for the development of symptoms of DM should be undertaken.

Diagnostic Criteria

- The diagnosis of DM includes glycemic outcomes exceeding threshold values with one of three testing options ([Table 43-5](#)).^{10,23} Confirmation of abnormal values must be made on a subsequent day for diagnosis unless unequivocal symptoms of hyperglycemia exist, such as polydipsia, polyuria, and polyphagia. Either A1c, fasting plasma glucose (FPG), or OGTT are appropriate tests for detecting DM.
- The ADA categorizes patients demonstrating A1c between 5.7% and 6.4% (0.057 and 0.064 or 39 and 46 mmol/mol Hb), IFG, or IGT as having increased risk for future diabetes.

Table 43-5

ADA Criteria for the Diagnosis of Diabetes¹⁰

1. Symptoms of diabetes plus a casual plasma glucose concentration greater than or equal to 200 mg/dL (11.1 mmol/L). *Casual* is defined as any time of day without regard to time since the last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.
or
2. FPG greater than or equal to 126 mg/dL (7 mmol/L). *Fasting* is defined as no caloric intake for at least 8 hours.
or
3. Two-hour postload glucose greater than or equal to 200 mg/dL (11.1 mmol/L) during an OGTT. The test should be performed as described by the WHO using a glucose load containing the equivalent of 75 g of anhydrous glucose dissolved in water.
or
4. A1c greater than or equal to 6.5% (0.065; 48 mmol/mol Hb). The test should be performed in a laboratory using a method that is NGSP certified to the DCCT assay.

ADA, American Diabetes Association; A1c, hemoglobin A1c; DCCT, Diabetes Control and Complications Trial; FPG, fasting plasma glucose; Hb, hemoglobin; NGSP, National Glycohemoglobin Standardization Program; OGTT, oral glucose tolerance test; WHO, World Health Organization.

In the absence of unequivocal hyperglycemia, these criteria should be confirmed by repeat testing on a different day. The OGTT is not recommended for routine clinical use.

The categorization thresholds of glucose status for FPG determination and the OGTT are listed in Table 43-6.^{10,23} IFG and IGT may coexist or may be identified independently. FPG level represents hepatic glucose production during the fasting state, whereas postprandial glucose levels in the OGTT may reflect glucose uptake in peripheral tissues, insulin sensitivity, or a decreased first-phase insulin response. The OGTT identifies people with either IFG or IGT and therefore potentially more people at increased risk for DM and cardiovascular disease. The OGTT is a more cumbersome test to perform

Table 43-6

ADA Categorization of Glucose Status¹⁰

	mg/dL	mmol/L
FPG		
• Normal	Less than 100	Less than 5.6
• IFG (prediabetes)	100–125	5.6–6.9
• Diabetes	Greater than or equal to 126	7.0
2-hour postload plasma glucose (OGTT)		
• Normal	Less than 140	7.8
• IGT (prediabetes)	140–199	7.8–11.0
• Diabetes	Greater than or equal to 200	11.1

ADA, American Diabetes Association; FPG, fasting plasma glucose; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; OGTT, oral glucose tolerance test.

Patient Encounter, Part 1

GH is a 56-year-old African American man who presents to his physician for a follow-up appointment for hypertension. Upon questioning, GH states that he has noticed more frequent trips to the bathroom than usual and his appetite has substantially increased. He denies much physical activity, although he has lost approximately 15 lb (6.8 kg) since his last visit 6 months ago. He is concerned about developing diabetes and heart disease like both of his parents.

PMH: Allergic rhinitis, hypercholesterolemia, hypertension

FH: Father has diabetes, hypertension, and a history of myocardial infarction at age 54 years; mother has diabetes and a history of stroke at age 70 years; brother has hypercholesterolemia

SH: Smokes ½ pack per day for 20 years; denies alcohol or illicit drug use

Allergies: sulfa and penicillin

Medications:

- Hydrochlorothiazide 25 mg by mouth once daily
- Simvastatin 20 mg by mouth once daily
- Fluticasone nasal spray, one spray each nostril daily

VS: BP 134/85 mm Hg, P 82 beats/min, RR 20, T 38°C (100°F)

Height: 6 ft, 3 in (190.5 cm)

Weight: 285 lb (129.5 kg)

Waist circumference: 46.5 in (118.1 cm)

ROS: (+) Fatigue, (–) N/V/D, HA, SOB, chest pain

What risk factors does this patient have for diabetes?

Which type of diabetes does his characteristics suggest?

What additional information is needed to diagnose this patient with diabetes?

than either the A1c or FPG; however, the efficacy of interventions for primary prevention of T2DM have been demonstrated among patients with IGT, not among those with IFG or specific A1c levels.

TREATMENT**Goals of Therapy**

- 4 *DM treatment goals include reducing, controlling, and managing long-term microvascular, macrovascular, and neuropathic complications; preserving β-cell function; preventing acute complications from high blood glucose levels; minimizing hypoglycemic episodes; and maintaining the patient's overall quality of life. To achieve the majority of these goals, near-normal blood glucose levels are fundamental; thus, glycemic control remains a primary objective in diabetes management. Two landmark trials, the Diabetes Control and Complications Trial (DCCT)² and the United Kingdom*

Prospective Diabetes Study (UKPDS),³ showed that lowering blood glucose levels decreased the risk of developing chronic complications. A near-normal blood glucose level can be achieved with appropriate patient education, lifestyle modification, and medications.

Proper care of DM requires goal setting and assessment for glycemic control, self-monitoring of blood glucose (SMBG), monitoring of blood pressure and lipid levels, regular monitoring for the development of complications, dietary and exercise lifestyle modifications, and proper medication use. The complexity of proper DM self-care principles has a dramatic impact on a patient's lifestyle and requires a highly disciplined and dedicated person to maintain long-term control.

► Setting and Assessing Glycemic Targets

5 Patients and clinicians can evaluate disease state control of the patient's diabetes by monitoring daily blood glucose values, A1c or estimated average glucose (eAG) values, blood pressure, and lipid levels. SMBG enables patients to obtain their current blood glucose level at any time easily and relatively inexpensively. The A1c test provides a weighted-mean blood glucose level from the previous 3 months.

Self-Monitoring of Blood Glucose SMBG is the standard method for routinely checking blood glucose levels. Each reading provides a point-in-time evaluation of glucose control that can vary widely depending on numerous factors, including food, exercise, stress, and time of day.

By examining multiple individual points of data, patterns of control can be established. Therapy can be evaluated from these patterns, and adjustments can be made to improve overall blood glucose control. The ADA premeal plasma glucose goals are 70 to 130 mg/dL (3.9 to 7.2 mmol/L) and peak postprandial plasma glucose goals are less than 180 mg/dL (10 mmol/L).¹⁰ The American Association of Clinical Endocrinologists (AACE) supports tighter SMBG controls with premeal goals of less than 110 mg/dL (6.1 mmol/L) and peak postmeal goals of less than 140 mg/dL (7.8 mmol/L).²³ For patients using multiple daily insulin injections or insulin pump therapy, the ADA recommends that SMBG be performed at least three times daily.¹⁰ The optimal frequency of testing in patients using less frequent insulin injections, non-insulin therapies, or medical nutrition therapy (MNT) is still unknown, and the cost effectiveness of routine SMBG in non-insulin-treated patients has been called into question.^{10,24} Some regimen of SMBG among patients with T2DM has been associated with an A1c reduction of 0.4% (0.004; 4 mmol/mol Hb).²⁵ Each patient should be educated regarding how often and when to perform SMBG, and these measurements should be evaluated and used by both the patient and his or her healthcare providers to help the patient gain and maintain blood glucose control.¹⁰

Typically, in SMBG, a drop of blood is placed on a test strip that is then read by a blood glucose monitor. Recent technological advancements have decreased the blood sample size required to as small as 0.3 microliters, provided the capability of alternate-site testing, and allowed for the delivery of readings in as few as 5 seconds. Many SMBG devices can

download or transfer information to a computer program that can summarize and produce graphs of the data. Identifying patterns in the patient's blood glucose data can aid practitioners in modifying treatment for better glucose control. Specific therapy adjustments can be made for patterns found at certain times of the day, on certain days, or with large day-to-day variances.

Although most testing occurs by lancing the fingertip to produce a blood droplet, alternate-site testing has been approved for testing the palm, arm, leg, and abdomen. Alternate-site testing was developed as a means to decrease the pain encountered with repeated fingersticks by using body locations that have a lower concentration of nerve endings.

In choosing a glucose meter for a patient, several additional factors may aid in the best selection for the patient. Larger display areas or units with audible instructions and results may be better suited for older individuals and those with visual impairment. Patients with arthritis or other conditions that decrease dexterity may prefer larger meters with little or no handling of glucose strips. Younger patients or busy professionals may prefer smaller meters with features such as faster results, larger memories, reminder alarms, and downloading capabilities. Several continuous glucose sensors are now available that work with or independently of insulin pumps. These monitors provide blood glucose readings, primarily through interstitial fluid (ISF). A small sterile disposable glucose-sensing device called a sensor is inserted into the subcutaneous tissues. This sensor measures the change in glucose in ISF and sends the information to a monitor, which stores the results. The monitor must be calibrated daily by entering several blood glucose readings obtained at different times using a standard blood glucose meter.

Hemoglobin A1c Glucose interacts spontaneously with Hb in red blood cells to form glycosylated derivatives. The most prevalent derivative is A1c. Greater amounts of glycation occur when blood glucose levels increase. Because Hb has a life span of approximately 3 months, levels of A1c provide a marker reflecting the average glucose levels over this timeframe.¹⁰ The ADA goal for persons with DM is less than 7% (0.07; 53 mmol/mol Hb), whereas the AACE supports a goal of less than or equal to 6.5% (0.065; 48 mmol/mol Hb).^{10,23} Testing A1c levels should occur at least twice a year for patients who are meeting treatment goals and four times per year for patients not meeting goals or those who have had recent changes in therapy.

Estimated Average Glucose The eAG is used to correlate A1c values with readings that patients obtain from their home glucose monitors.¹⁰ The equation to convert from A1c to eAG is: eAG (mg/dL) = $28.7 \times \text{A1c} - 46.7$ (or eAG [mmol/L] = $1.59 \times \text{A1c} - 2.59$ for A1c expressed as a percentage).²⁶ The goal eAG is 154 mg/dL (8.5 mmol/L), which corresponds with an A1c of less than 7%, and an eAG of 240 mg/dL (13.3 mmol/L) would be equivalent to an A1c of 10%.

Ketone Monitoring Urine and blood ketone testing is important in people with T1DM, in pregnancy with

preexisting diabetes, and in GDM. People with T2DM may have positive ketones and develop diabetic ketoacidosis (DKA) if they are ill.

The presence of ketones may indicate a lack of insulin or ketoacidosis, a condition that requires immediate medical attention. When there is a lack of insulin, peripheral tissues cannot take up and store glucose. This causes the body to think it is starving, and because of excessive lipolysis, ketones, primarily β -hydroxybutyric and acetoacetic acid, are produced as byproducts of free fatty acid metabolism in the liver. Glucose and ketones are osmotically active, and when an excessive amount of ketones is formed, the body gets rid of them through urine, leading to dehydration. Patients with T1DM should test for ketones during acute illness or stress or when blood glucose levels are consistently elevated above 300 mg/dL (16.7 mmol/L). This commonly occurs when insulin is omitted or when diabetes is poorly controlled due to nonadherence, illness, or other reasons. Women with preexisting diabetes before pregnancy or with GDM should check ketones using their first morning urine sample or when any symptoms of ketoacidosis such as nausea, vomiting, or abdominal pain are present. Positive ketone readings are found in normal individuals during fasting and in up to 30% of first morning urine specimens from pregnant women. Urine ketone tests using nitroprusside-containing reagents can give false-positive results in the presence of several medications, including captopril. False-negative readings have been reported when test strips have been exposed to air for an extended period of time or when urine specimens have been highly acidic, such as after large intakes of ascorbic acid. Currently, available urine ketone tests are not reliable for diagnosing or monitoring treatment of ketoacidosis. Blood ketone testing methods that quantify β -hydroxybutyric acid, the predominant ketone body, are available and are the preferred way to diagnose and monitor ketoacidosis. Home tests for β -hydroxybutyric acid are available. The specific treatment of DKA may include rehydration, correction of electrolyte imbalances, and insulin administration.

► Blood Pressure, Lipids, and Monitoring for Complications

The ADA standards of medical care address many of the common comorbid conditions, as well as complications that result from the progression of DM. [Table 43–7](#) presents goals for blood pressure measurements, lipids values, and monitoring parameters for complications associated with diabetes.

General Approach to Therapy

► Type 1 Diabetes Mellitus

Treatment of T1DM requires providing exogenous insulin to replace the endogenous loss of insulin from the nonfunctional pancreas. Ideally, insulin therapy mimics normal insulin physiology. The basal-bolus approach attempts to reproduce

Table 43–7

ADA Recommended Goals of Therapy

Area	Goals
Glycemia	
A1c	Less than 7% (0.07; 53 mmol/mol Hb) Evaluate every 3 months until in goal; then every 6 months
eAG	Less than 154 mg/dL (8.5 mmol/L)
Preprandial plasma glucose	70–130 mg/dL (3.9–7.2 mmol/L)
Peak postprandial plasma glucose ^a	Less than 180 mg/dL (less than 10.0 mmol/L)
Blood Pressure	
	Less than 130/80 mm Hg Evaluate at every visit
Lipids	
LDL	Evaluate at least yearly Less than 100 mg/dL (2.59 mmol/L) or less than 70 mg/dL (1.81 mmol/L) if high risk
HDL	Greater than 40 mg/dL (1.03 mmol/L) for males; greater than 50 mg/dL (1.29 mmol/L) for females
Triglycerides	Less than 150 mg/dL (1.70 mmol/L)
Monitoring for Complications	
Eyes	Dilated eye exam yearly
Feet	Feet should be examined at every visit
Urinary microalbumin	Yearly

A1c, hemoglobin A1c; ADA, American Diabetes Association; eAG, estimated average glucose; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

^aPeak postprandial glucose measurements should be made 1 to 2 hours after the beginning of the meal.

basal insulin response using intermediate- or long-acting insulin, whereas short- or rapid-acting insulin replicates bolus release of insulin physiologically seen around a meal in nondiabetics. A number of different regimens have been used through the years to more closely follow natural insulin patterns. As a rule, basal insulin makes up approximately 50% of the total daily dose. The remaining half is provided with bolus doses around three daily meals.

Exact doses are individualized to the patient and the amount of food consumed. T1DM patients frequently are started on about 0.6 unit/kg/day, and then doses are titrated until glycemic goals are reached. Most people with T1DM use between 0.6 and 1 unit/kg/day.

Currently, the most advanced form of insulin delivery is the insulin pump, also referred to as continuous subcutaneous insulin infusion (CSII). Using rapid-acting insulin only, these pumps are programmed to provide a slow release of small amounts of insulin as the basal portion of therapy, and larger boluses of insulin are injected by the patient to account for the consumption of food. Pramlintide, a synthetic analog of the naturally occurring hormone amylin, is another injectable blood glucose-lowering medication that can be used in people with T1DM or in people with T2DM using insulin for treatment. A more in-depth description is listed in the pharmacologic treatment section.

► Type 2 Diabetes Mellitus

Treatment of patients with T2DM has changed dramatically over the past decade with the addition of a number of new drugs and recommendations to maintain tighter glycemic control. **Figures 43–1** and **43–2** summarize 2009 treatment algorithms for T2DM.²⁷ Algorithms from AACE for T2DM can be found at <https://www.aace.com/sites/default/files/GlycemicControlAlgorithm.pdf> and from the 2012 ADA/European Association for the Study of Diabetes joint position statement at <http://care.diabetesjournals.org/content/early/2012/04/17/dc12-0413.short>. Lifestyle modifications including education, nutrition, and exercise are paramount to managing the disease successfully. Many patients assume that once pharmacologic therapy is initiated, lifestyle modifications are no longer necessary. Practitioners should

educate patients regarding this misconception. Because T2DM generally tends to be a progressive disease, blood glucose levels will eventually increase, making insulin therapy and lifestyle modifications the eventual required therapy in many patients. It may be necessary for patients to inject insulin to lower their blood glucose levels. Figure 43–2 is an illustration of a way to start insulin therapy while keeping the patient on some oral medications. This is usually done when several oral agents have been used with inadequate glucose-lowering results.²⁷

► Gestational Diabetes

An individualized meal plan consisting of three meals and three snacks per day is commonly recommended in GDM. Preventing **ketosis**, promoting adequate growth of the fetus,

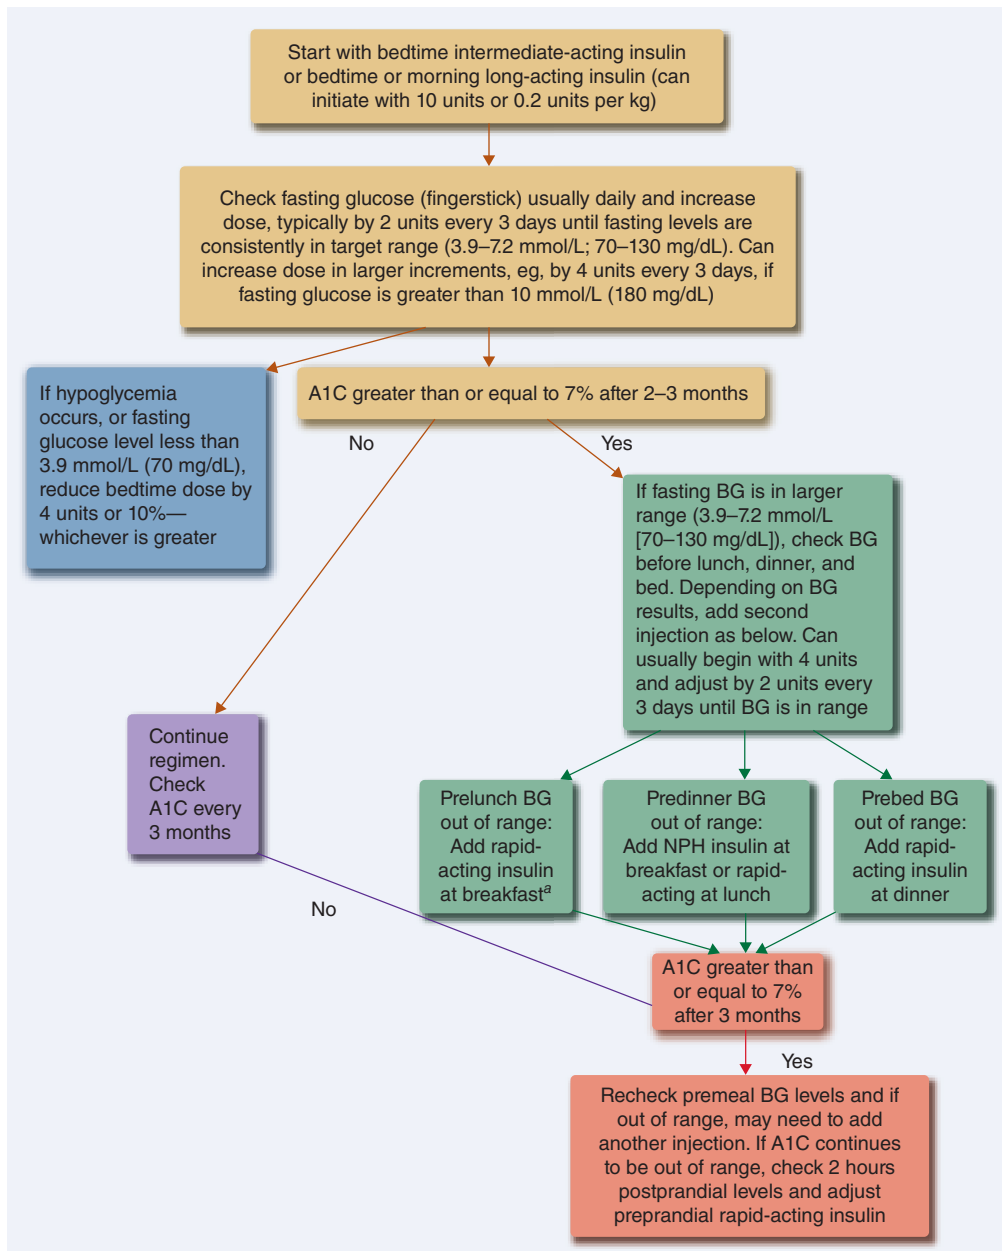

FIGURE 43–1. Initiation and adjustment of insulin regimens. Insulin regimens should be designed while taking lifestyle and meal schedule into account. The algorithm can only provide basic guidelines for initiation and adjustment of insulin. “Premixed insulins not recommended during adjustment of doses; however, they can be used conveniently, usually before breakfast and/or dinner, if the proportion of rapid- and intermediate-acting insulins is similar to the fixed proportions available. A1c of 7% is equivalent to 0.07 or 53 mmol/mol Hb. (A1c, hemoglobin A1c; BG, blood glucose; NPH, neutral protamine Hagedorn.) (Nathan DM, Buse JB, Davidson MB, et al. Medical management of hyperglycemia in type 2 diabetes: A consensus algorithm for the initiation and adjustment of therapy: A consensus statement from the American Diabetes Association and the European Association for the Study of Diabetes. *Diabetes Care* 2009;32:193–203; With permission.)

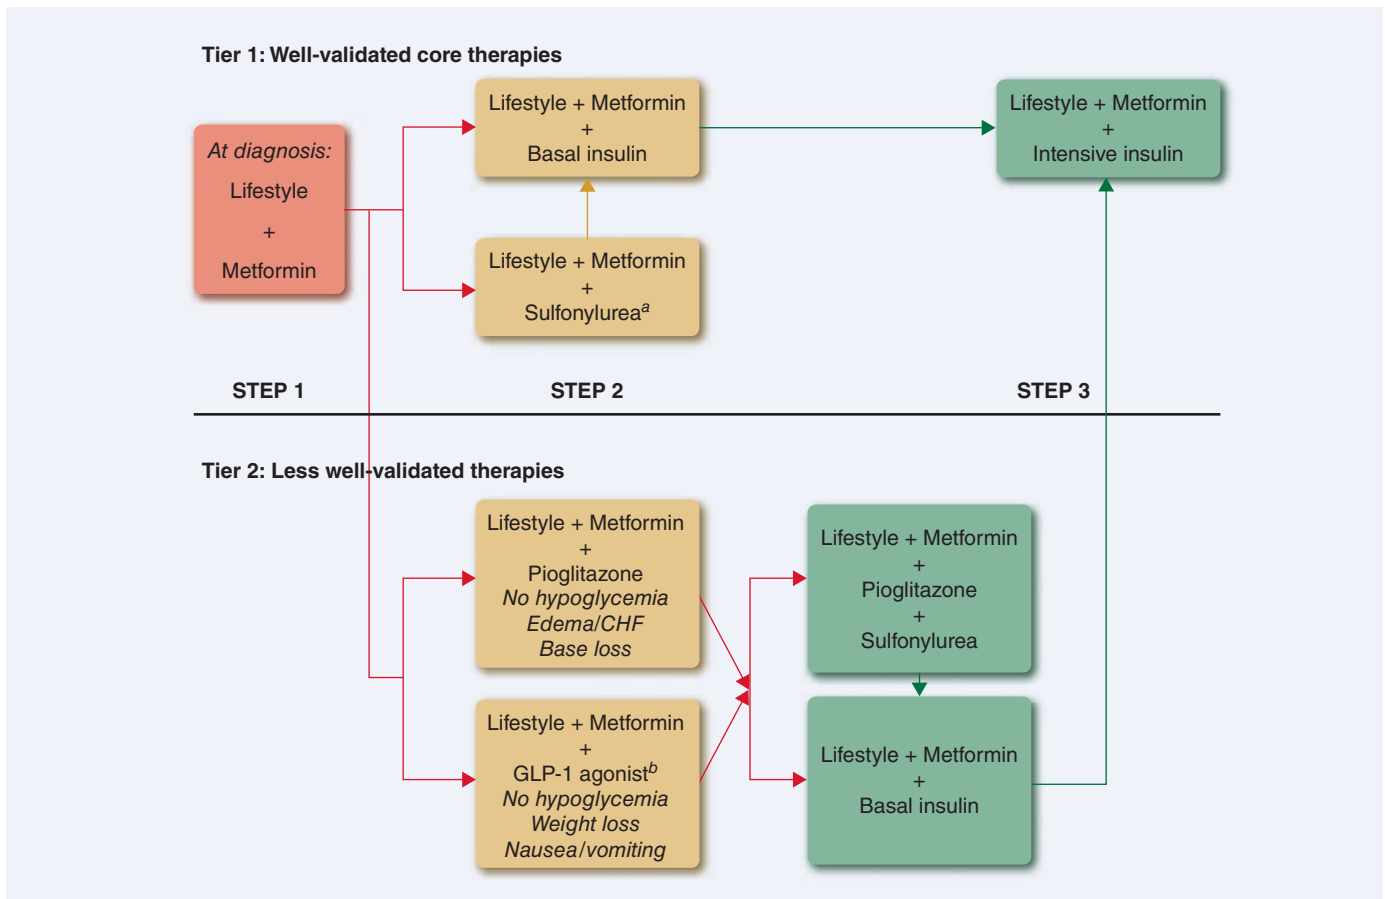

FIGURE 43-2. Algorithm for the metabolic management of type 2 diabetes mellitus; reinforce lifestyle interventions at every visit and check hemoglobin A1c every 3 months until A1c is less than 7% (0.07; 53 mmol/mol Hb) and then at least every 6 months. The interventions should be changed if A1c is greater than or equal to 7% (0.07; 53 mmol/mol Hb). ^aSulfonylureas other than glybenclamide (glyburide) or chlorpropamide. ^bInsufficient clinical use to be confident regarding safety. See Figure 43-1 for initiation and adjustment of insulin. (CHF, congestive heart failure; GLP-1, glucagon-like peptide-1.) (Nathan DM, Buse JB, Davidson MB, et al. Medical management of hyperglycemia in type 2 diabetes: A consensus algorithm for the initiation and adjustment of therapy: A consensus statement from the American Diabetes Association and the European Association for the Study of Diabetes. *Diabetes Care* 2009;32:193–203; With permission.)

maintaining satisfactory blood glucose levels, and preventing nausea and other undesired GI side effects are desired goals in these patients. Controlling blood sugar levels is important to prevent harm to the baby. An abundance of glucose causes excessive insulin production by the fetus, which, if left uncontrolled, can lead to the development of an abnormally large fetus. Infant hypoglycemia at delivery, hyperbilirubinemia, and complications associated with delivery of a large baby also may occur when blood glucose levels are not controlled adequately.

Insulin should be used when blood glucose levels are not maintained adequately at target levels by diet and physical activity. Even though there have been small studies showing the safety of using glyburide, metformin, and insulin glargine during pregnancy, the use of these agents is not recommended as a general rule. In women who develop GDM and cannot control blood glucose levels with lifestyle modifications, the use of insulin detemir, insulin aspart, lispro, or regular insulin has category B safety ratings.

Nonpharmacologic Therapy

► Medical Nutrition Therapy

- Despite the popular notion, there is not a “diabetic diet,” and the recommended meal plan for patients with diabetes should be low in fat, high in fiber, and low to moderate in calories and should achieve a balance of the various components and nutrients needed.¹⁰ MNT is considered an integral component of diabetes management and diabetes self-management education. People with DM should receive individualized MNT, preferably by a registered dietitian. As part of the diabetes management plan, MNT should not be a single education session but rather an ongoing dialog. MNT should be customized to take into account cultural, lifestyle, and financial considerations. MNT plans should integrate a variety of foods that the patient enjoys and allow for flexibility to encourage patient empowerment and improve patient adherence.

During these MNT educational and planning sessions, patients receive instructions on appropriate food selection, preparation, and proper portion control. The primary focus of MNT for patients with T1DM is matching optimal insulin dosing to carbohydrate consumption. In T2DM, the primary focus is portion control and controlling blood glucose, blood pressure, and lipids through individualizing limits of carbohydrates, saturated fats, sodium, and calories.

Carbohydrates are the primary contributor to postmeal glucose levels. However, recommended total daily carbohydrate intake should not be less than 130 g for most patients.²⁸ The percentages of fat, protein, and carbohydrate included in each meal should be individualized based on the specific goals of each patient.¹⁰

► Dietary Supplements

Patients may seek and use dietary supplements in the treatment of diabetes. Although there is insufficient evidence of efficacy for improved blood glucose control for any individual herb or supplement, those that have been studied do appear to be generally safe.²⁹ Data from randomized controlled trials do seem to support the efficacy of *Coccinia indica* and American ginseng for improving glucose control. Other studied supplements include chromium, *Gymnema sylvestris*, aloe vera, vanadium, *Momordica charantia*, and nopal. Patients will inquire about and use dietary supplements. It is important that pharmacists respect the patient's health beliefs, address their questions and concerns, and educate them on the differences between dietary supplements and prescribed therapies.

► Weight Management

Moderate weight loss in patients with T2DM has been shown to reduce cardiovascular risk, as well as delay or prevent the onset of DM in those with prediabetes.^{10,30} The recommended primary approach to weight loss is therapeutic lifestyle change (TLC), which integrates a 7% reduction in body weight and an increase in physical activity.¹⁰ A slow but progressive weight loss of 0.45 to 0.91 kg (1 to 2 lb) per week is preferred.³¹ Although individual target caloric goals should be set, a general rule for weight loss diets is that they should supply at least 1,000 to 1,200 kcal/day (about 4,200 to 5,000 kJ/day) for women and 1,200 to 1,600 kcal/day (about 5,000 to 6,700 kJ/day) for men. Because 80% of patients with T2DM are overweight, this strategy works best for these patients. Gastric reduction surgeries (gastric banding or procedures that bypass, transpose, or resect portions of the small intestine), when used as a part of a comprehensive approach to weight loss, are recommended for consideration in patients with T2DM and a BMI that exceeds 35 kg/m².¹⁰

► Physical Activity

Physical activity is also an important component of a comprehensive DM management program. Regular physical activity has been shown to improve blood glucose control and reduce cardiovascular risk factors such as hypertension and elevated

serum lipid levels.³⁰ Physical activity is also a primary factor associated with long-term maintenance of weight loss and overall weight control. Regular physical activity also may prevent the onset of T2DM in high-risk persons.

Before initiating a physical activity program, several considerations should be made. Patients should undergo a detailed physical examination, including screening for microvascular or macrovascular complications that may be worsened by a particular activity. Initiation of physical activities in an individual with a history of a sedentary lifestyle should begin with a modest increase in activity. Walking, swimming, and cycling are examples of low-impact exercises that could be encouraged. At the same time, gardening and usual housecleaning tasks are good exercises as well. Recommended physical activity goals for patients with T2DM include 150 minutes per week of moderate to vigorous aerobic exercise spread out during at least 3 days of the week with no more than 2 consecutive days between bouts of aerobic activity and moderate to vigorous resistance training at least 2 to 3 days per week.

► Psychological Assessment and Care

Mental health and social state have been shown to have an impact on a patient's ability to carry out DM management care tasks.¹⁰ Clinicians should incorporate psychological assessment and treatment into routine care. The ADA guidelines recommend ongoing psychological screening, including determining the patient's attitudes regarding DM; expectations of medical management and outcomes; mood and affect; general and diabetes-related quality of life; and financial, social, and emotional resources. Patients demonstrating poor self-management should be screened for diabetes-related distress, depression, anxiety, an eating disorder, and/or cognitive impairment.

► Immunizations

Influenza and pneumonia are common preventable infectious diseases that increase mortality and morbidity in persons with chronic diseases, including DM. Yearly influenza vaccinations, commonly called flu shots, are recommended for all patients with DM 6 months of age or older. Pneumococcal vaccination is also recommended for patients with DM who are 2 years of age or older as a one-time vaccination. A one-time revaccination is indicated for those older than age 64 years who were previously vaccinated when they were younger than 65 years old if the vaccine was administered more than 5 years earlier. Revaccination is also indicated in those with nephrotic syndrome or chronic renal disease and after transplantation. The hepatitis B vaccine series should also be administered as per the Center for Disease Control and Prevention's recommendations in patients with diabetes.

Pharmacotherapy

6 Oral and injectable agents are available to treat patients with T2DM who are unable to achieve glycemic control

through meal planning and physical activity. Currently, there are 11 classes of blood glucose–lowering agents available for the treatment of diabetes, including eight classes of oral agents and three injectable classes. Figure 43–1 shows a way to start insulin therapy for people with T2DM who are going to continue to take oral glucose-lowering medications.²⁷ **Table 43–8**^{27,31,32} lists the oral agents, Figure 43–2 displays the ADA Treatment Algorithm for Patients with T2DM,²⁷ and **Table 43–9** lists each non-insulin drug class with site of action and mechanism of action. The various classes of blood glucose–lowering agents target different organs and have different mechanisms of action. Each of these agents may be used individually or in combination with other medications that target different organs for synergistic effects.

► Sulfonylureas

Sulfonylureas represent the first class of oral blood glucose–lowering agents approved for use in the United States. These drugs are classified as being either first- or second-generation agents. Both classes of sulfonylureas are equally effective when given at equipotent doses. Today, the vast majority of patients receiving a sulfonylurea are prescribed a second-generation agent.

Sulfonylureas enhance insulin secretion by blocking ATP-sensitive potassium channels in the cell membranes of pancreatic β cells.¹³ This action results in membrane depolarization, allowing an influx of calcium to cause the translocation of secretory granules of insulin to the cell surface, and enhances insulin secretion in a non–glucose-dependent manner. However, the extent of insulin secretion depends on the blood glucose level. Whereas more insulin is released in response to higher blood glucose levels, the additional insulin secretion from sulfonylureas is less at near-normal glucose levels. Insulin is then transported through the portal vein to the liver, suppressing hepatic glucose production.

All sulfonylureas undergo hepatic biotransformation, with most agents being metabolized by the cytochrome P450 2C9 pathway. The first-generation sulfonylureas are more likely to cause drug interactions than second-generation agents. All sulfonylureas except tolbutamide require a dosage adjustment or are not recommended in renal impairment.³² In elderly patients or those with compromised renal or hepatic function, lower starting dosages are necessary.

Sulfonylureas' blood glucose–lowering effects can be observed in both fasting and postprandial levels. Monotherapy with these agents generally produce a 1.5% to 2% (0.015 to 0.02 or 16 to 22 mmol/mol Hg) decline in A1c concentrations and a 60- to 70-mg/dL (3.3 to 3.9 mmol/L) reduction in FBG levels.¹³ Secondary failure with these drugs occurs at a rate of 5% to 7% per year as a result of continued pancreatic β -cell destruction. One limitation of sulfonylurea therapy is the inability of these products to stimulate insulin release from β cells at extremely high glucose levels, a phenomenon called glucose toxicity. Common adverse effects include hypoglycemia and weight gain. There may be some cross-sensitivity in patients with sulfa allergy.

► Nonsulfonylurea Secretagogues (Glinides)

Although producing the same effect as sulfonylureas, nonsulfonylurea secretagogues, also referred to as meglitinides, have a much shorter onset and duration of action. Glinidine secretagogues also produce a pharmacologic effect by interacting with ATP-sensitive potassium channels on the β cells; however, this binding is to a receptor adjacent to those to which sulfonylureas bind.

The primary benefit of nonsulfonylurea secretagogues is in reducing postmeal glucose levels. These agents have demonstrated a reduction in A1c levels between 0.8% and 1% (0.008 and 0.01; 9 to 11 mmol/mol Hb). Because they have a rapid onset and short duration of action, they are to be taken 15 to 30 minutes before a meal.

They also may be used in combination therapy with other drugs to achieve synergistic effects. Combinations with biguanides are most commonly seen.

► Biguanides

The only biguanide approved by the Food and Drug Administration (FDA) and currently available in the United States is metformin. Metformin was approved in the United States in 1995. This agent is thought to lower blood glucose by decreasing hepatic glucose production and increasing insulin sensitivity in both hepatic and peripheral muscle tissues; however, the exact mechanism of action remains unknown. Metformin lowers both fasting blood sugar (FBS) and postmeal blood glucose.³¹ It has been shown to reduce A1c levels by 1.5 to 2% (0.015 to 0.02; 16 to 22 mmol/mol Hb) and FPG levels by 60 to 80 mg/dL (3.3 to 4.4 mmol/L) when used as monotherapy.¹³ Unlike the sulfonylureas, metformin retains the ability to reduce fasting glucose levels when they are over 300 mg/dL (16.7 mmol/L). Metformin does not affect insulin release from β cells of the pancreas, so hypoglycemia is not a common side effect.³²

Metformin significantly reduced all-cause mortality and the risk of stroke in overweight patients with T2DM compared with intensive therapy with sulfonylurea or insulin in the UKPDS.³³ It also reduced diabetes-related death and myocardial infarction compared with a conventional therapy arm. Given that metformin is the only oral antihyperglycemic medication proven to reduce mortality and is available generically, the ADA treatment algorithm (see Fig. 43–2) considers lifestyle modification and metformin as first-line therapy for T2DM.²⁷

Metformin has been shown to produce beneficial effects on serum lipid levels and has become a first-line agent for T2DM patients with metabolic syndrome. On average, triglyceride and low-density lipoprotein (LDL) cholesterol levels may be reduced by as much as 18.69% and 12.09%, respectively, but HDL cholesterol may improve by as much as 1.17%.³⁴ Metformin is often used in combination with a sulfonylurea or a thiazolidinedione (TZD) for synergistic effects.

Metformin does not undergo significant protein binding and is eliminated from the body unchanged in the urine. Patients with a calculated creatinine clearance of

Table 43-8

Oral Agents for the Treatment of T2DM^{27,31,32}

Drug Class	Target Organ	Blood Glucose Affected	Adjustment for Renal Impairment	Adjustment for Renal Impairment	Adjustment for Hepatic Impairment	Common Adverse Drug Reactions	Drugs		
			CrCl 30–50 mL/min (0.50–0.83 mL/s)	CrCl Less Than 30 mL/min (0.50 mL/s)			Trade	Generic/Commercially Available	Dosing Strategy (All Agents Are Taken Orally)
α-Glucosidase Inhibitors	Brush border of small intestine	Postprandial	Serum creatinine more than 2 mg/dL (177 μmol/L): Not recommended	Serum creatinine more than 2 mg/dL (177 μmol/L): Not recommended	No specific dose adjustment recommended	GI (flatulence, diarrhea)	Precose	Acarbose/Y	25 mg 3 × daily with first bite of each main meal Advance at 4–8 week intervals to a maximum of 100 mg 3 × daily
			Serum creatinine more than 2 mg/dL (177 μmol/L): Not recommended	Serum creatinine more than 2 mg/dL (177 μmol/L): Not recommended	No adjustment necessary	GI (flatulence, diarrhea)	Glyset	Miglitol/N	25 mg 3 × daily with first bite of each main meal Advance at 4–8 week intervals to a maximum of 100 mg 3 × daily
Glitinides (should not be used in combination with other insulin secretagogues)	Pancreas	Postprandial	20–40 mL/min (0.33–0.67 mL/s): Initial dose: 0.5 mg with careful titration	Less than 20 mL/min (0.33 mL/s): Not studied	Use conservative initial and maintenance doses and use longer intervals between dose adjustments	Hypoglycemia (although less risk than with sulfonylureas)	Prandin	Repaglinide/N	0.5 mg 15–30 minutes before each meal Double preprandial dose every 7 days to a maximum of 4 mg/dose or 16 mg/day (To be taken only if eating)
			No specific dose adjustment recommended	Use with caution in severe dysfunction	No dose adjustment needed in mild impairment; use with caution in moderate to severe dysfunction	Hypoglycemia (although less risk than with sulfonylureas)	Starlix	Nateglinide/Y	120 mg 3 × day before meals (To be taken only if eating)
Second-generation sulfonylureas	Pancreas	Fasting and postprandial	Not recommended	Not recommended	Use conservative dosing and avoid in severe disease	Hypoglycemia, weight gain	Micronase	Glyburide/Y	1.5–3 mg/day with breakfast Increase by 1.5 mg weekly to a maximum of 12 mg/day
			Not recommended	Not recommended	Use conservative dosing and avoid in severe disease	Hypoglycemia, weight gain	DiaBeta	Glyburide/Y	2.5–5 mg/day with breakfast Increase by 2.5 mg weekly to a maximum of 20 mg/day
			No specific dose adjustment recommended	No specific dose adjustment recommended	Initial dose: 2.5 mg/day	Hypoglycemia, weight gain	Glucotrol	Glipizide/Y	5 mg/day 30 minutes before a meal Increase by 5 mg weekly to a maximum of 40 mg/day; divide dose if greater than 15 mg/day

(Continued)

			No specific dose adjustment recommended	No specific dose adjustment recommended	No specific dose adjustment recommended	Hypoglycemia, weight gain	Glucator XL	Glipizide ER/Y	5 mg once daily before a meal Increase by 5 mg weekly to a maximum of 20 mg/day
			No specific dose adjustment recommended	Less than 22 mL/min (0.37 mL/s): Initial starting dose should be 1 mg	No specific dose adjustment recommended	Hypoglycemia, weight gain	Amaryl	Glimeperide/Y	1–2 mg with breakfast Increase by 2 mg every 1–2 weeks to a maximum of 8 mg/day
Biguanides	Liver	Fasting and postprandial	Avoid	Avoid	Avoid	GI (diarrhea, abdominal pain)	Glucophage Fortamet Riomet	Metformin/Y	500 mg/day to twice daily with meals Advance weekly to a maximum of 2000–2550 mg/day
							Glucophage ER, Glumetza	Metformin, ER/Y	500–1000 mg/day; dose may be increased by 500 mg weekly to a maximum of 2000 mg/day
Thiazolidinediones	Peripheral tissue	Fasting and postprandial	No adjustment necessary	No adjustment necessary	Clearance lower in Child-Pugh grade B/C; do not start if transaminases more than 2.5 × ULN and discontinue if ALT rises to and remains at more than 3 times ULN	Weight gain	Actos	Pioglitazone/N	15–30 mg/day Increase after 12 weeks to a maximum of 45 mg/day
Dipeptidyl peptidase-4 inhibitors	GI tract (increases GLP-1)	Fasting and postprandial	50 mg once daily	25 mg once daily	Child-Pugh score 7–9: No dosage adjustment necessary Child Pugh score more than 9: Not studied	Upper respiratory, diarrhea	Januvia	Sitagliptin/N	100 mg/day
			2.5 mg once daily	2.5 mg once daily	No dose adjustment necessary	UTI, headache	Onglyza	Saxagliptin/N	2.5 or 5 mg once daily
			No dose adjustment necessary	No dose adjustment necessary	No dose adjustment necessary	Headache, arthralgia, nasopharyngitis	Tradjenta	Linagliptin/N	5 mg/day
Dopamine receptor agonist	Hypothalamus	Postprandial	No dose adjustment necessary	No dose adjustment necessary	No specific dose adjustment recommended, although adjustment may be necessary because of extensive hepatic metabolism	Nausea, headache	Cycloset	Bromocriptine mesylate/N	0.8 mg once daily within 2 hours of waking; may increase in weekly intervals to 4.8 mg once daily
Bile acid sequestrant	Intestinal lumen	Fasting	No dose adjustment necessary	No dose adjustment necessary	No dose adjustment necessary	Constipation	Welchol	Colesevelam/N	1.875 g twice daily or 3.75 g once daily

ALT, alanine aminotransferase; CrCl, creatinine clearance; ER, extended release; GI, gastrointestinal; GLP-1, glucagon-like peptide-1; ULN, upper limit of normal; UTI, urinary tract infection.

Table 43-9

Site and Mechanism of Action for Non-Insulin Agents

Site of Action	Drug Class	Mechanism of Action
Pancreas	Sulfonylureas	Enhance insulin secretion
	Nonsulfonylurea secretagogues	Enhance insulin secretion
	GLP-1 agonists	Enhance insulin secretion and suppress glucagon secretion
	Pramlintide	Suppresses glucagon secretion
Liver	Biguanide	Decreases hepatic glucose production and increases insulin sensitivity
	Thiazolidinedione	Increases insulin sensitivity
Muscle	Biguanide	Increases insulin sensitivity
	Thiazolidinedione	Increases insulin sensitivity
Adipose tissue	Thiazolidinedione	Increases insulin sensitivity
Intestines	GLP-1 agonists	Increase satiety and regulate gastric emptying
	Pramlintide	Increase satiety and regulates gastric emptying
	Dipeptidyl peptidase-4 inhibitors	Increase endogenous GLP-1
	α -Glucosidase Inhibitors	Delay the absorption of carbohydrates

GLP-1, glucagon-like peptide-1

less than 60 mL/min (1.0 mL/s) should not receive this product.³² It is contraindicated in patients with a serum creatinine level greater than or equal to 1.4 mg/dL (124 μ mol/L) in women and 1.5 mg/dL (133 μ mol/L) in men. It should not be initiated in patients 80 years of age or older unless normal renal function has been established. Additionally, therapy with metformin should be withheld in patients undergoing surgery or radiographic procedures in which a nephrotoxic dye is used. Therapy should be withheld the day of the radiographic procedure, and renal function should be assessed 48 hours after the procedure. If renal function is normal, therapy may be resumed.

Primary side effects associated with metformin therapy are GI in nature, including decreased appetite, nausea, and diarrhea. These side effects can be minimized through slow titration of the dose and often subside within 2 weeks.²⁷ Interference with vitamin B₁₂ absorption has also been reported.¹³

Biguanides such as metformin are thought to inhibit mitochondrial oxidation of lactic acid, thereby increasing the chance of lactic acidosis occurring. Fortunately, the incidence of lactic acidosis in clinical practice is rare. Patients at greatest risk for developing lactic acidosis include those with renal impairment and those who are of advanced age.³² Metformin should be withheld promptly in cases of hypoxemia, sepsis, or dehydration. Patients should avoid consumption of excessive amounts of alcohol while taking metformin, and use of the drug should be avoided in patients with liver disease. It is common practice to evaluate liver function before initiation of metformin.

► Thiazolidinediones

Commonly referred to as TZDs or glitazones, thiazolidinediones have established a role in T2DM therapy. TZDs are known to increase insulin sensitivity by stimulating peroxisome proliferator-activated receptor gamma (PPAR- γ).¹³ Stimulation of PPAR- γ results in a number of intracellular

and extracellular changes including increased insulin sensitivity and decreased plasma fatty acid levels. As monotherapy, TZDs reduce FPG levels by around 60 to 70 mg/dL (3.3 to 3.9 mmol/L), and the effect on A1c is an up to 1.5% (0.015; 16 mmol/mol Hb) reduction. The onset of action for TZDs is delayed for several weeks and may require up to 12 weeks before maximum effects are observed.

Additional effects of TZDs are seen in the lipid profile. Both pioglitazone and rosiglitazone increase HDL cholesterol, with rosiglitazone increasing HDL an average of 2.4 mg/dL (0.06 mmol/L) and pioglitazone increasing HDL an average of 5.2 mg/dL (0.13 mmol/L).³⁴ Pioglitazone has been shown to decrease serum triglycerides 51.9 mg/dL (0.59 mmol/L) on average, but an increase in triglycerides has been observed with rosiglitazone. LDL cholesterol concentrations increase by 12.3 mg/dL (0.32 mmol/L) and 21.3 mg/dL (0.55 mmol/L) on average with pioglitazone and rosiglitazone, respectively.

The TZDs may produce fluid retention and edema; the mechanism by which this occurs is not completely understood.¹³ It is known that blood volume increases approximately 10% with these agents, resulting in approximately 4% to 5% of patients developing edema. Thus, these drugs are contraindicated in situations in which an increased fluid volume is detrimental such as heart failure. Fluid retention appears to be dose related and increases when combined with insulin therapy.

A few cases of hepatotoxicity have been reported with rosiglitazone and pioglitazone, but no serious complications have been reported, and symptoms typically reverse within several weeks of discontinuing therapy. Liver function tests should be performed at baseline and periodically. Patients with a baseline alanine aminotransferase (ALT) level greater than 2.5 times the upper limit of normal should not receive a TZD. If ALT levels rise to greater than three times the upper limit of normal in patients receiving a TZD and remain there, the medication should be discontinued.

Increased rates of upper and lower limb fractures are also known to occur with TZD therapy compared with other antihyperglycemic agents and, for this reason, the patient's baseline fracture risk should be considered before beginning TZD therapy. Premenopausal anovulatory women may begin to ovulate on TZD therapy, and therefore counseling should be provided to all women capable of becoming pregnant regarding this. As TZD therapy is pregnancy category C, proper precautions to avoid pregnancy should be used. In June 2011, the FDA alerted healthcare providers and patients that pioglitazone was found to be associated with an increased risk of bladder cancer after 1 year of therapy in an ongoing epidemiologic study.³² Although this study is ongoing, risk seems highest with higher dose exposure and longer duration of therapy. For this reason, patients with active bladder cancer should not use pioglitazone, and the drug should be used with caution in those with a history of bladder cancer.

A 2007 meta-analysis conducted by Nissen and colleagues reported a significantly greater risk of myocardial infarction with rosiglitazone compared with other oral agents.³⁵ A subsequent prospective study found rosiglitazone use to be associated with a nonsignificant increase in myocardial infarction risk and a nonsignificant reduction in stroke, but a trend toward increased cardiovascular risk in those patients with a history of ischemic heart disease.³⁶ In May 2011, the FDA chose to restrict access and distribution of rosiglitazone.³² It is currently only available through the Avandia-Rosiglitazone Medicines Access Program for patients currently clinically benefitting from the drug and in those with T2DM who cannot achieve adequate disease management with other agents or who are not willing to use pioglitazone-containing medications after counseling with their healthcare provider.

► *α*-Glucosidase Inhibitors

Acarbose and miglitol are *α*-glucosidase inhibitors currently approved in the United States. An enzyme that is along the brush boarder of the intestine cells called *α*-glucosidase breaks down complex carbohydrates into simple sugars, resulting in absorption.¹³ The *α*-glucosidase inhibitors work by delaying the absorption of carbohydrates from the intestinal tract, which reduces the rise in postprandial blood glucose concentrations. As monotherapy, *α*-glucosidase inhibitors primarily reduce postprandial glucose excursions. FPG concentrations have been decreased by between 40 and 50 mg/dL (2.2 and 2.8 mmol/L); however, A1c reductions range only from 0.3% to 1% (0.003 to 0.01; 3 to 11 mmol/mol Hb). Although these agents have been popular in Europe and other parts of the world, they have failed to gain widespread use in the United States. High incidences of GI side effects, including flatulence (42% to 74%), abdominal discomfort (12% to 19%), and diarrhea (29% to 31%), have limited their use.³² GI side effects occur as the result of intestinal bacteria in the distal gut metabolizing undigested carbohydrates and producing carbon dioxide and methane gas.¹³ Low initial doses followed by gradual titration may minimize GI side effects. The *α*-glucosidase inhibitors are contraindicated in

patients with short bowel syndrome or inflammatory bowel disease. In addition, neither drug in this class is recommended for patients with a serum creatinine greater than 2 mg/dL (177 μ mol/L).

► *Dipeptidyl Peptidase-4 Inhibitors (Gliptins)*

Sitagliptin, saxagliptin, and linagliptin are agents in a new class of diabetes drugs called dipeptidyl peptidase-4 (DPP-4) inhibitors. They are approved as adjunct to diet and exercise to improve glycemic control in adults with T2DM.³² These agents lower blood glucose concentrations by inhibiting DPP-4, the enzyme that degrades endogenous GLP-1.¹³ DPP-4 inhibitors increase the amount of endogenous GLP-1. The blood glucose-lowering effect of the gliptins is primarily on postprandial levels. Typical A1c reductions are 0.7% to 1% (0.007 to 0.01; 8 to 11 mmol/mol Hb). Common adverse effects include headache and nasopharyngitis. Hypoglycemia is not a common adverse effect with these agents because insulin secretion results from GLP-1 activation caused by meal-related glucose detection and not from direct pancreatic β -cell stimulation. Dosage adjustments for sitagliptin to 50 and 25 mg/day are recommended for patients with moderate (creatinine clearance, 30 to 49 mL/min [0.5 to 0.82 mL/s]) and severe (creatinine clearance less than 30 mL/min [0.50 mL/s]) renal impairment, respectively. Saxagliptin should be dosed at 2.5 mg/day with creatinine clearance less than 50 mL/min (0.83 mL/s) or if strong CYP3A4/5 inhibitors are being used concomitantly. Linagliptin, a substrate of CYP3A4, is dosed at 5 mg/day and requires no adjustment for renal or hepatic impairment.³²

The FDA revised the prescribing information for sitagliptin and sitagliptin–metformin to include information on reported cases of acute pancreatitis in patients using these products after postmarketing cases of acute pancreatitis, including hemorrhagic and necrotizing pancreatitis, were reported in patients taking sitagliptin.

► *Central-Acting Dopamine Agonist*

A quick release formulation of a central-acting dopamine agonist, bromocriptine, was approved by the FDA in May 2009 for the treatment of T2DM. The mechanism of action for how bromocriptine regulates glycemic control is unknown, but data indicate that bromocriptine administered in the morning improves insulin sensitivity, and this is likely a result of its affect on dopamine oscillations.¹³ When used to treat patients with T2DM, bromocriptine should be taken 2 hours after waking in the morning with food.³² The initial dose is 0.8 mg, titrated up weekly until a maximum dosage of 4.8 mg/day is achieved. A modest A1c reduction of 0.1% to 0.4% (0.001 to 0.004; 1 to 4 mmol/mol Hb) can be expected from this drug.¹³ Main side effects include rhinitis, dizziness, asthenia, headache, sinusitis, constipation, and nausea, and 24% of patients in clinical trials stopped taking bromocriptine because of untoward effects. Contraindications include syncopal migraine and women who are nursing.³²

► **Bile Acid Sequestrants**

Colesevelam is the only bile acid sequestrant currently approved as an adjunctive therapy to improve glycemic control in conjunction with diet, exercise, and insulin or oral agents for the treatment of T2DM. It acts on the intestinal lumen to bind bile acid, but whether this is the drug's only action that results in plasma glucose lowering or if a secondary systemic effect to bile acid binding is unknown.¹³ An A1c reduction of approximately 0.4% (0.004; 4 mmol/mol Hb) can be expected when added to metformin, sulfonylurea, or insulin. FPG is reduced about 5 to 10 mg/dL (0.3 to 0.6 mmol/L). LDL cholesterol is reduced 12% to 16%. Dosing for T2DM is six 625-mg tablets daily, which may be split into three tablets twice daily. Alternatively, a 3.75-g oral suspension can be used daily or a 1.875-g oral suspension packet can be used twice daily dissolved in a minimum of one-half to one cup of water. Common adverse effects include constipation and dyspepsia. Drug–drug interactions are possible because of absorption and can be particularly important in patients who are taking levothyroxine, glyburide, oral contraceptives, phenytoin, warfarin, and digoxin. These medications should not be taken together, and they should be separated by at least 4 hours before dosing colesevelam. Malabsorption of fat-soluble vitamins (A, D, E, and K) is also a concern.

► **Insulin**

Insulin is the one agent that can be used in all types of DM and has no specific maximum dose, meaning it can be titrated to suit each individual patient's needs. **7** *Insulin is the primary treatment to lower blood glucose levels for patients with T1DM, and injected amylin can be added to decrease fluctuations in blood glucose levels.* An insulin treatment algorithm for T2DM is found in Figure 43–2.²⁷

Insulin is available commercially in various formulations that vary markedly in terms of onset and duration of action. Insulin can be divided into two main classes, basal and bolus, based on their length of action to mimic endogenous insulin physiology. Most formulations are available as U-100, indicating a concentration of 100 unit/mL. Insulin is typically refrigerated, and most vials are good for 28 days at room temperature.³² Insulin detemir can be stored at room temperature for 42 days. Specific details of insulin products are listed in [Table 43–10](#).^{32,37}

The most common route of administration for insulin is subcutaneous injection using a syringe or pen device. Patients should be educated to rotate their injection sites to minimize lipohypertrophy, a buildup of fat that decreases or prevents proper insulin absorption. Additionally, patients should understand that the absorption rate may vary among injection sites (abdomen, thigh, arm, and buttocks) because of differences in blood flow, with absorption occurring fastest in the abdomen and slowest in the buttocks. Differences in absorption of insulin based on site of injection do not appear to be significant when analog insulins such as aspart, detemir, glargine, glulisine, and lispro are administered.

Insulin syringes are distinguished according to the syringe capacity, syringe markings, and needle gauge, and length. Insulin pens are self-contained systems of insulin delivery. The primary advantage of the pen system is the patient does not have to draw up the dose from the insulin vial.

Bolus Insulins

Regular Insulin. Regular insulin is unmodified crystalline insulin commonly referred to as natural or human insulin. It is a clear solution that has a relatively short onset and duration of action and is designed to cover insulin response to meals. On subcutaneous injection, regular insulin forms small aggregates called hexamers that undergo conversion to dimers followed by monomers before systemic absorption can occur. Patients should be counseled to inject regular insulin subcutaneously 30 minutes before consuming a meal. Regular insulin is the only insulin that can be administered IV.

Rapid-Acting Insulin. Three rapid-acting insulins have been approved in the United States: aspart, glulisine, and lispro. Substitution of one or two amino acids in regular insulin results in the unique pharmacokinetic properties characteristic of these agents. The onset of action of rapid-acting insulins varies from 15 to 30 minutes, with peak effects occurring 1 to 2 hours after administration and is dosed before or with meals.

Basal Insulins

Intermediate-Duration Insulin. Neutral protamine Hagedorn, better known as NPH insulin, is prepared by a process in which protamine is conjugated with regular insulin, rendering a product with a delayed onset but extended duration of action, and is designed to cover insulin requirements in between meals and/or overnight. With the advent of the long-acting insulins, NPH insulin use has declined because of (a) an inability to predict accurately when peak effects occur and (b) a duration of action of less than 24 hours. Additionally, protamine is a foreign protein that may increase the possibility of an allergic reaction.

NPH insulin can be mixed with regular insulin and used immediately or stored for future use up to 1 month at room temperature or 3 months in refrigeration. NPH insulin can be mixed with either aspart or lispro insulins, but it must be injected immediately after mixing. Whenever mixing insulin products with NPH insulin, the shorter acting insulin should be drawn into the syringe first.

Long-Duration Insulin. Two long-duration insulin preparations are approved for use in the United States. Glargine and detemir are designed as once-daily-dosing basal insulins. Insulin glargine differs from regular insulin by three amino acids, resulting in a low solubility at physiologic pH. The clear solution is supplied at a pH of 4, which precipitates on subcutaneous administration. Detemir binds to albumin in the plasma, which gives it sustained action. Neither glargine nor detemir can be administered IV or mixed with other insulin products.

Both glargine and detemir have been shown to produce slower, more prolonged absorption and a relatively constant concentration over 24 hours as compared with NPH. Although detemir is recommended for dosing in the evening

Table 43–10

Insulin Agents for the Treatment of T1DM and T2DM^{32,37}

Generic Name (Insulin)	Brand/Rx Only	Manufacturer	Strength	Onset (minutes)	Peak (hours)	Duration (hours)	Administration Options
Rapid-Acting Insulin							
Lispro	Humalog/yes	Eli Lilly	U-100	15–30	0.5–2.5	3–4	10-mL vial, 3-mL cartridge, and disposable pen
Aspart	Novolog/yes	Novo-Nordisk	U-100	15–30	1–3	3–5	10-mL vial, 3-mL cartridge, and disposable pen
Glulisine	Apidra/yes	Aventis	U-100	15–30	1–2	3–4	10-mL vial, 3-mL cartridge, and disposable pen
Short-Acting Insulin							
Regular	Humulin R/no	Eli Lilly	U-100, U-500	30–60	2–3	3–6	U-100 10-mL vial; U-500 20-mL vial
	Novolin R/no	Novo-Nordisk	U-100				10-mL vial, 3-mL cartridge, 3-mL <i>Innolet</i>
Intermediate-Acting Insulin							
Neutral protamine Hagedorn	Humulin N/no	Eli Lilly	U-100	2–4 hours	4–6	8–12	10-mL vial, 3-mL cartridge
	Novolin N/no	Novo-Nordisk	U-100				10-mL vial, 3-mL cartridge, 3-mL <i>InnoLet</i>
Long-Acting Insulin							
Glargine	Lantus/yes	Aventis	U-100	4–5 hours	Flat	22–24	10-mL vial, 3-mL cartridge for <i>Opticlik</i> (available in SoloSTAR disposable pen)
Detemir	Levemir/yes	Novo-Nordisk	U-100	3–4 hours	Flat	Up to 24	10-mL vial, 3-mL cartridge, 3-mL <i>Innolet</i> , 3-mL disposable <i>FlexPen</i>
Combination Insulin Products							
Neutral protamine Hagedorn and regular	Humulin 70/30/no	Eli Lilly	U-100	30–60	1.5–16	10–16	10-mL vial, 3-mL disposable pen
	Novolin 70/30/no	Novo Nordisk	U-100	30–60	2–12	10–16	10-mL vial, 3-mL cartridge, 3-mL <i>Innolet</i>
	Humulin 50/50/no	Eli Lilly	U-100	30–60	2–5.5	10–16	10-mL vial
Neutral protamine lispro and lispro	Humalog Mix 75/25/yes	Eli Lilly	U-100	15–30	1–6.5	15–18	10-mL vial, 3-mL disposable pen
Neutral protamine aspart and aspart	Novolog Mix 70/30/yes	Novo Nordisk	U-100	15–30	1–4	Up to 24	10-mL vial, 3-mL cartridge, 3-mL disposable <i>FlexPen</i>

if being used as a once-daily dose, it stands to reason that both glargine and detemir could be administered irrespective of meals or time of day.

Combination Insulin Products A number of combination insulin products are available commercially. NPH is available in combinations of 70/30 (70% NPH and 30% regular insulin) and 50/50 (50% NPH and 50% regular insulin). Two short-acting insulin analog mixtures are also available. Humalog mix 75/25 contains 75% insulin lispro protamine suspension and 25% insulin lispro. Novolog mix 70/30 contains 70% insulin aspart protamine suspension and 30% insulin aspart. The lispro and aspart insulin protamine suspensions were developed specifically for these mixture products and are not commercially available separately.

► Insulin Pump Therapy

Insulin pump therapy consists of a programmable infusion device that allows for basal infusion of insulin 24 hours daily

(Fig. 43–3), as well as bolus administration before meals and snacks. Currently, there are seven commercially available insulin pumps in the United States. Regular or rapid-acting insulin is delivered from a reservoir either by infusion set tubing or through a small canula. Most pump infusion sets are inserted in the abdomen, arm, or other infusion site by a small needle. Most patients prefer insertion in abdominal tissue because this site provides optimal insulin absorption. Infusion sets should be changed every 2 to 3 days to reduce the possibility of infection.

Patients use a carbohydrate-to-insulin ratio to determine how many units of insulin are required. More specifically, an individual's ratio is calculated to determine how many units of the specific insulin being used in the pump “covers” for a certain amount of carbohydrates to be ingested at a particular meal. The 450 rule (for regular insulin) or the 500 rule (for rapid-acting insulin) is commonly used. To calculate the ratio using the 500 rule, the patient would divide 500 by his or her total daily dose of insulin. For example, if a patient were using 25 units of insulin daily, his or her carbohydrate-to-insulin

FIGURE 43-3. Insulin pump and placement.

ratio would be 500:25, or 20:1. This ratio theoretically means that 1 unit of rapid-acting insulin should cover 20 g of carbohydrate. If blood sugar levels are below or above the desired blood glucose target, the amount of insulin can be adjusted. Once this ratio is determined, patients can eat more or fewer carbohydrates at a given meal and adjust the bolus dose accordingly.

In addition to mealtime boluses, correction doses based on premeal glucose readings are also used. The amount of additional insulin for the correction is based on either the 1500 rule for regular insulin or the 1800 rule for rapid-acting insulin. For example, if using rapid-acting insulin, divide 1800 by the patient's total daily insulin dose. The resulting value will represent the reduction in glucose (mg/dL) produced by one unit of insulin. If a patient is injecting 10 units of rapid-acting insulin before each of his or her 3 meals and 20 units of Lantus in the evening, his or her total daily dose would be 60 units. Using the 1800 rule, we find that 1800 divided by 60 is 30. Thus, 1 unit of rapid-acting insulin would be added for every 30 mg/dL the patient's glucose is above the premeal goal as a correction factor. The correction dose would be given in addition to the bolus dose needed based on the patient's carbohydrate-to-insulin ratio and the amount of carbohydrates present in the meal he or she is about to consume.

Insulin pump therapy may be used to lower blood glucose levels in any type of DM; however, patients with T1DM are the most likely candidates to use these devices. Use of an insulin pump may improve blood glucose control, reduce wide fluctuations in blood glucose levels, and allow individuals to have more flexibility in timing and content of meals and exercise schedules. Insulin pump therapy is not for everyone, and the complexity associated with its use, cost, increased need for blood glucose monitoring, and psychological factors may prevent individuals from using this technology optimally.

► **Noninsulin Injectable Agents**

Glucagon-Like Peptide 1 Agonists Glucagon-like peptide 1 (GLP-1) agonists enhance glucose-dependent insulin secretion while suppressing inappropriately high glucagon secretion in the presence of elevated glucose, which results in reduced hepatic glucose production.¹³ These agents are also a part of the group of drugs that act as insulin agonists by producing supraphysiologic levels of GLP-1 (**Table 43-11**).^{13,38,39} Exenatide and liraglutide are both indicated for the treatment of T2DM to improve glycemic control.³² In a 26-week head-to-head trial in patients with T2DM with a baseline A1c between 7% and 11% (0.07 and 0.11; 53 and 97 mmol/mol Hb) who were taking metformin, sulfonylurea, or both, exenatide lowered A1c 0.8% (0.008; 9 mmol/mol Hb), but liraglutide lowered A1c a significantly greater amount at 1.1% (0.011; 12 mmol/mol Hb).⁴⁰ Both drugs produced similar weight loss, with an average reduction of 3.24 kg (7.13 lb) for liraglutide and 2.87 kg (6.31 lb) for exenatide.

GLP-1 agonists lower blood glucose levels by (a) producing glucose-dependent insulin secretion; (b) reducing postmeal glucagon secretion, which decreases postmeal glucose output; (c) increasing satiety which decreases food intake; and (d) regulating gastric emptying, which allows nutrients to be absorbed into the circulation more smoothly.¹³ For exenatide, the t_{\max} (defined as time after administration when the maximum plasma concentration is reached) is approximately 2 hours, and the plasma half-life is around 3.3 to 4 hours. Plasma concentrations are detected up to 10 hours after injection, although pharmacodynamic action lasts for approximately 6 hours. Hence, exenatide is recommended for twice-daily dosing in its immediate-release dosage form. A once weekly extended-release dosage form is also available.³⁹ Liraglutide's half-life is 13 hours, making it suitable for once-daily dosing.

Table 43-11

Noninsulin Injectable Agents for the Treatment of Diabetes^{13,38,39}

Generic Name (Brand)	Type of Diabetes	Dosage Strengths ^a	Starting Dosage	Doses/Day	Titration Interval	Maximum Dose	Time to Effect (minutes)	Comments and Cautions
Pramlintide ^b (Symlin)	1	15, 30, 45, 60 mcg	15	3	3–7 days	60 mcg	20	Take just before major meals; reduce insulin by 50% Maintenance dose 30–60 mcg
	2	60, 120 mcg	60	3	3–7 days	120 mcg	20	Side effects: Hypoglycemia, nausea, vomiting Available in SymlinPen 60 and 120
Exenatide ^b (Byetta, Bydureon)	2	Immediate-release: 5 mcg, 10 mcg, extended-release: 2 mg	Immediate-release: 5 mcg, extended-release: 2 mg	Immediate-release: 2, extended-release: N/A; once-weekly	Immediate-release: 1 month, extended-release: N/A	Immediate-release: 10 mcg, extended-release: 2 mg	Immediate-release: 15–30	Inject immediate-release formulation 15–20 minutes before 2 meals of the day with 6 hours separating the meals; prefilled disposable pen; may delay absorption of oral drugs; separate doses by 1 hour Extended-release formulation can be administered regardless of meals Side effects: Nausea, vomiting, diarrhea, increased hypoglycemia with sulfonylureas
		Liraglutide ^b (Victoza)	2	6 mg/3 mL pen	0.6 mg	1	1 week	1.8 mg

^aPramlintide supplied as 0.6 mg/mL in 5-mL vials. Exenatide immediate-release supplied as 250 mcg/mL, 1.2 mL for the 5-mcg prefilled pen, and 2.4 mL for the 10-mcg per dose prefilled pen. Exenatide extended-release supplied as 2 mg sterile powder plus 0.65 mL diluent in single use trays. Liraglutide supplied in 6 mg/3 mL prefilled pen, which can be dialed to the desired dose of 0.6, 1.2, or 1.8 mg.

^bGeneric not available in United States.

Exenatide is eliminated renally and is not recommended in patients with a creatinine clearance of less than 30 mL/min (0.50 mL/s).³² No specific dose adjustments are recommended for liraglutide in renal impairment. An increased risk of hypoglycemia occurs when GLP-1 agonists are used in combination with a sulfonylurea.¹³ Hypoglycemia is not encountered when used as monotherapy or in conjunction with metformin and/or thiazolidinedione therapy. The main side effects of GLP-1 agonist therapy include nausea, vomiting, and diarrhea. These GI adverse effects tend to lessen over time. No major drug interactions have been found with exenatide. GLP-1 agonists delay absorption of other medications, so it is best to take concomitant medications 1 hour before or 3 hours after a GLP-1 agonist if rapid absorption of the concomitant medication is required.

GLP-1 agonists have been associated with cases of acute pancreatitis. For this reason, neither drug should be used in a patient with a history of pancreatitis. Any patient presenting with symptoms of acute pancreatitis, including abdominal pain, nausea, and vomiting, should have GLP-1 agonist therapy discontinued until pancreatitis can be ruled out. Both liraglutide and exenatide extended-release packagings contain a black box warning about thyroid C-cell tumors. They are contraindicated in patients with a personal or family history of medullary thyroid cancer and in those with a history of multiple endocrine tumors.

Exenatide is currently available in 5- and 10-mcg injectable prefilled disposable pens and a 2 mg extended-release injectable suspension. Initial therapy of the immediate-release product is 5 mcg twice daily, injected zero to 60 minutes

before the morning and evening meals. Patients who do not eat breakfast can take their first dose before lunch. Doses are then increased after a month to 10 mcg if the patient's blood glucose is improving and nausea is limited. Exenatide extended-release 2 mg is administered by subcutaneous injection once every 7 days immediately after the powder is suspended and can be dosed at any time of day and without regard to meals. Liraglutide is available in 6-mg/3 mL prefilled disposable pens that can be dialed to the desired dose of 0.6, 1.2, or 1.8 mg. Liraglutide should be dosed at 0.6 mg/day for at least 1 week and then increased to 1.2 mg/day for at least 1 week before being increased to the maximum dose of 1.8 mg if needed. Liraglutide can be dosed at any time of day regardless of meals.

Amylin Pramlintide acetate was approved for use in the United States in March 2005 (see Table 43–11).³⁸ This agent is a synthetic analog of human amylin, which is a naturally occurring neuroendocrine peptide that is cosecreted by the β cells of the pancreas in response to food. Amylin secretion is completely deficient in patients with T1DM, or relatively deficient in patients with T2DM. Pramlintide is given by subcutaneous injection before meals to lower postprandial blood glucose elevations. Pramlintide generally results in an average weight loss of 1 to 2 kg (2.2 to 4.4 lb).

Pramlintide is indicated as combination therapy with insulin in patients with types 1 or 2 DM. It has been shown to decrease A1c by an additional 0.4% to 0.5% (0.004 to 0.005; 4 to 5 mmol/mol Hb). Pramlintide slows gastric emptying without altering absorption of nutrients, suppresses glucagon secretion, and leads to a reduction in food intake by increasing satiety. By slowing gastric emptying, the normal initial postmeal spike in blood glucose is reduced.

Hypoglycemia, nausea, and vomiting are the most common side effects encountered with pramlintide therapy, although pramlintide itself does not produce hypoglycemia. To decrease the risk of hypoglycemia, doses of short-acting, rapid-acting, or premixed insulins should be reduced by 50% before pramlintide is initiated. Some practitioners will not decrease the premeal insulin dose this much because of fear of loss of glucose control. Primarily, the kidneys metabolize pramlintide, but dosage adjustments in liver or kidney impairment are not required.

Pramlintide has the potential to delay the absorption of orally administered medications. When rapid absorption is needed for the efficacy of an agent, pramlintide should be administered 2 hours before or 1 hour after this drug. Pramlintide should not be used in patients receiving medications that alter GI motility, such as anticholinergic agents, or drugs that slow the absorption of nutrients such as α -glucosidase inhibitors. A disposable pen formulation is now on the market and available as SymlinPen 60 for patients with T1DM and SymlinPen 120 for people with T2DM. The number of days the pen will last will vary depending on the daily dose. The amount of medication is 1.5 mL in the SymlinPen 60 and 2.7 mL in the SymlinPen 120.

Treatment of Concomitant Conditions

► Glucose Control and Cardiovascular Health

The results of three trials have recently been released showing the relationship between glucose control and cardiovascular health. The Action to Control Cardiovascular Risk in Diabetes (ACCORD),⁴¹ Action in Diabetes and Vascular Disease (ADVANCE),⁴² and Veterans Affairs Diabetes Trial (VADT)⁴³ examined if cardiovascular risks could be decreased or prevented with intensive glucose lowering. Although ACCORD was stopped early after interim analysis showed an increased risk of mortality in the intensive treatment group, both ADVANCE and VADT found that intensive therapy was no different than standard glycemic control in terms of macrovascular event rates.^{41–43} The findings of these trials, when taken into context with long term follow-up information from the UKPDS⁴⁴ and DCCT^{45,46} trials, seem to show the following: (1) 3 to 5 years of intensive glycemic control does not improve the risk of macrovascular complications in patients with long-standing T2DM and (2) a decrease in macrovascular risk from improved glycemic control may take more than a decade to be realized.

► Coronary Heart Disease

Cardiovascular disease is the major cause of morbidity and mortality for patients with DM.¹⁰ Interventions targeting smoking cessation, blood pressure control, lipid management, antiplatelet therapy, and lifestyle changes (including diet and exercise) can reduce the risk of cardiovascular events and should be considered as important as glycemic control in the management of a patient with DM. All DM patients with a history of cardiovascular disease should be prescribed aspirin 75 to 162 mg/day as a secondary prevention strategy. For those with aspirin allergy, another antiplatelet option such as clopidogrel 75 mg/day should be used. Choosing if antiplatelet therapy is appropriate for a patient with DM and no history of cardiovascular disease can be more difficult because evidence is less clear regarding benefit. The ADA currently recommends that antiplatelet therapy should be considered for any patient with DM as a primary prevention strategy if that patient's risk of cardiovascular event is considered to be greater than 10% over 10 years. This includes most men older than 50 years of age and most women older than 60 years of age who have at least one additional cardiovascular risk factor. Clinical judgment is required for patients with an estimated cardiovascular risk of 5% to 10% to determine if the possible benefit of antiplatelet therapy outweighs the potential for harm from bleeding.

► Dyslipidemia

The National Cholesterol Education Program Adult Treatment Panel III guidelines classify the presence of DM to be of the same risk equivalence as coronary heart disease (CHD).¹⁹ The primary target for lipid-lowering treatment in most patients with DM is LDL cholesterol with a goal of less

than 100 mg/dL (2.59 mmol/L). For patients at high cardiovascular risk, including those with a history of cardiovascular disease, the LDL target may be set more stringently at 70 mg/dL (1.81 mmol/L). Only when triglyceride levels exceed 500 mg/dL (5.65 mmol/L) should they replace LDL as the patient's primary therapeutic goal. Because of potent LDL cholesterol-lowering ability and the known benefit in terms of improved cardiovascular morbidity and mortality, statins are considered first-line therapy for hyperlipidemia. Because statin therapy has been shown to benefit even patients with relatively low-baseline LDL cholesterol levels, it is also important to note that the ADA guidelines currently call for all patients with DM to be prescribed a statin who fall into either of the following two categories: (1) those who have overt cardiovascular disease and (2) those who do not have overt cardiovascular disease but are older than age 40 years and have one or more other cardiovascular disease risk factors.¹⁰ Once LDL cholesterol goals are achieved with statin therapy, some patients will continue to have elevated non-HDL cholesterol produced by elevated triglyceride levels and low HDL cholesterol. Although it was common practice in the past to add niacin or fibrate therapy onto statin therapy in such patients, cardiovascular outcome benefit has not been proven with combination therapy over statin therapy alone in patients with prior cardiovascular disease or DM.^{47,48}

► Hypertension

8 Uncontrolled blood pressure plays a major role in the development of macrovascular events as well as microvascular complications, including retinopathy and nephropathy, in patients with DM. The ADA recommends that systolic blood pressure goals for patients with DM be individualized but generally set at less than 130 mm Hg.¹⁰ The diastolic blood pressure goal for patients with DM is less than 80 mm Hg. In addition, there are several general principles regarding the treatment of hypertension in diabetes patients. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers are recommended as initial therapy because of their beneficial effects on renal function. Initial combination therapy with an ACE inhibitor and dihydropyridine calcium channel blocker has been shown to reduce cardiovascular morbidity and mortality versus those receiving ACE inhibitor therapy combined with a thiazide diuretic.⁴⁹ However, thiazide diuretics work synergistically with ACE inhibitors and angiotensin II receptor blockers and can be added on for those who fail to reach blood pressure goals with a single agent alone as long as the patient's estimated glomerular filtration rate remains at 30 mL/min/1.73 m² (0.29 mL/s/m²) or higher.¹⁰ Alternatively, a loop diuretic can be used.

It can be expected that most patients will require more than one agent to reach blood pressure goal. Renal function and serum potassium levels should be monitored closely in all patients taking an ACE inhibitor, angiotensin II receptor blocker, and/or diuretic. ACE inhibitors and angiotensin II receptor blockers are contraindicated in patients who are pregnant and in those with bilateral renal artery stenosis.

Patient Encounter, Part 2: Follow-Up Visit

GH returns in 3 days with results of his fasting blood work requested by his physician. The physician also requests that his blood glucose level, A1c, and vital signs be obtained again today. The results are listed below.

VS: BP 122/76 mm Hg, P 70 beats/min, RR 19, T 38°C (100°F)

A1c (today): 7.9% (0.079; 63 mmol/mol Hb)

FPG (today): 189 mg/dL (10.5 mmol/L)

Labs (2 days ago):

- Na: 136 mEq/L (136 mmol/L)
- K: 3.6 mEq/L (3.6 mmol/L)
- Cl: 98 mEq/L (98 mmol/L)
- CO₂: 24 mEq/L (24 mmol/L)
- BUN: 15 mg/dL (5.4 mmol/L)
- SCr: 1.3 mg/dL (115 μmol/L)
- Glu: 172 mg/dL (9.5 mmol/L)

GH is diagnosed with T2DM. Identify the goals of treatment for this patient.

What nonpharmacologic and pharmacologic alternatives are available for this patient for his diabetes?

What is the most appropriate initial therapy for this patient in regards to his diabetes?

What additional interventions are recommended for this patient today?

► Human Immunodeficiency Virus (HIV) and Acquired Immune Deficiency Syndrome (AIDS)

Patients with risk factors for diabetes are more likely to develop diabetes when exposed to highly active antiretroviral therapy.⁵⁰ Universal screening of all HIV patients for diabetes is controversial, but most clinicians support screening for those with risk factors, especially if those risk factors include positive family history and central adiposity. Disturbances in glucose homeostasis are a known side effect of protease inhibitor therapy. Indinavir and ritonavir block insulin-mediated glucose disposal, causing insulin resistance, but amprenavir and atazanavir have no effect on this pathway. Indinavir also increases hepatic glucose production and release and causes insulin to lose its ability to suppress hepatic glucose production. Nelfinavir, lopinavir, and saquinavir cause a 25% reduction in β-cell function, reducing first-phase insulin release. Drug selection for treating protease inhibitor–induced hyperglycemia should address the mechanism behind the adverse effect. Protease inhibitor therapy avoidance should be considered in patients with preexisting glucose abnormalities and in those with a first-degree relative with diabetes. Metformin should be used with caution in patients taking the nucleoside reverse transcriptase inhibitors stavudine, zidovudine, and didanosine because of an increased risk for lactic acidemia.

► Antipsychotic Drug Therapy

An association has been recognized between second-generation antipsychotics and the development of diabetes.⁵¹ Risk seems to be highest with clozapine and olanzapine, but data are conflicting for risperidone and quetiapine. Aripiprazole and ziprasidone have not, as of yet, shown an increased risk for diabetes with their use. Nutrition and physical activity counseling is recommended for all patients with mental illness who are overweight or obese, especially if they are beginning second-generation antipsychotic therapy. After therapy initiation, the patient's weight should be assessed at weeks 4, 8, and 12 and then every 3 months. In the event of weight gain greater than or equal to 5% of the patient's baseline weight, a therapeutic adjustment should be considered. For patients who develop worsening glycemia or dyslipidemia while on antipsychotic therapy, it is recommended that a switch to a second-generation antipsychotic with less weight gain or diabetes potential be considered.

Treatment of Acute Complications

► Hypoglycemia

- Hypoglycemia, or low blood sugar, can be defined clinically as a blood glucose level of less than 50 mg/dL (2.8 mmol/L). Individuals with DM can experience symptoms of hypoglycemia at varying blood glucose levels. Patients who have regular blood glucose levels as high as 300 to 400 mg/dL (16.7 to 22.2 mmol/L) may experience symptoms of hypoglycemia when blood glucose levels are lowered to the middle to upper 100 mg/dL (5.6 mmol/L) range. Most people whose blood glucose levels are controlled adequately may experience symptoms when levels fall below 70 mg/dL (3.9 mmol/L). Symptoms of hypoglycemia include shakiness, sweating, fatigue, hunger, headaches, and confusion.

Common causes of hypoglycemia include delayed or inadequate amounts of food intake, especially carbohydrates, excessive doses of medications (e.g., sulfonylureas and insulin), exercising when insulin doses are reaching peak effect, or inadequately adjusted drug therapy in patients with impaired renal or hepatic function. Patients experiencing symptoms of hypoglycemia should check their blood glucose level, consume 15 g of carbohydrate, and wait 10 to 15 minutes for symptom resolution. Examples of acceptable treatments may include a small box of raisins, 4 oz (approximately 120 mL) of orange juice, 8 oz (approximately 240 mL) of skim milk, or three to six glucose tablets. In patients receiving an α -glucosidase inhibitor in combination with a sulfonylurea or insulin, hypoglycemia should be treated with glucose tablets or skim milk owing to the mechanism of action of the α -glucosidase inhibitors.

- For patients whose blood glucose levels have dropped below 50 mg/dL (2.8 mmol/L), as much as 30 g of carbohydrate may be necessary to raise blood glucose levels adequately. For patients with hypoglycemia experiencing a loss of consciousness, a glucagon emergency kit should be administered by the intramuscular or subcutaneous route. It is important to contact emergency medical personnel in this

particular situation. The patient should be rolled onto his or her side to prevent aspiration because many patients receiving the glucagon injection vomit.

► Diabetic Ketoacidosis

- Diabetic ketoacidosis is a reversible but potentially life-threatening medical emergency that results from a relative or absolute deficiency in insulin.⁵² Without insulin, the body

Patient Encounter, Part 3: Follow-Up

GH returns in 1 month for a follow-up visit. He brings his blood glucose readings from the past week for review in addition to more fasting blood work. Blood glucose readings are in units of mg/dL (mmol/L). His most recent medication list is below. There are no changes to his health record from previous visits.

Medications:

- Hydrochlorothiazide 25 mg by mouth once daily
- Simvastatin 20 mg by mouth once daily
- Fluticasone nasal spray, one spray each nostril daily as needed
- Metformin 1000 mg by mouth twice daily

VS: BP 154/96 mm Hg, P 78 beats/min, RR 18, T 38°C (100°F)

Labs:

- Total cholesterol: 240 mg/dL (6.2 mmol/L)
- HDL: 41 mg/dL (1.06 mmol/L)
- LDL: 163 mg/dL (4.22 mmol/L)
- TG: 183 mg/dL (2.07 mmol/L)
- AST: 28 U/L (0.47 μ Kat/L)
- ALT: 31 U/L (0.52 μ Kat/L)

Day	FPG	PPG
Monday	118 (6.5)	168 (9.3)
Tuesday	122 (6.8)	187 (10.4)
Wednesday	134 (7.4)	140 (7.8)
Thursday	110 (6.1)	244 (13.5)
Friday	98 (5.4)	257 (14.3)
Saturday	128 (7.1)	297 (16.5)
Sunday	116 (6.4)	240 (13.3)

Are this patient's blood glucose levels within target? What pattern seems to be established?

Based on the information available from this encounter and previous encounters, develop a care plan for this patient. The plan should include (a) identification and assessment of all drug-related needs and/or problems, (b) a detailed therapeutic plan to address each need and problem, and (c) monitoring parameters to assess safety and efficacy.

Table 43-12

Management of Diabetic Ketoacidosis⁵²

1. Confirm diagnosis (increased plasma glucose, positive serum ketones, metabolic acidosis)
2. Admit to hospital; intensive care setting may be necessary for frequent monitoring or if pH less than 7 or unconscious
3. Assess serum electrolytes (K⁺, Na⁺, Mg²⁺, Cl⁻, bicarbonate, phosphate), acid-base status—pH, HCO₃⁻, Pco₂, β-hydroxybutyrate, and renal function (creatinine, urine output)
4. Replace fluids: 0.9% saline 1 L/h over first 1–3 hours; subsequently, 0.45% saline at 4–14 mL/kg/h; change to 5% dextrose with 0.45% saline when plasma glucose reaches 250 mg/dL (13.9 mmol/L)
5. Administer regular insulin: IV (0.15 U/kg bolus followed by 0.1 unit/kg/h infusion), Check glucose hourly and double insulin infusion until glucose level falls at steady hourly rate of 50–70 mg/dL (2.8–3.9 mmol/h). Alternatively, could use SC or IM routes, although dosing regimen different. If initial serum potassium is less than 3.3 mmol/L (3.3 mEq/L), do not administer insulin until the potassium is corrected to greater than 3.3 mmol/L (3.3 mEq/L)
6. Assess patient: What precipitated the episode (e.g., nonadherence, infection, trauma, infarction, cocaine)? Initiate appropriate workup for precipitating event (cultures, chest x-ray, ECG)
7. Measure chemistry (especially K⁺, bicarbonate, phosphate and anion gap) every 2–4 hours until stable
8. Replace K⁺: If K⁺ is less than 3.3 mEq/L (3.3 mmol/L), hold insulin and give 40 mEq (40 mmol) of K⁺ per liter of IV fluid. If K⁺ is greater than 5 mEq/L (5 mmol/L), do not give K⁺ but check level every 2 hours. When K⁺ greater than 3.3 mEq/L (3.3 mmol/L) but less than 5 mEq/L (5 mmol/L), ECG normal, urine flow and normal creatinine documented, administer 20–30 mEq/L (20–30 mmol/L) of IV fluid to maintain K⁺ at 4–5 mEq/L (4–5 mmol/L)
9. Continue above until patient is stable, glucose goal is 150–250 mg/dL (8.3–13.9 mmol/L), and acidosis is resolved. Insulin infusion may be decreased to 0.05–0.1 unit/kg/h
10. Administer intermediate- or long-acting insulin as soon as patient is eating. Allow for overlap in insulin infusion and subcutaneous insulin injection

Cl, chloride; ECG, electrocardiogram; HCO₃⁻, serum bicarbonate; IM, intramuscular; IV, intravenous; K, potassium; Mg, magnesium; Na, sodium; Pco₂, partial pressure of carbon dioxide in the arterial blood; SC, subcutaneous.

cannot use glucose as an energy source and must obtain energy via lipolysis. This process produces ketones and leads to acidosis. Although DKA occurs frequently in young patients with T1DM on initial presentation, it can occur in adults as well. Often, precipitating factors such as infection, omission, or inadequate administration of insulin can cause DKA. Signs and symptoms develop rapidly within 1 day or so and commonly include fruity or acetone breath; nausea; vomiting; dehydration; polydipsia; polyuria; and deep, rapid breathing.

Hallmark diagnostic criteria for DKA include hyperglycemia (greater than 250 mg/dL, 13.9 mmol/L), ketosis (anion gap greater than 12 mEq/L [12 mmol/L]), and acidosis (arterial pH less than or equal to 7.3). Typical fluid deficit is 5 to 7 L or more, and major deficits of serum sodium and potassium are common.

The severity of DKA depends on the magnitude of the decrease in arterial pH, serum bicarbonate levels, and the mental state rather than the magnitude of the hyperglycemia.

Treatment goals of DKA consist of reversing the underlying metabolic abnormalities, rehydrating the patient, and normalizing the serum glucose. Fluid replacement with normal saline at 1 to 1.5 L/h for the first hour is recommended to rehydrate the patient and to ensure the kidneys are perfused.

Potassium and other electrolytes are supplemented as indicated by laboratory assessment. The use of sodium bicarbonate in DKA is controversial and generally only recommended when the pH is less than or equal to 7 after 1 hour of hydration. Regular insulin at 0.1 unit/kg/h by continuous IV infusion is the preferred treatment in DKA to regain metabolic

control rapidly. When plasma glucose values drop below 250 mg/dL (13.9 mmol/L), dextrose 5% should be added to the IV fluids. During the recovery period, it is recommended to continue administering insulin and to allow patients to eat as soon as possible. Dietary carbohydrates combined with insulin assist in the clearance of ketones. See [Table 43-12](#) for the management of DKA.⁵²

► Hyperosmolar Hyperglycemic State

Hyperosmolar hyperglycemic state (HHS) is a life-threatening condition similar to DKA that also arises from inadequate insulin, but HHS occurs primarily in older patients with T2DM. DKA and HHS also differ in that HHS lacks the lipolysis, ketonemia, and acidosis associated with DKA. Patients with hyperglycemia and dehydration lasting several days to weeks are at the greatest risk of developing HHS. Infection; silent myocardial infarction; cerebrovascular accident; mesenteric ischemia; acute pancreatitis; and the use of medications such as steroids, thiazide diuretics, calcium channel blockers, propranolol, and phenytoin are known precipitating causes of HHS. Two main diagnostic criteria for HHS are a plasma glucose value of greater than 600 mg/dL (33.3 mmol/L) and a serum osmolality of greater than 320 mOsm/kg (320 mmol/kg). The extreme hyperglycemia and large fluid deficits resulting from osmotic diuresis are major challenges to overcome with this condition. Similar to DKA, the treatment of HHS consists of aggressive rehydration, correction of electrolyte imbalances, and continuous insulin infusion to normalize serum glucose. However, in patients with HHS, blood

glucose levels should be reduced gradually to minimize the risk of cerebral edema.

Treatment of Long-Term Complications

► Retinopathy

Diabetic retinopathy occurs when the microvasculature that supplies blood to the retina becomes damaged. This damage permits leakage of blood components through the vessel walls. Diabetic retinopathy is the leading cause of blindness in adults 20 to 74 years of age in the United States.¹⁰ The risk of retinopathy is increased in patients with long-standing DM, chronic hyperglycemia, hypertension, and nephropathy. Glaucoma, cataracts, and other eye disorders occur earlier and more frequently in patients with DM.

The ADA recommends that patients with DM receive a dilated eye examination annually by an ophthalmologist or optometrist. Examinations should begin within 5 years of diagnosis of T1DM and shortly after diagnosis of T2DM. Glycemic control is the best prevention for slowing the progression of retinopathy along with optimal blood pressure control. Early retinopathy may be reversed with improved glucose control.

► Neuropathy

9 *Peripheral neuropathy is a common complication reported in T2DM. This complication generally presents as pain, tingling, or numbness in the extremities.* The feet are affected more often than the hands and fingers. A number of treatment options have been tried with mixed success. Current options include pregabalin, gabapentin, low-dose tricyclic antidepressants, duloxetine, venlafaxine, topiramate, nonsteroidal anti-inflammatory drugs, and topical capsaicin.

Autonomic neuropathy is also a common complication as DM progresses. The clinical presentation of autonomic neuropathy may include **gastroparesis**, resting tachycardia, orthostatic hypotension, impotence, constipation, and hypoglycemic autonomic failure. Therapy for each individual autonomic complication is addressed separately.

► Microalbuminuria and Nephropathy

Diabetes mellitus is the leading contributor to end-stage renal disease. Early evidence of nephropathy is the presence of albumin in the urine. Therefore, as the disease progresses, larger amounts of protein spill into the urine. The ADA recommends urine protein tests annually in T2DM patients. For children with T1DM, annual urine protein testing should begin with the onset of puberty or 5 years after the diagnosis of diabetes. The most common form of screening for protein in the urine is a random collection for measurement of the urine albumin-to-creatinine ratio. The desirable value is less than 30 mcg of albumin per milligram of creatinine (3.4 mg/mmol creatinine).

Microalbuminuria is defined as between 30 and 300 mcg of albumin per milligram of creatinine (3.4 to 34 mg/mmol creatinine). The presence of microalbuminuria is a strong

risk factor for future kidney disease in T1DM patients. In patients with T2DM, microalbuminuria has been found to be a strong risk factor for macrovascular disease.

Glycemic control and blood pressure control are primary measures for the prevention of progression of nephropathy. ACE inhibitors and angiotensin II receptor blockers prevent the progression of renal disease in patients with T2DM. Treatment of advanced nephropathy includes dialysis and kidney transplantation.

► Foot Ulcers

10 *Lower extremity amputations are one of the most feared and disabling sequelae of long-term uncontrolled DM. A foot ulcer is an open sore that develops and penetrates to the subcutaneous tissues. Complications of the feet develop primarily as a result of peripheral vascular disease, neuropathies, and foot deformations.*

Peripheral vascular disease causes ischemia to the lower limbs. This decreased blood flow deprives the tissues of oxygen and nutrients and impairs the ability of the immune system to function adequately. Symptoms of peripheral vascular disease include intermittent claudication, cold feet, pain at rest, and loss of hair on the feet and toes. Smoking cessation is the single most important treatment for peripheral vascular disease. In addition, exercising by walking to the point of pain and then resting and resuming can be a vital therapy to maintain or improve the symptoms of peripheral vascular disease. Pharmacologic intervention with pentoxifylline or cilostazol also may be useful to improve blood flow and reduce the symptoms of peripheral vascular disease.

Neuropathies play a large part in the development of foot ulcers. Loss of sensation in the feet allows trauma to go unnoticed. Autonomic neuropathy can cause changes in blood flow, perspiration, skin hydration, and possibly, bone composition of the foot. Motor neuropathy can lead to muscle atrophy, resulting in weakness and changes in the shape of the foot. To prevent foot complications, the ADA recommends daily visual examination of the feet and a foot check performed at every physician visit. Sensory testing with a 10-gauge monofilament can detect areas of neuropathy. Treatment consists of glycemic control, preventing infection, debriding dead tissues, applying dressings, treating edema, and limiting ambulation. Untreated foot problems may develop gangrene, necessitating surgical intervention.

Special Situations

► Hospitalized Care

The NICE-SUGAR (intensive versus conventional glucose in critically ill patients) trial compared intensive (81 to 108 mg/dL [4.5 to 6.0 mmol/L]) with conventional (less than 180 mg/dL [10.0 mmol/L]) glucose control using IV insulin in 6,104 intensive care unit patients.⁵³ At 90 days, intensively controlled patients had an increased absolute risk of death of 2.6% (829 patients in the intensively controlled and 751 patients in the conventionally controlled groups died).

Significantly more hypoglycemia was observed in the intensively controlled group.

Current recommendations call for critically ill patients to be started on IV insulin therapy at a threshold of 180 mg/dL (10.0 mmol/L).¹⁰ A goal range of 140 to 180 mg/dL (7.8 to 10.0 mmol/L) is recommended for the majority of patients. More stringent goals may be considered for selected critically ill patients, but only if hypoglycemia can be avoided.

Scheduled subcutaneous insulin regimens with basal, nutritional, and correction components are recommended for patients who are not critically ill. Goals of less than 140 mg/dL (7.8 mmol/L) for fasting glucose and less than 180 mg/dL (10.0 mmol/L) for random glucose are recommended for noncritically ill patients.

Blood glucose levels can be measured by several methods. Arterial samples are usually 5 mg/dL (0.3 mmol/L) higher than capillary values and 10 mg/dL (0.6 mmol/L) greater than venous values. When preparing an insulin infusion for a patient, several factors must be considered. Insulin will

absorb to glass and plastic, reducing the amount of insulin actually delivered by 20% to 30%. Priming the tubing decreases the variability of insulin infused. Therefore, when patients can be converted safely from infusion to needle and syringe therapy, the total daily dose should be reduced by 20% to 50% of the daily infusion amount. When transferring someone from IV insulin drip to subcutaneous insulin, basal insulin should be administered several hours before the drip is discontinued to prevent loss of glycemic control. IV drip protocols are institution specific.

► Sick Days

Patients should monitor their blood glucose levels more frequently during sick days because it is common for illness to increase blood glucose values.⁵⁴ Patients with T1DM should check their glucose and urine for ketones every 4 hours when sick. Patients with T2DM may also need to check for ketones when their blood glucose levels are greater than 300 mg/dL

Patient Encounter, Part 4: Insulin Therapy

GH returns to the office for his annual checkup. It has been 5 years since he was first diagnosed with diabetes. His updated information is below. His past medical and family histories are unchanged. He states that he has been adherent to his medications and lifestyle changes. He complains that he has a burning and tingling constantly in both of his feet.

SH

- Smokes ½ pack cigarettes per day for 25 years
- Drinks 6 pack of beer on the weekends
- Denies illicit drug use

Allergies

- Sulfa
- Penicillin

Medications

- Hydrochlorothiazide 25 mg by mouth once daily
- Lisinopril 20 mg by mouth once daily
- Simvastatin 40 mg by mouth once daily
- Fluticasone nasal spray, one spray each nostril daily as needed
- Metformin 1000 mg by mouth twice daily
- Pioglitazone 30 mg by mouth once daily
- Multivitamin by mouth once daily

Meal history: Has been consuming approximately 45 to 60 g of carbohydrates per meal 3 times a day; saturated fat is limited to 15 g/day, and sodium is 2,000 mg/day

Physical activity: Was walking 4 or 5 days per week for 30 minutes at moderate intensity but has not done so recently

VS: BP 145/92 mm Hg, P 85 beats/min, RR 20, T 38°C (100°F)

Height: 6 ft, 3 in (190.5 cm)

Weight: 270 lb (123 kg)

Labs:

- Na: 139 mEq/L (139 mmol/L)
- K: 5 mEq/L (5 mmol/L)
- Cl: 103 mEq/L (103 mmol/L)
- CO₂: 23 mEq/L (23 mmol/L)
- BUN: 16 mg/dL (5.7 mmol/L)
- SCr: 0.9 mg/dL (80 μmol/L)
- FPG: 190 mg/dL (10.5 mmol/L)
- A1c: 10.7% (0.107; 93 mmol/mol Hb)
- AST: 28 U/L (0.47 μKat/L)
- ALT: 31 U/L (0.52 μKat/L)
- Fasting lipid profile:
 - Total cholesterol: 202 mg/dL (5.22 mmol/L)
 - LDL: 118 mg/dL (3.05 mmol/L)
 - HDL: 43 mg/dL (1.11 mmol/L)
 - TG: 205 mg/dL (2.32 mmol/L)

What therapeutic options are available for this patient to lower his blood glucose to goal?

Which insulin and starting dose would be most appropriate for this patient?

What additional medications, screenings, labs, and/or referrals are recommended for GH at this point?

(16.7 mmol/L). Patients should continue to take their medications while sick. T1DM patients may require additional insulin coverage, and some with T2DM who are currently on oral medication regimens may require insulin during an acute illness. Patients should be advised to maintain their normal caloric and carbohydrate intake while ill as well as to drink plenty of noncaloric beverages to avoid dehydration.

Patient Care and Monitoring

1. Assess the patient for development or progression of DM and DM-related complications.
2. Evaluate SMBG for glycemic control, including FPG and postprandial levels.
 - Are the blood glucose values too high or low?
 - Are there specific times of day or specific days not in control?
 - Is hypoglycemia occurring?
3. Assess the patient for changes in quality-of-life measures such as physical, psychological, and social functioning and well-being.
4. Perform a thorough medication history of prescription, over-the-counter, and herbal product use.
 - Are there any medication problems, including presence of adverse drug reactions, drug allergies, and drug interactions?
 - Is the patient taking any medications that may affect blood glucose control?
5. Review all available laboratory data (some settings may have only patient-reported values) for attainment of ADA goals (Table 43–7). What therapy goals are not being met? What tests or referrals to other members of the healthcare team are needed?
6. Recommend appropriate therapy and develop a plan to assess effectiveness.
7. Stress adherence to prescribed lifestyle and medication regimen.
8. Provide patient education on diabetes, lifestyle modifications, appropriate monitoring, and drug therapy:
 - Causes of DM complications and how to prevent them.
 - How lifestyle changes including diet and exercise can affect diabetes.
 - How to perform SMBG and what to do with the results.
 - When to take medications and what to expect.
 - What adverse effects may occur?
 - What warning sign(s) should be reported to the physician?

When having difficulty eating a normal diet, patients may be advised to use nondiet beverages, sports drinks, broths, crackers, soups, and nondiet gelatins to provide normal caloric and carbohydrate intake and avoid hypoglycemia. With proper management, patients can decrease their chance of illness-induced hospitalization, particularly DKA and HHS.

OUTCOME EVALUATION

- The success of therapy for DM is measured by the ability of the patient to manage his or her disease appropriately between healthcare provider visits.
- Appropriate therapy necessitates adequate patient education about the disease, development of a meal plan to which patients can comply, and integration of a regular exercise program.
- Patient care plans should include a number of daily evaluations to be performed by the patient, such as examining the feet for any sores, cuts, or abrasions; checking the skin for dryness to prevent cracking and chafing; and monitoring blood glucose values as directed. Weekly appraisals of weight and blood pressure are also advised.
- Until A1c levels are at goal, quarterly visits with the patient's primary healthcare provider are recommended. Table 43–7 summarizes the specific ADA goals for therapy. The practitioner should review SMBG data and a current A1c level for progress and address any therapeutic or educational issues.
- At a minimum, yearly laboratory evaluation of serum lipids, urinary microalbumin, and serum creatinine should be performed.

Abbreviations Introduced in This Chapter

A1c	Hemoglobin A1c
AACE	American Association of Clinical Endocrinologists
ACCORD	Action to Control Cardiovascular Risk in Diabetes
ACE	Angiotensin-converting enzyme
ADA	American Diabetes Association
ADVANCE	Action in Diabetes and Vascular Disease
AIDS	Acquired immunodeficiency syndrome
ALT	Alanine aminotransferase
AST	Aspartate aminotransferase
ATP	Adenosine triphosphate
BG	Blood glucose
BMI	Body mass index
BUN	Blood urea nitrogen
CDC	Centers for Disease Control and Prevention
CHD	Coronary heart disease
CHF	Congestive heart failure
Cl	Chloride

CrCl	Creatinine clearance
CSII	Continuous subcutaneous insulin infusion
DCCT	Diabetes Control and Complications Trial
DKA	Diabetic ketoacidosis
DM	Diabetes mellitus
DPP-4	Dipeptidyl peptidase-4
eAG	Estimated average glucose
ECG	Electrocardiogram
ER	Extended release
FBG	Fasting blood glucose
FBS	Fasting blood sugar
FDA	Food and Drug Administration
FPG	Fasting plasma glucose
GDM	Gestational diabetes mellitus
GI	Gastrointestinal
GIP	Glucose-dependent insulinotropic polypeptide
GLP-1	Glucagon-like peptide-1
Hb	Hemoglobin
HCO ₃	Serum bicarbonate
HDL	High-density lipoprotein cholesterol
HHS	Hyperosmolar hyperglycemic state
HIV	Human immunodeficiency virus
HLA	Human leukocyte antigen
IFG	Impaired fasting glucose
IGT	Impaired glucose tolerance
IKK-β	I-kappa-B kinase-β
IM	Intramuscular
ISF	Interstitial fluid
IV	Intravenous
K	Potassium
LADA	Latent autoimmune diabetes in adults
LDL	Low-density lipoprotein cholesterol
Mg	Magnesium
MNT	Medical nutrition therapy
Na	Sodium
NGSP	National Glycohemoglobin Standardization Program
NICE-SUGAR	Intensive versus conventional glucose control in critically ill patients
NPH	Neutral protamine Hagedorn
OGTT	Oral glucose tolerance test
Pco ₂	Partial pressure of carbon dioxide in arterial blood
PPAR-γ	Proximoso proliferator activator receptor gamma
PPG	Postprandial glucose
SC	Subcutaneous
SCr	Serum creatinine
SMBG	Self-monitoring of blood glucose
T1DM	Type 1 diabetes mellitus
T2DM	Type 2 diabetes mellitus
TG	Triglycerides
TLC	Therapeutic lifestyle change
TZDs	Thiazolidinediones
UKPDS	United Kingdom Prospective Diabetes Study
ULN	Upper limit of normal
UTI	Urinary tract infection
VADT	Veterans Affairs Diabetes Trial
WHO	World Health Organization

Thyroid Disorders

Michael D. Katz

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Explain the major components of the hypothalamic–pituitary–thyroid axis and the interaction among these components.
2. Discuss the prevalence of thyroid disorders, including subclinical (mild) and overt (typical signs and/or symptoms present) hypothyroidism and hyperthyroidism.
3. Discuss the relationship between serum thyroid-stimulating hormone (TSH) levels and primary thyroid disease and the advantages for the use of TSH levels over other tests such as serum T_4 (thyroxine) and T_3 (triiodothyronine) levels.
4. Identify the typical signs and symptoms of hypothyroidism and the consequences of inadequate treatment.
5. Describe the clinical use of levothyroxine (LT_4) in the treatment of hypothyroidism.
6. Discuss the issues regarding LT_4 product bioequivalence and the advantages of maintaining patients on the same product.
7. Describe the management of hypothyroidism and hyperthyroidism in pregnant women.
8. Identify the typical signs and symptoms of Graves' disease and the consequences of inadequate treatment.
9. Discuss the pharmacotherapy of Graves' disease, including the advantages and disadvantages of antithyroid drugs versus radioactive iodine, adverse effects, and patient monitoring.
10. Describe the potential effects of amiodarone, lithium, and interferon- α on thyroid function.

KEY CONCEPTS

- 1 The thyroid gland is the largest endocrine gland in the body, residing in the neck anterior to the trachea between the cricoid cartilage and the suprasternal notch. The thyroid gland produces two biologically active hormones, thyroxine (T_4) and triiodothyronine (T_3). The parafollicular C cells of the thyroid gland produce calcitonin.
- 2 In most patients with thyroid hormone disorders, the measurement of a serum thyroid-stimulating hormone (TSH) level is adequate for the initial screening and diagnosis of hypothyroidism and hyperthyroidism. Serum-free thyroxine (FT_4) and triiodothyronine (FT_3) levels may be helpful in distinguishing subclinical (mild) thyroid disease from overt disease. The target TSH for most patients being treated for thyroid disorders should be the mean normal value of 1.4 milli international units/L (mIU/L) or 1.4 micro international units/mL (μ IU/mL) (target range, 0.5 to 2.5 mIU/L or 0.5 to 2.5 μ IU/mL), although patients must be individually titrated based on resolution of signs and symptoms as well as biochemical tests. The target TSH may be different in patients being treated with levothyroxine (LT_4) for thyroid cancer.
- 3 Hypothyroidism can affect virtually any tissue or organ in the body. The most common symptoms, such as fatigue, lethargy, sleepiness, cold intolerance, and dry skin, are nonspecific and can be seen with many other disorders. The classic overt signs, such as myxedema and delayed deep tendon reflexes, are seen uncommonly now because more patients are screened or seek medical attention earlier. Patients with mild (also known as subclinical) hypothyroidism may have subtle symptoms that progress so slowly that they are not noticed easily by the patient or family. The lack of overt or specific signs and symptoms emphasizes the importance of using the serum TSH level to identify patients with hypothyroidism. Treatment of patients with mild thyroid disease is controversial.

- 4 There are three major goals in the treatment of hypothyroidism: replace the missing hormones, relieve signs and symptoms, and achieve a stable biochemical euthyroid state.
- 5 Despite the availability of a wide array of thyroid hormone products, it is clear that synthetic LT_4 is the treatment of choice for almost all patients with hypothyroidism. LT_4 mimics the normal physiology of the thyroid gland, which secretes mostly T_4 as a prohormone. Peripheral tissues convert T_4 to T_3 as needed based on metabolic demands. If T_3 is used to treat hypothyroidism, the peripheral tissues lose their ability to control local metabolic rates. LT_4 also has distinct pharmacokinetic advantages over T_3 . With a 7- to 10-day half-life, LT_4 provides a very smooth dose-response curve with little peak and trough effect. In a small number of patients who have impairment of conversion of T_4 to T_3 , addition of T_3 may be warranted.
- 6 There is no evidence that one LT_4 product is better than another. However, given the evidence that these products do have different bioavailabilities, patients should be maintained on the same LT_4 product. Given the generic substitution regulations of most states, this is best accomplished by prescribing a brand-name product or otherwise ensuring that the product remains constant and not allowing substitution in the way allowed by state regulations or mandated by insurance companies.
- 7 The goals of treating hyperthyroidism are to relieve signs and symptoms, reduce thyroid hormone production to normal levels and achieve biochemical euthyroidism, and prevent long-term adverse sequelae.
- 8 Agranulocytosis is one of the most serious adverse effects of antithyroid drug therapy.
- 9 The growth and spread of thyroid carcinoma are stimulated by TSH. An important component of thyroid carcinoma management in many patients is the use of LT_4 to suppress TSH secretion. Early in therapy, patients receive the lowest LT_4 dose sufficient to fully suppress TSH to undetectable levels. Controlled trials show that suppressive LT_4 therapy reduces tumor growth and improves survival.
- 10 Patients receiving amiodarone must receive monitoring for thyroid abnormalities. Baseline measurements of serum TSH, FT_4 , FT_3 , antithyroid peroxidase antibody (anti-TPOAb), and TSH receptor-stimulating antibodies (TSHR-SAb) should be performed. TSH, FT_4 , and FT_3 should be checked 3 months after initiation of amiodarone and then at least a TSH every 3 to 6 months.

Thyroid disorders are common. More than 2 billion people, or 38% of the world's population, have iodine deficiency, resulting in 74 million people with **goiters**.

Although overt iodine deficiency is not a significant problem in developed countries, a number of common thyroid conditions exist. The most common conditions are **hypothyroidism** and **hyperthyroidism**, which often require long-term pharmacotherapy. Undetected or improperly treated thyroid disease can result in long-term adverse sequelae, including increased mortality. It is important that clinicians are aware of the prevalence of thyroid disorders, the methods of identifying thyroid disorders, and the appropriate therapy. This chapter focuses on the most common pharmacologically treated thyroid disorders.

THYROID HORMONE PHYSIOLOGY AND BIOSYNTHESIS

1 The thyroid gland is the largest endocrine gland in the body, residing in the neck anterior to the trachea between the cricoid cartilage and the suprasternal notch. The thyroid gland produces two biologically active hormones, thyroxine (T_4) and triiodothyronine (T_3). Thyroid hormones are essential for proper fetal growth and development, particularly of the central nervous system (CNS). After delivery, the primary role of thyroid hormone is in the regulation of energy metabolism. These hormones can affect the function of virtually every organ in the body. 1 The parafollicular C cells of the thyroid gland produce calcitonin. The function of calcitonin and its therapeutic use are discussed in other chapters in this book.

T_4 and T_3 are produced by the **organification** (binding of iodine to tyrosine residues of thyroglobulin) of iodine in the thyroid gland. Iodine is actively transported into the thyroid follicular cells. This inorganic iodine is oxidized by **thyroid peroxidase** and covalently bound to tyrosine residues of **thyroglobulin**. These iodinated tyrosine residues, monoiodotyrosine and diiodotyrosine, couple to form T_4 and T_3 . Eighty percent of thyroid hormone is synthesized as T_4 and is stored in the thyroid bound to thyroglobulin. Thyroid hormones are released from the gland when needed, primarily under the influence of thyroid-stimulating hormone (TSH), which is also called thyrotropin, from the anterior pituitary. T_4 and T_3 are transported in the blood by three proteins, 70% to thyroid-binding globulin (TBG), 15% to transthyretin (thyroid-binding prealbumin), and 15% to albumin. T_4 is 99.97% protein bound, and T_3 is 99.7% protein bound, with only the unbound or free fractions physiologically active. The high degree of protein binding results in a long half-life of these hormones: approximately 7 to 10 days for T_4 and 24 hours for T_3 .

Most of the physiologic activity of thyroid hormones is from the actions of T_3 . T_4 can be thought of primarily as a prohormone. Eighty percent of needed T_3 is derived from the conversion of T_4 to T_3 in peripheral tissue under the influence of tissue deiodinases. These deiodinases allow end organs to produce the amount of T_3 needed to control local metabolic functions. These enzymes also catabolize T_3 and T_4 to biologically inactive metabolites.

The production and release of thyroid hormones are regulated by the hypothalamic–pituitary–thyroid axis (Fig. 44–1).

FIGURE 44-1. Hypothalamic–pituitary–thyroid axis. Thyrotropin-releasing hormone (TRH) is synthesized in the neurons within the paraventricular nucleus of the hypothalamus. TRH is released into the hypothalamic–pituitary portal circulation and carried to the pituitary, where it activates the pituitary to synthesize and release thyrotropin (TSH). TSH activates the thyroid to stimulate the synthesis and secretion of thyroxine (T₄) and triiodothyronine (T₃). T₄ and T₃ inhibit TRH and TSH secretion, closing the feedback loop.

Hypothalamic thyrotropin-releasing hormone (TRH) stimulates the release of TSH (thyrotropin) when there are physiologically inadequate levels of thyroid hormones. TSH promotes the production and release of thyroid hormones from the gland. As circulating thyroid hormone levels rise to needed levels, negative feedback results in decreased release of TSH and TRH. The release of TRH is inhibited by somatostatin and its analogs, and the release of TSH can be inhibited by dopamine, dopamine agonists, and high levels of glucocorticoids.

SPECTRUM OF THYROID DISEASE

There are two general modes of presentation for thyroid disorders: changes in the size or shape of the gland and changes in secretion of hormone from the gland. In some cases, structural changes can result in changes in hormone secretion. Thyroid nodules and goiters in **euthyroid** patients are common problems. Patients with a goiter who are biochemically euthyroid often require no specific pharmacotherapy unless the goiter is caused by iodine deficiency. In developing countries, iodized salt is the primary therapy in treating goiter. Thyroid nodules, seen in 4% to 7% of adults, may be

malignant or may autonomously secrete thyroid hormones. A discussion of thyroid nodules is beyond the scope of this chapter; however, thyroid cancer is discussed briefly in the context of levothyroxine (LT₄) suppressive therapy. Refer to other resources for a more extensive review of thyroid cancer management.

Changes in hormone secretion can result in hormone deficiency or excess. Although patients with overt hypothyroidism and hyperthyroidism may have dramatic signs and symptoms, most patients have subtle signs and symptoms that progress slowly over time. The availability of sensitive and specific biochemical tests for the diagnosis of thyroid hormone disorders has facilitated screening and earlier diagnosis, including in those with mild or subclinical thyroid disorders. Screening of newborns for congenital hypothyroidism has reduced the incidence of mental retardation and neonatal hypothyroidism (**cretinism**) dramatically in the United States. However, congenital hypothyroidism owing to iodine deficiency remains a significant worldwide public health problem.

EPIDEMIOLOGY OF THYROID DISEASE

A number of studies have assessed the epidemiology of thyroid hormone abnormalities. The 1999 to 2002 National Health and Nutrition Examination Survey (NHANES) reported the prevalence of thyroid hormone disorders in 4,392 people 12 years of age and older in a sample representing the geographic and ethnic distribution of the U.S. population. Hypothyroidism was found in 3.7% (3.4% mild) and hyperthyroidism in 0.5% of the sample.¹ The prevalence of hypothyroidism was higher in older age groups and in whites and Hispanics; blacks had a lower prevalence of hypothyroidism. The prevalence of hypothyroidism correlated with age. Compared with the total population, people aged 50 to 79 years had an almost twofold higher prevalence, and those aged 80 years and older had a fivefold higher prevalence. Pregnant women also had a higher prevalence of hypothyroidism. The Colorado Thyroid Health Survey assessed thyroid function in 25,862 subjects attending a health fair.² The overall prevalence of an abnormal TSH level was 11.7% of the study population, with 9.4% hypothyroid (9% subclinical) and 2.2% hyperthyroid (2.1% subclinical). Of the 916 subjects taking thyroid medication, 60% were euthyroid, with an equal distribution between subclinical hypothyroidism and hyperthyroidism. The NHANES study also found that many patients receiving thyroid medications had an abnormal TSH level. These findings imply that many patients who are receiving thyroid medications are not being managed successfully.

PATIENT ASSESSMENT AND MONITORING

The assessment of patients for thyroid disorders entails a history and physical examination. In many patients with mild or subclinical thyroid disease, there may be an absence

Table 44-1

Selected Thyroid Tests for Adults

Test	Reference Range	Comments
TSH	0.5–4.5 mIU/L ^a	Gold standard; may be lowered by dopamine, dopamine agonists, glucocorticoids, octreotide, recovery from severe nonthyroidal illness
FT ₄ Anti-TPOAb	0.7–1.9 ng/dL (9.0–24.5 pmol/L) Variable ^b	May be normal in mild thyroid disease Present in autoimmune hypothyroidism; predicts more rapid progression from subclinical to overt hypothyroidism
TSHR-SAb	Undetectable	Confirms Graves' disease

Anti-TPOAb, antithyroid peroxidase antibody; FT₄, free T₄ (thyroxine); TSH, thyroid-stimulating hormone; TSHR-SAb, TSH receptor-stimulating antibodies.

^aMilli international units/L (mIU/L) = micro international units/mL (μIU/mL); clinical laboratories use either unit of measurement.

^bAnti-TPOAb reference ranges are highly variable from one laboratory to another depending on the method used. Results greater than the upper cutoff are considered abnormal and are consistent with increased risk for autoimmune thyroid disease.

of specific signs and symptoms, and the physical examination findings may be normal. Various diagnostic tests can be used, including serum thyroid hormone(s), TSH, thyroid antibody levels, and imaging techniques to evaluate patients for thyroid disorders. Reference ranges for selected laboratory tests are given in Table 44-1. The laboratory assessment of patients with suspected thyroid disorders must be based on the continuum of disease from subclinical or mild to overt (Fig. 44-2).

TSH Levels

2 In most patients with thyroid hormone disorders, the measurement of a serum TSH level is adequate for the initial screening and diagnosis of hypothyroidism and hyperthyroidism. Serum free thyroxine (FT₄) and triiodothyronine (FT₃) levels may be helpful in distinguishing subclinical (mild) thyroid disease from overt disease. The target TSH for most patients being treated for thyroid disorders should be the mean normal value of 1.4 milli international units/L (mIU/L) or 1.4 micro international units/mL (μIU/mL) (target range, 0.5

2.5 mIU/L or 0.5 to 2.5 μIU/mL), although patients must be individually titrated based on resolution of signs and symptoms as well as biochemical tests. The target TSH may be different in patients being treated with LT₄ for thyroid cancer.

TSH is a highly sensitive bioassay of the thyroid axis. A twofold change in serum-free T₄ levels will result in a 100-fold change in TSH levels. This biologic magnification by TSH allows the TSH to be used in early diagnosis as well as in closely titrating therapy in hypothyroidism and hyperthyroidism. In patients with primary hypothyroidism or hyperthyroidism resulting from gland dysfunction, there is an inverse relationship between the TSH level and thyroid function. High TSH signifies hypothyroidism (or iatrogenic underreplacement), and low TSH signifies hyperthyroidism (or iatrogenic over-replacement). There is controversy regarding the normal or laboratory reference ranges for TSH. NHANES showed that the mean TSH level in a normal population was 1.46 milli international units/L (milli international units/L = micro international units/mL; clinical laboratories use either unit of measurement, usually expressed as mIU/L or μIU/mL), but the values were not normally distributed.³ Although most laboratories quote the upper limit of normal for TSH as 4 or 5 mIU/L, 95% of subjects had a TSH level of between 0.5 and 2.5 mIU/L. The population of subjects whose TSH level was 2.5 to 4.5 mIU/L may have had mild hypothyroidism, or the non-normal distribution may reflect different normal ranges in a heterogeneous (age, sex, race) population. The mean normal TSH in the elderly appears to be higher even in people with no clinical evidence of hypothyroidism, and there is some evidence that normal TSH ranges are sex and ethnicity specific.⁴ The target TSH for most patients being treated for thyroid disorders is not the same as the reference range. Ideally, the TSH should be the mean normal value of 1.4 mIU/L or 1.4 μIU/mL (target range, 0.5 to 2.5 mIU/L or 0.5 to 2.5 μIU/mL). The upper limit of the target range may be higher in the elderly. Therapy may be titrated within the target TSH range to maximally improve patient signs and symptoms without causing adverse effects of over- or undertreatment.

FIGURE 44-2. The continuum of thyroid disorders. (FT₄, free T₄; TSH, thyroid-stimulating hormone.)

Serum T₄ and T₃ Levels

Serum T₄ and T₃ levels are used commonly to assess thyroid function. Older screening tests of thyroid function measure total serum T₄ or T₃ levels. Because of the high degree of protein binding of these hormones, the free fraction can be altered by changes in the levels of binding proteins or the degree of protein binding. Because a number of factors can alter protein binding, these older assays are very insensitive and should no longer be used even with protein-binding adjustment factors such as the free T₄ index. Free or unbound T₄ (FT₄) and T₃ (FT₃) assays are readily available and are more sensitive in identifying thyroid dysfunction than the older total assays.⁶ However, patients with mild hypothyroidism or hyperthyroidism have normal FT₄ levels despite abnormal TSH levels.

Other Diagnostic Tests

Global tests of thyroid gland function can be performed to assess the rate of hormone synthesis. The radioactive iodine uptake (RAIU) is elevated in those with hyperthyroidism and can aid in identifying **thyrotoxicosis** owing to nonthyroid gland sources. Radionuclide thyroid scans are used in the evaluation of thyroid nodules. Because many thyroid disorders are autoimmune, measurement of various serum antithyroid antibodies can be performed. Antithyroid peroxidase antibodies (anti-TPOAb) and antithyroglobulin antibodies (anti-TGAb) are present in many patients with hypothyroidism. Most patients with Graves' disease have TSH receptor-stimulating antibodies (TSHR-SAb) as well as elevated anti-TPOAb and antimicrosomal antibodies.

HYPOTHYROIDISM

Hypothyroidism is the most common clinical disorder of thyroid function. It is the clinical syndrome that results from inadequate secretion of thyroid hormones from the thyroid gland. The vast majority of hypothyroid patients have primary gland failure, but rare patients have pituitary or hypothalamic failure. Most studies define hypothyroidism based on a serum TSH level above the upper limit of the laboratory reference range. In adults, 1.4% of women and 0.1% of men are biochemically hypothyroid. However, the incidence is highly age dependent. In the Colorado Thyroid Health Study, by age 64 years, 12% of women and 5% of men were hypothyroid, and in the over 74 years age group, the incidence in men approached that of women.² Most epidemiologic studies of hypothyroidism in the elderly show a prevalence of 6% to 12%. There is a strong correlation between the presence of anti-TPOAb or anti-TGAb and the risk of developing hypothyroidism. In patients with subclinical hypothyroidism and positive anti-TPOAb, 5% per year will progress to overt hypothyroidism.⁷ Other risk factors for the development of hypothyroidism include the postpartum state, family history of autoimmune thyroid disorders, a previous history of head and neck or thyroid surgery, head and neck irradiation, other autoimmune endocrine disorders such as type 1 diabetes and Addison's disease, other non-endocrine autoimmune diseases

such as celiac disease and pernicious anemia, history of treatment for hyperthyroidism, treatment with amiodarone or lithium, and an iodine-deficient diet.⁸

Screening for Hypothyroidism

Because the prevalence of hypothyroidism is high in certain populations, screening may be useful. Screening for hypothyroidism in women older than age 35 years is as cost effective as screening for breast cancer and hypertension, although some organizations recommend screening of adults after the age of 50 or 60 years.⁹ Others advocate a case-finding approach, defined as performing a TSH determination in patients based on risk factors or the presence of signs and symptoms.^{10,11} Refer to Clinical Presentation and Diagnosis of Hypothyroidism for more information regarding screening and diagnosis.

Causes of Hypothyroidism

The most common causes of hypothyroidism are listed in **Table 44-2**.^{8,12} Up to 90% of patients with autoimmune thyroiditis have circulating anti-TPOAbs. The autoimmune inflammatory response results in a lymphocytic infiltration of the thyroid gland and its eventual destruction.

Iatrogenic hypothyroidism can occur after thyroid irradiation or surgery and excessive doses of antithyroid drugs. Several drugs can cause hypothyroidism, including iodine-containing drugs such as amiodarone and iodinated radiocontrast media, lithium, interferon- α , multi- and tyrosine kinase inhibitors (imatinib, sunitinib, sorafenib), *p*-aminosalicylic acid, ethionamide, sulfonyleureas, valproic acid, and aminoglutethimide.¹³ Iodine deficiency is a common worldwide cause of hypothyroidism, including congenital hypothyroidism in newborns. Patients with hypothalamic or pituitary disease often have other signs of pituitary disease, such as hypogonadism, and their TSH levels are low.

Signs and Symptoms of Hypothyroidism

3 *Hypothyroidism can affect virtually any tissue or organ in the body. The most common symptoms, such as fatigue, lethargy, sleepiness, cold intolerance, and dry skin, are nonspecific and can be seen with many other disorders. The classic overt*

Table 44-2

Common Causes of Hypothyroidism¹¹⁻¹³

Primary Hypothyroidism

Autoimmune thyroiditis (Hashimoto's disease)
Iatrogenic (irradiation, surgery)
Drugs (amiodarone, radiocontrast media, lithium, interferon- α , tyrosine kinase inhibitors)
Silent thyroiditis (including postpartum)
Iodine deficiency and excess

Secondary Hypothyroidism

Pituitary disease
Hypothalamic disease

Clinical Presentation and Diagnosis of Hypothyroidism¹¹⁻¹³

Symptoms

- Fatigue
- Lethargy
- Sleepiness
- Mental impairment
- Depression
- Cold intolerance
- Hoarseness
- Dry skin
- Decreased perspiration
- Weight gain
- Decreased appetite
- Constipation
- Menstrual disturbances
- Arthralgia
- Paresthesia

Signs

- Slow movements
- Slow speech

- Hoarseness
- Bradycardia
- Dry skin
- Nonpitting edema (myxedema)
- Hyporeflexia
- Delayed relaxation of reflexes

Screening/Diagnosis

A TSH level of 4.5 to 10 mIU/L may constitute mild or subclinical hypothyroidism. A TSH level greater than 10 mIU/L signifies overt hypothyroidism.⁹ The free T₄ level will be normal (0.7 to 1.9 ng/dL or 9.0 to 24.5 pmol/L) in mild or subclinical hypothyroidism and low (less than 0.7 ng/dL or 9.0 pmol/L) in patients with obvious signs and/or symptoms.

⁹Milli international units/L (mIU/L) = micro international units/mL (μIU/mL); clinical laboratories use either unit of measurement.

signs, such as **myxedema** and delayed deep tendon reflexes, are seen uncommonly now because more patients are screened or seek medical attention earlier. Patients with mild (also known as subclinical) hypothyroidism may have subtle symptoms that progress so slowly that they are not noticed easily by the patient or family. The lack of overt or specific signs and symptoms emphasizes the importance of using the serum TSH level to identify patients with hypothyroidism. Treatment of patients with mild thyroid disease is controversial.

Mild (Subclinical) Hypothyroidism

Mild or subclinical hypothyroidism is present when a patient has an elevated TSH (usually below 10 mIU/L or 10 μIU/mL), normal FT₄, and no overt hypothyroid signs and symptoms.¹²⁻¹⁷ Many of these patients have autoimmune thyroiditis and anti-TPO antibodies, and some will progress to overt hypothyroidism. Although patients may not express the typical symptoms of hypothyroidism, many patients do have mild, nonspecific symptoms (e.g., fatigue, cold intolerance, constipation). Recent studies have shown subclinical hypothyroidism to be a risk factor for cardiovascular mortality and to be associated with decreased myocardial contractility, decreased exercise tolerance, elevated low-density lipoprotein (LDL) cholesterol, and neuropsychiatric symptoms.¹⁵

Sequelae of Hypothyroidism

Hypothyroidism is a chronic disease that may result in significant long-term sequelae. Hypercholesterolemia is

associated with hypothyroidism, increasing the long-term risk of cardiovascular disease and cardiovascular mortality. Between 4% and 14% of patients with hypercholesterolemia are found to be hypothyroid. The Colorado Thyroid Health Study showed a direct correlation between the degree of TSH elevation and the rise in serum cholesterol.² Hypothyroidism also may result in increased systemic vascular resistance, decreased cardiac output, and increased diastolic blood pressure. Hypothyroidism can cause significant neuropsychiatric problems, including a dementia-like state in the elderly that is reversible with LT₄ therapy. Maternal hypothyroidism can have dire consequences for developing fetuses. Fetuses are almost completely dependent on maternal thyroid hormones during the first trimester, a time crucial for development of the CNS. Inadequately treated maternal hypothyroidism results in increased risk of miscarriage and developmental impairment in the child.¹⁸

Myxedema coma is seen in advanced hypothyroidism. These patients develop CNS depression, respiratory depression, cardiovascular instability, and fluid and electrolyte disturbances. Myxedema coma often is triggered by an underlying acute medical condition such as infection, stroke, trauma, or administration of CNS depressant drugs.

Treatment of Hypothyroidism

4 There are three major goals in the treatment of hypothyroidism: replace the missing hormones, relieve signs and symptoms, and achieve a stable biochemical euthyroid state. Although

Table 44-3

Thyroid Preparations

Drug (Brand Name)	Content	Relative Dose	Comments
LT ₄ (Synthroid, Levoxy, Unithroid), other brands, and generics	Synthetic LT ₄ ; 25-, 50-, 75-, 88-, 100-, 112-, 125-, 137-, 150-, 175-, 200-, and 300-mcg tablets; 500-mcg vial for injection	60 mcg	Gold standard for treating hypothyroidism; products not therapeutically equivalent; full replacement dose, 1–1.6 mcg/kg/day; when switching from animal product, lower calculated daily dose by 25–50 mcg; IV form rarely needed
Liothyronine (Cytomel)	Synthetic T ₃ ; 5-, 15-, 25-, and 50-mcg tablets	15 mcg	Rarely needed in treatment of hypothyroidism; rapid absorption and pharmacologic effect; increased toxicity versus LT ₄ ; no outcome benefit to combining with LT ₄
Thyroid (desiccated) USP (Armour, others)	Desiccated pork or beef thyroid glands; contains T ₃ and T ₄ ; 15-, 16.25-, 30-, 32.5-, 48.75-, 60-, 65-, 90-, 97.5-, 120-, 130-, 162.5-, 180-, 195-, 240-, 260-, 300-, and 325-mg tablets	65 mg	Nonphysiologic for humans; unpredictable hormone content and stability; T ₃ content may cause toxicity; no role in modern therapy
Liotrix (Thyrolar)	Synthetic T ₄ , T ₃ in fixed 4:1 ratio; ¼-, ½-, 1-, 2-, 3-strength tablets	12.5/50 mcg T ₃ :T ₄ (1 strength)	Nonphysiologic T ₄ :T ₃ ratio; T ₃ content may cause toxicity; no role in modern therapy

IV, intravenous; LT₄, levothyroxine; T₃, triiodothyronine; T₄, thyroxine.

these goals should not be difficult to achieve, 20% to 40% of treated patients are not receiving optimal pharmacotherapy.

► Thyroid Hormone Products

A number of thyroid hormone products are marketed in the United States (Table 44-3). These products include synthetic LT₄ and T₃, combinations of synthetic LT₄ and T₃, and animal-derived products. **5** *Despite the availability of a wide array of thyroid hormone products, it is clear that synthetic LT₄ is the treatment of choice for almost all patients with hypothyroidism.^{11,12} LT₄ mimics the normal physiology of the thyroid gland, which secretes mostly T₄ as a prohormone. Peripheral tissues convert T₄ to T₃ as needed based on metabolic demands. If T₃ is used to treat hypothyroidism, the peripheral tissues lose their ability to control local metabolic rates. LT₄ also has distinct pharmacokinetic advantages over T₃. With a 7- to 10-day half-life, LT₄ provides a very smooth dose-response curve with little peak and trough effect. In a small number of patients who have impairment of conversion of T₄ to T₃, addition of T₃ may be warranted. T₃, with a 24-hour half-life, provides a significant peak and trough effect, and many patients have symptoms of thyrotoxicosis after each dose is administered. The use of compounded T₃ products that have not been approved by the Food and Drug Administration (FDA) should be strongly discouraged. For patients who have difficulty adhering to a once-daily regimen, a once-weekly LT₄ regimen is safe and effective.^{11,12}*

Animal-derived products such as desiccated thyroid are obtained from cow and pig thyroid and have various degrees of purity. These products contain both LT₄ and T₃, but the amount of T₃ is much higher (T₄:T₃ = 4:1) than what would be found in the human thyroid gland (T₄:T₃ = 14:1). With the

desiccated thyroid products, there are concerns about standardizing the amount of hormone and lot-to-lot variability. Thyroglobulin products were removed from the U.S. market several years ago. Although some patients want to use these agents because they are “natural,” they are in no way natural for humans. With the strong evidence supporting the safety and efficacy of LT₄ in the treatment of hypothyroidism, there is no rationale for the use of these animal-derived products. Patients who are being treated with these agents should be strongly encouraged to switch to synthetic LT₄. Additionally, patients should be encouraged to not purchase thyroid hormone- or iodine-containing products from health food stores or from questionable Internet sites.

Several studies have been published that evaluate the use of LT₄ and T₃ combinations in ratios that mimic human physiology. A meta-analysis of 11 randomized, controlled clinical trials comparing LT₄ and T₃ combinations with LT₄ monotherapy show no outcome benefit with combination therapy.¹⁹ Except in rare circumstances (e.g., patients with impaired T₄-to-T₃ conversion), there is no rationale for using combinations of LT₄ and T₃ to treat hypothyroidism.

► Bioequivalence and LT₄ Product Selection

LT₄ products have a long history of bioavailability problems.²⁰ Over the years, LT₄ bioavailability has increased, so maintenance doses today are significantly lower than those seen before the early 1980s. Currently, the average bioavailability of LT₄ products is about 80%. Because of long-standing concerns about LT₄ bioequivalence and because LT₄ products had never undergone formal approval by the FDA under the 1938 Food, Drug, and Cosmetics Act, the FDA mandated that all manufacturers of LT₄ products submit an Abbreviated

New Drug Application (ANDA) to keep their products on the U.S. market after 2001.²¹ Products approved under this process would have to comply with FDA manufacturing and bioequivalence standards. This FDA action has resulted in many changes in the U.S. LT_4 market, as well as renewed interest in LT_4 bioequivalence. Since 2001, a variety of brand and generic products had been approved by the FDA. Some of the generic products carry AB ratings (bioequivalence) to certain brand products.²²

For many years, there have been concerns regarding the FDA bioequivalence methodology for LT_4 products. FDA bioequivalence standards allow a -20% to $+25\%$ variance in pharmacokinetic parameters between the test and reference products. Many people believe this degree of allowed variance is not appropriate for a narrow-therapeutic-index (NTI) drug such as LT_4 .²³ Furthermore, there are unique challenges to performing bioequivalence studies with an endogenous hormone such as LT_4 . Because these single-dose pharmacokinetic studies are done in healthy volunteers, the pharmacokinetic data are a combination of endogenous and exogenous LT_4 . Seventy percent of the area under the curve (AUC) in these studies consists of the subjects' endogenous T_4 . Thus, it is doubtful that bioavailability differences among products could be detected. Blakesley and colleagues showed the standard FDA bioequivalence methodology would rate 600-, 450-, and 400-mcg LT_4 doses as bioequivalent.²⁴ This study also showed that mathematically removing the subjects' endogenous T_4 level (baseline correction) improves the sensitivity of the analysis, allowing a distinction between 33% and 25% but not 12.5% dose differences. Based on these data, since 2003, the FDA has required that LT_4 bioequivalence data undergo baseline correction. Although this method has improved the ability to identify large differences in LT_4 bioequivalence, small but clinically significant differences will not be identified. In 2008, the FDA adopted stricter criteria for LT_4 tablet shelf-life potency (95% to 105% of stated potency vs. standard 90% to 110%), which may reduce the inpatient variability seen during long-term LT_4 therapy. As of August 2011, the FDA Pharmaceutical Science and Clinical Pharmacology Advisory Committee was considering stricter guidelines for the determination of the bioequivalence of NTI drugs, including the use of TSH as a pharmacodynamic marker of LT_4 bioequivalence.

More important than bioequivalence is the therapeutic equivalence of LT_4 products. Will patients have the same outcomes if bioequivalent products are used? A study by Dong and colleagues helps to answer this question.²⁵ Twenty-two well-controlled hypothyroid women were randomly switched to the same dose of four different products every 6 weeks. Nonbaseline corrected bioequivalence data showed these products to be bioequivalent. However, as each product switch occurred, more of the subjects had an abnormal TSH level.²⁶ By the end of the third product switch, 52% had an abnormal TSH level. This is strong evidence that LT_4 products are not therapeutically equivalent even if they are rated as bioequivalent by the FDA.

Evidence does exist that small differences in the LT_4 dose can result in large changes in TSH. The impact on TSH of

small changes in LT_4 dose was assessed in 21 adult therapeutically optimized hypothyroid patients.²⁷ When the daily dose was reduced by 25 mcg, 78% had an elevated TSH level. When the daily dose was increased by 25 mcg, 55% had a low TSH level. Clearly, differences in the LT_4 dose or bioavailability within the FDA-allowed variance for bioequivalent products can cause significant changes in TSH.

6 *There is no evidence that one LT_4 product is better than another. However, given the evidence that these products do have different bioavailabilities, patients should be maintained on the same LT_4 product. Given the generic substitution regulations of most states, this is best accomplished by prescribing a brand-name product or otherwise ensuring that the product remains constant and not allowing substitution in the way allowed by state regulations or mandated by insurance companies.* Although practitioners are pressured by insurance companies and employers to substitute LT_4 products as a cost-saving measure, such switching is not in the best interest of the patient and should not be allowed. If patients are switched to a different product, the prescriber should be notified, and a TSH determination should be done in 6 to 8 weeks to allow dose retitration. The economic impact of retitration must be considered when formularies are changed to reduce the drug acquisition cost.

► Therapeutic Use of LT_4

- LT_4 is indicated for patients with overt hypothyroidism.²⁸ However, the need for treatment is controversial in patients with mild or subclinical disease. There are no large clinical trials that show an outcome benefit with treating these patients, and the therapeutic decision must be individualized. In patients without symptoms who have underlying heart disease, high cardiovascular risk, goiter, positive anti-TPOAb and/or are infertile or pregnant, LT_4 replacement should be considered.¹⁴ Patients with mild or subclinical hypothyroidism do not need to be started on the full replacement dose because they still have some endogenous hormone production. Start these patients on 25 to 50 mcg/day and titrate every 6 to 8 weeks based on TSH levels. Over time, it is likely that the LT_4 dose will need to be increased slowly as the patient's thyroid gland loses residual function.

In patients younger than age 65 years with overt hypothyroidism, the average LT_4 replacement dose is 1.6 mcg/kg/day (use ideal body weight in obese patients²⁹). However, there is wide interpatient variability in the optimal replacement dose, so individual dose titration is necessary. If there is no history of cardiac disease, these patients may be started on the full replacement dose.

The full replacement dose in patients older than age 75 years is lower, about 1 mcg/kg/day.³⁰ In the elderly, the starting dose should be 25 to 50 mcg/day, and the dose should then be titrated to the target TSH value. In patients with ischemic heart disease, start with 12.5 to 25 mcg/day and slowly titrate. If the patient develops angina or other forms of myocardial ischemia, lower the dose and titrate more slowly. At the start of therapy and with each change in dose, recheck the TSH in 6- to 8-week intervals. If the TSH is not in the target

Patient Encounter 1, Part 1

WM, a 49-year-old woman, comes to the clinic complaining of fatigue, lethargy, heavy periods, dry skin, and feeling cold all the time for the past 6 months. She thought it was because she was going through “the change,” but the symptoms have not improved despite her primary care provider telling her she was not perimenopausal. She has noticed a 4.8-kg (10.5-lb) weight gain over the past 6 months. Her provider gave her a prescription for sertraline, but she did not get it filled because she did not think she was depressed. She takes no medications other than occasional acetaminophen for headache and milk of magnesia for constipation. Her vital signs and physical examination, including pelvic examination findings, are normal.

Labs

Serum cholesterol: 220 mg/dL (5.7 mmol/L; normal, less than 200 mg/dL, or 5.2 mmol/L); LDL cholesterol 101 mg/dL (2.6 mmol/L; normal less than 130 mg/dL or 3.36 mmol/L)

TSH: 8.6 mIU/L (reference range, 0.5 to 4.5 mIU/L)^a

Free T₄: 0.9 ng/dL (11.5 pmol/L; reference range, 0.7 to 1.9 ng/dL, or 9 to 24.5 pmol/L)

PE: Wt: 74 kg (163 lb); ht: 5 ft, 5 in (165 cm); BMI: 27.2 kg/m²

Should WM receive LT₄ therapy? Why or why not?

If treatment is indicated, what initial dose of LT₄ would you choose?

If treatment is not indicated, how would you monitor the patient?

What would you tell WM regarding the significance of her symptoms, elevated TSH level, and risk versus benefits of LT₄ therapy?

^aMilli international units/L (mIU/L) = micro international units/mL (μIU/mL); clinical laboratories use either unit of measurement.

range (0.5 to 2.5 mIU/L or μIU/mL), change the dose by 10% to 20% and then recheck the TSH 6 to 8 weeks later. As the dose is titrated, assess the patient’s symptoms. Many patients will improve quickly, and younger patients will feel the best if the TSH is titrated to low-normal to middle-normal levels (0.5 to 1.5 mIU/L or μIU/mL).

► Risks of Over- and Undertreatment

Patients receiving LT₄ therapy who are not maintained in a euthyroid state are at risk for long-term adverse sequelae. In general, overtreatment and a suppressed TSH are more common than undertreatment with an elevated TSH.³¹ Patients with long-term overtreatment are at higher risk for atrial fibrillation and other cardiovascular morbidities, depression or mental status changes, and postmenopausal osteoporosis.

Elderly patients being treated with LT₄ have a dose-related risk of fractures even if their TSH is not suppressed below normal values.³² Although studies have not defined a specific TSH target range for the elderly, these patients should receive close monitoring and dose adjustments to prevent overtreatment with LT₄. Patients who are undertreated are at higher risk for hypercholesterolemia and other cardiovascular problems, depression or mental status changes, and obstetric complications.

► Alterations in LT₄ Dose Requirements

A number of factors can alter LT₄ dose requirements (Table 44–4), including time of administration and drug–drug and drug–food interactions. LT₄ has the greatest and most consistent bioavailability when taken in the evening on an empty stomach.³³ The most common cause of increased dose requirement is the coadministration of LT₄ with calcium or iron supplements (including prenatal vitamins). Counsel patients that they should take the LT₄ dose at least 2 hours before or 6 hours after the calcium or iron dose. The most common cause of decreased dose requirement is aging.

Table 44–4

Factors That Alter LT₄ Dose Requirements

Increased Dose Requirement	Decreased Dose Requirement
Decreased LT₄ absorption Malabsorption syndromes	Aging Delivery of pregnancy
Drugs or diet Calcium Iron Aluminum Fiber Soy Cholestyramine or colestipol Sucralfate Sodium polystyrene sulfonate Phosphate binders Tube feeding	Withdrawal of interacting substance
Increased TBG Pregnancy Cirrhosis Estrogen therapy Tamoxifen, raloxifene therapy Hereditary	
Increased clearance Rifampin Carbamazepine Phenytoin Phenobarbital	
Impaired deiodination Amiodarone	
Mechanism unknown Sertraline, ? other serotonin-modulating drugs Lovastatin Critical illness	

LT₄, levothyroxine; TBG, thyroxine-binding globulin.

Table 44-5

Monitoring LT₄ Therapy

- Serum TSH
 - Every 6–12 months or if change in clinical status
 - 6–8 weeks after any dose or product change
 - As soon as possible in pregnancy; then monthly
- Same product prescribed and dispensed with every refill
- Watch for mg/mcg dosing errors
- Assess patient's understanding of disease, therapy, and need for adherence and tight control
- Assess for signs and symptoms of over- and undertreatment
- Identify potential interactions between LT₄ and foods and/or drugs

LT₄, levothyroxine; TSH, thyroid-stimulating hormone.

► Patient Monitoring

Patients on stable LT₄ therapy do not need frequent monitoring. In most patients, measuring a TSH every 6 to 12 months along with an assessment of clinical status is adequate (Table 44-5). If the patient's clinical status changes (e.g., pregnancy), more frequent monitoring may be necessary. LT₄ prescriptions should be written as microgram doses to avoid potential errors when written as milligram doses.

Patient education is an important component of care. Treatment adherence rates (at least 80% of doses taken) in hypothyroid patients are 68%, slightly less than adherence rates seen in hypertensive patients.³⁴ Educate patients about the benefits of proper therapy, the importance of adherence, consistency in time and method of administration, and the importance of receiving a consistent LT₄ product. Some patients take excessive amounts of LT₄ in an effort to “feel better” or as a weight loss treatment. Explain to patients that excessive amounts of LT₄ will not improve symptoms more than therapeutic doses will and can cause serious

Patient Encounter 1, Part 2

One year later, WM comes to you for routine follow-up stating that she has felt progressively worse since her last visit 2 months ago. Her most recent TSH determination, obtained 2 days ago, was 14.2 mIU/L (reference range, 0.5 to 4.5 mIU/L).^a

Why is LT₄ therapy indicated?

What would you recommend regarding her LT₄ dose and monitoring?

What instructions would you give WM regarding her LT₄ therapy?

^aMilli international units/L (mIU/L) = micro international units/mL (μIU/mL); clinical laboratories use either unit of measurement.

problems and that this drug is not an effective treatment for obesity.

► Special Populations and Conditions

- **Hypothyroidism and Pregnancy** Hypothyroidism during pregnancy has a variety of maternal and fetal adverse effects.^{18,35} During pregnancy, β-human chorionic gonadotropin (β-hCG) acts as a TSH receptor agonist, increasing the amount of thyroid hormone available for fetal growth and development. Maternal hypothyroidism results in an increased rate of miscarriage and decreased intellectual capacity of the child. Endocrinologists recommend a TSH measurement as soon as the pregnancy is confirmed. Most hypothyroid women who become pregnant will quickly need an increased dose of LT₄, typically 20% to 50% above the prepregnancy dose.³⁵ One study suggests increasing the woman's pregnancy dose by two tablets per week as soon as the pregnancy is diagnosed.³⁶ The increased dose should be maintained throughout the pregnancy, with monthly TSH monitoring to keep the TSH in the middle- to low-normal range. After delivery, the LT₄ dose usually can be reduced to prepregnancy levels, although patients with preexisting autoimmune thyroiditis may have increased postpartum dose requirements. Because prenatal vitamins contain significant amounts of calcium and iron, remind these patients to take the LT₄ dose at least 2 hours before or 6 hours after the vitamin.

Children Congenital hypothyroidism is still seen in the United States (fewer than 0.02% of newborns⁶), and all newborns in the United States undergo screening with a TSH level. As soon as the hypothyroid state is identified, the newborn should receive the full LT₄ replacement dose. The replacement dose of LT₄ in children is age dependent. In newborns, the usual dose is 10 to 17 mcg/kg/day. LT₄ tablets may be crushed and mixed with breast milk or formula, but it is best to administer LT₄ to infants and children on an empty stomach.³⁷ Serum FT₄ levels (target, 1.6 to 2.2 ng/dL or 20.6 to 28.3 pmol/L) are used for dose titration in infants because the TSH level may not respond to treatment as it does in older children and adults. By 6 months of age, the required dose is reduced to 5 to 7 mcg/kg/day, and from ages 1 to 10 years, the dose is 3 to 6 mcg/kg/day. After age 12 years, adult doses can be given.

Myxedema Coma This is a life-threatening condition owing to severe, long standing hypothyroidism and has a mortality rate of 60% to 70%. These patients are given 300 to 500 mcg LT₄ intravenously initially, using caution in patients with underlying cardiac disease. Although administration of T₃ would provide a more rapid onset of action, there is no evidence that T₃ improves outcomes in patients with myxedema coma. Historically, glucocorticoids, such as hydrocortisone 50 to 100 mg every 6 hours, are administered owing to concern about simultaneous adrenal insufficiency. Although there is no strong evidence for an outcome benefit, the use of glucocorticoids is reasonable because such treatment may be lifesaving, and the risks of a short course of corticosteroids at this dose are low. As patients improve, the LT₄ dose can be given orally in a typical full replacement dose.

Patient Care and Monitoring: Hypothyroidism

1. Use serum TSH to identify patients with hypothyroidism and to monitor LT₄ replacement therapy.
2. Use synthetic LT₄ as the treatment of choice for hypothyroidism.
3. Provide LT₄ replacement to patients with overt hypothyroidism.
4. Consider replacement therapy in patients with a TSH level of greater than 4.5 but less than 10 mIU/L^a who have subtle symptoms (e.g., mild fatigue, lethargy), an elevated cholesterol level, underlying heart disease, or positive anti-TPOAbs.
5. Patients with mild hypothyroidism may be started at 25 to 50 mcg/day of LT₄.
6. Patients with overt hypothyroidism who are older than 12 and younger than 65 years of age and who do not have cardiac disease may receive the calculated full replacement LT₄ dose (1.6 mcg/kg/day based on ideal body weight if obese).
7. Elderly patients or those with cardiac disease should be started at a lower LT₄ dose (e.g., 12.5 to 25 mcg/day).
8. Measure serum TSH 6 to 8 weeks after starting or any dose change. If the TSH level is not in the target range, alter the dose by 10% to 20% increments.
9. The target TSH for patients on LT₄ replacement therapy for hypothyroidism is 0.5 to 2.5 mIU/L. Younger patients often feel best at a TSH level in the low- to middle-normal range (i.e., 0.5 to 1.5 mIU/L).
10. Provide a brand-name LT₄ product, and do not allow the patient to switch to different products. If the product is switched, check a TSH in 6 weeks and retitrate the dose.
11. Provide LT₄ prescriptions as microgram, not milligram, doses to avoid errors.
12. Check a TSH every 6 to 12 months in stable patients receiving LT₄ replacement.
13. Make sure that patients understand the importance of adherence and the risks of over- and underuse of LT₄.
14. At each visit, assess the patient for signs and symptoms of over- and undertreatment.
15. Monitor for drug interactions, such as LT₄ absorption problems caused by calcium and iron.
16. Check a TSH in pregnant women as soon as the pregnancy is diagnosed. In hypothyroid pregnant women, check the TSH monthly, and expect to increase the LT₄ dose early in the first trimester. Maintain the TSH in the low- to middle-normal range. After delivery, reduce the LT₄ dose to the prepregnancy dose.

^aMilli international units/L (mIU/L) = micro international units/mL (μIU/mL); clinical laboratories use either unit of measurement.

HYPERTHYROIDISM AND THYROTOXICOSIS

Hyperthyroidism is much less common than hypothyroidism. In NHANES, 0.5% of the population was hyperthyroid, with the highest incidences in women overall and in men and women in the over 80 years of age groups.¹ The Colorado Thyroid Health Study showed a hyperthyroid incidence of 2.2% (2.1% subclinical).²

Causes of Thyrotoxicosis and Hyperthyroidism

Hyperthyroidism is related to excess thyroid hormone secreted by the thyroid gland. Thyrotoxicosis is any syndrome caused by excess thyroid hormone and can be related to excess hormone production (hyperthyroidism). The common causes of thyrotoxicosis are shown in [Table 44-6](#).³⁸⁻⁴⁰ Graves' disease is the most common cause of hyperthyroidism. Thyrotoxicosis in the elderly is more likely caused by toxic thyroid nodules or multinodular goiter than by Graves' disease. Excessive intake of thyroid hormone may be caused by overtreatment with prescribed therapy. Surreptitious use of thyroid hormones also may occur, especially in health professionals or as a self-remedy for obesity. Thyroid hormones

can be obtained easily without a prescription from health food stores or Internet sources. Refer to Clinical Presentation and Diagnosis of Hyperthyroidism for information regarding screening and diagnosis.

Table 44-6

Causes of Thyrotoxicosis^{39,40}

Primary hyperthyroidism

- Graves' disease
- Toxic multinodular goiter
- Toxic adenoma
- Thyroid cancer
- Struma ovarii
- Iodine excess (including radiocontrast, amiodarone)

Thyrotoxicosis without hyperthyroidism

- Subacute thyroiditis
- Silent (painless) thyroiditis
- Excess thyroid hormone intake (thyrotoxicosis factitia)
- Drug-induced (amiodarone, iodine, lithium, interferons)

Secondary hyperthyroidism

- TSH-secreting pituitary tumors
- Trophoblastic (hCG-secreting) tumors
- Gestational thyrotoxicosis

hCG, human chorionic gonadotropin; TSH, thyroid-stimulating hormone.

Clinical Presentation and Diagnosis: Hyperthyroidism^{39,40}

Symptoms

- Nervousness
- Fatigue
- Weakness
- Increased perspiration
- Heat intolerance
- Tremor
- Hyperactivity, irritability
- Palpitations
- Appetite change (usually increased)
- Weight change (usually weight loss)
- Menstrual disturbances (often oligomenorrhea)
- Diarrhea

Signs

- Hyperactivity
- Tachycardia

- Atrial fibrillation (especially in elderly adults)
- Hyperreflexia
- Warm, moist skin
- Ophthalmopathy, dermopathy (Graves' disease)
- Goiter
- Muscle weakness

Screening/Diagnosis

- Low TSH level (less than 0.5 mIU/L) signifies thyrotoxicosis.
- Free T₄ is elevated in overt hyperthyroidism but may be normal in mild hyperthyroidism.
- Increased radioiodine uptake in the thyroid indicates increased hormone production by the thyroid gland.
- Almost all patients with Graves' disease will have positive TSHR-SAbs and positive anti-TPOAbs.

Clinical Manifestations of Thyrotoxicosis

Many of the signs and symptoms seem to be related to autonomic hyperactivity. As with hypothyroidism, the clinical manifestations of hyperthyroidism may be subtle and slowly progressive. Screening of patients for thyroid disease may identify patients with subclinical or mild thyrotoxicosis. Patients may seek medical attention only after a long period of thyrotoxicosis or owing to an acute complication such as atrial fibrillation. The clinical manifestations of thyrotoxicosis in the elderly may be blunted or atypical. These patients may present only with atrial fibrillation, depression, or altered mental status or cognition.

Subclinical Hyperthyroidism

Subclinical or mild hyperthyroidism is defined as a low TSH level with a normal FT₄ level.¹⁴ Although there may be few or no symptoms in these patients, there are several areas of concern.¹⁷ Some patients progress to overt thyrotoxicosis. Patients with subclinical hyperthyroidism have been shown to experience long-term cardiovascular and bone sequelae. The impact of subclinical hyperthyroidism on cardiovascular mortality is not clear.¹⁴⁻¹⁷ Several studies have shown that prolonged subclinical thyrotoxicosis speeds the loss of bone mineral density and increases fracture rates in postmenopausal women.¹⁷ Treatment of patients with subclinical hyperthyroidism is controversial but should be considered in patients with TSH levels less than 0.1 mIU/L (less than 0.1 μ IU/mL), postmenopausal women, and patients with underlying cardiovascular disease.¹⁷ Patients who do not have a fully suppressed (below the lower limit of detection) TSH or

other risk factors for hyperthyroid complications (e.g., osteoporosis, cardiac arrhythmias) may just undergo observation, with TSH testing every 6 months to identify progression of the hyperthyroid state.

Graves' Disease

Graves' disease is an autoimmune syndrome that includes hyperthyroidism, diffuse thyroid enlargement, **exophthalmos** and other eye findings, and skin findings.³⁸ The prevalence of Graves' disease in the United States is approximately 0.4% in women and 0.1% in men. The peak age of incidence is 20 to 49 years, with a second peak after 80 years of age. Hyperthyroidism results from the production of TSHR-SAbs (TSH receptor-stimulating antibodies) in at least 80% of patients with clinical Graves' disease. These antibodies have TSH agonist activity, thereby stimulating hormone synthesis and release. These antibodies cross-react with orbital and fibroblastic tissue, resulting in ophthalmopathy and dermopathy. Although the underlying cause of Graves' disease is not known, heredity seems to play a role. Subclinical Graves' disease may become acutely overt in the presence of iodine excess, infection, stress, parturition, smoking, and lithium and cytokine therapy.

Several features of Graves' disease are distinct from other forms of thyrotoxicosis. Clinically apparent ophthalmopathic changes are seen in 20% to 40% of patients³⁸ and include **exophthalmos**, **proptosis**, **chemosis**, **conjunctival injection**, and periorbital edema. Eyelid retraction causes a typical staring or startled appearance (**Fig. 44-3**). Patients may complain of vague eye discomfort and excess tearing. In severe cases, the eyelids are unable to close completely, resulting in corneal damage. In very severe cases, the optic

FIGURE 44-3. Features of Graves' disease. (A) Facial appearance: exophthalmos, eyelid retraction, periorbital edema, and proptosis. (B) Thyroid dermopathy over lateral aspects of the shins (*arrow*). (C) Thyroid clubbing, or acropachy (*arrow*). (From Jameson JL, Weetman AP. Disorders of the thyroid gland. In: Kasper DL, Braunwald E, Fauci AS, et al., eds. *Harrison's Principles of Internal Medicine*. 16th ed. New York: McGraw-Hill; 2004:2114.)

nerve can be compressed, resulting in permanent vision loss. All patients with suspected or known Graves' disease must be evaluated and monitored by an ophthalmologist.

• Dermopathy occurs in 5% to 10% of patients with Graves' disease and usually is associated with severe ophthalmopathy. Skin findings include hyperpigmented, nonpitting induration of the skin, typically over the pretibial area (pretibial myxedema), the dorsa of the feet, and the shoulder areas. **Clubbing** of the digits (thyroid acropachy) is associated with long-standing thyrotoxicosis.

Treatment of Hyperthyroidism

Treatment of thyrotoxicosis caused by hyperthyroidism is similar regardless of the underlying cause.³⁹⁻⁴⁴ 7 *The goals of treating hyperthyroidism are to relieve signs and symptoms, reduce thyroid hormone production to normal levels and achieve biochemical euthyroidism, and prevent long-term adverse sequelae.*

► β -Blockers

Because many of the manifestations of hyperthyroidism appear to be mediated by the β -adrenergic system, β -adrenergic blockers are used to rapidly relieve palpitations, tremor, anxiety, and heat intolerance. Because β -blockers do not reduce the synthesis of thyroid hormones, they are used only until more specific antithyroid therapy is effective. Because nonselective agents can impair the conversion of T_4 to T_3 , propranolol and nadolol are used. An initial propranolol dose of 20 to 40 mg four times daily should be titrated to relieve signs (target heart rate less than 90 beats/min) and symptoms. β -Blockers should not be used in patients with

decompensated heart failure or asthma. When a contraindication to β -blockers exists, clonidine or diltiazem may be used for rate control.

► Methods to Reduce Thyroid Hormone Synthesis

Excess production of thyroid hormone can be reduced in four ways: iodides, antithyroid drugs, radioactive iodine, and surgery.

• **Iodide** Large doses of iodide inhibit the synthesis and release of thyroid hormones. Serum T_4 levels may be reduced within 24 hours, and the effects may last for 2 to 3 weeks. Iodides are used most commonly in Graves' disease patients before surgery and to quickly reduce hormone release in patients with thyroid storm. Potassium iodide is administered either as a saturated solution (SSKI) that contains 38 mg iodide per drop or as Lugol's solution, which contains 6.3 mg iodide per drop. The typical starting dose is 120 to 400 mg/day. Iodide therapy should start 7 to 14 days before surgery. Iodide should not be given before radioactive iodine treatment because the iodide will inhibit concentration of the radioactivity in the thyroid. Iodides also are used to protect the thyroid from radioactive iodine fallout after a nuclear accident or attack. Daily administration of 30 to 100 mg iodide markedly reduces thyroid gland uptake of radioactive iodine. The most frequent toxic effects with iodide therapy are hypersensitivity reactions, "iodism" (characterized by palpitations, depression, weight loss, and pustular skin eruptions), and gynecomastia.

• **Antithyroid Drugs** The thionamide agents propylthiouracil (PTU) and methimazole (MMI) are used in the United States to treat hyperthyroidism. Carbimazole, an MMI prodrug, is

used in some countries (10 mg carbimazole = 6 mg MMI). These drugs inhibit thyroid hormone synthesis by interfering with thyroid peroxidase-mediated iodination of tyrosine residues in thyroglobulin. PTU has the added effect of inhibiting the conversion of T_4 to T_3 . The thionamides also have immunosuppressant effects. In patients with Graves' disease treated with thionamides, TSHR-SAb levels and other immune mediators decrease over time. Both drugs are well absorbed from the gastrointestinal (GI) tract. PTU has a half-life of 1 to 2.5 hours, whereas the half-life of MMI is 6 to 9 hours.

Antithyroid drugs are used as primary therapy for Graves' disease or as preparative therapy before surgery or radioactive iodine administration. The decision to use antithyroid drugs as primary therapy must be weighed against the risks and benefits of radioiodine or surgery. Patient preference must be considered.

In most patients, there is no clear efficacy advantage of one thionamide over the other, but in the United States, MMI use has increased dramatically since the mid-1990s in lieu of PTU.⁴⁵ Although PTU has the advantage of inhibiting T_4 -to- T_3 conversion, MMI can be given as a single daily dose and may have a better overall safety profile, particularly less hepatotoxicity. MMI is preferred to normalize thyroid function before radioactive iodine therapy, although both thionamides increase the failure rate of radioactive iodine therapy.⁴⁶ The usual starting dose of MMI is 10 to 20 mg/day, and the usual starting dose of PTU is 50 to 150 mg three times daily. Thyroid hormone levels drop in 2 to 3 weeks, and after 6 weeks, 90% of patients with Graves' disease will be euthyroid. Thyroid function testing should be performed every 4 to 6 weeks until stable. After the patient becomes euthyroid, the antithyroid drug dose often can be decreased (5 to 10 mg/day MMI, 100 to 200 mg/day PTU) to maintain the euthyroid state. Excessive doses of antithyroid drugs will result in hypothyroidism.

Remission of Graves' disease occurs in 40% to 60% of patients after 1 to 2 years of therapy. Antithyroid therapy may be stopped or tapered after 12 to 24 months. Relapse usually occurs in the first 3 to 6 months after stopping antithyroid therapy. Levels of TSHR-SAb after a course of treatment may have predictive value for the risk of relapse in that antibody-positive patients almost always will relapse. However, antibody-negative patients also may relapse after therapy is stopped. About 75% of women in remission who become pregnant will have a postpartum relapse. When therapy is discontinued, a therapeutic strategy should be in place in the event of relapse. Many patients will opt for radioactive iodine as a long-term solution.

Antithyroid drugs are associated with an overall low rate of adverse effects, although serious adverse effects can occur. In 2010, the FDA released a new boxed warning on severe liver injury with PTU.⁴⁷ The warning includes a statement that PTU should only be used in patients who cannot tolerate MMI. Skin rash, arthralgias, and GI upset are seen in 5% of patients. Although the drug can be continued in the presence of a minor skin rash, the development of arthralgia warrants discontinuation. Hepatotoxicity is an uncommon but

potentially serious or fatal adverse effect, occurring in 0.1% to 0.2% of patients. However, transient rises in aminotransferase enzyme levels are seen in up to 30% of patients treated with PTU. Severe hepatocellular damage can occur from PTU, whereas MMI can cause cholestatic jaundice. Antineutrophil cytoplasmic antibody (ANCA) vasculitis is another potentially serious but uncommon reaction that is more common with PTU, and patients may develop a drug-induced lupus syndrome.

8 *Agranulocytosis is one of the most serious adverse effects of antithyroid drug therapy.* Agranulocytosis must be distinguished from a transient decrease in white blood cell count seen in up to 12% of adults and 25% of children with Graves' disease. Agranulocytosis occurs in 0.3% of patients, and the incidence may be the same with PTU and MMI therapy. Agranulocytosis almost always occurs within the first 3 months of therapy, and it occurs suddenly and unpredictably. Patients will present with fever, malaise, and a sore throat, and the absolute neutrophil count will be less than 1,000/ mm^3 ($1 \times 10^9/\text{L}$). Patients may develop sepsis and die rapidly. Agranulocytosis is thought to be autoimmune mediated. If agranulocytosis occurs, discontinue the antithyroid drug immediately, administer broad-spectrum antibiotics if the patient is febrile, and consider the administration of granulocyte colony-stimulating factor. The white blood cell count should recover in 1 or 2 weeks. Patients who develop agranulocytosis should not be switched to another thionamide drug. Monitoring for agranulocytosis is controversial owing to its sudden and unpredictable nature. Most practitioners do not recommend routine monitoring of the complete blood count, although early detection could improve patient outcomes. Patients initiating thionamide therapy must be informed about the signs and symptoms of agranulocytosis and other serious side effects. Patients should be counseled to report signs and symptoms suggestive of infection, such as fever and sore throat lasting more than 2 or 3 days, bruising, pruritic rash, jaundice, dark urine, arthralgias, abdominal pain, nausea or fatigue.

Radioactive Iodine Radioactive iodine, typically ^{131}I , produces thyroid **ablation** without surgery. ^{131}I is well absorbed after oral administration. The iodine is concentrated in the thyroid gland and has a half-life of 8 days. Over a period of weeks, thyroid cells that have taken up the ^{131}I begin to develop abnormalities and necrosis. Eventually, thyroid cells are destroyed, and hormone production is reduced. After a single dose, 40% to 70% of patients will be euthyroid in 6 to 8 weeks, and 80% will be cured. In most patients, hypothyroidism will develop, and long-term LT_4 replacement will be necessary. Because ^{131}I has a slow onset of action, most patients are treated initially with β -blockers and antithyroid drugs. MMI is the preferred agent before the administration of ^{131}I . MMI is discontinued 3 to 5 days before the administration of ^{131}I and is restarted 3 to 7 days later. MMI is then slowly tapered over the next 4 to 6 weeks as thyroid function normalizes. β -Blockers can be continued during ^{131}I therapy. The dose of ^{131}I is based on the estimated weight of the patient's thyroid gland (typical dose,

10 to 15 mCi [370 to 555 MBq]). Radioactive iodine therapy is contraindicated during pregnancy and breastfeeding. Radioactive iodine therapy may acutely worsen Graves' ophthalmopathy. Patients with prominent eye disease may be started on prednisone 40 mg/day, with the dose tapered over 2 to 3 months. Radioactive iodine also may cause a painful thyroiditis, which may necessitate anti-inflammatory therapy. No long-term carcinogenic effect of ^{131}I has been demonstrated in clinical trials.

Surgery Subtotal thyroidectomy is indicated in patients with very large goiters and thyroid malignancies and those who do not respond or cannot tolerate other therapies. Patients must be euthyroid before surgery, and they are often administered iodide preoperatively to reduce gland vascularity. The overall surgical complication rate is 2.7%. Postoperative hypothyroidism occurs in 10% of patients who undergo subtotal thyroidectomy. After thyroidectomy, serum calcium and intact parathyroid hormone levels should be monitored for early identification of postoperative hypoparathyroidism. Postoperative administration of 1,250 to 2,500 mg/day of calcium and 0.5 mcg/day of calcitriol may be given and then tapered over 1 to 2 weeks if the patient does not develop hypoparathyroidism.

► Special Conditions and Populations

Graves' Disease and Pregnancy^{39,48} Pregnancy may worsen or precipitate thyrotoxicosis in women with underlying Graves' disease owing to the TSH agonist effect of β -hCG.

Untreated maternal thyrotoxicosis may result in increased rates of miscarriage, premature delivery, eclampsia, and low-birth-weight infants. Fetal and neonatal hyperthyroidism may occur as a result of transplacental passage of TSHR-SABs. Because radioactive iodine is contraindicated and surgery is best avoided during pregnancy, most patients are treated with antithyroid drugs. PTU is considered the treatment of choice, particularly in the first trimester, because of a rare but well-documented teratogenic effect of MMI. Patients receiving prepregnancy MMI should be switched to PTU as soon as the pregnancy is diagnosed. The lowest possible dose of PTU to maintain maternal euthyroidism should be used. Given the potential maternal adverse effects of PTU (e.g., hepatotoxicity), it may be preferable to switch from PTU to MMI for the second and third trimesters.⁴⁷ Antithyroid therapy in excessive doses may suppress fetal thyroid function. Although PTU and MMI are found in breast milk, nursing mothers should be switched to MMI after delivery because of the risk of hepatotoxicity from PTU in the mother and infant.

Pediatric Hyperthyroidism³⁹ β -Blockers are administered to children who are symptomatic or have a heart rate greater than 100 beats/min. MMI is the preferred antithyroid drug therapy in children at a dose of 0.2 to 0.5 mg/kg/day. Once a euthyroid state is achieved, the MMI dose can be reduced by 50% or more to maintain euthyroidism. As in adults, antithyroid drugs are administered to children with Graves' disease for 1 to 2 years. If remission does not occur in that

Patient Encounter 2

TS is a 29-year-old woman who comes to the clinic stating, "I'm so jumpy and sweaty and hungry, and I'm losing weight. I think I'm losing my mind. What is wrong with me? Is it because I'm pregnant?" She first noticed these symptoms 4 months ago, and they have worsened steadily since she became pregnant 2 months ago. She feels anxious for no reason and has trouble sleeping. She has noticed that her appetite has increased, although she has lost about 1 kg (2.2 lb) over the past 2 months despite being pregnant. Sometimes she can feel her heart beating in her chest, but she denies chest pain or syncope. Her only medications are a prenatal vitamin, occasional ibuprofen for headaches, and an herbal product for boosting energy. She thinks that her mother had some kind of thyroid problem when she was pregnant.

PE:

VS: Pulse 122 beats/min, BP 106/71, RR 12, temperature 37.4°C (99.3°F)

HEENT: Diffusely enlarged thyroid; mild exophthalmos

CV: Tachycardic, RRR

Exts: Fine tremor

Skin: Warm, moist, and soft

ECG: Sinus tachycardia

Uterine ultrasound: 6-week-size fetus

Labs

Electrolytes, complete blood count normal. TSH less than 0.1 mIU/L (reference range 0.5 to 2.5 mIU/L)^a; free T_4 (FT_4) 3.6 ng/dL (46.3 pmol/L; reference range 0.7 to 1.9 ng/dL, or 9.0 to 24.5 pmol/L); +ve TSHR-SABs

What therapeutic options exist for TS's Graves' disease while she is pregnant?

Could the herbal product be causing any of her signs and symptoms?

What pharmacotherapy would you recommend? Would you change it after she has her baby?

How would you initiate and titrate therapy?

What would you tell TS regarding the cause of her signs and symptoms, significance of her abnormal thyroid function tests, and therapeutic options?

^aMilli international units/L (mIU/L) = micro international units/mL ($\mu\text{IU/mL}$); clinical laboratories use either unit of measurement.

Patient Care and Monitoring: Hyperthyroidism

1. A low or undetectable TSH level identifies thyrotoxicosis.
2. Refer the patient for a diagnostic assessment to identify the underlying cause. Identify Graves' disease by the presence of eye and/or skin findings and the presence of TSHR-SAbs.
3. Refer patients with Graves' disease to an ophthalmologist for assessment and monitoring.
4. Treat severe or troublesome autonomic signs and symptoms with a nonselective β -blocker such as propranolol 20 to 40 mg four times daily. Titrate the β -blocker dose based on signs and symptoms.
5. In patients with excess thyroid hormone production, reduce hormone production with an antithyroid drug and/or radioactive iodine. Choose therapy based on patient-specific factors and preference.
6. Antithyroid drugs have a delayed effect. After 2 to 4 weeks of therapy, adjust the dose if the TSH is not in the target range (0.5 to 2.5 mIU/L).^a When the patient is euthyroid, consider reducing the dose of antithyroid drug to avoid hypothyroidism.
7. MMI is the antithyroid drug of choice in most patients.
8. Treat pregnant hyperthyroid women with PTU.
9. Consider stopping antithyroid therapy in patients with Graves' disease after 12 to 18 months to see if remission has occurred.
10. Monitor patients on antithyroid drugs for signs and symptoms of adverse effects.
 - a. Baseline CBC with differential and liver profile
 - b. Repeat CBC when patient has a febrile illness. Routine monitoring of WBC is not recommended.
 - c. Repeat liver panel if signs or symptoms of hepatotoxicity occur (some recommend routine monitoring during the first 6 months of therapy).
 - d. Assess any skin rash or development of arthralgias.
11. If radioactive iodine is given, make sure that antithyroid drugs are stopped 4 to 6 days before treatment.
12. Several months after radioactive iodine, expect that the patient will require permanent LT_4 replacement.

^aMilli international units/L (mIU/L) = micro international units/mL (μ IU/mL); clinical laboratories use either unit of measurement.

time, long-term antithyroid drug therapy, radioactive iodine, or surgical therapy is offered. Long-term studies with ^{131}I use in children show no increased risk of thyroid cancer or leukemia.

Thyroid Storm^{39,49} Thyroid storm is a life-threatening condition caused by severe thyrotoxicosis. Signs and symptoms include high fever, tachycardia, tachypnea, dehydration, delirium, coma, and GI disturbances. Thyroid storm is precipitated in a previously hyperthyroid patient by infection, trauma, surgery, radioactive iodine treatment, and sudden withdrawal from antithyroid drugs. Patients are treated with a short-acting β -blocker such as intravenous (IV) esmolol, IV or oral iodide, and large doses of PTU (500 to 1,000 mg load; then 250 mg every 4 hours) or MMI (60 to 80 mg/day). Supportive care with acetaminophen to suppress fever, fluid and electrolyte management, and antiarrhythmic agents are important components of therapy. IV hydrocortisone 300 mg initially and then 100 mg every 8 hours is used often because of the potential presence of adrenal insufficiency.

NONTHYROIDAL ILLNESS (EUTHYROID SICK SYNDROME)

A number of changes in the hypothalamic–pituitary–thyroid axis occur during acute illness.^{50,51} These changes are termed *nonthyroidal illness* or *euthyroid sick syndrome*. The type and degree of abnormalities depend on the severity of

illness. Mild to moderate medical illness, surgery, or starvation causes a decrease in serum T_3 levels owing to decreased peripheral conversion of T_4 to T_3 . The reduced T_3 levels do not correlate with ultimate mortality and are thought to be an adaptive response to stress. Patients with more severe illness, especially those in the intensive care unit, frequently have reduced total T_4 levels, although FT_4 levels often are normal. In critically ill patients, there is a correlation between the degree of serum T_4 reduction and mortality. In most acutely ill patients who are euthyroid, the TSH level is normal. However, administration of dopamine, octreotide, or high doses of glucocorticoids can reduce TSH levels. During recovery from acute illness, the TSH level may become modestly elevated to renormalize serum T_4 levels. During this time, thyroid function tests may be misinterpreted to indicate hypothyroidism. Despite the sometimes very low T_4 levels, there is no evidence that LT_4 administration has any benefit. Patients with possible thyroid abnormalities during acute illness should be evaluated by an endocrinologist.

THYROID CANCER AND LT_4 SUPPRESSION

9 The growth and spread of thyroid carcinoma are stimulated by TSH. An important component of thyroid carcinoma management is the use of LT_4 to suppress TSH secretion. Early in therapy, patients receive the lowest LT_4 dose sufficient to

fully suppress TSH to undetectable levels. Controlled trials show that suppressive LT_4 therapy reduces tumor growth and improves survival. These patients are purposefully “overtreated” with LT_4 , sometimes to a fully-suppressed TSH level, and rendered subclinically hyperthyroid. Postmenopausal women should receive aggressive osteoporosis therapy to prevent LT_4 -induced bone loss. Other thyrotoxic complications, such as atrial fibrillation, should be monitored and managed appropriately.

DRUG-INDUCED THYROID ABNORMALITIES

Drugs can affect thyroid function in a number of ways.^{13,52} The effects of drugs on thyroid hormone protein binding, LT_4 absorption, and metabolism have been discussed previously. Several commonly used medications can alter thyroid hormone secretion.

Amiodarone

Amiodarone is a commonly prescribed antiarrhythmic drug that contains two iodide atoms, constituting 38% of its mass.⁵³ Each 200-mg dose of amiodarone provides 75 mg of iodide. Amiodarone deiodination releases about 6 mg of free iodine daily, 20 to 40 times more than the average daily intake of iodine in the United States. Amiodarone blocks conversion of T_4 to T_3 , inhibits entry of T_3 into cells, and decreases T_3 receptor binding. Amiodarone causes rapid reduction in serum T_3 levels, increases free and total T_4 levels, and increases TSH level. After 3 months of therapy, TSH levels usually return to normal, although the serum T_3 and T_4 level changes may remain. Most of these patients are euthyroid because the free T_3 levels are in the low-normal range. Amiodarone can frequently cause thyroid abnormalities in previously euthyroid patients. In a study of amiodarone treatment of persistent atrial fibrillation, 25.8% of patients developed subclinical hypothyroidism, and 5% developed overt hypothyroidism.⁵⁴ Hyperthyroidism occurred in 5.3%. Thyroid abnormalities, when they occurred, were seen within 6 months of initiation of amiodarone therapy in almost all patients. Amiodarone-induced hypothyroidism is more common in iodine-sufficient areas of the world. Patients with underlying autoimmune thyroiditis are much more likely to develop amiodarone-induced hypothyroidism. Amiodarone-induced hypothyroidism occurs most commonly within the first year of therapy. If amiodarone cannot be discontinued, LT_4 therapy will be effective in most patients. If amiodarone can be stopped, thyroid function will return to normal in 2 to 4 months.

Amiodarone is more likely to cause thyrotoxicosis in iodine-deficient areas. Type 1 amiodarone-induced thyrotoxicosis is caused by iodine excess and typically occurs in patients with preexisting multinodular goiter or subclinical Graves' disease. Type 2 amiodarone-induced thyrotoxicosis is a destructive thyroiditis that occurs in patients with no underlying thyroid disease. Amiodarone-induced thyrotoxicosis is more common in men. Because amiodarone has β -blocking activity, palpitations and tachycardia may

be absent. In type 1 thyrotoxicosis, amiodarone should be discontinued. If amiodarone therapy cannot be stopped, larger doses of antithyroid drugs may be needed to control thyrotoxicosis. In type 2 thyroiditis, stopping amiodarone may not be necessary because spontaneous resolution may occur. Prednisone 40 to 60 mg/day will quickly improve thyrotoxic symptoms. Prednisone may be tapered after 1 to 2 months of therapy.

10 Patients receiving amiodarone must receive monitoring for thyroid abnormalities. Baseline measurements of serum TSH, FT_4 , FT_3 , anti-TPOAbs, and TSHR-SABs should be performed. TSH, FT_4 , and FT_3 should be checked 3 months after initiation of amiodarone and then at least a TSH every 3 to 6 months.

Lithium

- Lithium is associated with hypothyroidism in up to 34% of patients, and hypothyroidism may occur after years of therapy.⁵⁵ Lithium appears to inhibit thyroid hormone synthesis and secretion. Patients with underlying autoimmune thyroiditis are more likely to develop lithium-induced hypothyroidism. Patients may require LT_4 replacement even if lithium is discontinued.

Interferon- α

- Interferon- α causes hypothyroidism in up to 39% of patients being treated for hepatitis C infection. Patients may develop a transient thyroiditis with hyperthyroidism before becoming hypothyroid. The hypothyroidism may be transient as well. Asians and patients with preexisting anti-TPOAbs are more likely to develop interferon-induced hypothyroidism. The mechanism of interferon-induced hypothyroidism is not known. If LT_4 replacement is initiated, it should be stopped after 6 months to reevaluate the need for replacement therapy.

Tyrosine Kinase Inhibitors

Tyrosine kinase inhibitors (TKIs) are an emerging class of targeted antineoplastic agents used in several types of malignancies, including thyroid cancer.¹³ Several TKIs have significant effects on thyroid function, both in previously hypothyroid patients on LT_4 replacement and in previously euthyroid patients. Imatinib has been shown to cause a fourfold increase in TSH levels in patients being treated for thyroid cancer. Sunitinib and sorafenib have been associated with primary hypothyroidism in 20% to 40% of treated patients. Some sorafenib patients developed mild hyperthyroidism before becoming hypothyroid. Patients receiving TKI therapy should have baseline and periodic thyroid function monitoring.

OUTCOME EVALUATION

- Desired outcomes include relieving signs and symptoms and achieving a euthyroid state.
- Success of therapy for thyroid disorders must be based not only on short-term improvement of the patient's clinical status and abnormal laboratory values but also on achievement of a long-term euthyroid state. Maintaining

TSH level in the normal range improves symptoms and reduces the risk of long-term complications.

- Because pharmacotherapy often is lifelong, especially in patients with hypothyroidism, patients must undergo periodic monitoring to avoid the long-term complications of hypothyroidism and hyperthyroidism. In hypothyroid patients, such monitoring may involve simply asking the patient about signs and symptoms and a yearly measurement of the TSH level.
- Any change in the patient's clinical status, such as a new pregnancy or a major change in body weight, necessitates a reevaluation of therapy. Patients at high risk for complications, such as pregnant women, the elderly, and patients with underlying cardiac disease, must be monitored more closely.
- Patients should be educated and periodically reminded about the importance of adherence and long-term tight control, the need for periodic clinical and laboratory monitoring, and the importance of staying on one LT_4 product.
- In hyperthyroid patients, relieving signs and symptoms and achieving a euthyroid state are the desired outcomes. The method of achieving these outcomes may change over time with the use of antithyroid drugs versus radioactive iodine.
- Patients with hyperthyroidism also must undergo periodic clinical and laboratory monitoring, with more frequent monitoring if there is a change in the patient's clinical status.
- Patients who receive antithyroid drugs must be monitored for adverse drug events such as agranulocytosis.
- Patients who receive radioactive iodine must be monitored for the development of hypothyroidism.
- In patients with thyroid cancer, the desired outcomes with LT_4 therapy often are different from those in hypothyroid patients.
- LT_4 doses sufficient to suppress tumor growth may result in a suppressed TSH and mild hyperthyroidism. These patients must be monitored closely for complications of the mild hyperthyroid state, such as bone mineral loss and development of atrial fibrillation.

Abbreviations Introduced in This Chapter

ANCA	Antineutrophil cytoplasmic antibody
ANDA	Abbreviated New Drug Application
Anti-TGAb	Antithyroglobulin antibody
Anti-TPOAb	Antithyroid peroxidase antibody
AUC	Area under the (time-concentration) curve
β -hCG	β -Human chorionic gonadotropin
CNS	Central nervous system
FDA	Food and Drug Administration
FT_3	Free T_3
FT_4	Free T_4

GI	Gastrointestinal
hCG	Human chorionic gonadotropin
IV	Intravenous
LDL	Low density lipoprotein
LT_4	Levothyroxine
MMI	Methimazole
NHANES	National Health and Nutrition Examination Survey
NTI	Narrow therapeutic index
PTU	Propylthiouracil
RAIU	Radioactive iodine uptake
SSKI	Saturated solution of potassium iodide
T_3	Triiodothyronine
T_4	Thyroxine
TBG	Thyroxine-binding globulin
TKI	Tyrosine kinase inhibitor
TRH	Thyrotropin-releasing hormone
TSH	Thyroid-stimulating hormone (thyrotropin)
TSHR-SAB	Thyroid-stimulating hormone receptor-stimulating antibodies

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Adrenal Gland Disorders

Devra K. Dang, Judy T. Chen, Frank Pucino Jr.,
and Karim Anton Calis

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Explain the regulation and physiologic roles of hormones produced by the adrenal glands.
2. Recognize the clinical presentation of patients with adrenal insufficiency.
3. Describe the pharmacologic management of patients with acute and chronic adrenal insufficiency.
4. Recommend therapy monitoring parameters for patients with adrenal insufficiency.
5. Recognize the clinical presentation of Cushing's syndrome and the physiologic consequences of cortisol excess.
6. Describe the pharmacologic and nonpharmacologic management of patients with Cushing's syndrome.
7. Recommend strategies to prevent the development of hypercortisolism and hypocortisolism.
8. Recommend therapy monitoring parameters for patients with Cushing's syndrome.

KEY CONCEPTS

- 1 Signs and symptoms of adrenal insufficiency reflect the disturbance of normal physiologic carbohydrate, fat, and protein homeostasis caused by inadequate cortisol production and inadequate cortisol action.
- 2 Lifelong glucocorticoid replacement therapy may be necessary for patients with adrenal insufficiency, and mineralocorticoid replacement therapy is usually required for those with Addison's disease.
- 3 During an acute adrenal crisis, the immediate treatment goals are to correct volume depletion, manage hypoglycemia, and provide glucocorticoid replacement.
- 4 Patients with known adrenal insufficiency should be educated regarding the need for additional glucocorticoid replacement and prompt medical attention during periods of excessive physiologic stress.
- 5 Patients with Cushing's syndrome caused by endogenous or exogenous glucocorticoid excess typically present with similar clinical manifestations.
- 6 Surgical resection is considered the treatment of choice for Cushing's syndrome from endogenous causes if the tumor can be localized and if there are no contraindications.
- 7 Pharmacotherapy is generally reserved for patients (1) in whom the ectopic adrenocorticotrophic hormone-secreting tumor cannot be localized, (2) who are not surgical

candidates, (3) who have failed surgery, (4) who have had a relapse after surgery, or (5) in whom adjunctive therapy is required to achieve complete remission.

- 8 In drug-induced Cushing's syndrome, discontinuation of the offending agent is the best management option. However, abrupt withdrawal of the glucocorticoid can result in adrenal insufficiency or exacerbation of the underlying disease.
- 9 Glucocorticoid dosages less than 7.5 mg/day of prednisone or its equivalent for less than 3 weeks generally would not be expected to lead to suppression of the hypothalamic-pituitary-adrenal axis.

INTRODUCTION

The adrenal glands are important in the synthesis and regulation of key human hormones. They play a crucial role in water and electrolyte homeostasis, as well as regulation of blood pressure, carbohydrate and fat metabolism, physiologic response to stress, and sexual development and differentiation. This chapter focuses on pharmacologic and nonpharmacologic management of the two most common conditions associated with adrenal gland dysfunction: glucocorticoid insufficiency (e.g., Addison's disease) and glucocorticoid excess (Cushing's syndrome). Other adrenal disorders such as **congenital adrenal hyperplasia**, **pheochromocytoma**, hypoaldosteronism, and hyperaldosteronism are beyond the scope of this chapter.

PHYSIOLOGY, ANATOMY, AND BIOCHEMISTRY OF THE ADRENAL GLAND

The adrenal gland is located on the upper segment of the kidney (Fig. 45-1). It consists of an outer cortex and an inner medulla. The adrenal medulla secretes the catecholamines epinephrine (also called adrenaline) and norepinephrine (also called noradrenaline), which are involved in the regulation of the sympathetic nervous system. The adrenal cortex consists of three histologically distinct zones: the outer zona glomerulosa, the zona fasciculata, and an innermost layer called the zona reticularis. Each zone is responsible for production of different hormones (Fig. 45-2).

The zona glomerulosa is responsible for the production of the mineralocorticoids **aldosterone**, 18-hydroxycorticosterone, corticosterone, and deoxycorticosterone. Aldosterone promotes renal sodium retention and potassium excretion. Its synthesis and release are regulated by renin in response to decreased vascular volume and renal perfusion. Adrenal aldosterone production is regulated by the **renin-angiotensin-aldosterone system**.

The zona fasciculata is the middle layer and produces the glucocorticoid hormone **cortisol**. Cortisol is responsible for maintaining homeostasis of carbohydrate, protein, and fat metabolism. Its secretion follows a circadian rhythm, generally beginning to rise at approximately 4 AM and peaking around 6 to 8 AM. Thereafter, cortisol levels decrease throughout the day, approach 50% of the peak value by 4 PM, and reach their nadir around midnight.¹ The normal rate of cortisol production is approximately 8 to 15 mg/day.² Cortisol plays a key role in the body's response to stress. Its production increases markedly during physiologic stress, such as during acute illness, surgery, or trauma. In addition, certain conditions such as alcoholism, depression, anxiety

FIGURE 45-1. Anatomy of the adrenal gland. (Reprinted, with permission, from Smith SM, Gums JG. Adrenal gland disorders. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. *Pharmacotherapy: A Pathophysiologic Approach*. 8th ed. New York: McGraw-Hill; 2011:1327.)

disorder, obsessive-compulsive disorder, poorly controlled diabetes, morbid obesity, starvation, anorexia nervosa, and chronic renal failure are associated with increased cortisol levels. High total cortisol levels are also observed in the presence of increased cortisol binding globulin (the carrier protein for 80% of circulating cortisol molecules), which is seen in pregnancy or other high-estrogen states (e.g., exogenous estrogen administration).¹ Cortisol is converted in the liver to an inactive metabolite known as cortisone.

The zona reticularis produces the androgens androstenedione, dehydroepiandrosterone (DHEA), and the sulfated form of dehydroepiandrosterone (DHEA-S). Only a small amount of testosterone and estrogen is produced in the adrenal glands. Androstenedione and DHEA are converted in the periphery, largely to testosterone and estrogen.

Adrenal hormone production is controlled by the hypothalamus and pituitary. **Corticotropin-releasing hormone** (CRH) is secreted by the hypothalamus and stimulates secretion of **adrenocorticotropic hormone** (ACTH; also known as corticotropin) from the anterior pituitary. ACTH in turn stimulates the adrenal cortex to produce cortisol. When sufficient or excessive cortisol levels are reached, a negative feedback is exerted on the secretion of CRH and ACTH, thereby decreasing overall cortisol production. The control of adrenal androgen synthesis also follows a similar negative feedback mechanism. Figure 46-1 depicts the hormonal regulation with the hypothalamic-pituitary-adrenal (HPA) axis.

ADRENAL INSUFFICIENCY

Epidemiology and Etiology

Adrenal insufficiency generally refers to the inability of the adrenal glands to produce adequate amounts of cortisol for normal physiologic functioning or in times of stress. The condition is usually classified as primary, secondary, or tertiary depending on the etiology (Table 45-1). The estimated prevalence of primary adrenal insufficiency and secondary adrenal insufficiency are approximately 60 to 143 and 150 to 280 cases per million persons, respectively. Whereas primary adrenal insufficiency is usually diagnosed in the third to fifth decades of life, secondary adrenal insufficiency is commonly detected during the sixth decade.^{1,3} Adrenal insufficiency is more prevalent in women than in men, with a ratio of 2.6 to 1.¹ Chronic adrenal insufficiency is rare.

Pathophysiology

Primary adrenal insufficiency, also known as Addison's disease, occurs when the adrenal glands are unable to produce cortisol. It occurs from destruction of the adrenal cortex, usually from an autoimmune process. In general, the clinical manifestations are observed when destruction of the cortex exceeds 90%.⁴ **1** *Signs and symptoms of adrenal insufficiency reflect the disturbance of normal physiologic carbohydrate, fat, and protein homeostasis caused by inadequate cortisol production and inadequate cortisol action.* Primary adrenal

FIGURE 45-2. The adrenal cortex consists of three histologically distinct zones: the outer zona glomerulosa, the middle zona fasciculata, and an innermost layer called the zona reticularis. Each zone is responsible for production of different hormones. The zona glomerulosa is responsible for the production of mineralocorticoids such as aldosterone. The zona fasciculata produces cortisol and the zona reticularis produces androgens. (ADX, adrenodoxin; CYP11A1, side chain cleavage enzyme; CYP11B1, 11-beta-hydroxylase; CYP11B2, aldosterone synthase; CYP17A1, 17-alpha-hydroxylase/17,20 lyase; CYP21A2, 21-alpha-hydroxylase; DHEA, dehydroepiandrosterone; DHEAS, dehydroepiandrosterone sulfate; H6PDH, hexose-6-phosphate dehydrogenase; HSD3B2, 3-beta-hydroxysteroid dehydrogenase type 2; HSD11B1, 11-beta-hydroxysteroid dehydrogenase type 1; HSD11B2, 11-beta-hydroxysteroid dehydrogenase type 2; HSD17B, 17-beta-hydroxysteroid dehydrogenase; PAPSS2, PAPS synthase type 2; POR, P450 oxidoreductase; SRD5A, 5-alpha-reductase; SULT2A1, DHEA sulfotransferase.) (Adapted, with permission, from Arlt W. Disorders of the adrenal cortex. In: Longo DL, Fauci AS, Kasper DL, et al., eds. *Harrison's Principles of Internal Medicine*. New York: McGraw-Hill; 2012.)

insufficiency usually develops gradually. Patients may remain asymptomatic in the early stages with signs and symptoms present only during times of physiologic stress. Persistent signs and symptoms of hypocortisolism typically occur with disease progression. Additionally, primary adrenal insufficiency may be accompanied by a reduction in aldosterone and androgen production.

Secondary adrenal insufficiency occurs as a result of a pituitary gland dysfunction, whereby decreased production and secretion of ACTH leads to a decrease in cortisol

synthesis. Tertiary adrenal insufficiency is a disorder of the hypothalamus that results in decreased production and release of CRH, which in turn decreases pituitary ACTH production and release. In contrast to Addison's disease (i.e., primary adrenal insufficiency), aldosterone production is unaffected in the secondary and tertiary forms of the disease. Chronic adrenal insufficiency often has a good prognosis if diagnosed early and treated appropriately.

Acute adrenal insufficiency (i.e., adrenal crisis) results from the body's inability to sufficiently increase endogenous

Table 45-1

Etiologies of Adrenal Insufficiency^{1,4,6,18-20}**Primary Adrenal Insufficiency (Addison's disease)**

- Autoimmune: accounts for 70% to 90% of all cases of primary adrenal insufficiency
- Infectious or granulomatous diseases
 - Cytomegalovirus
 - Fungal (histoplasmosis, coccidioidomycosis, cryptococcosis, *Blastomyces dermatitidis* infections)
 - HIV (human immunodeficiency virus), AIDS (acquired immunodeficiency syndrome)
 - Mycobacterial, cytomegaloviral, *Pneumocystis jirovecii*, and *Toxoplasma gondii* infections
 - Sarcoidosis
 - Tuberculosis
- Medications: inhibitors of steroidogenesis (etomidate, ketoconazole, metyrapone, mitotane)
- Hemorrhagic: bilateral adrenal hemorrhage or infarction usually caused by anticoagulant therapy, coagulopathy, thromboembolic disease, or meningococcal infection; causes acute adrenal insufficiency
- Adrenalectomy
- Adrenoleukodystrophy (in men)
- Adrenomyeloneuropathy
- Infiltrative disorders: amyloidosis, hemochromatosis
- Genetic causes
 - Congenital adrenal hyperplasia
 - Familial glucocorticoid deficiency and hypoplasia
- Metastatic malignancy

Secondary Adrenal Insufficiency

- Drug induced (most common cause of secondary adrenal insufficiency)
 - Chronic glucocorticoid administration at supraphysiologic doses
 - Megestrol acetate: has glucocorticoid-like activity
 - Mifepristone (RU 486): antagonizes glucocorticoid receptors
 - Possibly tyrosine kinase inhibitors: adrenal damage observed in rats and monkeys; asymptomatic decreased response to ACTH-stimulation test observed in humans
- Cushing's syndrome
- **Panhypopituitarism**
- Pituitary tumor
- Transsphenoidal pituitary microsurgery
- Pituitary irradiation
- Traumatic brain injury

Tertiary Adrenal Insufficiency

- Hypothalamic failure
- Drug-induced: chronic glucocorticoid administration at supraphysiologic doses

ACTH, adrenocorticotropic hormone.

cortisol during periods of excessive physiologic stress. Adrenal crisis can occur when patients with chronic adrenal insufficiency do not receive adequate glucocorticoid replacement during stressful conditions such as those experienced during surgery, infection, acute illness, invasive medical procedures, or trauma. Acute adrenal insufficiency can also result from bilateral adrenal infarction caused by hemorrhage, embolus, sepsis, or adrenal vein thrombosis. Patients who are critically ill may also experience impaired HPA axis function, with an overall prevalence rate of 10% to 20%, and as high as 60% in those experiencing septic

shock. These patients are also at risk for the life-threatening consequences of an adrenal crisis. To better recognize this condition, the term *critical illness-related corticosteroid insufficiency* was recently coined by the American College of Critical Care Medicine Task Force.⁵ Additionally, an abrupt discontinuation or rapid tapering of glucocorticoids, given chronically in supraphysiologic doses, may lead to adrenal crisis. This condition results from prolonged suppression of the HPA axis and subsequent adrenal gland atrophy and hypocortisolemia. Other drugs associated with adrenal insufficiency include those that inhibit production (e.g., ketoconazole) or increase metabolism (e.g., the cytochrome P-450 subfamily IIIA polypeptide 4 [CYP450 3A4] inducer rifampin) of cortisol.⁴ Regardless of the etiology, patients experiencing an adrenal crisis require immediate glucocorticoid treatment because manifestations such as circulatory collapse can lead to life-threatening sequelae.

Treatment and Outcome Evaluation**► Chronic Adrenal Insufficiency**

The general goals of treatment are to manage symptoms and prevent development of adrenal crisis. **2** *Lifelong glucocorticoid replacement therapy may be necessary for patients with adrenal insufficiency, and mineralocorticoid replacement therapy is usually required for those with Addison's disease.* Glucocorticoids with sufficient mineralocorticoid activity are generally required. However, the addition of a potent mineralocorticoid such as fludrocortisone, along with adequate salt intake, is sometimes needed to prevent sodium loss, hyperkalemia, and intravascular volume depletion. Mineralocorticoid supplementation typically is not indicated for the treatment of secondary or tertiary adrenal insufficiency because aldosterone production is often unaffected. Moreover, patients with secondary or tertiary adrenal insufficiency may only require replacement therapy until the HPA axis recovers. Hydrocortisone is often prescribed because it most closely resembles endogenous cortisol with its relatively high mineralocorticoid activity and short half-life and allows the design of regimens that simulate the normal circadian cycle.⁶ Other glucocorticoids, however, can be used. The pharmacologic characteristics of the commonly used glucocorticoids are presented in **Table 45-2**. Because patients with primary adrenal insufficiency can experience DHEA deficiency, DHEA replacement also has been tried. Several small clinical studies, consisting mostly of women, suggest that treatment with DHEA can improve mood and fatigue and provide a general sense of well-being.⁷⁻¹⁰ However, a recent meta-analysis of 10 studies found that DHEA use in women only slightly improved health-related quality of life and depression but did not affect anxiety or sexual well-being; it concluded that the totality of available data does not support routine supplementation with DHEA.¹¹ The use of DHEA remains controversial and requires further study. Management strategies for chronic adrenal insufficiency are outlined below:^{1,3,6}

Clinical Presentation and Diagnosis of Chronic Adrenal Insufficiency^{1,3,4,6}

General

- The symptoms develop gradually, especially in the early stages, may be vague, and mimic those of other medical conditions.
- The cardinal symptoms and signs are weakness and fatigue requiring rest periods, gastrointestinal symptoms, weight loss, and hypotension. These symptoms are due to cortisol deficiency.
- Patients with autoimmune adrenal insufficiency may have other autoimmune disorders such as type 1 diabetes mellitus and autoimmune **thyroiditis**.

Symptoms (Percent Prevalence)

- Weakness and fatigue are the most common (99%).
- Anorexia, nausea, and diarrhea (56–90%). These may range from mild to severe with vomiting and abdominal pain.
- Hypoglycemia may occur in some patients.
- **Amenorrhea** may occur in some women.
- Salt craving may occur in some (approximately 22%) patients with primary adrenal insufficiency due to aldosterone deficiency.

Signs

- Weight loss (97%).
- Hypotension (less than 110/70 mm Hg) and **orthostasis** (87%).
- Dehydration, hypovolemia, and hyperkalemia (in primary adrenal insufficiency only) due to aldosterone deficiency.
- Decreased serum sodium and chloride levels due to aldosterone deficiency. Hyponatremia can also be present in secondary adrenal insufficiency due to cortisol

deficiency and increased antidiuretic hormone secretion leading to subsequent water retention.

- Increased serum blood urea nitrogen and creatinine due to dehydration.
- **Hyperpigmentation** of skin and mucous membranes (92%). This is usually observed around creases, pressure areas, areolas, genitalia, and new scars. Dark freckles and patches of vitiligo may be present. Hyperpigmentation, due to increased ACTH levels, occurs in most patients with primary adrenal insufficiency but does not occur in secondary or tertiary adrenal insufficiency.
- Personality changes (irritability and restlessness) due to cortisol deficiency.
- Loss of axillary and pubic hair in women due to decreased androgen production.
- Blood count abnormalities (normocytic, normochromic anemia, relative lymphocytosis, neutrophilia, eosinophilia) due to cortisol and androgen deficiency.

Laboratory Tests (Also See Table 45–3)

- Decreased basal and stress-induced cortisol levels
- Decreased aldosterone level (in primary adrenal insufficiency only)
- Lack of increase in cortisol and aldosterone level after ACTH stimulation

Other Diagnostic Tests (Also See Table 45–3)

- Computed tomography (CT) scan or magnetic resonance imaging (MRI) of the adrenal glands, pituitary, and/or hypothalamus can aid in determining the etiology.
- The presence of anti-adrenal antibodies is suggestive of an autoimmune etiology.

Clinical Presentation and Diagnosis of Acute Adrenal Insufficiency (Adrenal Crisis)^{1,3,4}

General

- Onset of symptoms is acute and precipitated by excessive physiologic stress.

Symptoms

- Severe weakness and fatigue
- Abdominal or flank pain

Signs

- Severe dehydration leading to hypotension and shock (circulatory collapse). Hypovolemia may not be responsive to intravenous hydration and may require the use of vasopressors.
- Tachycardia.
- Nausea, vomiting.
- Fever.

- Confusion.
- Hypoglycemia.
- Laboratory abnormalities are similar to those observed in chronic adrenal insufficiency.

Laboratory Tests

- The unstimulated serum cortisol and rapid ACTH stimulation tests are useful in the diagnosis of adrenal crisis (**Table 45–3**). The insulin tolerance test is contraindicated due to preexisting hypoglycemia. The metyrapone test is also contraindicated since metyrapone inhibits cortisol production.

Note: Due to the life-threatening nature of this condition, empiric treatment should be started before laboratory confirmation in patients who present with the clinical picture of an acute adrenal crisis.

Table 45-2

Pharmacologic Characteristics of Commonly Used Glucocorticoids

Glucocorticoid	Estimated Potency Relative to Hydrocortisone		Equivalent Dose (mg)
	Glucocorticoid (Anti-Inflammatory) Activity	Mineralocorticoid (Sodium-Retaining) Activity	
Short Acting (Half-Life Less Than 12 Hours)			
Hydrocortisone	1	1	20
Cortisone	0.8	0.8	25
Intermediate Acting (Half-Life 12–36 Hours)			
Prednisone	4	0.25	5
Prednisolone	4	0.25	5
Methylprednisolone	5	Less than 0.01	4
Triamcinolone	5	Less than 0.01	4
Long Acting (Half-Life Greater Than 48 Hours)			
Betamethasone	25	Less than 0.01	0.6-0.75
Dexamethasone	30–40	Less than 0.01	0.75

Modified from Williams GH, Dluhy RG. Disorders of the adrenal cortex. In: Kasper DL, Braunwald E, Fauci A, et al., eds. Harrison's Principles of Internal Medicine. New York: McGraw-Hill, 2005:2147.

- For the treatment of primary adrenal insufficiency (Addison's disease), 12 to 15 mg/m² of oral hydrocortisone is typically administered in two divided doses, with two-thirds of the dose given in the morning upon awakening to mimic the early morning rise in endogenous cortisol and the remaining one-third of the dose given in the late afternoon to avoid insomnia and allow for the lowest concentration in the blood at around midnight. Hydrocortisone may also be given in three doses, but this may decrease adherence. The longer acting glucocorticoids (e.g., prednisone, dexamethasone) may provide a more prolonged clinical response, thereby avoiding symptom recurrence that can occur at the end of the dosing interval with short-acting agents such as hydrocortisone. Longer acting agents also may improve adherence in some patients. Monitor the patient's weight, blood pressure, and serum electrolytes along with symptom resolution and general well-being; adjust dosages accordingly as needed. Doses of hydrocortisone, dexamethasone, prednisone, and other glucocorticoids may need to be increased or decreased in patients taking CYP450 3A4 inducers (e.g., phenytoin, rifampin, barbiturates) or inhibitors (e.g., protease inhibitors), respectively. Monitor for adverse drug reactions related to glucocorticoid administration. Glucocorticoid therapy at physiologic replacement doses should not lead to the development of Cushing's syndrome; however, careful monitoring should still be performed, and the smallest effective dose used. Educate patients regarding the need for increased glucocorticoid dosage during excessive physiologic stress. In addition, administer oral fludrocortisone at a daily dose of approximately 0.05 to 0.2 mg in the morning. Monitor for resolution of hypotension, dizziness, dehydration, hyponatremia, and hyperkalemia; and increase the dose if needed. Conversely, consider decreasing the dose if adverse reactions from mineralocorticoid administration such as hypertension, hypokalemia, fluid retention,

and other significant adverse events occur. In patients receiving hydrocortisone, it should be kept in mind that this drug also possesses mineralocorticoid activity. All patients with primary adrenal insufficiency should also maintain an adequate sodium intake (~3 to 4 g/day). Last, although controversial, consider giving 50 mg/day of DHEA (in the morning) to female patients who do not experience an improvement in mood and well-being even with adequate glucocorticoid and mineralocorticoid replacement. In these patients, monitor serum DHEA-S (aim for the middle range of normal levels in healthy young people) and free testosterone level.

- Patients with secondary and tertiary adrenal insufficiency are treated with oral hydrocortisone or a longer acting glucocorticoid in the same manner as previously described for primary adrenal insufficiency. However, patients with secondary and tertiary adrenal insufficiency may require a lower dose. Some patients (e.g., those with drug-induced adrenal insufficiency or adrenal insufficiency after treatment for Cushing's syndrome) only require glucocorticoid replacement temporarily, which can be discontinued after recovery of the HPA axis. Monitor for progression of the underlying etiology of adrenal insufficiency. Fludrocortisone therapy is generally not needed.

► Acute Adrenal Insufficiency

- 3 During an acute adrenal crisis, the immediate treatment goals are to correct volume depletion, manage hypoglycemia, and provide glucocorticoid replacement. Volume depletion and hypoglycemia can be corrected by giving large volumes (~2 to 3 L) of intravenous (IV) normal saline and 5% dextrose solution.¹ Glucocorticoid replacement can be accomplished by administering IV hydrocortisone, starting at a dose of 100 mg every 6 hours for 24 hours, increasing to 200 to 400 mg/day if complications occur, or decreasing to 50 mg every 6 hours after achieving hemodynamic stability. The

Table 45-3

Tests for Diagnosing Adrenal Insufficiency^{4,6}

Test	Procedure	Rationale	Finding in Adrenal Insufficiency	Comments
Screening and Diagnostic Tests for Adrenal Insufficiency				
Unstimulated serum cortisol measurement	Measure serum cortisol at 6–8 AM	Serum cortisol level peaks in the early morning	<ul style="list-style-type: none"> • Serum cortisol greater than 18 mcg/dL (497 nmol/L) is normal • Serum cortisol less than 3 mcg/dL (83 nmol/L) is indicative of adrenal insufficiency 	<ul style="list-style-type: none"> • Used as a general initial screening test for the presence of adrenal insufficiency. Evaluate result in conjunction with those from the other tests
Rapid ACTH stimulation test (also called cosyntropin stimulation test)	Measure serum cortisol 30–60 minutes after administering cosyntropin 250 mcg IV	Increased cortisol secretion in normal individuals in response to ACTH stimulation but not in adrenal insufficiency	Serum cortisol concentration less than 18 mcg/dL (497 nmol/L)	<ul style="list-style-type: none"> • Used as the gold standard test for diagnosing primary adrenal insufficiency • False-negative results may occur if the ACTH deficiency is of recent onset (less than 1 month) • Although not widely accepted, a low-dose (1 mcg) ACTH stimulation test has been useful for the diagnosis of partial adrenal insufficiency • If measured serum cortisol concentration is low, measure plasma ACTH, aldosterone, and renin concentrations to differentiate between primary and secondary or tertiary adrenal insufficiency (see below)
Insulin tolerance test (insulin-induced hypoglycemia test)	Administer insulin IV to induce hypoglycemia; then measure serum cortisol during symptomatic hypoglycemia (confirm that blood glucose is less than 40 mg/dL [2.2 mmol/L])	Evaluates ability of entire HPA axis to respond to stress (hypoglycemia)	Serum cortisol concentration less than 18 mcg/dL (497 nmol/L) is indicative of secondary adrenal insufficiency	<ul style="list-style-type: none"> • If the result of the rapid ACTH stimulation test is normal, either this or the overnight metyrapone test is still needed to evaluate for secondary adrenal insufficiency. The insulin tolerance test is considered the gold standard • Contraindicated in patients with a seizure history, older than 60 years, or with cardiovascular or cerebrovascular disease • Requires close medical supervision • Contraindicated in adrenal crisis
Overnight metyrapone test	Administer metyrapone at midnight; then measure serum cortisol at 8 AM the next day	Metyrapone inhibits cortisol synthesis. Its administration leads to rise in levels of ACTH and the precursor of cortisol. Patients with adrenal insufficiency do not exhibit this	Normal response is a decrease in serum cortisol to less than 5 mcg/dL (138 nmol/L) and an increase in the cortisol precursor to more than 7 mcg/dL (193 nmol/L). Response not seen in secondary adrenal insufficiency	<ul style="list-style-type: none"> • Distinguishes between normal individuals and patients with secondary adrenal insufficiency • Contraindicated in adrenal crisis
Tests for Differential Diagnosis of Primary, Secondary, and Tertiary Adrenal Insufficiency				
Plasma ACTH concentration	Measure plasma ACTH	In primary adrenal insufficiency, hypocortisolism leads to elevated plasma ACTH concentration via positive HPA axis feedback	<ul style="list-style-type: none"> • Primary adrenal insufficiency: elevated plasma ACTH • Secondary or tertiary adrenal insufficiency: plasma ACTH low or inappropriately normal 	<ul style="list-style-type: none"> • Evaluate result of test in combination with those from the plasma aldosterone and plasma renin tests

(Continued)

Table 45-3

Tests for Diagnosing Adrenal Insufficiency^{4,6} (Continued)

Test	Procedure	Rationale	Finding in Adrenal Insufficiency	Comments
Plasma aldosterone concentration	Measure plasma aldosterone from same blood samples as those used in ACTH stimulation test	Patients with primary adrenal insufficiency may experience a reduction in aldosterone production	<ul style="list-style-type: none"> Primary adrenal insufficiency: low plasma aldosterone Secondary or tertiary adrenal insufficiency: aldosterone concentration is usually normal (greater than or equal to 5 ng/dL [139 pmol/L]) 	<ul style="list-style-type: none"> Evaluate result of test in combination with those from the plasma ACTH and plasma renin tests
Plasma renin concentration or activity	Measure plasma renin concentration or activity	Mineralocorticoid deficiency occurs in primary adrenal insufficiency but is usually not present in secondary or tertiary adrenal insufficiency	<ul style="list-style-type: none"> Primary adrenal insufficiency: elevated plasma renin Secondary or tertiary adrenal insufficiency: plasma renin concentration or activity is usually normal 	<ul style="list-style-type: none"> Evaluate result of test in combination with those from the plasma ACTH and plasma aldosterone concentration tests

ACTH, adrenocorticotropic hormone or corticotrophin; HPA, hypothalamic–pituitary–adrenal; IV, intravenous.

Patient Encounter 1, Part 1: Presentation and Medical History

GH is a 48-year-old woman who presents to the primary care clinic with complaints of fatigue and asking for a prescription for “vitamin injections.” She states that she has been feeling very tired for the past year. Upon further questioning, she also complains of dizziness, especially with positional changes, and intermittent nausea, abdominal pain, and diarrhea.

PMH:

- Tuberculosis: completed treatment course
- History of candidal vulvovaginitis
- Chronic obstructive pulmonary disease with frequent exacerbations (3 times in past 8 months) requiring prednisone taper therapy
- Depression

FH: Father with coronary artery disease, mother with diabetes

SH: Part-time factory worker, smokes 1 pack per day, denies alcohol use and illicit drug use

Current Meds:

- Fluticasone/salmeterol DPI 500/50 mcg one inhalation twice daily
- Tiotropium 18 mcg inhale contents of one capsule once daily

- Albuterol MDI two puffs q4h as needed
- Sertraline 100 mg once daily
- Loperamide 2 mg as needed for diarrhea (nonprescription)

PE

VS: Sitting BP, 106/68 mm Hg; P, 74 beats/min; standing BP, 96/68 mm Hg; RR, 14 breaths/min; weight, 130 lb (59.1 kg) with 5-lb (2.3-kg) loss in past 6 months; height, 5 ft 2 in (157.5 cm)

Skin: Hyperpigmentation increases of palms

CV: RRR, normal S₁, S₂; no murmurs, rubs, or gallops

Labs (fasting): Serum electrolytes: sodium, 133 mEq/L (133 mmol/L); potassium, 5.2 mEq/L (5.2 mmol/L); chloride, 98 mEq/L (98 mmol/L); bicarb, 30 mEq/L (30 mmol/L); blood urea nitrogen (BUN), 25 mg/dL (8.9 mmol/L); creatinine, 1.2 mg/dL (106 μmol/L); glucose, 60 mg/dL (3.3 mmol/L)

Which signs or symptoms of adrenal insufficiency does GH exhibit?

Does GH's presentation offer any clues as to the etiology or classification of adrenal insufficiency?

Which tests would be most useful for determining the etiology and confirming the diagnosis of adrenal insufficiency?

hydrocortisone dose can then be tapered to a maintenance dose by the fourth or fifth day, and fludrocortisone can be added if needed.¹ For comprehensive recommendations for the treatment of patients with critical illness–related corticosteroid insufficiency, readers are referred to the 2008 consensus statements from the American College of Critical Care Medicine Task Force.⁵

4 Patients with known adrenal insufficiency should be educated regarding the need for additional glucocorticoid replacement and prompt medical attention during periods of excessive physiologic stress. Although the dosage of glucocorticoid is generally individualized, a common recommendation is to double the maintenance dose of hydrocortisone if the patient experiences fever or undergoes invasive dental or diagnostic procedures.⁶ Patients who experience vomiting or diarrhea may not adequately absorb oral glucocorticoids and may benefit from parenteral therapy until symptoms resolve. Before major surgery, additional glucocorticoid replacement (higher dose and parenteral route) must be given to prevent adrenal crisis. A sample protocol is as follows¹:

- Correct electrolytes, blood pressure, and fluid status as necessary.
- Give 100 mg of hydrocortisone sodium phosphate or hydrocortisone sodium succinate intramuscularly (also,

Patient Encounter 1, Part 2: Treatment

After appropriate laboratory and diagnostic tests are performed, GH is diagnosed with Addison's disease.

How should her chronic primary adrenal insufficiency be treated?

What monitoring parameters (therapeutic and toxic) should be implemented?

make sure this is readily available to the operating room).

- Give 50 mg of hydrocortisone intramuscularly or intravenously in the recovery room and then every 6 hours for the first 24 hours.
- If patient is hemodynamically stable, reduce the dosage to 25 mg every 6 hours for 24 hours and then taper to a maintenance dosage over 3 to 5 days.
- Resume previous fludrocortisone dose when the patient is taking oral medications.
- Maintain or increase hydrocortisone dosage to 200 to 400 mg/day if fever, hypotension, or other complications occur.

Patient Care and Monitoring: Adrenal Insufficiency

1. Evaluate patients presenting with the typical clinical manifestations for chronic or acute adrenal insufficiency.
2. Perform initial screening tests to confirm the presence of adrenal insufficiency.
3. After the diagnosis is confirmed, perform further testing to differentiate between primary, secondary, and tertiary adrenal insufficiency.
4. In patients presenting with acute adrenal crisis who have not been previously diagnosed with adrenal insufficiency, immediate treatment with injectable hydrocortisone and IV saline and dextrose solutions should be initiated before confirmation of the diagnosis because of the life-threatening nature of this condition. Determine and correct the underlying cause of the acute adrenal crisis (e.g., infection).
5. Glucocorticoid replacement therapy is necessary for patients with adrenal insufficiency, and mineralocorticoid replacement therapy is required for those with Addison's disease.
6. In patients with chronic adrenal insufficiency, when excessive physiologic stress is anticipated (e.g., pending surgery), devise a strategy to give supplemental doses of glucocorticoid during this period. Monitor the patient for signs of an acute adrenal crisis and develop a plan to treat this emergency condition.
7. Monitor the patient for adequacy of treatment as well as adverse reactions from glucocorticoid and/or mineralocorticoid therapy.
8. Determine the duration of treatment for patient with secondary and tertiary adrenal insufficiency.
9. Provide patient education regarding disease state and its treatment:
 - Causes of adrenal insufficiency, including drug-induced etiologies.
 - How to recognize the clinical manifestations.
 - How to prevent an acute adrenal crisis (adhere to therapy and do not abruptly stop glucocorticoid treatment). There may be a need to increase the dose of glucocorticoid during excessive physiologic stress.
 - Administration of parenteral glucocorticoid during an acute adrenal crisis.
 - Need to notify all healthcare providers of condition.
 - Encourage wearing or carrying a medical alert (e.g., bracelet, card).
 - Counsel on dietary and pharmacologic therapy, including duration of treatment and potential adverse consequences of glucocorticoid and mineralocorticoid replacement.

HYPERCORTISOLISM (CUSHING'S SYNDROME)

Epidemiology and Etiology

Cushing's syndrome refers to the pathophysiologic changes associated with exposure to supraphysiologic cortisol concentrations (endogenous hypercortisolism) or pharmacologic doses of glucocorticoids (exogenous hypercortisolism). Cushing's syndrome from endogenous causes is a rare condition with an estimated incidence of two to five cases per million persons per year.¹² Patients receiving chronic supraphysiologic doses of glucocorticoids, such as those with rheumatologic disorders, are at high risk of developing Cushing's syndrome.

Pathophysiology

Cushing's syndrome can be classified as ACTH dependent or ACTH independent (**Table 45-4**). ACTH-dependent Cushing's syndrome results from ACTH-secreting (or rarely CRH-secreting) **adenomas**. ACTH-independent Cushing's syndrome is caused by either excessive cortisol secretion by the adrenal glands (independent of ACTH stimulation) or by exogenous glucocorticoid administration. **5** *Patients with Cushing's syndrome caused by endogenous or exogenous glucocorticoid excess typically present with similar clinical manifestations.* The term *Cushing's disease* refers specifically to Cushing's syndrome from an ACTH-secreting pituitary adenoma. The plasma ACTH concentration is elevated in ACTH-dependent conditions but not in ACTH-independent causes because elevated cortisol concentrations suppress pituitary ACTH secretion via negative feedback. ACTH and cortisol concentrations are elevated episodically in ACTH-dependent disease caused by random hypersecretion of ACTH.⁴ Other major differences among the vast etiologies of Cushing's syndrome are shown in **Table 45-5**.

Physiologic cortisol secretion follows a circadian pattern, with cortisol levels rising in the early morning, peaking at approximately 6 to 8 AM, and then declining steadily throughout the remainder of the day until they reach a nadir at midnight. This circadian rhythm is lost in most patients with Cushing's syndrome. As such, detection of elevated midnight cortisol concentrations can be useful in the diagnosis of Cushing's syndrome.

Cushing's disease and adrenal **carcinomas** cause adrenal androgen hypersecretion in high enough concentrations to result in signs of androgen excess such as acne, menstrual irregularities, and **hirsutism**, and cause **virilization** in women.⁴ Drug-induced Cushing's syndrome from glucocorticoid administration occurs most commonly in patients receiving oral therapy, but other routes such as inhalation, dermal, nasal, and intraarticular have also been implicated.¹³ Over-the-counter products, including dietary supplements, should also be evaluated because they may contain corticosteroids. Drug-induced Cushing's syndrome has been reported with the use of Chinese herbal products adulterated with corticosteroids.^{14,15} The risk of glucocorticoid-induced Cushing's syndrome appears to increase with higher doses and/or longer treatment durations.¹³

Left untreated, patients with Cushing's syndrome may experience severe complications of hypercortisolism, resulting in up to a nearly fourfold increase in mortality.¹⁶ Mortality in patients with Cushing's is mostly attributed to cardiovascular disease. Hypertension, hyperglycemia, and hyperlipidemia are common findings and can be associated with cardiac hypertrophy, atherosclerosis, and hypercoagulability. Osteopenia, osteoporosis, and increased fractures also have been reported.¹⁶ Prevention and management of these conditions are discussed elsewhere in this text. Children may experience linear

Table 45-4

Etiologies of Cushing's Syndrome^{1,13,21,22}

ACTH Dependent

- ACTH-secreting pituitary tumor (*Cushing's disease*): 70% of cases of endogenous Cushing's syndrome
- ACTH-secreting nonpituitary tumors (ectopic ACTH syndrome): 15% of cases of endogenous Cushing's syndrome; usually from small cell lung carcinoma, bronchial carcinoids, or pheochromocytoma or from thymus, pancreatic, ovarian, or thyroid tumor; the tumor is usually disseminated (difficult to localize)
- CRH-secreting nonpituitary tumors (ectopic CRH syndrome): rare

ACTH Independent: 15% of cases of endogenous Cushing's syndrome

- Unilateral adrenal adenoma
- Adrenal carcinoma
- Bilateral nodular adrenal hyperplasia: rare (less than 1%)

Drug-Induced Cushing's Syndrome (ACTH independent): most common cause of Cushing's syndrome

- Prescription glucocorticoid preparations (most routes of administration)
- Nonprescription and herbal products with glucocorticoid activity (e.g., nonprescription anti-itch products with hydrocortisone, herbal products with magnolia bark or those claiming to contain adrenal cortex extracts or other byproducts)
- Other drugs with glucocorticoid activity (e.g., megestrol acetate, medroxyprogesterone)

ACTH, adrenocorticotropic hormone or corticotropin; CRH, corticotropin-releasing hormone.

Table 45-5

Differences Among the Major Etiologies of Cushing's Syndrome^{4,16,23}

	ACTH Dependent		ACTH Independent		
	Pituitary Dependent (Cushing's Disease)	Ectopic ACTH Syndrome	Exogenous Glucocorticoid Administration	Adrenal Adenoma	Adrenal Carcinoma
Onset of signs and symptoms	Gradual	Rapid	Gradual to rapid	Gradual	Rapid
Symptoms severity	Mild to moderate	Atypical	Mild to severe	Mild to moderate	Severe
Dominant sex and age	Female; 20–40 years (range, childhood to 70 years)	Male; adults	Female and male; all ages	Female	Female; children
Virilization	+	+	+	+	+++
Abdominal mass	0	0	0	0	++
Plasma ACTH concentration	Slightly elevated	Elevated	Low	Low	Low
CRH stimulation test	Response	Rare response	Decreased or no response	No response	No response
High-dose dexamethasone suppression test	Between 50% and 80% cortisol suppression	Less cortisol suppression	No cortisol suppression	No cortisol suppression	No cortisol suppression
Pituitary MRI	Tumor	Normal	Normal	Normal	Normal
Adrenal gland CT or MRI	Normal or bilateral hyperplasia	Normal or bilateral hyperplasia	No change	Mass(es)	Mass(es)

0, none; +, mild; ++, moderate; +++, pronounced; ACTH, adrenocorticotropic hormone or corticotropin; CRH, corticotropin-releasing hormone; CT, computed tomography; MRI, magnetic resonance imaging.

growth retardation from reduced growth hormone secretion and inhibition of epiphyseal cartilage development in long bones.^{12,16}

Treatment

The goal of treatment in patients with Cushing's syndrome is reversal of hypercortisolism and management of the associated comorbidities, including the potential for long-term sequelae such as cardiac hypertrophy. **6** *Surgical resection is considered the treatment of choice for Cushing's syndrome from endogenous causes if the tumor can be localized and if there are no contraindications.* The treatment of choice for Cushing's syndrome from exogenous causes is gradual discontinuation of the offending agent.

► Nonpharmacologic Therapy

• **Transsphenoidal pituitary microsurgery** is the treatment of choice for Cushing's disease. Removal of the pituitary tumor can bring about complete remission or cure in 78% to 97% of cases. HPA axis suppression associated with chronic hypercortisolism can result in prolonged adrenal insufficiency lasting for months after surgery and requiring exogenous glucocorticoid administration. Pituitary

irradiation or bilateral **adrenalectomy** is usually reserved for patients who are not surgical candidates or for those who relapse or do not achieve complete remission after pituitary surgery. Because the response to pituitary irradiation can be delayed (several months to years), concomitant treatment with cortisol-lowering medication may be necessary. Bilateral adrenalectomy is also used for the management of adrenal carcinoma and in patients with poorly controlled ectopic Cushing's disease in whom the ACTH-producing lesion cannot be localized. Bilateral laparoscopic adrenalectomy achieves an immediate and total remission (nearly 100% cure rate), but these patients require lifelong glucocorticoid and mineralocorticoid supplementation.^{17,18} **Nelson syndrome** may develop in nearly 20% to 50% of patients who undergo bilateral adrenalectomy without pituitary irradiation. This condition presumably results from persistent hypersecretion of ACTH by the intact pituitary adenoma, which continues to grow because of the loss of feedback inhibition by cortisol. Treatment of Nelson syndrome may involve pituitary irradiation or surgery.⁴

• The treatment of choice in patients with adrenal adenomas is unilateral laparoscopic adrenalectomy. These patients require glucocorticoid supplementation during and after surgery caused by atrophy of the contralateral adrenal gland and suppression of the HPA axis. Glucocorticoid therapy is continued until recovery of the remaining adrenal

Clinical Presentation and Diagnosis of Cushing's Syndrome^{1,12,13}

General

- Patients with Cushing's syndrome caused by either endogenous or exogenous glucocorticoid excess typically present with similar clinical manifestations.
- Differential diagnoses include diabetes mellitus and the metabolic syndrome because patients with these conditions share several similar characteristics with patients who have Cushing's syndrome (e.g., obesity, hypertension, hyperlipidemia, hyperglycemia, and insulin resistance). In women, the presentations of hirsutism, menstrual abnormalities, and insulin resistance are similar to those of polycystic ovary syndrome. Cushing's syndrome can be differentiated from these conditions by identifying the classic signs and symptoms of truncal obesity, "moon facies" with facial plethora, a "buffalo hump" and supraclavicular fat pads, red-purple skin striae, and proximal muscle weakness.
- True Cushing's syndrome also must be distinguished from other conditions that share some clinical presentations (as well as elevated plasma cortisol concentrations) such as depression, alcoholism, obesity, and chronic illness—the so-called pseudo-Cushing's states.

Signs and Symptoms (Percent Prevalence)

General appearance

- Weight gain and obesity manifesting as truncal obesity (90%)
- A rounded and puffy face ("moon facies") (75%)
- Dorsocervical ("buffalo hump") and supraclavicular fat accumulation
- Hirsutism (excessive hair growth) (75%)

Skin changes from atrophy of dermis and connective tissue

- Thin skin
- Facial plethora (70%)
- Skin striae ("stretch marks" that are usually red or purple in appearance and greater than 1 cm) (50%)
- Acne (35%)
- Easy bruising (40%)
- Hyperpigmentation

Metabolic

- Hyperglycemia that can range from impaired glucose tolerance (75%) to diabetes mellitus (20% to 50%)
- Hyperlipidemia (70%)
- Polyuria (30%)
- Kidney stones (15% to 50%)
- Hypokalemic alkalosis (from mineralocorticoid effect of cortisol)

Cardiovascular

- Hypertension (from mineralocorticoid effect of cortisol) (85%)
- Patients are at risk of the cardiovascular complications of hypertension, hyperlipidemia, and hyperglycemia.
- Peripheral edema

Genitourinary

- Menstrual irregularities (the most typical presentation is amenorrhea) (70%)
- Erectile dysfunction (85%)

Other

- Psychiatric changes such as depression, emotional lability, psychosis, euphoria, anxiety, and decreased cognition (85%)
- Sleep disturbances
- Osteopenia (80%) and osteoporosis, usually affecting trabecular bone
- Linear growth impairment in children
- Proximal muscle weakness (65%)
- Avascular necrosis (more common in iatrogenic cases)
- Glaucoma and cataracts
- Impaired wound healing and susceptibility to opportunistic infections
- Hypothyroidism

Laboratory Tests

- The diagnosis of Cushing's syndrome and its etiology is often complex and generally requires the involvement of endocrinologists and specialized testing centers.
- Initial screening tests to confirm the presence of hypercortisolism and differentiate Cushing's syndrome from conditions with similar presentations include 24-hour urinary-free cortisol and overnight low-dose dexamethasone suppression test (DST) (Table 45–6).
- The midnight plasma cortisol or combined dexamethasone suppression plus CRH test are less commonly used.
- Typically, a combination of at least two screening tests is used to establish the preliminary diagnosis.
- After the diagnosis is confirmed, additional tests can be performed to determine the etiology.

Other Diagnostic Tests

Imaging studies may be used to distinguish between pituitary, ectopic, and adrenal tumors (Table 45–5).

Table 45-6

First-Line Screening Tests in Patients with Characteristics of Cushing's Syndrome^{1,12,16}

Test	Test Procedure and Measurement	Rationale	Typical Finding in Cushing's Syndrome	Comments
24-hour urinary-free cortisol	Collect urine over 24 hours and measure unbound cortisol excreted by kidneys	Urinary cortisol is elevated in hypercortisolic states	Urinary-free cortisol greater than four times the upper reference limit is indicative of Cushing's syndrome. Values between one and four times the upper reference limit suggest either Cushing's syndrome or pseudo-Cushing's syndrome	<ul style="list-style-type: none"> • Easy to perform but should not be used alone because sensitivity and specificity depend on the assay used • To exclude periodic hypercortisolism, three or more samples should be obtained (with urinary creatinine measurement to assess completeness of the collection) • Distinguishes Cushing's syndrome from obesity (no elevation). However, false-positive results if other pseudo-Cushing's states, physiologic stress, or pregnancy • False-negative results if decreased renal function, or subclinical hypercortisolism
Overnight low-dose DST	Give 1 mg oral dexamethasone at 11 PM; then measure plasma cortisol at 8 to 9 AM the next morning	Dexamethasone administration suppresses morning plasma cortisol in normal individuals	Plasma cortisol greater than 14.3 µg/dL (395 nmol/L) is diagnostic for Cushing's syndrome. Plasma cortisol less than 1.2 µg/dL (33 nmol/L) is not suggestive of Cushing's syndrome	<ul style="list-style-type: none"> • Simple to perform and inexpensive • Can be used in conjunction with or instead of the urinary-free cortisol test • Can also use the 2-day 2-mg DST • False-positive result if pseudo-Cushing's states, physiologic stress, pregnancy, estrogen treatment, uremia, taking inducers of dexamethasone metabolism (e.g., phenytoin), or decreased dexamethasone absorption • False-negative result if subclinical hypercortisolism or slow metabolism of dexamethasone
Late-night salivary cortisol	Collect salivary cortisol concentration at 11 PM	Loss of circadian rhythm of cortisol secretion (no nadir at night) in Cushing's syndrome but not in pseudo-Cushing's states	Elevated late-night salivary cortisol	<ul style="list-style-type: none"> • Diagnostic criteria need further validation • Easiest screening test to perform (sample can be collected at home by patient) • Can be used in conjunction with or instead of the urinary-free cortisol test

DST, dexamethasone suppression test.

gland is achieved. Patients with adrenal carcinomas have a poor prognosis, with a 5-year survival rate of 20% to 58% because of the advanced nature of the condition (metastatic disease). Surgical resection to reduce tumor burden and size, pharmacologic therapy, or bilateral laparoscopic adrenalectomy are the treatment options commonly used to manage this condition.^{1,18}

Pharmacologic Therapy

7 Pharmacotherapy is generally reserved for patients (1) in whom the ectopic ACTH-secreting tumor cannot be localized, (2) who are not surgical candidates, (3) who have failed surgery, (4) who have had a relapse after surgery, or (5) in whom adjunctive therapy is required to achieve complete remission.¹⁹ The drugs used are classified according to their mechanism and site of action (Table 45-7). The most widely used therapeutic class is the adrenal steroidogenesis

inhibitors.¹⁹ Agents in this class include ketoconazole, etomidate, and metyrapone. Steroidogenesis inhibitors can improve hypercortisolism by inhibiting enzymes involved in the biosynthesis of cortisol. Because of their potential to cause adrenal suppression, temporary glucocorticoid replacement and in some cases mineralocorticoid supplementation may be needed during and after treatment. Centrally acting neuromodulators of ACTH release such as bromocriptine, cyproheptadine, octreotide, ritanserin, and valproic acid are generally ineffective.

8 In drug-induced Cushing's syndrome, discontinuation of the offending agent is the best management option. However, abrupt withdrawal of the glucocorticoid can result in adrenal insufficiency or exacerbation of the underlying disease.¹³ **9** Glucocorticoid dosages less than 7.5 mg/day of prednisone or its equivalent for less than 3 weeks generally would not be expected to lead to suppression of the HPA axis.^{2,18} However, in patients receiving pharmacologic doses

Table 45-7

Pharmacologic Treatments for Cushing's Syndrome^{17,24-26}

Drug	Mechanism of Action	Dosage ^a : Initial, Usual, Maximum Dosing Adjustment for Renal and/or Hepatic Failure	Common and/or Major Adverse Reactions	Comments
Inhibitors of Adrenal Steroidogenesis				
Ketoconazole ^b (oral administration)	Inhibits several cytochrome P450 enzymes, including 17,20-lyase, 17-hydroxylase, and 11 β -hydroxylase; also inhibits cholesterol synthesis	<i>Adults:</i> 200 mg twice daily; 600–800 mg/day in two divided doses; NTE 1,200 mg/day in two or three divided doses <i>Pediatric:</i> safety and effectiveness have not been established Extensively metabolized by liver, and dosing adjustment should be considered in severe liver disease; dosing adjustment not needed in renal disease	Generally well tolerated Transaminase elevations, GI intolerance, and rash Gynecomastia, testicular function impairment, and adrenal insufficiency at high doses (more than 600 mg/day)	<ul style="list-style-type: none"> Effective in a majority of causes; rapid clinical improvement seen Monitor efficacy with urinary cortisol Monitor liver transaminases for hepatotoxicity Useful in women with hirsutism and patients with hyperlipidemia Requires gastric acidity for dissolution and absorption, therefore not useful in patients with achlorhydria and those taking proton pump inhibitors or round-the-clock antacids or histamine-2 receptor blockers
Metrapone ^b (oral administration)	Inhibits 11-hydroxylase. Also suppresses aldosterone synthesis	<i>Adults:</i> 750 mg/day; 500–4,000 mg/day in four divided doses; NTE 6 g/day <i>Pediatric:</i> safety and effectiveness have not been established Dosages in special populations (liver and kidney disease, elderly patients) have not been established	Generally well tolerated Hirsutism, acne, adrenal insufficiency, GI intolerance, rash, hypokalemia, edema, hypertension	<ul style="list-style-type: none"> Used in Cushing's disease, ectopic ACTH syndrome, and adrenal carcinoma Also used as a test to diagnose adrenal insufficiency
Etomidate ^b (IV administration)	Inhibits 17,20-lyase, 17-hydroxylase, and 11 β -hydroxylase	<i>Adults:</i> Limited clinical experience, 1.6–4.2 mg/h intermittently <i>Pediatric:</i> safety and effectiveness have not been established Extensively metabolized in the liver to inactive metabolites; because of changes in protein binding, dosing adjustment may be needed in kidney and liver disease	Injection site pain, nausea, vomiting, myoclonus	<ul style="list-style-type: none"> IV route of administration limits use
Adrenolytic Agent				
Mitotane ^b (oral administration)	Inhibits steroidogenesis at lower doses and is adrenolytic at higher doses; inhibits 11 β -hydroxylase and cholesterol side-chain cleavage; reduces aldosterone synthesis	<i>Adults:</i> 2–6 g/day in three or four divided doses; 9–10 g/day in three or four divided doses; elderly patients may require a dose decrease <i>Pediatric:</i> safety and effectiveness have not been established Primarily metabolized by the liver and dosing adjustment may be needed in liver disease	GI intolerance (high incidence), fatigue, dizziness, somnolence, gynecomastia Hyperlipidemia requiring lipid-lowering treatment Adrenal insufficiency requiring glucocorticoid replacement therapy	<ul style="list-style-type: none"> Used primarily for adrenal carcinoma but can also be used in other types of Cushing's syndrome Efficacy takes several weeks Lower rate of relapse when used with pituitary radiation; also enables lower doses and therefore lower rate of adverse reactions
Peripheral Glucocorticoid Antagonist				
Mifepristone (RU 486) ^b (oral administration)	Antagonizes glucocorticoid receptors	<i>Adults and children:</i> up to 20 mg/kg/day Do not exceed 600 mg/d in renal impairment or mild-to-moderate hepatic impairment. Do not use in severe hepatic impairment.	Nausea, fatigue, headache, hypokalemia, arthralgia, vomiting, peripheral edema, hypertension, dizziness, decreased appetite, endometrial hypertrophy, prolonged QT interval. Has abortifacient and embryotoxic properties	<ul style="list-style-type: none"> FDA-approved for the control of hyperglycemia secondary to hypercortisolism in adult patients with endogenous Cushing's syndrome who have type 2 diabetes mellitus or glucose intolerance and have failed surgery or are not candidates for surgery. Not FDA-approved in children. Increases cortisol and ACTH levels via antagonism of negative feedback of ACTH secretion Requires cautious use since limited clinical experiences and cannot use cortisol or ACTH levels to monitor efficacy of treatment Quicker effectiveness compared to the other drug treatment options

^aDosing guidelines (including age ranges) for children have not been definitively established.

^bThese medications do not have FDA-approved indications for the treatment of Cushing's syndrome in either adults or children.

ACTH, adrenocorticotropic hormone or corticotropin; FDA, Food and Drug Administration; GI, gastrointestinal; IV, intravenous; NTE, not to exceed.

of glucocorticoids for prolonged periods, gradual tapering to near-physiologic levels (5 to 7.5 mg/day of prednisone or its equivalent) should precede drug discontinuation. Administration of a short-acting glucocorticoid in the morning and use of alternate-day dosing may reduce the risk of adrenal suppression. Testing of the HPA axis may be useful in assessing adrenal reserve. In some cases, supplemental glucocorticoid administration during excessive physiologic stress may be needed for up to 1 year after glucocorticoid discontinuation.¹³ Table 45–8 lists strategies to prevent the development of hypercortisolism and hypocortisolism.

OUTCOME EVALUATION

- Monitor patients receiving surgical, medical, or radiation therapy for resolution of the clinical manifestations of hypercortisolism. Symptoms often improve immediately after surgery and soon after initiation of drug therapy. However, it may take months for symptoms to resolve after radiation therapy.
- Monitor for normalization of serum cortisol concentrations.
- Patient Care and Monitoring discusses additional evaluation strategies.

Table 45–8

Principles of Glucocorticoid Administration to Avoid Hypercortisolism or Hypocortisolism

To Prevent Hypercortisolism and Development of Cushing’s Syndrome

- Give the lowest glucocorticoid dose that will manage the disease being treated and for the shortest possible duration.
- If feasible, give glucocorticoid via administration routes that minimize systemic absorption (e.g., inhalation or dermal).
- If feasible, administer glucocorticoid treatment every other day (calculate the total 48-hour dose and give as a single dose of intermediate-acting glucocorticoid in the morning).⁴
- Avoid concurrent administration of drugs that can inhibit glucocorticoid metabolism.

To Prevent Hypocortisolism and Development of Adrenal Insufficiency or Adrenal Crisis

- Assess patients at risk for adrenal insufficiency with screening tests (e.g., serum cortisol, rapid ACTH stimulation).
- If the patient requires discontinuation from chronic treatment with supraphysiologic doses of glucocorticoid, the following discontinuation protocol can be used:⁴
 - Gradually taper the dose to approximately 20 mg of prednisone or equivalent per day, given in the morning.
 - Then change glucocorticoid to every other day administration, in the morning.
 - Stop the glucocorticoid when the equivalent physiologic dose is reached (20 mg/day of hydrocortisone or 5–7.5 mg/day of prednisone or equivalent).
 - Understand that recovery of the HPA axis may take up to 1 year after glucocorticoid discontinuation during which the patient may require supplementation therapy during periods of physiologic stress.
- Evaluate patients at risk for adrenal insufficiency as a result of treatment(s) of Cushing’s syndrome and initiate glucocorticoid and mineralocorticoid replacement therapy as appropriate.
- Avoid concurrent administration of drugs that can induce glucocorticoid metabolism.
- Educate patients about:
 - The need for replacement or supplemental glucocorticoid and mineralocorticoid therapy
 - How to administer parenteral glucocorticoid if unable to immediately access medical care during an emergency
 - Need to wear or carry medical identification regarding their condition (e.g., card, bracelet)

ACTH, adrenocorticotropic hormone or corticotropin; HPA, hypothalamic–pituitary–adrenal.

Patient Encounter 2

YZ is a 61-year-old man who presents to the certified diabetes educator for diabetes education and instruction in self-monitoring of blood glucose. He was recently diagnosed with type 2 diabetes based on glycosylated hemoglobin testing by his primary care physician. He also has diagnoses of hypertension, atrial fibrillation, dyslipidemia, depression, and spinal stenosis. He complains of thirst, polyuria, and fatigue. Physical examination reveals an obese (body mass index, 37 kg/m²) gentleman with truncal obesity, dorsocervical fat, reddish abdominal striae, several small bruises on abdomen and extremities, and

facial plethora. The diabetes educator suggests evaluation for possible Cushing’s syndrome.

Which findings are suggestive of Cushing’s syndrome?

Aside from Cushing’s syndrome, what are some major differential diagnoses for YZ’s clinical presentation?

The primary care physician performs a 24-hour urinary-free cortisol test. The result is four times the upper reference limit. Can this result be used to establish the diagnosis of Cushing’s syndrome?

Patient Care and Monitoring: Cushing's Syndrome

1. Patient evaluation should include a thorough history of all medications and herbal or dietary supplements.
2. Perform initial screening tests to confirm Cushing's syndrome and rule out those with pseudo-Cushing's conditions.
3. After the diagnosis is confirmed, perform further testing to determine etiology of Cushing's syndrome.
4. Attempt to taper glucocorticoid if Cushing's syndrome is from exogenous administration.
5. If the patient has endogenous Cushing's syndrome, determine if patient is an appropriate candidate for surgical resection of the tumor. Does the patient have any conditions that contraindicate surgical resection such as advanced disease (metastatic adrenal carcinoma)?
6. Develop a formal plan to assess the response and complications associated with surgery¹⁷:
 - Measure plasma cortisol post surgery to determine if the patient displays persistent hypercortisolism (surgical treatment failure) or hypocortisolism (adrenal insufficiency requiring steroid replacement therapy).
 - In patients demonstrating hypocortisolism:
 - Monitor for signs and symptoms of glucocorticoid withdrawal (headache, fatigue, malaise, myalgia).
 - Monitor for signs and symptoms of adrenal insufficiency.
 - Monitor morning cortisol or response to ACTH stimulation every 3 to 6 months to assess for HPA axis recovery. Discontinue glucocorticoid replacement therapy when cortisol concentrations are greater than 19 mcg/dL (524 nmol/L) on either test.
 - Monitor cortisol, ACTH, low-dose dexamethasone suppression, or other tests to assess for risk of relapse of hypercortisolism.
 - Monitor for development of pituitary hormone deficiency.
7. If surgical resection does not achieve satisfactory disease control or is not indicated, evaluate the patient for pituitary radiation or bilateral adrenalectomy with concomitant pituitary radiation.
 - Monitor patients treated with pituitary radiation for development of pituitary hormone deficiency.
8. Evaluate patients with adrenal adenomas for unilateral adrenalectomy.
9. Give glucocorticoid and mineralocorticoid replacement to patients who undergo adrenalectomy (permanently in the case of bilateral adrenalectomy).
10. Evaluate patient for appropriateness of pharmacologic therapy depending on the etiology of Cushing's syndrome.
11. Monitor the patient for response to therapy, need for dose adjustments, and presence of adverse drug reactions.
12. When disease control is achieved, continue to monitor biochemical markers and patient for development of complications of Cushing's syndrome, as relapse may occur.
13. Provide patient education regarding disease state and treatment:
 - Causes of Cushing's syndrome, including drug-induced etiologies
 - How to recognize the clinical manifestations of Cushing's syndrome
 - Possible sequelae of Cushing's syndrome
 - How to reduce the modifiable cardiovascular and metabolic complications
 - Advantages and disadvantages of potential treatment options
 - Possible adverse consequences of treatment
 - Need for glucocorticoid and mineralocorticoid replacement after treatment, if appropriate
 - Importance of adherence to therapy.

Abbreviations Introduced in This Chapter

ACTH	Adrenocorticotrophic hormone or corticotropin
ADX	Adrenodoxin
AIDS	Acquired immunodeficiency syndrome
BUN	Blood urea nitrogen
CRH	Corticotropin-releasing hormone
CT	Computed tomography
CYP450 3A4	Cytochrome P450 subfamily IIIA, polypeptide 4
CYP11A1	Side chain cleavage enzyme
CYP17A1	17-alpha-hydroxylase/17,20 lyase
CYP21A2	21-alpha-hydroxylase
CYP11B1	11-beta-hydroxylase
CYP11B2	Aldosterone synthase
DHEA	Dehydroepiandrosterone
DHEA-S	Sulfated form of dehydroepiandrosterone
DST	Dexamethasone suppression test
GI	Gastrointestinal
H6PDH	Hexose-6-phosphate dehydrogenase
HIV	Human immunodeficiency virus
HPA	Hypothalamic-pituitary-adrenal
HSD3B2	3-beta-hydroxysteroid dehydrogenase type 2
HSD11B1	11-beta-hydroxysteroid dehydrogenase type 1
HSD11B2	11-beta-hydroxysteroid dehydrogenase type 2
HSD17B	17-beta-hydroxysteroid dehydrogenase
IV	Intravenous or intravenously
MRI	Magnetic resonance imaging
PAPSS2	PAPS synthase type 2
POR	P450 oxidoreductase
SRD5A	5-alpha-reductase
SULT2A1	DHEA sulfotransferase

Pituitary Gland Disorders

Judy T. Chen, Devra K. Dang, Frank Pucino Jr.,
and Karim Anton Calis

LEARNING OBJECTIVES

● **Upon completion of the chapter, the reader will be able to:**

1. List the mediators and primary effects of pituitary hormones.
2. Identify clinical features of patients with acromegaly.
3. Discuss the role of surgery and radiation therapy for patients with acromegaly.
4. Select appropriate pharmacotherapy for patients with acromegaly based on patient-specific factors.
5. Identify clinical features of children and adults with growth hormone (GH) deficiency and select appropriate pharmacotherapy for these patients.
6. Recommend monitoring parameters necessary to assess therapeutic outcomes and adverse effects in patients receiving GH therapy.
7. List common etiologies of hyperprolactinemia.
8. Identify clinical features of patients with hyperprolactinemia.
9. Select appropriate pharmacologic and nonpharmacologic treatments for patients with hyperprolactinemia based on patient-specific factors.

KEY CONCEPTS

- 1 Surgical resection of the pituitary tumor through transsphenoidal pituitary microsurgery is the treatment of choice for most patients with growth hormone (GH)-producing pituitary adenomas.
- 2 Somatostatin analogs are the mainstay of pharmacotherapy for the treatment of acromegaly when surgery is contraindicated or has failed, or as an adjuvant therapy until radiation effect is sustained.
- 3 Pegvisomant, as monotherapy or adjuvant therapy to somatostatin analogs, is indicated for patients who do not tolerate or have an inadequate response to other treatment options.
- 4 Dopamine agonists may be appropriate for patients with markedly elevated insulin-like growth factor-I (IGF-I) levels who have GH and prolactin cosecreting tumors, or as an additive therapy to somatostatin analog in patients with partial response to somatostatin.
- 5 Prolonged exposure to elevated GH and IGF-I levels can lead to serious complications in patients with acromegaly. Comorbid conditions such as hypertension, diabetes, dysrhythmias, coronary artery disease, and heart failure should be aggressively managed to prevent vascular and neuropathic complications.
- 6 Recombinant GH therapy is the main pharmacologic treatment for GH deficiency in both children and adults.
- 7 Although comparative trials have not been conducted, recombinant GH products appear to have similar efficacy for treating GH deficiency as long as the regimen follows currently approved guidelines.
- 8 Dopamine agonists are the first-line treatment of choice for all patients with symptomatic hyperprolactinemia; transsphenoidal surgery and radiation therapy are reserved for patients who are resistant to or severely intolerant of pharmacologic therapy.
- 9 Women who become pregnant while taking a dopamine agonist should discontinue treatment immediately to minimize fetal exposure. Because cabergoline has a long half-life, women who plan to become pregnant should discontinue the drug at least 1 month before planned conception.

PHYSIOLOGY OF THE PITUITARY GLAND

The pituitary gland, located at the base of the brain in proximity to the nasal cavity, is a small endocrine gland about the size of a pea weighing approximately 600 mg. The pituitary gland is referred to as the “master gland” because it is responsible for

the regulation of many other endocrine glands and body systems. Growth, development, metabolism, reproduction, and stress homeostasis are among the functions influenced by the pituitary. Functionally, the gland consists of two distinct sections: the anterior pituitary lobe (adenohypophysis) and the posterior pituitary lobe (neurohypophysis). The pituitary receives neural and hormonal input from the inferior hypothalamus via blood vessels and neurons contained in the pituitary stalk (infundibulum).

The posterior pituitary is innervated by nervous stimulation from the hypothalamus, resulting in the release of specific hormones to exert direct tissue effects. The hypothalamus synthesizes two hormones, oxytocin and vasopressin. These hormones are stored and released from the posterior pituitary lobe. Oxytocin exerts two actions, it: (a) promotes uterine contractions during labor and

(b) contracts the smooth muscles in the breast to stimulate the release of milk from the mammary gland during lactation. Vasopressin, also known as antidiuretic hormone (ADH), is essential for proper fluid and electrolyte balance in the body. Specifically, vasopressin increases the permeability of the distal convoluted tubules and collecting ducts of the nephrons to water. This causes the kidneys to excrete less water in urine. Consequently, the urine becomes more concentrated as water is conserved.

In contrast to the posterior pituitary lobe, the anterior pituitary lobe is under the control of several releasing and inhibiting hormones secreted from the hypothalamus via a portal vein system. The anterior pituitary, in turn, synthesizes and secretes six major hormones. **Figure 46-1** summarizes the physiologic mediators and effects of each of these hormones.

FIGURE 46-1. Hypothalamic–pituitary–target-organ axis. The hypothalamic hormones regulate the biosynthesis and release of eight pituitary hormones. Stimulation of each of these pituitary hormones produces and releases trophic hormones from their associated target organs to exert their principal effects. These trophic hormones regulate the activity of endocrine glands. Subsequently, increased serum concentration of the trophic hormones released from the target organs can inhibit both the hypothalamus and the anterior pituitary gland to maintain homeostasis (negative feedback). Inhibin is produced by the testes in men and the ovaries in women during pregnancy. Inhibin directly inhibits pituitary production of follicle-stimulating hormone (FSH) through a negative feedback mechanism. Melanocyte-stimulating hormone (MSH) produced by the anterior pituitary is not illustrated in the figure. (–), inhibit; (+), stimulate; ACTH, adrenocorticotropic hormone (corticotropin); ADH, antidiuretic hormone (vasopressin); CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GABA, γ -aminobutyric acid; GH, growth hormone (somatotropin); GHIH, growth hormone–inhibiting hormone (somatostatin); GHRH, growth hormone–releasing hormone; GnRH, gonadotropin-releasing hormone; IGF-I, insulin-like growth factor-I; LH, luteinizing hormone; LHRH, luteinizing hormone–releasing hormone; PRH, prolactin-releasing hormone; T₃, triiodothyronine; T₄, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone (thyrotropin).

Hormonal Feedback Regulatory Systems

The hypothalamus is responsible for the synthesis and release of hormones that regulate the pituitary gland. Stimulation or inhibition of the pituitary hormones elicits a specific cascade of responses in peripheral target glands. In response, these glands secrete hormones that exert a negative feedback on other hormones in the hypothalamic–pituitary axis (see Fig. 46–1). This negative feedback serves to maintain body system homeostasis. In general, high circulating hormone levels inhibit the release of hypothalamic and anterior pituitary hormones.

Damage and destruction of the pituitary gland may result in secondary hypothyroidism, **hypogonadism**, adrenal insufficiency, growth hormone (GH) deficiency, hypoprolactinemia, or insufficiency or absence of all anterior pituitary hormones (i.e., **panhypopituitarism**). A tumor (adenoma) located in the pituitary gland may result in excess secretion of a hormone or may physically compress the gland and suppress adequate hormone release. The type, location, and size of a pituitary tumor often determine a patient's clinical presentation. This chapter discusses the pathophysiology and role of pharmacotherapy in the treatment of **acromegaly**, GH deficiency, and **hyperprolactinemia**. The following hormones are discussed elsewhere in this textbook: adrenocorticotrophic hormone (ACTH or corticotropin), thyroid-stimulating hormone (TSH or thyrotropin), luteinizing hormone (LH), follicle-stimulating hormone (FSH), vasopressin (ADH), and oxytocin.

GROWTH HORMONE (SOMATOTROPIN)

Somatotropin or GH is the most abundant hormone produced by the anterior pituitary lobe. The GH-secreting **somatotropes** account for 50% of hormone-secreting cells in the anterior pituitary. GH is regulated primarily by the hypothalamic–pituitary axis. The hypothalamus releases growth hormone–releasing hormone (GHRH) to stimulate GH synthesis and secretion, whereas somatostatin inhibits it.¹ Upon stimulation by GHRH, somatotropes release GH into the circulation, thereby stimulating the liver and other peripheral target tissues to produce insulin-like growth factors (IGFs). These IGFs, also known as somatomedins, are the peripheral GH targets. There are two types of IGFs, **IGF-I** and **IGF-II**. IGF-I is the hormone generally responsible for growth of bone and other tissues, whereas IGF-II is primarily responsible for regulating fetal growth. High levels of IGF-I inhibit GH secretion through somatostatin, thereby inhibiting GHRH secretion at the hypothalamus.¹ The hypothalamus also may stimulate the release of somatostatin to inhibit GH secretion. The effects of IGF-I in peripheral tissues are both GH dependent and GH independent.² GH is an anabolic hormone with direct “anti-insulin” metabolic effects. By stimulating protein synthesis and shifting the body's energy source from carbohydrates to fats, GH promotes a diabetic state (Table 46–1).² GH controls somatic growth and has a critical role in the development of normal skeletal muscle, myocardial muscle, and bone.

Table 46–1

Effects of Growth Hormone²

	Mechanism of Action(s)	Effect(s)
Lipid metabolism	Increases the use of fat by stimulating triglyceride breakdown and oxidation of adipocytes	Increases breakdown of fat (lipolysis) Increases circulating fatty acid levels Increases lean body mass
Protein metabolism	Stimulates protein anabolism by increasing amino acid uptake and protein synthesis and decreasing oxidation of proteins	Increases muscle mass
Carbohydrate metabolism	Suppresses the ability of insulin to stimulate uptake of glucose in peripheral tissues	Decreases glucose utilization
	Decreases insulin receptor sensitivity	Insulin resistance
	Impairs postreceptor insulin action	Hyperglycemia
	Stimulates glucose synthesis in the liver (gluconeogenesis)	Increases hepatic glucose output

In healthy individuals, GH is secreted in a pulsatile pattern throughout a 24-hour period with several short bursts occurring mostly during the night. The most intense period of GH secretion occurs within the first 1 to 2 hours of slow-wave sleep (stage 3 or 4 deep sleep).¹ In between these bursts, basal concentration of GH falls to very low or undetectable levels because of its short half-life in the blood (~19 minutes). The amount of GH secretion fluctuates throughout a person's lifetime. Secretion of GH is lowest during infancy, increases during childhood, peaks during adolescence, and then declines gradually during the middle years.¹ These changes are parallel to an age-related decline in lean muscle mass and bone mineral density.

Growth Hormone Excess

► Epidemiology and Etiology

Acromegaly affects both genders equally, and the average age of presentation is 44 years. Approximately 50 to 70 people per 1 million population are affected, with an estimated annual incidence of three to four cases per 1 million people.^{3,4} In more than 95% of the cases, overproduction of GH is caused by a benign pituitary tumor (adenoma), whereas malignant tumors occur in fewer than 1%.⁵ Most pituitary adenomas occur spontaneously as a result of a sporadic genetic mutation acquired during life. Depending on the size of the tumor, pituitary adenomas are classified as: (a) microadenomas if they are 10 mm or less in diameter; or (b) macroadenomas

FIGURE 46-2. Before and after photographs of a patient with acromegaly. Compare the photographs (A) before the onset of acromegaly and (B) after approximately 20 years when the diagnosis was well established. Notice the coarsening of facial features, with an enlarged nose, lips, and forehead.

if they are greater than 10 mm. Rarely, nonpituitary tumors cause acromegaly. These tumors can produce GH, but more commonly they secrete GHRH and result in excessive GH and IGF-I production.

► Pathophysiology

Acromegaly is a rare disorder that manifests gradually over time and typically occurs after fusion of the epiphyses (growth plates) of the long bones.³ The facial features of an acromegalic patient are depicted in [Figure 46-2](#). **Gigantism** refers to GH excess that occurs during childhood before epiphyseal closure and results in excessive linear growth ([Figure 46-3](#)).⁶

Because the signs and symptoms of acromegaly are insidious, diagnosis of this disorder is often delayed for up to 10 years after the initial presentation of symptoms. Therefore, it is important for practitioners to be vigilant in identifying

this disease in the early stages.³ Diagnosis of acromegaly is based on both clinical and biochemical findings. Because secretion of GH fluctuates throughout the day, a single random measurement is never reliable for diagnosing GH excess.¹ However, GH-mediated IGF-I production results in relatively stable serum IGF-I concentrations during the day, which correlate positively with 24-hour mean GH levels.¹ This makes elevated IGF-I level an ideal screening test for acromegaly and a reliable monitoring biochemical marker to assess disease activity and response to therapy.^{3,7} Because IGF-I levels may fluctuate with age and gender, it is important to compare IGF-I levels with age- and sex-matched population values.⁷ Other conditions such as nutritional status, liver dysfunction, insulin levels, and illness also can affect IGF-I levels. The measurement of serum GH secreted by the pituitary in response to an oral glucose tolerance test (OGTT) is the primary biochemical test for diagnosing acromegaly. GH

FIGURE 46-3. Example of gigantism. A 22-year-old man with gigantism caused by excess growth hormone is shown to the left of his identical twin. The increased height (A), enlarged hand (B), and enlarged foot (C) of the affected twin are evident. The features of the twins began to diverge at age 13 years. (Reproduced from Gagel RF, McCutcheon IE. Pituitary gigantism. *New Eng J Med* 1999;540:524; With permission.)

Clinical Presentation and Diagnosis of Acromegaly^{3,7-9}

General

The patient will experience slow development of soft tissue overgrowth affecting many body systems. Signs and symptoms may progress gradually over 7 to 10 years.

Symptoms

- Headache and compromised visual function (loss of peripheral vision and blurred vision) caused by the actual tumor mass and its close proximity to the optic structures
- Weakness, low blood sugar, or weight loss caused by disruption of adrenal function (i.e., ACTH deficiency) by effect of tumor mass on the pituitary
- Fatigue and weight gain caused by disruption of thyroid function (i.e., TSH deficiency) by effect of tumor mass on the pituitary
- Absence of regular menstrual periods (**amenorrhea**), impotence, and decreased libido caused by disruption of the gonadotropin secretion (i.e., LH and FSH)
- Excessive sweating, joint pain, nerve pain, and abnormal neurologic sensations (paresthesias) related to elevated GH and IGF-I levels

Signs

- Coarsening of facial features
- Increased hand volume
- Increased ring and shoe size
- Increased spacing between teeth
- Increased acne or oily skin
- Enlarged tongue
- Deepening of voice
- Thick, irregular, patchy skin discoloration
- Enlarged nose, lips, and forehead (frontal bossing)
- Abnormal protrusion of the mandible (prognathia) and bite abnormalities
- Inappropriate secretion of breast milk (galactorrhea)
- Abnormal enlargement of various organs (organomegaly) such as liver, spleen, and heart
- Carpal tunnel syndrome caused by nerve compression from the swollen tissue

Laboratory Tests

- Random GH level greater than 1 ng/mL (1 mcg/L) or nadir GH level greater than 0.4 ng/mL (0.4 mcg/L) after an OGTT and elevated IGF-I level compared with age- and sex-matched control values.
- Loss of other hormonal functions caused by tumor mass compression of the anterior pituitary.
- Measure prolactin level in all patients because prolactin cosecretion is common.
- Glucose intolerance may be present in up to 50% of patients.

Additional Clinical Sequelae

- Cardiovascular diseases: hypertension, coronary heart disease, cardiomyopathy, left ventricular hypertrophy, and arrhythmia.
- Osteoarthritis and joint damage develop in up to 90% of patients.
- Respiratory disorders and **sleep apnea** occur in up to 70% of patients.
- Type 2 diabetes mellitus develops in 56% of patients.
- Increased risk for the development of esophageal, colon, and stomach cancer.

Other Diagnostic Tests

- Perform MRI examination of the pituitary to locate the tumor and validate the diagnosis.
- Obtain serum prolactin levels to assess for hyperprolactinemia and hypopituitarism.
- Without obvious pituitary tumor but proven acromegaly, measurement of GHRH may be helpful to detect ectopic tumors.

Adapted from Sheehan AH, Yanovski JA, Calis KA. Pituitary gland disorders. In: Dipiro JT, Talbert RL, Yee GC, et al, eds. *Pharmacotherapy. A Pathophysiologic Approach*. 8th ed. New York: McGraw-Hill; 2011:1345–1360.

is suppressed after administration of a 75-g oral glucose challenge because postprandial hyperglycemia inhibits secretion of GH for at least 1 hour. Measurement of GH concentrations at baseline and then every 30 minutes for a total of 2 hours after administration of OGTT is recommended.³ If the GH level does not decline to less than 1 ng/mL (1 mcg/L) during the test, the patient is diagnosed with acromegaly.³ With the increased sensitivity of the current GH assay, use of a lower nadir cutoff of 0.4 ng/mL (0.4 mcg/L) for GH level has been

suggested for detecting even modest elevations in GH levels.³ In addition to clinical presentation, elevated IGF-I serum concentration helps to confirm the diagnosis.

► Acromegaly Treatment

Goals Patients with untreated acromegaly experience a two- to fourfold increase in mortality rate primarily because of cardiovascular and pulmonary diseases.¹⁰ Normalization

of GH and IGF-I levels lowers the mortality risk and may improve overall life expectancy. Adequate hormonal control of the disease also may alleviate associated comorbidities, especially cardiovascular, pulmonary, metabolic, and respiratory abnormalities.¹¹ Reduction of IGF-I levels alone does not appear to be a reliable predictor of long-term outcome.^{12,13} The goals of therapy are as follows:³

- Normalize biochemical markers.
 - Reduce random GH to less than 1 ng/mL (1 mcg/L). When using a more sensitive GH assay, suppression of GH levels to less than 0.4 ng/mL (0.4 mcg/L) after OGTT would be indicative of disease control.
 - Normalize IGF-I levels to age- and sex-matched control values.
- Ablate or reduce tumor size to relieve tumor mass effect.
- Prevent tumor recurrence and control tumor size.
- Preserve normal pituitary function.
- Improve clinical signs and symptoms.
- Alleviate significant morbidities.
- Reduce mortality rates to those of the general population.

Surgical Treatment The American Association of Clinical Endocrinologists (AACE) published medical guidelines for the diagnosis and treatment of acromegaly (Fig. 46–4).

- According to these guidelines, ① *surgical resection of the pituitary tumor through transsphenoidal pituitary microsurgery is the treatment of choice for most patients with GH-producing pituitary adenomas.*³ When performed by experienced surgeons, approximately 70% to 80% of patients with microadenomas and fewer than 50% of patients with macroadenomas achieve biochemical control.¹⁰ Complete resection of a macroadenoma may be difficult if the tumor has already invaded the surrounding nerves and tissues. In such cases, debulking of the tumor along with adjunctive radiation and/or pharmacotherapy may improve treatment outcome. Infrequent surgical complications include meningitis, serious visual impairment, cerebrospinal fluid leakage, diabetes insipidus, and permanent hypopituitarism.³ Relative contraindications to surgery include patient frailty, acromegaly-associated comorbidities, and medically unstable conditions such as airway difficulties, severe hypertension, or uncontrolled diabetes.

Pharmacologic Therapy Pharmacologic therapy is often necessary for patients in whom surgery is not an option.

- Somatostatin analogs, GH receptor antagonists, and dopamine agonists are the primary pharmacologic therapies used for the management of acromegaly (Table 46–2).^{3,5} Pharmacologic therapy avoids hypopituitarism and other surgical risks.
- **Somatostatin Analog (GH-Inhibiting Hormone)** ② *Somatostatin analogs are the mainstay of pharmacotherapy for the treatment of acromegaly when surgery is contraindicated or has failed, or as an adjuvant therapy until radiation effect is sustained.*³ These agents mimic endogenous somatostatins and bind to somatostatin receptors in the pituitary to cause

potent inhibition of GH, insulin, and glucagon secretion. Long-term treatment can sustain hormone suppression, alleviate soft tissue manifestations, and reduce tumor size. Use of the first-generation somatostatin analog octreotide is limited by its extremely short duration of action, which necessitates frequent injections of at least three times per day. The long-acting preparations of octreotide and lanreotide are considered the cornerstone of therapy because of improved patient adherence and acceptability. Typically, at least a 2-week trial of short-acting octreotide is recommended to determine efficacy and tolerance before switching to a long-acting preparation. The long-acting formulations can be administered every 14 to 28 days. Somatostatin analogs modestly reduce pituitary tumor size in 25% to 70% of patients depending in part on whether they are used as adjuvant or de novo therapy.³ Their efficacy and safety have been demonstrated in long-term studies (up to 9 years with octreotide and 4 years with lanreotide).^{14–16} Long-acting octreotide effectively suppresses GH levels and achieves normal IGF-I levels in 67% and 57% of patients, and lanreotide slow-release formulation achieved lower response rates of 48% and 47%, respectively.¹⁷ However, the response rate of long-acting octreotide may be overestimated because of differences in subject selection.¹⁷ The efficacy of lanreotide autogel, given by deep subcutaneous injection, is comparable to intramuscularly administered depot formulations of lanreotide and octreotide in achieving clinical and biochemical control.³ Because somatostatin analogs can achieve substantial relief of clinical symptoms with significant reduction in tumor size, it is important to monitor patients for tumor recurrence if treatment is discontinued.^{17,18} It is not yet known whether use of somatostatin analogs before surgery has additional benefits over surgery alone.³

Somatostatin analogs are generally well tolerated. Common adverse effects include transient gastrointestinal (GI) disturbances such as diarrhea, abdominal pain, flatulence, constipation, and nausea.¹⁸ These adverse GI effects usually subside within the first 3 months of therapy.⁴ Somatostatin analogs inhibit gallbladder contractility and decrease bile secretion; therefore, their major adverse effect is development of biliary sludge and asymptomatic gallstones (cholelithiasis). Biliary sludge is a predisposing factor for the high incidence of cholelithiasis observed in up to 20% of patients.⁴ Cholelithiasis typically occurs in patients treated for 12 months or longer and is unrelated to age, gender, or dose. Somatostatin analog-induced gallstones should be managed according to standard guidelines.⁴ Additionally, somatostatin analogs may alter the balance of counterregulatory hormones (i.e., glucagon, insulin, and GH), resulting in either hypoglycemia or hyperglycemia.¹⁴ Octreotide also may suppress pituitary release of TSH, leading to decreased thyroid hormone secretion and subsequent hypothyroidism in 12% of treated patients. Close monitoring of thyroid function and glucose metabolism is recommended. Sinus bradycardia, conduction abnormalities, and arrhythmias have been reported with octreotide and lanreotide. Because of the potential adverse effects of the somatostatin analogs, concomitant use with insulin, oral hypoglycemic agents, beta-blockers, or calcium

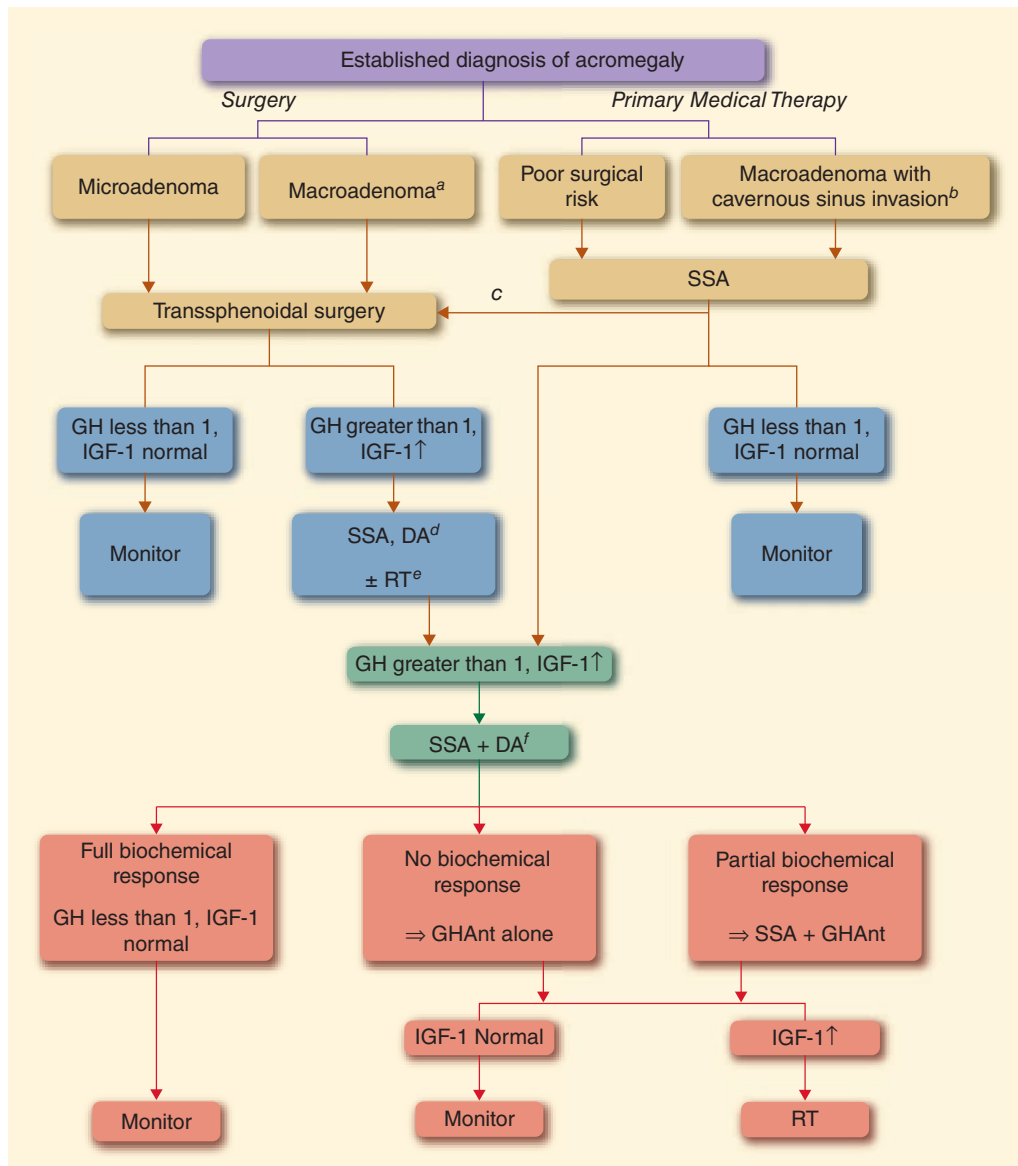

FIGURE 46-4. Treatment algorithm for acromegaly.³ ^aVisual field compromise is absolute indication for surgery. ^bPrimary medical therapy can be considered if there is no visual field deficit and there is no possibility of surgical cure because of cavernous sinus involvement. ^cReconsider surgery to debulk tumor to improve response to medical therapy, reduce medical comorbidities, or comply with patient preference. ^dConsider a dopamine agonist (DA) in the setting of a modest disease; ^eConsider radiotherapy (RT) in patients with residual tumor after therapy. This decision is based on several factors, including age, reproductive status, pituitary function, insurance coverage, and patient preference regarding long-term medical therapy. ^fAddition of DA in the setting of modest disease. GH, growth hormone; GHAnt, growth hormone antagonist; IGF-I, insulin-like growth factor-I; SSA, somatostatin analogue. (Modified from Katznelson L, Atkinson JL, Cook DM, et al. American Association of Clinical Endocrinologists medical guidelines for clinical practice for the diagnosis and treatment of acromegaly—2011 update. *Endocr Pract* 2011;17(Suppl 4):1–44; With permission.

channel blockers may require careful dosage adjustment. Somatostatin analogs may also alter the bioavailability and elimination of cyclosporine, and monitoring of cyclosporine serum concentration is necessary.

GH-Receptor Antagonist The advent of a GH-receptor antagonist represents a novel approach to the treatment of acromegaly. Pegvisomant is the only genetically engineered

GH-receptor antagonist that blocks the action of GH. The effects of pegvisomant work independently of tumor characteristics, somatostatin, and dopamine receptors.¹⁹ Up to 95% of patients with acromegaly treated with long-term pegvisomant (median dose, 15 mg/day) achieved normal age-related IGF-I levels and experienced significant improvement in clinical symptoms of GH excess.²⁰ In patients previously resistant to somatostatin analog therapy, normal IGF-I

Table 46–2

Comparison of Various Drugs for Treatment of Acromegaly^{3,5}

Drug Class	Dopamine Agonist	Somatostatin Analog			GH Receptor Antagonist	
Medication	Cabergoline	Octreotide (Sandostatin)	Octreotide LAR (Sandostatin LAR)	Lanreotide SR	Lanreotide Autogel (Somatuline Depot)	Pegvisomant (Somavert)
Starting dose	0.5–1 mg/week orally	50 mcg SC 3 × daily	20 mg IM every 4 weeks	60 mg IM every 2 weeks	90 mg deep SC every 4 weeks ^a	10 mg SC daily after initial loading dose of 40 mg
Maximal dose	4 mg/week orally	200 mcg SC 3 × daily	40 mg IM every 4 weeks ^b	120 mg IM every 7 days	120 mg deep SC every 4 weeks	40 mg SC daily ^c
Dosage in hepatic insufficiency	Dosage reduction may be recommended for patients with severe hepatic failure	—	Cirrhosis: 10 mg IM every 4 weeks	Dosage reduction may be necessary; no guidelines available	Moderate to severe impairment: starting dose 60 mg every 4 weeks	Discontinue therapy if liver function tests are elevated at least 5 × the upper limit of normal or transaminase at least 3 × upper limit of normal with any increase in serum total bilirubin
Dosage in renal failure	None	Dialysis dependent: adjustment may be necessary; no guidelines available	Dialysis-dependent renal impairment: 10 mg IM every 4 weeks	Dosage reduction may be necessary; no guidelines available	Moderate to severe impairment: starting dose, 60 mg every 4 weeks	None
Side effects	Nausea, GI cramps, headache, hypotension, nasal congestion	Nausea, GI cramps, gallstones	Nausea, GI cramps, gallstones	Nausea, GI cramps, gallstones	Nausea, GI cramps, gallstones	Headache, fatigue, abnormal liver enzymes
Monitoring suggestions	GH, IGF-I, and prolactin level 4–6 weeks after each dose change	GH and IGF-I 3 months after dose change	GH and IGF-I 3 months after dose change	GH and IGF-I 3 months after dose change	GH and IGF-I 3 months after dose change	Liver function tests monthly for 6 months, quarterly for next 6 months, then biannually for the next year; MRI every 6 months; IGF-I (not GH) after first year, then yearly

GH, growth hormone; GI, gastrointestinal; IGF-I, insulin-like growth factor-I; IM, intramuscularly; LAR, long-acting release; MRI, magnetic resonance imaging; SC, subcutaneously; SR, slow-release.

^aIn the United States, initiate lanreotide at 90 mg every 28 days for 3 months and then titrate accordingly based on patient response. Different labeled dosing guidelines exist for the United Kingdom and Canada.

^bProduct labeling recommends a maximum of 30 mg IM every 4 weeks.

^cAlternative dose administration protocol of twice a week or once a week have been used.³

Adapted from AACE Medical Guidelines for Clinical Practice for the diagnosis and treatment of acromegaly. *Endocr Pract* 2004;10:213–225 by permission of publisher, American Association of Clinical Endocrinologists (AACE) Corp.

concentrations were achieved in 75% of patients treated with pegvisomant²¹ and in 69% to 100% of patients treated with pegvisomant and somatostatin analog therapy.^{22–24} Pegvisomant therapy may have favorable effects on glucose tolerance (the body's ability to metabolize glucose) and insulin sensitivity (capacity of cells to respond to insulin).²¹ However, use of pegvisomant is associated with significant dose-dependent increases in GH despite declining IGF-I levels.²⁰ The dose-dependent increase in GH is troubling because it has been suggested that persistent elevation of GH levels may be indicative of tumor growth. Although currently available data suggest that pegvisomant does not promote tumor growth, careful monitoring with periodic imaging scans is nonetheless indicated, especially when administering pegvisomant to patients at risk for visual damage from large tumors that may impinge on the optic chiasm.^{20,25}

3 *Pegvisomant, as monotherapy or adjuvant therapy to somatostatin analogs, is indicated for patients who do not tolerate or have an inadequate response to other treatment options.*³ The long-term efficacy and safety of pegvisomant in acromegaly remain to be established. Pegvisomant appears to be well tolerated with minimal adverse effects, including self-limiting injection site reactions, elevated liver enzymes, headache, increased sweating, and abdominal complaints.¹⁹ Although elevations of liver enzymes often are self-limiting and not associated with symptoms,³ hepatotoxicity has been reported in clinical trials with a higher risk observed in diabetics receiving combined pegvisomant and somatostatin analogs.^{20,26} Therefore, serum transaminases, total bilirubin, and alkaline phosphatase should be assessed before initiating therapy and periodically thereafter. Use caution when administering pegvisomant to patients with elevated liver function tests. Discontinue therapy if the patient presents with clinical signs and symptoms of hepatic injury.

Dopamine Agonists Dopamine is one of the neurotransmitters that can increase GH secretion in healthy adults. However, dopamine agonists administered to patients with acromegaly exert the opposite effect and suppress GH release from the tumor. The first dopamine agonist for acromegaly, bromocriptine, achieved normal IGF-I levels in fewer than 10% of patients and was associated with significant adverse effects including nausea, dizziness, and headaches.¹⁰ The large doses of bromocriptine required to achieve the desired response are often associated with dose-limiting toxicity such as GI discomfort and orthostatic hypotension. Cabergoline, the selective long-acting agonist with improved tolerability, can effectively normalize IGF-I levels in 35% of patients and reduce GH levels in 44% of patients.²⁷ Acromegalic patients with coexisting hyperprolactinemia also had a more favorable response to cabergoline, with 50% of patients achieving normal IGF-I levels, 56% GH suppression, and 65% tumor shrinkage.²⁷ Although orally administered dopamine agonists are the least expensive medical therapy for managing acromegaly, the major disadvantage is their relative lack of efficacy compared with existing therapeutic options.

4 *Dopamine agonists may be appropriate for patients with markedly elevated IGF-I levels who have GH and prolactin*

*cosecretion tumors, or as an additive therapy to somatostatin analog in patients with partial response to somatostatin.*³ Although cardiac valvular abnormalities have been observed in patients using higher doses of cabergoline for Parkinson's disease, similar findings have not been reported in patients with pituitary adenomas.^{3,28} Nonetheless, patients who require prolonged therapy with higher doses of cabergoline warrant echocardiographic monitoring for potential cardiac abnormalities.²⁹

• **Radiation Therapy** Radiation therapy is an important adjunctive therapy in patients with residual GH excess after surgery or pharmacologic therapy. Treatment involves the use of radiation to destroy rapidly growing tumor cells and often results in a reduction in tumor size. A major complication resulting from radiation therapy is hypopituitarism, requiring lifelong hormone replacement.³ There is also the potential for optic nerve damage if the pituitary tumor is near the optic tracts. Radiation therapy may take 10 to 20 years before its full effects become evident.³ Owing to delay in onset of radiation effectiveness, pharmacologic therapy with a somatostatin analog often is indicated as bridge therapy.³ Men and women who desire to have children should be warned that pituitary irradiation therapy may impair fertility because of subsequent gonadotropin deficiency.³

► Outcome Evaluation

- Lifelong biochemical assessment is critical for determining therapeutic outcomes. Although some patients may experience a rapid decline in GH levels after surgery, stabilization of IGF-I levels usually occurs 3 months after surgery but rarely may be delayed for up to 12 months. Fully assess pituitary function 2 to 3 months after surgery.³ GH and IGF-I levels should be measured 3 to 6 months postoperatively to assess treatment response.³ Additionally, IGF-I levels should be measured annually in all postsurgical patients to monitor for potential pituitary tumor recurrence.³
- Assess magnetic resonance imaging (MRI) 3 to 4 months after surgery and 3 to 6 months after starting medical therapy.⁷ Because up to 10% of pituitary tumors may recur within 15 years after surgery,¹² continual postoperative monitoring is recommended.
- For patients treated with somatostatin analogs, assess baseline fasting blood glucose, thyroid function tests, and heart rate. Thereafter, periodically monitor patients for adverse reactions such as GI disturbances, glucose intolerance, signs and symptoms of thyroid abnormalities, bradycardia, and arrhythmias in patients receiving long-term somatostatin analogs. Reevaluate IGF-I and GH levels at 3-month intervals to determine therapeutic response and inquire about symptoms of gallbladder disease (e.g., intermittent pain in the upper right abdomen) during follow-up appointments.³ If normalization of GH and IGF-I levels is not fully achieved after 1 year, perform MRI 6 months later and annually thereafter to monitor tumor mass.³

Patient Encounter 1: Acromegaly: Medical History, Physical Examination, and Diagnostic Tests

JS is a 42-year-old man who presents to his endocrinologist with chief complaints of “not feeling like myself over the past 10 years!” He noticed dramatic physical changes and complaints of “my nose and forehead grew bigger; my face and hands became puffy!” He also noticed his shoes are too tight and “I need to be buy bigger shoes every year.” He attributes the “numbness in [his] hands” to arthritis. JS reports increased fatigue, sweating, worsening headaches, and somnolence.

PMH: Hypertension for 12 years; type 2 diabetes mellitus for 5 years

FH: Mother died of diabetes at age 50. Father died of myocardial infarction at an unknown age

SH: Single, previously a successful freelance journalist, currently unemployed; graduate-level education

Meds: Enalapril/hydrochlorothiazide 10/25 mg once daily; metformin 1000 mg twice daily; glimepiride 8 mg once daily; acetaminophen 500 mg every 8 hours as needed for joint pain

ROS:(+) Deepening of voice

PE:

VS: BP 128/72 mm Hg, P 76 beats/min, RR 18 breaths/min, T 37.5°C (99.5°F)

HEENT: Ophthalmic examination reveals normal visual acuity and peripheral fields; protruding jaw and large fleshy nose

CV: RRR, normal S₁, S₂; no murmurs, rubs, gallops

Abd: Soft, nontender, nondistended; (+) bowel sounds, (–) hepatosplenomegaly

Rectal: Heme (–) stool

Labs: Electrolytes and renal function are within normal limits. Fasting blood glucose level is 180 mg/dL (10 mmol/L), HbA_{1c} is 7.9% (63 mmol/mol), and (–) microalbumin. GH level 1 hour after an OGTT is 5 ng/mL (5 mcg/L). Elevated IGF-I level at 800 ng/mL (800 mcg/L).

MRI: Reveals a pituitary tumor approximately 4 mm in diameter

Given this information, what signs and symptoms of acromegaly does JS exhibit?

What clinical complications often accompany JS's diagnosis?

Identify your treatment goals for JS.

What nonpharmacologic and pharmacologic treatment options are available for JS?

What additional considerations are needed based on patient's unemployed status?

- For patients treated with a GH receptor antagonist, GH levels are not measured because pegvisomant is a modified GH molecule that is detected in commercial GH assays, resulting in falsely elevated GH levels. Therefore, IGF-I level is the principal biochemical marker used to assess response to pegvisomant therapy. After appropriate dose titration, monitor IGF-I levels every 6 months.³ Concern for tumor growth requires careful monitoring of tumor size; therefore, performing MRI every 6 months during the first year of therapy and annually thereafter is recommended.³ Because of the potential for hepatotoxicity with pegvisomant therapy, it is mandatory to monitor liver enzymes prior to initiation of therapy, monthly during the first 6 months, quarterly for the next 6 months, and then biannually thereafter.³ More frequent monitoring of liver enzymes is warranted in patients with elevated liver enzymes at baseline.³
- For patients receiving dopamine agonists, the maximal suppression of GH and IGF-I levels may take up to 3 months to achieve. After stable control of biochemical markers is achieved with dopamine agonists or somatostatin analogs, monitor GH and IGF-I levels annually.³
- With conventional multidose radiation therapy, the most rapid decline in GH serum levels occurs within the first 2 years; monitor GH levels at the second year and annually thereafter.^{3,12} Patients who receive single-dose radiation therapy should be evaluated at 6-month intervals because response is observed earlier. Repeatedly assess pituitary function over the years after radiation therapy.³
- **5** Prolonged exposure to elevated GH and IGF-I can lead to serious complications in patients with acromegaly. Aggressively manage comorbid conditions such as hypertension, diabetes, dysrhythmias, coronary artery disease, and heart failure to prevent vascular and neuropathic complications (**Table 46–3**).^{3,30}

Growth Hormone Deficiency**► Epidemiology and Etiology**

In the United States, GH deficiency affects approximately 50,000 adults, with around 6,000 new cases diagnosed annually.³¹ Approximately 10,000 to 15,000 children have growth failure owing to GH deficiency. Children may present with GH deficiency at any time during their developmental stages. The evaluation for GH deficiency in a child of short stature should be deferred until appropriate exclusion of other identifiable causes of growth failure, such as hypothyroidism, chronic illness, malnutrition, genetic syndromes, and skeletal disorders, has occurred. Also, several medications, such as somatostatin analogs, gonadotropin-releasing hormone

Table 46-3

Assessment of Acromegaly Complications at Diagnosis and Follow-up

At the Time of Diagnosis	During Long-Term Follow-Up
Glucose tolerance test (with concurrent GH sampling)	Fasting blood glucose, HbA _{1c} if diabetes is present
Serum cholesterol and lipid profile	Annually
Echocardiography	Annually (in presence of cardiomyopathy)
ECG	Annually
Exercise ECG	If angina is present
Colonoscopy	Every 2–3 years
DEXA (hypogonadal only)	Every 2–3 years
Sleep assessment	Annually (if altered at diagnosis)
Blood pressure monitoring	Annually or change of treatment (if hypertensive)
Echo-Doppler of carotid artery	As indicated by clinical features

DEXA, dual-energy x-ray absorptiometry; ECG, electrocardiography; GH, growth hormone; HbA_{1c}, glycated hemoglobin A_{1c}.

From Giustina A, Casanueva FF, Cavagnini F, et al. Diagnosis and treatment of acromegaly complications. *J Endocrinol Invest* 2003;26:1242–1247; With permission.

(GnRH) agonists, methoxamine, phentolamine, isoproterenol, glucocorticoids, cimetidine, methylphenidate, and amphetamine derivatives, may induce GH insufficiency.³²

► Pathophysiology

Growth hormone deficiency exists when GH is absent or produced in inadequate amounts. GH deficiency may be congenital, acquired, or result from disruption of the hypothalamus–pituitary axis. GH deficiency may be an isolated condition or occasionally be accompanied by other endocrine disorder (e.g., panhypopituitarism). Because GH is frequently undetectable with random sampling, a stimulation or provocative test usually is performed to confirm the diagnosis in both adults and children in whom GH deficiency is suspected. Numerous pharmacologic agents such as insulin-induced hypoglycemia, arginine plus GHRH, and glucagon have been used to stimulate the pituitary to produce GH.³³ These tests may be associated with adverse effects and therefore require close medical supervision. The gold standard for diagnosis of adults with GH deficiency is the insulin tolerance test (ITT), with glucagon as an alternative if GHRH is unavailable.³⁴ Adults exhibiting a peak GH level of less than 5 ng/mL (5 mcg/L) after an ITT would warrant treatment.³⁴ In prepubertal children, measurement of IGF-I concentrations may be useful in evaluating GH deficiency, with 100% specificity and 70% to 90% sensitivity.³⁵ In children, the diagnosis of GH deficiency is further supported if height is more than 2 standard deviations below the population mean (age- and sex-matched).³¹ Failure of linear growth is an almost universal presenting feature of childhood GH deficiency.

Patient Care and Monitoring: Acromegaly

1. Assess the patient's clinical signs and symptoms to determine the severity of acromegaly.
2. Review the biochemical disease markers to assess the severity of acromegaly.
3. Review the available diagnostic data to determine pituitary tumor size and location. Determine if the patient has a coexisting prolactin secreting tumor. Determine if the tumor extends toward the optic chiasm or if it is continuous on the optic tracts.
4. Assess presence of acromegaly complications. Identify any significant comorbidities associated with acromegaly that require immediate treatment or early diagnosis.
5. Determine what treatment options the patient has tried in the past.
6. Evaluate patient for presence of surgical contraindications to transsphenoidal microsurgery. Determine if the patient is able or willing to undergo surgical intervention.
7. Develop a formal plan to assess patient's response and complications to surgical intervention. Measure both GH and IGF-I levels.
8. If surgical intervention does not achieve satisfactory disease control, select subsequent appropriate pharmacologic therapy based on patient-specific factors. In selecting therapy, be sure to consider if the patient has any contraindications or allergies to therapies.
9. Evaluate patient for presence of adverse drug reactions, drug allergies, and drug interactions.
10. Develop a plan to assess efficacy of pharmacologic therapy. Also consider if the patient's therapy requires any dose adjustments.
11. Assess biochemical markers annually once disease control is achieved.
12. Routinely assess acromegaly complications; include blood pressure, glucose tolerance, fasting lipid profile, cardiac evaluations (if clinically indicated), colonoscopy, dual-energy x-ray absorptiometry (DEXA) scan (hypogonadal only), evaluation of residual pituitary function and sleep apnea.
13. Provide patient education in regard to disease state, and nondrug and drug therapy. Discuss with the patient:
 - Possible complications of acromegaly
 - How to reduce the modifiable cardiovascular and metabolic risk factors
 - Potential effectiveness and disadvantages of existing treatment options
 - Importance of adherence to therapy
 - Potential adverse effects that may occur

Clinical Presentation and Diagnosis of Growth Hormone Deficiency in Children^{9,31}

General

The patient will have a physical height that is greater than 2 standard deviations below the population mean for a given age and gender.

Signs

- The patient will present with reduced growth velocity and delayed skeletal maturation.
- Children with GH-deficient or GH-insufficient short stature also may present with abdominal obesity, prominence of the forehead, and immaturity of the face.

Laboratory Tests

- Patients will exhibit a peak GH level of less than 10 ng/mL (10 mcg/L) after a GH stimulation test.
- Reduced IGF-I concentration also may be present.

- Because GH deficiency may be accompanied by the loss of other pituitary hormones, hypoglycemia and hypothyroidism also may be noted.

Other Diagnostic Tests

- Perform MRI or computed tomography (CT) scan of the hypothalamic–pituitary region to detect structural or developmental anomaly.
- Perform radiography of the left wrist and hand for children older than 1 year of age to estimate bone age (knee and ankle for children younger than 1 year of age).

Adapted from Sheehan AH, Yanovski JA, Calis KA. Pituitary gland disorders. In: Dipiro JT, Talbert RL, Yee GC, et al, eds. *Pharmacotherapy. A Pathophysiologic Approach*. 8th ed. New York: McGraw-Hill; 2011:1345–1360.

Childhood GH deficiency may or may not continue into adulthood. The use of insulin-induced hypoglycemia as a provocative GH stimulation test is currently the gold standard for diagnosing GH deficiency in adults.³⁷ Most adults with GH deficiency have overt pituitary disease and present with nonspecific clinical disorders distinct from pediatric GH deficiency. Adults with more than three pituitary hormone deficiencies and a low serum IGF-I level are considered GH deficient and do not require further GH stimulation test.³⁶ Additionally, adult GH deficiency presumably is associated with an increased risk of death from cardiovascular diseases.³⁷

► Treatment Goals

The goal of treatment for GH deficiency is to correct associated clinical symptoms.³¹ In children, prompt diagnosis and early initiation of treatment are important to maximize final adult height. In adults, efforts should be made to achieve normal physiologic GH levels in an attempt to reverse metabolic, functional, and psychological abnormalities.³³

► Pharmacologic Therapy

GH Therapy **6** *Recombinant GH therapy is the main pharmacologic treatment for GH deficiency in both children and adults.* It promotes skeletal, visceral, and general body growth; stimulates protein anabolism; and affects bone, fat, and mineral metabolism (see Table 46–1).² GH therapy requires subcutaneous or intramuscular administrations. Because two-thirds of GH secretion normally occurs during sleep, it is recommended to administer injections in the evening.³⁸ Many preparations of synthetic GH are available with a variety of injection devices to make administration more appealing and easier. Protropin (somatrem) and Tev-Tropin (somatropin) are approved by the Food and Drug Administration (FDA) for use in children, and other somatropin products such as

Nutropin, Nutropin AQ, Humatrope, Norditropin, Genotropin, Omnitrope, and Saizen are FDA approved in both children and adults.

7 *Although comparative trials have not been conducted to date, recombinant GH products appear to have similar efficacy for treating GH deficiency as long as the regimen follows currently approved guidelines.* GH secretion decreases with age. Therefore, older adults with GH deficiency often require substantially lower replacement doses than younger individuals. The optimal therapeutic approach is to initiate GH therapy at lower doses.³⁴ Table 46–4 lists the recommended GH replacement doses for children and adults.^{34,39} Conventional weight-based regimens are not recommended in adults because of a lack of evidence supporting higher dosages in heavier individuals and greater potential for adverse effects.^{33,37} Maintenance doses may be lower with chronic GH therapy.⁴⁰ For elderly patients, lower GH replacement doses often are adequate because of increased GH sensitivity.^{33,34} Women with intact hypothalamic–pituitary–gonadal axis or on estrogen therapy (or oral contraceptives) generally require a higher GH dose than men.³⁴ Carefully monitor patients requiring replacement therapy with estrogens, thyroid hormones, or glucocorticoids because of potential interactions with GH therapy.³³ Monitor patients at 1- to 2-month intervals and titrate replacement doses in increments of 0.1 to 0.2 mg/day based on individual clinical and biochemical responses.³⁴ The conversion of international units (IU or mU) to milligram is a 3:1 ratio.³¹ Selection of an injection device depends on patient preference because there is currently no difference in clinical outcomes among the various injection systems.^{34,39}

Evidence has suggested that GH treatment in GH-deficient children can increase short-term growth and improve final adult height.³¹ Beneficial effects of GH therapy in adults with GH deficiency have been demonstrated in subsequent studies to normalize body composition and metabolic process;

Clinical Presentation and Diagnosis of Growth Hormone Deficiency in Adults^{33,36–38}

General

The patient likely will have a history of childhood-onset GH deficiency; hypothalamic or pituitary disorder; or the presence of three or four other pituitary hormone deficiencies caused by head trauma, tumor, infiltrative diseases, surgery, or radiation therapy.

Symptoms

- Reduced strength and exercise capacity
- Defective sweating
- Psychological problems
- Low self-esteem
- Depression
- Fatigue or listlessness
- Sleep disturbance
- Anxiety
- Social isolation
- Emotional lability and impaired self-control
- Poor marital and socioeconomic performance

Signs

- Increased fat mass (especially abdominal obesity)
- Reduced lean body mass

- Reduced muscle strength
- Reduced exercise performance
- Thin, dry skin; cool peripheries; poor venous access
- Depressed affect, labile emotions
- Impaired cardiac function as evidenced by abnormal echocardiography or stress test results

Laboratory Tests

- Patients will exhibit a peak GH level of less than 5 ng/mL (5 mcg/L) after a GH stimulation test. Insulin tolerance test (ITT) is the gold standard stimulation test. Low or low-normal IGF-I level also may be present. Presence of three or more pituitary hormone deficiencies with a low IGF-I level do not require further stimulation test.
- Increased low-density lipoprotein cholesterol, total cholesterol, triglycerides; decreased high-density lipoprotein cholesterol.
- Reduced bone mineral density associated with an increased risk of fracture.
- Increased insulin resistance and increased prevalence of impaired glucose tolerance.
- GH deficiency may be accompanied by the loss of other pituitary hormones.

Table 46-4

Dose Recommendations for Growth Hormone Deficiency in Children and Adults^{34,39}

	Growth Hormone Replacement Dose	Dose Titration
Children ³⁹	Dosing Range	<ul style="list-style-type: none"> • Evaluate every 3–6 months based on height and height velocity. • Monitor IGF-I and IGFBP-3 yearly. • Monitor TSH and T₄ for hypothyroidism. • Reduce dose if serum IGF-I level is substantially above normal after 2 years of therapy.
Prepubertal children Adolescents	25–50 mcg/kg/day 25–100 mcg/kg/day	
Adults ³⁴	Starting Dose	<ul style="list-style-type: none"> • Increase dose by 0.1–0.2 mg/day based on clinical response, serum IGF-I levels, and side effects at 1- to 2-month intervals. Longer time intervals and smaller dose titration may be necessary in older adults. • Clearance may be reduced in patients with severe hepatic dysfunction; specific dosing suggestions are not available. • Patients with chronic renal failure tend to have decreased clearance; specific dosing suggestions are not available.
Age less than 30 years	0.4–0.5 mg/day ^a	
Age 30–60 years	0.2–0.3 mg/day	
Age greater than 60 years	0.1–0.2 mg/day	
Diabetes or glucose intolerance (overweight, obese, or history of gestational diabetes)	0.1–0.2 mg/day	
Hepatic impairment	—	
Renal impairment	—	

^aMight require a higher dose for patients transitioning from pediatric treatment.

IGFBP-3, insulin-like growth factor-bind protein 3; IGF-I, insulin-like growth factor-I; T₄, thyroxine; TSH, thyroid-stimulating hormone.

improve cardiac risk profile, bone mineral density, quality of life, and psychological well-being; and increase muscle strength and exercise capacity.³⁷ Although long-term efficacy of GH replacement in adults has been demonstrated in a 10-year prospective study,⁴⁰ overall reduction in mortality with GH therapy remains to be established.

Practitioners should begin GH therapy as soon as possible to optimize long-term growth, especially for young children in whom GH deficiency is complicated by fasting hypoglycemia.³¹ Selection of the optimal GH replacement dose will need to be individualized depending on response, financial resources, and product availability. Although the appropriate time to discontinue therapy remains controversial in childhood GH deficiency, it is reasonable to continue GH replacement until the child has reached satisfactory adult height, achieved documented epiphyseal closure, or failed to respond to therapy.³¹ Management of the transition between pediatric and adult GH replacement remains a challenge because limited data are available. For patients in a transition phase who may be restarting GH therapy, the initial dose is approximately half of the pediatric and adult doses combined.³⁴ Starting GH therapy at a low dose and gradually titrating upward may decrease the potential for adverse effects. The optimal duration of treatment with GH therapy remains unclear, but lifelong therapy may be required. However, GH replacement should be discontinued if therapeutic benefit is not achieved after 2 years of therapy.³⁴

In both children and adults, treatment with GH may mask underlying central hypothyroidism and adrenal insufficiency.⁴¹ Treatment with GH also may induce insulin resistance and lead to the development of glucose intolerance in patients with preexisting risk factors. Adults are more susceptible to dose-related adverse effects of GH-induced symptoms, such as edema, arthralgia, myalgia, and carpal tunnel syndrome, which may necessitate dose reductions in up to 40% of adults.

Children treated with GH replacement therapy rarely experience significant adverse effects. Benign increases in intracranial pressure related to GH therapy may manifest as headaches, visual changes, or altered levels of consciousness. This condition is generally reversible upon discontinuation of treatment. Often, GH therapy can be restarted with smaller doses without symptom recurrence. In rapidly growing children, a slipped capital femoral epiphysis may occur when the femoral head shifts in a backward direction in relation to the femoral shaft.³⁹ There is no evidence that this problem is caused by GH therapy, but any child who experiences a change in gait during treatment should be evaluated by an orthopedic surgeon.³⁹ Presently, there is no compelling evidence that GH replacement therapy is associated with an increased risk of leukemia, solid tumor, or tumor recurrence.^{31,33,34} GH replacement therapy is contraindicated in all patients with active malignancy.³⁴ However, in children with a history of malignancies, it would be prudent to wait for a 1-year tumor-free period (5 years for adults) before initiating GH therapy.³¹ Any patients treated for a prior malignancy may be at risk for a second malignancy and should be monitored carefully for tumor recurrence.³¹ Other rare findings associated with GH replacement therapy include

breast development, pancreatitis, juvenile osteochondritis (inflammation of a bone and its cartilage), worsening of scoliosis, and increased pigmentation.³⁹ Because deaths have been reported with use of GH in children with Prader-Willi syndrome who are severely obese or suffer from respiratory impairments, use of GH is contraindicated in these individuals. The ongoing multinational safety surveillance study (Safety and Appropriateness of Growth hormone treatments in Europe [SAGhE]) should provide important information on the long-term safety of GH replacement in children.⁴²

Insulin-Like Growth Factor-I Therapy Mecasermin (Increlex) is the only recombinant IGF-I replacement therapy for the treatment of growth failure in children with severe primary IGF-I deficiency or with GH gene deletions who have developed neutralizing antibodies to GH. This product has not been evaluated in patients with GH deficiency aside from those with genetic abnormalities.

► Outcome Evaluation

- Children with GH deficiency should be evaluated by a pediatric endocrinologist every 3 to 6 months. Monitor for an increase in height and change in height velocity to assess response to GH therapy.^{31,39} Every effort should be made to maximize height before the onset of puberty. After final adult height is reached and GH is discontinued for at least 1 month, retest and reevaluate the patient using the adult GH-deficiency diagnostic criteria.^{34,39}
- Assess patients with scoliosis for further curvature of the spine.
- Although GH and IGF-I levels do not always correlate with growth response, measure IGF-I levels yearly to assess adherence to therapy and patient response. If the IGF-I levels are substantially above the normal range 2 years after GH replacement therapy, the dose should be reduced.³⁹ IGF-I level may be used as a guide to gradually reduce replacement dose after epiphyseal closure.
- Routine monitoring of fasting lipid profile, bone mineral density, and body composition in children is not typically required during GH replacement but should be done before and after discontinuation of therapy.^{31,39}
- In adults, measurement of serum IGF-I, along with careful clinical evaluation, appears to be the most reliable way to assess the appropriateness of the GH dose. Measure IGF-I serum concentrations annually and 6 weeks after dosage adjustments.³⁷
- Continuously monitor for dose-related adverse effects such as edema, arthralgia, myalgia, and carpal tunnel syndrome.
- Evaluate psychological well-being. Assess patients' bone mineral density every 2 to 3 years.³⁴
- When maintenance therapy is achieved, assess body composition (body mass index [BMI], waist circumference, waist-to-hip ratio), metabolic status (fasting glucose level, free thyroxine serum, hemoglobin A1c), cardiac risk factors

Patient Care and Monitoring: GH Deficiency in Children

1. Assess the child's growth characteristics and compare the physical height with a population standard (e.g., Centers for Disease Control and Prevention Growth Charts).
2. Obtain a thorough history and physical examination that may indicate the possible presence of GH deficiency. Exclude other identifiable causes of growth failure, such as hypothyroidism, chronic illness, malnutrition, genetic syndromes, and skeletal disorders.
3. Perform imaging tests of the hypothalamic–pituitary region to detect structural or developmental anomalies. Perform radiography of the wrist and hand to estimate bone age.
4. Perform a provocative test to measure GH and IGF-I levels.
5. Initiate GH replacement therapy based on patient preference. Make sure that the child does not have any contraindications to GH therapy.
6. Develop a formal plan to assess response (increase in height and change in height velocity) and adverse effects of GH replacement therapy. Make dosage adjustments when appropriate.
7. May continue GH replacement therapy until child reaches satisfactory adult height, achieves documented epiphyseal closure, or fails to respond to treatment.
8. Review and retest the child using adult GH deficiency diagnostic criteria when the child reaches final adult height.
9. Provide patient education in regard to disease state and drug therapy. Discuss with the child and parents:
 - GH deficiency
 - Potential effectiveness and disadvantages of existing GH replacement therapy
 - Importance of adherence to therapy
 - Potential for adverse effects or need for lifelong replacement

Patient Care and Monitoring: GH Deficiency in Adults

1. Assess the patient's clinical signs and symptoms to determine the severity of GH deficiency.
2. Perform a provocative test to measure GH levels.
3. Evaluate the patient for the presence of metabolic abnormalities and cardiovascular and fracture risks.
4. Initiate GH replacement therapy based on patient preference. Make sure the patient does not have any contraindications to GH therapy.
5. Develop a plan to assess the efficacy and adverse effects of GH therapy and consider if the patient's therapy requires any dose adjustments based on IGF-I level, patient response, and adverse effects.
6. Provide patient education in regard to disease state and drug therapy. Discuss with the patient:
 - Possible complications of GH deficiency
 - How to reduce the modifiable cardiovascular and metabolic risk factors
 - Potential disadvantages and effectiveness of existing GH replacement therapy
 - Importance of adherence to therapy
 - Potential for adverse effects or need for lifelong replacement

(e.g., fasting lipid profile), hypothalamic–pituitary–adrenal axis function (e.g., morning serum cortisol response to ACTH stimulation), and testosterone concentrations at 6- to 12- month intervals.^{33,34}

conditions, secretion of prolactin is predominantly under inhibitory control by dopamine, which acts on the D₂ receptors located on the lactotroph cells. Increases of hypothalamic thyrotropin-releasing hormone in primary hypothyroidism can stimulate the release of prolactin.

PROLACTIN

Prolactin is an essential hormone for normal production of breast milk after childbirth. It also plays a pivotal role in a variety of reproductive functions. Prolactin is regulated primarily by the hypothalamus–pituitary axis and secreted solely by the lactotroph cells of the anterior pituitary gland. Under normal

Hyperprolactinemia

► Epidemiology and Etiology

Hyperprolactinemia affects women of reproductive age more than men. Although this disorder occurs in less than 1% of the general population, the estimated prevalence in

Table 46–5

Causes of Hyperprolactinemia^{9,32,43–46}**Physiologic Causes**

Pregnancy
 Stress (including exercise and hypoglycemia)
 Breast stimulation
 Breastfeeding
 Coitus
 Sleep
 Meal

Increased Prolactin Production

Ovarian: polycystic ovarian syndrome
 Oophorectomy (removal of an ovary)
 Pituitary tumors
 Adenomas
 Microprolactinoma (less than 10 mm diameter)
 Macroprolactinoma (greater than or equal to 10 mm diameter)
 Hypothalamic stalk interruption (prevent dopamine from reaching the pituitary)
 Hypophysitis (inflammation)
 Ectopic tumors

Hypothalamic Prolactin Stimulation

Primary hypothyroidism
 Adrenal insufficiency

Reduced Prolactin Elimination

Chronic renal failure
 Hepatic cirrhosis

Neurogenic Causes

Chest wall injury (e.g., surgery, herpes zoster)
 Spinal cord lesions

Abnormal Molecules

Macroprolactinemia

Medications

Dopamine antagonists: antipsychotics^a, phenothiazines, metoclopramide, domperidone
 Dopamine-depleting agents: reserpine, *α*-methyl dopa
 Prolactin stimulators: serotonin reuptake inhibitors, dexfenfluramine, estrogens; progestins, antiandrogens, gonadotropin-releasing hormone analogs, benzodiazepines, tricyclic antidepressants, monoamine oxidase inhibitors, protease inhibitors, histamine₂ receptor antagonists
 Other: isoniazid, cocaine, opioids, verapamil

Seizures**Idiopathic (Unknown)**

^aAtypicals (olanzapine and clozapine) other than risperidone may cause an early but transient elevation in prolactin.³²

Adapted in part, with permission, from Sheehan AH, Yanovski JA, Calis KA. Pituitary gland disorders. In: Dipro JT, Talbert RL, Yee GC, et al, eds. *Pharmacotherapy. A Pathophysiologic Approach*. 8th ed. New York: McGraw-Hill; 2011:1345–1360.

women with reproductive disorders (e.g., amenorrhea) is as high as 15% to 43%.⁴³ The etiologies of hyperprolactinemia are presented in **Table 46–5**.^{9,32,43–46} Any medications that antagonize dopamine or stimulate prolactin release can induce hyperprolactinemia.^{9,32,43,44} Therefore, it is important to exclude medication-induced hyperprolactinemia from other common causes such as pregnancy, primary hypothyroidism, benign prolactin-secreting pituitary adenoma (prolactinoma), and renal insufficiency. Prolactinomas are

the most common pituitary tumors. They are classified as microprolactinomas if they are less than 10 mm in diameter and as macroprolactinomas if they are 10 mm or larger in diameter.⁴⁴ In general, microprolactinomas rarely increase in size, but macroprolactinomas have the potential to enlarge and invade the surrounding tissues.⁴⁷

▶ Pathophysiology

Hyperprolactinemia is a condition of elevated serum prolactin. It is the most common endocrine disorder of the hypothalamic–pituitary axis. High prolactin levels inhibit the release of gonadotropin-releasing hormone by the hypothalamus and subsequently suppress secretion of LH and FSH from the anterior pituitary. High prolactin levels result in reduced gonadal hormone levels, often leading to reproductive dysfunction and galactorrhea (inappropriate breast milk production).

In combination with clinical symptoms, one or more serum prolactin concentrations greater than 25 ng/mL (25 mcg/L) will confirm the diagnosis of hyperprolactinemia in women.⁴⁵ A number of physiologic factors such as eating, exercise, and stress can transiently elevate prolactin levels.⁹ Therefore, prolactin measurements should be obtained at rest, preferably in the morning under fasting conditions.⁴³ If an intravenous line is present or planned, it is prudent to wait at least 2 hours after line insertion before measuring serum prolactin to decrease detecting transient physiologic increases in prolactin level (see **Table 46–5**).^{9,32,43–46} Although medication-induced hyperprolactinemia is typically associated with prolactin concentrations of 25 to 100 ng/mL (25 to 100 mcg/L), metoclopramide, risperidone, and phenothiazines have been associated with concentrations greater than 200 ng/mL (200 mcg/L). Prolactin concentrations greater than 250 ng/mL (250 mcg/L) are almost always associated with the presence of a macroprolactinoma.⁴⁵

▶ Treatment Goals for Hyperprolactinemia

Because hyperprolactinemia is often associated with hypogonadism, the goals for management of hyperprolactinemia are to correct the clinical consequences of hypogonadism and reduce its associated risk for osteoporosis, as follows⁴⁶:

- Normalize prolactin level.
- Improve clinical symptoms.
- Restore normal fertility.
- Restore and maintain normal gonadal function.
- Protect against the development of osteoporosis.
- Prevent disease recurrence.
- If a pituitary tumor is present:
 - Ablate or reduce tumor size to relieve tumor mass effect.
 - Preserve normal pituitary function.
 - Prevent progression of pituitary tumor or hypothalamic disease.

Clinical Presentation and Diagnosis of Hyperprolactinemia^{9,44,46}

General

Hyperprolactinemia most commonly affects women of reproductive age and is very rare in men.

Signs and Symptoms

Premenopausal women

- Headache and compromised or loss of vision caused by the prolactin-secreting tumor and its close proximity to the optic structures.
- Clinical presentation is associated with the degree of prolactin elevation:
 - Prolactin greater than 100 ng/mL (100 mcg/L): hypogonadism, galactorrhea, and amenorrhea
 - Prolactin 51 to 75 ng/mL (51 to 75 mcg/L): **oligomenorrhea** (infrequent menstruation)
 - Prolactin 31 to 50 ng/mL (31 to 50 mcg/L): decreased libido and infertility
- Increased body weight may be associated with a prolactin-secreting pituitary tumor.
- The degree of hypogonadism generally is proportionate to the degree of prolactin elevation.
- Excessive hair growth (hirsutism) and acne also may be present owing to relative androgen excess compared with low estrogen levels.

Men

- Decreased libido, decreased energy, erectile dysfunction, impotence, decreased sperm production, infertility, gynecomastia, and rarely, galactorrhea.
- Impotence is unresponsive to treatment and is associated with reduced muscle mass, loss of pubic hair, and osteoporosis.

Laboratory Tests

- Prolactin serum concentrations at rest will be greater than 20 ng/mL (20 mcg/L) in men or 25 ng/mL (25 mcg/L) in women with at least three measurements.
- Obtain β -human chorionic gonadotropin (β -hCG) level to exclude pregnancy.
- Obtain TSH level to exclude primary hypothyroidism.
- Obtain blood urea nitrogen and serum creatinine tests to exclude renal failure.

Other Diagnostic Tests

- Perform MRI to locate the tumor, exclude a pseudo-prolactinoma, and validate the diagnosis.
- Consider a bone mineral density test in patients with long-term hypogonadism.

Additional Clinical Sequelae

- The prolonged suppression of estrogen in premenopausal women with hyperprolactinemia leads to decreases in bone mineral density and significant risk for the development of osteoporosis.
- Risk for ischemic heart disease may be increased with untreated hyperprolactinemia.

Adapted, with permission, from Sheehan AH, Yanovski JA, Calis KA. Pituitary gland disorders. In: Dipiro JT, Talbert RL, Yee GC, et al, eds. *Pharmacotherapy. A Pathophysiologic Approach*. 8th ed. New York: McGraw-Hill; 2011:1345–1360.

► General Approaches to Treatment

Management of drug-induced hyperprolactinemia is to discontinue the offending agent, if clinically feasible, and replace it with an appropriate alternative that does not cause hyperprolactinemia.⁴⁵ When the offending agent cannot be discontinued, cautious use of hormone replacement, bisphosphonate therapy, or dopamine agonists may be considered depending on the patient's clinical circumstances.⁴⁸ Treatment options for the management of hyperprolactinemia include (a) clinical observation, (b) pharmacologic therapy with dopamine agonists, (c) transsphenoidal pituitary adenomectomy, and (d) radiation therapy. Clinical observation and close monitoring are justifiable in patients with asymptomatic elevation of prolactin.⁴⁵ **8** *Dopamine agonists are the first-line treatment of choice for all patients with symptomatic hyperprolactinemia; transsphenoidal surgery and radiation therapy are reserved for patients who are resistant to or severely intolerant of pharmacologic therapy.*⁴⁷

However, in patients with underlying psychiatric symptoms, use of dopamine agonists in addition to an antipsychotic therapy may exacerbate the underlying psychosis and should be used with caution in consultation with a mental health clinician.³²

Pharmacologic Therapy Dopamine is the principal neurotransmitter responsible for the inhibition of prolactin secretion from the anterior pituitary. Thus, dopamine agonists are the main pharmacologic therapy used for management of hyperprolactinemia.⁴⁵ Treatment with dopamine agonists has proven to be extremely effective in normalizing serum prolactin level, restoring gonadal function, decreasing tumor size, and improving visual fields.⁴⁵ Patients with macroprolactinomas generally require a higher dose to normalize prolactin levels compared with patients with microprolactinomas.⁴⁹

Two dopamine agonists—bromocriptine and cabergoline—are used for the management of hyperprolactinemia

Table 46-6

Comparison of Dopamine Agonists for Treatment of Hyperprolactemia^{43,50}

	Bromocriptine (Parlodel)	Cabergoline
Starting dose	0.625–1.25 mg/day at bedtime	0.5 mg/week or 0.25 mg twice/week
Titrating dose	1.25 mg increments at 1-week interval	0.5 mg increment at 4-week intervals
Usually effective dose	2.5–15 mg/day	1–2 mg/week
Maximal dose	40 mg/day	4.5 mg/week
Dosing frequency	2–3 divided doses per day	Once or twice weekly
Dosage in hepatic insufficiency	May be required in acute hepatitis or cirrhosis; no guidelines are available	Dose reductions may be recommended for patients with severe hepatic failure (Child-Pugh scores of 10 or higher)
Dosage in renal failure	None	None
Adverse effects	Dizziness, headache, syncope, nausea, vomiting, GI cramps, orthostatic hypotension, nasal congestion	Similar but orthostatic hypotension less common
Cost	Moderately expensive	More expensive

GI, gastrointestinal.

(Table 46-6).^{43,50} Because these two dopamine agonists are ergot derivatives, they are contraindicated in combination with potent cytochrome P-450 subfamily IIIA polypeptide 4 (CYP3A4) inhibitors, including protease inhibitors (e.g., ritonavir and indinavir), azole antifungals (e.g., ketoconazole and itraconazole), and some macrolide antibiotics (e.g., erythromycin and clarithromycin). Furthermore, ergot derivatives can cause constriction of peripheral and cranial blood vessels. These medications are also contraindicated in patients with uncontrolled hypertension, severe ischemic heart disease, or peripheral vascular disorders. Caution should be exercised with concomitant use of other ergot derivatives and in patients with impaired renal or hepatic function; dementia; concurrent antihypertensive therapy; or a history of psychosis, peptic ulcer disease, or cardiovascular disease.

Bromocriptine Bromocriptine directly binds to the D₂ receptors on the lactotroph cells to exert its effect. Bromocriptine normalizes prolactin level in more than 90% of patients, restores menstrual cycles, and reduces tumor size in 62% of patients.⁴³ Adverse effects such as nausea, dizziness, and orthostatic hypotension often limit 5% to 10% of patients from continuing treatment. To reduce risk of adverse effects, start bromocriptine at a low dose (e.g., 0.625 to 1.25 mg) at bedtime (taken with a snack) to decrease adverse effects.⁴⁷ Slowly titrate up to the optimal therapeutic dose (2.5 to 15 mg/day) because most adverse effects subside with continual treatment.⁴⁹ In women, if the adverse GI effects are not tolerable, bromocriptine can be administered vaginally at a reduced dose (2.5 mg/day).⁵¹ Owing to its short half-life of only 6 hours, bromocriptine must be administered in divided doses, which may compromise patient adherence.

Cabergoline Cabergoline has a higher affinity for D₂ receptors than bromocriptine. It is a long-acting dopamine agonist capable of inhibiting pituitary prolactin secretion for at least 7 days after a single oral dose.⁵⁰ The prolonged duration of action allows for once- or twice-weekly administration. Cabergoline appears to be significantly better tolerated than bromocriptine.⁴³ Transient elevations of serum alkaline

phosphatase, bilirubin, and aminotransferases have been reported in a few patients treated with cabergoline. Cabergoline is more effective in normalizing prolactin levels and restoring menses than bromocriptine.⁵⁰ It also may be effective in treating hyperprolactinemia in patients who are resistant to or intolerant of bromocriptine and in men and women with micro- and macroprolactinomas.⁴³ Given its favorable safety and efficacy profile and ease of administration, cabergoline has replaced bromocriptine as first-line therapy for the management of hyperprolactinemia.⁴⁵ Withdrawal of pergolide from the U.S. market due to increased risk for valvular heart disease raised concerns about the safety of cabergoline. In patients with prolactinomas, tricuspid regurgitation was associated with higher cabergoline cumulative dose of more than 280 mg.⁵² However, recent studies suggest the lower doses of cabergoline commonly used in the management of hyperprolactinemia do not appear to increase the risk of clinically significant valvular heart diseases.^{53,54}

► Nonpharmacologic Therapy

- In a small number of patients who have failed or are intolerant of dopamine agonists, transsphenoidal adenomectomy may be necessary.⁴⁵ Surgical treatment is also considered in patients with nonprolactin-secreting tumors or macroprolactinomas that jeopardize the optic chiasm.⁴⁴ Nonetheless, surgical intervention does not reliably lead to long-term cure and may cause permanent complications.⁴⁶ Radiation therapy is reserved for failures of both pharmacologic therapy and surgery.⁴⁴ However, normalization of prolactin levels with radiation therapy may take 20 years to show full benefit, and radiation-induced hypopituitarism may require lifelong hormone replacement.⁴⁵

► Management of Hyperprolactinemia in Pregnancy

Most women with hyperprolactinemia require dopamine agonist therapy to achieve regular ovulatory cycles and pregnancy. Because restoration of the ovulatory cycle may

Patient Encounter 2: Hyperprolactinemia: Medical History, Physical Examination, and Diagnostic Tests

PR is a 23-year-old woman who presents to the primary care clinic with complaints of irregular menstruation and milky fluid discharge from both breasts for a few months. Her last menstrual period was 3 weeks ago.

PMH: Schizophrenia for 5 years, major depression for 6 years

FM: Mother has severe depression. Father, deceased, had an “unknown” mental illness and myocardial infarction at age 45.

SH: Single college student; sexually active (occasional use of condoms)

Meds: Sertraline 200 mg once daily; risperidone 8 mg once daily; ibuprofen 200 mg two tablets every 4 to 6 hours as needed for mild headaches and menstrual cramps

ROS: Negative, other than in history of present illness

PE:

HEENT: Ophthalmic examination reveals normal visual acuity and fields. (–) goiter

VS: BP 112/70 mm Hg, P 72 beats/min, RR 19 breaths/min, T 37.1°C (98.8°F)

CV: RRR, normal S₁, S₂; no murmurs, rubs, or gallops

Breasts: (+) bilateral expressible galactorrhea with no other abnormality

Abd: Soft, nontender, nondistended; (+) bowel sounds; (–) hepatosplenomegaly

Rectal: Heme (–) stool

Labs: Electrolytes, renal and thyroid function, FSH, LH, and testosterone are within normal limits. Elevated prolactin at 89 ng/mL (89 mcg/L)

Imaging: MRI did not reveal a pituitary tumor

Given this information, what signs and symptoms does PR have for hyperprolactinemia?

What other laboratory test would also be appropriate to obtain based on the patient's history and diagnosis?

What are other potential causes of hyperprolactinemia in this patient?

Identify your treatment goals for PR.

What nonpharmacologic and pharmacologic treatment options are available for PR?

occur within 1 week of initiating therapy, it is necessary to caution patients regarding their potential to become pregnant.⁵⁵

Overall, there is reassuring worldwide evidence that bromocriptine use during pregnancy does not increase fetal malformations, spontaneous miscarriage, ectopic pregnancy, or multiple births.^{43,47} Furthermore, no teratogenic effects have been reported in women who received cabergoline during pregnancy.^{47,56} Despite these data, **9** *women who become pregnant while taking a dopamine agonist should discontinue treatment immediately to minimize fetal exposure.⁴⁵ Because cabergoline has a prolonged half-life, women who plan to become pregnant should discontinue the drug at least 1 month before planned conception.⁵⁰*

Microadenomas rarely cause complications during pregnancy. However, untreated macroprolactinomas carry about a 31% risk of tumor enlargement and potentially can jeopardize vision.⁴⁵ Therefore, monitor female patients with macroprolactinomas closely for the development of headache and visual impairments. Baseline and routine visual field examinations are essential. Evidence of abnormal visual fields may indicate tumor growth and should be followed by an MRI. If tumors enlarge, bromocriptine is the preferred choice over cabergoline because of greater experience with this drug during pregnancy.^{45,47}

Outcome Evaluation

- Assess patients for tolerability to dopamine agonists.
- Monitor clinical symptoms associated with hyperprolactinemia every month for the first 3 months
- to assess therapeutic efficacy and assist with dose titration.
- Evaluate the patient for symptoms, such as headache, visual disturbances, menstrual cycles in women, and sexual function in men, to assess clinical response to therapy.⁴⁵
- When the prolactin level is normalized and clinical symptoms of hyperprolactinemia have resolved, monitor prolactin level every 6 to 12 months.^{46,49}
- If the prolactin level is well controlled with dopamine agonist therapy for 2 years with significant tumor reduction, gradually taper therapy to the lowest effective dose or consider discontinuing therapy.⁴⁵ Check prolactin levels after each dose reduction.
- If the prolactin levels remain unchanged for 1 year at the reduced dose, dopamine agonist therapy may be discontinued.
- It is essential to monitor prolactin levels every 6 months or annually to detect the possibility of permanent remission of pituitary disease.⁴⁶
- The need to continue dopamine agonists in postmenopausal women with microprolactinomas must be reassessed because these patients have a higher probability of maintaining normal prolactin levels after treatment is discontinued.⁴⁴
- In patients with macroprolactinomas, monitor visual field at baseline and repeat the test 1 month after initiation of a dopamine agonist.

Patient Care and Monitoring: Hyperprolactinemia

1. Assess the patient's clinical signs and symptoms of hyperprolactinemia.
 2. Review the available diagnostic data to determine severity and exclude other common causes of hyperprolactinemia.
 3. Obtain a thorough medication history to exclude medication-induced hyperprolactinemia.
 4. Determine the patient's plan regarding pregnancy because this influences treatment.
 5. Educate the patient about safety and efficacy of dopamine agonists. Make sure the patient does not have any contraindications or allergies to drug therapies.
 6. Develop a formal plan to assess response and adverse effects of dopamine agonists. When appropriate, be sure to make dose adjustments.
 7. If the prolactin level remains normal for 2 years, reassess the need to continue treatment. Make sure the patient is taking the lowest effective dose for management of hyperprolactinemia.
 8. Provide patient education in regard to disease state and nondrug and drug therapy. Discuss with the patient:
 - Risk factors associated with hyperprolactinemia
 - Potential disadvantages and effectiveness of existing dopamine agonist therapy
 - Potential disadvantages and effectiveness of surgery and radiation treatment
 - Importance of adherence to therapy
 - Potential for adverse effects or long-term complications
- Repeat the MRI 6 months after initiating therapy or if an increase in symptoms or rise in prolactin levels suggests the presence of tumor growth.⁴⁹
 - Discontinuation of therapy in patients with macroprolactinomas usually leads to tumor regrowth and recurrence of hyperprolactinemia. This decision warrants careful consideration.

Abbreviations Introduced in This Chapter

AACE	American Association of Clinical Endocrinologists
ACTH	Adrenocorticotrophic hormone or corticotropin
ADH	Antidiuretic hormone
β -hCG	β -Human chorionic gonadotropin
BMI	Body mass index
CRH	Corticotropin-releasing hormone
CT	Computed tomography
CYP3A4	Cytochrome P-450 subfamily IIIA polypeptide 4
DA	Dopamine agonist
DEXA	Dual-energy x-ray absorptiometry
ECG	Electrocardiography
FDA	Food and Drug Administration
FSH	Follicle-stimulating hormone
GABA	γ -Aminobutyric acid
GH	Growth hormone or somatotropin
GHIH	Growth hormone-inhibiting hormone or somatostatin
GHRH	Growth hormone-releasing hormone
GI	Gastrointestinal
GHAnt	Growth hormone antagonist
GnRH	Gonadotropin-releasing hormone
HbA _{1c}	Glycated hemoglobin A _{1c}
IGF	Insulin-like growth factor
IGF-I	Insulin-like growth factor-I
IGF-II	Insulin-like growth factor-II

IGFBP-3	Insulin-like growth factor-bind protein-3
IM	Intramuscularly
ITT	Insulin tolerance test
LAR	Long-acting release
LH	Luteinizing hormone
LHRH	Luteinizing hormone-releasing hormone
MRI	Magnetic resonance imaging
MSH	Melanocyte-stimulating hormone
OGTT	Oral glucose tolerance test
PRH	Prolactin-releasing hormone
RT	Radiation therapy
SAGhE	Safety and Appropriateness of Growth hormone treatments in Europe
SC	Subcutaneous
SR	Slow release
SSA	Somatostatin analog
SSRI	Selective serotonin reuptake inhibitor
T ₃	Triiodothyronine
T ₄	Thyroxine
TRH	Thyrotropin-releasing hormone
TSH	Thyroid-stimulating hormone or thyrotropin

Pregnancy and Lactation: Therapeutic Considerations

Ema Ferreira, Évelyne Rey, and Caroline Morin

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Explain the principles of embryology and teratology.
2. Identify known teratogens and drugs of concerns during lactation.
3. Compare the main sources of drug information during pregnancy and lactation.
4. Evaluate the risks of a drug when taken during pregnancy or lactation.
5. Apply a systematic approach to counseling on the use of drugs during pregnancy and lactation.
6. Recommend the appropriate dose of folic acid to prevent congenital anomalies.
7. Describe physiologic changes during pregnancy and their impact on pharmacokinetics.
8. Choose an appropriate treatment for common conditions in a pregnant or lactating woman.

KEY CONCEPTS

- 1 Although the risk of drug-induced teratogenicity is of concern, the actual risk of birth defects from most drug exposures is small.
- 2 Health professionals should know which medications could be teratogenic or of concern during breast-feeding.
- 3 The risk of birth defects is most often higher during organogenesis.
- 4 Counsel all women of childbearing age on the use of folic acid–containing multivitamins to prevent congenital anomalies.
- 5 Most drugs are safe during breast-feeding.
- 6 When possible, treat conditions occurring during pregnancy with nonpharmacologic treatments instead of drug therapy.
- 7 Evaluate the need for treatment, including benefits and risks. Avoid treatments that do not show evidence of benefit or that can be delayed until after pregnancy or breast-feeding.

Medication use during pregnancy and lactation is a challenge for health professionals, as pregnant and breast-feeding women are usually excluded from clinical trials. Therefore, it is important to know on which information sources to rely, how to interpret the data retrieved from these sources, and how to communicate this

information to patients. This chapter reviews the available resources that help to guide therapy, general strategies to reduce risks of drug use in pregnant and lactating women, and specific recommendations for some common conditions treated during pregnancy and lactation.

EPIDEMIOLOGY AND ETIOLOGY

Use of Medications During Pregnancy and Lactation

Studies conducted in the United States have estimated that at least two-thirds of pregnant women take medications during pregnancy.^{1,2} Moreover, since approximately one-half of pregnancies are unplanned, many women are exposed to medications before being aware of their pregnancy.³

The most popular medications are vitamins and minerals, analgesics, antacids, antibiotics, antiemetics, laxatives, asthma medication, cold and flu medications, and medications for topical administration (e.g., antifungals, antibiotics, corticosteroids).^{1,2}

One study from the Netherlands indicates that 65.9% of breast-feeding women took at least one medication (53% after exclusion of vitamins and minerals) over a 6-month period.⁴

► Background Risks of Anomalies in Pregnancy

Table 47-1 describes the baseline risks of congenital anomalies and some obstetrical complications observed in the general

Patient Encounter, Part 1

MM, a 39-year-old woman, comes to your office after a positive urine pregnancy test. You collect the following data:

Estimated gestational age: Not sure, irregular menstrual cycles

PMH: Infertility, obesity, type 2 diabetes, no previous pregnancies

FH: Diabetes, hypertension, hypothyroidism

SH: Unemployed; cigarettes, one-half pack daily; no alcohol or illicit substances

Meds: Metformin 500 mg orally twice daily, atorvastatin 20 mg daily, ramipril 2.5 mg daily; all discontinued 1 week ago

Allergy: Eggs, penicillin

ROS: Morning nausea with daily vomiting; tiredness; dizziness; abdominal bloating

VS: Weight: 198 lb (90 kg)/height: 63 inches (160 cm), BP 130/85 mm Hg, P 90 bpm, RR 12; slight enlargement of thyroid;

Last week blood glucose results between 144 to 198 mg/dL (8.0 to 11.0 mmol/L) before meals.

How will you estimate gestational age?

What prenatal screening would you perform at this time?

What is the appropriate counseling to do at this time?

What are the risks of drugs taken in the first weeks of pregnancy? What resources will you use to find the appropriate information?

What do you recommend for her pharmacologic treatment?

population. This will be important when evaluating the risks associated with drugs and in order to counsel pregnant women.

► Causes of Congenital Anomalies

1 Although the risk of drug-induced teratogenicity is of concern, the actual risk of birth defects from most drug exposures is small. Medications are associated with fewer than 1% of all congenital anomalies, although they may play a more important role through interaction with genetic factors. Because it is a modifiable cause of anomalies, it is important to evaluate and manage drug use in pregnant women and women planning a pregnancy. 2 Health professionals should know which medications could be teratogenic. Other causes of anomalies include monogenetic conditions (8% to 18%), chromosomal disorders (7% to 10%), maternal infections (1%), maternal conditions (1% to 3%; e.g., maternal diabetes), multifactorial heredity (23% to 50%), and unknown causes (34% to 43%).⁵

PATHOPHYSIOLOGY

Age of Pregnancy

The age of pregnancy can be defined as gestational or post-conceptional ages.⁶ *Gestational age* (GA) is the term used in clinical practice. It is calculated from the first day of the last menstruation (or by ultrasound dating if menstrual cycles are irregular or if dates are unknown).

Postconceptional age (PCA) is calculated from the day of conception, which is 14 days shorter than gestational age if the menstrual cycle is 28 days. Some references in the field of teratology and embryology refer to PCA to describe stages of pregnancy.

Principles of Embryology

Pregnancy is usually divided into three trimesters of 13 weeks.⁶ However, it can be divided more precisely into three phases: implantation and pre-differentiation, organogenesis (or embryogenesis), and fetogenesis. Table 47-2 describes these phases and the effects that drugs could have if taken during these phases, and Figure 47-1 illustrates the critical periods of human in utero development. 3 The risk of birth defects is most often higher during organogenesis.

► Teratogens

• A teratogen is an exogenous agent that can modify normal embryonic or fetal development. Teratogenicity can manifest as structural anomalies, a functional deficit, cancer, growth retardation, and death (spontaneous abortion, stillbirth).

• Even if we use the term *teratogen* in this chapter, we agree with some authors who have suggested to avoid this term and to use instead *teratogenic exposure*. *Teratogenic exposure* implies that we have to consider the exposure level (dose) and timing of exposure to a medication during pregnancy to

Table 47-1

Occurrence of Some Obstetrical Complications and Risk of Congenital Anomalies in the General Population

	Risk of Occurrence in Population (%)
Spontaneous abortion/miscarriage (pregnancy loss that occurs after the pregnancy is known and before 20 weeks of GA)	10–15
Prematurity (any birth that occur before 37 completed weeks of gestation)	12.8
Congenital anomalies (percentage of live births):	
• Minor malformations (recognized at birth or during childhood)	10–15
• Major malformations at birth	3
• Major malformations at 1 year old	6–7
Low birth weight (less than 2,500 g)	7.7

GA, gestational age.

Data from Refs. 61 and 62.

Table 47-2

Phases of Embryonic and Fetal Development

Phase of Development	Stage of Pregnancy	What Happens During This Phase of Development	Potential Teratogenic Effect
Implantation and predifferentiation	0–14 days after conception (14–28 days after last menstrual period)	<i>All-or-none period</i> Very little contact between the blastocyst and the mother's blood Cells are pluripotent, capacity to repair a damage remains Cells are fragile at this moment. If too many are killed, a miscarriage will occur before the pregnancy is detected	Spontaneous abortion or miscarriage Even if stopped during this period, prolonged half-life drugs could cause organogenesis problems
Organogenesis (embryogenesis)	From day 14 until the 9th week after conception (From day 28 until the 11th week after last menstrual period)	Organs are formed; most critical period for structural anomalies Organs are formed at different times; period of sensitivity for a potential teratogen could be different for each organ Refer to Figure 47-1 for the time frame of organ formation	Major or minor structural anomalies
Fetogenesis	After the organogenesis and until birth	The fetus grows and organs begin to function (e.g., kidneys are formed during organogenesis, but glomerular filtration begins during fetogenesis) Active cell growth, proliferation, and migration (eg., CNS)	Fetal growth retardation Functional deficit (e.g., renal insufficiency, pulmonary hypertension, neurologic impairment)

Data from Refs. 6 and 11.

FIGURE 47-1. Embryonic and fetal development. The horizontal bars represent potential sensitivity to teratogens. The colored areas represent the more critical times. Embryonic period is in post-conceptual weeks. (Reprinted with permission from Moore KL. The Developing Human. New York: Elsevier, p 976: copyright 1974.)

determine whether it could lead to a higher risk of a specific malformation.⁷

Criteria have been proposed to determine whether a causal relationship between congenital anomalies and a medication is plausible (teratogenic effect).^{3,7} Exposure to the medication must have happened during the critical period of development of the organ for which a malformation is noticed (Figure 47-1). In addition, a pattern of anomaly or a specific syndrome have to be present, and the observed effects must be reproducible in at least two studies conducted on different populations. A rare anomaly associated to a rare exposure is also indicative of a teratogenic effect (e.g., ear anomalies and isotretinoin).

Other criteria are considered (the probability of finding an association between a medication and a malformation increases with the number of criteria present):

- Strength of the association
 - Same effects observed in animal studies
 - Biological plausibility based on pharmacologic effect
 - Higher incidence of the anomaly in the population with the use of the medication followed by a decreased incidence once the medication is no longer available (e.g., thalidomide and limb anomalies)
 - Dose-response relationship
- With these criteria, there are approximately 30 medications or classes of medication established to be teratogens. They are shown in [Table 47-3](#). If a drug is not on this list, it does not necessarily mean that it is safe to use during pregnancy. We must be careful at not interpreting a lack of data as an absence of a problem.

RISK EVALUATION

Desired Outcomes

- The primary goal for drug use during pregnancy and lactation is to effectively treat maternal or fetal conditions when necessary while minimizing risk to the developing embryo/fetus or the neonate.

Medication and Pregnancy

► *Data Published on Medication Safety During Pregnancy*

Classical randomized controlled trials that are done in the general population are usually not available to evaluate the safety of medications during pregnancy and lactation. Most available data come from postmarketing reports. The evaluation of medication safety during pregnancy is challenging, as the clinician has to rely on different data from reports of different quality, which is sometimes limited or difficult to interpret.

Animal studies are now mandatory before marketing a medication. Animal data are very important to identify high-risk medications and prevent congenital anomalies. However, they must be interpreted with great caution because of many limitations; the major ones are that different species do not

share the same pharmacodynamics and pharmacokinetics for a same medication, and usually much higher doses than those used in clinical settings are administered.⁸

Case reports and case series provide the first published data on the use of medications during pregnancy. A causal relationship between a single case report and an anomaly cannot usually be established unless a rare anomaly is repeatedly associated with the use of a specific medication.

Cohort studies and company registries try to compare the risks observed after exposure to a medication with the risk observed in a control group or in the general population. When studying structural anomalies, it is important to select women exposed to medication during organogenesis. Cohort studies usually evaluate the general risk of malformations and are not powerful enough to assess the risk associated with rare anomalies. When a signal of association between an anomaly and a drug exposure is observed, a case-control study can be conducted to clarify the relationship. A case-control study also has more power to detect rare anomalies. When several studies have been published using very similar methodologies, meta-analyses can be conducted to reach higher statistical power.⁸

► *Sources of Information on the Use of Drugs During Pregnancy and Lactation*

- Specialized information sources provide data on the use of medications during pregnancy and lactation. Some of these sources are listed in [Table 47-4](#).

The 1979 FDA regulations establishing pregnancy categories for drugs (A, B, C, D, and X) are well known to health-care providers. For many years, this system of categorization has been criticized by teratologists, genetic counselors, and other experts in the field who recommend relying on other information sources.⁹ They assert that the FDA categories are too simplistic, can lead to a misperception of the risk, and do not take into account other important information such as expected incidence, severity of anomalies, degree of risk, gestational timing of exposure, and route of administration.⁹ In May 2008, the FDA proposed that the categories be removed and replaced by a short statement. This statement includes the description and the risk of fetal defects, the sources of data (animal or human data), a comparison with the population baseline risk of birth defects, and the relationship with the dosage. An equivalent section for drug use during lactation will be inserted.⁹ This new regulation is not yet available. Meanwhile, clinicians should rely on other information sources to evaluate the risk of a medication during pregnancy.

► *Communication of the Information*

Communication of data on medication use during pregnancy can be challenging¹⁰:

- Data may be limited or contradictory.
- Taking medications during pregnancy is a source of anxiety for many women and for their healthcare providers.

Table 47-3

Medications with Proven Teratogenic Effects in Humans

Drug or Drug Class	Teratogenic Effects	Critical Period
Alkylating agents Amiodarone	Malformations of many different organs Transitory hypothyroidism (17%, goiter in 18% of these cases) or hyperthyroidism (3%)	Organogenesis From 10th week after conception
Androgens (danazol, testosterone)	Masculinization of genital organs in female fetus	Danazol: from 6th week after conception Testosterone: not defined
Angiotensin conversion enzyme inhibitors Angiotensin II receptor antagonists	Renal failure, anuria, oligohydramnios , pulmonary hypoplasia, intrauterine growth restriction, limbs contracture, skull hypoplasia	After the first trimester
Anticonvulsants • Carbamazepine • Phenytoin • Phenobarbital • Valproic acid	NTDs (for carbamazepine and valproic acid); oral cleft , skeletal, urogenital, craniofacial, digital, and cardiac malformations; microcephalia Risk of major malformations estimated at 5–10% depending on the agent used (about 5% for carbamazepine, 10–14% for valproic acid). Valproic acid: abnormal neurologic development Oral cleft (risk of 3–4/1,000 versus 1/1,000 in general population)	7–14 weeks (gestational age); higher risk between 8 and 11 weeks. Neurologic development: not established
Systemic corticosteroids Diethylstilbestrol	Oral cleft (risk of 3–4/1,000 versus 1/1,000 in general population)	Organogenesis
	Girls: Cervical or vaginal adenocarcinoma, incidence of less than 1.4/1,000 exposures. Structural genital anomalies (e.g., of cervix, vagina) in 25% of cases Boys: Genital anomalies, spermatogenesis anomalies	First and second trimesters
Fluconazole high doses	Skeletal and craniofacial malformations, cleft palate (with chronic dose more than 400 mg/day; not reported with 150 mg single dose)	Not defined, but cases are reported where exposure was for most parts of pregnancy
Radioactive iodine (¹³¹ I)	Thyroid suppression (goiter)	From 10th week after conception (consider the dosage and time to eliminate the product on a case-by-case basis)
Isotretinoin, acitretin, etretinate, and vitamin A (more than 10,000 IU/day)	CNS, skull, eyes and ears malformations, micrognathia , oral cleft, cardiac malformations, thymus anomalies, mental retardation: estimated at 25–30% (may be higher for neurologic development impairment) Contraindicated throughout pregnancy Isotretinoin: discontinue 1 month before pregnancy, prescribed under a special program called iPLEDGE Acitretin, etretinate: discontinue 2–3 years before pregnancy (alcohol consumption decreases elimination)	Organogenesis (risk of teratogenic effect after organogenesis not excluded)
Lithium	Cardiac malformations: risk of 0.9–6.8% (higher risks from small studies that included also minor cardiac anomalies) (general population risk: approximately 1%) Includes Ebstein's anomaly : risk estimated at 0.05–0.1%	Cardiac organogenesis
Methimazole/propylthiouracil	Methimazole: aplasia cutis, syndrome including choanal atresia, esophageal atresia, facial anomalies, developmental delay; risk probably low Methimazole/propylthiouracil: fetal hypothyroidism in 2–10% of infants whose mothers were treated for Graves disease or goiter	Organogenesis Second and third trimesters
Methotrexate	CNS and cranial malformations, oral cleft, skeletal and limb malformations It is recommended to stop the medication 3 months before pregnancy	Organogenesis
Misoprostol Mycophenolate mofetil	Moebius syndrome ± limb anomalies ± CNS anomalies Ear anomalies, oral cleft, other anomalies (causality to be confirmed)	Organogenesis Uncertain
Nonsteroidal anti-inflammatory drugs	In utero closure of ductus arteriosus (constriction is rare before 25 weeks, 50–70% at 30 weeks and 100% at 32 weeks (gestational age) and pulmonary hypertension	Third trimester
Penicillamine Tetracyclines Thalidomide	Cutis laxa Teeth discoloration Limb anomalies Cardiac, urogenital, GI, and ear malformations Prescribed under a special program called STEPS (System for Thalidomide Education and Prescribing Safety)	Not defined 14 weeks postconceptional 20–36 days after conception
Trimethoprim Warfarin/acenocoumarol	Cardiac and urogenital malformations, neural tube defects, oral cleft Warfarin embryopathy including nasal hypoplasia, epiphysis dysplasia, vertebral malformations	Organogenesis Between 4th and 7th week postconception

Data from Refs. 3, 6, 7, 11, and 27.

- Pregnant women tend to overestimate their risk of an anomaly associated with medication use and to lower their risk associated with the undertreatment of their disease.
- Many people, including healthcare providers, cannot properly understand numbers and probability.
- The objective when transmitting information is to give precise data that will help the patient to make an informed decision for her health and the health of her baby. Unconfirmed hypotheses should not be transmitted to patients. The information should include a well-grounded assessment of risks, including baseline risks in the general population, risks associated with the medication, and those of not treating the disease during pregnancy. Women often have misconceptions and misperceptions about the use of medications during pregnancy.^{3,8}

When dealing with numbers (e.g., percentages, probabilities), some authors suggest some tips to facilitate risk communication^{3,10,11}:

- Absolute risks instead of relative risks should be used.
- Negatively and positively framed information should be used at the same time (e.g., 3% chance of having a malformed child; 97% chance of having a normal child).
- Visual aids should be used when appropriate.
- The same denominator should be used when discussing probabilities.

Finally, to determine a woman's risk of birth defects, it is important to obtain good medical, obstetrical, and

pharmacologic histories (including nonprescribed medications) and to take into account exposure to alcohol, tobacco, and other recreational drugs.¹¹ All these elements can influence a woman's risk and the perception of risk.

► Preconception Care

Adverse pregnancy outcomes, which include prematurity, low birth weight, and birth defects, are major health concerns and can lead to serious health problems. One contributing factor to these adverse outcomes is the late start in prenatal care, which can delay the identification and modification of biomedical, behavioral, and social risk factors that can affect pregnancy outcomes. Strategies to improve pregnancy outcomes include taking folic acid, avoiding alcohol, smoking cessation, optimizing the treatment and management of chronic illnesses (e.g., diabetes, epilepsy, hypertension, maternal phenylketonuria), screening for infections (e.g., human immunodeficiency virus [HIV], sexually transmitted infections), appropriate vaccination, and reaching a healthy weight.¹²

► Folic Acid

Folic acid is an essential vitamin that plays an important role in the prevention of congenital anomalies, particularly neural tube defects (NTD). Approximately one in every 1000 pregnancies is affected by an NTD.¹³ Recent data indicate that folic acid may also be involved in the reduction of other congenital anomalies, including cardiovascular, oral clefts, limb deformities, and urinary malformations.¹⁴ **4**

All women of childbearing age should be counseled on the appropriate dose of folic acid to prevent congenital anomalies.

- The American College of Obstetricians and Gynecologists (ACOG) and the U.S. Services Task Force recommend that every woman of childbearing age take 0.4 to 0.8 mg of folic acid daily, beginning 1 month before pregnancy and through the first 2 to 3 months, because nutritional sources alone are not sufficient.^{14,15} Women at higher risk of NTD (e.g., those who have had a previous child or a first-, second or third-degree relative with a neural tube defect, those with prepregnancy diabetes, those with epilepsy taking carbamazepine or valproic acid) are counseled to take 4 mg of folic acid per day.¹⁵ The Society of Obstetricians and Gynecology of Canada advocates the use of higher doses of folic acid for a broader range of women including obese women and Sikh, Celtic, and Northern Chinese women, who are at higher risk of having a child with an NTD.¹⁶

► Iron Supplements

Anemia is a common problem during pregnancy; it is defined as a hemoglobin level less than 11 g/dL (110 g/L; 6.83 mmol/L) during the first and third trimesters and less than 10.5 g/dL (105 g/L; 6.52 mmol/L) during the second trimester.¹⁷ Maternal symptoms of anemia include fatigue, palpitations, and decreased resistance to exercise and infections. Fetal risks are prematurity, low birth weight, and perinatal death. Recommendations are that all pregnant women be screened for anemia, and those with iron deficiency should

be treated with oral iron preparations in addition to prenatal vitamins.¹⁷ Iron supplementation decreases the prevalence of maternal anemia at delivery. It is unclear whether supplementing nonanemic pregnant women will improve perinatal outcomes.¹⁷

► Impact of Physiologic Changes During Pregnancy on Pharmacokinetics

Absorption Drug absorption is affected in several ways during pregnancy, and it is difficult to predict the final repercussion on drug efficacy. Decreased gastrointestinal transit can result in a delay in drug peak effect, prolonging the time of contact of drugs with the intestinal mucosa, and possibly enhancing absorption of certain drugs. The higher gastric pH may affect the absorption of weak bases or acids. Skin, tissue, and lung absorption might also be increased by physiologic changes during pregnancy.¹⁸

Distribution The volume of distribution increases for most drugs during pregnancy due to plasma volume expansion

and the presence of amniotic fluid, the placenta, and the fetus. This results in a decrease in maximal concentrations of drugs and in their half-life. In addition, hypoalbuminemia and decreased protein binding of drugs increases free fraction of some medications.^{18,19}

Metabolism During pregnancy the activity of some isoenzymes is increased (e.g., CYP3A4, CYP2A6, CYP2D6, CYP2C9), and the activity of others is decreased (e.g., CYP1A2, CYP2C19). It is difficult to predict the net impact on drug effect since there is a wide interindividual variability and since some drugs are metabolized by several isoenzymes.^{18,19}

Renal Elimination Renal blood flow and glomerular filtration are increased significantly during pregnancy. The impact of this increase is more important for drugs that are eliminated in the urine.¹⁹

Table 47-5 shows clinical recommendations based on pharmacokinetic changes during pregnancy for several drugs.^{6,19,20}

Table 47-5

Altered Pharmacokinetics During Pregnancy: Clinical Implications and Management

Drugs	Pharmacokinetic Changes	Recommendations and Monitoring
Aminoglycosides	$\uparrow V_d, \uparrow Cl, \downarrow t_{1/2}$	Monitor peaks and troughs; increase doses if necessary
Antiretrovirals	Variable Cl and C_{max}	Monitor clinical response; drug levels can be useful to adjust drug dosage of some antiretrovirals
Caffeine	$\uparrow t_{1/2}$	Risk of more frequent and prolonged side effects; decrease caffeine consumption
Carbamazepine	$\downarrow Cl (T_1, T_2, T_3)$ $\uparrow Cl$	Measure free fraction (preferably); increase dose according to clinical response and levels
Digoxin	$\downarrow t_{1/2}$ $\uparrow Cl$ $\downarrow C_{max}$	Follow plasma levels; adjust according to clinical response and plasma levels; increase doses if necessary; to treat fetal disease, higher doses might be required; digoxin-like immunoreactive substance might alter levels.
Fluoxetine and other SSRIs	$\uparrow Cl (T_3)$	Increase dose according to clinical response; consider decreasing dose after delivery
Heparin LMWH	$\uparrow Cl (T_1, T_2, T_3)$	Consider increasing frequency of administration If necessary, follow anti-Xa levels
Lamotrigine	$\uparrow Cl (T_1, T_2, T_3)$	Measure drug levels at least every trimester; increase dose according to clinical response and levels; return to prepregnancy dose after delivery
Levothyroxine (T4)	$\downarrow ff$	Increase dose at the beginning of pregnancy; follow TSH levels at least every trimester; return to prepregnancy dose after delivery
Lithium	$\uparrow Cl (T_1, T_2, T_3)$ $\downarrow t_{1/2}$	Measure drug levels at least every trimester and monthly in third trimester; increase dose according to levels if necessary; return to prepregnancy dose after delivery
Nicotine	$\downarrow t_{1/2}$ $\uparrow Cl (T_2, T_3)$	Higher doses might be required (smoking cessation) at T2 and T3; however, increased transdermal absorption might lead to higher nicotine plasma levels
Nifedipine	$\uparrow Cl (T_3)$	Monitor clinical effect; increase doses/frequency of administration if necessary
Phenytoin	$\downarrow C_{total}$ $\uparrow C_{total}$ $\uparrow Cl (T_3)$	Measure free fraction; increase dose according to clinical response and levels
Valproic acid	$\downarrow t_{1/2}$ $\downarrow C_{total}$ $\uparrow ff$	Measure free fraction if a prepregnancy reference level is available; dose will remain the same in most cases. Increase dose according to clinical response and levels.

\uparrow , increase; \downarrow , decrease; \leftrightarrow , unchanged; C_{max} , maximum serum concentration; Cl, clearance; ff, free fraction; T, trimester; $t_{1/2}$, elimination half-life; LMWH, low-molecular-weight heparins; C_{total} , total concentration; SSRI: selective serotonin reuptake inhibitor.

Data from Refs. 6, 19, and 20.

Medication and Lactation

According to a 2005 policy statement from the American Academy of Pediatrics (AAP), new mothers should breast-feed exclusively for 6 months. Approximately 46% of new mothers report that they breast-feed exclusively at birth. However, this figure drops to 17% at 6 months, as many new mothers supplement breast-feeding with other foods or quit entirely by this point.²¹

► Drug Transfer into Breast Milk

To study drug effects in a breast-fed infant, serum drug levels could be measured to help evaluate safety in the infant; however, these data are often not available. Therefore, in most instances, the approximate quantity of drug ingested by the breast-fed infant is estimated using published measured drug concentrations in breast milk. With these data, one can calculate the percentage of pediatric dose or the relative infant dose (percentage of maternal dose adjusted by weight), assuming an average of 150 mL/kg/day of milk ingested by a breast-fed infant.

- Percentage of pediatric dosage =

$$\left(\frac{\text{Quantity of medication taken from milk by the baby (mg/kg/day)}}{\text{Usual initial daily pediatric dose (mg/kg/day)}} \right) \times 100$$

- Maternal dose adjusted by weight or relative infant dose =

$$\left(\frac{\text{Quantity of medication taken from milk by the baby (mg/kg/day)}}{\text{Maternal dose adjusted by weight (mg/kg/day)}} \right) \times 100$$

In the latter equation, maternal dose refers to the dose used by patients in the published study or case report, not to the dose of your actual patient.

Usually, a percentage of less than 10% of the pediatric dose or, when a pediatric dose is not available, a percentage of less than 10% of maternal dose adjusted by weight, is acceptable in full-term healthy infants.²²

► Drug Pharmacokinetics

If clinical data are not available on drug transfer into breast milk, choose drugs that are highly protein bound, have a high molecular weight, have a short half-life, have no active metabolites, and are well tolerated by children.²²

► Drugs of Concern During Breast-Feeding

5 Most drugs are safe during breast-feeding. However, use of some drugs creates some concern and requires a more thorough assessment by the clinician (Table 47-6). **2** Health professionals should know which medications are of concern during breast-feeding. One should also consider the additive side effects of medication for the baby when the mother is taking a combination of medications.

Table 47-6

Drugs of Concern During Breast-Feeding

Drug or Class	Comments
Drugs that can decrease the breast milk production	
Clomiphene	Has been used to suppress lactation
Ergot derivatives (bromocriptine, cabergoline, ergotamine)	Have been used to suppress lactation
Estrogens	Hormonal contraceptives with ethinylestradiol should be delayed for 4–6 weeks following delivery.
Pseudoephedrine	Do not use in women with low milk production; a few doses will probably not have significant clinical effect
Drugs for which use during breast-feeding may expose the neonate to a significant quantity and may necessitate a strict follow-up	
β -blocking agents (acebutolol, atenolol, sotalol)	Neonatal β -blockade reported Concern for acebutolol, atenolol and sotalol, but some other β -blocking agents are safe to use.
Amiodarone	May accumulate because of long half-life; possible neonatal thyroid and cardiovascular toxicity
Antineoplastics	Neonatal myelosuppression possible
Chloramphenicol	Severe side effects reported when used to treat babies (blood dyscrasia, grey baby syndrome)
Ergotamine	Symptoms of ergotism (vomiting and diarrhea) reported
Illicit drugs	Unknown contents and effects
Lamotrigine	A breast-fed infant could have blood concentrations between 10% and 50% of the maternal blood concentrations. One single case of apnea in a breast-fed infant, no other side effect was reported in about 100 breast-fed babies. Follow for rash and CNS side effects.
Lithium	Up to 50% of maternal serum levels have been measured in infants; cases of infant toxicity have been reported
Phenobarbital/primidone	Drowsiness and reduced weight gain reported. Up to 25 % of a pediatric dose can be ingested via breast milk.
Radioactive iodine-131	Long radioactive half-life (21–42 days)
Tetracyclines	Chronic use may lead to dental staining or decreased epiphyseal bone growth

Data from Refs. 6 and 22.

CONDITIONS PREVALENT IN PREGNANCY AND LACTATION

6 When possible, treat conditions occurring during pregnancy with nonpharmacologic treatments instead of drug therapy.

7 Evaluate the need for treatment, including benefits and risks. Avoid treatments that do not show evidence of benefit or that can be delayed until after pregnancy or breast-feeding.

Clinical Confirmation and Associated Problems of Pregnancy and Lactation

Confirmation of Pregnancy

Positive urine human chorionic gonadotropin followed by positive ultrasound, fetal heart sounds, and/or fetal movement.

Pregnancy Dating and Gestational Age

Calculated from the first day of the last menstrual period.

Due dates typically are estimated at 40 weeks of gestation; however, infants delivered between 37 completed weeks and 42 weeks are considered full term.

Pregnancy Symptoms

First trimester: Menstrual spotting, missed menses, fatigue, breast tenderness, increased urination, mood swings, nausea/vomiting, headache, heartburn, constipation

Second trimester: Frequent urination, heartburn, constipation, dry skin, edema, **linea nigra**, **melasma**

Third trimester: Backache, edema, shortness of breath

Routine Pregnancy Visits

In a normal, uncomplicated pregnancy, visits should occur monthly until 28 weeks of gestation, every 2 to 3 weeks from 28 to 36 weeks of gestation, and then weekly until delivery.

Examination for each of the following is performed at each visit:

- Blood pressure
- Weight
- Urine for protein and glucose
- Uterine size
- Fetal heart rate
- Fetal movement

Routine Lab Testing for Normal Pregnancies (First Trimester Unless Otherwise Indicated)

- Human immunodeficiency virus
- Purified protein derivative (PPD) test for tuberculosis (high risk)
- Venereal Disease Research Laboratory (VDRL) slide test for syphilis
- Rubella immunity
- Cervical cytology
- Blood and Rh type
- Hepatitis B surface antigen
- Hepatitis C antibodies (if high risk)
- Bacterial vaginosis testing if symptomatic or at high risk (previous preterm labor)
- Antibody screen for Rh antibodies
- Hemoglobin and hematocrit for anemia (repeated at 26–32 weeks)
- Urinalysis with culture for asymptomatic bacteriuria

- Gonorrhea and chlamydia
- Screens for neural tube defects if indicated (at 15–20 weeks) and Down's syndrome
- Gestational diabetes screening (at 24–28 weeks)
- Group B *Streptococcus* screening (at 35–37 weeks)

Assessing Suitability of the Cervix for Labor Induction

Suitability is based on cervical dilation, length, consistency, and position. These findings are translated to a numerical rating called the Bishop score. A Bishop score of less than 6 indicates that pharmacologic therapy is needed to ripen the cervix prior to delivery.

Selected Problems Experienced During Pregnancy or Lactation

Hyperemesis gravidarum. Severe, persistent nausea and vomiting during pregnancy accompanied by dehydration, electrolyte disturbance, ketonuria, and weight loss.

Bacteriuria. Often asymptomatic in pregnancy. Diagnosed by positive urine culture.

Bacterial vaginosis. Clinically diagnosed by presence of three of the following:

- White, noninflammatory discharge
- **Clue cells** on microscopic examination
- Vaginal pH greater than 4.5
- A fishy odor before or after addition of 10% potassium hydroxide (i.e., "whiff" test)

Vulvovaginal candidiasis. Typical symptoms include vaginal itching and discharge. Clinical characteristics include:

- Vaginal pH less than 4.5
- Observation of yeast on Gram stain or wet preparation
- Thick, white, "cottage cheese-like" discharge

Chlamydia and gonorrhea. Typically asymptomatic. Diagnosed by positive culture.

Genital herpes simplex virus. Characterized by vesicular or ulcerative lesions. Diagnosis confirmed by virologic or serologic testing. Prodrome manifests as pain, burning, or itching at the site where lesions will develop.

Pelvic inflammatory disease. Difficult to diagnose in pregnancy. Symptoms may include:

- Uterine/ovarian tenderness
- Cervical motion tenderness
- Fever
- Abnormal cervical or vaginal discharge
- Presence of white blood cells in vaginal secretions
- Elevated erythrocyte sedimentation rate
- Elevated C-reactive protein

(Continued)

Clinical Confirmation and Associated Problems of Pregnancy and Lactation (Continued)

Syphilis. A single genital lesion may characterize early disease. Diagnosed by positive serologic testing (e.g., VDRL or rapid plasma reagin [RPR] test).

Trichomoniasis. Symptoms may include vulvar irritation and yellow-green discharge. Diagnosed after microscopic visualization of the organism.

Preterm labor. Onset of labor prior to 37 weeks of gestation.

Group B streptococcus. Diagnosed by positive culture on vaginal and rectal swab.

Mastitis. Characterized by localized redness, tenderness, and warmth on one breast accompanied by fever and flulike symptoms. Although uncommon, symptoms also may be bilateral.

Nipple candidiasis. Typical symptoms include nipple pain, itching, burning, and/or breast pain that persist after feeding.

Gestational diabetes. See Chapter 43.

Hypertension in pregnancy. Asymptomatic or presence of neurologic, hepatic, or cardiovascular symptoms. Check for proteinuria.

Nausea and Vomiting

As many as 85% of pregnant women suffer from nausea or vomiting.²³ Nonpharmacologic measures, such as lifestyle (rest, avoidance of nausea triggers) and dietary changes (small and frequent meals, fluid restriction during meals, avoiding spicy or fatty foods, consuming crackers upon rising, and elimination of pills with iron, if possible) should be used as first-line management. Acupuncture and acupressure also can be helpful.²³

The combination of pyridoxine (vitamin B₆) and doxylamine is well studied during pregnancy and is the first-line pharmacologic treatment of nausea and vomiting during pregnancy (Table 47-7).²³ This combination is not available in the United States, and the ingredients have to be administered separately. When the combination of pyridoxine/doxylamine is insufficient, other drugs such as metoclopramide or diphenhydramine can be prescribed; ondansetron is another alternative.²³

Constipation

Up to 40% of pregnant women will suffer from constipation.²⁴ Nonpharmacologic treatment is the mainstay of

constipation treatment in pregnant patients. Pregnant women should be counseled to eat a high-fiber diet, drink plenty of fluids, exercise regularly, and avoid prolonged time on the toilet. Bulk-forming laxatives, such as psyllium and calcium polycarbophil, are first-line agents (Table 47-7). If these methods fail, emollients or osmotic agents can be tried. Stimulant laxatives, such as bisacodyl and senna, are acceptable second-line agents for short-term or intermittent use.⁶ During lactation, bulk-forming, emollient, osmotic laxatives, and the stimulant laxatives are safe for use.²²

Heartburn

Heartburn affects a majority of pregnant women.²⁵ Nonpharmacologic recommendations for the treatment of heartburn during pregnancy include small and frequent meals, remaining upright after eating, elevating the head of the bed, and avoiding factors known to decrease lower esophageal sphincter tone (e.g., smoking, chocolate, coffee, fatty foods, and peppermint).²⁵

Calcium- or magnesium-containing antacids are first-line therapies. If antacids fail to improve symptoms, ranitidine can be recommended, as it is the drug with the best safety data among the H₂ blockers (Table 47-7).²⁵ Omeprazole, sucralfate, and metoclopramide are also safe in pregnancy (Table 47-7).^{26,27}

All the drugs used for heartburn during pregnancy are acceptable during lactation.²²

Nasal Congestion and Rhinitis

Do not underestimate the impact of nasal congestion and rhinitis, especially if it is chronic and associated with snoring and sleep disorders. Rest, fluids, humidified air, nasal saline, and acetaminophen are the mainstays of therapy for the common cold. Recommend avoiding irritants and known allergens and raising the head of the bed at 30 to 45 degrees. Nasal strips might be helpful.²⁸

Treat nasal congestion as in the nonpregnant population, being mindful to do the following: (a) Avoid oral decongestants during the first trimester owing to the risk of fetal

Patient Encounter, Part 2

At 24 weeks of pregnancy, MM is admitted for acute pyelonephritis. Blood glucose levels are between 108 and 180 mg/dL (6.0 and 10.0 mmol/L). Urine culture reports the presence of *E. coli* and group B *Streptococcus*.

Medication:

Methyldopa 500 mg orally twice daily

ASA 81 mg orally at bedtime

Levothyroxine 100 mcg orally daily

Insulin NPH 46 units subcutaneously at bedtime

Insulin aspart 10 units subcutaneously before every meal

What treatment do you recommend at this time?

Table 47-7

Medication Dosing Recommendations During Pregnancy and Lactation

Drug	Dosage	Comments
Micronutrients and Vitamins		
Calcium	1,000–1,300 (elemental calcium) mg/day	To be taken with vitamin D
Folic acid	0.4–0.8 mg orally daily 4 mg orally daily	RDA: 0.5 mg (breast-feeding)–0.6 mg (pregnancy) Higher dose during first trimester recommended for women at higher risk of having a child with NTD, (e.g., personal or family history [FH] of NTD, medication known to cause NTD, or prepregnancy diabetes)
Iron	27 mg (elemental iron) orally daily	RDA for pregnancy RDA for breast-feeding: 9–10 mg
Vitamin D	60–200 mg (elemental iron) orally per day 600 IU orally daily 400 IU orally daily (breast-fed infants)	Higher doses to treat iron-deficiency anemia RDA during pregnancy and lactation Dose recommended for breast-fed infants
Nausea and Vomiting		
Diphenhydramine or dimenhydrinate	25–50 mg orally 4 × daily as needed	
Doxylamine	12.5 mg orally 3–4 × daily as needed	Can be taken with pyridoxine
Metoclopramide	5–15 mg orally 3–4 × daily as needed	
Meclizine	12.5–50 mg orally daily as needed	
Pyridoxine	25 mg orally 3 × daily as needed	Can be taken with doxylamine
Ondansetron	4–8 mg orally 3 times daily as needed	
Heartburn		
Antacids (calcium carbonate, magnesium hydroxide)	Product-specific dosing, refer to product monograph	
Ranitidine	150 mg orally twice daily	
Metoclopramide	5–10 mg orally 3–4 × daily	
Omeprazole	20 mg orally daily	
Sucralfate	1 g orally 4 × daily	
Constipation		
Polycarbophil	2 tablets 1–4 × daily	
Psyllium	Product specific dosing, usually 1 packet/scoopful in water up to 3 × daily	
Docusate	100–400 mg orally per day (given in 1 or 2 doses)	
Bisacodyl	5–10 mg orally (tablets) or rectally (suppositories) as needed	
Senna	17.2 mg orally (tablets or syrup) once or twice daily or rectally (suppositories) as needed	
Lactulose	15–30 mL daily or twice daily	
Nasal Congestion		
Decongestants		
Oxymetazoline	0.05% spray, 2–3 sprays in each nostril twice daily for 3–5 days	Avoid using more than 3–7 days to prevent rebound congestion
Pseudoephedrine	60 mg orally every 4–6 hours	Short term (3–5 days) second and third trimesters only.
Antihistamines		
Chlorpheniramine	4 mg every 4–6 hours	
Cetirizine	10 mg orally daily	
Loratadine	10 mg orally daily	
Sodium cromolyn	2.6 mg nasal spray, 3–4 × daily	
Nasal Corticosteroids		
Budesonide	32 mcg spray, 1–4 sprays daily	First-line agents for chronic congestion
Beclomethasone	50–100 mcg spray, twice daily	
Fluticasone	100 mcg spray daily	

(Continued)

Table 47-7

Medication Dosing Recommendations During Pregnancy and Lactation (Continued)

Drug	Dosage	Comments
Urinary Tract Infections		
Asymptomatic bacteriuria and uncomplicated acute cystitis		
Nitrofurantoin	100 mg orally 4 × daily	For 3 to 7 days
Cephalexin	250–500 mg orally 4 × daily	
Amoxicillin	500 mg orally 3 × daily	
Acute pyelonephritis		
Ampicillin + gentamicin	1–2 g IV every 6 hours + 1.5 mg/kg/dose IV every 8 hours	Switch to oral antibiotic after 48 hours afebrile and treat for a total of 10 to 14 days, for example: <ul style="list-style-type: none"> • cephalexin 500 mg orally 4 × daily • cefprozil 500 mg orally 2 × daily • amoxicillin clavulanate 875/125 mg orally 2 × daily
Cefazolin	1–2 g every IV 8 hours	
Cefuroxime	0.75–1.5 g IV every 8 hours	
Ceftriaxone	1–2 g IV or IM every 24 hours	
Prophylaxis		
Nitrofurantoin	100 mg orally at bedtime	Start after the end of the treatment for pyelonephritis and continue until 4 to 6 weeks after delivery.
Cephalexin	250 mg orally at bedtime	
Bacterial Vaginosis		
Metronidazole	250 mg orally 3 × daily for 7 days or 500 mg orally twice a day for 7 days 0.75% vaginal gel, once or twice daily for 5 days	
Clindamycin	300 mg orally twice daily for 7 days 100-mg ovules intravaginally at bedtime for 3 days	Use oral formulation during pregnancy and intravaginal formulation during breast-feeding
Vulvovaginal Candidiasis		
Butoconazole	2% cream, 5 g intravaginally for 3–6 days	Longer treatments are recommended during pregnancy
Clotrimazole	1% cream, 5 g intravaginally for 6 days 100-mg vaginal tablet daily for 7 days 2% cream, 5 g intravaginally for 3 days 200-mg vaginal tablet daily for 3 days	
Miconazole	2% cream, 5 g intravaginally for 7 days 100-mg vaginal suppository daily for 7 days 4% cream, 5 g intravaginally for 3 days 200-mg vaginal tablet daily for 3 days	
Terconazole	0.4% cream, 5 g intravaginally for 7 days 0.8% cream, 5 g intravaginally for 3 days 80-mg vaginal tablet daily for 3 days	
Nystatin	100,000-unit vaginal tablet, 1 tablet for 14 days	
Chlamydia		
Azithromycin	1 g orally (1 dose only)	Quinolones are not first choice for reasons of resistance mainly.
Amoxicillin	500 mg orally 3 × daily for 7 days	
Erythromycin base	500 mg orally 4 × daily for 7 days or 250 mg orally 4 × daily for 14 days	Avoid erythromycin estolate during pregnancy due to potential maternal hepatotoxicity
Doxycycline	100 mg orally twice daily for 7 days	During lactation only. Doxycycline should be avoided in pregnant women (discoloration of teeth if used after 16 weeks of gestational age).
Gonorrhea (Uncomplicated)		
Ceftriaxone	250 mg intramuscularly once	
Cefixime	400 mg orally once	
Azithromycin	2 g orally once	For cephalosporin-allergic patients Treats chlamydia also.
Pharynx infection	Doses as above	
Ceftriaxone + azithromycin		

(Continued)

Table 47-7

Medication Dosing Recommendations During Pregnancy and Lactation (Continued)

Drug	Dosage	Comments
Genital Herpes Simplex Virus (Uncomplicated)		
Acyclovir	<p><i>First episode:</i> 400 mg orally 3 × daily for 7–10 days, or 200 mg 5 × daily for 7–10 days</p> <p><i>Recurrent episode:</i> 400 mg orally 3 × daily for 5 days, or 800 mg twice daily for 5 days, or 800 mg 3 × daily for 2 days</p> <p><i>Suppressive therapy:</i> 400 mg orally 3 × daily</p>	From 36 weeks until delivery
Syphilis		
Benzathine penicillin G	<p>Primary, secondary, or early latent: 2.4 million units intramuscularly once</p> <p>Late latent or of unknown duration or tertiary: 2.4 million units intramuscularly 3 × at 1-week interval</p>	Desensitize penicillin-allergic patients during pregnancy; first-line agent during lactation
Aqueous crystalline penicillin G	<p>Neurosyphilis 3–4 million units 6 × daily for 10–14 days or Procaine penicillin 2.4 million units daily + probenecid 500 mg 4 × daily</p>	Desensitize penicillin-allergic patients during pregnancy; also first-line agent during lactation
Trichomoniasis		
Metronidazole	2 g orally for 1 dose	During lactation, temporarily stop breast-feeding for 12 hours (most important for premature or very young infants).
Preterm Labor Prevention		
17- α -hydroxyprogesterone Progesterone (micronized)	<p>250 mg IM each week</p> <p>Intravaginal suppositories 100 mg daily or 90 mg (8%) gel</p>	<p>To prevent premature labor; start at 16–20 weeks' gestation</p> <p>To prevent premature labor; start at 16–20 weeks' gestation</p>
Premature Rupture of Membranes		
Ampicillin	2 g IV every 6 hours for 48 hours followed by amoxicillin	Ampicillin/amoxicillin are used with erythromycin
Amoxicillin	250–500 mg orally 3 × daily for 5 days	Ampicillin/amoxicillin are used with erythromycin
Erythromycin base	250 mg IV every 6 hours × 48 hours followed by 333 mg 3 × daily for 5 days	Ampicillin/amoxicillin are used with erythromycin
Fetal Lung Maturation		
Betamethasone	12 mg IM every 24 hours for 2 doses	
Dexamethasone	6 mg IM or IV every 12 hours for 4 doses	
Preterm Labor		
Nifedipine (short acting)	30-mg oral load (divided over at least 1 hour), then 10–20 mg every 4–6 hours for 48 hours	Maternal adverse reactions include headache, flushing, dizziness, transient hypotension, and maternal pulmonary edema.
Magnesium sulfate	4–6 g IV bolus over 20 minutes, then 2–3 g/h IV drip	Contraindicated in women with myasthenia gravis, and serious complications such as maternal pulmonary edema and cardiac arrest have been reported. More benign side effects such as flushing, headache, and nausea often lead to discontinuation.
Indomethacin	50–100 mg oral load, then 25–50 mg orally every 6 hours × 48 hours	Avoid in women with a history of renal or hepatic impairment, aspirin or nonsteroidal anti-inflammatory drug (NSAID) allergy, peptic ulcer disease, other bleeding disorders, or after 32 weeks of pregnancy. Reports of increased risk of maternal postpartum hemorrhage, and neonatal complications (e.g., premature closure of the ductus arteriosus , necrotizing enterocolitis, bronchopulmonary dysplasia, renal insufficiency, and intraventricular hemorrhage) are worrisome.

(Continued)

Table 47-7

Medication Dosing Recommendations During Pregnancy and Lactation (Continued)

Drug	Dosage	Comments
Group B Streptococcus		
Penicillin G	5 million units IV initially, then 2.5–3 million units IV every 4 hours until delivery	
Ampicillin	2 g IV initially, then 1 g IV every 4 hours until delivery	
Cefazolin	2 g IV initially, then 1 g IV every 8 hours until delivery	
Clindamycin	900 mg IV every 8 hours until delivery	
Vancomycin	1 g IV every 12 hours until delivery	
Preeclampsia/Eclampsia		
Magnesium sulfate	4 g IV bolus over 20 minutes, then 1 g/h IV drip	Use same dose for fetal neuroprotection
Severe Hypertension		
First choices		
Labetalol	10–20 mg IV over 2 minutes; could be repeated every 15–30 minutes (30 mg total dose) Or 1–2 mg/minute IV drip	Not for asthmatic women. May cause fetal bradycardia
Nifedipine (short acting)	5–10 mg orally; could be repeated after 30 minutes	Maternal adverse reactions include headache, flushing, dizziness, transient hypotension, and maternal pulmonary edema.
Hydralazine	5 mg IV or IM; could be repeated IV every 30 minutes (30 mg total dose) Or 0.5–10 mg/hour IV drip	May cause tachycardia, headaches, hypotension
Second choice		
Clonidine	0.05–0.2 mg orally (maximum: 0.8 mg daily)	May cause hypotension, drowsiness
Nonsevere Hypertension		
First choices		
Methyldopa	250–500 mg orally 2–4 × daily	May cause orthostatic hypotension, drowsiness, depression, hemolytic anemia, positive antibodies antinuclear
Labetalol	100–400 mg orally 2–4 × daily	Not for asthmatic women. May cause hypotension, tiredness, headaches, hepatotoxicity
Nifedipine extended release	20–60 mg orally 1–2 × daily	May cause tachycardia, headaches, edema
Second choices		
Hydralazine	10–50 mg orally 2–4 × daily with methyldopa or labetalol	May cause tachycardia, headaches, hypotension, lupus-like syndrome
Metoprolol	25–100 mg orally 2 × daily	Not for asthmatic women; may cause fetal bradycardia
Clonidine	0.05–0.2 mg orally for a (maximum: 0.8 mg daily)	May cause hypotension, drowsiness
Hydrochlorothiazide	12.5–50 mg orally once daily	May cause hypokalemia, dehydration
Thyroid Diseases		
Hypothyroidism		
Levothyroxine	1–2 mcg/kg orally according to thyroxine-stimulating hormone (TSH) level	
Hyperthyroidism		
Propylthiouracil	50–100 mg orally 1–3 × daily according to T4 levels	Use the lowest dose to avoid fetal effects. Be aware of hepatotoxicity.
Anticoagulation		
Heparin and low-molecular-weight heparin	Same as nonpregnant and nonlactating population	

(Continued)

Table 47-7

Medication Dosing Recommendations During Pregnancy and Lactation (Continued)

Drug	Dosage	Comments
Mastitis		
Outpatient Treatment		
Dicloxacillin	500 mg orally 4 × daily	Treat for 10–14 days
Cephalexin	500 mg orally 4 × daily	
Amoxicillin 875 mg + 125 mg clavulanate	1 tablet orally 2 × daily	
Inpatient Treatment for More Severe Cases		
Oxacillin	2 g IV every 4 hours	Treat IV for 24–48 hours until afebrile then continue with outpatient treatment
Nafcillin	2 g IV every 4 hours	
Clindamycin	600–900 mg IV every 8 hours	If MRSA
Vancomycin	1 g IV every 8–12 hours	
Breast Candidiasis		
Mother		
Clotrimazole, miconazole, or nystatin	Topical cream	After each feeding and for 1 week after symptoms have resolved. Also treat infant even if asymptomatic
Fluconazole	200–400 mg orally for 1 dose followed by 100–200 mg orally daily	
Infant		
Nystatin oral solution	100,000–200,000 units (1–2 mL) to be swabbed into infant's mouth 4 × daily, after feedings	If topical treatment not efficacious, add fluconazole; use until 1 week after symptoms have resolved (minimum of 2 weeks of treatment). Also treat infant even if asymptomatic.
Clotrimazole or miconazole topical cream	Apply in a thin layer in infant's mouth 4 × daily, after feedings	
Other Treatments for Candidiasis		
Gentian violet 0.5–1% solution	To be swabbed into infant's mouth once daily for 5 days before a feeding	To be used if other options fail. Can stain clothes and skin. If nipples or mouth are not violet after application and the feeding, reapply the treatment

MRSA, methicillin-resistant *Staphylococcus aureus*; NTD, neural tube defect; RDA, recommended daily allowance.

Data from Refs. 6, 17, 23–25, 28–31, 33–37, 40, 41, 43, 44, 46–49, 51–54, 56, 57, 59, 60, 63–66.

gastrochisis (incidence 4 to 6 per 10,000 treated women). After the first trimester, pseudoephedrine is the preferred agent for short-term use if a topical decongestant or nasal saline solution is not effective.^{6,27} (b) Stop topical decongestants after 3 to 7 days in order to minimize the incidence of rebound congestion. (c) Most first- and second-generation antihistamines are safe in pregnancy at recommended dosages. (d) Nasal corticosteroids are the best drugs for chronic rhinitis.^{6,27,28}

During lactation, all the drugs previously used during pregnancy can be continued.^{22,27} A lower breast milk production has been noticed in a few women following a treatment with pseudoephedrine.²²

Urinary Tract Infections

Urinary tract infections during pregnancy, including asymptomatic disease, are associated with higher risks of hypertension, low birth weight, and preterm delivery. Asymptomatic bacteriuria and cystitis cause acute pyelonephritis more often in pregnancy than in nonpregnant women.²⁹ Acute pyelonephritis may lead to septic shock and adult respiratory distress syndrome and should be treated

aggressively with intravenous antibiotics. Outpatient treatment with intramuscular therapy alone or followed by oral treatment is feasible for some women (e.g., stable and pregnancy less than 24 weeks).²⁹ Treatment reduces pregnancy complications.^{30,31}

Antimicrobial therapy should target *Escherichia coli* infection.²⁶ Safe agents for empirical therapy include penicillins in combination with a beta-lactamase inhibitor, cephalosporins, and nitrofurantoin (Table 47-7).^{29–31} Nitrofurantoin must not be used for the treatment of pyelonephritis. Sulfonamides, ampicillin, and amoxicillin are second-line choices in areas where bacterial resistance is known.^{29,32} Avoid trimethoprim-sulfamethoxazole during organogenesis (congenital malformations) and near term (theoretical risk of neonatal jaundice) unless there are no other suitable choices.^{27,33} Quinolones should be reserved for resistant infections due to theoretical concerns of arthropathy.²⁷

Repeat urine culture 10 days after completion of therapy and monthly thereafter in case of acute pyelonephritis. After completion of the acute episode of pyelonephritis, recommend suppressive therapy prophylaxis for the remainder of the pregnancy and for 4 to 6 weeks after delivery.²⁹

Bacterial Vaginosis

Bacterial vaginosis is associated with adverse pregnancy outcomes such as premature rupture of the membranes, chorioamnionitis, preterm birth, and postpartum endometritis.³⁴ Treatment is recommended in all symptomatic women and in asymptomatic women at high risk for preterm delivery. The Centers for Disease Control and Prevention (CDC) recommends oral metronidazole or clindamycin for the treatment of bacterial vaginosis in pregnant women (Table 47-7).³⁴ Metronidazole is deemed safe for use during all stages of pregnancy.²⁸⁻³⁰ Oral antimicrobials are preferred to intravaginal antimicrobials, and clindamycin vaginal cream should be avoided due to association with low birth weight and neonatal infection.³⁴

Since the cure rate is expected to be around 70%, it is important to do a culture during pregnancy 1 month after completion of therapy.³⁴

During lactation, clindamycin or metronidazole vaginal formulations are the preferred therapies for bacterial vaginosis (Table 47-7).

Vulvovaginal Candidiasis

Only symptomatic vulvovaginal candidiasis should be treated in pregnant or lactating women. First-line treatment is topical azole therapy for 7 days in pregnant women; shorter courses can be used during lactation. Oral fluconazole is not a first-line treatment during pregnancy; it can be used during breast-feeding (Table 47-7).³⁴

Sexually Transmitted Infections

Sexually transmitted infections (STI) have various consequences during pregnancy and require treatment. Table 47-8 presents the risks during pregnancy, the indications for treatment, and the recommended follow-up for chlamydia, gonorrhea, syphilis, herpes simplex, and trichomoniasis.

Preterm Labor

Preterm birth, especially before 32 weeks of pregnancy, is the major cause of short- and long-term neonatal mortality and morbidity. The underlying pathophysiologic conditions are diverse, and most are unknown. There is a wide variation in management, diagnosis, and treatment of preterm labor across the world.

► Antenatal Corticosteroids

The most beneficial intervention in preterm labor is the administration of antepartum corticosteroids. A single course of antenatal corticosteroids should be administered between 24 and 34 weeks' gestation to women at risk of preterm delivery within 7 days (Table 47-7).³⁵ This approach decreases the incidence and severity of neonatal respiratory distress syndrome, intraventricular hemorrhage, **necrotizing enterocolitis**, and death.³⁵ A single rescue course may be used in some women, but current guidelines do not support the use of repeated courses of corticosteroids.³⁶

Table 47-8

Management of Main Sexually Transmitted Infections During Pregnancy and Lactation

	Indications of Treatment	Associated Risks During Pregnancy	When to Repeat Testing During Pregnancy	Other
Chlamydia trachomatis	All women with a positive test, even if asymptomatic	Preterm labor; neonatal infection	Third trimester: Less than 25 years of age, those at increased risk of infection or if first screening positive	Repeat testing 3–4 weeks after therapy
Gonorrhea	All women with a positive test, even if asymptomatic	Preterm labor; neonatal infection	Third trimester: (or 3–6 months after first trimester) if first screening positive or if at risk of reinfection	Repeat testing 3 weeks after therapy
Herpes Simplex	Active lesions; disseminated Starting at 36 weeks: prevention of recurrence at term	Neonatal infection, especially if acquired near time of delivery (30–50%)		Cesarean section if active genital herpetic lesions at delivery; evaluate newborn for herpes infection
Syphilis	All women with confirmed positive serology	In utero fetal and neonatal infection; congenital malformations	At 28–32 weeks and at delivery if at risk of reinfection, if untested before, if positive serology in the first trimester, or if was previous stillborn at more than 20 weeks	Penicillin-allergic women must undergo desensitization; therapy is efficacious to treat the fetus and to prevent transmission; be aware of Jarisch-Herxheimer reaction; fetal evaluation should include ultrasounds.
Trichomoniasis	Symptomatic women	Premature rupture of membranes, preterm birth, low birth weight; neonatal infection		Therapy does not decrease perinatal mortality

Data from Workowski KA, Berman S. Sexually transmitted diseases treatment guidelines, 2010. MMWR Recomm Rep 2010;59:1–110.

► Tocolytic Agents

Tocolytic therapy is used to buy time to complete a course of corticosteroids and to delay delivery to allow transfer of the patient to a center with neonatal intensive care unit facilities. Agents commonly used as tocolytics in the United States include magnesium sulfate, terbutaline, indomethacin, and nifedipine (Table 47-7).³⁷ Few head-to-head comparisons have been made between tocolytic agents. All have limited benefits. Agent selection is based on maternal status and potential adverse drug reactions, as there is no clear first-line tocolytic drug.³⁷ A systematic review concludes that nifedipine offers the best benefit-to-risk ratio, but some authors opine that this conclusion is based on studies of poor quality.^{38,39} Combined tocolytics and prolonged or repeated tocolytic therapy should not be used because it may lead to increased fetal risk without evidence of efficacy.^{37,38}

Magnesium sulfate administered to women at risk of imminent preterm birth may prevent neonatal cerebral palsy.^{40,41} The gestational age at which it should be administered is not yet established.^{40,41}

The FDA has recently advised against the use of terbutaline in pregnant women due to the risk of serious side effects including increased heart rate, transient hyperglycemia, hypokalemia, cardiac arrhythmias, pulmonary edema, and myocardial ischemia.⁴²

Indomethacin also prolongs pregnancy, but it has not been independently associated with decreased neonatal morbidity.³⁷ It may be of particular benefit in women with **hydramnios**.³⁴ Do not use after 32 weeks of pregnancy.

► Antibiotics

The administration of a 7-day course of parenteral (2 days) and oral therapy (5 days) with ampicillin or amoxicillin and erythromycin in the presence of premature rupture of the membranes (before 34 weeks' gestation) is associated with a delay in delivery and a reduction in maternal and neonatal morbidity.⁴³

► Progesterone

Progesterone is recommended to prevent preterm birth in women with previous preterm delivery.⁴⁴ This medication may also be useful in women with a sonographic short cervix.⁴⁵

Group B *Streptococcus* Infection

Maternal transmission of group B *Streptococcus* during the intrapartum period is a cause of neonatal sepsis and death. All pregnant women should be screened for group B *Streptococcus* disease using vaginal and rectal swabs between 35 and 37 weeks of gestation. Antibiotic therapy is effective in reducing the incidence of early-onset neonatal group B *Streptococcus* infection when administered to high-risk groups of women.⁴⁶ Empirical treatment should be started for group B *Streptococcus* at the time of membrane rupture and continued until delivery (Table 47-7). The antibiotic of choice for group B streptococcal disease is penicillin G, although ampicillin or clindamycin are good alternatives.⁴⁷ Resistance has developed with the use of some alternative choices for penicillin-allergic patients.

Examine the neonate for signs and symptoms of sepsis until 48 hours after birth. If present, a full diagnostic workup (including complete blood cell count and blood culture) should be initiated and empirical antibiotic therapy started.⁴⁷

Thyroid Disorders

Care of pregestational hypothyroidism and hyperthyroidism is presented in Chapter 44.

The target thyroxine-stimulating hormone (TSH) level is below 2.5 microunits/mL (2.5 milliunits/L) in the first trimester and below 3 microunits/mL (3 milliunits/L) in the second and third trimesters.⁴⁸ Because pregnancy induces significant changes in thyroid function, transient gestational hypothyroidism or hyperthyroidism may occur and may have adverse effects on the pregnancy and the fetus/neonate, even if subclinical.⁴⁸

Universal screening of thyroid disorders in pregnancy is debated, as well as the assessment of antibodies to thyroid peroxidase. The most appropriate management of this condition is unknown.⁴⁸

Although there are no solid data on the impact of thyroid replacement therapy on either short-term maternal and neonatal morbidity nor on long-term infant neurologic outcomes, it is recommended to treat subclinical hypothyroidism in pregnant women.⁴⁸

Gestational hyperthyroidism associated with **hyperemesis gravidarum** is self-remitting and does not require antithyroid treatment. In overt maternal hyperthyroidism, current guidelines recommend propylthiouracil in the first trimester (methimazole is associated with fetal malformations) and methimazole thereafter, because of the increased risk of hepatotoxicity with propylthiouracil (Table 47-7).⁴⁸ Check for signs of fetal hypothyroidism (induced by antithyroid drugs) or hyperthyroidism (induced by maternal thyroid-stimulating antibodies). The lowest dose necessary to keep T4 levels in the upper range of the normal should be used. I¹³¹ should not be used in pregnancy. If required, surgery should be done in the second trimester.⁴⁸

Evaluate TSH level 6 to 12 weeks after delivery in all women with thyroid disorders during pregnancy. All newborns must be evaluated for thyroid dysfunction. Thyroid replacement drugs and antithyroid drugs can be used during lactation.²²

Hypertension

Hypertensive disorders in pregnancy include preexisting (chronic) hypertension and pregnancy-induced hypertension (gestational hypertension or preeclampsia). Both increase the risks of maternal and perinatal morbidity and mortality. Preeclampsia (hypertension and proteinuria) is a syndrome produced by endothelial dysfunction. Women may present with seizures (eclampsia), neurologic, hepatic, and renal and/or coagulation complications, as well as fetal death and intrauterine growth restriction. Delivery is the only treatment for preeclampsia. Intravenous magnesium sulfate may be used to prevent eclampsia (Table 47-7).⁴⁹

Severe hypertension in pregnancy (systolic blood pressure ≥ 160 mm Hg or diastolic blood pressure ≥ 110 mm Hg) is an emergency and should be treated aggressively, under maternal and fetal monitoring (Table 47-7).⁴⁹ Treatment of nonsevere hypertension is debated. Although antihypertensive drugs do prevent severe hypertension, they do not prevent preeclampsia and could decrease fetal growth.⁵⁰ First-line drugs include methyldopa, labetalol, and nifedipine (Table 47-7). Do not use angiotensin-converting enzyme inhibitors, angiotensin receptor inhibitors, or renin inhibitors (fetopathy). Caution is advised with atenolol, as it has been associated with intrauterine growth restriction.

Low-dose aspirin (75 to 160 mg) is useful in high-risk women in preventing preeclampsia, preterm birth, and fetal/neonatal death.⁵¹ Calcium supplements (1 g/day) are also helpful in preventing preeclampsia.⁵²

See all women with hypertensive disorders 6 to 12 weeks after delivery to monitor blood pressure, proteinuria, and cardiovascular risk markers and counsel them on future pregnancy, healthy diet, and lifestyle.

Diabetes

Diabetes in pregnancy includes pregestational diabetes and gestational diabetes (Chapter 43). Women with pregestational diabetes should be counseled about the increased risk of complications such as miscarriage, fetal/neonatal death, malformations, macrosomia, and preeclampsia, as well as a need for cesarean section. Euglycemia at conception and during pregnancy is the best approach in preventing poor pregnancy outcomes. Women with type 2 diabetes may be started on insulin before pregnancy if they do not achieve optimal control with oral agents. Gestational diabetes is associated with neonatal macrosomia, preeclampsia, and cesarean section, but not with major fetal malformations.

Diet and exercise are important nonpharmacologic treatments. Weight gain during pregnancy should be adapted to prepregnancy weight.

Insulin is the first-line treatment during pregnancy. Although limited data are available on long-acting insulins (detemir, glargine), they could be continued if diabetes control is satisfactory. In women with gestational diabetes, glyburide and metformin represent interesting alternatives.⁵³ Metformin and glyburide do not cause fetal malformations. Limited data are available for other antidiabetic agents. Metformin may be used in women with polycystic ovary syndrome to decrease miscarriage and gestational diabetes.⁵⁴

Intravenous drip insulin should be used during labor. After delivery, insulin doses are decreased to pregestational doses to prevent maternal hypoglycemia.

Limited data are available on use of hypoglycemic agents during lactation. Insulin should be used if glucose levels are very high. Metformin may be used during lactation based on its pharmacologic profile, but follow-up data in infants are lacking.

Evaluate for the presence of underlying diabetes in all women with gestational diabetes with a 75-g oral glucose tolerance test 6 to 12 weeks after delivery. Counsel these women on healthy diet, weight loss, and exercise.

Anticoagulation

Heparins are used for various purposes during and after pregnancy: treatment or prevention of thromboembolism, prevention of prosthetic heart valve thrombosis, and prevention of pregnancy complications. The risk of thromboembolic events is increased during pregnancy and postpartum, and anticoagulation is required in some women during these periods, even if they were not anticoagulated before pregnancy.⁵⁵

Low-molecular-weight heparins are preferred to unfractionated heparin. Both are safe during pregnancy and lactation. Doses should be specific to the underlying condition (consult reference 55).

Women with prosthetic heart valves should be managed by a multidisciplinary specialist team. Warfarin may be used in these women in the second trimester and early third trimester since valve thrombosis has been reported with heparin therapy, but warfarin is associated with bleeding at delivery and a risk of teratogenesis during the first trimester after 6 weeks of gestational age (Table 47-3).⁵⁵

Anticoagulation should be used after delivery in women at high risk of thromboembolism.⁵⁵

Warfarin and heparins are safe for use during lactation.²²

Enhancement of Lactation

Optimization of breast-feeding techniques is the first approach when decreased lactation is suspected. No drug is currently approved by the FDA for lactation enhancement, but dopamine antagonists, metoclopramide and domperidone, which increase prolactin levels are sometimes used for this purpose.^{56,57} Metoclopramide's maternal side effects include fatigue, irritability, headache, and extrapyramidal symptoms. Very few side effects in the infant have been reported. However, domperidone is not available in the United States, and the FDA issued a warning against domperidone use in 2004 owing to reports of cardiac arrhythmia and sudden death associated with high IV doses prescribed for gastric disorders in cancer patients.⁵⁷

Mastitis

Bacterial mastitis is seen typically within the first 6 weeks of breast-feeding and is characterized by localized signs of inflammation (redness, swelling, heat, or pain), and engorgement. Fever, shivering, and malaise can also occur. The most commonly encountered bacteria are *Staphylococcus aureus* (including methicillin-resistant), followed by *Streptococcus*, *Staphylococcus epidermidis*, and *E. coli*.⁵⁸

Nonpharmacologic measures, such as cold or warm compresses and more frequent breast-feeding or breast pumping, should be encouraged. Several antibiotics can be used (Table 47-7). Analgesics (e.g., acetaminophen, ibuprofen, or naproxen) can be used to relieve pain.^{22,58,59}

Breast Candidiasis

Diagnosis of breast candidiasis is mainly based on signs and symptoms. Candidiasis presents with severe and persistent nipple pain, which can be throbbing and radiating to the breasts and back. The pain is usually more intense during

Patient Encounter, Part 3

At 37 weeks gestation, MM is admitted for preeclampsia. She is induced for labor.

What special care will you provide during labor?

and immediately after breast-feeding. The breast-fed infant can be symptomatic or asymptomatic. *Candida albicans* is the most commonly found type of *Candida* species. It is recommended to breast-feed more frequently than usual for a shorter period of time. Milk does not have to be discarded; however, clothes and towels in contact with the breasts and the baby's mouth should be washed in hot water. Antifungal

treatment must be given to the mother and the baby simultaneously (Table 47-7). If no improvement is seen within 24 to 48 hours, the treatment should be reevaluated. Analgesics (e.g., acetaminophen, ibuprofen, or naproxen) can be used to relieve pain.⁶⁰

Patient Encounter, Part 4

After 48 hours of labor, MM delivers by cesarean section a healthy 9-lb (4.1 kg) baby. She plans to breast-feed.

What treatment plan do you recommend after delivery?

Can her prepregnancy medication be restarted while she breast-feeds?

Patient Care and Monitoring

- Provide prenatal counseling regarding lifestyle modifications (healthy diet, exercise, avoidance of tobacco, alcohol, and illicit or unnecessary drugs) and medication use during pregnancy. When possible, attain good control of maternal medical conditions prior to conception. Identify patients at risk of psychosocial problems. Immunize as needed (avoid live vaccines).
- Perform routine screening at first appointment during pregnancy
 - Hematocrit and hemoglobin levels
 - Urinalysis and urine culture
 - Determination of blood group and Rhesus type
 - Determination of immunity to rubella virus
 - Syphilis and sexually transmitted diseases
 - Cervical cytology (if needed)
 - Hepatitis B surface antigen
 - HIV antibody testing
- Recommend appropriate folic acid and multivitamins prior to conception.
- After pregnancy is achieved, encourage lifestyle modifications, routine pregnancy monitoring and care, and medication adherence.
- 6** *When possible, treat pregnancy conditions with nonpharmacologic treatments instead of using drug therapy.*
- When considering pharmacologic treatment, evaluate the following:
 - 7** *Evaluate the need for treatment, including benefits and risks. Avoid treatments that have not shown evidence of benefit and those that can be delayed until after pregnancy and breast-feeding.*
 - Are the symptoms related to benign conditions of pregnancy (e.g., palpitations)? How bothersome are the symptoms (e.g., nausea and vomiting)? In case of chronic treatment, does it need to be continued during pregnancy (e.g., dyslipidemia)? Is the condition interfering with other pathologies (e.g., nausea and diabetes)? Could starting/continuing/stopping the treatment pose a risk for the fetus/neonate?
 - Is an effective treatment available?
 - What are the maternal side effects of the drug?
 - Which is the best drug when used alone?
 - Which is the drug with the best safety data in pregnancy/lactation?
- Encourage breast-feeding. If maternal drug therapy is required during breast-feeding, try to choose short-acting agents with the longest history of safe use in lactation, and administer immediately after feedings.
 - Avoid treatments that have shown no evidence of benefit or that can be delayed until after breast-feeding.
 - If possible, select drugs that are used in neonates or children and that are well tolerated.
 - When possible, select drugs that yield low percentages of pediatric or relative infant doses (preferably less than 10%).
 - Consider infant age when analyzing safety of a drug during breast-feeding. Premature or very young children will be more sensitive to drug effects than older children.
 - Avoid drugs that can hinder breast milk production.
- Monitor infants for birth defects and/or unusual reactions that may be due to maternal drug use. Report suspected drug-related reactions to the FDA or pharmaceutical companies.

Abbreviations Introduced in This Chapter

ACOG	American College of Obstetricians and Gynecologists
CDC	Centers for Disease Control and Prevention
GA	Gestational age
NSAID	Nonsteroidal anti-inflammatory drug

Contraception

Julia M. Koehler and Kathleen B. Haynes

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Discuss the physiology of the normal female reproductive system.
2. Compare the efficacy of oral contraceptives with that of other methods of contraception.
3. State the mechanism of action of hormonal contraceptives.
4. Discuss the risks associated with the use of contraceptives, and state absolute and relative contraindications to their use.
5. List side effects associated with the use of various contraceptives, and recommend strategies for minimizing or eliminating such side effects.
6. Describe advantages and disadvantages of various contraceptives, including both oral and nonoral formulations.
7. Cite important drug interactions that may occur with oral contraceptives.
8. Provide appropriate patient education regarding the important differences between various barrier methods of contraception.
9. Discuss how emergency contraception (EC) may be employed to prevent accidental pregnancy.
10. Provide appropriate patient education regarding the use of oral contraceptives, and recommend and discuss the use of nonoral contraceptives when appropriate.

KEY CONCEPTS

- 1 Heavy smokers (greater than or equal to 15 cigarettes per day) who are 35 years of age or older as well as patients with a history of thromboembolic disease, stroke, coronary artery or ischemic heart disease, peripheral vascular disease, any estrogen-dependent neoplasm, undiagnosed abnormal uterine or vaginal bleeding, or migraine headache disorder with focal neurologic deficits should not take estrogen-containing contraceptives.
- 2 Side effects associated with the use of combination oral contraceptives may be minimized by appropriately adjusting either the total estrogen or progestin content.
- 3 Clinicians should be aware of the many drugs that may potentially interact with contraceptives—especially those that may reduce the effectiveness of contraceptives.
- 4 Nonoral forms of contraceptives, such as the transdermal patch and the transvaginal ring, eliminate the need for daily administration and, as such, may enhance patient convenience and adherence.

- 5 Oral, transdermal, and transvaginal contraceptives, as well as intrauterine devices (IUDs) and most barrier contraceptives, do not protect against sexually transmitted diseases (STDs).
- 6 When a contraceptive dose is missed, the risk of accidental pregnancy may be increased. Depending on how many doses were missed, the contraceptive formulation being used, and the phase of the cycle during which doses were missed, counseling regarding the use of additional methods of contraception may be warranted.

Historically, the 1950s represented an important time in the control of human fertility. It was during that decade that the first combination oral contraceptives (COCs) were developed. Shortly after the discovery that the exogenous administration of hormones such as progesterone successfully blocked ovulation, the use of hormonal steroids quickly became the most popular method of contraception worldwide. Specifically, COCs represent the most commonly used reversible form of contraception today, and it is

estimated that nearly 100 million women worldwide take oral contraceptives.¹ Of the 62 million women in the United States who are of childbearing age (15 to 44 years), it is estimated that more than 38 million are currently using a contraceptive method.² Although the choice of contraceptive method varies greatly according to the age of the user, oral contraceptives are the leading choice among women in the United States who are under the age of 30.² Since the introduction of oral contraceptives, many newer forms of contraceptives have been developed and are available for use in the United States. Today, a variety of hormone delivery systems, such as transdermal systems, transvaginal systems, and intrauterine devices (IUDs), are available and offer women effective and potentially more convenient alternatives to oral contraceptives.

EPIDEMIOLOGY

According to the National Survey of Family Growth, approximately 6.39 million pregnancies occur annually in the United States.³ It is estimated that nearly half of all pregnancies that occur each year in the United States are unintended.^{2,3} Contributing to the risk of unintended pregnancy is the fact that approximately 7% of all women who are at risk of becoming pregnant do not use any form of contraception.^{2,3} In addition, many women who do use contraceptives use their chosen method of contraception imperfectly, and this also increases the risk of unintended pregnancy. For patients with certain medical conditions, such as epilepsy, hypertension, ischemic heart disease, sickle cell disease, lupus, or thromboembolic mutations, unintended pregnancy can further increase the risk for adverse health events.⁴ The provision of appropriate and adequate instruction to patients regarding how to use contraceptive methods effectively is essential in order to reduce the risk of unintended pregnancy and, for some women, the associated increase in risk for adverse health-related events.

Exposure to STDs is also a concern for women who are sexually active. It is estimated that 19 million people in the United States become newly infected annually with an STD.⁵ Given that not all methods of contraception protect the user against STDs, the provision of proper patient education by healthcare professionals regarding this risk is absolutely essential.

PHYSIOLOGY

- The female menstrual cycle is divided into four functional phases: follicular, ovulatory, luteal, and menstrual.⁶ The follicular phase begins the cycle, and ovulation generally occurs around day 14. The luteal phase then begins and continues until menstruation occurs.⁶ The menstrual cycle is regulated by a negative-feedback hormone loop between the hypothalamus, anterior pituitary gland, and ovaries⁶ (Fig. 48-1).

- Initially, the hypothalamus releases gonadotropin-releasing hormone (GnRH), which stimulates the anterior pituitary to produce follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The levels of FSH and LH released vary

depending on the phase of the menstrual cycle. Just prior to ovulation, FSH and LH both are at their peak levels. The FSH helps to promote growth of the follicle in preparation for ovulation by causing granulosa cells lining the follicle to grow and produce estrogen. The LH promotes androgen production by theca cells in the follicle, promotes ovulation and oocyte maturation, and converts granulosa cells to cells that secrete progesterone after ovulation.

- Conception is most likely to occur when viable sperm are present in the upper region of the reproductive tract at the time of ovulation. Fertilization occurs when a spermatozoon penetrates an ovum. Approximately 6 to 8 days after ovulation, attachment of the early embryo to the lining of the uterine cavity—implantation—occurs.

PREVENTION OF PREGNANCY: CONTRACEPTIVES AND DEVICES

Goals of Contraception/Desired Outcome

The most common goal of contraception is the prevention of pregnancy. However, some patients use contraceptive methods for other benefits, such as menstrual cycle regulation, reduction of premenstrual symptoms, or treatment of acne.

Choice of Contraceptives: Important Considerations

When helping a patient with contraceptive selection, the most important goal is finding an option the patient is comfortable with and the clinician feels is beneficial for the patient. It is imperative to explain the side effects, safety concerns, and noncontraceptive benefits of each alternative to the patient so that she may make an informed decision. Fertility goals vary for each patient. It must be determined whether the goal is to postpone conception, space out the next pregnancy, or avoid further pregnancy altogether. Also, a clinician must understand the patient's desire to have or not have a regular bleeding pattern, because many contraceptives will affect menses.

As discussed later in this chapter, contraindications exist for various forms of contraception. Patients must be evaluated by a healthcare professional to rule out medical contraindications to certain contraceptives. The physical examination also allows healthcare professionals to identify other medical concerns, such as hypertension, diabetes, or liver disease, that need to be considered when selecting an appropriate contraceptive agent. Clinicians also should review family history for potential risks with certain forms of birth control.

Sexual behavior of the female must be determined to understand the risk for STDs. Women not in a monogamous relationship must consider their risk of STDs as a factor in their contraceptive decision. Some barrier methods protect against STDs, but hormonal contraceptives do not prevent STDs if used alone.

Personal preference plays a large role when determining the best contraceptive option. For instance, if a woman is not interested in using a method that interrupts sexual activity,

FIGURE 48-1. Menstrual cycle events. ^aEstradiol: 40 pg/mL = 147 pmol/L; 250 to 400 pg/mL = 918 to 1,468 pmol/L; 125 to 250 pg/mL = 459 to 918 pmol/L. ^bProgesterone: 1 ng/dL = 0.032 nmol/L; 10 to 15 ng/dL = 0.32 to 0.48 nmol/L. (Adapted with permission from Hatcher RA, Namnoum AB. The menstrual cycle. In: Hatcher RA, Trussel J, Nelson AL, et al. Contraceptive Technology, 19th rev. ed. New York: Ardent Media, 2007:7-18.)

then a diaphragm would be an inappropriate choice. Preference of the sexual partner may also be important. Certain agents such as male condoms require the male partner to play an active role in contraception.

Cost may also be an issue for patients. Insurance may not cover all forms of contraception, and patients may have to bear the entire cost for certain options.

Efficacy of Contraceptives

- The accidental pregnancy rate for women who do not use any form of contraception is unknown. Therefore, it is difficult to determine the true efficacy of contraceptives in preventing unwanted pregnancy. **Table 48-1** shows the percentage of women who experience unintended pregnancy within 1 year of contraceptive use with ongoing sexual activity.⁷

Oral Contraceptives (Combination)

COCs contain a synthetic estrogen and one of several steroids with progestational activity. Most oral contraceptives contain one of three types of estrogen: ethinyl estradiol (EE), which is pharmacologically active; mestranol, which is converted by the liver to EE; or estradiol valerate, which is metabolized to estradiol and valeric acid. Many different progestins are found in the various oral contraceptives. These include norethindrone, norethindrone acetate, ethynodiol diacetate, norgestrel, levonorgestrel, desogestrel, norgestimate, drospirenone, and dienogest.

- The primary mechanism by which COCs prevent pregnancy is through inhibition of ovulation. FSH and LH regulate the production of estrogen and progesterone by the ovaries. Secretion of estrogen and progesterone by the

Table 48-1

Unintended Pregnancy Rates

Method	Percentage of Women Experiencing Unintended Pregnancy Within First Year of Use		Percentage of Women Continuing Use at 1 Year ^c
	Typical Use ^a	Perfect Use ^b	
No method	85	85	
Spermicides	29	18	42
Withdrawal	27	4	43
Fertility awareness–based methods	25		51
Standard days method		5	
Two-day method		4	
Sponge			
Parous women	32	20	46
Nulliparous women	16	9	57
Diaphragm	16	6	57
Condom			
Female (reality)	21	5	49
Male	15	2	53
Combination pill and mini-pill	8	0.3	68
Ortho Evra patch	8	0.3	68
NuvaRing	8	0.3	68
Depo-Provera	3	0.3	56
IUD			
ParaGard (copper T)	0.8	0.6	78
Mirena (LNG-IUS)	0.2	0.2	80
Implanon	0.05	0.05	
Female sterilization	0.5	0.5	100
Male sterilization	0.15	0.1	100

^aAmong *typical* couples who initiate use of a method (not necessarily for the first time), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason. Estimates of the probability of pregnancy during the first year of typical use for spermicides, withdrawal, periodic abstinence, the diaphragm, the male condom, the pill, and Depo-Provera are taken from the 1995 National Survey of Family Growth corrected for under-reporting of abortion.

^bAmong couples who initiate use of a method (not necessarily for the first time) and who use it *perfectly* (both consistently and correctly), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.

^cAmong couples attempting to avoid pregnancy, the percentage who continue to use a method for 1 year.

Adapted from Trussel J. Choosing a contraceptive: Efficacy, safety, and personal considerations. In: Hatcher RA, Trussel J, Nelson AL, et al. *Contraceptive Technology*, 19th rev. ed. New York: Ardent Media, 2007:19–48.

ovaries occurs in a cyclic manner, which determines the regular hormonal changes that occur in the uterus, vagina, and cervix associated with the menstrual cycle. Cyclic changes in the levels of estrogen and progesterone in the blood, together with FSH and LH, modulate the development of ova and the occurrence of ovulation. The estrogen component of COCs is most active in inhibiting FSH release.¹ However, at sufficiently high doses, estrogens also may cause inhibition of LH

release. In low-dose COCs, the progestin component causes suppression of LH.¹ Ovulation is prevented by this suppression of the midcycle surge of both FSH and LH¹ and mimics the physiologic changes that occur during pregnancy.
