

Pharmacotherapy Principles & Practice

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Pharmacotherapy Principles & Practice

THIRD EDITION

Editors

**Marie A. Chisholm-Burns,

ABOUT THE EDITORS

Marie A. Chisholm-Burns, BS Pharm, PharmD, MPH, FCCP, FASHP, is Dean and Professor at the University of Tennessee College of Pharmacy. She received her BS and PharmD degrees from the University of Georgia, and completed a residency at Mercer University Southern School of Pharmacy and at Piedmont Hospital in Atlanta, Georgia. She has served in elected positions in numerous professional organizations. Dr. Chisholm-Burns has greater than 250 publications and more than \$8 million in external funding as principal investigator. In 2008 and 2011, textbooks co-edited by Dr. Chisholm-Burns, *Pharmacotherapy Principles and Practice* and *Pharmacy Management, Leadership, Marketing, and Finance*, respectively, received the Medical Book Award from the American Medical Writers Association. She has also received numerous awards and honors including the Robert K. Chalmers Distinguished Pharmacy Educator Award from the American Association of Colleges of Pharmacy, the Clinical Pharmacy Education Award from the American College of Clinical Pharmacy, the Daniel B. Smith Practice Excellence Award from the American Pharmacists Association, the Nicholas Andrew Cummings Award from the National Academies of Practice, the Award of Excellence from the American Society of Health-System Pharmacists, and the Rufus A. Lyman Award for most outstanding publication in the American Journal of Pharmaceutical Education (in 1996 and 2007). Dr. Chisholm-Burns lives in Memphis, is married, and has one child, John Fitzgerald Burns Jr. She enjoys writing, cycling, and playing chess.

Barbara G. Wells, BS Pharm, PharmD, FCCP, FASHP, is Dean and Professor Emeritus at the University of Mississippi School of Pharmacy and Executive Director Emeritus of the Research Institute of Pharmaceutical Sciences. She completed a residency in psychiatric pharmacy practice at the University of Tennessee. She is a past president and chair of the Board of the American Association of Colleges of Pharmacy (AACP) and the American College of Clinical Pharmacy (ACCP). She is a past member of the NIH Advisory Committee on Research on Women's Health and of the FDA Psychopharmacologic Drugs Advisory Committee. Her primary instructional interests are in psychiatric therapeutics, and she has received six teaching awards, including the Robert K. Chalmers Distinguished Pharmacy Educator Award from AACP and the Paul F. Parker Award from ACCP. Other books that she coedits are *Pharmacotherapy: A Pathophysiologic Approach* and the *Pharmacotherapy Handbook*. She enjoys a leisurely or working weekend on her houseboat named Euphoria on Pickwick Lake.

Terry L. Schwinghammer, BS Pharm, PharmD, BCPS, FCCP, FASHP, FAPhA is Professor and Chair of the Department of Clinical Pharmacy at the West Virginia University School of Pharmacy. He received his BS and PharmD degrees from Purdue University and completed a pharmacy residency at Indiana University Hospitals. He has practiced in adult inpatient and ambulatory care settings. Dr. Schwinghammer is a past recipient of the APhA-APPM Distinguished Achievement Award in Clinical/Pharmacotherapeutic Practice and is a Distinguished Practitioner in the National Academies of Practice. His teaching focuses on pharmacotherapy of rheumatic diseases and physical assessment. In addition to authoring over 60 publications, he is coeditor of the *Pharmacotherapy Casebook* and *Pharmacotherapy Handbook* and is Editor-in-Chief of AccessPharmacy (www.AccessPharmacy.com). He has been elected to membership in the Rho Chi Pharmaceutical Honor Society and the Phi Lambda Sigma Pharmacy Leadership Society. He was named a Distinguished Alumnus of Purdue University in 2004. His hobby is collecting apothecary antiques, and he enjoys boating and water skiing with his family.

x ABOUT THE EDITORS

Patrick M. Malone, BS Pharm, PharmD, FASHP, is Professor and Associate Dean of Internal Affairs at The University of Findlay College of Pharmacy. Dr. Malone received his BS in Pharmacy from Albany College of Pharmacy and PharmD from the University of Michigan. He completed a clinical pharmacy residency at the Buffalo General Hospital, Drug Information Fellowship at the University of Nebraska Medical Center, and US West Fellowship in Academic Development and Technology at Creighton University. His practice and teaching have centered on drug information, and he is the first author for all four editions of *Drug Information—A Guide for Pharmacists*. Dr. Malone was also the drug information pharmacist at the XIII Winter Olympics. He has approximately 100 publications and numerous presentations and has held various offices in national organizations. He was the Director of the Web-Based Pharmacy Pathway at Creighton University Medical Center, from its initial establishment until after graduation of the first class. His hobby is building and flying radio-controlled aircraft.

Jill M. Kolesar, BS Pharm, PharmD, BCPS, FCCP, is a Professor at the University of Wisconsin and the Director of the 3P Laboratory at the University of Wisconsin Carbone Comprehensive Cancer Center. She received a BS in pharmacy from the University of Wisconsin and a PharmD from the University of Texas. Dr. Kolesar also completed an oncology residency and fellowship at the University of Texas Health Science Center in San Antonio. Dr. Kolesar is the author of more than 100 peer reviewed publications and has received more than \$1.2 million in external funding as a principal investigator. She holds two US and international patents for novel technologies invented in her laboratory and founded Helix Diagnostics based on this technology. She has served on the National Cancer Institute Central IRB, and is currently a member of the Pharmacology Taskforce, an advisory group to the Investigational Drug Steering Committee of the NCI. She also chairs the Lung Biology Subcommittee for the Thoracic Committee of the Eastern Cooperative Oncology Group. Dr. Kolesar received the Innovations in Teaching Award from AACP, and has served in multiple elected offices of national and international pharmacy organizations. Other books she coedits are *Top 300 Pharmacy Flash Cards*, *Pharmacogenomics: Applications to Patient Care* and *The Pharmacogenomics Handbook*. Dr. Kolesar loves to read, run, ski, and travel with her husband and five children. She has completed 2 marathons and 14 half-marathons.

Joseph T. DiPiro, BS Pharm, PharmD, FCCP, is Executive Dean of the South Carolina College of Pharmacy, which is an integrated program of the Colleges of Pharmacy at the University of South Carolina and the Medical University of South Carolina. He received his BS in pharmacy from the University of Connecticut and PharmD from the University of Kentucky. He served a residency at the University of Kentucky Medical Center and a fellowship in Clinical Immunology at Johns Hopkins University. He is the Editor of the *American Journal of Pharmaceutical Education*. Dr. DiPiro has published over 120 refereed papers in academic and professional journals. He is also an editor for *Pharmacotherapy: A Pathophysiologic Approach*, and an author of *Concepts in Clinical Pharmacokinetics*. He was a President of the American College of Clinical Pharmacy and has served on the Research Institute Board of Trustees. In 2002, the American Association of Colleges of Pharmacy selected Dr. DiPiro for the Robert K. Chalmers Distinguished Educator Award. He has also received the Russell R. Miller Literature Award and the Education Award from the American College of Clinical Pharmacy, and the Award for Sustained Contributions to the Literature from the American Society of Health-System Pharmacists. He is an avid runner and has completed 15 marathons.

CONTRIBUTORS

Julie B. Dumond, PharmD

Research Assistant Professor, Eshelman School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

Chapter 87

Megan J. Ehret, PharmD, MS, BCPP

Associate Professor, Department of Pharmacy Practice, School of Pharmacy, University of Connecticut, Storrs, Connecticut

Chapter 29

Clayton English, PharmD

Assistant Professor, Department of Pharmacy Practice, Albany College of Pharmacy and Health Sciences, Colchester, Vermont

Chapter 29

John Erramouspe, PharmD, MS

Professor, Pharmacy Practice and Administrative Sciences, Idaho State University, Pocatello, Idaho

Chapter 42

Edward Faught, MD

Professor, Department of Neurology, Emory University, Atlanta, Georgia

Chapter 31

Ema Ferreira, BPharm, MSc, PharmD, FCHSP

Pharmacist in Obstetrics and Gynecology, Clinical Associate Professor, CHU Ste-Justine, Faculty of Pharmacy, Université de Montréal, Montreal, Quebec, Canada

Chapter 47

Jack E. Fincham, PhD, RPh

Professor, University of Missouri-Kansas City, School of Pharmacy, Division of Pharmacy Practice and Administration, Kansas City, Missouri

Chapter 1

Steven Gabardi, PharmD, FCCP, BCPS

Abdominal Organ Transplant Clinical Specialist, Brigham and Women's Hospital, Boston, Massachusetts; Assistant Professor of Medicine, Harvard Medical School, Boston, Massachusetts

Chapter 55

Angie L. Goeser-Iske, PharmD

Pharmacist, Integrus Health, Oklahoma City, Oklahoma

Chapter 65

Maqual R. Graham, PharmD

Associate Professor of Pharmacy Practice and Administration, University of Missouri-Kansas City School of Pharmacy, Kansas City, Missouri

Chapter 102

Phyllis A. Grauer, PharmD

Clinical Assistant Professor, College of Pharmacy, Ohio State University, Columbus, Ohio

Chapter 4

Erika L. Grigg, MD

Section of Gastroenterology, Georgia Health Sciences University, Augusta, Georgia

Chapter 18

David R. P. Guay, PharmD

Professor Emeritus, Department of Experimental and Clinical Pharmacology, College of Pharmacy, University of Minnesota, Minneapolis, Minnesota

Chapter 53

John G. Gums, PharmD, FCCP

Professor of Pharmacy and Medicine, Director of Clinical Research in Family Medicine, Associate Chair, Department of Pharmacotherapy and Translational Research, University of Florida, Gainesville, Florida

Chapter 58

Julie Haase, PharmD

Pharmacy Practice Resident, Creighton University Medical Center, Omaha, Nebraska

Appendix E

Tracy M. Hagemann, PharmD, FCCP, FPPAG

Associate Professor, Clinical and Administrative Sciences, University of Oklahoma College of Pharmacy, Oklahoma City, Oklahoma

Chapter 68

Stuart T. Haines, PharmD, BCPS, BC-ADM

Professor, Department of Pharmacy Practice and Science, University of Maryland School of Pharmacy, Baltimore, Maryland; Clinical Pharmacy Specialist, West Palm Beach VA Medical Center, West Palm Beach, Florida

Chapter 10

Kim Hawkins, MS, APRN-NP

Assistant Professor, Creighton University School of Nursing, Omaha, Nebraska

Appendix E

Kathleen B. Haynes, PharmD

Clinical Coordinator, Bridges to Health, Community Health Network, Indianapolis, Indiana
Chapter 48

Keith A. Hecht, PharmD, BCOP

Clinical Associate Professor of Pharmacy Practice, School of Pharmacy, Southern Illinois University, Edwardsville, Illinois
Chapter 97

Nancy Heideman, PharmD, BCPS

Clinical Specialist-Pediatrics, University of New Mexico Hospital, Albuquerque, New Mexico
Chapter 95

Richard Heideman, MD

Professor of Pediatrics, University of New Mexico, Albuquerque, New Mexico
Chapter 95

Brian A. Hemstreet, PharmD, BCPS

Associate Professor, Director, Pharmaceutical Care Learning Center, Department of Clinical Pharmacy, University of Colorado School of Pharmacy, Aurora, Colorado
Chapter 19

Elizabeth D. Hermsen, PharmD, MBA, BCPS-ID

Clinical Scientific Director, Cubist Pharmaceuticals, Lexington, Massachusetts; Adjunct Associate Professor, University of Nebraska Medical Center, College of Pharmacy, Omaha, Nebraska
Chapter 76

Gerald Higa, PharmD

Professor, Schools of Pharmacy and Medicine, Mary Babb Randolph Cancer Center, Morgantown, West Virginia
Chapter 89

Michelle L. Hilaire, PharmD, CDE, BCPS

Clinical Associate Professor of Pharmacy Practice, University of Wyoming School of Pharmacy, Faculty Pharmacist, Fort Collins Family Medicine Residencies, Fort Collins, Colorado
Chapter 62

Jamie C. Holmes, PharmD

Assistant Professor, Department of Pharmacy Practice, Rosalind Franklin University of Medicine and Science, North Chicago, Illinois
Chapter 33

Marlon S. Honeywell, PharmD

Interim Associate Dean for Academic Affairs and Professor, College of Pharmacy and Pharmaceutical Sciences, Florida A&M University, Tallahassee, Florida
Chapter 80

Jaime R. Hornecker, PharmD, BCPS

Clinical Associate Professor of Pharmacy Practice, University of Wyoming School of Pharmacy, Laramie, Wyoming
Chapter 73

Melissa L. Hunter, PharmD

Drug Information Director, School of Pharmacy, University of Wyoming, Laramie, Wyoming
Chapter 62

Jill Isaacs, MS, APRN-NP

Assistant Professor, Creighton University School of Nursing, Omaha, Nebraska
Appendix E

Matthew K. Ito, PharmD, FCCP, FNLA, CLS

Professor, Department of Pharmacy Practice, Oregon State University/Oregon Health and Science University College of Pharmacy, Portland, Oregon
Chapter 12

Cherry W. Jackson, PharmD, BCPP, FASHP

Professor, Department of Pharmacy Practice, Auburn University; Professor, Department of Psychiatric and Behavioral Neurobiology, School of Medicine, University of Alabama, Birmingham, Alabama
Chapter 38

Ziba Jalali

Assistant Professor, College of Medicine, University of Nebraska Medical Center, Omaha, Nebraska
Chapter 76

Tommy Johnson, PharmD, BC-ADM, CDE, FADE

Professor and Chair, Presbyterian College School of Pharmacy, Clinton, South Carolina
Chapter 43

Mikael D. Jones, PharmD, BCPS

Clinical Associate Professor, Pharmacy Practice and Science, College of Pharmacy, University of Kentucky, Lexington, Kentucky
Chapter 61

Stephanie Kaiser, PharmD

Clinical Pharmacy Specialist, VA Medical Center, Danville, Illinois
Chapter 5

Angela D.M. Kashuba, BScPhm, PharmD, DABCP

Associate Professor, Eshelman School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina
Chapter 87

Michael D. Katz, PharmD

Professor and Director, International Education,
Department of Pharmacy Practice and Science, College of
Pharmacy, University of Arizona, Tucson, Arizona
Chapter 44

Deanna L. Kelly, PharmD, BCPP

Professor of Psychiatry, Director, Treatment Research
Program, Maryland Psychiatric Research Center,
University of Maryland School of Medicine, Baltimore,
Maryland
Chapter 37

Jacqueline M. Klootwyk, PharmD, BCPS

Assistant Professor of Pharmacy Practice, Jefferson School
of Pharmacy, Thomas Jefferson University, Philadelphia,
Pennsylvania
Chapter 49

Emily Knezevich, PharmD, BCPS, CDE, RP

Associate Professor of Pharmacy Practice, School of
Pharmacy and Health Professions, Creighton University,
Omaha, Nebraska
Appendix E

Jon Knezevich, PharmD, BCPS

Assistant Professor of Pharmacy Practice, School of
Pharmacy and Health Professions, Creighton University,
Omaha, Nebraska
Appendix E

Julia M. Koehler, PharmD, FCCP

Associate Dean for Clinical Education and External
Affiliations, Professor of Pharmacy Practice, Butler
University College of Pharmacy and Health Sciences,
Indianapolis, Indiana
Chapter 48

Michael D. Kraft, PharmD, BCNSP

Clinical Associate Professor, University of Michigan
College of Pharmacy, Assistant Director—Education and
Research, University of Michigan Health System, Ann
Arbor, Michigan
Chapter 100

Sum Lam, PharmD

Associate Clinical Professor, Department of Clinical
Pharmacy Practice, College of Pharmacy and Allied
Health Professions, St. John's University, Queens,
New York; Clinical Specialist in Geriatric Pharmacy,
Divisions of Geriatric Medicine and Pharmacy, Winthrop
University Hospital, Mineola, New York
Chapter 53

Rebecca M. T. Law, PharmD, BScPharm

Associate Professor, School of Pharmacy and Faculty of
Medicine (Cross-Appointment: Discipline of Family
Medicine), Memorial University of Newfoundland, St.
John's, Newfoundland and Labrador, Canada
Chapter 64

Amber P. Lawson, PharmD, BCCP

Clinical Pharmacy Specialist, Hematology/Oncology,
University of Kentucky Healthcare, Lexington, Kentucky
Chapter 98

Ellyn M. Lee, MD

Assistant Professor, Department of Medicine, Director
of Palliative Medicine, University of Arizona, Tucson,
Arizona
Chapter 2

Jeannie K. Lee, PharmD, BCPS

Assistant Professor, Department of Pharmacy Practice and
Science, Assistant Professor, Department of Medicine,
Colleges of Pharmacy and Medicine, University of
Arizona; Clinical Pharmacy Specialist, Geriatrics,
Southern Arizona VA Health Care System; Research
Associate and Faculty, Arizona Center on Aging, Tucson,
Arizona
Chapter 2

Mary Lee, PharmD, BCPS, FCCP

Professor of Pharmacy Practice, Chicago College of
Pharmacy, Vice President and Chief Academic Officer,
Midwestern University, Chicago, Illinois
Chapter 52

Russell E. Lewis, PharmD, FCCP, BCPS

Professor, University of Houston College of Pharmacy;
Adjunct Professor, University of Texas M.D. Anderson
Cancer Center, Houston, Texas
Chapter 84

Teresa V. Lewis, PharmD, BCPS

Assistant Professor, Department of Pharmacy, Clinical and
Administrative Sciences, College of Pharmacy, University
of Oklahoma Health Sciences Center, Oklahoma City,
Oklahoma
Chapter 68

Cara Liday, PharmD, BCPS, CDE

Associate Professor, Department of Pharmacy Practice,
College of Pharmacy, Idaho State University; Clinical
Pharmacist, InterMountain Medical Clinic, Pocatello,
Idaho
Chapter 51

Susanne E. Liewer, PharmD, BCOP

Clinical Pharmacy Specialist—Stem Cell Transplant,
Nebraska Medical Center; Clinical Assistant Professor,
College of Pharmacy, University of Nebraska Medical
Center, Omaha, Nebraska

Chapter 97

Cameron C. Lindsey, PharmD, BC-ADM, CDE, BCACP

Professor of Pharmacy Practice and Administration,
University of Missouri-Kansas City School of Pharmacy,
Kansas City, Missouri

Chapter 102

Melissa Lipari, PharmD

Clinical Assistant Professor, Wayne State University Eugene
Applebaum College of Pharmacy and Health Sciences;
Clinical Pharmacy Specialist, Ambulatory Care, St. John
Hospital and Medical Center, Detroit, Michigan

Chapter 20

Karl Madaras-Kelly, PharmD, MPH

Professor, Department of Pharmacy Practice, College of
Pharmacy, Idaho State University, Boise, Idaho

Chapter 69

Mark A. Malesker, PharmD, FCCP, FCCP, FASHP, BCPS

Professor of Pharmacy Practice and Medicine, Creighton
University, Omaha, Nebraska

Chapters 27 and 28

Michelle T. Martin, PharmD, BCPS, BCACP

Clinical Pharmacist, University of Illinois Medical Center
at Chicago; Clinical Assistant Professor, University of
Illinois at Chicago College of Pharmacy, Chicago, Illinois

Chapter 14

Spencer T. Martin, PharmD, BCPS

Clinical Pharmacy Manager, Cardiac Transplantation,
Department of Pharmacy and Department of Advanced
Cardiac Care, New York Presbyterian Hospital/Columbia
Medical Center, New York City, New York

Chapter 55

Kathryn R. Matthias, PharmD, BCPS (AQ ID)

Assistant Professor, University of Arizona College of
Pharmacy, University of Arizona Medical Center, Tucson,
Arizona

Chapter 79

J. Russell May, PharmD, FASHP

Clinical Professor, Department of Clinical and
Administrative Pharmacy, University of Georgia College
of Pharmacy, Augusta, Georgia

Chapter 54

Joseph E. Mazur, PharmD, BCPS, BCNSP

Critical Care Clinical Specialist, Medical Intensive Care
Unit; Clinical Associate Professor, South Carolina College
of Pharmacy, Charleston, South Carolina

Chapter 77

Trevor McKibbin, PharmD, MS

Assistant Professor, Department of Clinical Pharmacy,
College of Pharmacy, University of Tennessee, Memphis,
Tennessee

Chapter 92

Patrick J. Medina, PharmD, BCOP

Associate Professor, College of Pharmacy, University of
Oklahoma, Oklahoma City, Oklahoma

Chapter 91

Damian M. Mendoza, PharmD, CGP

Clinical Instructor in Pharmacy Practice and Science,
University of Arizona College of Pharmacy; Clinical
Pharmacy Specialist, Geriatrics, Southern Arizona VA
Health Care System, Tucson, Arizona

Chapter 2

April D. Miller, PharmD, BCPS

Clinical Pharmacist, Critical Care Residency Program
Director, Vidant Medical Center, Greenville, North
Carolina

Chapter 70

Sarah J. Miller, PharmD, BCNSP

Professor, Department of Pharmacy Practice, University of
Montana Skaggs School of Pharmacy; Pharmacy Clinical
Coordinator, Saint Patrick Hospital, Missoula, Montana

Chapter 101

Beverly C. Mims, PharmD

Associate Professor of Pharmacy Practice, Howard
University, College of Pharmacy, Clinical Pharmacist,
Howard University Hospital, Washington, DC

Chapter 21

M. Jane Mohler, RN, MPH, PhD

Associate Professor, Section of Geriatrics, General and
Palliative Medicine, University of Arizona, Tucson,
Arizona

Chapter 2

Caroline Morin, BPharm, MSc

Associated Clinician, Université de Montreal Pharmacist,
Centre Image, Obstetrics and Gynecology, CHU
Ste-Justine, Montreal, Quebec, Canada

Chapter 47

Lee E. Morrow, MD, MSc

Associate Professor, Division of Pulmonary and Critical Care Medicine, Nebraska and Western Iowa Veterans Affairs Hospital and Creighton University School of Medicine, Omaha, Nebraska

Chapters 27 and 28

Milap C. Nahata, PharmD, MS

Professor of Pharmacy, Pediatrics and Internal Medicine; Chair, Division of Pharmacy Practice and Administration, College of Pharmacy, Ohio State University; Associate Director OSU Medical Center, Department of Pharmacy, Columbus, Ohio

Chapter 3

Rocsanna Namdar, PharmD

Department of Clinical Pharmacy, University of Colorado, Boulder, Colorado

Chapter 75

Melinda M. Neuhauser, PharmD, MPH

Clinical Pharmacy Specialist, Infectious Diseases, VA Pharmacy Benefits Management Services, Hines, Illinois

Chapter 81

Douglas A. Newton, MD, MPH

Child and Adolescent Psychiatrist, Clinical Chief, Colorado Permanente Medical Group, Denver, Colorado

Chapter 40

Tien M.H. Ng, PharmD, FCCP, BCPS AQ-C

University of Southern California, School of Pharmacy, Los Angeles, California

Chapter 6

Kimberly J. Novak, PharmD, BCPS

Clinical Pharmacy Specialist, Pediatric Pulmonary Medicine, Nationwide Children's Hospital; Clinical Assistant Professor, Ohio State University College of Pharmacy, Columbus, Ohio

Chapter 16

Edith A. Nutescu, PharmD, FCCP

Clinical Professor, Departments of Pharmacy Practice and Administration, Center for Pharmacoeconomic Research, Clinical Manager, Antithrombosis Clinic, University of Illinois at Chicago, College of Pharmacy and Medical Center, Chicago, Illinois

Chapter 10

Catherine M. Oliphant, PharmD

Associate Professor of Pharmacy Practice, College of Pharmacy, Idaho State University, Meridan, Idaho

Chapter 69

Ali J. Olyaei, PharmD

Professor, Department of Medicine and Pharmacy Practice, Oregon State University and Oregon Health and Sciences University, Portland, Oregon

Chapter 55

Christine Karabin O'Neil, BS, PharmD, BCPS, CGP, FCCP

Professor of Pharmacy Practice, Division of Clinical, Social and Administrative Sciences, Duquesne University, School of Pharmacy, Pittsburgh, Pennsylvania

Chapter 34

Vinita B. Pai, PharmD, MS

Assistant Professor of Clinical Pharmacy, Ohio State University, College of Pharmacy; Clinical Pharmacy Specialist, Pediatric Blood and Marrow Transplant Program, Nationwide Children's Hospital, Columbus, Ohio

Chapter 3

David Parra, PharmD, FCCP, BCPS

Clinical Pharmacy Specialist in Cardiology, VA Medical Center, West Palm Beach Florida; Clinical Associate Professor, Department of Experimental and Clinical Pharmacology, University of Minnesota College of Pharmacy, Minneapolis, Minnesota

Chapter 5

Charles Peloquin, PharmD, FCCP

Professor, Emerging Pathogens Institute, University of Florida, Gainesville, Florida

Chapter 75

Susan L. Pendland, MS, PharmD

Adjunct Associate Professor, University of Illinois at Chicago, Chicago, Illinois; Clinical Staff Pharmacist, Saint Joseph Berea Hospital, Berea, Kentucky

Chapter 81

Hanna Phan, PharmD, BCPS

Assistant Professor, Department of Pharmacy Practice and Science, Assistant Professor, Department of Pediatrics, Colleges of Pharmacy and Medicine, University of Arizona; Clinical Pharmacy Specialist, Pediatric Pulmonary Medicine, Arizona Respiratory Center, University of Arizona Medical Center, Tucson, Arizona

Chapter 3

Trinh Pham, PharmD, BCOP

Associate Clinical Professor, University of Connecticut, School of Pharmacy, Storrs, Connecticut

Chapter 93

Bradley G. Phillips, PharmD, FCCP, BCPS

Millikan-Reeve Professor and Head, Department of Clinical and Administrative Pharmacy, University of Georgia College of Pharmacy, Athens, Georgia

Chapter 41

Beth Bryles Phillips, PharmD, FCCP, BCPS

Clinical Professor, University of Georgia College of Pharmacy; Director VAMC/UGA Ambulatory Care Residency Program, Athens, Georgia

Chapter 56

Amy M. Pick, PharmD, BCOP

Associate Professor of Pharmacy Practice, Creighton University School of Pharmacy and Health Professions, Omaha, Nebraska

Chapter 96

Melissa R. Pleva, PharmD, BCPS, BCNSP

Clinical Pharmacist and Adjunct Clinical Assistant Professor, University of Michigan Health System and College of Pharmacy, Ann Arbor, Michigan

Chapter 100

Frank Pucino Jr., PharmD, MPH

Clinical Investigator, National Institute of Arthritis and Musculoskeletal and Skin Diseases (NIAMS), National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK); National Institutes of Health, Bethesda, Maryland

Chapters 45 and 46

Kelly R. Ragucci, PharmD, FCCP, BCPS, CDE

Professor and Assistant Dean, Clinical Pharmacy and Outcome Sciences, South Carolina College of Pharmacy, Medical University of South Carolina Campus, Charleston, South Carolina

Chapter 50

Gowtham A. Rao, MD, PhD, MPH

University of South Carolina School of Medicine, University of South Carolina, College of Pharmacy, William J.B. Dorn Veterans Affairs Medical Center, Columbia, South Carolina

Chapter 82

Évelyne Rey, MD, MSc

Professor, Department of Medicine and of Obstetrics and Gynecology, University of Montreal, CHU Sainte Justine Montreal, Quebec, Canada

Chapter 47

Anastasia Rivkin, BS, PharmD, BCPS

Associate Professor and Division Director of Pharmacy Practice, Arnold and Marie Schwartz College of Pharmacy and Health Sciences, Long Island University, Brooklyn, New York

Chapter 67

Leigh Ann Ross, PharmD, BCPS

Associate Dean for Clinical Affairs, Chair and Associate Professor, Department of Pharmacy Practice, University of Mississippi School of Pharmacy, Jackson, Mississippi

Chapter 35

Warren E. Rose, PharmD

Assistant Professor, Pharmacy Practice Division, University of Wisconsin School of Pharmacy, Madison, Wisconsin

Chapter 79

Brendan S. Ross, MD

Staff Physician, G.V. (Sonny) Montgomery Veterans Affairs Medical Center; Clinical Associate Professor, Department of Pharmacy Practice, University of Mississippi School of Pharmacy, Jackson, Mississippi

Chapter 35

John C. Rotschafer, PharmD, FCCP

Professor, College of Pharmacy, University of Minnesota, Minneapolis, Minnesota

Chapter 85

Heather M. Rouse, PharmD, BCPS

Clinical Pharmacy Specialist, Adult Critical Care, Penn State Milton S. Hershey Medical Center, Hershey, Pennsylvania

Chapter 23

Laurajo Ryan, PharmD, MSc, BCPS, CDE

Clinical Associate Professor, Department of Medicine, University of Texas at Austin College of Pharmacy, University of Texas Health Science Center, Pharmacotherapy Education Research Center, Austin, Texas

Chapter 22

Melody Ryan, PharmD, MPH

Associate Professor, Departments of Pharmacy Practice and Science and Neurology, University of Kentucky, Lexington, Kentucky

Chapter 30

Sarah L. Scarpace, PharmD, BCOP

Assistant Dean for Pharmacy Professional Affairs and Associate Professor, Pharmacy Practice, Albany College of Pharmacy and Health Sciences, Stratton Veterans' Affairs Medical Center, Albany, New York

Chapter 99

Lauren S. Schlesselman, MEd, PharmD

Assistant Clinical Professor and Director of Assessment and Accreditation, Department of Pharmacy Practice, University of Connecticut School of Pharmacy, Storrs, Connecticut

Chapter 83

Kristine S. Schonder, PharmD

Assistant Professor, Department of Pharmacy and Therapeutics, University of Pittsburgh School of Pharmacy, Pittsburgh, Pennsylvania

Chapter 26

Julie Sease, PharmD, BCPS, CDE

Associate Professor, Department of Pharmacy Practice,
Presbyterian College School of Pharmacy, Clinton,
South Carolina

Chapter 43

Roohollah Sharifi, MD

Section Head of Urology, Jesse Brown Veterans
Administration Hospital, Chicago, Illinois

Chapter 52

Kayce Shealy, PharmD, BCPS

Assistant Professor of Pharmacy Practice, Presbyterian
College School of Pharmacy, Clinton, South Carolina

Chapter 43

Bradley W. Shinn, PharmD

Associate Professor of Pharmacy Practice, University of
Findlay College of Pharmacy, Findlay, Ohio

Chapter 76

Judith A. Smith, PharmD, BCOP, CPHQ, FCCP, FISOPP

Associate Professor, Department of Gynecologic Oncology
and Reproductive Medicine, Division of Surgery, The
University of Texas M.D. Anderson Cancer Center,
Houston, Texas

Chapter 94

Philip H. Smith, MD, IAAAAI

Assistant Professor of Medicine, Georgia Health Sciences
University, Augusta, Georgia

Chapter 54

Steven M. Smith, PharmD

Assistant Professor, Department of Clinical Pharmacy,
School of Pharmacy, University of Colorado Denver,
Aurora, Colorado

Chapter 58

**Sarah A. Spinler, PharmD, FCCP, FAHA, FASHP, AACC,
BCPC (AQ Cardiology)**

Professor of Clinical Pharmacy, Philadelphia College of
Pharmacy, University of the Sciences in Philadelphia,
Philadelphia, Pennsylvania

Chapter 8

Mary K. Stamatakis, BS, PharmD

Associate Dean and Associate Professor, West Virginia
University School of Pharmacy, Morgantown, West
Virginia

Chapter 25

Robert J. Straka, PharmD, FCCP

Professor and Head, Experimental and Clinical
Pharmacology Department, University of Minnesota
College of Pharmacy, Minneapolis, Minnesota

Chapter 5

S. Scott Sutton, PharmD, BCPS

Associate Professor, South Carolina College of Pharmacy,
University of South Carolina, Columbia, South Carolina

Chapter 82

Marc A. Sweeney, RPh, BSPHarm, PharmD, MDiv

Professor and Dean, School of Pharmacy, Cedarville
University, Cedarville, Ohio

Chapter 4

Robert K. Sylvester, PharmD

Professor, Department of Pharmacy Practice, College of
Pharmacy, Nursing and Allied Sciences, North Dakota
State University; Oncology Clinical Specialist, Sanford
Health Medical Center, Fargo, North Dakota

Chapter 66

Eljim P. Tesoro, PharmD, BCPS

Clinical Pharmacist, Neurosciences ICU, Clinical Assistant
Professor, College of Pharmacy, University of Illinois
Medical Center at Chicago, Chicago, Illinois

Chapter 32

Christian J. Teter, PharmD, BCPP

Assistant Professor, Psychopharmacology, Department of
Pharmacy Practice, College of Pharmacy, University of
New England, Portland, Maine

Chapter 36

Janine E. Then, PharmD, BCPS

Unit-based Pharmacist, University of Pittsburgh Medical
Center, Presbyterian-Shadyside Hospital, Pittsburgh,
Pennsylvania

Chapter 23

Maria Miller Thurston, PharmD, BCPS

PGY-2 Ambulatory Care Resident, University of Georgia
College of Pharmacy, Charlie Norwood Veterans Affairs
Medical Center, Augusta, Georgia

Chapter 56

James E. Tisdale, PharmD, BCPS, FCCP, FAPhA, FAHA

Professor, College of Pharmacy, Purdue University; Adjunct
Professor, School of Medicine, Indiana University,
Indianapolis, Indiana

Chapter 9

Mary A. Ullman, PharmD

Pharmacist, Regions Hospital, St. Paul, Minnesota

Chapter 85

Elena M. Umland, PharmD

Associate Dean for Academic Affairs, Associate Professor
of Pharmacy, Thomas Jefferson School of Pharmacy,
Thomas Jefferson University, Philadelphia, Pennsylvania

Chapter 49

Heather L. VandenBussche, PharmD

Professor, Department of Pharmacy Practice, Ferris State University College of Pharmacy, Kalamazoo, Michigan
Chapter 72

Orly Vardeny, PharmD, MS

Assistant Professor, University of Wisconsin School of Pharmacy, Madison, Wisconsin
Chapter 6

Nicole D. Verkleeren, PharmD, BCPS

Clinical Pharmacy Specialist, Critical Care, Forbes Regional Hospital, Monroeville, Pennsylvania
Chapter 15

Mary L. Wagner, PharmD, MS

Associate Professor, Department of Pharmacy Practice and Administration, Ernest Mario School of Pharmacy, Rutgers, The State University of New Jersey, Piscataway, New Jersey
Chapter 33

Geoffrey C. Wall, PharmD, FCCP, BCPS, CGP

Professor of Clinical Sciences, Drake University College of Pharmacy and Health Sciences, Internal Medicine Clinical Pharmacist, Iowa Methodist Medical Center, Des Moines, Iowa
Chapter 59

Heidi J. Wehring, PharmD, BCPP

Assistant Professor, Department of Psychiatry, Maryland Psychiatric Research Center, University of Maryland School of Medicine, Washington, DC
Chapter 37

Elaine Weiner, MD

Assistant Professor, Department of Psychiatry, University of Maryland Medical School, Catonsville, Maryland
Chapter 37

Lydia E. Weisser, DO

Clinical Director, Mississippi State Hospital, Whitfield, Mississippi
Chapter 39

Timothy E. Welty, PharmD, MA, FCCP, BCPS

Professor and Chair, Department of Clinical Sciences, College of Pharmacy and Health Sciences, Drake University, Des Moines, Iowa
Chapter 31

Tara R. Whetsel, PharmD, BCACP

Clinical Associate Professor, West Virginia University School of Pharmacy, Morgantown, West Virginia
Chapter 15

Sheila Wilhelm, PharmD, BCPS

Clinical Assistant Professor, Wayne State University Eugene Applebaum College of Pharmacy and Health Sciences, Clinical Pharmacy Specialist, Internal Medicine, Harper University Hospital, Detroit, Michigan
Chapter 20

Lori Wilken, PharmD, CDE, AE-C

Clinical Pharmacist, University of Illinois Medical Center at Chicago; Clinical Assistant Professor, Ambulatory Care Pharmacy, University of Illinois at Chicago College of Pharmacy, Chicago, Illinois
Chapter 14

Amy Robbins Williams, PharmD, BCOP

Assistant Professor of Pharmacy Practice, Union University School of Pharmacy, Jackson, Tennessee
Chapter 88

Dianne Williams May, PharmD, BCPS

Campus Director for Pharmacy Practice Experiences, Clinical Associate Professor, Division of Experience Programs and Department of Clinical and Administrative Pharmacy, University of Georgia College of Pharmacy, Augusta, Georgia
Chapters 17 and 18

Susan R. Winkler, PharmD, FCCP, BCPS

Professor and Chair, Department of Pharmacy Practice, Northwestern University Chicago College of Pharmacy, Downers Grove, Illinois
Chapter 11

Ann K. Wittkowsky, PharmD, CACP, FASHP, FCCP

Clinical Professor, University of Washington School of Pharmacy, Director, Anticoagulation Services, University of Washington Medical Center, Seattle, Washington
Chapter 10

G. Christopher Wood, PharmD, FCCP

Associate Professor, Department of Clinical Pharmacy, University of Tennessee Health Science Center, College of Pharmacy, Memphis, Tennessee
Chapter 13

REVIEWERS

Rita R. Alloway, PharmD, FCCP

Research Professor, Director, Transplant Clinical Research, University of Cincinnati College of Medicine, Cincinnati, Ohio

Alexander K. Berg, PharmD, PhD

Clinical Pharmacology Fellow, Department of Molecular Pharmacology and Experimental Therapeutics, Mayo Clinic Rochester, Minnesota

Margaret T. Bowers, RN, MSN, FNP-BC, AACC

Assistant Professor, Duke University School of Nursing, Nurse Practitioner Duke Heart Failure Program, Durham, North Carolina

Jeffrey Bratberg, PharmD, BCPS

Clinical Associate Professor of Pharmacy Practice, URI College of Pharmacy, Kingston, Rhode Island; Adjunct Associate Professor of Medicine, Alpert Medical School of Brown University, Infectious Diseases Specialist, Roger Williams Medical Center, Providence, Rhode Island

Mary Brennan, DNP, ACNP-BC, GNP-BC, ANP, RN

Clinical Assistant Professor, New York University College of Nursing, Coordinator, Acute Care Nurse Practitioner Program, New York, New York

Denise Buonocore, MSN

Acute Care Nurse Practitioner HF Service, St. Vincent's Multispecialty Group, Bridgeport, Connecticut

Katie E. Cardone, PharmD, BCACP

Assistant Professor, Department of Pharmacy Practice, Albany College of Pharmacy and Health Sciences, Albany, New York

Elias B. Chahine, PharmD, BCPS

Assistant Professor of Pharmacy Practice, Department of Pharmacy Practice, Palm Beach Atlantic University, West Palm Beach, Florida; Clinical Pharmacist, Department of Pharmaceutical Services, JFK Medical Center, Atlantis, Florida

Amber N. Chiplinski, PharmD, BCPS

Clinical Assistant Professor, West Virginia University School of Pharmacy, Clinical Pharmacy Specialist, Internal Medicine Martinsburg Veterans Affairs Medical Center, Martinsburg, West Virginia

Jennifer Confer, PharmD, BCPS

Clinical Assistant Professor, West Virginia University School of Pharmacy, Critical Care Clinical Pharmacy Specialist, Cabell Huntington Hospital, Huntington, West Virginia

PREFACE

Pharmacotherapy Principles & Practice, a winner of the Medical Book Award from the American Medical Writers Association, has been well received and adopted by many pharmacy, nursing, and physician assistant schools. Chapters are written by content experts and reviewed critically by pharmacists, nurse practitioners, physician assistants, and physicians who are authorities in their fields. Written in a concise style that facilitates in-depth understanding of essential topics, the third edition meets the same high-quality expectations as previous editions.

Now more than ever, healthcare practitioners have a critical responsibility to their patients and society to deliver high-quality and cost-effective care. Development of these practice abilities requires an integration of knowledge, skills, attitudes, beliefs, and values that can be acquired only through a structured learning process that includes classroom work, independent study, mentorship, and ultimately, direct involvement in the care of patients in interprofessional settings. With its 102 chapters, *Pharmacotherapy Principles & Practice*, Third Edition, facilitates learning by using multiple teaching techniques and enhanced features. The textbook opens with an introductory chapter followed by chapters on pediatrics, geriatrics, and palliative care. The remainder of the book consists of 98 disease-based chapters that review disease etiology, epidemiology, pathophysiology, and clinical presentation, followed by clear therapeutic recommendations for drug selection, dosing, and patient monitoring.

Pharmacotherapy Principles & Practice is designed to meet classroom and independent study needs of today's learners in the health care professions. The following features were designed in collaboration with educational design specialists to enhance learning and retention:

- *Structured learning objectives* are included at the beginning of each chapter, with information in the text that corresponds to each learning objective identified by a vertical rule with a circle in the margin, allowing the reader to quickly find content related to each objective.
- *Key concepts related to patient assessment and treatment* are listed at the beginning of each chapter to help focus learning. Numbered icons are used throughout the chapter to identify content that develops these concepts.
- *Patient encounters* are distributed throughout each chapter to facilitate development of critical thinking skills and lend clinical relevance to the scientific foundation provided. This feature has been enhanced in the third edition.
- *Patient care and monitoring guidelines* are placed near the end of each chapter to assist students in their general approach to assessing, treating, and monitoring patients for therapeutic response and adverse events.

- *Up-to-date literature citations* for each chapter are provided to support treatment recommendations.
- *Tables, figures, text boxes, and algorithms* are used liberally to enhance understanding of pathophysiology, clinical presentation, drug selection, pharmacokinetics, and patient monitoring.
- *Medical abbreviations and their meanings* are placed at the end of each chapter to facilitate learning the accepted shorthand used in real-world healthcare settings.
- *A glossary of medical terms* is included as an appendix to the book; the first use of each glossary term in a chapter appears in bold colored font.
- *Self-assessment questions and answers for each chapter* are located in the Online Learning Center to facilitate self-evaluation of learning.
- *Laboratory values* are expressed as both conventional units and Systemè International (SI) units to facilitate learning by those in countries where these units of measure are the standard.
- *Appendices* contain: (1) conversion factors and anthropometrics; (2) common laboratory tests and their reference ranges; (3) common medical abbreviations; and (4) how to write a prescription.

The Online Learning Center at www.ChisholmPharmacotherapy.com provides self-assessment questions, a testing center that has the ability to grade and provide immediate feedback on the self-assessment questions as well as reporting capabilities, and other features designed to support learning.

A companion text, *Pharmacotherapy Principles and Practice Study Guide: A Case-Based Care Plan Approach*, is available to further enhance learning by guiding students through the process of applying knowledge of pharmacotherapy to specific patient cases. This study guide contains approximately 100 patient cases that correspond to chapters published in *Pharmacotherapy Principles & Practice*.

We acknowledge the commitment and dedication of the more than 182 contributing authors and more than 55 reviewers of the chapters contained in this text. A special thanks goes to the educators who have adopted this text in their courses. We also extend our thanks to McGraw-Hill Medical, especially Michael Weitz, Peter Boyle, and Laura Libretti, as well as the support teams at our individual universities for their dedication to this project.

Introduction

Jack E. Fincham

INTRODUCTION

Health professionals are given significant responsibilities in our healthcare system. These roles may be taken for granted by patients until a pharmacist, nurse practitioner, physician assistant, physician, or others perform assigned tasks that make a major impact on the lives of patients and patients' families in countless ways. The exemplary manner in which health professionals provide necessary care to patients is a hallmark of health professional practice and delivery of healthcare in the United States. Patients are thus well served, and fellow health professionals share knowledge and expertise specific to their profession. Despite this, many problems remain in the U.S. healthcare system; there were close to 50 million uninsured individuals in the United States in 2010, representing between 16% and 17% of the population.¹ This dramatic number of 50 million is but 10 million less than the entire population of either France or the United Kingdom. It is simply staggering in scope and has implications for the future collective health of the U.S. population. These figures are basically unchanged from the year 2009, except for the number of uninsured.

Countless other Americans are underinsured. They may have partial coverage, but for these Americans the high price of deductibles, copays, and monthly payments for insurance create an economic dilemma each time they seek care or pay premiums. According to the U.S. Centers for Medicare and Medicaid Services, National Health Expenditure data, well over \$2.71 trillion was spent on healthcare in the United States during 2010, amounting to \$8,327 per person, which amounts to 17% of the U.S. gross domestic product (GDP), some of it no doubt unnecessarily so.¹ By 2020, expenditures are projected to \$4.64 trillion, which would be a projected \$13,709 per person, 19% of the U.S. GDP. It is anticipated that with the enhanced focus on quality of the Patient Protection and Affordable Care Act, passed in 2009, that unnecessary expenditures and duplicative healthcare service may be reduced and lower the misspent money in parts of the health expenditures in the United States.

The use of medications in the healthcare system provides enormous help to many; lives are saved or enhanced, and lifespans are lengthened. Many other uses of medications lead to significant side effects, worsening states of health, and premature deaths. So how can we separate these disparate pictures of drug use outcomes? You, within your practices and within your healthcare workplace networks, can help to

promote the former and diminish the latter. The authors of the chapters in this book have written informative, current, and superb chapters that can empower you to positively influence medication use.

DRUG USE IN THE HEALTHCARE SYSTEM

Spending on drugs, as a percentage of total healthcare, increased 5.3% in 2009 compared with the previous year.² Drivers for this significant increase include increases in available technologies, numbers of patients, prescriptions per patient, and number of seniors taking advantage of the Medicare Part D drug benefit.

Significant numbers of medications are used daily in the United States. Over one decade (1997 to 2007) prescriptions purchased zoomed from \$2.2 billion to \$3.8 billion.³ The average number of prescriptions per capita in the United States rose from 8.9 in 1997 to 12.6 in 2007.³ Problems occurring with drug use can include:

- Medication errors
- Suboptimal drug, dose, regimen, dosage form, and duration of use
- Unnecessary drug therapy
- Therapeutic duplication
- Drug–drug, drug–disease, drug–food, or drug–nutrient interactions
- Drug allergies
- Adverse drug effects, some of which are preventable

Clinicians are often called upon to identify, resolve, and prevent problems that occur due to undertreatment, overtreatment, or inappropriate treatment. Individuals can purchase medications through numerous outlets, including pharmacies, mail-order pharmacies, supermarkets, convenience stores, via the Internet, from physicians, from healthcare institutions, and through any number of additional outlets. Herbal remedies are also marketed and sold in numerous outlets. The monitoring of positive and negative outcomes of the use of drugs can be disjointed and incomplete. Clinicians and students in the health professions need to take ownership of these problems and improve patient outcomes resulting from drug use.

It is important to realize that, although clinicians are the gatekeepers for patients to obtain prescription drugs, patients can obtain prescription medications from numerous sources. Patients may also borrow from friends, relatives, or even casual acquaintances. In addition, patients obtain over-the-counter (OTC) medications from physicians through prescriptions, on advice from pharmacists and other health professionals, through self-selection, or through the recommendations of friends or acquaintances. Through all of this, it must be recognized that there are both formal (structural) and informal (word-of-mouth) components at play. Health professionals may or may not be consulted regarding the use of medications, and in some cases they are unaware of the drugs patients are taking. In addition, herbal remedies or health supplements may be taken without the knowledge or input of a health professional.

External variables may greatly influence patients and their drug-taking behaviors. Coverage for prescribed drugs allows those with coverage to obtain medications with varying cost-sharing requirements. However, many do not have insurance coverage for drugs or other health-related needs. With Medicare Part D coverage for outpatient prescription medications, more elderly people have access to needed therapy than ever before.⁴

Self-Medication

Self-medication can be defined as a patient decision to consume a drug with or without the approval or direction of a health professional. Self-medication activities of patients have increased dramatically in the late 20th and early 21st centuries. Many factors affecting patients have fueled this increase. There are ever-increasing ways to purchase OTC medications. Many prescription items switched to OTC classification in the last 50 years, which has dramatically and significantly fueled the rapid expansion of OTC drug use. In addition, patients are increasingly comfortable with self-diagnosing and self-selection of OTC remedies. In many studies,⁵ self-medication with nonprescribed therapies exceeds the use of prescription medications in the patient groups assessed.

Patients' use of self-selected products has the potential to provide enormous benefits.⁶ Through the rational use of drugs, patients may avoid more costly therapies or expenditures for other professional services. Self-limiting conditions, and even some chronic health conditions (e.g., allergies and dermatologic conditions), if appropriately treated through patient self-medication, allow the patient to have a degree of autonomy in healthcare decisions.

Compliance Issues

Patient noncompliance with prescription regimens is one of the most understated problems in the healthcare system. Noncompliance has enormous ramifications for patients, caregivers, and health professionals. Noncompliance is a multifaceted problem with a need for interprofessional, multidisciplinary solutions. Interventions that are organizational

(how clinics are structured), educational (patient counseling, supportive approach), and behavioral (impacting health beliefs and expectations) are necessary. Noncompliance leads to lack of disease control and a high discrepancy in how patients respond to therapies.⁷ Identifying psychosocial interventions, which engage patients to self-manage their therapies, has proven efficacy.⁷ Acknowledging barriers that people perceive in complying helps identify how to assist patients to overcome these distracters.⁷ Compliant behavior can be enhanced through actions with the patients. Many times what is necessary is referral to specific clinicians for individualized treatment and monitoring to enhance compliance. The case histories provided in this text will allow you to follow what others have done in similar situations to optimally help patients succeed in improving compliance rates and positive health outcomes.

Drug Use by the Elderly

Various components of drug use in the elderly are worth noting. Problems with health literacy (i.e., understanding medical terminology and directions from providers) are more common among the elderly.⁸ The burgeoning population of the elderly, coupled with their lack of health literacy, means that this issue will become even more problematic.⁹

Over the next decade, seniors will spend \$1.8 trillion on prescription medications. Medicare proposals to provide a drug benefit for seniors have been suggested to cost \$400 billion over a 10-year period. Thus the most elaborate current drug program will pay only 22% of seniors' drug costs. Enhanced use of pharmacoeconomic tenets to select appropriate therapy, while considering cost and therapeutic benefits for seniors and others, will become even more crucial.

Unnecessary drug therapy and overmedication are problems with drug use in the elderly. A joint effort by health professionals working together is the best approach to aiding seniors in achieving optimal drug therapy. Evaluation of all medications taken by seniors at each patient visit can help prevent polypharmacy from occurring.¹⁰

IMPACTING THE PROBLEMS OF DRUG USE

Medication Errors

There is no more glaring issue in medication use and monitoring than the need to reduce medication errors. Untold morbidity and mortality occur due to the many errors occurring in medication use. Studies have shown that reconciling the patient's medications, with coordination by caregivers, can reduce medication errors.¹¹ Current changes in how drugs are prescribed, such as electronic prescribing, barcode identification of patients, and electronic medication records, can all reduce medication errors.^{12,13} As technologies are increasingly used, benefits will expand.

Incorporation of three key interventions (computerized physician order entry [CPOE], additional staffing, and bar coding) have been shown in an institutional setting to help

reduce medication errors.¹³ Being able to track drug ordering, dispensing, and administration electronically has been shown to be cost effective in the long run.¹⁴ Nurses and office staff have been proven a valuable resource for reporting prescribing errors, especially with ongoing reminders to scrutinize orders.¹⁵

The Epidemic of Prescribed Drug Abuse

In 2009, approximately 7.0 million persons were current users of psychotherapeutic drugs taken nonmedically (2.8% of the U.S. population). This class of drugs is broadly described as those targeting the CNS, including drugs used to treat psychiatric disorders. These are the medications most commonly abused:

- Pain relievers: 5.3 million
- Tranquilizers: 2.0 million
- Stimulants: 1.3 million
- Sedatives: 0.4 million¹⁶

The most prominent group of abused drugs in the United States at present is prescription and OTC medications. These drugs now have more first-time abusers than most commonly thought of drugs of abuse, such as marijuana, and are now overtaking marijuana use as the first type of drugs abused. The main source for these drugs is the family medicine cabinet. Bond and colleagues¹⁷ in describing a large-scale database study (National Poison Data System of the American Association of Poison Control Centers) from a 2001 to 2008 study note that prevention efforts have proved inadequate in the face of rising availability of prescription medications, particularly more dangerous medications such as particularly opioids, sedative-hypnotics, and cardiovascular agents.¹⁷ Abuse of prescription medications by adolescents is an ascending problem that all health professionals must address and work together to try to lessen in intensity.

HEALTHCARE REFORM

The potential for healthcare reform (Patient Protection and Affordable Care Act [PPACA]), passed by the U.S. Congress in 2009 to enhance patient outcomes and the quality of care provided to Americans, is very significant. The inclusion of health professionals in segments of the innovative medical homes and accountable care organizations will help physicians and primary care providers reach more patients needing care.¹⁸

Incorporation of primary care providers, clinics, and healthcare institutions will enable information sharing electronically to better reduce errors, enhance outcomes, and help to save precious dollars in the healthcare system. Health professionals have already been shown to provide savings in pilot projects. An average savings of \$1,595 per patient was achieved by 9 pharmacists working with 88 Medicaid patients in a pilot project sponsored by the Centers for Medicare and Medicaid Services in a primary care setting.¹⁹

There are also covered preventive aspects enabled by the PPACA that include immunizations, screenings, and other

offering at no charge as components of the PPACA. The provision of these preventive activities by health professionals will serve patients long term very nicely and work to prevent costly care later on.

That discussion about the potential for healthcare reform to influence patient care and outcomes must be tempered by the view that things may change suddenly with legislation or U.S. Supreme Court decisions regarding the constitutionality of the legislation; also, states have been active in negating certain components or the entire legislation as it applies to them, and the outcomes of the elections of 2012 will certainly influence the eventual scope and form of the PPACA.

SUMMARY

Health professionals are at a crucial juncture as we face an uncertain, yet promising future. Technological advances, including electronic prescribing, may stem the tide of medication errors and inappropriate prescribing. These technological enhancements for physician order entry (via personal electronic devices, tablet devices, tablet computers, or through web access to pharmacies) have been implemented to reduce drug errors. Health professionals face daunting challenges in ensuring appropriate use of pharmacotherapy. Sophisticated computer technology can further empower health professionals to play an ever-increasing and effective role in helping patients to practice safe and effective use of prescribed medicine. Healthcare reform has the potential to have a dramatic impact on your practices in the healthcare system for the length of your careers.

This book is written by content experts in the material they cover. They are among the thought and practice forefront of delivery of healthcare services in the United States. The thorough analysis of common disease states, discussion of therapies to treat these conditions, and specific advice to provide to patients to help them self-medicate when appropriate and safe to do so will help you immensely in your practices. The use of material in this text, which incorporates materials written by the finest minds in pharmacy practice and education, can enable you to play a crucial role in improving the drug use process for patients, providers, payers, and society. The purpose of this book is to help hone your skills so you can make a real improvement in the therapies you provide to your patients. As current and future clinicians, you can rely on the information laid out here to enhance your knowledge and allow you to assist your patients with the sound advice they expect. Use the text, case histories, and numerous examples detailed here to expand your therapeutic skills and to help you have a positive impact on your patients in the years to come.

You can help to reverse medication-related problems, improve outcomes of care both clinically and economically, and enable drug use to meet stated goals and objectives. This text provides a thorough analysis and summary of treatment options for commonly occurring diseases and the medications or alternative therapies used to treat these conditions successfully.

M. Jane Mohler, and Ellyn M. Lee

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Explain the growth pattern of the elderly population.
2. Discuss age-related pharmacokinetic and pharmacodynamic changes.
3. Identify drug-related problems and associated morbidities commonly experienced by older adults.
4. Describe major components of geriatric assessment.
5. Recognize interprofessional patient care functions in various geriatric practice settings.

KEY CONCEPTS

- 1 Population aging is an incontrovertible trend.
- 2 Older Americans use considerably more healthcare services than younger Americans, and their healthcare needs are often complex.
- 3 All four components of pharmacokinetics—absorption, distribution, metabolism, and excretion—are affected by aging; the most clinically important and consistent is the reduction of renal elimination of drugs.
- 4 In general, the pharmacodynamic changes that occur in the elderly tend to increase their sensitivity to drug effects.
- 5 Comorbidities and polypharmacy complicate elderly health status, particularly when polypharmacy includes inappropriate medications that lead to drug-related problems.
- 6 Older adults are at greater risk for medication nonadherence due to the high prevalence of multiple comorbidities, including cognitive deficit, polypharmacy use, and financial barriers.
- 7 The clinical approach to assessing older adults frequently goes beyond a traditional “history and physical” used in general internal medicine practice.
- 8 Consideration of geriatric patients’ vision, hearing, swallowing, cognition, motor impairment, and education and literacy levels during counseling and education can lead to enhanced medication adherence.
- 9 Long-term care geriatric practices emphasize the interprofessional team approach.

The growth of the aging population and increasing lifespan require that healthcare professionals gain knowledge necessary to meeting the needs of this patient group. Despite the availability and benefit of numerous pharmacotherapies to treat their diseases, elderly patients commonly experience drug-related problems resulting in additional morbidities. Therefore, it is essential for clinicians serving older adults across all healthcare settings to understand the epidemiology of aging, age-related physiological changes, drug-related problems prevalent in the elderly, comprehensive geriatric assessment, and interprofessional approaches to geriatric care.

EPIDEMIOLOGY AND ETIOLOGY

As humans age, they are at increasingly elevated risk of disease, disability, and death primarily for three reasons: (a) genetic predisposition; (b) reduced immunological surveillance; and (c) the accumulated effects of physical, social, environmental, and behavioral exposures over the life course. Human relationships, social conditions, and networks interact with these accumulating exposures, and differences in time and place influence health outcomes by age cohort. Combined, these factors result in considerable variation by age in health states and healthcare requirements. All elders experience increasing vulnerability and **homeostasis** as they age. Although resilient elders are able successfully to maintain high levels of physical and cognitive functioning, avoid chronic conditions, and remain socially engaged, others suffer functional decline, **frailty**, disability, or death. There is an urgent need for all clinicians to better understand the epidemiology of aging in order that healthcare needs of the elderly can be comprehensively addressed, and so that safe, quality services can be provided efficiently to optimize functioning and health-related quality of life for the aged.¹

Sociodemographics

► Population

1 *Population aging is an incontrovertible trend.* In 2010, 40.3 million U.S. residents were 65 years and older (13% of the total population), nearly 5.5 million people were 85 years or older (the “oldest-old”), and over 53,000 were centenarians.² The baby boomers (those born between 1946 and 1964) began turning 65 years in 2011; their numbers will double to 71.5 million in 2030, representing nearly 20% of the total U.S. population.³ In 2010, there were a total of 22.9 million women and 17.4 million men (an average ratio of 100 women to 77.3 men) 65 years and older; this ratio widens as elders age. The oldest-old are projected to increase from 5.3 million in 2006 to nearly 21 million in 2050.³ In addition, minority elder populations are projected to increase to 8.1 million in 2010 (20.1%), and up to 12.9 million in 2020 (23.6%), including disproportionate increases in Hispanics (254%); Asians and Pacific Islanders (208%); African Americans (147%); and Native Americans, Eskimos, and Aleuts (143%).³ Surviving baby boomers will be proportionally more women, more racially diverse, better educated, and have more financial resources than were elders in previous generations.

► Economics

More elders are enjoying higher economic prosperity than ever before, with net worth increasing by nearly 80% for older Americans over the past 20 years. Still, major inequalities persist, with older blacks and those without high school diplomas reporting smaller economic gains and fewer financial resources.⁴ Considerable disparities exist; the 2005 median net worth of households headed by whites 65 years and older was \$226,900 compared with black elder household net worth of \$37,800 (a sixfold difference).⁴

► Education and Health Literacy

By 2007, more than 75% of U.S. elders had graduated from high school, and nearly 20% had a bachelor’s degree or higher. Still, substantial educational differences exist among racial and ethnic minorities. Whereas more than 80% of non-Hispanic white elders had high school degrees in 2007, only 72% of Asians, 58% of blacks, and 42% of Hispanic elders were graduates. Nearly 40% of people 75 years or older have low

health literacy, more than any other age group.⁴ Despite these limitations, the Pew Trust reports that more than 8 million Americans (22%) 65 years or older increasingly use the Internet,⁵ and large healthcare plans such as the Veterans Administration are increasingly offering online health information to support this need. These advances in literacy are important because communication between healthcare providers and elders is vitally important in providing quality care, supporting self-care, and in negotiating the healthcare system.

Health Status

► Life Expectancy

Although Americans are living longer than ever before, an estimated average of 78.14 years overall in 2008, U.S. life expectancy lags behind that of many other industrialized

nations.⁶ There is nearly a 6-year gap between 2008 estimated life expectancy in men (75.29 years) and women (81.13 years).⁶ Disparities in mortality persist, with estimated 2008 life expectancy in the white population nearly 5 years higher than that of the black population.⁶ More than a third of U.S. deaths in 2000 were attributed to three risk behaviors: smoking, poor diet, and physical inactivity, accounting for nearly 35% of deaths. Currently, only 9% of Americans older than 65 years smoke; however, nearly 54% of men and 21% of women are former smokers.⁷ Overweight elders 65 to 74 years of age increased from 57% to 73% in 2004 largely due to inactivity and a diet high in refined foods, saturated fats, and sugared beverages, and deficient in whole grains, fruits, vegetables, nuts, and seeds.⁴ Despite the proven health benefits of regular physical activity, more than half of the older population is sedentary; 47% of those 65 to 74 years and 61% older than 75 years report no physical activity.⁸

The 2007 National Health Interview Survey indicated that 39% of non-Hispanic white elders reported “very good” or “excellent” health, compared with 29% of Hispanics and 24% of blacks.⁹ Chronic diseases disproportionately affect older adults and are associated with disability, diminished quality of life, and increased costs for healthcare and long-term care. About 80% of older adults have at least one chronic condition, and 50% have at least two. The prevalence of certain chronic conditions differs by sex, with women reporting higher levels of arthritis (54% versus 43%), and men reporting higher levels of heart disease (37% versus 26%) and cancer (24% versus 19%).⁵ Although many older Americans report multiple chronic health conditions, the rate of functional limitations among the elderly actually declined between 1992 and 2005 from 49% to 42%.⁴ Among the 15 leading causes of death, age-adjusted death rates decreased significantly from 2004 to 2005 for the top three leading causes: heart disease (33%), cancer (22%), and stroke (8%), although chronic lower respiratory diseases, unintentional injuries, Alzheimer’s disease, influenza and pneumonia, hypertension, and Parkinson’s disease increased.⁶ Figure 2–1 specifies the most common chronic conditions of elders, by sex. Frailty is a common biological syndrome in the elderly. Once frail, elders may rapidly progress toward failure to thrive and death. Only 3% to 7% of elders between the ages of 65 and 75 years are frail, increasing to more than 32% in those older than 90 years.¹⁰

► Healthcare Utilization and Cost

2 *Older Americans use considerably more healthcare services than younger Americans, and their healthcare needs are often complex.* Although in 2005 hospital stays for those 65 years or older were half of what they had been in 1970 (5.5 versus 12.6 days), they accounted for more than 65% of hospitalizations overall, with longer lengths of stay corresponding to increasing age.¹¹ Nine persons per 1,000 aged 65 to 74 years lived in nursing homes in 2004, compared with 36 of 1,000 aged 75 to 84 years, and 139 of 1,000 aged 85 years or older¹¹; as the aged live longer, more will require institutional care. After adjusting for inflation, healthcare costs increased significantly among older Americans from \$8,644 in 1992 to \$13,052 in 2004, three to five times greater than the cost for

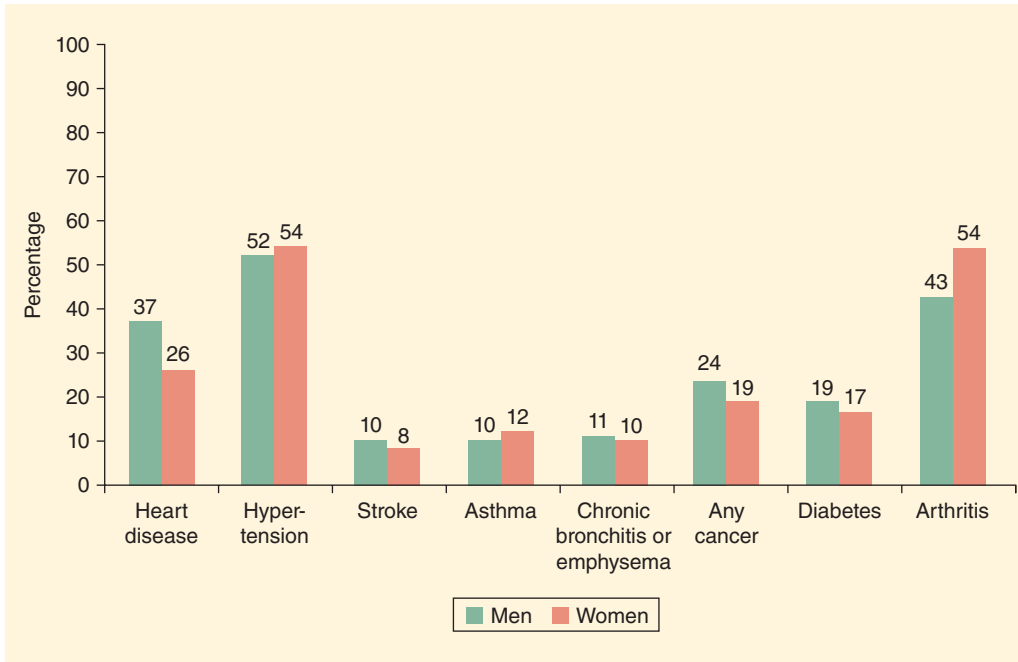

FIGURE 2-1. Percentage of people 65 years and older who reported having selected chronic conditions, by sex, 2005 to 2006. Note: Data are based on a 2-year average from 2005 to 2006. Reference population: These data refer to the civilian noninstitutionalized population. (From Centers for Disease Control and Prevention, National Center for Health Statistics, National Health Interview Survey.)

someone younger than 65 years. Medicare spending has grown nearly ninefold in the past 25 years, to more than \$507 billion in 2008, and Medicare roles are expected to increase to \$78 million by 2030.⁵

By knowing and applying the epidemiology of aging, clinicians can better understand the multiple points of potential pharmaceutical intervention to postpone disease, disability, and mortality, to avoid error, and to promote health, functioning, and health-related quality of life.

Patient Encounter, Part 1

RV is an 83-year-old woman who has lived in the United States for 62 years but speaks mostly Spanish. She finished 6th grade in Mexico and does not understand medical information. She presents to the Interprofessional Geriatric Clinic for a comprehensive medication review. Her chronic conditions include diabetes, stroke, hypertension, depression, seizure disorder, arthritis, insomnia, and glaucoma. RV uses 16 prescription medications for the described conditions including her eye drops; she also has five medications she “keeps on hand” for as-needed use. She is overweight and reports eating high amount of refined foods since she stopped cooking due to glaucoma. She watches TV most of the day and stays indoors; denies smoking or drinking alcohol.

What information is consistent with epidemiology of aging?

Which of RV's medical conditions are commonly found in older adults?

What additional information do you need before you review RV's medications and make recommendations?

AGE-RELATED CHANGES

In basic terms, pharmacokinetics is what the body does to the drug, and pharmacodynamics is what the drug does to the body. **3** *All four components of pharmacokinetics—absorption, distribution, metabolism, and excretion—are affected by aging, the most clinically important and consistent is the reduction of renal elimination of drugs.*¹² As people age, they become more frail and are more likely to experience altered and variable drug pharmacokinetics and pharmacodynamics compared with younger people. Even though this alteration is influenced more by a patient's clinical state than their chronological age, the older patient is more likely to be malnourished and suffering from diseases that affect pharmacokinetics and pharmacodynamics.¹³ For example, chronic uncontrolled diabetes has a greater impact on reducing renal function than age-related decline. Clinicians have the responsibility to use pharmacokinetic and pharmacodynamic principles to improve the care of elderly patients and avoid harmful side effects of the drugs used.

Pharmacokinetic Changes

► Absorption

- Multiple changes occur throughout the GI tract with aging, but little evidence indicates that drug absorption is significantly altered. The changes include decreases in overall surface of the intestinal epithelium, gastric acid secretion, and splanchnic blood flow.¹² Peristalsis is weaker, and also gastric emptying is delayed. These changes slow absorption in the stomach, especially for enteric-coated and delayed-release preparations. Despite the decreased rate, the extent of absorption is not significantly altered. Delays in absorption may lead to a longer time required to achieve peak drug effects, but it does not significantly alter the amount of drug

absorbed, and drug movement from the GI tract into circulation is not meaningfully altered.^{12,13} Similarly, reduced gastric acid with aging has not been shown to affect drug absorption. Relative **achlorhydria** and reduction in intrinsic factor production are caused by atrophy of gastric cells in the stomach. These changes can decrease the absorption of nutrients such as vitamin B₁₂, calcium, and iron.¹³

Aging facilitates atrophy of the epidermis and dermis along with a reduction in barrier function of the skin. Tissue blood perfusion is reduced, leading to decreased or variable rates of transdermal, subcutaneous, and intramuscular drug absorption. Therefore, intramuscular injections should generally be avoided in the elderly due to unpredictable drug absorption.¹² Additionally, because saliva production decreases with age, medications that need to be absorbed rapidly by the buccal mucosa are absorbed at a slower rate.¹³ Yet, for most drugs, absorption is not significantly affected in elderly patients and the changes just described are clinically inconsequential.¹⁴

► Distribution

- Elderly patients can undergo significant structural changes in the body that alter drug distribution, half-life, and duration of action. Main factors that affect distribution of drugs in the body are changes in body fat and water and changes in protein binding. Lean body mass can decrease by as much as 12% to 19% through loss of skeletal muscle in the elderly.
- Thus, blood levels of drugs primarily distributed in muscle increase (e.g., digoxin), presenting a risk factor for over-medication.¹³ A concern with frail elderly, having low muscle mass, is the risk of adverse effects when they receive higher doses per unit of body weight. While lean muscle mass decreases, adipose tissue can increase by 14% to 35% in the elderly (18% to 36% in men and 33% to 45% in women). Fat-soluble drugs have an increased volume of distribution (V_d), leading to higher tissue concentrations and prolonged duration of action. Greater V_d leads to an increased half-life and an increase in time required to reach a steady-state serum concentration. Examples of lipophilic drugs with increased V_d are diazepam (lipophilic benzodiazepine), amiodarone, and verapamil.^{12,13}
- Total body water decreases by about 10% to 15% by age 80. This lowers V_d of hydrophilic drugs leading to higher plasma drug concentrations than in younger adults when equal doses are used.^{12,13} Toxic drug effects may be enhanced when dehydration occurs and when the extracellular space is reduced by diuretic use. Examples of commonly used hydrophilic drugs are aspirin, lithium, and ethanol. Elderly also experience a decline in gastric alcohol dehydrogenase, further increasing the peak effect of ethanol. Likewise, plasma albumin concentration decreases by 10% to 20%, although disease and malnutrition contribute more to this decrease than age alone.¹² In patients with an acute illness, rapid decreases in serum albumin can increase drug effects. Examples of highly protein-bound drugs include warfarin, phenytoin, and diazepam.¹³ For most drugs these changes are not clinically important because the changes just cited

can alter peak levels of single doses, but mean serum concentrations at steady state are not altered unless clearance is affected.¹³

The clinical importance of the decrease in binding proteins and increase in free fraction of drugs lies in the interpretation of serum drug levels of highly protein-bound drugs with narrow therapeutic indices. Most labs measure and report the total amount of drug in the serum, both bound and unbound. However, the unbound (free) drug is pharmacologically active. In a malnourished patient with hypoalbuminemia, a higher percentage of the total drug level consists of free drug than in a patient with normal serum albumin. A common example is phenytoin. If a hypoalbuminemic patient has a low-normal total phenytoin level, and a clinician increases the phenytoin dose, the free phenytoin concentration may increase to a toxic level.¹⁴

► Metabolism

Drug metabolism is affected by age, acute and chronic diseases, and drug–drug interactions. The liver is the primary site of drug metabolism, which undergoes changes with age. Although there is not a consistent decline in the capacity of the liver to metabolize all drugs, older patients have decreased metabolism of many drugs.^{12,14} There is also a decline with age in the liver's ability to recover from injury. Liver mass is reduced by 20% to 30% with advancing age, and hepatic blood flow is decreased by as much as 40%. These changes can drastically reduce the amount of drug delivered to the liver per unit of time, reduce its metabolism, and increase the elimination half-life.¹³ Metabolic clearance of some drugs is decreased by 20% to 40% (e.g., amiodarone, amitriptyline, warfarin, and verapamil), but for others it is unchanged. Drugs with a low hepatic extraction are usually not affected by hepatic hemoperfusion.¹³ Drugs that have high **extraction ratios** have significant first-pass metabolism, resulting in higher bioavailability for older adults. For example, the effect of morphine is increased due to a decrease in clearance by around 33%. Similar increases in bioavailability associated with reduced clearance can be seen with propranolol, levodopa, and hydroxymethylglutaryl coenzyme-A (HMG-CoA) reductase inhibitors (statins). Elderly patients may experience a similar clinical response to that of younger patients using lower doses.¹³

The effect of aging on liver enzymes (cytochrome P450 system, known as the CYP450 system) may lead to a decreased elimination rate of drugs that undergo oxidative phase I metabolism, but this is controversial.¹³ Originally, it was thought that the CYP450 system was impaired in the elderly, leading to a decrease in drug clearance and an increase in serum half-life. Studies have not consistently confirmed this, and although there is an age-related increase in half-life of some drugs, it may be attributed to other factors such as changes in V_d . Thus variations in the CYP450 activity may not be due to aging but to lifestyle (e.g., smoking), illness, or drug interactions.^{13,14} A patient's nutritional status plays a role in drug metabolism as well. Frail elderly have a more diminished drug metabolism than those with healthy body weight.¹²

Age does not have an effect on phase II hepatic metabolism, known as conjugation or glucuronidation, but conjugation is reduced with frailty. Temazepam and lorazepam are examples of drugs that undergo phase II metabolism.¹³

► Elimination

- The most clinically important pharmacokinetic change in the elderly is the decrease in renal drug elimination.¹² As people age, renal blood flow, renal mass, glomerular filtration rate, filtration fraction, and tubular secretion decrease. After age 40, there is a decrease in the number of functional glomeruli, and renal blood flow declines by approximately 1% yearly. From age 25 to 85 years, average renal clearance declines by as much as 50% and is independent of the effects of disease.¹²⁻¹⁴ Still, the impact of age on renal function is variable and not always a linear decline.¹⁴ Longitudinal studies have suggested that a percentage (up to 33%) of elderly patients do not experience this age-related decline in renal function. Clinically significant effects of decreased renal clearance include prolonged drug half-life, increased serum drug level, and increased potential for **adverse drug reaction** (ADR).¹² Special attention should be given to renally eliminated drugs with a narrow therapeutic index (e.g., digoxin, aminoglycosides). Monitoring serum concentration and making appropriate dose adjustment for these agents can prevent serious ADR resulting from drug accumulation.¹³ It is important to note that despite a dramatic decrease in renal function (creatinine clearance) with aging, serum creatinine may remain fairly unchanged and remain within normal limits. This is because elderly patients, especially the frail elderly, have decreased muscle mass resulting in less creatinine production for input into circulation.^{12,13}
- Because chronic kidney disease can be overlooked if a clinician focuses only on the serum creatinine value, drugs can be dosed inappropriately.

For the reasons previously stated, creatinine clearance should always be calculated when starting or adjusting drugs in the elderly. Clearance measure using 24-hour urine collection is impractical, costly, and often done inaccurately. The Cockcroft-Gault equation is the most widely used formula for estimating renal function and adjusting drug doses. It incorporates serum creatinine, age, gender, and weight. See Chapter 25 (Table 25-2) for more details.

$$\text{Creatinine clearance} = \frac{(140 - \text{Age}) \times \text{Weight (kg)}}{\text{Serum creatinine} \times 72} \\ \times (0.85 \text{ if female})$$

when serum creatinine is expressed in mg/dL. Or:

$$\text{Creatinine clearance} = \frac{(140 - \text{Age}) \times \text{Weight (kg)} \times 1.23}{\text{Serum creatinine}} \\ \times (0.85 \text{ if female})$$

When serum creatinine is expressed in mol/L.

This equation is also used by drug manufacturers to determine dosing guidelines. The Cockcroft-Gault equation provided the best balance between predictive ability and bias in a study that compared it with the Modification of Diet in Renal Disease (MDRD) and Jelliffe “bedside” clearance equations.¹³ Understand that the predictive formulas can significantly overestimate actual renal function, especially in the chronically ill, debilitated elderly.

Pharmacodynamic Changes

Pharmacodynamics refers to the actions of a drug at its target site and the body’s response to that drug. Pharmacodynamic changes associated with aging are not as well known as that of pharmacokinetics, but a better understanding of these effects can enhance the quality of medication prescribing.

- **4** *In general, the pharmacodynamic changes that occur in the elderly tend to increase their sensitivity to drug effects.* Most pharmacodynamic changes in the elderly are associated with a progressive reduction in homeostatic mechanisms and changes in receptor properties. Although the end result of these changes is an increased sensitivity to the effects of many drugs, a decrease in response can also occur.¹⁵ The changes in the receptor site include alterations in binding affinity of the drug, number or density of active receptors at the target organ, structural features, and postreceptor effects (biochemical processes/signal transmission). These include receptors in the adrenergic, cholinergic, and dopaminergic systems, as well as γ -aminobutyric acid (GABA) and opioid receptors.^{12,13}

► Cardiovascular System

- Decreased homeostatic mechanisms in older adults increase their susceptibility to orthostatic hypotension when taking drugs that affect the cardiovascular system and lower the arterial blood pressure. This is explained by a decrease in arterial compliance and baroreceptor reflex response, which limits their ability to compensate quickly for postural changes in blood pressure. It has been estimated that as many as 5% to 33% of the elderly experience drug-induced orthostasis. Examples of drugs other than typical antihypertensives that have a higher likelihood of causing orthostatic hypotension in geriatric patients are tricyclic antidepressants, antipsychotics, loop diuretics, direct vasodilators, and opioids.^{12,13,15} Older patients have a decreased β -adrenergic receptor function, and they are less sensitive to β -agonists and β -adrenergic antagonists effects in the cardiovascular system and possibly in the lungs, but their response to α -agonists and antagonists is unchanged.^{13,15} Increased hypotensive and heart rate response (to a lesser degree) to calcium channel blockers (e.g., verapamil) are reported. Increased risk of developing drug-induced QT prolongation and **torsade de pointes** is also present.¹⁵ Therefore, clinicians must start medications at low doses and titrate slowly, closely monitoring the patient for any adverse response.

► Central Nervous System

- Overall, geriatric patients exhibit a greater sensitivity to the effects of drugs that gain access to the CNS. In most

cases, lower doses are required for adequate response, and patients have a higher incidence of adverse effects. For example, lower doses of opioids provide sufficient pain relief for older patients, whereas conventional doses can cause oversedation and respiratory depression.^{12,13,15}

The blood–brain barrier becomes more permeable as people age; thus more medications can cross the barrier. Examples of problematic medications include benzodiazepines, antidepressants, neuroleptics, and antihistamines. There is a decrease in the number of cholinergic neurons as well as nicotinic and muscarinic receptors, decreased choline uptake from the periphery, and increased acetylcholinesterase.^{13,15} The elderly have a decreased ability to compensate for these imbalances of the neurotransmitters, which can lead to movement and memory disorders. Older patients have an increased number of dopamine type 2 receptors, which makes them more susceptible to delirium from anticholinergic and dopaminergic drugs. At the same time, they have a reduced number of dopamine and dopaminergic neurons in the substantia nigra of the brain resulting in higher incidence of extrapyramidal symptoms from antidopaminergic medications (e.g., antipsychotics).^{12,15}

► Fluids and Electrolytes

Fluid and electrolyte homeostatic mechanism is decreased in the geriatric population. The elderly experience more severe dehydration with equal amounts of fluid loss compared with younger adults. The multitude of factors involved include decreased thirst and cardiovascular reflexes, decreased fluid intake, decreased ability of the kidneys to concentrate urine, increased atrial natriuretic peptide, decreased aldosterone response to hyperkalemia, and decreased response to antidiuretic hormone. The result is an increased incidence of hyponatremia, hyperkalemia, and prerenal azotemia, especially when the patient is taking a thiazide or loop diuretic (e.g., hydrochlorothiazide, furosemide). Angiotensin-converting enzyme inhibitors have an increased potential to cause hyperkalemia and acute renal failure. Thus these agents need to be started low, titrated slowly, and monitored frequently.^{12,15}

► Glucose Metabolism

An inverse relationship between glucose tolerance and age has been reported. This is likely due to a reduction in insulin secretion and sensitivity (greater insulin resistance). Consequently, there is an increased incidence of hypoglycemia when using sulfonylureas (e.g., glyburide, glipizide).¹² Due to an impaired autonomic nervous system, elderly patients may have a decreased response to, or awareness of, hypoglycemia (may not experience the sweating, palpitations, or tremors but instead will experience the neurological symptoms of syncope, ataxia, confusion, or seizures).

► Anticoagulants

The geriatric population is more sensitive to anticoagulant effects of warfarin compared with younger people. When

similar plasma concentrations of warfarin are attained, there is greater inhibition of vitamin K–dependent clotting factors in older patients than in young. Overall, the risk of bleeding is increased in the elderly, and when overanticoagulated, the likelihood of morbidity and mortality is higher. This is further complicated by the presence of concomitant prescriptions/herbals/supplements, drug–drug interactions, nonadherence, confusion, and acute illness. Close monitoring of the **international normalized ratio (INR)** and screening for appropriate use is paramount. In contrast, there is no association between age and response to heparin.¹²

Patient Encounter, Part 2

RV's current chronic medications include (1) amlodipine 5 mg by mouth twice daily, (2) benazepril 20 mg by mouth every evening, (3) furosemide 40 mg by mouth every morning (patient takes irregularly), (4) fluoxetine 10 mg by mouth every evening, (5) glyburide 2 mg 1 tablet by mouth twice daily, (6) phenytoin 100 mg by mouth three times a day, (7) eszopiclone 3 mg by mouth at bedtime, (8) calcium (plus vitamin D) 600 mg by mouth twice daily, (9) oxycodone-acetaminophen 5–325 mg 1 to 2 tablets by mouth every 6 hours as needed for pain, (10) brimonidine 0.1% 1 drop in each eye twice daily, (11) brinzolamide 1% 1 drop in each eye twice daily, (12) timolol 0.5% 1 drop in each eye twice daily, (13) bimatoprost 0.3% 1 drop in each eye at bedtime, (14) serum tears 1 drop in each eye 4 times daily, (15) diphenhydramine 25 mg by mouth at bedtime, and (16) acetaminophen 500 mg by mouth 4 times daily as needed for pain. She has no known drug allergies.

RV's son (interpreter) states that one of her providers thought RV may need to double her phenytoin dose. She was recently hospitalized for dehydration and is recovering from "low kidney function."

VS: BP 98/60, P: 70 bpm, RR: 14, T: 38.4°C (101.1°F)

Ht: 5'2" (157 cm), Wt: 63 kg

Labs: Na 141 mEq/L (141 mmol/L), K 4.6 mEq/L (4.6 mmol/L), Cl 98 mEq/L (98 mmol/L), CO₂ 25 mEq/L (25 mmol/L), BUN 55 mg/dL (19.6 mmol/L), creatinine 1.6 mg/dL (141 μmol/L), glucose 92 mg/dL (5.1 mmol/L), albumin 2.7 g/dL (27 g/L), HgbA1c 6.4% (0.064; 46 mmol/mol Hgb)

What is RV's estimated creatinine clearance?

How does phenytoin serum concentration react to RV's albumin level?

What steps should be taken prior to increasing phenytoin dose in this patient?

What potential drug-related problems does RV have?

DRUG-RELATED PROBLEMS

5 *Comorbidities and polypharmacy complicate elderly health status, particularly when polypharmacy includes inappropriate medications that lead to drug-related problems.*

It is reported that 28% of hospitalizations in older adults are due to medication-related problems including nonadherence and ADRs. Studies using the Beers criteria indicate that 14% to 40% of the frail elderly are prescribed at least one inappropriate drug, and unnecessary medication use was detected in 44% of older veterans at the time of hospital discharge.¹⁶ Drug-related problems, including ADRs and therapeutic failure, lead to morbidity and mortality in nursing facilities and accrue healthcare cost of nearly \$4 billion yearly.¹⁷ Collaboration among interprofessional providers and older patients can ensure appropriate therapy, minimize adverse drug events, and maximize medication adherence.

Polypharmacy

Polypharmacy is defined as taking multiple medications concurrently (some report at least four and others at least five). Polypharmacy is prevalent in older adults who compose 14% of the U.S. population but receive 36.5% of all prescription drugs.¹⁶ According to the Centers for Disease Control and Prevention, polypharmacy is the primary cause of drug-related adverse events in older adults. Medication use rises with age. An estimated 50% of the community-dwelling elderly take 5 or more medications, and 12% of them take 10 or more.¹⁸ Also, common use of dietary supplements and herbal products in this population adds to polypharmacy. In nursing home settings, patients receiving nine or more chronic medications increased from 17% in 1997 to 27% in 2000.¹⁶ Among various reasons for polypharmacy, an apparent one is a patient receiving multiple medications from different providers who treat the patient's comorbidities without coordinated care. Thus medication reconciliation will become increasingly important as the aging population continues to grow.

A recent review that analyzed studies aimed at reducing polypharmacy in elderly emphasized complete evaluation of all medications by healthcare providers at each patient visit to prevent polypharmacy.¹⁹ Efforts should be made to reduce polypharmacy by discontinuing any medication without indication. However, clinicians should also understand that appropriate polypharmacy is indicated for older adults who have multiple diseases, and support should be provided for optimal adherence. Drug-related problems associated with polypharmacy can be identified by performing a comprehensive medication review during each patient encounter (see Patient Care and Monitoring box).

Inappropriate Prescribing

Inappropriate prescribing is defined as prescribing medications that cause a significant risk of an adverse event when there is an effective and safer alternative. It also includes prescribing a medication outside the bounds of accepted medical

standards. The incidence of prescribing potentially inappropriate drugs to elderly patients has been reported to be as high as 12% in those living in the community and 40% in nursing home residents.^{20,21} At times, medications are continued long after the initial indication has resolved. The clinician prescribing for older adults must understand the rate of adverse reactions and drug–drug interactions, the evidence available for using a specific medication, and patient use of over-the-counter (OTC) medications and herbal supplements.^{20,22}

Screening tools have been developed to help the clinician identify potentially inappropriate drugs. The most utilized and well known is the Beers criteria,²³ first developed in 1991. It was most recently updated in 2012 by the American Geriatric Society using a systematic review of the evidence. It includes 53 medications or medication classes that are potentially inappropriate in elderly patients. The new Beers criteria are divided into three categories: (a) medications that should be avoided regardless of disease/condition, (b) medications to avoid in certain diseases/conditions, and (c) medications to use with caution.²³

Some of the more common medications referred to in the Beers criteria²³ include the following:

- Tertiary Tricyclic Antidepressants (TCAs) like amitriptyline (strong anticholinergic and sedative properties)
- Benzodiazepines including diazepam (increased risk of falls, fractures, and cognitive impairment)
- First generation Antihistamines like diphenhydramine (confusion and sedation with a prolonged effect)
- Nonsteroidal anti-inflammatory drugs (NSAIDs) (increased potential to cause GI bleeding, exacerbate heart failure, and cause kidney injury)
- Spironolactone greater than 25 mg/d (avoid in patients with heart failure or CrCl less than 30 mL/min due to increased hyperkalemia risk)

Examples of drug/disease combinations reported as potentially inappropriate are as follows:

- Strongly anticholinergic drugs in patients with bladder outlet obstruction or benign prostatic hyperplasia
- Metoclopramide and antipsychotics in patients with Parkinson's disease (worsening of symptoms) and antipsychotics in patients with dementia (increased risk of stroke and mortality)
- Benzodiazepines, anticholinergics, antispasmodics, and muscle relaxants with cognitive impairment

In 2008, a new screening tool of elderly patients' medicines was developed. The Screening Tool of Older People's Potentially Inappropriate Prescriptions (STOPP) tool, designed by 18 experts in geriatric pharmacotherapy, incorporates current clinical evidence to identify potentially inappropriate medications (PIMs) in older patients.²⁴ It is arranged according to relevant physiological system and incorporates commonly encountered instances of potentially inappropriate prescribing (drug–drug and drug–disease interactions, drugs increasing fall risk, and duplicate drug class prescriptions).²⁴

Screening Tool to Alert Doctors to the Right Treatment (START) was designed to aid physicians in prescribing certain medications that have evidence of benefit in geriatric patients in selected clinical situations.^{25,26} Whereas the STOPP criteria identify commission errors or inappropriately prescribed meds, the START criteria is a tool to identify omission errors. There is no convincing evidence that using the START/STOPP criteria reduces morbidity, mortality, or cost, but it can be used in a time-efficient manner to evaluate older patients' medications comprehensively. Its use can enhance clinical judgment in prescribing for older patients, thereby avoiding unnecessary and potentially harmful prescribing cascades.²⁴

Examples of STOPP criteria²⁴ include:

- Cardiovascular system
 - Digoxin more than 125 mcg/day with impaired renal function
 - Diltiazem or verapamil with New York Heart Association class III or IV heart failure
- CNS
 - Tricyclic antidepressant with dementia
 - Prolonged use of first-generation antihistamines
- Urogenital system
 - Bladder antimuscarinic drugs with dementia

Examples of START criteria²⁵ include:

- Cardiovascular system
 - Warfarin in the presence of atrial fibrillation, where there is no contraindication
 - Angiotensin-converting enzyme inhibitor in chronic heart failure, where no contraindication exists
- Locomotor system
 - Bisphosphonate in patients taking glucocorticoids for more than 1 month
 - Calcium and vitamin D supplement in patients with known osteoporosis

Although the Beers criteria is commonly referred to in the literature and used in clinical practice, there is little evidence available reporting a tangible benefit to patients in terms of clinical outcomes, and all outcome studies are retrospective. Some studies have compared the performance of STOPP with that of the Beers criteria in detecting PIMs and adverse drug events causing hospital admission or emergency department visits. STOPP criteria identified a significantly higher proportion of patients requiring hospitalization as a result of PIM-related adverse events than Beers criteria in one study.²⁴ Another study found that of the adverse events that were avoidable and contributory to the hospitalization, the drugs involved were 2.8 times more likely to be on the STOPP list than the Beers list.²⁷

As noted previously, the consequences of inappropriate prescribing are widespread and vary in severity. It is important to note that these medications are “potentially” inappropriate, and alternatives should be used or focused monitoring for adverse effects should be provided. Practical strategies for

appropriate medication prescribing include establishing a partnership with patients and caregivers to enable them to understand and self-monitor their medication regimen. Providers should perform drug–drug and drug–disease interaction screening, and use time-limited trials to evaluate the benefits and risks of new regimens.²²

Undertreatment

Much has been written about the consequences of over-medication and polypharmacy in the elderly. However, underutilization of medications is harmful in the elderly as well, resulting in reduced functioning and quality of life, and increased morbidity and mortality. There are instances when an indicated drug is truly contraindicated appropriately preventing its use, when a lower dose is indicated, or when prognoses dictate withholding of aggressive therapy. Outside of these scenarios, many elders still do not receive the therapeutic interventions that would provide benefit. This occurs for many reasons including the belief that treatment of the patient's primary problem is enough intervention, cost, concerns of nonadherence, fear of adverse effects and associated liability, starting low and slow and failing to increase to an appropriate dose, skepticism regarding secondary prevention for elders, or frank **ageism**. A study found evidence of underprescribing in 64% of older patients, and those on more than eight medications at the highest risk. Interestingly, the lack of proven beneficial therapy did not depend on age, race, sex, comorbidity, cognitive status, and dependence in activities of daily living.²⁸ Common categories of geriatric undertreatment are listed in [Table 2-1](#).

Table 2-1

Common Categories of Geriatric Undertreatment

Therapy	Concern
Anticoagulation in patients with atrial fibrillation	Providers may be overly concerned with risk of bleeding or the risk of falls if anticoagulated
Malignant and nonmalignant pain complaints	Providers are often hesitant to prescribe opioids due to possible cognitive and bowel side effects, concerns about addiction; patients may often be hesitant to take opioids
Antihypertensive therapy	Providers may underestimate the benefit on stroke and cardiovascular events, and/or fail to add the second or third medication needed to attain control
β -Blocker treatment in heart failure	Providers are concerned about complications in high-risk patients despite the substantial evidence of mortality reduction
Statin treatment for hyperlipidemia	Providers may underestimate benefit or have high concern for adverse events
Treatment of osteopenia/osteoporosis in men and women at risk of fractures	Providers often fail to screen for bone mineral density and are therefore unaware to offer treatment

A reasoned clinical assessment strategy to weigh the potential benefit versus harm of the older patient's complete medication regimen is required. Once obvious contraindications have been dismissed, the patient's (a) goals and preferences, (b) prognosis, and (c) time until therapeutic benefit will be achieved should be taken into consideration to determine whether the therapy can meet treatment goals. Underprescribing can best be avoided by using careful clinical assessment strategies, improving adherence support, and increasing financial coverage of drugs.

Adverse Drug Reaction

ADR is defined by the World Health Organization as a reaction that is noxious and unintended, which occurs at dosages normally used in humans for prophylaxis, diagnosis, or therapy. (See the glossary for the American Society of Health-System Pharmacists' definition of an ADR.²⁹) ADRs increase with polypharmacy use, and older adults commonly experience ADRs. In fact, ADRs are the most frequently occurring drug-related problem among elderly nursing home residents, and the yearly occurrence in outpatient elderly is noted to be 5% to 33%.³⁰

Seven predictors of ADRs in older adults have been identified³⁰: (a) taking more than four medications; (b) more than 14-day hospital stay; (c) having more than four active medical problems; (d) general medical unit admission versus geriatric ward; (e) alcohol use history; (f) lower Mini-Mental State Examination score (confusion, dementia); and (g) two to four new medications added during a hospitalization. Similarly, there are four predictors for severe ADRs experienced by the elderly³¹: (a) use of certain medications including diuretics, NSAIDs, antiplatelets, and digoxin; (b) number of drugs taken; (c) age; and (d) comorbidities. Suggested strategies to preventing ADRs in older adults are described in [Table 2-2](#).³¹ Particular caution must be taken when

prescribing drugs that alter cognition in the elderly, including antiarrhythmics, antidepressants, antiemetics, antihistamines, anti-Parkinson's, antipsychotics, benzodiazepines, digoxin, histamine-2 receptor antagonists, NSAIDs, opioids, and skeletal muscle relaxants.²¹

One of the most damaging ADRs that frequently occur in older adults is medication-related falls. Falls are associated with a poor prognosis ranging from premature institutionalization to early death. Extrinsic factors for falling include taking certain medications or polypharmacy. A systematic review concluded that psychotropic medications including benzodiazepines, antidepressants, and antipsychotics have a strong association with increased risk of falls, whereas anti-epileptics and antihypertensives have a weak association.³² Comprehensive fall prevention strategies should always include medication simplification and modification to avoid or resolve ADRs.

Nonadherence

America's other drug problem is the term given to medication nonadherence by the National Council on Patient Information and Education.³³ Nonadherence to chronic pharmacotherapies is prevalent and escalates healthcare costs associated with worsening disease and increased hospitalization.³³ *Medication adherence* is a term used to describe a patient's medication-taking behavior, generally defined as the extent to which one adheres to an agreed regimen derived from collaboration with their healthcare provider. The word "adherence" is often preferred over "compliance" because medication compliance implies the patient passively complying to provider's medication orders with no attempts made at collaboration.³⁴

Older adults are at greater risk for medication nonadherence due to high prevalence of multiple comorbidities, including cognitive deficit, polypharmacy use, and financial barriers. Numerous barriers to optimal medication adherence exist and include patient's lack of understanding, provider's failure to educate, polypharmacy leading to complex regimen and inconvenience, treatment of asymptomatic conditions (such as hypertension and dyslipidemia), and cost of medications.³⁴ Factors influencing medication nonadherence are listed in [Table 2-3](#).

Table 2-2

Strategies to Prevent Adverse Drug Reactions in Older Adults

- Evaluating comorbidities, frailty, and cognitive function
- Identifying caregivers to take responsibility for medication management
- Evaluating renal function and adjusting doses appropriately
- Monitoring drug effects
- Recognizing that clinical signs or symptoms can be an ADR
- Minimizing number of medications prescribed
- Adapting treatment to patient's life expectancy
- Realizing that self-medication and nonadherence are common and can induce ADRs

ADR, adverse drug reaction.

Adapted, with permission, from Merle L, Laroche ML, Dantoine T, et al. Predicting and preventing adverse drug reactions in the very old. *Drugs Aging* 2005;22(5):375–392.

Table 2-3

Factors Influencing Medication Nonadherence

Three or more chronic medical conditions	Living alone in the community
Five or more chronic medications	Recent hospital discharge
Three times or more per day dosing or 12 or more medication doses per day	Caregiver reliance
Four or more medication changes in past 12 months	Low health literacy
Three or more prescribers	Medication cost
Significant cognitive or physical impairments	History of medication nonadherence

Patient Encounter, Part 3

RV and her son are both willing to work with the new regimen after this comprehensive medication review. RV has been living with the son for more than 2 years after her stroke, but she is thinking about transitioning to a long-term care facility. Even though she is overweight, she has lost 5 kg in the last 6 months and developed a new coccyx ulcer. Today her pain score is 7/10.

What recommendations can be made about RV's medication regimen at this time?

If RV transitions to a long-term care facility, which quality indicators would be of concern?

Following is a list of six “how” questions to ask when assessing medication adherence³⁵:

1. How do you take your medicines?
2. How do you organize your medicines to help you remember to take them?
3. How do you schedule your meal and medicine times?
4. How do you pay for your medicines?
5. How do you think the medicines are working for your conditions?
6. How many times in the last week/month have you missed your medicine?

Although no single intervention has found to improve adherence consistently, patient-centered multicomponent interventions such as combining education, convenience, and serial follow-up have resulted in a positive impact on medication adherence and associated health outcomes.³⁶ Future research needs include adherence studies evaluating belief-related variables, such as personal and cultural beliefs, in larger and more ethnically diverse samples of older populations.

GERIATRIC ASSESSMENT

- The term *geriatric assessment* is used to describe the interprofessional team evaluation of the frail, complex elderly patient. Such a team may include but is not limited to a geriatrician, nurse, pharmacist, case manager/social worker, physical therapist, occupational therapist, speech therapist, psychologist, nutritionist, dentist, optometrist, and audiologist. Assessment may be performed in a centralized geriatric clinic or by a series of evaluations performed in separate settings after which the team may conduct an interprofessional case conference to discuss the patient's assessment and plan. For a healthy, active elderly patient, the assessment might require only two to three members of this team, with coordination of care provided by the patient's geriatrician.

Patient Interview

- 7 The clinical approach to assessing older adults frequently goes beyond a traditional “history and physical” used in general internal medicine practice.³⁷ Functional status must be determined, which includes the activities of daily living (ADLs) and instrumental activities of daily living (IADLs). Refer to **Table 2-4** for descriptions of ADLs and IADLs. Evidence of declining function in specific organ systems is sought. Of particular importance is cognitive assessment, which may require collateral history from family, friends, or other caregivers, and is important in determination of the patient's capacity to consent to medical treatment.³⁸ The mini-cog mental status examination,³⁹ shown in **Figure 2-2**, is a quick tool to assess patient's cognitive impairment. Commonly there is decreased visual acuity, hearing loss, dysphagia, and manual dexterity. Decreased skin integrity, if present, greatly increases risk for pressure ulcers. Sexual function is a sensitive but important area, and it should be specifically inquired about. Cardiac, renal, hepatic, and digestive insufficiencies can have significant implications for pharmacotherapy. Inadequate nutrition may lead to weight loss and impaired functioning at the cellular or organ level as discussed previously. See **Table 2-5** for common problems experienced by older adults.
- It is important to identify “**geriatric syndromes**” such as frailty, instability and falls, osteoporosis, insomnia, and incontinence that have an impact on quality of life and must be recognized. Common diseases present with atypical symptoms such as thyroid dysfunction and depression presenting as delirium. It is also important to assess for

Table 2-4

Activities of Daily Living and Instrumental Activities of Daily Living

ADLs

Transfers	Dressing	Mobility	Eating
Bathing	Toileting	Grooming	

IADLs

Using transportation	If still driving, assess driving ability (including cognitive function, medications that can impair driving ability, vision, neuromuscular conditions that may interfere with reaction time, ability to turn head) at the time of license renewal
Using the telephone	Check for emergency phone numbers located near the telephone
Management of finances	Assess the ability to balance checkbook and pay bills on time
Cooking	Check for safe operation of appliances and cooking tools as well as ability to prepare balanced meals
Housekeeping	Check for decline in cleanliness or neatness
Medication administration	Assess organization skills and adherence

ADL, activity of daily living; IADL, instrumental activity of daily living.

Three item recall

1. Ask the patient if you may test his or her memory.
2. Give the patient 3 words (e.g., apple, table, penny) to repeat and remember.
3. Have the patient repeat the 3 words from memory later (e.g., after the clock drawing test).

Clock drawing test

1. Have the patient draw the face of a clock, including numbers.
2. Instruct the patient to place the hands at a specific time, such as 11:10.

Correct

Incorrect hands and inserted number

A positive dementia screen

1. Failure to remember all 3 words.
2. Failure to remember 1-2 words plus an abnormal clock drawing.

FIGURE 2-2. The mini-cog mental status examination. (Adapted from Borson S, Scanlan J, Brush M, Vitaliano P, Dokmak A. The mini-cog: A cognitive “vital signs” measure for dementia screening in multi-lingual elderly. *Int J Geriatr Psychiatry* 2000;15(11):1021–1027.)

caregiver stress and be aware of older patients’ support systems. These may include family, friends, religious and social networks, as well as home health aides, homemakers, or sitters. Without such networks, the older adult may not be able to continue to live independently. Assessment of home safety

Table 2-5**The Is of Geriatrics: Common Problems in Older Adults**

Immobility	Instability
Isolation	Intellectual impairment
Incontinence	Impotence
Infection	Immunodeficiency
Inanition (malnutrition)	Insomnia
Impaction	Iatrogenesis
Impaired senses

is often necessary for the frail elderly. In addition, look for signs and symptoms of elder abuse, neglect, or exploitation. Health professionals are required to report suspicion of elder mistreatment to Adult Protective Services.⁴⁰

Drug Therapy Monitoring

Geriatric patients often are frail, and they have multiple drugs, medical comorbidities, and prescribers. It is essential that there be a single individual, a pharmacist, nurse, or primary care physician, who oversees the patient’s drug therapy. The providers need to be aware of the patient’s Medicare Part C or D plan, and what type of coverage these plans afford. What is the copayment for generic, preferred, and nonpreferred drugs? Is the patient responsible for all drug costs during the Medicare “donut hole” period? (The first \$2,250 of medication is partially subsidized, but the patient pays 100% of the next \$2,850.⁴¹) Many Medicare patients, especially the socioeconomically challenged, have limited understanding of the complex Medicare drug benefit. This problem is compounded when the prescriber also does not understand the patient’s insurance program.⁴² Providers can assist patients by prescribing generic medication that are offered through retail pharmacy discount plans (\$4 retail pharmacy programs do not bill insurance, so the cost of those medications are not counted toward the \$2,250 benefit) and help patients apply for the medication assistance programs offered by drug manufacturers. Particularly challenging in the geriatric population is identifying the cause(s) of nonadherence to medical regimens. Providers assessing elderly patients’ medication regimens should keep the following questions in mind:

- Are medications skipped or reduced due to cost?
- Can the patient benefit from sample drugs? Starting a patient on a free drug sample may increase patient costs in the long term because samples typically are newer, expensive drugs.⁴²
- Is there an educational barrier such as low health literacy?
- Does the patient speak English but only read in another language?
- Can the patient see labels and written instructions?
- Does the patient have hearing problems? Patients might not admit they cannot hear instructions. Understanding instructions seems to be more about health literacy rather than a sensory problem.
- Can the patient manipulate pill bottles, syringes, inhalers, eye/ear drops?
- Has the patient’s cognitive functioning worsened over time such that they can no longer follow the medication regimen?

Homeostenosis and comorbidities require more frequent monitoring for adverse effects: symptoms, abnormal laboratory results, drug interactions, and drug levels (see [Table 2-6](#)).

Table 2-6

Centers for Medicare and Medicaid Services Guidelines for Monitoring Medication Use

Drug	Monitoring
Acetaminophen (more than 3 g/day)	Hepatic function tests
Aminoglycosides	Serum creatinine, drug levels
Hypoglycemic agents	Blood glucose levels
Antiepileptic agents (older)	Drug levels
Angiotensin-converting enzyme inhibitors	Potassium level, serum creatinine
Antipsychotic agents	Extrapyramidal adverse effects
Appetite stimulants	Weight, appetite, blood clots
Digoxin	Serum creatinine, drug levels
Diuretic	Electrolyte levels, renal function
Erythropoiesis stimulants	Blood pressure, iron and ferritin levels, complete blood count
Fibrates	Hepatic function test, complete blood count
Iron	Iron and ferritin levels, complete blood count
Lithium	Drug levels
Niacin	Blood sugar levels, hepatic function tests
Statins	Hepatic function tests
Theophylline	Drug levels
Thyroid replacement	Thyroid function tests
Warfarin	Prothrombin time/international normalized ratio

Adapted from DiPiro JT, Talbert RL, Yee GC, et al. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011.

Documentation

Clear, current, and correct medication lists must be available to patients and all individuals involved with their care. It is especially important for geriatric patients to bring their list, or preferably their medication containers, to each visit with medical providers. Medications taken may require verification with the pharmacist, caregivers, or family. Transitions in patient care, such as hospital to subacute nursing facility or home, are points of vulnerability for medication errors because medications may have been deleted or added.⁴³ It is now standard of care to conduct medication reconciliation upon hospital admission and discharge to ensure that the medication list is up to date.

Patient Education

Poor adherence in the geriatric age group could be related to inadequate patient education. “Ask me 3” cues the patient to ask three important questions of their providers to improve health literacy⁴⁴:

1. What is my main problem?
2. What do I need to do?
3. Why is it important for me to do this?

The provider can assess patient grasp of medication instructions by asking the patient to repeat instructions initially and again in 3 minutes (teach-back method).

8 Consideration of geriatric patients' vision, hearing, swallowing, cognition, motor impairment, and education and literacy levels during counseling and education can lead to enhanced medication adherence. Specific routes of drug administration, such as metered-dose inhalers, ophthalmic/otic drops, and subcutaneous injections, may be difficult for older patients. More time needs to be spent in advising the patient and/or caregivers of potential ADRs and when to notify the provider about ADRs. (See Patient Care and Monitoring box for detailed information regarding patient education.)

GERIATRIC PRACTICE SITES

Ambulatory Geriatric Clinic

Ambulatory geriatric clinics are established to provide a multitude of primary care needs specifically tailored to the elderly population. Patients are usually referred by their primary care physicians due to the desire for increased access to services (patients-to-physician ratio), the complexity of the patient's chronic conditions and medications, and the need for specialized knowledge in geriatric treatment. It is common for the appearance of cognitive impairment to be the catalyst for a referral to such clinic. These clinics take advantage of the enhanced knowledge base gained from using multiple members of the healthcare team. Interprofessional geriatrics primary care teams can consist of one or more of the following: geriatrician, clinical pharmacist, nurses (registered nurse [RN], licensed practical nurse [LPN]), social worker, physical/occupational therapist, and dietician. The interprofessional team holds regular meetings to discuss patients and combine input on their care plans from each specialty area. The geriatrician assumes the overall care of the patient. This person has specialized training in treating the older population encompassing patient's physical, medical, emotional, and social needs. The clinical pharmacist assists in optimizing medication regimen by conducting comprehensive medication review, screening and resolving potential drug-related problems, and educating patients and caregivers about medications and monitoring parameters. Clinical pharmacists' effectiveness can be enhanced with the specialty certification in geriatrics. Nurses provide medical triage and day-to-day patient care activities such as obtaining vitals and providing wound care. Social workers are involved in various aspects from assessing mood and cognitive status of patients to obtaining placement in higher levels of care. Physical/occupational therapists are often involved in assessing the patient's functional status and the need for further therapy, and they help maintain a safe home environment. They provide adaptive equipments such as grab bars, raised toilet seat and shower bench for the bathroom, and cane or walker for ambulation. Nutritionists evaluate the patient's nutritional status and educate on proper diet and weight management. From these successful clinical strategies, specialty geriatric clinics have developed including a multidisciplinary geriatric oncology clinic⁴⁵ and a community-based memory clinic.⁴⁶

Long-Term Care

Long-term care provides support for people who are dependent to varying degrees in ADLs and IADLs, numbering about 9 million people older than 65 years as of 2008.⁴⁷ Care is provided in the patient's home, in community settings such as adult care homes or assisted living facilities, as well as in nursing homes. Long-term care is expensive, typically several thousand dollars per month. Most care is provided at home by unpaid family members or friends. Medicare covers all or part of the cost of skilled nursing care for a limited period posthospitalization.^{47,48} Medicare does not cover long-term care. Financing of long-term care comes from patients' and family savings and/or private long-term care insurance. When a patient's assets have been depleted, Medicaid provides

basic nursing home care.⁴⁸ However, this care is heavily discounted, often resulting in economizing such as lower caregiver-to-patient ratios and higher number of patients per room. Nursing homes are highly regulated by state and federal government through the Center for Medicare and Medicaid Services.⁴⁷ Initial and continuing certification of the facility depends on periodic state and federal review of the facility. Auditors' ratings are available to consumers in an online Nursing Home Report Card.⁴⁹ **Quality indicators** are used by facility administrators and government overseers to identify problem areas, including the following⁵⁰:

- Use of nine or more medications in single patient
- Prevalence of indwelling catheters
- Prevalence of antipsychotic, anxiolytic, and hypnotic use

Patient Care and Monitoring

1. Drug-related problems in the elderly patient can be identified by performing a comprehensive medication review.
2. Have the patient bring all of their medication bottles to the visit including:
 - Prescription medications
 - OTC drugs
 - Vitamin supplements
 - Herbal products
3. Identify the indication for all medications used by the patient.
4. Review medication doses to determine any underdose and/or overdose.
5. Screen for drug–drug, drug–disease, drug–vitamin/herbal, drug–food interactions.
6. Ensure that patient is not using any agents to which he or she has allergies or intolerances.
7. Assess medication adherence by single or combination methods (use combination methods whenever possible):
 - Self-report
 - Refill history
 - Tablet/capsule count
 - Demonstration of use for nonoral agents
8. Inquire about any adverse drug reactions experienced by the patient.
9. Identify untreated indication or undertreatment, including preventative therapy such as aspirin, calcium plus vitamin D, etc.
10. Assess vital signs including pain.
11. Evaluate laboratory findings to assess the following:
 - Renal function
 - Hepatic function
 - Therapeutic drug monitoring (e.g., digoxin, warfarin, phenytoin)
 - Therapeutic goals for chronic disease (e.g., HgbA1c, LDL-C)
12. Perform medication regimen tailoring when indicated:
 - Discontinue unnecessary medications/supplements/herbals
 - Simplify dosing times to minimize complex regimen
 - Tailor regimen to individual's daily routine to improve adherence
13. Recognize any physical or functional barriers that can be overcome, such as providing nonchild-resistant caps and tablet cutters.
14. Provide medication education and adherence aid:
 - Verbal and written information about medications and/or disease states in health literacy-sensitive manner
 - Specific product education for nonoral agents (e.g., inhalers, insulins, ophthalmic/otic drops, etc.)
 - Medication chart/list to include generic and brand names, indications, doses, directions for use, timing of doses, etc.
 - Information on medication storage, expiration date, and refill status
 - Medication organizer (e.g., pill box, blister packs) when indicated
 - List of future appointments
15. Promote self-monitoring and lifestyle modification:
 - Use of blood pressure monitoring device and glucose meter
 - Diet and exercise
 - Smoking cessation
 - Immunizations

- Use of physical restraints
- Prevalence of depression in patients without antidepressant therapy
- Clinical quality measures such as pressure ulcers
- Moderate daily pain or excruciating pain in residents

9 *Long-term care geriatric practices emphasize the inter-professional team approach.* The medical director leads regular meetings with all disciplines delivering care. These may include director of nursing, rehabilitation services (physical, occupation, and speech therapy), pharmacist, social worker, nutritionist, case manager, and psychologist. The pharmacist conducts a monthly drug review of each patient's medication list.⁴³ The physician is alerted to medication concerns and approves the patient's orders every 60 days. Such a team approach is vital to coordinate care for the typical frail, complex long-term care patient.

Abbreviations Introduced in This Chapter

ADL	Activities of daily living
ADR	Adverse drug reaction
GABA	Gamma aminobutyric acid
HgbA1c	HemoglobinA1c
IADL	Instrumental activities of daily living
INR	International normalized ratio
LDL-C	Low-density lipoprotein-cholesterol
MDRD	Modification of diet in renal disease
NSAID	Nonsteroidal anti-inflammatory drug
OTC	Over the counter
SSRI	Selective serotonin reuptake inhibitor
V_d	Volume of distribution

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Define different age groups within the pediatric population.
2. Explain general pharmacokinetic and pharmacodynamic differences in pediatric versus adult patients.
3. Identify factors that affect selection of safe and effective drug therapy in pediatric patients.
4. Identify strategies for appropriate medication administration to infants and young children.
5. Apply pediatric pharmacotherapy concepts to make drug therapy recommendations, assess outcomes, and effectively communicate with patients and caregivers.

KEY CONCEPTS

- 1 Despite the common misconception of pediatric patients as “smaller adults” where doses are scaled only for their smaller size, there are multiple factors to consider when selecting and providing drug therapy for patients in this specific population.
- 2 Due to multiple differences including age-dependent development of organ function in pediatric patients, pharmacokinetics, efficacy, and safety of drugs within the pediatric population often differs from adults; thus pediatric dosing should not be calculated based on a single factor of difference.
- 3 It is appropriate to use a drug off-label when no alternatives are available; however, clinicians should refer to published studies and case reports for available safety, efficacy, and dosing information.
- 4 Medication errors among pediatric patients are possible due to differences in dose calculation and preparation; it is important to identify potential errors through careful review of orders, calculations, dispensing, and administration of drug therapy to infants and children.
- 5 Comprehensive and clear parent/caregiver education improves medication adherence, safety, and therapeutic outcomes; thus caregiver education is essential because they are often responsible for the administration and monitoring of drug therapy in infants and young children.

INTRODUCTION

Pediatric clinical practice involves the care of infants, children, and adolescents with the goal of optimizing their health,

growth, and development toward adulthood. Clinicians serve as advocates for this unique and vulnerable patient population to optimize their well-being.

There is a continued need for pediatric healthcare resources, evidenced by the annual increase in the number of infants born in the United States.¹ Ambulatory care settings, such as the pediatrician office and emergency department, as well as hospitals, require the expertise of knowledgeable clinicians with pediatric experience. In fact, national data have noted the lack of appropriate services and supplies for pediatric patients at many institutions.² Pediatric care accounts for a considerable amount of total patient care annually. For example, patients younger than 15 years accounted for more than 20% of outpatient visits in the United States in 2008.³ Among pediatric visits, more than half of the medications documented were new drug therapies with the majority being antibiotics.^{4,5} 1 *Despite the common misconception of pediatric patients as “smaller adults” where doses are scaled only for their smaller size, there are multiple factors to consider when selecting and providing drug therapy for patients in this specific population.* Pediatric patients significantly differ within their age groups and from adults regarding drug administration, psychosocial development, and organ function development, which affect the efficacy and safety of pharmacotherapy.

FUNDAMENTALS OF PEDIATRIC PATIENTS

Classification of Pediatric Patients

- Pediatric patients are those younger than 18 years, although some pediatric clinicians may care for patients up to age 21. Unlike an adult patient, whose age is commonly measured

Table 3-1

Pediatric Age Groups, Age Terminology, and Weight Classification

Age Group	Age
Neonate	Less than or equal to 28 days (4 weeks) of life
Infant	29 days to less than 12 months
Child	1–12 years
Adolescent	13–17 years (most common definition)
Age Terminology	Definition
Gestational age (GA)	Age from date of mother's first day of last menstrual period to date of birth
Full term	Describes infants born at 37-weeks gestation or greater
Premature	Describes infants born before 37-week gestation
Small for GA	Neonates with birth weight below the 10th percentile among neonates of the same GA
Large for GA	Neonates with birth weight above the 90th percentile among neonates of the same GA
Chronological or postnatal age	Age from birth to present, measured in days, weeks, months, or years
Corrected or adjusted age	May be used to describe the age of a premature child up to 3 years of age: Corrected age = Chronological age in months – [(40 – GA at birth in weeks) ÷ 4 weeks]. For example, if a former 29-week GA child is now 10 months old chronologically, his corrected age is approximately 7 months: 10 months – [(40–29 weeks) ÷ 4 weeks] = 7.25 months
Weight Classification	Definition
LBW infant	Premature infant with birth weight between 1,500 and 2,500 g
VLBW infant	Premature infant with birth weight 1,000 g to less than 1,500 g
ELBW infant	Premature infant with birth weight less than 1,000 g

GA, gestational age; LBW, low birth weight; VLBW, very low birth weight. ELBW, extremely low birth weight.

Based on defined terms in American Academy of Pediatrics, Committee on Fetus and Newborn. Age terminology during the perinatal period. Pediatrics 2004;114:1362–1364.

in years, a pediatric patient's age can be expressed in days, weeks, months, and years. Patients are classified based on age and may be further described based on other factors, including birth weight and prematurity status (Table 3-1).⁶

Growth and Development

Children are monitored for physical, motor, cognitive, and psychosocial development through clinical recognition of timely milestones during routine well-child visits. As a newborn continues to progress to infant, child, and adolescent stages, different variables are monitored to assess growth compared with the general population of similar age and size. Growth charts are used to plot head circumference, weight, length or stature, weight-for-length, and body mass index for a graphical representation of a child's growth compared with the general pediatric population. These markers of growth and development are both age- and gender-dependent; thus the use of the correct tool for measurement is important. For children younger than 2 years, one should use the World Health Organization growth standards (Fig. 3-1).⁷ For children 2 years and older, the Centers for Disease Control and Prevention (CDC) Growth Charts (Fig. 3-2) are used.⁸ These tools assess whether a child is meeting the appropriate physical growth milestones, thereby allowing identification of nutritional issues such as poor weight and height gain (e.g., failure to thrive).

Differences in Vital Signs

Normal values for heart rate and respiratory rate vary based on their age. Normal values for blood pressure vary based

on gender and age for all pediatric patients, and also height percentile for patients older than 1 year. Normal values for blood pressure in pediatric patients can be found in various national guidelines and other pediatric diagnostic references.^{9,10} In general, blood pressure increases with age, with average blood pressures of 70/50 in neonates, increasing throughout childhood to 110/65 in adolescents.^{9,11} Heart rates are highest in neonates and infants, ranging from 85 to 205 beats per minute (bpm) and decrease with age, reaching adult rates (60 to 100 bpm) around 10 years of age. Respiratory rates are also higher in neonates and infants (30 to 60 breaths/minute), decreasing with age to adult rates around 15 years of age (12 to 16 breaths/minute).

Another vital sign commonly monitored in children by their caregivers is body temperature, especially when they seem "warm to the touch." The American Academy of Pediatrics (AAP) recommends rectal temperature measurement in children less than 4 years of age, using a digital thermometer. For children 4 years or older, axillary or oral temperature measurement is appropriate because the child is more able to cooperate when asked. Axillary thermometers can be used in children as young as 3 months but may be less accurate. Tympanic (otic) temperature readings are also used for all ages; however, these temperatures may be less accurate and can be affected by cerumen accumulation. Generally, rectal temperature is greater than oral temperature by 0.6°C (1°F), and oral temperature is 0.6°C (1°F) higher than axillary temperatures.¹² Low-grade fevers are considered those ranging from 37.8° to 39°C (100° to 102°F), with antipyretic treatment (e.g., acetaminophen)

FIGURE 3-1. Example of WHO growth chart of girls, birth to 24 months: Head circumference-for-age and weight-for-length percentile, 2000. (From Centers for Disease Control and Prevention from the WHO Growth Standards. World Health Organization (WHO) Growth Standards, 2009 [updated September 9, 2010], http://www.cdc.gov/growthcharts/who_charts.htm.)

considered in cases of temperature greater than 38.3°C (101°F, any measurement route) accompanied by patient discomfort. Formal definition of fever, like other vital signs, is also age dependent, with a lower temperature threshold for neonates (38°C or 100.4°F) and infants (38.2°C or 100.7°F).^{13,14}

Also sometimes considered as the fifth vital sign, pain assessment is more challenging to assess in neonate, infants,

and young children due to their inability to communicate symptoms. Indicators of possible pain include physiological changes such as increased heart rate, respiratory rate, and blood pressure, decreased oxygen saturation, as well as behavior changes such as prolonged, higher pitch crying and facial expressions.¹⁵ Laboratory values also vary depending on age. Normal ranges are often noted by the laboratory facility on reported results.

FIGURE 3–2. Example of CDC growth chart of boys, 2 to 20 years: Body mass index for age percentile, 2000. (From National Center for Health Statistics and National Center for Chronic Disease Prevention and Health Promotion. Center for Disease Control Growth Charts, 2000 [updated September 9, 2010], <http://www.cdc.gov/growthcharts>.)

Fluid Requirements

Fluid requirement and balance are important to monitor in pediatric patients, especially in premature neonates and infants. Maintenance fluid requirement can be calculated based on body surface area for patients greater than 10 kg with a range of 1,500 to 2,000 mL/m² per day. However, a weight-based method of determining normal maintenance fluid requirement for children is often used (Table 3–2).

Table 3–2 Maintenance Fluid Calculations by Body Weight	
Patient Body Weight	Maintenance Fluid Requirement
Less than 10 kg	100 mL/kg/day
11–20 kg	1,000 mL + 50 mL/kg over 10 kg
More than 20 kg	1,500 mL + 20 mL/kg over 20 kg

Patient Encounter, Part 1

MM is a 36-week GA premature baby boy weighing 2,650 g, length 47 cm, born to a 21-year-old woman this morning. He requires maintenance IV fluids until his further assessment for total parenteral nutrition is complete.

What is MM's weight classification as a neonate?

Calculate MM's corrected age for MM 6 months from today.

How much maintenance fluid would you recommend for MM at birth?

EFFECTS OF PHARMACOKINETIC AND PHARMACODYNAMIC DIFFERENCES ON DRUG THERAPY

Drug selection strategy may be similar or different depending on age and disease state, as a result of differences in pathophysiology of certain diseases and pharmacokinetic and pharmacodynamic parameters among pediatric and adult patients. It is noteworthy that pediatric patients may require the use of different medications from those used in adults affected by certain diseases. For example, phenobarbital is commonly used for treatment of neonatal seizures but not often used for treatment of seizures in adults, due to differences in seizure etiology and availability of extensive data regarding its use in neonates compared with newer antiepileptic medications. There also exist commonalities between pediatric and adult patients, such as therapeutic serum drug concentrations required to treat certain diseases. For example, gentamicin peak and trough serum concentrations needed to treat gram-negative pneumonia are the same in children as in adults. The appropriate selection and dosing of drug therapy for a pediatric patient depends on a number of specific factors such as age, weight, height, disease being treated, comorbidities, developmental pharmacokinetics, and available drug dosage forms. Pediatric drug doses are often calculated based on body weight (e.g., mg/kg/dose) compared with uniform dosing for adult patients (e.g., mg/day or mg/dose) for adult patients. Thus, accurate weight should be available while prescribing or dispensing medications for this patient population. Pediatric doses may exceed adult doses by body weight for certain medications due to differences in pharmacokinetics and pharmacodynamics; hence, the use of pediatric drug dosing guides is recommended.

2 Due to multiple differences including age-dependent development of organ function in pediatric patients, pharmacokinetics, efficacy, and safety of drugs within the pediatric population often differs from adults; thus pediatric dosing should not be calculated based on a single factor of difference. Equations proposed to calculate pediatric doses based on adjusted age or weight such as the Clark's, Fried's, or Young's rule should

not be routinely used to calculate pediatric doses because they account for only one factor of difference, age or weight, and lack integration of the effect of growth and development on drug pharmacokinetics and pharmacodynamics in this population. For **off-label** medication dosing when no alternative treatment is available and limited dosage guidelines have been published, clinicians may choose to estimate a pediatric dose based on body surface area ratio.

$$\text{Approximate pediatric dose} = \text{Adult dose} \times [\text{BSA (in m}^2\text{)} \div 1.73 \text{ m}^2]$$

Limitations for this dose-estimating approach include the need for the patient to be of normal height and weight for age, and lack of incorporation of exact pharmacokinetic differences regarding each medication.¹⁶

Absorption

- Oral absorption may be different in premature infants and neonates due to differences in gastric acid secretion and pancreatic and biliary function. Full-term neonates have a gastric pH of 6 to 8 at birth and pH 1 to 3 by 48 hours of age. Gastric acid output per kilogram is lower in premature infants and increases with age to adult levels by 6 months of age.^{17,18} Low gastric acid secretion can result in increased serum concentrations of weak bases and acid-labile medications, such as penicillin, and decreased serum concentrations of weak acid medications, such as phenobarbital, due to increased ionization. Additionally, gastric emptying time and intestinal transit time are delayed in premature infants, increasing drug contact time with the GI mucosa and drug absorption.¹⁹ Diseases such as gastroesophageal reflux, respiratory distress syndrome, and congenital heart disease may further delay gastric emptying time. Pancreatic exocrine and biliary function are also reduced in newborns, with about 50% less secretion of amylase and lipase than adults, reaching adult values as early as the end of the first year and as late as 5 years of age. Deficiency in pancreatic secretions and bile salts in newborns can result in decreased bioavailability of prodrug esters, such as erythromycin, which requires solubilization or intraluminal hydrolysis.¹⁸ Due to limited data on oral bioavailability of medications in infants and children for newer agents, some drug dosing recommendations may be extrapolated from adult safety and efficacy studies and case reports.
- Topical or percutaneous absorption in neonates and infants is increased due to a thinner stratum corneum, increased cutaneous perfusion, and greater body surface-to-weight ratio. Hence, application of topical medications should be limited to the smallest amount possible. Increased percutaneous absorption can lead to high serum concentrations of topically applied drugs such as corticosteroids, lidocaine, or chlorhexidine, as well as inactive additives such as propylene glycol, potentially causing adverse effects.
- Intramuscular absorption in premature and full-term infants can be erratic due to variable perfusion, poor muscle contraction, and decreased muscle mass compared with older patients.²⁰ Intramuscular administration may be appropriate

for some medications; however, use of this route of administration can be painful and is usually reserved when other routes are not accessible, e.g., for initial IV doses of ampicillin and gentamicin for neonatal sepsis.

Rectal absorption can also be erratic and is not a commonly recommended route of administration if there are other routes available (e.g., oral). This route is useful in cases of severe nausea and vomiting or status epilepticus. For medications that undergo extensive first-pass metabolism, bioavailability increases as the blood supply bypasses the liver from the lower rectum directly to the inferior vena cava.²⁰ Availability of rectal dosage forms varies, with acetaminophen suppositories and diazepam gel as examples of medications used by the rectal route in pediatric patients. Rectal use of oral medications or other dosage forms is based on limited studies and case reports.

Volume of Distribution

In pediatric patients, apparent volume of distribution (V_d) is normalized based on body weight and expressed as L/kg.

Extracellular fluid and total body water per kilogram of body weight are increased in neonates and infants, resulting in higher V_d for water-soluble drugs such as aminoglycosides and decreases with age. Therefore, neonates and infants often require higher individualized doses by weight (mg/kg) than older children and adolescents to achieve the same therapeutic serum concentrations.^{20–23} Neonates and infants have a lower normal range for serum albumin (2 to 4 g/dL, 20 to 40 g/L), reaching adult levels after 1 year of age. This affects highly protein-bound drugs such as phenytoin, resulting in lower total serum concentrations needed to achieve therapeutic unbound serum concentrations.²⁰

Because premature neonates have lower body adipose composition compared with older children and adults, they have a decreased V_d for lipid-soluble drugs such as midazolam and require lower doses by body weight. Lipid-soluble drugs may also reach higher concentrations in the CNS due to an immature blood–brain barrier.²⁴

Metabolism

Drug metabolism is slower at birth in full-term infants compared with adolescents and adults, with further delay in premature neonates. Phase 1 reactions and enzymes, such as oxidation and alcohol dehydrogenase, are impaired in premature neonates and infants and do not fully develop until later childhood or adolescence. Accordingly, the use of products containing ethanol or propylene glycol can result in increased toxicities, including respiratory depression, hyperosmolarity, metabolic acidosis, and seizures, and they should be avoided in neonates and infants. Cytochrome P450 isoenzymes (e.g., CYP2C9, CYP1A2) develop at various ages, ranging from a few months to 3 years of age, with delayed development in premature infants.²¹

Among phase 2 reactions, sulfate conjugation by sulfotransferases is well developed at birth in term infants.

Glucuronidation by the uridine diphosphate glucuronosyltransferases, in contrast, is immature in neonates and infants, requiring at least several months to develop to adult values at approximately 4 years of age. In neonates, this deficiency results in adverse effects including cyanosis, ash gray color of the skin, limp body tone, and hypotension, also known as “gray baby syndrome” with use of chloramphenicol.²⁵ Products containing benzyl alcohol or benzoic acid should be avoided in neonates due to immature glycine conjugation, resulting in accumulation of benzoic acid. This accumulation can lead to “gasping syndrome,” which includes respiratory depression, metabolic acidosis, hypotension, seizures or convulsions, and gasping respirations.²⁶ Acetylation via *N*-acetyltransferase reaches adult maturation at around 1 year of life, but its impact is not well understood regarding neonatal drug therapy.¹⁸ Thus, reduced dosing of medications undergoing hepatic metabolism may be required for full-term and premature neonates. Conversely, hepatic enzyme activity increases to nearly twice as much as adults at 6 months of age and may continue to be high through puberty, around 9 to 12 years of age.²⁰ These children may require higher doses per kilogram of body weight for hepatically metabolized medications. Common examples include antiepileptic medications such as phenytoin, carbamazepine, and valproic acid. This increase in metabolism slows to adult levels as the child goes through puberty into adulthood.²⁰

Elimination

Renal drug clearance is reduced in infants and slowest in premature neonates, due to immature renal function, resulting in the need for longer dosing intervals for renally cleared medications, such as vancomycin, to prevent accumulation. Glomerular filtration rate (GFR) is lowest in premature neonates, increasing with age and peaking at 3 to 12 years of age, after which there is a gradual decline to approximate adult value. For example, vancomycin is often given every 18 to 24 hours in a low birth weight (LBW) premature neonate, every 6 hours in children with normal renal function, and every 8 to 12 hours in adult patients with normal renal function. Children with cystic fibrosis also present with greater renal clearance of drugs such as aminoglycosides, compared with children without the disease, requiring higher doses by weight and more frequent dosing intervals.²⁷

Pediatric creatinine clearance (CrCl), an indicator of GFR, is normalized due to variable body size (mL/min/1.73 m²). The use of the Cockcroft-Gault or Jelliffe equations for estimating CrCl in adults should not be used for evaluating patients younger than 18 years.^{28,29} The Schwartz’s equation is a common method of estimating pediatric CrCl for LBW infants up to 21 years of age (Fig. 3–3). This equation uses patient length (cm), serum creatinine (mg/dL), and a constant, *k*, which depends on age for all patients and also gender for those older than 2 years.³⁰ Because serum creatinine is a crude marker of GFR, the Schwartz equation, as with other estimation calculations, carries limitations including the potential for overestimating GFR in patients with moderate to severe

$$\text{CrCl} = \frac{kL}{\text{SCr}}$$

Age	k
Low birth weight less than 1 yr	0.33
Full term less than 1 yr	0.45
1–12 yr	0.55
13–21 yr (female)	0.55
13–21 yr (male)	0.70

k = Proportionality constant

L = Length in cm

SCr = Serum creatinine in mg/dL

CrCl = Creatinine clearance (or estimated glomerular filtrate rate) in mL/min/1.73 m²

FIGURE 3-3. Schwartz equation for estimation of creatinine clearance (CrCl) in pediatric patients 6 months to 21 years of age. (Schwartz GJ, Brion LP, Spitzer A. The use of plasma creatinine concentration for estimating glomerular filtration rate in infants, children, and adolescents. *Pediatr Clin North Am* 1987;34(3):571–590.)

renal insufficiency.^{31,32} Urine output is also a parameter used to assess renal function in pediatric patients, with a urine output more than 1 to 2 mL/kg/h considered normal.

COMMON PEDIATRIC ILLNESSES

There may be similarities and differences in illnesses such as infections, asthma, allergic rhinitis, attention deficit hyperactivity disorder, diabetes, and seizure disorders between children and adults. These have been discussed throughout this textbook. The incidence of previously common childhood illness such as measles, mumps, and rubella has significantly decreased as a result of en masse vaccination of infants and children. The Advisory Committee on Immunization Practices (ACIP) within the CDC releases and updates child and adolescent immunization schedules every year. Patients' immunization records should be reviewed routinely for needed immunizations based on these schedules.³³ Most of the common illnesses in children leading to missed school and/or need for clinician consultation are ambulatory in nature; however, some complications may require hospitalization.

Presentation of common childhood illnesses may vary depending on age and development. Older children and adolescents are able to communicate symptoms verbally, making assessment and treatment easier, unlike infants and younger children who are less able to do so. In such cases, changes in vital signs, such as respiratory rate, heart rate, body temperature, and changes in oral intake, feeding pattern, and urine output, are used as indicators of potential illness. Parents may also note subjective items such as changes in mood (e.g., increased irritability or "fussiness").

Patient Encounter, Part 2

MM is now 7 weeks old (weight: 4.5 kg) and presents to the community pharmacy with a 2-day history of lethargy, poor oral intake, and fever. The pharmacist refers the child to seek medical attention at the emergency department. MM is admitted to the general pediatric ward for further assessment including a neonatal sepsis and meningitis rule-out. Blood samples, cerebral spinal fluid, and urine were collected for Gram stain and culture, still pending results. History of present illness reveals that his aunt who had a considerable flare-up of cold sores was babysitting him for the past week. He was empirically started on ampicillin 225 mg (50 mg/kg/dose) IV q 6 h, cefuroxime 225 mg IV q 6 h (50 mg/kg/dose), and acyclovir 90 mg IV q 8 h (20 mg/kg/dose). Given his poor oral intake on admission, the team requests addition of maintenance IV fluids and a nutrition consultation.

How much maintenance fluid would you recommend for MM now?

Because acyclovir can affect renal function, MM's creatinine clearance should be assessed. Using the most appropriate method, calculate a creatinine clearance for MM.

SPECIFIC CONSIDERATIONS IN DRUG THERAPY

In addition to differences in pharmacokinetics and pharmacodynamic parameters, other factors including dosage formulations, medication administration techniques, and parent/caregiver education should be considered when selecting drug therapy.

Off-Label Medication Use

Currently, there is a lack of pediatric dosing, safety, and efficacy information for more than 75% of drugs approved in adults.³⁴ Off-label use of medication is the use of a drug outside of its approved labeled indication. Such use is not considered improper or illegal; however, decision for use should be based on clinical judgment and in the best interest of the patient.³⁵ Off-label use occurs in both outpatient and inpatient settings. About 80% of hospitalized pediatric patients receive

at least one off-label medication.³⁴ This includes the use of a medication in the treatment of illnesses not listed on the manufacturer's package insert, use outside the licensed age range, dosing outside those recommended, or use of a different route of administration.³⁶ Such off-label use in infants and children is frequently based on limited data. **3** *It is appropriate to use a drug off-label when no alternatives are available; however, clinicians should refer to published studies and case reports for available safety, efficacy, and dosing information.* FDA regulatory changes, such as extended patent exclusivity, provide incentives for a pharmaceutical manufacturer to market new drugs for pediatric patients. However, such incentives are not available for generic drugs.

Routes of Administration and Drug Formulations

Depending on age, disease, and disease severity, different routes of administration may be considered. Use of rectal route of administration is reserved in cases where oral administration is not possible and IV route is not necessary. Topical administration is often used for treatment of dermatologic ailments. Transdermal routes are often not recommended, unless it is an approved indication such as the methylphenidate transdermal patch for treatment of attention deficit hyperactivity disorder. The injectable route of administration is used in patients with severe illnesses or when other routes of administration are not possible. As done with adult patients, IV compatibility and access should be evaluated when giving parenteral medications. Dilution of parenteral medications may be necessary to measure smaller doses for neonates. However, a higher concentration of parenteral medications may be necessary for patients with fluid restrictions such as premature infants and patients with cardiac anomalies and/or renal disease. Appropriate stability and diluent selection data should be obtained from the literature.

When oral drug therapy is needed, one must also consider the type of dosage form available. Children younger than 6 years are often not able to swallow oral tablets or capsules and may require oral liquid formulations. The child's ability to swallow a solid dosage form should be determined before selecting a drug product. Not all oral medications, especially those unapproved for use in infants and children, have a commercially available liquid dosage form. Use of a liquid formulation compounded from a solid oral dosage form is an option when data are available. Factors such as drug stability, suspendability, dose uniformity, and palatability should be considered when compounding a liquid formulation.³⁷ Commonly used **suspending agents** include methylcellulose and carboxymethylcellulose (e.g., Ora-Plus). Palatability of a liquid formulation can be enhanced by using simple syrup or OraSweet. If no dietary contraindications or interactions exist, doses can be mixed with food items such as pudding, fruit-flavored gelatin, chocolate syrup, applesauce, or other fruit puree immediately before administration of individual doses. Honey, although capable of masking unpleasant taste of medication, may contain spores of *Clostridium botulinum* and should not be given to infants younger than 1 year due to

increased risk for developing botulism. Most hospitals caring for pediatric patients compound formulations in their inpatient pharmacy. Limited accessibility to compounded oral liquids in community pharmacies poses a greater challenge. A list of community pharmacies with compounding capabilities should be maintained and provided to the parents and caregivers before discharge from the hospital.

Common Errors in Pediatric Drug Therapy

Prevention of errors in pediatric drug therapy begins with identification of possible sources. The error rate for medications is as high as 1 in 6.4 orders among hospitalized pediatric patients. Off-label use of medications increases risk of medication error and has been attributed to difference in frequency of errors compared with adults. One of the most common reasons for medication errors in this specialized population is incorrect dosing such as calculation error.³⁸ **4** *Medication errors among pediatric patients are possible due to differences in dose calculation and preparation; it is important to identify potential errors through careful review of orders, calculations, dispensing, and administration of drug therapy to infants and children.* It is crucial to verify accurate weight, height, and age for dosing calculations and dispensing of prescriptions because pediatric patients are a vulnerable population for medication error. Consistent units of measurements in reporting patient weight (kg), height (cm), and age (weeks and years) should be used. Dosing units such as mg/kg, mcg/kg, mEq/kg, or units/kg should also be used accurately. Given the age-related differences in metabolism of additives such as propylene glycol and benzyl alcohol, careful consideration should be given to the active and inactive ingredients when selecting a formulation.

Decimal errors, including trailing zeroes (e.g., 1.0 mg misread as 10 mg) and missing leading zeroes (e.g., 0.5 mg misread as 5 mg) in drug dosing or body weight documentation are possible, resulting in several-fold overdosing. Strength or concentration of drug should also be clearly communicated by the clinician in prescription orders. Similarly, labels that look alike may lead to drug therapy errors (e.g., mistaking a vial of heparin for insulin when compounding parenteral solutions). Dosing errors of combination drug products can be prevented by using the right component for dose calculation (e.g., dose of sulfamethoxazole/trimethoprim is calculated based on the trimethoprim component).

Use of standardized concentrations and programmable infusion pumps, such as smart pumps with built-in libraries, is encouraged to minimize errors with parenteral medications, especially those for continuous infusions such as inotropes. Introduction of technological advances such as computer physician order entry (CPOE) systems with ability for dose range checks by weight for pediatric medication orders and the use of barcode technology for dispensing of medications have decreased medication errors.³⁹ Other technological advances for medication safety include the use of enhanced photoemission spectroscopy to scan small samples of compounded IV solutions of high-risk IV drugs for appropriate drug and concentration.⁴⁰

Prevention of medication errors is a joint effort between healthcare professionals, patients, and parents/caregivers. Obtaining a complete medication history including over-the-counter (OTC) and complementary and alternative medicines (CAMs), simplification of medication regimen, clinician awareness for potential errors, and appropriate patient/parent/caregiver education on measurement and administration of medications are essential in preventing medication errors.

Complementary and Over-the-Counter Medication Use

Between 30% and 70% of children with a chronic illness (e.g., asthma, attention deficit hyperactivity disorder, autism, cancer) or disability use CAMs.⁴¹ CAMs can include mind-body therapy (e.g., imagery, hypnosis), energy field therapies (e.g., acupuncture, acupressure), massage, antioxidants (e.g., vitamins C and E), herbs (e.g., St. John's wort, kava, ginger, valerian), prayer, immune modulators (e.g., echinacea), or other folk/home remedies. In a survey of pediatric medical staff, 65% of clinicians were aware of their patient's CAM use; however, communication between CAM providers and pediatric clinicians is rare (4%). Thus it is important to encourage communication about CAM use, including interdisciplinary discussion between CAM providers and pediatric healthcare providers.⁴² It is critical to realize that there are limited data establishing efficacy of various CAM therapies in children.⁴¹ For example, colic is a condition of unclear etiology in which an infant cries inconsolably for over a few hours in a 24-hour period, usually during the same time of day. Symptoms of excessive crying usually improve by the third month of life and often resolve by 9 months of age. No medication has been approved by the FDA for this condition. Some parents are advised by family and friends to use alternative treatments, such as gripe water, to treat colic. Gripe water is an oral solution containing a combination of ingredients such as chamomile and sodium bicarbonate, not regulated by the FDA. In addition, some gripe water products may contain alcohol, which is not recommended for infants due to their limited metabolism ability (i.e., alcohol dehydrogenase). Further, some CAM products (e.g., St. John's wort) can interact with prescription drugs and produce undesired outcomes. It is important to assess OTC product use in pediatric patients. For example, treatment of the common cold in children is similar to adults, including symptom control with adequate fluid intake, rest, use of saline nasal spray, and acetaminophen (10 to 15 mg/kg/dose every 6 to 8 hours) or ibuprofen (4 to 10 mg/kg/dose every 8 hours) for relief of discomfort and fever. Other products such as a topical vapor rub or oral honey have demonstrated some potential for alleviation of symptoms such as cough, based on survey studies of parents for children of 2 years and older.^{43,44} Unlike adults, symptomatic relief through the use of pharmacologic agents, such as OTC combination cold remedies, is not recommended for pediatric patients younger than 4 years. Currently, the FDA does not recommend the use of OTC cough and cold medications (e.g., diphenhydramine and dextromethorphan) in children younger than 2 years; however, the Consumer

Healthcare Products Association, with the support of the FDA, has voluntarily changed product labeling of OTC cough and cold medications to state "do not use in children under 4 years of age." This is due to increased risk for adverse effects (e.g., excessive sedation, respiratory depression) and no documented benefit in relieving symptoms. It has also been noted that these medications may be less effective in children younger than 6 years compared with older children and adults.^{45,46} Also noteworthy is the potential for medication error with use of OTC products in older children, such as cold medications containing diphenhydramine and acetaminophen. A parent/caregiver may inadvertently overdose a child on one active ingredient, such as acetaminophen, by administering acetaminophen suspension for fever and an acetaminophen-containing combination product for cold symptoms. The use of aspirin in patients younger than 18 years with viral infections is not recommended due to the risk of Reye's syndrome. While making an appropriate recommendation for an OTC product for a pediatric patient, the parent/caregiver should always be referred to their pediatrician for further advice and evaluation when severity of illness is a concern.

- Clinicians should respect parents'/caregivers' beliefs in the use of CAM and OTC products and encourage open discussion with the intention of providing information regarding their risks and benefits to achieve desired health outcomes as well as optimize medication safety.

Medication Administration to Pediatric Patients and Caregiver Education

- Considering the challenges in cooperation from infants and younger children, medication administration can become a difficult task for any parent or caregiver. One should also consider factors that may affect adherence to prescribed therapy including caregiver and/or patient's personal beliefs, socioeconomic limitation, and fear of adverse drug effects. One common factor to consider is ease of measurement and administration when selecting and dosing pediatric drug therapy. Clinicians should check concentrations of available products and round doses to a measurable amount. For example, if a patient were to receive an oral formulation, such as amoxicillin 400 mg/5 mL suspension, and the dose was calculated to be 4.9 mL, the dose should be rounded to 5 mL for ease of administration. Rounding the dose by 10% to the closest easily measurable amount is commonly practiced for most medications; however, drugs with narrow therapeutic indices are exceptions to this guideline.

The means or devices for measuring and administering medications by the caregivers should also be closely considered. Special measuring devices as well as clear and complete education about their use are essential. Oral syringes are accurate and offered at most community pharmacies for the measurement of oral liquid medications. Oral droppers that are included specifically with a medication may be appropriate for use in infants and young children. Medicine cups are not recommended for measuring doses for infants and young children due to the possible inaccuracy of measuring

Patient Encounter, Part 3

MM is now 36 months old, and his mother calls the clinic and tells you that her son is “just miserable” with a runny nose, cough, and a fever (axillary temperature) of 38.3°C (101°F). She wanted to know if she could use baby aspirin instead of the acetaminophen that does not seem to help. She also wanted to know which cough and cold preparation would be most appropriate for MM.

What additional information would you need to help MM and his mom?

What is your recommendation regarding use of aspirin for MM's fever?

What would you recommend for MM's cold symptoms?

smaller doses. Household dining or measuring spoons are not accurate or consistent and should not be used for the administration of oral liquids.

5 *Comprehensive and clear parent/caregiver education improves medication adherence, safety, and therapeutic*

outcomes; thus caregiver education is essential because they are often responsible for administration and monitoring of drug therapy in infants and young children. Information about the drug including appropriate and safe storage away from children, possible drug interactions, duration of therapy, importance of adherence, possible adverse effects, and expected therapeutic outcomes should be provided. Parent/caregiver education is important in both inpatient and outpatient care settings and should be reviewed at each point of care.

Because parents/caregivers are often sole providers of home care for ill children, it is important to demonstrate appropriate dose preparation and administration techniques to the caregivers before medication dispensing. First, a child should be calm for successful dose administration. Yet, calming a child is often a challenge during many methods of administration (e.g., otic, ophthalmic, rectal). Parents/caregivers should explain the process in a simple and understandable form to the child because this may decrease the child's potential anxiety. In addition, it is also recommended to distract younger children using a favorite item such as toy or to reward cooperative or “good” behavior during medication administration. Helpful tips regarding administration of selected dosage forms in pediatric patients are listed in [Table 3–3](#).⁴⁷

Table 3–3**Helpful Tips for Medication Administration for Selected Dosage Forms⁴⁷**

Dosage Form	Recommendations
Ophthalmic drops or ointment	<ul style="list-style-type: none"> • Wash hands thoroughly prior to administration • Position child laying down in supine position • Avoid contact of applicator tip to surfaces, including the eye • Drops should be placed in the pocket of the lower eyelid • Ointment strip should be placed along the pocket of the lower eyelid
Otic drops	<ul style="list-style-type: none"> • Wash hands thoroughly prior to administration • Position child laying down in prone position • Tilt head to expose treated ear, gently pull outer ear outward, then due to age-dependent change in angle of Eustachian tube: <ul style="list-style-type: none"> • If child less than 3 years of age, gently pull downward and back; apply drops • If child more than 3 years of age, gently pull upward and back; apply drops
Nasal drops	<ul style="list-style-type: none"> • Wash hands thoroughly prior to administration • Position child laying down in supine position • Slightly tilt head back; place drops in nostril(s) • Remain in position for appropriate distribution of medication
Rectal suppository	<ul style="list-style-type: none"> • Similar to adult administration; challenging route for administration • For younger patients (i.e., less than 3 years), a smaller finger (e.g., pinky finger) should be used to insert suppository
Metered-dose inhalers	<ul style="list-style-type: none"> • Use a spacer <ul style="list-style-type: none"> • For younger children, use one with a mask, be sure the mask is secured/placed closely up against the child's face, avoiding gaps between face and mask and creating a seal to ensure medication delivery • Child should take slow breaths in with each dose • Wait at least one minute between doses

Patient Encounter, Part 4

MM is now 4 years old, brought by his father to the pediatrician. He has a 4-day history of left ear pain, excessive crying, decreased appetite, and difficulty sleeping over the past 2 days. The child's temperature last night was 39°C (102.2°F) by electronic axial thermometer. The father gave the child several doses of ibuprofen, but the pain or temperature did not improve and none was given this morning. He has considerable recurrences of acute otitis media each year often treated with amoxicillin. He has had three episodes in the last 8 months, with the last episode treated 2 months ago using oral amoxicillin 90 mg/kg/day divided every 12 hours but developed a rash. He is also presenting with wheeze and cough. Dad states that he was recently diagnosed with asthma, but lost their prescription for his asthma medication and so never started it.

Home medications: Ibuprofen suspension (100 mg/5 mL) as needed for pain and fever.

PE:

General: crying, tugging on his left ear, coughing with wheeze

VS: T 39°C (102.2°F), BP 93/50 mm Hg, HR 115 bpm, RR 30 bpm, Wt 35 lb (16 kg), Ht 101.6 cm (40 in)

HEENT: Tympanic membranes erythematous (L>R); left ear is bulging and nonmobile. Throat erythematous; nares patent.

Pulmonary: Wheeze bilaterally, no congestion noted

Diagnosis: (1) Acute otitis media, left ear and (2) newly diagnosed asthma, untreated

You and the pediatrician decide to start MM on oral cefdinir suspension (250 mg/5 mL) at 7 mg/kg/dose q 12 h for a total of 10 days and continue ibuprofen (100 mg/5 mL) at 10 mg/kg/dose every 6 to 8 hours as needed for fever or pain. In addition to treatment for acute otitis media, he needs treatment of asthma, so he is restarted on fluticasone HFA MDI 44 mcg 2 puffs twice a day with a spacer. MM's dad also asks about the use of an herbal supplement (from his traditional Eastern medicine herbalist) advertised for asthma because his brother-in-law uses it in addition to his prescribed asthma therapy.

Based on the information available, create a care plan for MM. The plan should include:

- Statement of the drug-related needs and/or problems,*
- Patient-specific detailed therapeutic plan with specific dosing,*
- Parent/caregiver education points, and*
- Approach to Dad's inquiry about herbal supplement use for MM's asthma.*

Accidental Ingestion in Pediatric Patients

Over 1.2 million accidental ingestions occurred in children younger than 6 years in 2001; these often occur in the home.⁴⁸ Ingested substances can vary, from household cleaning solutions to prescription and nonprescription medications. Medications account for the majority of fatalities involving accidental ingestions.⁴⁹ Management of accidental ingestions varies depending on the ingested substance, the amount, and the age and size of the child. Clinicians receiving calls regarding management of accidental ingestions should direct them to the local or regional poison control center for specific recommendations, which can be located through the American Association of Poison Control Centers (www.aapcc.org).

Inducing emesis is not recommended for suspected ingestions of acidic or alkaline substances. The American Academy of Clinical Toxicology and the AAP do not recommend the use of ipecac syrup because it can decrease effectiveness of activated charcoal treatment administered in the emergency department and compromise patient outcomes.⁴⁸ Use of activated charcoal is considered for treatment of

patients in the emergency department with an intact airway who present soon after an ingestion of an adsorbable agent. The recommended dose of activated charcoal is 10 to 25 g/dose or 0.5 to 1 g/kg/dose for infants younger than 1 year, 25 to 50 g/dose or 0.5 to 1 g/kg/dose orally for children up to 12 years of age, and 25 to 100 g/dose for adolescents and adults.⁵⁰ Symptoms of toxicities from the substance ingested during hospitalization should be monitored. Parents/caregivers should continue monitoring at home following discharge.

Abbreviations Introduced in This Chapter

AAP	American Academy of Pediatrics
ACIP	Advisory Committee on Immunization Practices
bpm	Beats per minute
CAM	Complementary and alternative medicine
CDC	Centers for Disease Control and Prevention
CPOE	Computer physician order entry
CrCl	Creatinine clearance
ELBW	Extremely low birth weight

Patient Care and Monitoring

For all pediatric patients, review and consider the following to offer optimal drug therapy:

- Gestational age, postnatal age, and corrected age if the patient is a neonate
- Patient's demographic information including age, weight (and birth weight if a neonate), and gender
- Disease or illness for which treatment is needed
- Past medical history including comorbidities
- Medication history current and past (including OTC and complementary and alternative products)
- History of medication adherence
- Other concurrent medications
- Previous therapy failures
- Medication allergies and/or intolerances
- Patient and caregivers beliefs regarding illness, medication use
- Available routes of administration
 - Can the patient take medications orally?
 - If IV medication is needed, what types of IV accesses are available? For example, does the patient have a central or peripheral line?
 - Is intramuscular administration needed?
- Fluid status—Is the patient dehydrated, balanced, or edematous?
- Available data regarding safe and effective dosing of selected drug
- Verification of accurate dose calculation
 - Verify weight and dosing units (e.g., mg/kg/day, mg/kg/dose)
 - Is the dosing interval appropriate?
- Is the dose an easily measurable amount for the caregiver?
- Will the drug be administered at home and/or a daycare facility or school?
- Does the parent/caregiver need additional documentation for medication administration at other locations?
- Are additional supplies for medication administration at other locations needed?
- Educate parent/caregiver/patient regarding selected drug therapy including purpose, dose, administration, duration therapy, possible side effects, etc.
- Regular assessment of weight
 - Premature neonates and infants can change frequently, check weight daily
 - Depending on illness in older children, daily weight check may be necessary when admitted to hospital; it should be checked at every outpatient clinic visit
- Organ function
 - For drugs that undergo extensive hepatic metabolism and clearance, assess liver function at baseline and periodically (depending on severity of illness)
 - For drugs that undergo extensive renal elimination
 - Note changes in serum creatinine and urine output
 - Calculate creatinine clearance using Schwartz's or Traub-Johnson's equations
- Measure drug serum concentrations when appropriate
- Monitor clinical outcomes of pharmacotherapy
- Monitor, manage, and prevent adverse drug events
- Prevent drug-drug or drug-food interactions

GA	Gestational age
GFR	Glomerular filtration rate
HFA	Hydrofluoroalkane
LBW	Low birth weight
MDI	Metered-dose inhaler
OTC	Over-the-counter
V_d	Volume of distribution (apparent)
VLBW	Very low birth weight

Palliative Care

Marc A. Sweeney and Phyllis A. Grauer

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Describe the philosophy of palliative care including hospice care and its impact on medication therapy management.
2. Discuss the therapeutic management of palliative care patients and how it differs from and is similar to traditional patient care at the end of life.
3. List the most common symptoms experienced by the terminally ill patient.
4. Explain the pathophysiology of the common symptoms experienced in the terminally ill patient.
5. Assess the etiology of symptoms in the patient with a life-limiting illness.
6. Describe the pharmacologic rationale of medication therapy used for symptom management in the terminally ill patient.
7. Recommend nonpharmacologic and pharmacologic management of symptoms in a terminally ill patient.
8. Develop a patient-specific palliative care management plan.
9. Educate patients and caregivers regarding palliative care management plan, including rationale of treatment, importance of medication adherence, and assessment and monitoring of desired outcomes.

KEY CONCEPTS

- 1 According to the World Health Organization (WHO), “Palliative care is defined as the active total care of patients whose disease is not responsive to curative treatment. The goal of palliative care is to achieve the best quality of life for patients and their families.”
- 2 The goals of palliative care include enhancing quality of life while maintaining or improving functionality.
- 3 Palliative care is appropriate for all life-limiting diseases including cancer; chronic obstructive pulmonary disease; dementia, including Alzheimer’s disease; Parkinson’s disease; chronic cardiac disease; stroke, renal failure; hepatic failure; multiorgan failure; diabetes mellitus; etc.
- 4 Following a complete assessment of the patient, developing a comprehensive therapeutic plan that uses the fewest number of medications to achieve the highest quality of life is essential.
- 5 Palliative care is more than just pain management. It includes the treatment of symptoms resulting in the discomfort for the patient, which may include nausea

and vomiting, agitation, anxiety, depression, delirium, dyspnea, anorexia and cachexia, constipation, diarrhea, pressure ulcers, and edema.

- 6 Involving the patient, family, and caregivers in the development of the therapeutic plan demonstrates responsible palliative care.
- 7 Positive therapeutic outcomes include resolution of symptoms while minimizing adverse drug events.
- 8 Patient and caregiver education is vital to ensuring positive outcomes.

INTRODUCTION

1 According to the WHO, “Palliative care is an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual.” The goal of **palliative care** is to achieve the best **quality of life** for patients and their families.¹ “Palliate” literally means “to cloak.” The WHO goal of achieving high quality of life

depends on management of disease-related symptoms while honoring the patient's goals for care.² Palliative care is an approach to care focusing on patients and their families and the challenges they face associated with life-threatening illness.³ The goal is to prevent and relieve suffering by means of early identification, assessment, and treatment of pain and other physical symptoms including associated psychosocial, emotional, and spiritual concerns.¹ The WHO goes on to state that the most effective palliative care is provided by a team of healthcare professionals. Palliative medicine is rapidly becoming a well-recognized medical specialty throughout the world.⁴ This expanding specialty is much needed due to the increased number of patients with chronic, slowly debilitating diseases.²

The term *palliative care* is frequently used synonymously with **hospice**, and although hospice programs provide palliative care, palliative care has a much broader application. The goals for both types of care are similar; however, differences do exist. In the United States, hospice is defined by Medicare and other third-party payers as a medical or third-party benefit available to individuals who have less than or equal to 6 months life expectancy if the disease runs its typical course.⁵ Hospice care guidelines and regulations are primarily defined by federal regulations. Palliative care outside of the umbrella of hospice care, in contrast, is not currently regulated and does not have the same reimbursement structure. Palliative care services may be provided at any point during the disease process and are not limited to the last 6 months of life; therefore, patients and families may receive benefits from palliative care services beginning at the time of diagnosis of a life-limiting illness. Palliative care, whether it is through a hospice program or a palliative care service, may be delivered to patients in all care settings including the hospital, outpatient clinic, extended-care facility, or at home.⁶ Palliative medicine has become widely accepted as a specialty practice in medicine. Palliative care is not only a philosophy of patient care but a highly organized system to deliver care.⁷ The foundation for providing quality palliative care centers around the active participation of an interdisciplinary group or team of professionals who work closely together to meet the goals of the patient and family. Palliative care team members include representatives from medicine, nursing, social work, pastoral or related counseling, pharmacy, nutrition, rehabilitation, and other professional disciplines. The involvement of multiple disciplines provides a holistic approach to the patient's care.

2 *The goals of palliative care include enhancing quality of life while maintaining or improving functionality.*^{7,8} Given this goal of patient care, palliative care should most logically be delivered to patients from the onset of any chronic, life-altering disease. Palliative care is not a new concept, in fact, it is one of the oldest approaches to patient care. Before many of our modern medical and therapeutic advancements were developed, curative treatments were not normally available.⁹ Provision of comfort and addressing quality of life during illness was considered the mainstay for patient care. During the 20th century, advances in medical care, nutrition, public health, and trauma care resulted in fewer patient deaths attributed to acute illness or injury. Medical management

shifted focus from comfort to a death-denying approach with prolonging life as the primary goal. With this shift in focus, palliative care became less of an emphasis until 1967 when the first modern hospice was established in London, England. Today the palliative care philosophy attempts to combine enhanced quality of life, compassionate care, and patient and family support with modern medical advances.

EPIDEMIOLOGY AND ETIOLOGY

Although the modern hospice model of care originated in England in 1967, the first hospice in the United States was founded in 1974. Since then, hospice acceptance and utilization has increased in the United States. The number of Medicare beneficiaries enrolled in hospice increased by 100% between 2000 and 2005.¹⁰ Medicare spending for hospice care tripled during that same time period, reflecting a greater number of patients receiving the benefits of this type of care. The Medicare Hospice Benefit is now the fastest growing benefit in the Medicare program, representing 3% of Medicare costs.¹¹ Currently, approximately 5,000 hospice agencies care for patients across the United States. In 2009 approximately 69% of hospice patients were cared for in the home, and 83% of hospice patients were older than 65 years.¹² When the Medicare Hospice Benefit was introduced in 1982, most patients had a terminal diagnosis of cancer, representing more than 90% of beneficiaries.¹³ According to the 2010 National Hospice and Palliative Care Organization (NHPCO) report, Facts and Figures on Hospice Care in America, 83% of patients are covered by the Medicare Hospice Benefit. Approximately 40% of patients receiving the Medicare Hospice Benefit have a cancer diagnosis, with the majority of hospice patients having other chronic or life-limiting diseases.¹⁴ In 2009, the top four noncancer diagnoses for hospice admission were debility, heart disease, dementia, and lung disease. In 2009, NHPCO estimated that approximately 41.6% of all deaths in the United States were under the care of a hospice program. The median length of stay in hospice was 21 days, and the mean length of stay was 69 days. Unfortunately, also in 2009, approximately 34% of hospice patients died or were discharged within 7 days of admission to hospice care.¹² The underutilization of the hospice allowable eligibility benefit of 6 months prognosis results in less time for patients and families to benefit from the many services offered through hospice care.

According to a study published in 2007, hospice patients live 29 days longer than nonhospice patients, with the largest difference noted in chronic heart failure patients.¹⁵ Lung cancer patients receiving early palliative care survived 23% longer than those with delayed palliative care, according to a 2010 study.¹⁶ Early referrals to hospice appear to improve the overall care of the patient and offer prolonged survival in some patients. The integration of palliative care prior to the patient's eligibility for hospice care may prove to even further benefit the survival and quality of life and care of patients.

Because healthcare providers have an increasing recognition of the benefit of palliative care for patients with all life-limiting illness, increased integration of this model of care

has extended to other disease states beyond cancer. Understanding differences and similarities in the pathophysiology of various disease states and their respective symptoms equips palliative care providers to develop appropriate individualized plans of care for patients that are disease state specific.

PATHOPHYSIOLOGY

- In many respects, understanding the pathophysiology of multiple end-stage disease states is daunting, yet in palliative care, the emphasis is not so much on the disease state management as it is on the assessment and appropriate treatment of associated physical, psychological, social, and spiritual symptoms. Palliative care focuses on symptom management for patients with progressive life-limiting illnesses from diagnosis through death where the pathophysiological impact of disease on a patient's symptoms may vary greatly depending on the stage of a patient's illness. 3 *Palliative care is appropriate for all life-limiting diseases including cancer; chronic obstructive pulmonary disease; dementia, including Alzheimer's disease; Parkinson's disease; chronic cardiac disease; stroke; renal failure; hepatic failure; multiorgan failure; diabetes mellitus; etc.*

For the purpose of this chapter, pathophysiology is not a primary focus. Rather, the philosophy of managing physical, psychological, social, and spiritual symptoms to maintain quality of life and prevent suffering is discussed within the context of progressively incurable illnesses. Although palliative care prior to the last several months before death may coexist with aggressive disease state management to extend life, as the patient approaches the end of life, philosophy and management generally moves away from those principles and concerns related to the disease state management of patients where prolonging life is the goal.

CLINICAL PRESENTATION AND DIAGNOSIS

Cancer

- Palliative care is most commonly associated with patients who have cancer. Regardless of whether or not the cancer is curable, most patients have various degrees of physical, psychological, social, and spiritual symptoms that arise once a diagnosis is confirmed. The primary site of solid tumor and hematologic cancers associated with limited life include, but are not limited to, lung, bronchus, breast, colon, rectum, pancreas, prostate, ovaries, uterus, brain, esophagus, liver, kidneys, bladder, lymph system, bone marrow, and skin. The spread of cancer cells (metastases) to distant areas are associated with poorer prognosis. Once a cancer patient has failed curative and life-prolonging therapy, prognosis and disease trajectory is easier to determine than in patients with other life-limiting diseases. The change in focus from cure to symptom control becomes apparent and therefore more acceptable. Symptoms associated with cancer depend on both the primary tumor site and the location of metastatic spread.

Symptoms may also result from the effects of cancer treatments such as chemotherapy and radiation. (See Chaps. 88 to 99 for specific cancers and their treatments.)

End-Stage Heart Failure

Heart disease is the leading cause of death in the United States. Many forms of heart disease result in sudden death; however, the disease progression of heart failure is protracted yet unpredictable. Advanced heart failure (class III to IV or stage C or D) is characterized by persistent symptoms that limit activities of daily living despite optimal drug therapy.

- Common symptoms include fatigue, breathlessness, anxiety, fluid retention, and pain. In heart failure, standard medication management is intended to reduce the progression of cardiac remodeling and is considered disease modifying. However, as patients approach the final months of life, with the exception of cholesterol-lowering agents, these same cardiac medications are also palliative and should not be discontinued prematurely without cause (Fig. 4-1). Exacerbations of heart failure symptoms should be aggressively treated as long as the patient is responsive to therapy and wishes to receive treatment. In hospice, this can often be accomplished through medication manipulation in the patient's home without the need for hospitalization (see Chap. 6).

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) has a prolonged and variable course. Patients with COPD have a high number of physician visits and hospital admissions.

- Palliative care treatment is directed at reducing symptoms, reducing the rate of decline in lung function, preventing and treating exacerbations, and maintaining quality of life. In end-stage COPD, bronchodilators and anti-inflammatory agents become less effective. As patients decline, their ability to use inhalers appropriately becomes more difficult.

Drug	Survival	Functional Status
Diuretic	→	↑
ACEI	↑	↑
Spirolactone	↑	↑
β-Blocker	↑	↑
Digoxin	→	↑

FIGURE 4-1. Drugs, their use in Class III–IV heart failure, and their effects on survival, hospital admissions, and functional status. →, survival does not increase or decrease, but stays the same; ↑, survival increases. (Data from Strickland JM, Huskey AG. Palliative Care. Pharmacotherapy Self-Assessment Program, 5th ed. 2004:172.)

- Utilizing a nebulizer to administer bronchodilators allows for more reliable drug delivery to the site of action. Symptoms of late-stage disease include wheezing, chronic sputum production, cough, frequent respiratory infections, **dyspnea** with exertion progressing to dyspnea at rest, fatigue, pain, hypoxia, and weight loss. Pulmonary hypertension may also occur and can lead to cor pulmonale or right-sided heart failure (see Chap. 15).

End-Stage Kidney Disease

- Chronic kidney disease is progressive and leads to renal failure. In end-stage kidney disease, the only life-sustaining treatments are dialysis or renal transplant. Without treatment, kidney failure causes uremia, oliguria, hyperkalemia and other electrolyte disorders, fluid overload and hypertension unresponsive to treatment, anemia, hepatorenal syndrome, and uremic pericarditis. Symptoms associated with chronic kidney disease (stage 5) include fatigue, pruritus, nausea, vomiting, constipation, dysgeusia, muscle pain, agitation, and bleeding abnormalities. Palliative care in these patients includes the minimization of these symptoms; however, because many options for drug therapy will be cleared through the kidneys, agents should be chosen cautiously to avoid other complications (see Chap. 26).

End-Stage Liver Disease

- Like kidney disease, the only treatment to prolong life in advanced liver disease is transplant. Patients with end-stage liver disease typically present with ascites, jaundice, pruritus, or encephalopathy, and frequently all four symptoms. Additionally, bleeding disorders are common, and associated esophageal or gastric varices bleeds are the cause of death in about one-third of those who die from liver disease. Palliative care in these patients focuses on the symptom management of end-stage liver disease complications.

Human Immunodeficiency Virus/Acquired Immune Deficiency Syndrome (HIV/AIDS)

- Pharmacologic advances have changed the prognosis and progression of HIV/AIDS. Today, palliative care is predominantly directed toward patients who have not had access to drug therapy in the early stages of their disease. Patients with progressed HIV/AIDS are susceptible to acquire opportunistic infections and cancer that may hasten their death. Common symptoms observed in individuals with HIV/AIDS at the end of their life include fatigue, profound weight loss, breathlessness, nausea, GI disturbances, and pain. The goal of palliative care in these patients is to minimize common AIDS-related symptoms (see Chap. 87).

Stroke/Cerebral Vascular Accident

- Stroke can be a result of hemorrhage or ischemia. The prognosis of patients who have had a cerebral vascular accident (CVA) is unpredictable and may be extended, resulting in caregiver fatigue. Approximately one-third of patients who

- have a stroke will die within 2 years. Patients with stroke deal with loss of physical and cognitive function, poststroke pain, and frequent depression. Incontinence, aphasia, **dysphagia**, and seizures are also common. Patients who have dysphagia have a high incidence of aspiration pneumonia, which often is the cause of death (see Chap. 11).

Parkinson's Disease

- Parkinson's disease is a degenerative neurologic disease with a long chronic, progressive course evidenced by akinesia, rigidity, and tremor. The goal of therapy is to reduce symptoms and maintain or improve quality of life. Palliative care provides support to both the patient and caregiving system as patients become more disabled and as neuropsychiatric problems arise. Symptoms that frequently occur are skin infections and breakdown, constipation, pain, depression, hallucinations, and confusion. Individuals with Parkinson's disease often die from bronchial pneumonia due to dysphagia or complication from falls (see Chap. 33).

Amyotrophic Lateral Sclerosis (Lou Gehrig's Disease)

- Amyotrophic lateral sclerosis (ALS) is a chronic neurodegenerative disorder characterized by progressive loss of motor neurons. The median survival is approximately 3 years from the onset of symptoms with less than 15% of patients surviving 10 years. Initially symptoms of ALS present as limb weakness, with other symptoms developing in no particular order including cramps, spasticity, pain, dysarthria, sialorrhea, fatigue, insomnia, depression, fear and anxiety, involuntary emotional expression disorder, constipation, aspiration, and laryngospasm. Many patients do not have cognitive impairment; however, one-fourth to one-half of patients with ALS may have associated frontal lobe dementia. Disease progression eventually involves all systems except sphincter control and eye movement. Unless the individual has long-term mechanical ventilation, the cause of death is typically respiratory failure.

Alzheimer's Disease and Other Dementia

- Dementia is a progressive, nonreversible deterioration in cognitive function with associated behavioral dysfunction. Alzheimer's disease accounts for the majority of dementia cases; vascular, Parkinson's disease, dementia with Lewy body, and frontotemporal dementias are less prevalent. Drug therapy is targeted at slowing the progression of the cognitive symptoms and preserving the patient's function. As patients progress toward end-stage dementia, in addition to memory loss and personality and behavioral changes, they require assistance in basic activities of daily living such as feeding, dressing, and toileting. At this point they may not respond to their surroundings, may not communicate, or have impaired movements and dysphagia. Depression, agitation, delusions, compulsions, confusion, hallucinations, incontinence, and disruption of sleep/wake cycles are all common symptoms in

- end-stage dementias. Assessment of symptoms is challenging due to the cognitive impairment and frequent aphasia.
- Palliative care is not only directed toward the patient, but also emotional support is needed for those close to them (see Chap. 29).

Adult Failure to Thrive, Decline in Clinical Status, and Debility, Not Otherwise Specified

The diagnoses of “debility not otherwise specified”, “adult failure to thrive” and “decline in clinical status” are used to describe unknown or ill-defined causes of morbidity. These conditions are most commonly seen in the frail and elderly who may not have one specific terminal illness but may have one or more chronic illnesses. In the absence of a specific known terminal illness, these patients often have poor appetite, loss of weight, increased fatigue, and a progressive functional decline. These individuals may be eligible for the services provided by the Medicare Hospice Benefit.

TREATMENT

- 4 Following a complete assessment of the patient, developing a comprehensive therapeutic plan that utilizes the fewest number of medications to achieve the highest quality of life is essential. Many times, one drug may provide relief for multiple symptoms, resulting in better patient care, lower costs, and a decreased number of medications. Cost-effective drug recommendations are essential for hospice agencies to control costs, given that Medicare and most other third-party payers reimburse hospice at a fixed per-diem rate. Avoiding polypharmacy will reduce the incidence of adverse drug events related to drug interactions, excessive side effects, and duplications of therapy. The following list of symptoms includes common symptoms observed in palliative and end-of-life care; however, it is not comprehensive.
- 5 Palliative care is more than just pain management. It includes the treatment of symptoms resulting in the discomfort for the patient, which may include nausea and vomiting, agitation, anxiety, depression, delirium, dyspnea, anorexia and cachexia, constipation, diarrhea, pressure ulcers and edema.

It should be noted that many drugs used for the treatment of symptoms in palliative and end-of-life care are often prescribed for unapproved uses, administered by unapproved routes or in dosages higher than that recommended by the package insert. This “off-label” use of medication is not unique to palliative care.

Anxiety

A comprehensive review of anxiety disorders may be found in Chapter 40.

► Palliative Care Considerations

- Anxiety is “a state of fearfulness, apprehension, worry, emotional discomfort, or uneasiness that results from an unknown internal stimulus, is excessive, or is otherwise inappropriate to a given situation.”¹⁷

- Anxiety is closely related to fear, but fear has an identified cause or source of worry (e.g., fear of death). Fear may be more responsive to counseling than an anxiety state that the patient cannot attribute to a particular fearful stimulus. Anxiety disorders are the most prevalent class of mental disorders overall, so it is not surprising that anxiety is a common cause of distress at life’s end.

In addition to anxiety disorders, a variety of conditions can cause, mimic, or exacerbate anxiety.^{18,19} Delirium, particularly in its early stages, can easily be confused with anxiety. Physical complications of illness, especially dyspnea and undertreated pain, are common precipitants. Significant anxiety is present in most patients with advanced lung disease and is closely related to periods of oxygen desaturation. Medication side effects, especially akathisia from older antipsychotics and antiemetics (including and especially metoclopramide), can present as anxiety. Interpersonal, spiritual, or existential concerns can mimic and exacerbate anxiety. Patients with an anxious or dependent coping style are at high risk of anxiety as a complication of advanced illness. Short of making a diagnosis of a formal anxiety disorder, differentiating normal worry and apprehension from pathologic anxiety requires clinical judgment.

- Behaviors indicative of pathological anxiety include intense worry or dread, physical distress (e.g., tension, jitteriness, or restlessness), maladaptive behaviors and diminished coping and inability to relax.

Pathological anxiety may be complicated by insomnia, depression, fatigue, GI upset, dyspnea, or dysphagia. Anxiety can also worsen these conditions if they are already present. Untreated anxiety may lead to numerous complications, including withdrawal from social support, poor coping, limited participation in palliative care treatment goals, and family distress. Reassess the patient for anxiety with any change in behavior or any change in the underlying medical condition. Search for probable etiologies, and assess for formal anxiety disorders or other contributing factors. Appropriate assessment of anxiety is key to its management.

► Nonpharmacologic Treatment in Palliative Care

- Regardless of what treatment approach is chosen, the following principles apply. Ask questions and listen to patients’ concerns and fears. Offer emotional support and reassurance when appropriate. Err on the side of treatment—be willing to palliate anxiety. Assess treatment response and side effects frequently. Aim to provide maximum resolution of anxiety and educate patients and families about anxiety and its treatments.
- Psychotherapies can help in the management of anxiety, although the availability of trained therapists willing to make home visits, and limited stamina and attention span of seriously ill patients, typically make such therapies impractical in the hospice setting. Cognitive and behavioral therapies can be beneficial, including simple relaxation exercises or distraction strategies (i.e., focusing on something pleasurable or at least emotionally neutral). Encourage pastoral

care visits, especially if spiritual and existential concerns predominate.

When an underlying cause of anxiety can be identified, treatment is initially aimed at the precipitating problem, with monitoring to see if anxiety improves or resolves as the underlying cause is addressed.

► *Pharmacotherapy in Palliative Care*

- In most cases, management of pathological anxiety in the hospice setting involves pharmacologic therapies. Benzodiazepines are the gold standard for treatment; however, selective serotonin reuptake inhibitors (SSRIs), typical and atypical antipsychotics, and tricyclic antidepressants may also be appropriate based on the patient's life expectancy.²⁰ The primary goal of therapy for anxiety in hospice is patient comfort. Aim to prevent anxiety, not just treat it with as needed medications when it flares. Think of pain management as an analogy. As with all medications that act in the CNS, anxiolytics such as benzodiazepines should be dosed at the lower end of the dose range to prevent unnecessary sedation, particularly in the frail and elderly. However, recognize that standard or higher doses may be required. Avoid use of bupropion and psychostimulants for anxiety. Although effective for depression, they are ineffective for anxiety and may make anxiety worse. Many patients have difficulty swallowing as they approach the end of life. Lorazepam, alprazolam, and diazepam tablets are commonly crushed and placed under the tongue with a few drops of water if the liquid formulations are not readily available. Low-dose haloperidol is also used to treat anxiety in palliative care, particularly if delirium is present. Chapter 40 provides more detailed information on appropriate use of anxiolytic agents.

Delirium

► *Palliative Care Considerations*

- Delirium is a very common disorder in hospice, occurring in more than 80% of terminally ill patients, most often in the last few days of life.¹⁶ Potential causes of delirium in the hospice setting include, but are not limited to, medical illness, dehydration, hypoxia, sleep deprivation, metabolic disturbances, sepsis, side effects of drugs (particularly anticholinergic agents, benzodiazepines, opioids, corticosteroids, tricyclic antidepressants), urinary retention, urinary tract infection, constipation or impaction, uncontrolled pain, or alcohol or drug withdrawal.^{21,22}

A classic symptom of delirium is clouding of consciousness. This can be manifested by an inability to either maintain or shift attention. Patients also have impaired cognitive functioning, which may or may not include memory disturbances. "Sundowning" is very common phenomenon at the end of life, especially in the presence of delirium. It presents as daytime sleepiness and nighttime agitation and restlessness. Another common characteristic is fluctuation in severity of delirium symptoms during the course of the day. This can even occur within the course of a single hour or also from day to day. Patients who exhibit agitation from

their delirium are easy to identify, but those who present as withdrawn and with diminished responsiveness ("quiet" delirium) are more difficult to diagnose. It is not uncommon for patients to exhibit both quiet and agitated delirium. Treatment is the same for both types of delirium. Delirium is difficult to distinguish from dementia. Delirium more commonly presents as a sudden onset (e.g., hours to days), with an altered level of consciousness and a clouded sensorium. However, dementia more commonly presents gradually and with an unimpaired level of consciousness.

► *Nonpharmacologic Treatment in Palliative Care*

Establishing a safe, soothing environment where there are familiar objects such as photographs and familiar music can be helpful to calm the patient. Minimizing risk of injury is important when the patient is agitated. Providing education to families and caregivers about the causes of delirium, signs and symptoms, and how to best manage it will help reduce their anxiety and distress when it occurs.

► *Pharmacotherapy in Palliative Care*

- The most important initial step is to determine the goal of care. If possible, reverse the underlying cause of delirium to restore the patient to a meaningful cognitive status.^{16,21} If the precipitating factors cannot be reversed, initiate therapy to treat the symptoms. Patients who are not agitated may not require any treatment other than comfort measures. If the patient is irreversibly delirious and agitated, drug therapy is generally indicated.
- Antipsychotic (neuroleptic) drugs (conventional or atypical antipsychotics) are the drugs most commonly used to treat confusion and agitation associated with delirium. However, treatment of delirium with these drugs is an "off-label" indication. Atypical antipsychotics such as risperidone, olanzapine, quetiapine, ziprasidone, paliperidone, and aripiprazole account for a major portion of increasing medication costs in the geriatric population.²³
- Haloperidol, when given in doses less than 2 mg/day is well tolerated and nonsedating, and it is within the recommended dosing parameters for long-term care facilities. Doses greater than 4.5 mg/day are associated with increased incidence of extrapyramidal symptoms.²⁴ Cumulative doses of 35 mg or single IV doses greater than 20 mg have been associated with QTc prolongation.²⁵ When sedation is beneficial for terminal aggressive, agitated delirium, chlorpromazine is useful because it provides more sedation as compared with low-dose haloperidol. When patients are bedbound and in the final stages of life, orthostatic hypotension common with chlorpromazine is not a concern. Haloperidol and chlorpromazine are commonly given sublingually or rectally if swallowing becomes difficult, although these are not approved routes of administration. Haloperidol, but not chlorpromazine, can be given subcutaneously.²⁶
- Administering benzodiazepines alone in a patient with delirium can actually make the delirium and confusion worse, although it is sometimes helpful to add benzodiazepines along with antipsychotics if sedation is desired. Phenobarbital may also be used for this purpose.

Patient Encounter 1

LG is a 72-year-old male admitted to the hospital under the care of the palliative care team for management of uncontrolled symptoms. The patient has a primary diagnosis of prostate cancer with metastases to the bone and liver. LG has a past medical history that includes hypertension, chronic heart failure (CHF), and hypercholesterolemia. He is allergic to sulfa. The patient's chief complaint upon admission is pain, which he rates as a 7 on the pain scale (0–10), anxiety, depression, nausea and vomiting, and constipation. He describes his pain as an aching pain in the areas of his bone metastases. The pain increases with movement. He also has a constant deep pain in his right upper abdomen area but it is not as severe. LG is mostly bedbound due to pain.

VS: BP 124/88, RR 20, P 94, wt 61.4 kg (135 lb), ht 5'11" (180 cm)

Meds: Digoxin 0.125 mg by mouth daily; furosemide 40 mg by mouth daily; lisinopril 10 mg by mouth daily; spironolactone 25 mg by mouth daily; metoprolol XL 50 mg by mouth daily; simvastatin 40 mg by mouth daily; goserelin 10.8 mg subcutaneously every 3 months; zoledronic acid 4 mg IV every 4 weeks; hydrocodone/acetaminophen 5/325 1 to 2 tablets by mouth every 4 hours as needed; fentanyl patch 25 mcg/h; apply one patch every 72 hours; celecoxib 100 mg by mouth daily; multivitamin 1 tablet by mouth daily

What are the potential etiologies of the nausea and vomiting LG is experiencing?

What type of the pain is LG experiencing?

What questions would you ask LG during your assessment?

What potential drug–drug interactions may exist, and how would you monitor the patient for them?

What medications should be added, changed or discontinued?

List nonpharmacologic interventions that the practitioner should make to improve the care of LG.

Dyspnea

► Palliative Care Considerations

- Dyspnea is described as an uncomfortable awareness of breathing. It is a subjective sensation, and patient self-report is the only reliable indicator. Respiratory rate or PO_1 often does not generally correlate with the feeling of breathlessness.²⁷ Respiratory effort and dyspnea are not the same. Patients may report substantial relief of dyspnea from opioids with no change in respiratory rate. The prevalence of dyspnea varies from 12% to 74% and tends to worsen in the last week of life in terminally ill cancer patients to between 50% and 70%. A thorough history and physical examination should

be taken and possible reversible causes of dyspnea should be identified and treated, if present.

► Nonpharmacologic Treatment in Palliative Care

- Provide information and anticipate and proactively prepare the patient and family for worsening symptoms. Identify triggers that cause episodes of dyspnea and minimize them as much as possible. Educate patient and family regarding treatment of dyspnea, including the use of opioids and also benzodiazepines for dyspnea-associated anxiety. Prevent isolation and address spiritual issues that can worsen symptom. Encourage relaxation and minimize the need for exertion.
- Reposition to comfort, usually to a more upright position or with the compromised lung down. Avoid strong odors, perfumes, and smoking in the patient's presence or in close proximity. Improve air circulation/quality: provide a draft, use fans, or open windows and adjust temperature/humidity with air conditioner or humidifier.

► Pharmacotherapy in Palliative Care

- If no treatable causes can be identified or when treatments do not completely alleviate distressing symptoms, opioids are first-line agents for treating dyspnea.²⁸ Opioids suppress respiratory awareness, decrease response to hypoxia and hypercapnia, vasodilate, and have sedative properties. Low-dose opioids (e.g., starting oral dose of morphine ~5 mg) have been shown to be safe and effective in the treatment of dyspnea. Opioid doses should be titrated judiciously. Once an effective dose of an opioid has been established, converting to an extended-release preparation may simplify dosing. When using opioids, anticipate side effects and prevent constipation by initiating a stimulant laxative/stool softener combination.

Nebulized opioids for treatment of dyspnea are controversial. Study results have been inconsistent.^{29,30} Nonrandomized studies, case reports, and chart reviews describe anecdotal improvement in dyspnea using nebulized opioids; however, several controlled studies using nebulized opioids have provided inconclusive or negative results. However, nebulized opioids may be an alternative in patients who are not able or willing to take an oral agent or cannot tolerate adverse effects of systemic administration.

- Nebulized furosemide appears effective for dyspnea refractive to other conventional therapies.³¹ The hypothesized mechanism of action of nebulized furosemide is its ability to enhance pulmonary stretch receptor activity, inhibition of chloride movement through the membrane of the epithelial cell, and its ability to increase the synthesis of bronchodilating prostaglandins.
- Because anxiety can exacerbate dyspnea, benzodiazepines and antidepressants that have anxiolytic properties are frequently beneficial. Not all dyspnea is caused by low oxygen saturation. However, oxygen therapy is useful and beneficial for dyspnea if hypoxia is present.
- For known etiologies of dyspnea, consider the following:
 - **Bronchospasm or COPD exacerbation:** Albuterol, ipratropium, and/or oral steroids are effective for symptoms management. Nebulized bronchodilators are more effective than using

handheld inhalers in patients who are weak and have difficulty controlling their breathing.

- **Thick secretions:** If cough reflex is strong, loosen secretions by increasing fluid intake. Guaifenesin is used to thin secretions; however, its efficacy in the absence of hydration is controversial. Nebulized saline may also help loosen secretions. If the patient is unable to cough, hyoscyamine, glycopyrrolate, or scopolamine patch can effectively dry secretions.
- **Anxiety associated with dyspnea:** Consider benzodiazepines (e.g., lorazepam, diazepam).
- **Effusions:** Thoracentesis will be necessary.
- **Low hemoglobin:** Red blood cell transfusion (controversial) or erythropoietin (rarely used in hospice but might have a larger role in palliative care patients).
- **Infections:** Antibiotic therapy as appropriate.
- **Pulmonary emboli:** Anticoagulants for prevention and treatment or vena cava filter placement (rarely used in hospice but might have a larger role in palliative care patients).
- **Rales due to volume overload:** Reduction of fluid intake or diuretic therapy as appropriate.

Patient Encounter 2

NP is a 52-year-old male admitted to hospice with a primary diagnosis of chronic obstructive pulmonary disease (COPD). Other comorbidities include renal insufficiency, congestive heart failure, type 2 diabetes mellitus, hyperlipidemia, and hypothyroidism. The patient has no known drug allergies. NP has been hospitalized several times for respiratory failure and infections and no longer wants aggressive treatment. His appetite is poor and he is bedbound. NP's chief complaint is fatigue, shortness of breath, and edema.

VS: BP 90/50, RR 40, P 120, wt 76.4 kg (168 lb), ht 6'1" (185 cm)

Meds: fluticasone 500 mcg/salmeterol 50 mcg inhaled orally twice daily; tiotropium contents of 1 capsule (18 mcg) inhaled once daily; ipratropium bromide 18 mcg and albuterol 90 mcg aerosol oral inhaler 2 puffs every 2 hours as needed, insulin glargine 80 units subcutaneously daily, regular insulin administered on a sliding scale for fasting blood glucose more than 250 mg/dL; potassium chloride 10 mEq by mouth daily; furosemide 20 mg by mouth daily; levothyroxine 125 mcg daily; simvastatin 20 mg by mouth daily.

What potential interventions could the practitioner make to improve NP's care?

What medications could be added, changed, or discontinued?

What potential drug–drug interactions may exist? How would you monitor the patient for them?

Nausea and Vomiting

A comprehensive review of nausea and vomiting may be found in Chapter 20.

► Palliative Care Considerations

Up to 71% of palliative care patients will develop nausea and vomiting with ~40% experiencing these symptoms in the last 6 weeks of life. Chronic nausea can be defined as lasting longer than a week and without a well-identified or self-limiting cause such as chemotherapy, radiation, or infection.³² Four major mechanisms are correlated with the stimulation of the vomiting center (Fig. 4–2). Potentially reversible causes of nausea and vomiting should not be overlooked. Causes of chronic nausea in end-of-life patients may include autonomic dysfunction, constipation, antibiotics, nonsteroidal anti-inflammatory drugs (NSAIDs), other drugs, infection, bowel obstruction, metabolic abnormalities (e.g., renal or hepatic failure, hypercalcemia), increased intracranial pressure, anxiety, radiation therapy, chemotherapy, or untreated pain.

► Nonpharmacologic Treatment in Palliative Care

- Relaxation techniques may prove beneficial in some patients. Strong foods or odors should be avoided and, if possible, eliminate offending medications.

► Pharmacotherapy in Palliative Care

The clinical features of nausea and vomiting should guide the choice of antiemetics used (for a more comprehensive review, refer to Chap. 20). The following are examples of managing nausea and vomiting as it correlates with the etiology:

Chemoreceptor trigger zone (CTZ)-induced nausea and vomiting are caused by chemotherapeutic agents, bacterial toxins, metabolic products (e.g., uremia), and opioids. Dopamine (D₂), serotonin (5-HT), and neurokinin-1 are the primary neurotransmitters involved in this process. Therapy is based on blocking D₂ with D₂-antagonists including butyrophenones (e.g., haloperidol), phenothiazines, and metoclopramide.

- Because of their receptor specificity, serotonin₃ (5-HT₃) antagonists such as ondansetron, granisetron, dolasetron, and palonosetron have limited usefulness in nausea and vomiting at the end of life.³³ They are typically indicated with emetogenic chemotherapy and up to 10 to 14 days posttreatment. Aprepitant is a neurokinin-1 antagonist that is also indicated for the treatment of nausea due to highly emetogenic chemotherapy in combination with a 5-HT₃ antagonist and corticosteroid. Aprepitant should not be used as a sole agent.

- **Cerebral cortex**-induced nausea and vomiting can be caused by anxiety, taste, and smell, and also as a result of increased intracranial pressure. Corticosteroids are administered to decrease intracranial pressure due to tumor involvement. In addition to their usefulness in reducing intracranial pressure, corticosteroids have also been found to be effective in nonspecific nausea and vomiting. The mechanism of this

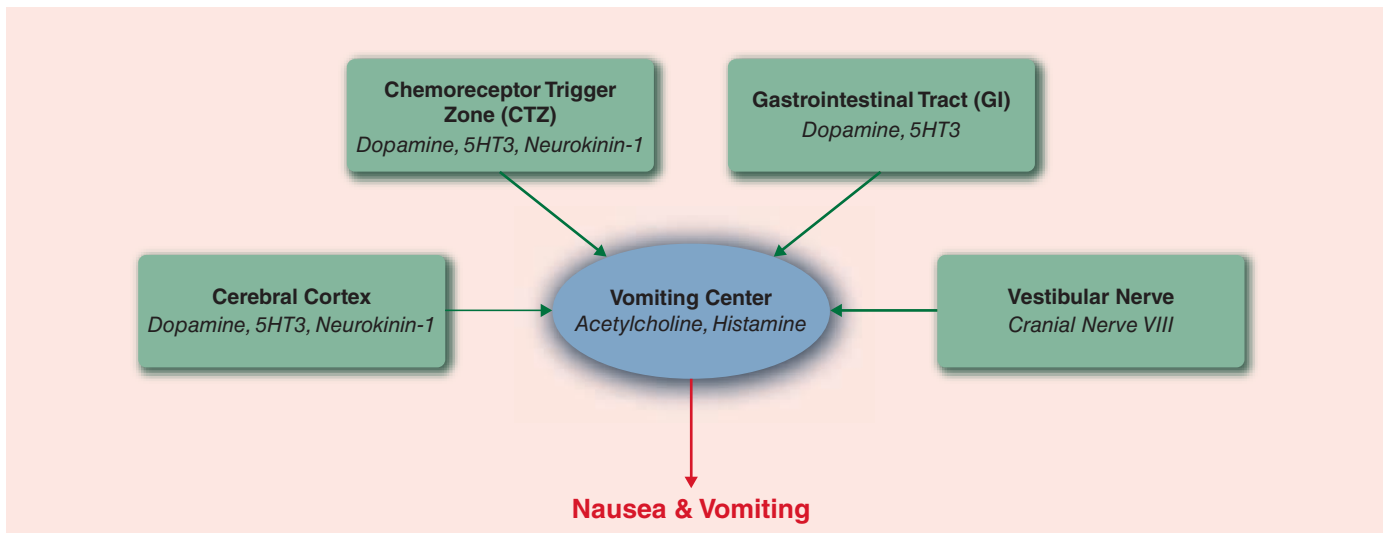

FIGURE 4-2. Mechanisms and associated neurotransmitters involved in nausea and vomiting.

action is unknown. Anxiolytics such as benzodiazepines are used to treat anxiety and “anticipatory” gustatory and olfactory stimulation.

Vestibular nausea and vomiting is triggered by motion. Opioids can sensitize the vestibular center resulting in movement-induced nausea. Ambulatory patients are more susceptible to vestibular nausea and vomiting than bedbound patients. Because histamine and acetylcholine are the predominant neurotransmitters here, antihistamines and anticholinergics are the drugs of choice in movement-induced nausea and vomiting.

GI tract stimulation occurs through vagal and sympathetic pathways. These pathways can be triggered by stimulation of either mechanoreceptors or chemoreceptors located in the gut. Gastric stasis, GI obstruction, drugs, metastatic disease, bacterial toxins, chemotherapeutic agents, and irradiation can lead to nausea and vomiting. Glossopharyngeal or vagus nerve stimulation in the pharynx by sputum, mucosal lesions, or infection (e.g., *Candida*) can also evoke nausea. The major neurotransmitters in the upper GI tract are D_2 , acetylcholine, and 5-HT. Metoclopramide is a 5-HT₄ agonist and increases gastric motility above the jejunum, whereas anticholinergics decrease GI spasticity and motility in nausea induced by gut hyperactivity. In high doses, metoclopramide also acts as a 5-HT₃ antagonist.

Autonomic failure causes gastroparesis resulting in anorexia, nausea, early satiety, and constipation. Delayed gastric emptying is frequently observed in patients with diabetes mellitus, chronic renal failure, and neurological disorders. Malnutrition, cachexia, lung and pancreatic cancers, HIV, radiotherapy, and drugs such as opioids, anticholinergics, antidepressants, and vasodilators have been associated with autonomic failure and resulting chronic nausea, poor performance, tachycardia, and malnutrition. Evaluate underlying causes, including multiple drugs that may cause gastroparesis. If drug therapy is indicated, metoclopramide is effective in improving gastric emptying.

GI irritation can cause nausea and vomiting due to generalized gastritis, hiatal hernia, gastroesophageal reflux disease (GERD), or peptic ulcer disease. Histamine₂ (H_2) antagonists or proton pump inhibitors (PPIs) are considered the drugs of choice for ongoing gastritis.

Refractory cases of nausea and vomiting often require judiciously selected combinations of medications from different classes (e.g., various combinations of haloperidol, metoclopramide, diphenhydramine, lorazepam, and dexamethasone).

Pain

A comprehensive review of pain management may be found in Chapter 34.

► Palliative Care Considerations

According to the SUPPORT study, 74% to 95% of very ill or dying patients still experience uncontrolled pain.³⁴ Although existing drug therapy affords the opportunity to manage more than 90% of pain, many patients needlessly suffer.⁴⁸ Conducting a comprehensive pain assessment is key to choosing appropriate therapeutic interventions. Because pain is subjective, both physical and humanistic factors must be considered. Patients in an end-of-life setting must also be evaluated for anxiety, depression, delirium, and other neurological influences that may heighten a patient’s awareness or response to pain.

► Nonpharmacologic Treatment in Palliative Care

Nonpharmacologic treatment is essential in chronic pain management. Physical, complementary, and cognitive behavioral interventions reduce the perception of pain and decrease the dose requirements of medications. Examples of such

strategies may include providing education and information about medical treatments (e.g., misconceptions and concerns about pain medications), massage, ice, heat, physical therapy, music therapy, imagery, pet therapy, and psychotherapy.

► Pharmacotherapy in Palliative Care

- Pain should be assessed thoroughly and frequently, especially at the onset of treatment. The approach of the World Health Organization (WHO) to pain management is appropriate for most nociceptive pain (see Chap. 34). Although opioid analgesics are not always necessary or appropriate for all types of pain, most patients with cancer-related pain require opioids. For chronic, constant pain, around-the-clock dosing of analgesics (preferably long-acting agents) is usually necessary and preferred.³⁵ When titrating opioid doses, increase daily maintenance doses by 25% to 50% if patients are routinely requiring three or more breakthrough doses per 24 hours as a result of around-the-clock maintenance dose failure. The around-the-clock maintenance doses should not be increased if breakthrough doses are used only for incident pain such as increased activity or dressing changes.

Fentanyl transdermal patches may be appropriate in some patients; however, many patients at the end of life experience fat and muscle wasting and dehydration, resulting in reduced and variable absorption. Fentanyl transdermal patches have a slow onset of action, contributing to difficulty in dose titration.

Only short-acting opioids should be used for breakthrough pain (e.g., immediate-release morphine, oxycodone, and hydromorphone are common examples). The dose of short-acting opioids for the treatment of breakthrough pain should be equal to 5% to 20% of the daily maintenance dose. Frequencies for breakthrough dosing should not exceed the following:

- **Oral:** Every 1 to 2 hours
- **Subcutaneous:** Every 20 to 30 minutes
- **IV:** Every 8 to 20 minutes
- Monitor for and appropriately treat common side effects of opioids. Common side effects of opioids include constipation, nausea and vomiting, itching, and transient sedation. Because constipation occurs with all chronic opioid therapy, prevention is imperative. Stimulant laxatives (senna or bisacodyl) with or without a stool softener (docusate) are the drugs of choice for opioid-induced constipation. Myoclonus, delirium, hallucinations, and hyperalgesia are possible signs of opioid-induced neurotoxicity and require rotation to another opioid or dose reduction. Respiratory depression is uncommon with the appropriate opioid dose titration. However, if dangerous opioid-induced respiratory depression does occur, small doses (0.1 mg) of the μ receptor antagonist naloxone are appropriate and can be repeated as necessary. The goal is to increase respirations to a safe level while preventing the patient from experiencing a loss of pain control.

Drugs that should not be used for treatment of pain during end-of-life care are listed in [Table 4-1](#).

Table 4-1

Drugs Not Recommended for Treatment in End-of-Life Care

Drug	Rationale
Meperidine	Meperidine has a short duration of analgesia (e.g., 2–3 hours) and its metabolite, normeperidine, may accumulate with repeated dosing, especially in geriatric patients, resulting in neurotoxicity
Opioid agonist-antagonists (e.g., pentazocine, butorphanol, nalbuphine)	The risk of precipitating withdrawal symptoms in opioid-dependent patients in addition to their ceiling dose and possible induction of psychomimetic effects (e.g., dysphoria, delusions, hallucinations) make this group of analgesics inappropriate for use

- Different types of pain may require specific types of analgesics or adjuvant medications. A few examples of types of pain other than nociceptive somatic pain that are commonly seen in patients with advanced illness are as follows.
- **Visceral pain** (nociceptive pain that is caused by stretching or spasms of visceral organs such as the GI tract, liver, and pancreas) should be treated with the standard WHO step approach to pain, with the addition of anticholinergic agents or, if inflammation is associated with the pain, corticosteroids.
- **Bone pain** (a common metastatic site of various cancers) is best treated with NSAIDs or corticosteroids in addition to standard opioid therapy.
- **Neuropathic pain** (pain caused by damage to the afferent nociceptive fibers) can be managed with tricyclic antidepressants, antiepileptic drugs, tramadol, tapentadol or *N*-methyl-D-aspartate antagonists such as ketamine. Methadone is an opioid μ -agonist that has a role in neuropathic pain given its added *N*-methyl-D-aspartate antagonist activity.

Terminal Secretions

► Palliative Care Considerations

Terminal secretions, or death rattle, is the noise produced by the oscillatory movements of secretions in the upper airways in association with the inspiratory and expiratory phases of respiration.^{36,37} As patients lose their ability to swallow and clear oral secretions, accumulation of mucus results in a rattling or gurgling sound produced by air passing through mucus in the lungs and air passages. The sound does not represent any discomfort for the patient. However, the sound is sometimes so distressing to the family that it should be treated. Terminal secretions are typically seen only in patients who are obtunded or are too weak to expectorate.

- Drugs that decrease secretions are best initiated at the first sign of death rattle because they do not affect existing respiratory secretions. These agents have limited or no impact when the secretions are secondary to pneumonia or pulmonary congestion or edema.

► **Nonpharmacologic Treatment in Palliative Care**

- Position the patient on his or her side or in a semiprone position to help facilitate drainage of secretions. If necessary, place the patient in the Trendelenburg position (lowering the head of the bed); this allows fluids to move into the oropharynx, facilitating an easy removal. Do not maintain this position for long because there is a risk of aspiration.
- Oropharyngeal suctioning is another option but may be disturbing to both the patient and visitors. Fluid intake can also be decreased, as appropriate.

► **Pharmacotherapy in Palliative Care**

- Anticholinergic drugs remain the standard of therapy for prevention and treatment of terminal secretions due to their ability to effectively dry secretions.^{36–38} Drugs used for this indication are similar pharmacologically, and one can be selected by anticholinergic potency, onset of action, route of administration, alertness of patient, and cost. The most commonly used anticholinergic agents are atropine, hyoscyamine, scopolamine, and glycopyrrolate.

Anticholinergic side effects are common and include blurred vision, constipation, urinary retention, confusion, delirium, restlessness, hallucinations, dry mouth, and heart palpitations. Unlike the other anticholinergics, glycopyrrolate does not cross the blood–brain barrier and is associated with fewer CNS side effects. Glycopyrrolate is a potent drying agent when compared with others agents and has the potential to cause excessive dryness.³⁸

Advanced Heart Failure

► **Palliative Care Considerations**

- Heart failure symptoms at the end of life may include hypotension, volume overload, edema, and fatigue. Patients should be assessed to confirm symptoms are related to heart failure rather than other disease states to ensure appropriate treatment strategies.^{39,40} The goals for advanced heart failure treatment will differ from traditional heart failure management. Drug therapy will be focused on symptom management rather than improving mortality. Prevention of cardiovascular disease through cholesterol reduction is no longer necessary at this point.

► **Nonpharmacologic Treatment in Palliative Care**

- Patients should be maintained in a comfortable position with feet elevated to minimize lower leg fluid accumulation. Minimizing high-salt foods and limiting fluid intake can help reduce fluid accumulation associated with a failing heart. The patient should not overexert during physical activity.

At this stage in heart failure, comfort becomes the primary initiative.

► **Pharmacotherapy in Palliative Care**

As patients approach the end of life, it is difficult to determine when certain medications for heart failure should be dose reduced or discontinued. The following general principles may help serve as a guide. However, each individual's history, prognosis, and current condition should be evaluated to determine appropriateness.

- If a patient becomes symptomatic due to hypotension, angiotensin-converting enzyme (ACE) inhibitor, angiotensin receptor blocker (ARB), and/or β -adrenergic blocker doses should be reduced or discontinued. For β -adrenergic blockers, in particular, this should be done gradually to avoid significant clinical deterioration. If volume overload occurs or persists while taking β -adrenergic blocker therapy, consider tapering off the medication. Likewise, for patients experiencing fatigue while taking a β -adrenergic blocking agent, consider tapering down the dose *only if* their heart rate does not increase with exertion. Consider discontinuing the ACE inhibitor (or the angiotensin receptor blocker) if the patient's renal function deteriorates (e.g., cardiorenal syndrome).

In patients with excessive fluid overload where sodium and water intake restrictions are not effective or not possible, consider increasing the dose of diuretic. However, vascular dehydration can occur in some patients with end-stage heart failure if the dose of diuretic is excessive.

- Digoxin toxicity is common; therefore, patients should be carefully monitored and therapy adjusted or discontinued as appropriate. The symptoms of digoxin toxicity including complaints of anorexia, nausea and vomiting, visual disturbances, disorientation, confusion, or cardiac arrhythmias.
- Hydroxymethylglutaryl coenzyme-A (HMG-CoA) reductase inhibitors (and other cholesterol-lowering medications) are likely to have a long-term effect rather than a palliative effect. If patients are eligible for hospice admission, consider discontinuing lipid lowering therapy.

Figure 4–1 provides a list of agents that improve functional status in advanced heart failure patients.

OUTCOME EVALUATION

- **6** *Involving the patient, family, and caregivers in the development of the therapeutic plan demonstrates responsible palliative care.* Before the implementation of drug therapy, the patient, family, and caregiver should be involved with the decision-making process. The practitioner should provide information about all reasonable options for care so that the patient, family and caregivers can collaborate with the healthcare team to meet their combined goals.
- **7** *Positive therapeutic outcomes include resolution of symptoms while minimizing adverse drug events.* When treating symptoms pharmacologically, adverse drug events must be avoided or minimized to prevent negative outcomes.

Patient Encounter 3

RD, a 73-year-old female, is admitted to the hospice inpatient unit with a complaint of fever, nausea and occasional vomiting, confusion, insomnia, and agitation. Her nausea started approximately 2 weeks ago and has progressively worsened. She has not had a bowel movement for 5 days. Her agitation and confusion began suddenly 2 days ago. The patient was admitted to hospice with a diagnosis of breast cancer with metastases to the brain, bone, liver, and lungs. RD also has a past medical history of osteoarthritis, hypertension, hypercholesterolemia, mild dementia, and frequent urinary tract infections. She has a Foley catheter in place. RD's family history is unknown. The patient's medical record states she is allergy to codeine.

Meds: Naproxen 500 mg every 6 hours as needed for osteoarthritis pain (started 4 weeks ago); enalapril 10 mg twice daily; simvastatin 40 mg by mouth daily; celecoxib 100 mg twice daily; acetaminophen 325 mg every 6 hours as needed for pain; morphine sustained-release tablets 15 mg every 12 hours, hydrocodone/acetaminophen 5/325 mg two tablets every 6 hours as needed for cancer pain; St. John's Wort (the patient takes as needed for depression)

What are potential causes of her nausea and vomiting and her confusion and agitation?

What potential drug–drug interactions and side effects exist in this patient?

What medications could be added, changed, and/or discontinued?

How does the patient's reported allergy to codeine impact potential treatment options?

- Patients with life-limiting diseases have emotional and spiritual issues that deserve attention by trained professionals. Addressing these concerns and providing support and coping skills can dramatically reduce the medication requirements for symptom control. Psychosocial and spiritual support is not only directed toward the patient in palliative care but also supports the family during the time of the illness and after the death of their loved one.
- **8** *Patient and caregiver education is vital to ensuring positive outcomes.* If the patient and caregiver are unaware of the purpose and goals for interventions used in palliative medicine, adherence to regimens will be hindered and outcomes will be compromised. Education regarding the role and value of the palliative care team will allow the patient and family to understand why palliative care is important to their overall quality of life. Patients will achieve the best possible outcomes when practitioners incorporate the interdisciplinary palliative care approach to care early in the disease progression of patients with life limiting illnesses.

Patient Care and Monitoring

Other symptoms that are commonly observed in palliative care that the practitioner should monitor:

- **Depression:** Patients may need to experience more immediate symptom relief than typical antidepressants may provide. Methylphenidate may be an appropriate option for treatment in patients with life expectancies less than 6 to 8 weeks.
- **Insomnia:** Many times patients experience insomnia due to a lack of appropriate symptom management. In addition to ensuring that all physical symptoms are controlled and that good sleep hygiene is practiced, addressing the emotional and spiritual concerns that patients frequently experience is critical for effectively managing insomnia.
- **Constipation:** Most patients experience constipation as a result of opioid use. Opioid-induced constipation requires management with a stimulant laxative such as senna or bisacodyl. Other causes of constipation include other drugs, including anticholinergic agents and calcium channel blockers, calcium, iron, and other dietary supplements, poor hydration, and immobility. Careful assessment of etiology is important before implementing treatment.
- **Diarrhea:** Patients experiencing fluid loss through excessive diarrhea need to be monitored for dehydration and electrolyte imbalance. Fluid replacement is typically the first line of therapy in addition to drug therapy to minimize the symptom. Overflow diarrhea from constipation or a bowel obstruction is often misdiagnosed and treated inappropriately, worsening the problem.
- **Dysphagia:** Difficulty swallowing is common in end-of-life patients and may necessitate that medications be given through alternative routes of administration. Knowledge of drug absorption and disposition when administered rectally, sublingually, and topically is key in good clinical decision making.

Abbreviations Introduced in This Chapter

5-HT	5-Hydroxytryptophan (serotonin)
ACE	Angiotensin-converting enzyme
ALS	Amyotrophic lateral sclerosis
ARB	Angiotensin receptor blocker
CHF	Chronic heart failure
COPD	Chronic obstructive pulmonary disease
CTZ	Chemoreceptor trigger zone
CVA	Cerebrovascular accident
ESRD	End-stage renal disease
GERD	Gastroesophageal reflux disease

HMG-CoA	Hydroxymethylglutaryl coenzyme-A
NSAID	Nonsteroidal anti-inflammatory drug
PEG	Percutaneous endoscopic gastrostomy
PICC	Peripherally inserted central catheter
PPI	Proton pump inhibitors
SSRI	Selective serotonin reuptake inhibitor
WHO	World Health Organization

5 Hypertension

Robert J. Straka, David Parra, and
Stephanie Kaiser

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Classify blood pressure (BP) levels and treatment goals.
2. Recognize underlying causes and contributing factors in the development of hypertension.
3. Describe the appropriate measurement of BP.
4. Recommend appropriate lifestyle modifications and pharmacotherapy for patients with hypertension.
5. Identify populations requiring special consideration when designing a treatment plan.
6. Construct an appropriate monitoring plan to assess hypertension treatment.

KEY CONCEPTS

- 1 Hypertension is widely prevalent and significantly contributes to cardiovascular morbidity, mortality, and associated healthcare costs.
- 2 The cause of hypertension is unknown in the majority of cases (primary hypertension), but for patients with secondary hypertension, specific causes can be identified.
- 3 Patients failing to achieve goal blood pressure (BP) despite adherence to optimal doses of three distinct antihypertensive agents (ideally, one being a diuretic) have resistant hypertension and should be evaluated for secondary causes of hypertension.
- 4 The pathophysiology of primary hypertension is heterogeneous but ultimately exerts its effects through the two primary determinants of BP: cardiac output (CO) and peripheral resistance (PR).
- 5 Appropriate technique in measuring BP is a vital component to the diagnosis and continued management of hypertension.
- 6 Drug selection for the management of patients with hypertension should be considered as adjunctive to nonpharmacologic approaches for BP lowering, and ultimately the attainment of target BP in many cases may be more important than the antihypertensive agent used.
- 7 Implementation of lifestyle modifications successfully lowers BP, often with results similar to those of therapy with a single antihypertensive agent.

- 8 An approach to selection of drugs for the treatment of patients with hypertension should be evidence based. Consideration should be given to the individual's comorbidities, co-prescribed medications, and practical patient-specific issues including costs.
- 9 Specific antihypertensive therapy is warranted for certain patients with comorbid conditions that may elevate their level of risk for cardiovascular disease (CVD).
- 10 The frequency of follow-up visits for patients with hypertension varies based on individual cases but is influenced by the severity of hypertension, comorbidities, and choice of agent selected.

INTRODUCTION

Despite efforts to promote awareness, treatment, and the means available to aggressively manage high blood pressure (BP), trends over the past 15 years demonstrate only modest improvements in its treatment and control. National and international organizations continually refine their recommendations of how clinicians should approach the management of patients with high BP, and although approaches vary to some degree, there are clear themes that emerge regardless of which national or international organization's algorithm is followed. The purpose of this chapter is to (a) provide a summary of key issues associated with the management of patients with hypertension, (b) discuss the basic approach to treating patients with hypertension and provide a functional summary of the currently prevailing themes of national guidelines, and (c) summarize salient pharmacotherapeutic

issues essential for clinicians to consider when managing patients with hypertension.

Various algorithms recommend nonpharmacologic and pharmacologic management with the underlying theme that achievement of BP targets mitigate end-organ damage, leading to substantial reductions in stroke, myocardial infarction (MI), end-stage renal disease, and heart failure (HF). Although references to other algorithms are mentioned, this chapter focuses primarily on the American Heart Association (AHA) Scientific Statement on the treatment of hypertension in the prevention and management of ischemic heart disease,¹ the American College of Cardiology Foundation (ACCF)/AHA expert consensus document on hypertension in the elderly,² and the *Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure*, more commonly referred to as the Joint National Committee Seventh Report (JNC 7) report.³ Additional references to recommendations from other authoritative organizations are made when pertinent. It should be noted that an update of the JNC 7 report (JNC 8) is expected to be released in 2012.

The JNC 7 report describes four stages of BP classification and provides guidance on nonpharmacologic and pharmacologic approaches to managing patients with hypertension. The four stages of BP classification include normal, prehypertension, stage 1 hypertension, and stage 2 hypertension (Table 5-1). These stages are defined as such to connote a level of risk and thus the need for varying intensities of intervention with drug therapy (Fig. 5-1).³ With the exception of individuals with “compelling indications,” recommendations for drug therapy typically begin with one or two (in the case of stage 2) antihypertensive drugs as an

initial step. Specific drug selection is guided by the presence of compelling indications—specific comorbid conditions. These compelling indications, such as HF, diabetes, and chronic kidney disease (CKD), represent specific conditions for which explicit evidence in the literature exists to document the utility of a particular agent or class of agents.

- Selection of drug therapy consequently involves an iterative process of considering multiple antihypertensive drugs as needed to achieve target BPs of less than 140/90 mm Hg for all patients, with more aggressive targets of less than 130/80 mm Hg for patients with diabetes or chronic (greater than 3 months) kidney disease (estimated glomerular filtration rate [GFR] less than 60 mL/min/1.73 m² [0.58 mL/s/m²] or the presence of albuminuria [300 mg/day or 200 mg/g creatinine or 22.6 mg/mmol creatinine]).³ In addition, the AHA scientific statement on the treatment of hypertension in the prevention and management of ischemic heart disease expands those in whom a lower BP target of less than 130/80 mm Hg should be pursued to include patients with known coronary artery disease or coronary artery disease risk equivalents (carotid artery disease, peripheral arterial disease, abdominal aortic aneurysm), or a 10-year Framingham risk score of greater than 10%. See Chapter 12, “Dyslipidemias.” In patients with left ventricular dysfunction, additional BP lowering to a target of less than 120/80 mm Hg may also be considered.¹ However, in contrast, the ACCF/AHA expert consensus document on hypertension in the elderly (patients 65 years of age or older) considers an achieved systolic BP of 140 to 145 mm Hg acceptable, if tolerated, in patients 80 years or older, whereas in those younger than 80 an achieved systolic BP of less than 140 mm Hg is appropriate.²

Table 5-1

Classification of BP in Children, Adolescents, and Adults^a

BP Classification	Adult SBP (mm Hg)	Adult DBP (mm Hg)	Children/Adolescents SBP or DBP Percentile ^b
Normal	Less than 120	and less than 80	Less than 90th
Prehypertension	120–139	or 80–89	90–95th or 120/80 mm Hg
Stage 1 hypertension	140–159	or 90–99	95–99th + 5 mm Hg ^c
Stage 2 hypertension	Greater than or equal to 160	Greater than or equal to 100	Greater than 99th + 5 mm Hg ^d

BP, blood pressure; DBP, diastolic blood pressure; SBP, systolic blood pressure.

^aDefined as 18 years old or more.

^bTables contain the 50th, 90th, and 99th percentiles of SBP and DBP standards based on percentile height by age and sex, which is used to compare the child's measured BP on three separate occasions. The difference in BP of the 95th and 99th percentiles is 7 to 10 mm Hg, which requires an adjustment of 5 mm Hg to accurately categorize stage 1 or 2 hypertension. If the systolic and diastolic percentile categories are different, then classify hypertension by the higher BP value.

^cChildren and adolescents' stage 1 hypertension is classified by BP levels that range from the 95th percentile to 5 mm Hg above the 99th percentile.

^dChildren and adolescents' stage 2 hypertension is classified by BP levels that are greater than 5 mm Hg above the 99th percentile.

Adapted from Chobanian AV, Bakris GL, Black HR, et al. Seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. *Hypertension* 2003;42:1206–1252.

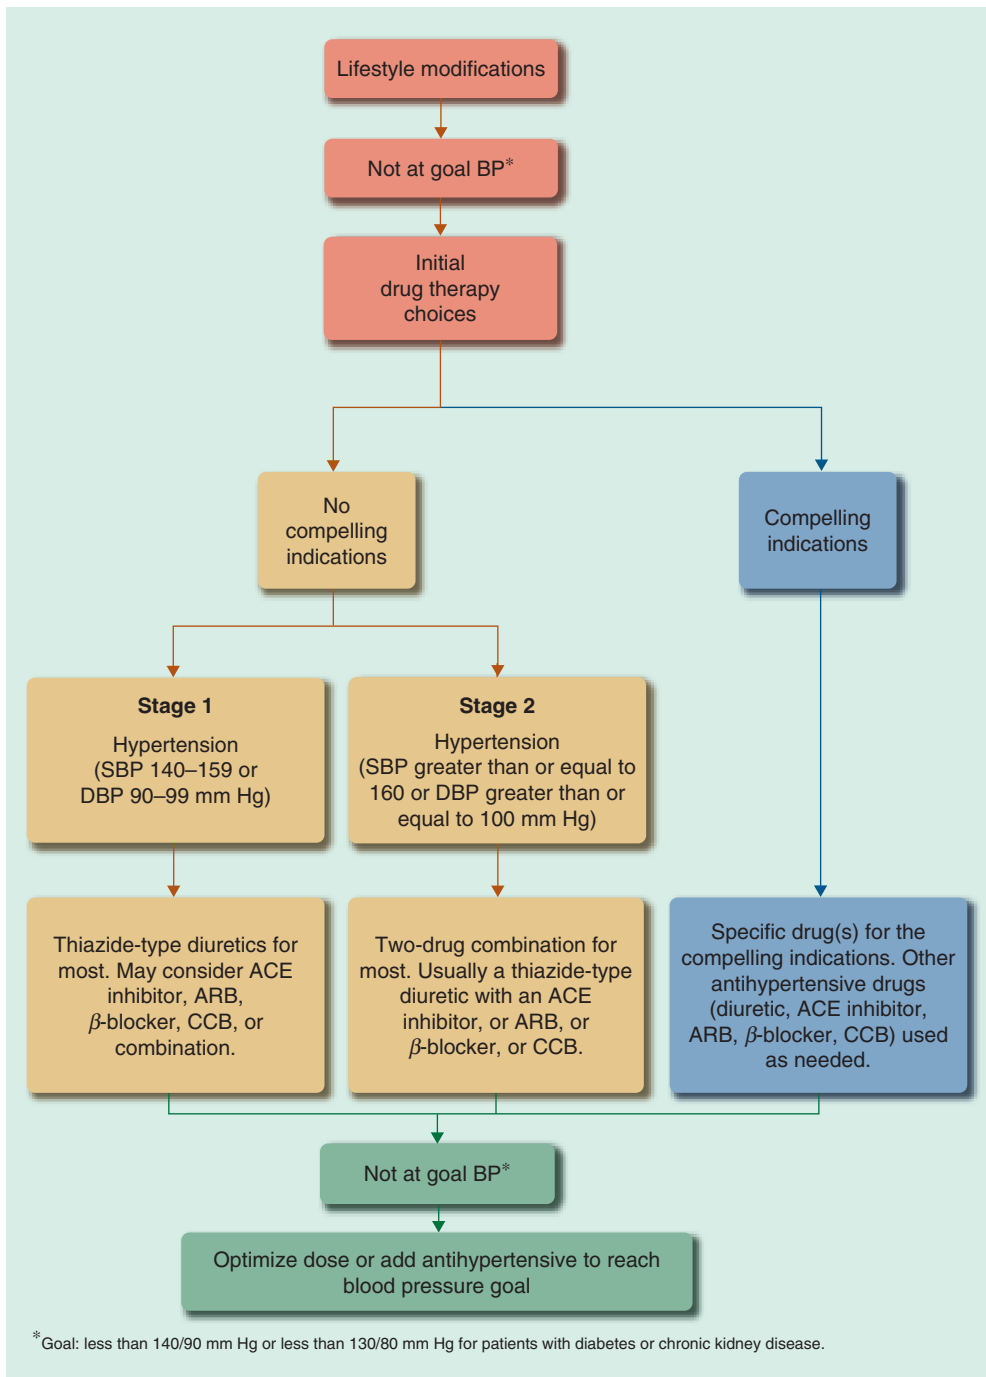

FIGURE 5-1. Algorithm for treatment of hypertension when patients are not at their goal BP. Compelling indications refer to specific indications where the selection of a particular antihypertensive drug class for a defined high-risk population is highly recommended. These recommendations are usually based on results from landmark randomized placebo-controlled outcome trials or consensus statements from clinical guidelines and are usually based on findings documenting superior outcomes in terms of morbidity and mortality. (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BP, blood pressure; CCB, calcium channel blocker; DBP, diastolic blood pressure; SBP, systolic blood pressure.) (From Chobanian AV, Bakris GL, Black HR, et al. Seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. *Hypertension* 2003;42:1206–1252.)

EPIDEMIOLOGY

1 *Hypertension is widely prevalent and significantly contributes to cardiovascular morbidity, mortality, and associated healthcare costs.* Worldwide prevalence of hypertension in 2000 was estimated to be 1 billion with a projected increase to over 1.5 billion by the year 2025.⁴ Globally, 51% of all strokes and 45% of ischemic heart disease deaths are attributable to hypertension, and it is the leading risk factor for cause of death worldwide.⁵ The prevalence of hypertension in the United States is among the highest in the world and

estimated to include over 76 million individuals (1 in 3 adults 20 years of age or older), with an estimated \$43.5 billion spent annually in direct and indirect costs. Furthermore, it is estimated that 29.7% of the U.S. population older than 20 years of age has prehypertension.⁶ The prevalence of hypertension differs based on age, sex, and ethnicity. As individuals become older, their risk of systolic hypertension increases. Individuals 40 years of age who do not have hypertension are estimated to have a remaining lifetime risk of 90% of eventually developing hypertension. In the United States, hypertension is slightly more prevalent in men than

Patient Encounter 1

A 52-year-old African American man comes into your clinic with concerns about his BP. He arrived after his morning BP measurements at home were 154/96 mm Hg, and when repeated 160/100 mm Hg. Upon examination in your clinic, seated BP in the left arm is 144/86 mm Hg and 142/84 mm Hg in the right arm. You request that the patient return to your clinic in 1 week for a follow-up BP. His seated BPs in the left arm 1 week later were 148/84 mm Hg and 144/80 mm Hg. The patient's physical examination was unremarkable, but his past medical history was significant for dyslipidemia and depression. His previous cholesterol panel revealed a high-density lipoprotein of 52 mg/dL (1.34 mmol/L), triglyceride level of 180 mg/dL (2.03 mmol/L), and total cholesterol of 198 mg/dL (5.12 mmol/L). Calculated low-density lipoprotein level is 110 mg/dL (2.84 mmol/L). All other laboratory values were within normal limits. Of note, he does smoke one pack of cigarettes per day. Current medications include aspirin, simvastatin, and citalopram.

Based on the information above, what stage of hypertension does this patient have?

What is the patient's BP target according to JNC 7 guidelines?

What is the patient's BP target using the recommendations from the 2007 American Heart Association Statement on the treatment of hypertension in the prevention and management of ischemic heart disease?

What steps are involved in assuring that the patient's BP measurements are accurate?

women before the age of 45 years, similar between the ages of 45 and 64 years, and higher in women than men thereafter. In addition, age-adjusted prevalence of hypertension is highest in non-Hispanic blacks (41.4%) when compared with non-Hispanic whites (28.1%) and Hispanic Americans (21.5%).⁶

ETIOLOGY

2 In most patients (greater than 90%), the cause of hypertension is unknown and referred to as primary hypertension as opposed to older nomenclature such as benign or essential hypertension.⁷ However, in some patients there is an identifiable cause of hypertension, referred to as secondary hypertension. Common causes of secondary hypertension include¹:

- CKD
- Coarctation of the aorta
- Cushing's syndrome and other glucocorticoid excess states
- Drug induced/related (Table 5-2)
- Pheochromocytoma
- Primary aldosteronism and other mineralocorticoid excess states

Table 5-2

Causes of Resistant Hypertension

Apparent Resistance

Improper blood pressure measurement
Failure to receive or take antihypertensive medication
Inadequate doses (subtherapeutic)
Improper antihypertensive selection or combination
White coat effect

True Resistance

Secondary hypertension
Medication effects and interactions
 Nonsteroidal anti-inflammatory medications
 Sympathomimetics (decongestants, anorectics, and stimulants)
 Cocaine, amphetamines, and other illicit drugs
 Recent caffeine or nicotine intake
 Oral contraceptive hormones
 Adrenal steroid hormones
 Erythropoietin
 Natural licorice (including some chewing tobacco)
 Cyclosporine and tacrolimus
 Herbal products (ma huang, guarana, bitter orange, blue cohosh)
 Vascular endothelial growth factor inhibitors (bevacizumab, sorafenib, sunitinib)
 Neurologic and psychiatric agents (e.g., venlafaxine, modafinil)
Volume overload
Excess sodium intake
Inadequate diuretic therapy
Fluid retention from kidney disease or potent vasodilators (e.g., minoxidil)
Comorbidities
 Obesity
 Excess alcohol intake
 Chronic pain syndromes
 Intense vasoconstriction (arteritis)
 Anxiety-induced hyperventilation/panic attacks
Genetic variation
 Genetic differences in drug efficacy or metabolism

Seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. *Hypertension* 2003;42:1206–1252; Izzo JL, Sica DA, Black HR, Council for High Blood Pressure Research (American Heart Association). *Hypertension Primer*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008.

- Renovascular hypertension
- Sleep apnea
- Thyroid or parathyroid disease

Identification of a secondary cause of hypertension is often not initially pursued unless suggested by routine clinical and laboratory evaluation of the patient or a failure to achieve BP control.

In addition to primary and secondary hypertension, the clinician may encounter what is referred to as resistant hypertension.⁸ **3** Patients failing to achieve goal BP despite adherence to optimal doses of three antihypertensive agents of different classes (ideally, one being a diuretic) have resistant hypertension and should be evaluated for secondary causes of hypertension. Several causes of resistant hypertension are listed in Table 5-2 and should be carefully considered in such patients.

PATHOPHYSIOLOGY

4 The pathophysiology of primary hypertension is heterogeneous but ultimately exerts its effects through the two primary determinants of BP: **cardiac output** (CO) and **peripheral resistance** (PR). The processes influencing these two determinants are numerous and complex, and although the underlying cause of primary hypertension remains unknown, it is most likely multifactorial. An in-depth review of these mechanisms is beyond the scope of this text. See additional sources for more information on the pathophysiology behind the primary and secondary causes of hypertension.^{7,9}

The development of primary hypertension can be summarized as an interplay between genetic and environmental factors and their subsequent interaction with multiple hypertensive mechanisms that can be classified as neural, renal, hormonal, and vascular. A brief description of these follows, but we remind you that no final common pathway has been identified, and as such, a single target for the treatment of primary hypertension remains elusive. Further complicating this is that different hemodynamic subsets and phenotypes of primary hypertension (e.g., diastolic hypertension in middle-aged persons, isolated systolic hypertension in the elderly, and obesity-related hypertension) may have different contributing mechanisms.⁷

Genetic Factors

Although multiple genetic polymorphisms have been associated with relatively small effects on hypertension including systolic blood pressure (SBP), diastolic blood pressure (DBP), and response to antihypertensive medications, replication of these findings in large populations are generally lacking. Consequently, the information available to date is far from being able to be used as a basis for any practical guidance for clinicians.⁷ Nevertheless, it is estimated that up to 60% of the familial association of BP has a genetic basis,^{10,11} and increasingly the genetic basis of variability in response to drug therapy continues to be pursued aggressively. Although progress related to understanding of drug response variability continues through utilizing novel approaches and large databases,¹² the status of these efforts and specific candidate gene approaches have yet to translate into any genetic-based guidance for clinicians seeking to use these tools when selecting and utilizing antihypertensive agents.¹³

Environmental Factors

As opposed to genetic factors, environmental factors contributing to hypertension are well characterized. Cigarette smoking (cigars and smokeless tobacco too) and caffeine cause transient increases in BP via norepinephrine release and, in the case of caffeine, by its antagonism of vasodilatory adenosine receptors.¹⁴ Acute alcohol ingestion may have a variable effect (increased due to sympathetic nerve activity or lowering due to vasodilation), which is transient, whereas chronic heavy consumption of alcohol and binge drinking raises the risk of hypertension.^{7,15} Many other environmental factors have been shown, or been proposed, to influence BP

and, in some cases, contribute to the development of hypertension. Some of the more common ones include obesity, physical inactivity, fetal environment (e.g., maternal malnutrition, increased fetal exposure to maternal glucocorticoids), postnatal weight gain, potassium and magnesium depletion, vitamin D deficiency, and environmental toxins (e.g., lead).⁷ Many of these environmental factors can and should be addressed by comprehensive dietary and lifestyle counseling by healthcare providers during patient encounters.

Neural Mechanisms

Overactivity of the sympathetic nervous system (SNS) in the early stages of primary hypertension manifests as increased heart rate, CO, and peripheral vasoconstriction. Despite this, it has been difficult to quantify the overall contribution of the SNS, and recent cardiovascular outcome trials have found that drugs targeting the SNS (α -adrenergic and β -adrenergic blockers) have not performed as well as other classes of drugs. Nevertheless, strategies aimed at targeting the SNS continue to be pursued with specific interest in invasive strategies aimed at severe refractory hypertension. These include baroreflex sensitization via implantation of a carotid sinus pacemaker and renal sympathetic denervation via catheter-based radiofrequency ablation.^{7,16}

Renal Mechanisms

The contribution of sodium to the development of primary hypertension is related to excess sodium intake and/or abnormal sodium excretion by the kidneys. Proposed mechanisms supporting either of these are numerous and complex.⁷ However, it is generally accepted that dietary salt is associated with increases in BP that can be lowered with reduction of sodium intake, particularly in individuals deemed salt sensitive.^{3,17} Although variables such as ethnicity and level of hypertension play a role, some 30% to 50% of subjects may be salt sensitive. For example, 29% of the participants in the Dietary Approaches to Stop Hypertension (DASH)-Sodium trial were deemed to be salt sensitive and responded to reductions in salt intake.^{17,18} In addition, there appears to be a threshold effect of sodium intake in the range of 50 to 100 mmol/day (1.2 to 2.4 g) and its impact on BP. The mean sodium intake per day is 175 mmol (4.1 g) for men and 120 mmol (2.7 g) for women in the United States, with the majority derived from processed foods.³ Although population-wide based reduction in dietary sodium intake via global policies has been widely advocated as an approach to reduce hypertension and cardiovascular disease (CVD), it is not universally accepted, with calls for further scientific investigation into the matter.^{19,20}

Hormonal Mechanisms

Since the discovery of renin over 100 years ago, the renin-angiotensin-aldosterone system (RAAS) has been extensively studied as a prime target or site of action for many effective antihypertensives.²¹ Renin is produced and stored

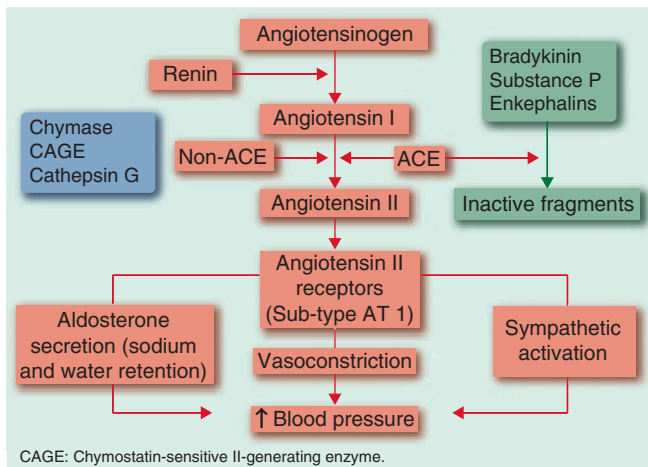

FIGURE 5-2. Diagram of the RAAS, a key system involved in the modulation of BP. The diagram depicts the pathways involved in the action of various antihypertensives including ACE inhibitors, ARBs, diuretics, and aldosterone antagonists. By inhibiting the action of angiotensin-converting enzymes, ACE inhibitors reduce both the formation of the vasoconstrictor angiotensin II and the degradation of vasodilating substances including bradykinin. ARBs primarily act through inhibition of the action of angiotensin II on the angiotensin-I receptors that modulate vasoconstriction. Aldosterone antagonists directly inhibit the actions of aldosterone; diuretics affect sodium and water retention at a renal level. (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blockers; AT1, angiotensin-1; BP, blood pressure; RAAS, renin-angiotensin aldosterone system.) (From Victor RG, Kaplan NM. *Kaplan's Clinical Hypertension*, 10th ed. Philadelphia, PA: Wolters Kluwer Lippincott Williams & Wilkins Health, 2010.)

in the juxtaglomerular cells of the kidney, and its release is stimulated by impaired renal perfusion, salt depletion, and β_1 -adrenergic stimulation. The release of renin is the rate-limiting step in the eventual formation of angiotensin II, which is primarily responsible for the pressor effects mediated by the RAAS (Fig. 5-2⁷). The role of the RAAS in primary hypertension is supported by the presence of high levels of renin, suggesting the system is inappropriately activated. Proposed mechanisms behind this inappropriate activation include increased sympathetic drive, defective regulation of the RAAS (nonmodulation), and the existence of a subpopulation of ischemic nephrons that release excess renin.⁷ However, there are also patients with primary hypertension and low levels of renin. This observation suggests that alternative mechanisms for hypertension unrelated to renin levels or activity may be in play, prompting renewed investigation into the use of plasma renin activity (PRA) measurements to guide antihypertensive therapy selection.²²⁻²⁴ In fact, it has been demonstrated that patients with low PRA (less than 0.65 ng/mL/h [0.18 ng/L/s]) respond preferentially to diuretics, aldosterone antagonists, and calcium channel blockers, whereas those with higher PRA levels respond preferentially

to renin-mediated therapies such as β -blockers, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and direct renin inhibitors.²⁵⁻²⁷

Vascular Mechanisms

- Elevated peripheral arterial resistance is the hemodynamic hallmark of primary hypertension. The increase in peripheral resistance typically observed may be due to a reduction in the arterial lumen size as a result of vascular remodeling. This remodeling, or change in vascular tone, may be modulated by various endothelium-derived vasoactive substances, growth factors, and cytokines. This increase in arterial stiffness or reduced compliance results in the observed increase in systolic BP.⁷

Contributing Comorbidities

- Several comorbidities have a high concurrence with the presence of hypertension leading to a higher risk of target organ damage, cardiovascular morbidity and mortality, and overall healthcare costs. Specifically, these include the presence of diabetes mellitus, dyslipidemia, obesity, and CKD. As such, the assessment of global cardiovascular risk in all patients with hypertension should be part of the management plan while also pursuing target BPs through nonpharmacologic and pharmacologic means. Regardless of the initiating process or processes leading to the development of hypertension, the ultimate goal is to reduce the risk of cardiovascular events and minimize target organ damage. This clearly requires the early identification of risk factors and treatment of patients with hypertension.

MEASUREMENT OF BLOOD PRESSURE

- 5** *Appropriate technique in measuring BP is a vital component to the diagnosis and continued management of hypertension.* Accurate measurement of a patient's BP identifies and controls for factors that may influence the variability in the measure. Failure to consider how each of these factors may influence BP measurement results in significant variation, leading to misclassification or inaccurate assessments of risk. Factors including body position, cuff size, device selection, auscultatory technique, and dietary intake prior to the clinic visit may contribute to such inaccuracies. Clinicians should instruct patients to avoid exercise, alcohol, caffeine, or nicotine consumption 30 minutes before BP measurement. Patients should be sitting comfortably with their back supported and arm free of constrictive clothing with legs uncrossed and feet flat on the floor for a minimum of 5 minutes before the first reading. Systolic and diastolic BP tend to increase when the cuff size is too small. Ideally, the cuff bladder should encircle at least 80% of the arm's circumference to ensure a more accurate measurement of BP.

Mercury sphygmomanometers are recommended for routine office measurements, but concerns of patient exposure and environmental contamination of mercury have fostered the development of other devices to measure BP.

Clinical Presentation and Diagnosis of Primary Hypertension

General

Age: Prevalence of hypertension is likely to be highest with middle-aged or older patients

Sex: In the United States, hypertension is slightly more prevalent in men than women before the age of 45 years, similar between the ages of 45 and 64 years, and higher in women than men thereafter

Symptoms

The patient with primary hypertension may be asymptomatic yet still have major CVD risk factors

Signs

Adult patients have an average of two or more BP readings (SBP and DBP) on two separate occasions indicating either:

	SBP (mm Hg)	DBP (mm Hg)
Normal	Less than 120	Less than 80
Prehypertension	120–139	or 80–89
Stage 1 hypertension	140–159	or 90–99
Stage 2 hypertension	Greater than or equal to 160	Greater than or equal to 100

Laboratory Tests (not necessarily indicative of hypertension but should be measured in patients with hypertension)

Fasting lipid panel:

- Low-density lipoprotein greater than 160 mg/dL (4.14 mmol/L)
- Total cholesterol greater than 240 mg/dL (6.21 mmol/L)
- HDL less than 40 mg/dL (1.03 mmol/L)
- Triglycerides greater than 200 mg/dL (2.26 mmol/L)

Fasting plasma glucose or hemoglobin A1c (does not need to be fasting):

- Impaired fasting glucose is 100–125 mg/dL (5.6–6.9 mmol/L)
- Diagnosis of diabetes with fasting glucose greater than or equal to 126 mg/dL (7.0 mmol/L) or a hemoglobin A1c

greater than or equal to 6.5% (0.065; 48 mmol/mol Hb) on two separate occasions, or a random plasma glucose reading of greater than or equal to 200 mg/L (11.1 mmol/L) with symptoms of diabetes

The following abnormal tests may indicate hypertension-related damage:

- Serum creatinine elevated (greater than 1.2 mg/dL [106 μmol/L])
- **Microalbuminuria**, which is diagnosed either from a 24-hour urine collection (20–200 mcg/min) or from elevated concentrations (30–300 mg/L) on at least two occasions. Use of the albumin-to-creatinine ratio (ACR) in a spot urine sample is becoming more common, and microalbuminuria is defined by this measure as 30–300 mg/g creatinine (3.4–33.9 mg/mmol creatinine)

Common Comorbidities and Factors Contributing to CV Risk

Diabetes mellitus
 Metabolic syndrome
 Insulin resistance
 Dyslipidemia
 Microalbuminuria/CKD
 Family history
 Central obesity
 Physical inactivity
 Tobacco use

Target Organ Damage

Heart (left ventricular hypertrophy, angina, prior myocardial infarction, prior coronary revascularization, HF)
 Brain (stroke or transient ischemic attack, dementia)
 CKD
 Peripheral arterial disease
 Retinopathy

However, there is no general consensus among healthcare providers as to an acceptable replacement for mercury sphygmomanometers.

To reduce deviations in BP measurement in the clinic, the patient and clinician should not talk during BP readings. The measurement arm is supported and positioned at heart level. If a mercury or aneroid device is used, then the palpatory method must be used first to estimate the SBP.²⁸ If an automated device is used, this is not necessary. After the patient's cuff is inflated above the systolic pressure, the mercury column should drop at a rate of 2 to 3 mm Hg/s. A stethoscope placed over the brachial artery in the antecubital fossa identifies the first and last

audible **Korotkoff sounds**, which should be taken as systolic and diastolic pressure, respectively. A minimum of two readings at least 1 minute apart are then averaged. If measurements vary by more than 5 mm Hg between the two readings, then one or two additional BP measurements are collected and the multiple readings averaged. BP classification is based on the average of two or more properly measured, seated BP readings on each of two or more office visits. Details and further recommendations for accurate measurement of BP in special populations can be reviewed in the American College of Cardiology (ACC)/AHA BP Measurement in Humans Statement for healthcare professionals.²⁸ Finally, the measurement of clinic

or office BPs is poorly correlated with assessments of BP in other settings. Consequently, under select circumstances, clinicians are increasingly using 24-hour ambulatory BP monitoring devices and home BP monitors. These tools are useful in identifying patients with **white coat hypertension** or with elevations of BP during the night. They may also aid in the management of refractory hypertension with minor target organ damage, those with suspected autonomic neuropathy, those with hypotensive symptoms, and patients with large differences between home and clinic BP measurements. Benefits derived from alternative BP monitoring may be of greater prognostic significance than traditional office-based measurements.²⁸

TREATMENT

Desired Outcomes

Hypertension management by nonpharmacologic and pharmacologic therapies has proven useful in reducing the risk of MI, HF, stroke, and kidney disease–associated morbidity and mortality. For every 20 mm Hg systolic or 10 mm Hg diastolic increase in BP above 115/75 mm Hg, there is a doubling of mortality for both ischemic heart disease and stroke.²⁹ The goal of BP management is to reduce the risk of CVD and target organ damage. Targeting a specific BP is actually a surrogate goal that has been associated with reductions in CVD and target organ damage.

General Approach to Treatment

6 *Drug selection for the management of patients with hypertension should be considered as adjunctive to nonpharmacologic approaches for BP lowering, and ultimately the attainment of target BP in many cases may be more important than the antihypertensive agent used.* Previous clinical research has established the relative value of using individual antihypertensive drugs versus placebo to achieve reduction in morbidity and mortality by lowering BP. However, as newer antihypertensive agents are developed, it is difficult to justify the comparison of newer agents to placebo on ethical grounds. Consequently, contemporary large outcome-based multicenter trials have been designed to compare one specific agent-based therapy (along with options to add others) versus another agent-based therapy (along with options to add others of a different class). These attempts at “head-to-head” comparisons and meta-analyses of multidrug regimen trials have, in general, provided evidence supporting the position that the main benefits of pharmacologic therapy are related to the achievement of BP lowering and are generally largely independent of the selection of an individual drug regimen. Inherent in this position is the realization that nonpharmacologic approaches alone are rarely successful in attaining target BPs, and multidrug therapy (sometimes as many as three or more agents) is necessary for most patients with hypertension.³⁰ The JNC 7 focuses on utilizing BP levels in determining the threshold and target for treatment, and the European Society of Cardiology also incorporates total

cardiovascular risk in determining thresholds for treatment. This approach results in a “flexible” definition of hypertension that depends on an individual’s total cardiovascular risk.⁸ Although acknowledging there are several approaches currently used to manage patients with hypertension, this chapter uses as its basis the AHA Scientific Statement on the treatment of hypertension in the prevention and management of ischemic heart disease, and the JNC 7 guidelines, while recognizing important recommendations in the ACCF/AHA expert consensus document on hypertension in the elderly.

Nonpharmacologic Treatment: Lifestyle Modifications

• Therapeutic lifestyle modifications consisting of nonpharmacologic approaches to BP reduction should be an active part of all treatment plans for patients with hypertension. The most widely studied interventions demonstrating effectiveness include:

- Weight reduction in overweight or obese individuals
- Adoption of a diet rich in potassium and calcium
- Dietary sodium restriction
- Physical activity
- Moderation of alcohol consumption

7 *Implementation of these lifestyle modifications successfully lowers BP (Table 5–3), often with results similar to those of therapy with a single antihypertensive agent.³¹ Combinations of two or more lifestyle modifications can have even greater effects with BP lowering. BP lowering in overweight patients may be seen by a weight loss of as few as 4.5 kg (10 lb). The DASH trial demonstrated that a diet high in fruits, vegetables, and low-fat dairy products, along with a reduced intake of total and saturated fat, significantly reduced BP in as little as 8 weeks.³² Sodium restriction in moderate amounts lowers BP, is generally well accepted, and is free of adverse effects, particularly in salt-sensitive individuals.^{17,18} Restriction of sodium intake to 2.4 g (100 mmol) of elemental sodium (6 g of sodium chloride or 1 teaspoon of table salt) should be easily achievable in most patients simply by avoidance of highly salted processed foods.³³ Simple dietary advice and instructions on reading packaging labels should be introduced to the patient initially and assessed and reinforced at subsequent office visits. As is the case with weight loss, changes in physical activity do not need to be profound to have a significant effect on BP. It is generally accepted that 30 minutes of moderately intense aerobic activity (e.g., brisk walking) most days of the week will lower BP.³¹ Although many patients can safely engage in moderately intense aerobic activity, individuals with known CVD, multiple risk factors with symptoms, or selected diabetic patients should undergo medical examination, possibly including exercise testing, prior to participation.^{34,35} The acute effects of alcohol on BP are variable as previously described. Abstinence from alcohol in heavy drinkers leads to a reduction in BP.³⁶ In addition, alcohol also attenuates the effects of antihypertensive*

Table 5-3

Lifestyle Modifications to Manage Hypertension^{a,3}

Modification	Recommendation	Approximate Systolic BP Reduction (Range)
Weight reduction	Maintain normal body weight (body mass index: 18.5–24.9 kg/m ²)	5–20 mm Hg/10 kg
Adopt DASH eating plan	Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat	8–14 mm Hg
Dietary sodium restriction	Reduce dietary sodium intake to no more than 100 mmol/day (2.4 g sodium or 6 g sodium chloride)	2–8 mm Hg
Physical activity	Engage in regular aerobic physical activity such as brisk walking (at least 30 min/day, most days of the week)	4–9 mm Hg
Moderation of alcohol consumption	Limit consumption to no more than 2 drinks (e.g., 24 oz [710 mL] beer, 10 oz [296 mL] wine, or 3 oz [89 mL] 80-proof whiskey) per day in most men and to no more than 1 drink per day in women and lighter weight persons	2–4 mm Hg

BP, blood pressure; DASH, Dietary Approaches to Stop Hypertension.

^aFor overall cardiovascular risk reduction, stop smoking. The effects of implementing these modifications are dose and time dependent and could be greater for some individuals.

therapy, which is mostly reversible within 1 to 2 weeks with moderation of intake.

In addition to their beneficial effects on lowering BP, lifestyle modifications also have a favorable effect on other risk factors such as dyslipidemia and insulin resistance, which are commonly encountered in the hypertensive population, and lifestyle modifications should be encouraged for this reason as well. Smoking cessation should also be encouraged for overall cardiovascular health despite its lack of chronic effects on BP.^{37,38} Although lifestyle modifications have never been documented to reduce cardiovascular morbidity and mortality in patients with hypertension, they do effectively lower BP to some extent in most hypertensive patients. This may obviate the need for drug therapy in those with mild elevations in BP or minimize the doses or number of antihypertensive agents required in those with greater elevations in BP.

Pharmacologic Treatment

8 *An approach to selection of drugs for the treatment of patients with hypertension should be evidence-based with considerations regarding the individual's coexisting disease states, co-prescribed medications, and practical patient-specific issues including cost.* The JNC 7 report and statements from other global organizations recommend drug therapy that is largely grounded in the best available evidence for superiority in outcomes—specifically morbidity and mortality.¹ The approach is often tempered with practical considerations related to competing options for specific comorbidities and issues regarding a patient's experience or tolerance for side effects and, in some cases, the cost of medications.

Although landmark trials such as the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) have provided some objective basis for comparisons between initiating antihypertensive drug therapy with

one class of antihypertensives versus another, there is room for criticism of these studies.^{30,39,40} Consequently, practical interpretations of their conclusions must always leave room for individualization based on clinical judgment. Overall, current clinical guidelines provide a reasonable basis for guiding the selection of drug classes for individuals based on their stage of hypertension, comorbidities, and special circumstances. The following section summarizes key features of specific drug classes and guideline recommendations for patients with hypertension. Finally, an overview of the specific oral antihypertensive drug classes in common use is summarized in [Table 5-4](#).

Diuretics

Many authorities recognize the value of diuretics in the management of patients with hypertension. Among others, the basis for endorsement of diuretics for a variety of patient types includes their practical attributes (acquisition cost and availability as combination agents), extent of experience, and favorable outcomes in placebo-controlled trials.^{1,3} These virtues are supported by results of studies such as ALLHAT.³⁰ This landmark double-blind study tested the hypothesis that newer antihypertensive agents would outperform thiazide-type diuretics when selected as initial drug therapy. After 4.9 years of follow-up in over 42,000 patients, the primary end point of fatal coronary heart disease and nonfatal MI was indistinguishable between chlorthalidone versus either amlodipine or lisinopril. A fourth arm examining doxazosin was terminated early based on a higher risk of HF for doxazosin compared with chlorthalidone.⁶⁵ In spite of these findings for the primary end point, differences in outcomes for select secondary end points demonstrated superiority of chlorthalidone over either of the two remaining comparison groups. These observations, along with perceived cost effectiveness (which was not specifically evaluated in this study), led the

Table 5-4

Commonly Used Oral Antihypertensive Drugs by Pharmacologic Class

Class	Drug Name and Usual Oral Dosage Range (mg/day)	Compelling Indications	Clinical Trials	Select Adverse Events	Comments ^a
Diuretic					
Thiazides	Chlorthalidone (Hygroton) 6.25–25 Indapamide (Lozol) 1.25–5 Hydrochlorothiazide 12.5–50 Metolazone (Zaroxolyn) 2.5–5	Heart failure stage A [chlorthalidone] High coronary disease risk [chlorthalidone] Diabetes [chlorthalidone] Stroke [perindopril + indapamide]	ALLHAT ³⁰ PROGRESS ⁴¹ HYVET ⁴²	Hypokalemia and other electrolyte imbalances Negative effect on glucose and lipids	Chlorthalidone is about twice as potent as hydrochlorothiazide Thiazide diuretics are generally more effective antihypertensive agents than loop diuretics Not first-line agents in pregnancy, but probably safe per JNC 7 Monitor electrolytes (i.e., decreased serum potassium) and metabolic abnormalities (i.e., dyslipidemia, hyperglycemia) Use caution in patients with gout Contraindications include hypersensitivity, anuria, renal decompensation
Loops	Bumetanide (Bumex) 1–4 Furosemide (Lasix) 40–160 Torsemide (Demadex) 2.5–10			Potassium-sparing diuretics may enhance hyperkalemic effects of drug therapies (e.g., ACE inhibitor, aldosterone antagonist)	Monitor electrolytes (i.e., decreased potassium) and metabolic abnormalities (i.e., dyslipidemia, hyperglycemia) Use with caution in patients with gout Contraindications include hypersensitivity, anuria, acute renal insufficiency, hyperkalemia
Potassium-sparing aldosterone antagonists	Amiloride (Midamor) 5–20 Triamterene (Dyrenium) 50–200 Spironolactone (Aldactone) 25–100 Eplerenone (Inspra) 50–200	Heart failure [spironolactone] Heart failure post-MI [eplerenone]	RALES ⁴³ EPHESUS ⁴⁴	Hyperkalemia Gynecomastia [spironolactone]	Monitor electrolytes (i.e., decreased potassium) and metabolic abnormalities (i.e., dyslipidemias, hyperglycemia) Use with caution in patients with gout Contraindications include hypersensitivity, anuria, acute renal insufficiency, hyperkalemia Eplerenone contraindicated as an antihypertensive in patients with estimated creatinine clearance less than 50 mL/min (0.83 mL/s) or serum creatinine greater than 1.8 mg/dL (159 μmol/L) for women or 2 mg/dL (177 μmol/L) in men as well as type 2 diabetes mellitus with microalbuminuria. Also contraindicated in patients concomitantly receiving strong CYP3A4 inhibitors or a serum potassium greater than 5.5 mEq/L (5.5 mmol/L) at initiation
β-Blocker					
Cardioselective	Atenolol (Tenormin) 25–100 Bisoprolol (Zebeta) 2.5–10 Metoprolol tartrate (Lopressor) 100–200 Metoprolol succinate (Toprol XL) 50–100	Heart failure [metoprolol XL, carvedilol, bisoprolol] Heart failure post-MI [carvedilol] Post-MI [propranolol, β ₁ -antagonists]	MERIT-HF ⁴⁵ COPERNICUS ⁴⁶ CAPRICORN ⁴⁷ BHAT ⁴⁸ CIBIS-II ⁴⁹	Bradycardia Heart block Heart failure Hypotension/syncope Dyspnea, bronchospasm Fatigue, dizziness, lethargy, depression	Caution with heart rate less than 60 and respiratory disease Selectivity of β ₁ agents is diminished at higher doses Abrupt discontinuation may cause rebound hypertension May mask signs/symptoms of hypoglycemia in diabetic patients

Nonselective	Nadolol (Corgard) 40–120 Nebivolol (Bystolic) 2.5–40 Propranolol (Inderal) 40–160 Propranolol long-acting (Inderal LA, InnoPran XL) 60–180 Timolol (Blocadren) 20–40	High coronary disease risk		Hyper/hypoglycemia, hyperkalemia, hyperlipidemia	Contraindicated in hypersensitivity, sinus node dysfunction or severe sinus bradycardia (in the absence of a pacemaker), heart block (greater than first-degree), cardiogenic shock, acute decompensated heart failure
Mixed α - and β -blocker	Carvedilol (Coreg) 25–100 Carvedilol CR (Coreg CR) 20–80 Labetalol (Trandate) 200–800				
CCBA					
Nondihydropyridine	Diltiazem long-acting (Cardizem SR, Cardizem CD, others) 180–420 Verapamil sustained-release (Calan SR, Isoptin SR, Verelan) 120–360	High coronary disease risk [verapamil-trandolapril] Diabetes	INVEST ⁵⁰ VALUE ⁴⁰ ASCOT ³⁹	Bradycardia, heart block [nondihydropyridines] Constipation [nondihydropyridines] Hypotension Peripheral edema, headache, flushing Gingival hyperplasia [dihydropyridines] Reflex tachycardia [dihydropyridine]	Caution with heart rate less than 60 [verapamil, diltiazem] Use caution in concomitant use with β -blocker; may potentiate heart block Extended-release formulations are preferred for once- or twice-daily medication administration Contraindicated in hypersensitivity, sinus node dysfunction, or severe sinus bradycardia (in the absence of a pacemaker) [nondihydropyridines], heart block (greater than first degree) in the absence of a pacemaker [nondihydropyridines], atrial fibrillation/flutter associated with accessory bypass tract [nondihydropyridines], severe hypotension (systolic less than 90 mm Hg) [nondihydropyridines], severe left ventricular dysfunction [nondihydropyridines]
Dihydropyridines	Amlodipine (Norvasc) 2.5–10 Felodipine (Plendil) 5–20 Isradipine SR (DynaCirc SR) 2.5–10 Nicardipine SR (Cardene SR) 60–120 Nifedipine long-acting (Adalat CC, Procardia XL) 30–60 Nisoldipine (Sular) 10–40				
ACE Inhibitor

authors of JNC 7 to endorse diuretics as initial drug therapy for most patients with hypertension. Nonetheless, substantial criticism of this trial has undermined the enthusiasm for diuretics as first-line therapy in the minds of some clinicians, as well as members of international guideline committees.⁸ Criticism of the differential BPs achieved in the various treatment groups, the artificial construct guiding the use of add-on drugs to base therapy, and the overrepresentation of African Americans exhibiting select end points have weakened the interpretability of the authors' conclusions. Furthermore, other contemporary studies have also challenged the status of diuretics as ideal baseline choices for initial antihypertensive drug therapy for all patients.^{39,40} This has refueled the debate over whether the means by which BP is lowered (drug selection) is more or less important than the extent and/or time taken to lower BP.⁶⁶ Furthermore, controversy has ignited as to whether the choice and dose of diuretic versus hydrochlorothiazide was partly responsible for the difference in study results, and it has raised the question whether chlorthalidone should be the preferred thiazide-type diuretic.⁶⁷ Nonetheless, diuretics remain supported by many as acceptable baseline initial therapy for hypertensive patients without compelling indications.

Key features of diuretics that must be kept in mind, along with evidence from outcome-based studies, include the diversity between the subtypes of diuretics and their corresponding diversity of pharmacologic actions. The four subtypes include thiazides, loop diuretics, potassium-sparing agents, and aldosterone antagonists. The latter will be discussed as a separate entity. Each subtype has clinically based properties that distinguish their roles in select patient populations. Thiazide diuretics are by far the most commonly prescribed subtype with the greatest number of outcome-based studies supporting their use. In the United States, hydrochlorothiazide and chlorthalidone represent the most commonly prescribed thiazide-type diuretics and have been the subject of most large outcome-based studies. Although subtle differences in pharmacokinetics between these agents exist, practical differences are limited to their relative diuretic potency. Chlorthalidone is considered approximately 1.5 to 2 times more potent than hydrochlorothiazide for BP reduction.⁶⁸ Several recent analyses have demonstrated the superiority of chlorthalidone over hydrochlorothiazide,^{67,69} leading some national guidelines to give preference to chlorthalidone over hydrochlorothiazide.⁷⁰ Because the relationship between antihypertensive efficacy and metabolic/electrolyte-related side effects of thiazide diuretics is considered dose related, attention to this differential in potency may be important. Specifically, select metabolic effects (hyperlipidemic and hyperglycemic) and electrolyte-related effects (hypokalemic, hypomagnesemic, hyperuricemic, and hypercalcemic) seem to increase with higher doses. This has led to national guidelines recommending doses not exceed 25 mg/day for chlorthalidone or 50 mg/day for hydrochlorothiazide.³ These metabolic effects may clearly complicate the management of higher risk patients with common comorbidities such as dyslipidemia or diabetes, or even those likely to be sensitive to the potassium- or magnesium-wasting effects of diuretics

(patients with dysrhythmias or those taking digoxin). Although rates of diabetes are higher following administration of thiazides, there is evidence that this can be greatly minimized by keeping potassium in the high normal range (i.e., above 4.0 mEq/L [4 mmol/L]).⁷¹ Furthermore, whether the development of new-onset diabetes in association with thiazide diuretic is of clinical significance is in question because the large ALLHAT and the Systolic Hypertension in the Elderly Program (SHEP) trials showed no significant adverse cardiovascular events from new diuretic-associated diabetes, whereas a smaller trial did.⁷² Nonetheless, clinicians should rarely approach the upper limits of these dosage ranges without careful assessment of their metabolic effects or potential to induce electrolyte disturbances. In this way, optimization of BP lowering potential may be achieved while minimizing potential adverse outcomes.

Another key feature of the thiazide-type diuretics is their limited efficacy in patients whose renal function, estimated by creatinine clearance, either approaches or is less than 30 mL/min (0.50 mL/s). In such cases, loop diuretics are regarded as superior to thiazide diuretics for lowering BP. Clinicians often fail to reevaluate the use of thiazide diuretics prescribed to individuals whose renal function has been declining with age and whose risk for the consequences of their metabolic effects such as increased uric acid and insulin resistance may be more significant.²

The loop diuretics, such as furosemide, bumetanide, torsemide, and ethacrynic acid, have a common site of action in the thick ascending limb of the loop of Henle.⁷³ Responsible for reabsorption of over 65% of the filtered sodium, their diuretic efficacy is clearly superior to that of the thiazides, potassium-sparing diuretics, and mineralocorticoids. Practically speaking, furosemide is the most common agent used as an alternative to thiazide-type agents for patients whose renal function has been compromised. With the exception of torsemide, which has a longer half-life, the loop diuretics should be administered twice daily versus once when utilized primarily for their antihypertensive (versus diuretic) effect. The most significant adverse effects related to loop diuretic use concern their potential for excessive diuresis leading to hyponatremia or hypotension. Additionally, hypokalemia, hypomagnesemia, and hypocalcemia may develop over time and contribute to the potential for cardiac arrhythmias. Overall relevance of drug-drug interactions and potential for aggravating select conditions (hyperglycemia, dyslipidemias, and hyperuricemia) should be routinely considered in the monitoring plan for those taking loop diuretics for extended periods of time.

Potassium-sparing diuretics that do not act through mineralocorticoid receptors include triamterene and amiloride. These agents are often prescribed with potassium-wasting diuretics in an attempt to mitigate the loss of potassium. When administered as a single entity or as one component of a combination product, these agents result in moderate diuresis. Potassium-sparing diuretics act on the late distal tubule and collecting duct, and thereby they have a limited ability to affect sodium reabsorption, which translates into modest diuresis. The most important adverse effects

associated with these agents are their potential to contribute to hyperkalemia. This is especially relevant in the context of those patients receiving other agents with potassium-sparing properties, such as ACE inhibitors, ARBs, and potassium supplements, as well as nonsteroidal anti-inflammatory drugs (NSAIDs). It is also relevant in those with moderate to severe renal impairment.

Aldosterone Antagonists

Aldosterone antagonists such as spironolactone and eplerenone (Fig. 5–2) modulate vascular tone through a variety of mechanisms besides diuresis. Their potassium-sparing effects mediated through aldosterone antagonism complement the potassium-wasting effects of more potent diuretics such as thiazide or loop diuretics. Patients with resistant hypertension (with or without primary aldosteronism) experience significant BP reductions with the addition of low-dose spironolactone (12.5 to 50 mg/day) to diuretics, ACE inhibitors, and ARBs.^{27,74,75} Although functional in this circumstance, it is important to recognize their potential to enhance the risk for hyperkalemia when used in conjunction with ACE inhibitors, ARBs, and direct renin inhibitors (DRIs). This is particularly relevant for individuals with comorbidities associated with reduced renal function or those receiving either potassium supplements, potassium-containing salt substitutes, or NSAIDs. The most commonly used potassium-sparing diuretic is spironolactone; however, eplerenone has been used with increasing frequency in patients with HF following acute myocardial infarction (AMI).⁴⁴ Although spironolactone is commonly associated with gynecomastia, eplerenone rarely causes this complication, presumably because of its greater specificity to block aldosterone while minimally affecting androgens and progesterone compared with spironolactone.⁷⁶ The risk of hyperkalemia is also more commonly reported with patients on spironolactone.⁷⁷

β -Blockers

Controversy surrounds the JNC 7 recommended role of β -blockers as first-line antihypertensive agents. For example,

a meta-analysis by Lindholm et al demonstrated a higher risk of stroke in patients treated for primary hypertension with β -blockers compared with other antihypertensives.⁷⁸ Moreover, Messerli et al showed that β -blockers were ineffective in preventing coronary heart disease, cardiovascular mortality, and all-cause mortality compared with diuretics for elderly patients (60 years of age or older) treated for primary hypertension.⁶⁹ Consequently, current evidence suggests patients with uncomplicated hypertension may not benefit as much, if at all, from β -blocker therapy relative to other antihypertensives.¹ This may be in part due to their tendency to reduce central aortic pressure and cardiac afterload to a lesser degree relative to other agents.⁷⁹ It must be noted that all of these analyses were conducted with a limited number of β -blockers such as atenolol and metoprolol tartrate. Whether newer formulations such as metoprolol succinate or agents with unique properties such as carvedilol or nebivolol would be more efficacious in reducing morbidity and mortality is unknown. The drug with the most prominent difference in the increased risk of stroke among the three β -blocker subgroups is atenolol. The concern regarding β -blocker use in hypertensive patients without compelling indications is reflected in AHA's recommendations and the European Society of Cardiology's abandonment of β -blockers as first-line antihypertensive agents. However, the role of β -blockers in patients with specific select comorbidities is well established (Table 5–5). Specific outcome-based studies conducted in patients with comorbidities such as HF and recent MI have clearly demonstrated a benefit from β -blocker use.⁸⁰ Their hemodynamic effects and antiarrhythmic properties make them desirable agents for hypertensive patients who suffer from ischemic conditions including AMI.⁷³ When used judiciously in hypertensive patients with HF, β -blocker inhibition of neurohormonal-mediated cardiac remodeling reduces morbidity and mortality relative to standard HF therapies. The mechanisms through which β -blockers affect BP are complex but most certainly include their modulation of renin (Fig. 5–2), which appears to result in a reduction in CO and/or reduction in PR along with their negative inotropic/chronotropic actions.

The specific pharmacologic properties of β -blockers are varied and diverse. An understanding of these properties may assist in the selection of one agent over others given a

Table 5–5

Compelling Indications for Individual Drug Classes³

Compelling Indication	Recommended Drug Class						
	Diuretic	Ald Ant	BB	CCBA	ACE-I	ARB	Dir Vaso
Heart failure	X	X	X		X	X	X
Postmyocardial infarction		X	X		X		
High coronary disease risk	X		X	X	X		
Diabetes	X		X	X	X	X	
Chronic kidney disease					X	X	
Recurrent stroke prevention	X				X		

ACE-I, angiotensin-converting enzyme inhibitor; Ald Ant, aldosterone antagonist; ARB, angiotensin receptor blocker; BB, β -blocker; CCBA, calcium channel blocking agent; Dir Vaso, direct vasodilator.

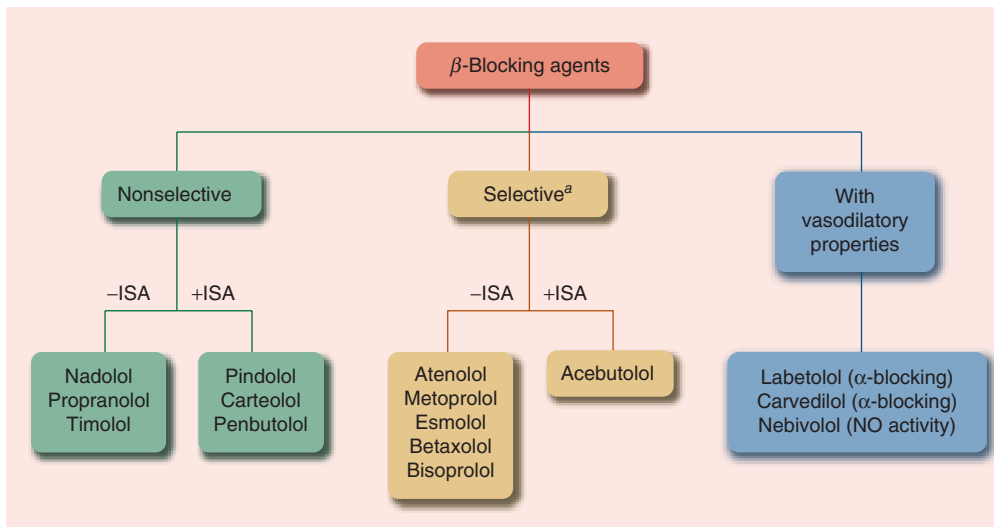

FIGURE 5-3. Flowchart listing various β -blocking agents separated by β -receptor activity and intrinsic sympathomimetic activity. ^a β -1 Cardioselective. (ISA, intrinsic sympathomimetic activity; NO, nitrous oxide.)

patient's specific condition(s). One of these properties is cardioselectivity—the property of some β -blockers that preferentially block β_1 -receptor versus β_2 -receptor. Another property exhibited by some β -blockers is membrane stabilization activity, which relates to the propensity of the β -blocker to possess some capacity for antiarrhythmic properties, in addition to β -receptor blocking properties. Some β -blockers (Fig. 5-3) possess properties referred to as intrinsic sympathomimetic activity (ISA).⁶ β -Blockers possessing this property effectively block the β -receptor at higher circulating catecholamine levels, such as during exercise, while having modest β -blocking activity at times of lower catecholamine levels, such as at rest.⁸¹

When selecting a β -blocker, some of these properties may be of practical value, whereas others, such as membrane stabilization activity and ISA, are of theoretical interest only. Because neither membrane stabilization activity nor ISA has directly proven value in the clinical setting, they are not discussed further other than to point out that β -blockers with ISA are not recommended for use in the post-MI patient.⁸² With regard to cardioselectivity, consider a patient with mild asthma, chronic obstructive pulmonary disease, or peripheral vascular disease (intermittent claudication). A β -blocker with relative cardioselectivity to block β_1 -receptors may be more desirable in such a patient, whereas a nonselective β -blocker (Fig. 5-3) may be potentially disadvantageous. In such a patient, low doses of cardioselective β -blockers may achieve adequate blockade of β_1 -receptors in the heart and kidneys while minimizing the undesirable effects of β_2 -receptor blockade on the smooth muscle lining the bronchioles. In doing so, hypertension may be managed while avoiding complications of the coexisting reactive airway disease, which is mediated by β_2 -receptor stimulation. Similarly, either because of a reduction in the β_2 -mediated vascular blood flow or by enhanced unopposed α -agonist-mediated vasoconstriction, a patient with peripheral vascular disease (intermittent claudication) may experience a worsening of symptoms with use of a nonselective β -blocker (Fig. 5-3). It is important to remember that cardioselectivity

depends on dose, with diminished selectivity exhibited with higher doses.

A limited number of β -blockers also possess vasodilatory properties that are either mediated through α_1 -receptor blockade (carvedilol, labetalol) or via L-arginine/nitric oxide-induced release from endothelial cells with subsequent increased nitric oxide bioavailability in the endothelium (nebivolol; Fig. 5-3). Reductions in PR through α_1 -receptor mediated blockade or via L-arginine/nitric oxide-induced release, in addition to β -blockade, may benefit patients with hypertension. Such combinations should theoretically contribute to enhanced reductions in vascular tone. Nonetheless, there has been no proven evidence of superior outcomes from the use of β -blockers with vasodilatory properties through either means compared with those with only β -blocking activity.

The adverse effects of β -blockers logically follow their pharmacology. Initiating β -blockers to treat patients with hypertension may have the potential to precipitate bradycardia, various degrees of heart block, or signs and symptoms of HF. The latter is usually limited to those with a subclinical diagnosis and should be considered in the elderly or those with documented reductions in left ventricular function. Conversely, abrupt discontinuation of β -blockers has been cited as a precipitating factor in the development of ischemic syndromes, especially for those patients in whom β -blockers were used for extended periods of time, at higher doses, or who had underlying ischemic heart disease. In such cases, the dose of these agents should be reduced (tapered) over a period of several days to perhaps 1 or even 2 weeks depending on patient-related factors. β -Blocker use in diabetics is usually a complex decision requiring consideration of their consequential effects on insulin, glucose availability, and effects on blocking the signs and symptoms of hypoglycemia against their potential for morbidity/mortality benefits for select candidates with comorbidities such as HF with reduced systolic function. Lastly, β -blockers, particularly first-generation agents (i.e., those other than carvedilol, nebivolol) have a greater effect on glucose metabolism as well as other

metabolic effects, and they should be used cautiously if at all with diuretics unless compelling indications exist for both.

Calcium Channel Blocking Agents

Exhibiting considerable interclass diversity, calcium channel blocking agents (CCBAs) are recognized as effective antihypertensives, particularly in the elderly. Patients with isolated systolic hypertension who were taking CCBAs experienced reduced CVD end points during several clinical trials. Two trials comparing amlodipine-based therapy to others furthered a theme of supporting the argument that regardless of the agents used, the evidence appears to indicate that the amount of BP lowering achieved may have more to do with event reduction than the specific agents or combinations of agents used to achieve them. Specifically, the Valsartan Antihypertensive Long-term Use Evaluation (VALUE) trial,⁴⁰ which compared valsartan-based therapy with amlodipine-based therapy in over 15,000 patients, and the Anglo-Scandinavian Cardiac Outcomes Trial-Blood Pressure Lowering Arm (ASCOT-BPLA) study,³⁹ which compared amlodipine-based therapy versus atenolol-based therapy in over 19,000 hypertensive patients, each failed to achieve their primary end point of composite cardiac mortality and morbidity. Yet cause-specific outcomes tended to favor the regimen affording the achievement of lower BPs—namely, the amlodipine-based therapy.

The diversity of pharmacologic properties among the subclasses of CCBAs is significant. A clinician's familiarity with these differences among subclasses helps categorize their expected effects on the cardiovascular system and potential risk of toxicities. Dihydropyridine CCBAs such as amlodipine are commonly associated with edema, especially when used at higher doses. Phenylalkylamine-verapamil and benzodiazepine-diltiazem are more commonly recognized for their electrophysiological effects, negative chronotropic effects, and negative inotropic effects. Many of these pharmacologic properties are exploited for their specific clinical utility. Given that verapamil and diltiazem (both are non-dihydropyridine CCBAs) effectively block cardiac conduction through the atrioventricular node, their value in the management of patients with atrial fibrillation in addition to hypertension is obvious, whereas secondary to their negative inotropic effects, they should be avoided in patients with left ventricular systolic dysfunction. In contrast, the dihydropyridine subclass of agents has no utility in managing atrial dysrhythmias but may be used safely (exception being nifedipine) in patients with left ventricular systolic dysfunction. Similarly, all three subclasses of CCBAs possess some coronary vasodilating properties and hence may be used in select patients for the management of patients with angina, in addition to their antihypertensive benefits.

ACE Inhibitors

ACE inhibitors have been extensively studied for the treatment of hypertension, and outcome based trials generally support their use for a wide array of patients, especially with

select comorbidities. This broad utility extends to the list of compelling indications (Table 5–5) for patients as described in JNC 7.³ These compelling indications include their qualified role in managing patients with hypertension who have type 1 diabetes,⁴⁰ HF,⁸³ post-MI,⁸² type 2 diabetes,⁸⁴ CKD,^{85,86} or recurrent stroke prevention.⁴¹ Comparative trials between ACE inhibitors and various other agents as initial drug therapy have also demonstrated some differences in outcomes for this class. In ALLHAT, ACE inhibitors appeared to perform less well than diuretics in terms of incidence of combined CVD and HF.³⁰ However, the Australian-New Zealand Blood Pressure-2 (ANBP2) trial seemed to suggest that ACE inhibitors may be equivalent to diuretics in terms of overall outcomes.⁸⁷ Because there are legitimate criticisms of both these trials (including the smaller number of overall events and choice of hydrochlorothiazide as the diuretic in ANBP2), it may only be safe to conclude that both diuretics and ACE inhibitors represent formidable agents as either first- or second-line hypertensive therapies that effectively achieve a target BP goal for most patients with or without comorbidities.

Although generally well tolerated, classic side effects associated with ACE inhibitors include their potential to cause hyperkalemia and a persistent dry cough. Modest elevations in serum potassium should be anticipated, particularly in patients with compromised renal function, those receiving concurrent NSAIDs, or those taking potassium supplementation or using a potassium-containing salt substitute. The elevations in potassium should be anticipated, if not prospectively considered, when starting or increasing the dose of an ACE inhibitor. Hyperkalemia is rarely a reason for discontinuation of therapy. Nonetheless, periodic monitoring of serum potassium is prudent for patients receiving ACE inhibitors. The dry cough associated with ACE inhibitors is thought to be caused by the accumulation of bradykinin resulting from a direct effect of inhibiting ACE. If a cough jeopardizes compliance with the agent, ARBs should be considered as possible alternative agents because there is less incidence of cough.

In general, the effects of ACE inhibitors on diminished renal function and potassium can be predicted given an understanding of their pharmacologic actions (Fig. 5–3). Inhibition of the generation of angiotensin II through ACE inhibition (or direct blockage of the angiotensin II receptor by angiotensin II receptor blockers) naturally would reduce the efferent renal artery tone, thereby changing the intraglomerular pressure. Although changes in the afferent renal artery tone also occur, the overall effects usually translate into a reduction in GFR, with resulting elevations of up to 30% in serum creatinine values.⁸⁶ It is important to recognize that such elevations in serum creatinine are not usually indications to discontinue use of the ACE inhibitor. Rather, possible dose reduction and continued monitoring for further increases in serum creatinine remains prudent. Alternatively, should elevations in serum creatinine exceed 30%, discontinuation is prudent until further evaluation can be made.

More rare forms of adverse effects of ACE inhibitors include blood dyscrasias, angioedema, and more serious effects on renal function. The latter include acute renal

failure in those with preexisting kidney dysfunction, bilateral renal artery stenosis, or unilateral renal artery stenosis in a patient with one functioning kidney.

Angiotensin Receptor Blockers

ARBs are another key class of agents whose role in managing patients with hypertension has been further defined by recently completed studies. ARBs are inhibitors of the angiotensin-1 (AT1) receptors (Fig. 5–3). AT1 receptor stimulation evokes a pressor response via a host of accompanying effects on catecholamines, aldosterone, and thirst.⁸⁸ Consequently, inhibition of AT1 receptors directly prevents this pressor response and results in upregulation of the RAAS. Upregulation of the RAAS results in elevated levels of angiotensin II, which have the added effect of stimulating the angiotensin-2 (AT2) receptors. AT2-receptor stimulation is generally associated with antihypertensive activity; however, long-term effects of AT2-receptor stimulation that involve cellular growth and repair are relatively unknown. What is clear is that ARBs differ from ACE inhibitors in that the former causes upregulation of the RAAS, whereas the latter blocks the breakdown of bradykinin. The therapeutic relevance resulting from these pharmacologic differences has yet to be fully evaluated through long-term clinical comparative trials in hypertensive patients. However, data from other patient populations (HF, high-risk coronary artery disease patients) suggest the clinical benefits of ARBs are less robust than those of ACE inhibitors.^{89,90} At this point, ARBs have emerged as an effective class of antihypertensives whose low incidence of side effects and demonstrated clinical role in patients with specific comorbidities have afforded them an attractive position in the antihypertensive armamentarium. Like ACE inhibitors, the antihypertensive effectiveness of ARBs is greatly enhanced by combining them with diuretics. Furthermore, they have proven their value as well-tolerated alternatives to ACE inhibitors for patients with CKD, diabetes mellitus, and post-AMI (Table 5–5). As of late, the addition of ARBs to standard therapy for patients with HF, including ACE inhibitors, have demonstrated additional incremental benefits for patients with systolic dysfunction⁹¹ or diastolic dysfunction⁸⁸ or as alternatives to ACE inhibitors when ACE inhibitors are not tolerated.⁹² Comparative studies with alternate (non-ACE inhibitors) antihypertensive regimens in patients with type 2 diabetes⁸⁸ and left ventricular hypertrophy⁵⁹ have demonstrated their usefulness as effective antihypertensives in these special populations. Studies (the Irbesartan Diabetic Nephropathy Trial [IDNT] and Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan [RENAAL; NIDDM refers to noninsulin-dependent diabetes mellitus]) have demonstrated superiority of delaying progression toward renal dysfunction for ARBs relative to alternative antihypertensives in type 2 diabetics.^{60,61,88} Although better tolerated than ACE inhibitors, ARBs have not been shown to demonstrate superiority of outcomes relative to ACE inhibitors. Like ACE inhibitors, patients may develop angioedema and, although estimates of cross-reactivity are reportedly modest

(less than 20%),⁹³ one should always exercise extreme caution when considering the use of an ARB in a patient with a known history of angioedema to an ACE inhibitor. This key observation, in addition to their relatively higher acquisition cost, has mitigated the growth of ARB use relative to ACE inhibitors.

Renin Inhibitors

Aliskiren is the first agent in the newest class of antihypertensive agents. Although similar to ACE inhibitors and ARBs in that it acts within the RAAS, it is unique in that it directly blocks renin, thereby reducing plasma renin activity and subsequently AT1 and AT2 with a resultant reduction in BP. This disruption of the negative feedback loop results in a compensatory increase in renin levels, the significance of which is not yet known. Aliskiren has been shown to be well tolerated and effective in reducing BP when used as monotherapy and in combination with hydrochlorothiazide or valsartan for patients with mild to moderate hypertension. However, long-term clinical trials evaluating efficacy and safety have yet to be completed, and thus the effects of aliskiren on morbidity and mortality are as yet unknown. Because of aliskiren's role in the RAAS, recommendations and precautions for monitoring serum potassium and kidney function should be similar to those of ACE inhibitors and ARBs.

α -Blockers

Generally, α_1 -blockers are considered inferior agents and should not be used as monotherapy. The ALLHAT trial had an α_1 -blocker arm that was discontinued early because doxazosin was associated with an increase in cardiovascular events.^{30,65} α_1 -Blockers may be considered as add-on therapy to other agents (i.e., fourth line) when hypertension is not adequately controlled. In addition, they may have a specific role in the antihypertensive regimen for elderly men with prostatism; however, their use is often curtailed by complaints of syncope, dizziness, or palpitations following the first dose and orthostatic hypotension with chronic use. The roles of doxazosin, terazosin, and prazosin in the management of patients with hypertension are limited due to the paucity of outcome data and the absence of a unique role for special populations or compelling indications from JNC 7.³

Central α_2 -Agonists

Limited by their tendency to cause orthostasis, sedation, dry mouth, and vision disturbances, clonidine, methyldopa, guanfacine, and guanabenz represent rare choices in contemporary treatment of patients with hypertension. Their central α_2 -adrenergic stimulation is thought to reduce sympathetic outflow and enhance parasympathetic activity, thereby reducing heart rate, CO, and total PR. Occasionally used for cases of resistant hypertension, these agents may have a role when other more conventional therapies appear

ineffective. The availability of a transdermal clonidine patch applied once weekly may offer an alternative to hypertensive patients with adherence problems. Of particular importance is the issue of severe rebound hypertension when clonidine is abruptly discontinued. The dose of this agent should be tapered when discontinuation is considered. If the patient is also receiving concomitant β -blocker therapy, the β -blocker should be tapered to discontinuation, ideally several days before discontinuation of clonidine is initiated.

Other Agents

Direct vasodilators such as hydralazine and minoxidil represent additional alternative agents used for patients with resistant hypertension. Primarily acting to relax smooth muscles in arterioles and activate baroreceptors, their use in the absence of concurrently administered β -blockers and diuretics is uncommon. This is due to the need to offset their tendency to cause reflex tachycardia and fluid retention. Other, more rare adverse effects include hydralazine-induced lupus-like syndrome and hypertrichosis from minoxidil. Before using either of these agents, see additional literature describing the appropriate use and monitoring of these agents.^{94,95} Although not commonly used, long-term nitrate administration has been shown in small short-term studies to lower BP, particularly in the elderly with elevated systolic pressure.^{96,97} Finally, reserpine, although slow to act, represents another rarely used alternative agent for those who are recalcitrant to more standard therapy. This agent is a long-acting depletor of the catecholamine norepinephrine from sympathetic nerve endings and via blockade of norepinephrine transport into its storage granules that causes reduced sympathetic tone leading to reductions in PR. Reserpine's association with numerous side effects including gastric ulceration, depression, and sexual side effects has limited its perception as a useful agent, but in low doses it can be well tolerated. In fact, the SHEP trial demonstrated the BP-lowering effectiveness of low-dose reserpine (0.05 mg/day) when combined with a diuretic, with similar cardiopulmonary and psychosocial side effects between the treatment and placebo groups.⁹⁸ In addition, low-dose reserpine was also used as add-on therapy in the ALLHAT trial.³⁰ Two additional agents, guanethidine and guanadrel, act as postganglionic sympathetic inhibitors inhibiting the release of norepinephrine as well as depleting norepinephrine from these nerve terminals. However, these agents have little role in the management of hypertension because of significant adverse effects.

SPECIAL PATIENT POPULATIONS

Compelling Indications and Special Considerations

9 *Specific antihypertensive therapy is warranted for certain patients with comorbid conditions that may elevate their level of risk for CVD.* Clinical conditions for which there is compelling evidence supporting one or more classes of drug therapy include³:

- Ischemic heart disease
- Heart failure
- Diabetes
- CKD
- Cerebrovascular disease

Compelling indications for specific drug therapies are summarized in Table 5–5.^{3,99} In patients with hypertension and angina, β -blockers and long-acting CCBAs are indicated due to their antihypertensive and antianginal effects.^{3,34} In addition, patients may benefit from the potential atherosclerotic plaque-stabilizing effects of amlodipine.¹ In patients at high risk of ischemic heart disease, such as diabetic patients with additional cardiovascular risk factors or chronic coronary artery or vascular disease, ACE inhibitors are particularly useful in reducing the risk of cardiovascular events regardless of whether the patient carries a concurrent diagnosis of hypertension.^{3,56,57} In patients intolerant to an ACE inhibitor, an ARB may be substituted, given the findings of the recently completed Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial (ONTARGET).⁹⁰

β -Blockers and ACE inhibitors are indicated for post-MI patients due to their proven reduction of cardiovascular morbidity and mortality in this population. Aldosterone antagonists are also indicated for the post-MI patient with reduced left ventricular systolic function and diabetes or signs and symptoms of HF.^{3,82}

Patients with asymptomatic left ventricular systolic dysfunction and hypertension should be treated with β -blockers and ACE inhibitors. Those with HF secondary to left ventricular dysfunction and hypertension should be treated with drugs proven to also reduce the morbidity and mortality of HF, including β -blockers, ACE inhibitors, ARBs, or aldosterone antagonists, along with diuretics as needed for symptoms. In African Americans with HF and left ventricular systolic dysfunction, combination therapy with nitrates and hydralazine not only affords a morbidity and mortality benefit but may also be useful as antihypertensive therapy if needed.⁶⁴ The dihydropyridine CCBAs amlodipine or felodipine may be used in patients with HF and left ventricular systolic dysfunction for uncontrolled BP; however, they offer no beneficial effect on morbidity and mortality due to HF yet carry the expected risk of worsening edema.⁸³ For patients with HF and preserved ejection fraction, antihypertensive therapies that should be considered include diuretics, β -blockers, ACE inhibitors, ARBs, CCBAs (including nondihydropyridine agents), and others as needed to control BP.^{3,83}

Patients with diabetes and hypertension should initially be treated with either ACE inhibitors, ARBs, β -blockers, diuretics, or CCBAs. There is a general consensus that therapy focused on RAAS inhibition by ACE inhibitors or ARBs may be optimal if the patient has additional cardiovascular risk factors such as left ventricular hypertrophy or CKD.^{3,59}

In patients with CKD and hypertension, ACE inhibitors and ARBs are preferred, usually in combination with a diuretic.⁸⁵ ACE inhibitors in combination with a thiazide

diuretic are also preferred in patients with a history of prior stroke or transient ischemic attack. This therapy reduces the risk of recurrent stroke, making it particularly attractive in these patients for BP control.⁹¹

There are several situations in the management of hypertension requiring special considerations including, but not limited to:

- Hypertensive crisis
- Elderly populations
- Isolated systolic hypertension
- Coronary artery disease
- Minority populations
- Pregnancy
- Pediatrics

Hypertensive crisis can be divided into hypertensive emergencies and hypertensive urgencies. A hypertensive emergency occurs when severe elevations in BP are accompanied by acute or life-threatening target organ damage such as AMI, unstable angina, encephalopathy, intracerebral hemorrhage, acute left ventricular failure with pulmonary edema, dissecting aortic aneurysm, rapidly progressive renal failure, accelerated malignant hypertension with papilledema, and eclampsia, among others. BP is generally greater than 220/140 mm Hg, although a hypertensive emergency can occur at lower levels, particularly in individuals without previous hypertension. The goal in a hypertensive emergency is to reduce mean arterial pressure by up to 25% to the range of 160/100 to 110 mm Hg in minutes to hours.^{3,100} IV therapy is generally required and may consist of the agents listed in [Table 5-6](#).⁴³ A hypertensive urgency is manifested as a severe elevation in BP without evidence of acute or life-threatening target organ damage. In these individuals, BP can usually be managed with orally administered short-acting medications (i.e., captopril, clonidine, or labetalol) and observation in the emergency department over several hours, with subsequent discharge on oral medications and follow-up in the outpatient setting within 24 hours.^{3,99}

The treatment of elderly patients (65 years of age or older) with hypertension, as well as those with isolated systolic hypertension, should follow the same approach as with other populations with the exception that lower starting doses may be warranted to avoid symptoms. Special attention should be paid to postural hypotension. This should include a careful assessment of orthostatic symptoms, measurement of BP in the upright position upon standing for 1 to 3 minutes, and caution to avoid volume depletion and rapid titration of antihypertensive therapy.³ The general recommended BP goal in uncomplicated hypertension in the elderly is less than 140/90 mm Hg. However, it is unclear whether the target SBP should be the same in those older than 80 years, and an achieved SBP of 140 to 145 mm Hg, if tolerated, can be acceptable, as well as attempts to avoid SBP of less than 130 mm Hg and a DBP of less than 65 mm Hg. A recently completed trial (HYVET) documented the benefits of antihypertensive therapy in patients older than 80 years because they experienced a significant reduction in all-cause mortality,

fatal stroke, and HF when treated with a diuretic (indapamide) with or without an ACE inhibitor (Perindopril) to a target SBP of less than 150 mm Hg.⁴² The BP achieved in the treated group was 144/78 mm Hg versus 161/84 mm Hg in those receiving placebo.⁴² In individuals with isolated systolic hypertension, the optimal level of diastolic pressure is not known, and although treated patients who achieve diastolic pressures less than 60 to 70 mm Hg had poorer outcomes in a landmark trial, their cardiovascular event rate was still lower than those receiving placebo.¹⁰⁰

In patients with coronary artery disease and hypertension, a recent AHA statement recommends a target BP of less than 130/80 mm Hg, with consideration given to less than 120/80 mm Hg if ventricular dysfunction is present. However, in patients with coronary artery disease and evidence of myocardial ischemia, caution is advised in inducing falls of DBP below 60 mm Hg if the patients also have diabetes mellitus or is older than 60 years. In patients with wide pulse pressures, lowering SBP may lead to very low DBP (less than 60 mm Hg), and the clinician must carefully assess for any untoward signs or symptoms.¹

While the treatment approach of hypertension in minority populations is similar, special consideration should be paid to socioeconomic and lifestyle factors that may be important barriers to BP control. In addition, in patients of African origin, diminished BP responses have been seen with ACE inhibitors and ARBs compared with diuretics or calcium channel blockers.³

Hypertension in pregnancy is a major cause of maternal, fetal, and neonatal morbidity and mortality. There are many categories of hypertension in pregnancy; however, preexisting hypertension and preeclampsia are treated differently. The therapeutic selection of an oral antihypertensive agent ([Table 5-7](#)) in a pregnant patient with chronic hypertension is determined with regard to fetal safety. Therapeutic options for acute severe hypertension in preeclampsia may be reviewed in JNC 7.³ Also refer to the American Society of Hypertension Position Article on Hypertension in Pregnancy for further information.¹⁰¹

Similar to the JNC 7 criteria (which has four stages for BP classification in adults), the measurement of three or more BPs in children and adolescents are compared with tables listing the 90th-, 95th-, and 99th-percentile BPs based on age, height, and gender that classify BP as normal, prehypertension, and stage 1 and stage 2 hypertension ([Table 5-1](#)).¹⁰² The prevalence of hypertension in adolescent populations is increasing and associated with obesity, sedentary lifestyle, or a positive family history, which increases the risk of CVD. The clinician should be aware that secondary causes are common in adolescents with hypertension, and the identification and aggressive modification of risk factors with nonpharmacologic and pharmacologic interventions is paramount for risk reduction of target organ damage. The 2004 National High Blood Pressure Education Program (NHBPEP) Working Group Report on Hypertension in Children and Adolescents provides specific recommendations to modify and treat risk factors in this population of patients. In addition, the American Heart Association released a source in

Table 5-6

Parenteral Antihypertensive Agents for Hypertensive Emergency^a

Drug	Dose Range	Onset of Action	Duration of Action	Adverse Effects ^b	Special Indications
Vasodilators					
Sodium nitroprusside	0.25–10 mcg/kg/min as IV infusion ^c	Immediate	1–2 minutes	Nausea, vomiting, muscle twitching, sweating, thiocyanate and cyanide intoxication	Most hypertensive emergencies; use with caution with high intracranial pressure or azotemia
Nicardipine hydrochloride	5–15 mg/h IV	5–10 minutes	15–30 minutes, may exceed 4 hours	Tachycardia, headache, flushing, local phlebitis	Most hypertensive emergencies except acute heart failure; use with caution with coronary ischemia
Fenoldopam mesylate	0.1–0.3 mcg/kg/min as IV infusion ^c	Less than 5 minutes	30 minutes	Tachycardia, headache, nausea, flushing	Most hypertensive emergencies; use with caution with glaucoma
Nitroglycerin	5–100 mcg/kg/min as IV infusion	2–5 minutes	5–10 minutes	Headache, vomiting, methemoglobinemia, tolerance with prolonged use	Coronary ischemia
Enalaprilat	1.25–5 mg every 6 hours IV	15–30 minutes	6–12 hours	Precipitous fall in pressure in high-renin states; variable response	Acute left ventricular failure; avoid in acute myocardial infarction
Hydralazine hydrochloride	10–20 mg IV 10–40 mg IM	10–20 minutes 20–30 minutes	1–4 hours IV 4–6 hours IM	Tachycardia, flushing, headache, vomiting, aggravation of angina	Eclampsia
Clevidipine	1–21 mg/h IV	2–4 minutes	5–15 minutes	Atrial fibrillation, fever, insomnia, nausea, headache, vomiting, postprocedural hemorrhage, acute renal failure, respiratory failure	Defective lipid metabolism (avoid use in these patients), severe aortic stenosis (avoid use)
Diazoxide	1–3 mg/kg or 50–100 mg every 5–15 minutes	2 minutes	3–12 hours	Hyperglycemia, sodium and water retention	Preeclampsia, eclampsia, impaired renal function
Furosemide	10–40 mg/h IV, maximum 80–160 mg/h IV	5 minutes	2 hours	Hypotension, electrolyte abnormalities, hearing impairment	Heart failure, fluid overload, adjunct therapy to vasodilators
Adrenergic Inhibitors					
Labetalol hydrochloride	20–80 mg IV bolus every 10 minutes	5–10 minutes	3–6 hours	Vomiting, scalp tingling, dizziness, bronchoconstriction, nausea, heart block, orthostatic hypotension	Most hypertensive emergencies except acute heart failure
Esmolol hydrochloride	250–500 mcg/kg/min IV bolus, then 50–100 mcg/kg/min by infusion; may repeat bolus after 5 minutes or increase infusion to 300 mcg/min	1–2 minutes	10–30 minutes	Hypotension, nausea, asthma, first-degree heart block, heart failure	Aortic dissection, perioperative
Phentolamine	5–15 mg IV bolus	1–2 minutes	10–30 minutes	Tachycardia flushing, headache	Catecholamine excess

IM, intramuscular.

^aThese doses may vary from those in the *Physicians' Desk Reference*.

^bHypotension may occur with all agents.

^cRequires special delivery system.

Table 5-7

Treatment of Chronic Hypertension in Pregnancy³

Agent	Comments
Methyldopa	Preferred first-line therapy on the basis of long-term follow-up studies supporting safety after exposure in utero. Surveillance data do not support an association between drug and congenital defects when the mother took the drug early in the first trimester
Labetalol	Increasingly preferred to methyldopa because of reduced side effects. The agent does not seem to pose a risk to the fetus, except possibly in the first trimester
β -Blockers	Generally acceptable on the basis of limited data. Reports of intrauterine growth restriction with atenolol in the first and second trimesters
Clonidine	Limited data; no association between drug and congenital defects when the mother took the drug early in the first trimester, but number of exposures is small
Calcium channel antagonists	Limited data; nifedipine in the first trimester was not associated with increased rates of major birth defects, but animal data were associated with fetal hypoxemia and acidosis. This agent should probably be limited to mothers with severe hypertension
Diuretics	Not first-line agents; probably safe; available data suggest that throughout gestation, a diuretic is not associated with an increased risk of major fetal anomalies or adverse fetal-neonatal events
Angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists	Contraindicated; reported fetal toxicity and death

Patient Encounter 2

A 27-year-old white woman presents to your clinic with a diagnosis of hypertension. She is 5'3" (160 cm) and weighs 76 kg (167 lbs). She denies using tobacco or alcohol. Fasting laboratory values were significant for glucose of 160 mg/dL (8.9 mmol/L), serum creatinine of 1.1 mg/dL (97 μ mol/L), hemoglobin A1c of 7.1% (0.071; 54 mmol/mol Hb), total cholesterol level of 212 mg/dL (5.48 mmol/L), triglyceride level of 200 mg/dL (2.26 mmol/L), and high-density lipoprotein level of 41 mg/dL (1.06 mmol/L). The calculated low-density lipoprotein level is 131 mg/dL (3.39 mmol/L). All other laboratory values are within normal limits. Urinalysis was unremarkable. The patient is in her second trimester of pregnancy. During the appointment, the patient states that she exercises two to three times a week for approximately 60 minutes. Because of her busy schedule, she admits that she eats a lot of microwave meals and canned soups. Her BP today in the clinic was 150/92 mm Hg with a pulse of 74 bpm. Her BP prior to pregnancy was 144/90 mm Hg.

What is the patient's target BP?

Based on the information presented, create a care plan for this patient's hypertension. This should include (a) goals of therapy, (b) a patient-specific therapeutic plan, and (c) a plan for appropriate monitoring to achieve goals and avoid adverse effects.

2008 guiding the role of ambulatory BP measurements in children and adolescents.¹⁰³ The *Nelson Textbook of Pediatrics* is also recommended for a comprehensive review of treatment of congenital and pediatric hypertension.¹⁰⁴

PATIENT CARE AND MONITORING

10 *The frequency of follow-up visits for patients with hypertension varies based on individual cases but is influenced by the severity of hypertension, comorbidities, and choice of agent selected.* A recent analysis of the VALUE trial found that achieving BP control within 6 months reduced CV events compared with a longer time to achieve goal.⁴⁰ In addition, another analysis found that the more times a patient is below goal, the lower the risk.^{8,105} These studies suggest there is an urgency to achieve and maintain BP control that may necessitate frequent assessment and adjustments (i.e., every 2 weeks). At a minimum, assessment of response to medications should be done at 1-month intervals.¹ In patients with stage 2 hypertension or those with comorbidities (e.g., diabetes, vascular disease, congestive HF, or CKD), shorter time frames of ≤ 2 weeks are more appropriate.⁵⁷ Once BP is controlled, annual or semi-annual monitoring for changes in serum biochemistries such as serum creatinine or potassium are recommended.¹ However, for patients with congestive heart failure, CKD, or diabetes, more frequent monitoring is necessary to adequately control comorbid conditions. Another aspect to monitoring relates to the importance of medication adherence. Confirmation of continued use of antihypertensive medications should be considered in the routine monitoring of patients on numerous medications for hypertension. Evaluation of side effects, lab abnormalities, and/or progression to target organ damage should also be considered at appropriate intervals. Given the generally asymptomatic nature of hypertension, patient motivation to adhere to prescribed medications becomes a key tool in controlling hypertension.¹

Given the chronic nature of hypertension, parsimony of medication regimens is a virtue of a good therapeutic plan.

Minimizing the number of medications a patient is required to take has the potential to enhance adherence and mitigate cost. Control of BP is often achieved by the use of two or even three or more BP-lowering medications.¹⁰⁶ Many combination products contain a diuretic as one of their active components. However, combination therapy may limit the ability of the clinician to titrate the dose of a specific agent. As such, the number of medications (“pill count”) may often be reduced through the use of combination products. This inherently simplifies the number of medications and copays a patient may have to endure to achieve effective BP control. These practicalities, although obvious, go a long way to optimize adherence, another challenge to maximizing therapy effectiveness.

OUTCOME EVALUATION

- Short-term goals are to achieve reduction in BP safely through the iterative process of using pharmacologic therapy, along with nonpharmacologic therapy or lifestyle changes.
- Lifestyle changes should address other risk factors for CVD including obesity, physical inactivity, insulin resistance, dyslipidemia, smoking cessation, and others.
- Monitoring for efficacy, adverse events, and adherence to therapy is key to achieving the long-term goals of reducing the risk of morbidity and mortality associated with CVD.

Patient Encounter 3

A 62-year-old Hispanic man arrives at your clinic complaining of elevated BP despite being on metoprolol tartrate 100 mg twice daily, chlorthalidone 25 mg once daily, and amlodipine 10 mg daily. He states that he has been adherent with all medications and diet. He does not smoke. Past medical history is significant for hypertension and osteoarthritis. Physical examination was unremarkable. Laboratory values were significant for serum creatinine of 0.8 mg/dL (71 μ mol/L), a potassium level of 3.6 mEq/L (3.6 mmol/L), total cholesterol of 220 mg/dL (5.69 mmol/L), HDL cholesterol of 35 mg/dL (0.91 mmol/L), triglyceride level of 150 mg/dL (1.70 mmol/L) and calculated LDL cholesterol of 155 mg/dL (4.01 mmol/L). The patient’s seated BP in the left arm is 152/86 mm Hg and 150/82 mm Hg in the right arm. His pulse is 58 bpm. A plasma renin activity was drawn, and the result was 0.3 ng/mL/h (0.08 ng/L/s). An aldosterone level returned within normal limits at 5 ng/dL (139 pmol/L).

Based on the information provided, does the patient have resistant hypertension?

What is that patient’s target BP using the recommendations from the 2007 American Heart Association Statement of the treatment of hypertension in the prevention and management of ischemic heart disease?

Based on the information presented, what pharmacological changes would you make to the patient’s medications to reduce his BP closer to goal and reduce his overall cardiovascular risk?

Patient Care and Monitoring

1. Measure patient BP twice, at least 1 minute apart in a sitting position, and then average the readings to determine if BP is adequately controlled.
2. Conduct a medical history. Does the patient have any compelling indications? Is the patient pregnant?
3. Conduct a medication history (prescription, over-the-counter, and dietary supplements) to determine conditions or causes of hypertension. Does the patient take any medications, supplements, herbal products, or foods that may elevate SBP or DBP? Does the patient have drug allergies?
4. Review available laboratory tests to examine electrolyte balance and renal function.
5. Discuss lifestyle modifications that may reduce BP with the patient. Determine what nonpharmacologic approaches might be or have been helpful to the patient.
6. Evaluate the patient if pharmacologic treatment has reached the target BP goal. If the patient is at the goal, skip to step 9.
7. If patient is not at goal BP, assess efficacy, safety, and compliance of the antihypertensive regimen to determine if a dose increase or additional antihypertensive agent (step 8) is needed to achieve goal BP.
8. Select an agent to minimize adverse drug reactions and interactions when additional drug therapy is needed. Does the patient have prescription coverage or is the recommended agent in the formulary?
9. Open a dialogue to address patient concerns about hypertension and management of the condition.
10. Provide a plan to assess effectiveness and safety of therapy. Follow-up at monthly intervals or less until BP is achieved, otherwise semiannual or annual clinic visits to assess electrolyte balance and renal function once BP target is achieved. Presence of comorbidities (i.e., CKD) may require more frequent follow-up.

Heart Failure

Orly Vardeny and Tien M. H. Ng

LEARNING OBJECTIVES

● **Upon completion of the chapter, the reader will be able to:**

1. Differentiate between the common underlying etiologies of heart failure, including ischemic, nonischemic, and idiopathic causes.
2. Describe the pathophysiology of heart failure as it relates to neurohormonal activation of the renin-angiotensin-aldosterone system and the sympathetic nervous system.
3. Identify signs and symptoms of heart failure and classify a given patient by the New York Heart Association Functional Classification and American College of Cardiology/American Heart Association Heart Failure Staging.
4. Describe the goals of therapy for a patient with acute or chronic heart failure.
5. Develop a nonpharmacologic treatment plan that includes patient education for managing heart failure.
6. Develop a specific evidence-based pharmacologic treatment plan for a patient with acute or chronic heart failure based on disease severity and symptoms.
7. Formulate a monitoring plan for the nonpharmacologic and pharmacologic treatment of a patient with heart failure.

KEY CONCEPTS

- 1 The most common causes of heart failure are coronary artery disease (CAD), hypertension, and dilated cardiomyopathy.
- 2 Development and progression of heart failure involves activation of neurohormonal pathways, including the sympathetic nervous system and the renin-angiotensin-aldosterone system (RAAS).
- 3 The clinician must identify potential reversible causes of heart failure exacerbations, including prescription and nonprescription drug therapies, dietary indiscretions, and medication nonadherence.
- 4 Symptoms of left-sided heart failure include dyspnea, orthopnea, and paroxysmal nocturnal dyspnea (PND), whereas symptoms of right-sided heart failure include fluid retention, GI bloating, and fatigue.
- 5 General therapeutic management goals for chronic heart failure focus on preventing onset of clinical symptoms or reducing symptoms, preventing or reducing hospitalizations, slowing or preventing disease progression, improving quality of life, and prolonging patient survival.
- 6 Nonpharmacologic treatment involves dietary modifications such as sodium and fluid restriction, risk factor reduction including smoking cessation, timely immunizations, and supervised regular physical activity.
- 7 Diuretics are used for relief of acute symptoms of congestion and maintenance of euvolemia.
- 8 Agents with proven benefits in improving symptoms, slowing disease progression, and improving survival in chronic heart failure target neurohormonal blockade; these include angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), β -adrenergic blockers, and aldosterone antagonists.
- 9 Combination therapy with hydralazine and isosorbide dinitrate is an appropriate substitute for angiotensin II antagonism in those unable to tolerate an ACE inhibitor or ARB or as add-on therapy in African Americans.
- 10 Treatment of acute heart failure targets relief of congestion and optimization of cardiac output utilizing oral or IV diuretics, IV vasodilators, and when appropriate, inotropes. Current treatment strategies in acute heart failure target improving hemodynamics while preserving organ function.

Heart failure (HF) is defined as the inadequate ability of the heart to pump enough blood to meet the blood flow and metabolic demands of the body.¹ High-output HF is characterized by an inordinate increase in the body's metabolic demands that outpaces an increase in **cardiac output** (CO) of a generally normally functioning heart. More commonly, HF is a result of low CO secondary to impaired cardiac function. The term *heart failure* refers to low-output HF for the purposes of this chapter.

HF is a clinical syndrome characterized by a history of specific signs and symptoms related to congestion and hypoperfusion. Because HF can occur in the presence or absence of fluid overload, the term *heart failure* is preferred over the former term *congestive heart failure*. HF results from any structural or functional cardiac disorder that impairs the ability of the ventricle to fill with or eject blood.¹ Many disorders, such as those of the pericardium, epicardium, endocardium, or great vessels, may lead to HF, but most patients develop symptoms due to impairment in left ventricular (LV) myocardial function.

The term *acute heart failure* (AHF) is used to signify either an acute decompensation of a patient with a history of chronic HF or to refer to a patient presenting with new-onset HF symptoms. Terms commonly associated with HF, such as *cardiomyopathy* and *LV dysfunction*, are not equivalent to HF but describe possible structural or functional reasons for the development of HF.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

HF is a major public health concern affecting approximately 6 million people in the United States. An additional 670,000 new cases are diagnosed each year. HF manifests most commonly in adults older than 60 years.² The growing prevalence of HF corresponds to (a) better treatment of patients with acute myocardial infarctions (MIs) who will survive to develop HF later in life, and (b) the increasing proportion of older adults due to the aging baby boomer population. The relative incidence of HF is lower in women compared with men, but there is a greater prevalence in women overall due to their longer life expectancy. Acute HF accounts for 12 to 15 million office visits per year and 6.5 million hospitalizations annually.² According to national registries, patients presenting with AHF are older (mean age: 75 years) and have numerous comorbidities such as coronary artery disease (CAD), renal insufficiency, and diabetes.²

Total estimated direct and indirect costs for managing both chronic and acute HF in the United States for 2009 was approximately \$37 billion. Medications account for approximately 10% of that cost.³ HF is the most common hospital discharge diagnosis for Medicare patients and the most costly diagnosis in this population.

The prognosis for patients hospitalized for AHF remains poor. Average hospital length of stay is estimated to be between 4 and 6 days, a number that has remained constant over the past decade.³ The in-hospital mortality rate has been

estimated at approximately 4%, but ranges from 2% to 20% depending on the report.⁴ In-hospital mortality increases to an average of 10.6% in patients requiring an intensive care unit admission. Readmissions are also high, with up to 30% to 60% of patients readmitted within 6 months of their initial discharge date.⁴ The 5-year mortality rate for chronic HF remains greater than 50%. Survival strongly correlates with severity of symptoms and functional capacity. Sudden cardiac death is the most common cause of death, occurring in approximately 40% of patients with HF.² Although therapies targeting the upregulated neurohormonal response contributing to the pathophysiology of HF have clearly impacted morbidity and mortality, long-term survival remains low.

Etiology

- HF is the eventual outcome of numerous cardiac diseases or disorders (**Table 6-1**).⁵ HF can be classified by the primary underlying etiology as ischemic or nonischemic, with 70% of HF related to ischemia. ① *The most common causes of HF are CAD, hypertension, and dilated cardiomyopathy.* CAD resulting in an acute MI and reduced ventricular function is a common presenting history. Nonischemic etiologies include hypertension, viral illness, thyroid disease, excessive alcohol use, illicit drug use, pregnancy-related heart disease, familial congenital disease, and valvular disorders such as mitral or tricuspid valve regurgitation or stenosis.

HF can also be classified based on the main component of the cardiac cycle leading to impaired ventricular function. A normal cardiac cycle depends on two components: systole and diastole. Expulsion of blood occurs during systole or contraction of the ventricles; diastole relates to filling of the ventricles. **Ejection fraction** (EF) is the fraction of the

Table 6-1

Causes of Heart Failure

Systolic Dysfunction (Decreased Contractility)

- Reduction in muscle mass (e.g., myocardial infarction)
- Dilated cardiomyopathies
- Ventricular hypertrophy
 - Pressure overload (e.g., systemic or pulmonary hypertension, aortic or pulmonic valve stenosis)
 - Volume overload (e.g., valvular regurgitation, shunts, high-output states)

Diastolic Dysfunction (Restriction in Ventricular Filling)

- Increased ventricular stiffness
- Ventricular hypertrophy (e.g., hypertrophic cardiomyopathy, pressure and/or volume overload)
- Infiltrative myocardial diseases (e.g., amyloidosis, sarcoidosis, endomyocardial fibrosis)
- Myocardial ischemia and infarction
- Mitral or tricuspid valve stenosis
- Pericardial disease (e.g., pericarditis, pericardial tamponade)

From Parker RB, Cavallari LH. Systolic heart failure. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A pathophysiologic approach*, 8th ed. New York, NY: McGraw-Hill, 2011:138, with permission.

volume present at the end of diastole that is pushed into the aorta during systole. Abnormal ventricular filling (**diastolic dysfunction**) and/or ventricular contraction (**systolic dysfunction**) can result in a similar decrease in CO and cause HF symptoms. Most HF is associated with evidence of LV systolic dysfunction (evidenced by a reduced EF) with or without a component of diastolic dysfunction, which coexists in up to two-thirds of patients. Isolated diastolic dysfunction, occurring in approximately one-third of HF patients, is diagnosed when a patient exhibits impaired ventricular filling with or without accompanying HF symptoms but normal systolic function. Long-standing hypertension is the leading cause of diastolic dysfunction. Ventricular dysfunction can also involve either the left or right chamber of the heart or both. This has implications for symptomatology because right-sided failure manifests as systemic congestion, whereas left-sided failure results in pulmonary symptoms.

PATHOPHYSIOLOGY

A basic grasp of normal cardiac function sets the stage for understanding the pathophysiological processes leading to HF and selecting appropriate therapy for HF. CO is defined as the volume of blood ejected per unit of time (liters per minute) and is a major determinant of tissue perfusion. CO is the product of heart rate (HR) and stroke volume (SV): $CO = HR \times SV$. The following sections describe how each parameter relates to CO.

HR is controlled by the autonomic nervous system, where sympathetic stimulation of β -adrenergic receptors results in an increase in HR and CO. SV is the volume of blood ejected with each systole. SV volume is determined by factors regulating **preload**, **afterload**, and contractility. Preload is a measure of ventricular filling pressure, or the volume of

blood in the left ventricle (also known as LV end-diastolic volume). Preload is determined by venous return as well as atrial contraction. An increase in venous return to the left ventricle results in the stretch of cardiomyocyte sarcomeres (or contractile units) and a subsequent increase in the number of cross-bridges formed between actin and myosin myofilaments. This results in an increase in the force of contraction based on the **Frank-Starling mechanism**.⁶ Afterload is the resistance to ventricular ejection and regulated by ejection impedance, wall tension, and regional wall geometry. Thus, elevated aortic and systemic pressures result in an increase in afterload and reduced SV. Contractility, also known as the **inotropic** state of the heart, is an intrinsic property of cardiac muscle incorporating fiber shortening and tension development. Contractility is influenced to a large degree by adrenergic nerve activity and circulating catecholamines such as epinephrine and norepinephrine.

Compensatory Mechanisms

In the setting of a sustained loss of myocardium, a number of mechanisms aid the heart when faced with an increased hemodynamic burden and reduced CO. They include the following: the Frank-Starling mechanism, tachycardia and increased afterload, and cardiac hypertrophy and remodeling (**Table 6-2**).^{5,7}

► Preload and the Frank-Starling Mechanism

- In the setting of a sudden decrease in CO, the natural response of the body is to decrease blood flow to the periphery to maintain perfusion to the vital organs such as the heart and brain. Therefore, renal perfusion is compromised due to both the decreased CO as well as the shunting of blood away from peripheral tissues. This results in activation

Table 6-2

Beneficial and Detrimental Effects of the Compensatory Responses in Heart Failure

Compensatory Response	Beneficial Effects of Compensation	Detrimental Effects of Compensation
Increased preload (through sodium and water retention)	Optimize stroke volume via Frank-Starling mechanism	Pulmonary and systemic congestion and edema formation Increased MVO_2
Vasoconstriction	Maintain blood pressure and perfusion in the face of reduced cardiac output	Increased MVO_2 Increased afterload decreases stroke volume and further activates the compensatory responses
Tachycardia and increased contractility (due to SNS activation)	Increase cardiac output	Increased MVO_2 Shortened diastolic filling time β_1 -Receptor downregulation, decreased receptor sensitivity
Ventricular hypertrophy and remodeling	Maintains cardiac output Reduces myocardial wall stress Decreases MVO_2	Precipitation of ventricular arrhythmias Increased risk of myocardial cell death Diastolic dysfunction Systolic dysfunction Increased risk of myocardial cell death Increased risk of myocardial ischemia Increased arrhythmia risk

MVO_2 , myocardial oxygen consumption; SNS, sympathetic nervous system.

of the renin-angiotensin-aldosterone system (RAAS). The decrease in renal perfusion is sensed by the juxtaglomerular cells of the kidneys leading to the release of renin and initiation of the cascade for production of angiotensin II. Angiotensin II stimulates the synthesis and release of aldosterone. Aldosterone in turn stimulates sodium and water retention in an attempt to increase intravascular volume and hence preload. In a healthy heart, a large increase in CO is usually accomplished with just a small change in preload. However, in a failing heart, alterations in the contractile filaments reduce the ability of cardiomyocytes to adapt to increases in preload. Thus, an increase in preload actually impairs contractile function in the failing heart and results in a further decrease in CO.

► Tachycardia and Increased Afterload

- Another mechanism to maintain CO when contractility is low is to increase HR. This is achieved through sympathetic nervous system (SNS) activation and the agonist effect of norepinephrine on β -adrenergic receptors in the heart. Sympathetic activation also enhances contractility by increasing cytosolic calcium concentrations. SV is relatively fixed in HF; thus HR becomes the major determinant of CO. Although this mechanism increases CO acutely, the **chronotropic** and inotropic responses to sympathetic activation increase myocardial oxygen demand, worsen underlying ischemia, contribute to proarrhythmia, and further impair both systolic and diastolic function.

Activation of both the RAAS and the SNS also contribute to vasoconstriction in an attempt to redistribute blood flow from peripheral organs such as the kidneys to coronary and cerebral circulation.⁷ However, arterial vasoconstriction leads to impaired forward ejection of blood from the heart due to an increase in afterload. This results in a decrease in CO and continued stimulation of compensatory responses, creating a vicious cycle of neurohormonal activation.

► Cardiac Hypertrophy and Remodeling

Ventricular hypertrophy, an adaptive increase in ventricular muscle mass due to the growth of existing myocytes, occurs in response to an increased hemodynamic burden such as volume or pressure overload.⁵ Hypertrophy can be concentric or eccentric. Concentric hypertrophy occurs in response to pressure overload such as in long-standing hypertension or pulmonary hypertension, whereas eccentric hypertrophy occurs after an acute MI. Eccentric hypertrophy involves an increase in myocyte size in a segmental fashion, as opposed to the global hypertrophy occurring in concentric hypertrophy. Although hypertrophy helps to reduce cardiac wall stress in the short term, continued hypertrophy accelerates myocyte cell death through an overall increase in myocardial oxygen demand.

Cardiac remodeling occurs as a compensatory adaptation to a change in wall stress and is largely regulated by neurohormonal activation, with angiotensin II and aldosterone being key stimuli.⁷ The process entails changes in myocardial and extracellular matrix composition and function that results in both structural and functional alterations to the heart. In

HF, the changes in cardiac size, shape, and composition are pathological and detrimental to heart function. In addition to myocyte size and extracellular matrix changes, heart geometry shifts from an elliptical to a less efficient spherical shape. Even after remodeling occurs, the heart can maintain CO for many years. However, heart function will continue to deteriorate until progression to clinical HF. The timeline for remodeling varies depending on the cardiac insult. For example, in the setting of an acute MI, remodeling starts within a few days.⁵ Chronic remodeling, however, is what progressively worsens HF, and therefore it is a major target of drug therapy.

Models of Heart Failure

Earlier models of HF focused on the hemodynamic consequences of volume overload from excess sodium and water retention, decreased CO secondary to impaired ventricular function, and vasoconstriction.⁸ Congestion was a result of fluid backup due to inadequate pump function. Therefore, drug therapy was focused on relieving excess volume using diuretics, improving pump function with inotropic agents, and alleviating vasoconstriction with vasodilators. Although these agents improved HF symptoms, they did little to slow the progressive decline in cardiac function or to improve survival.

► Neurohormonal Model

- Development and progression of HF involves activation of neurohormonal pathways including the sympathetic nervous system and the RAAS.* This model begins with an initial precipitating event or myocardial injury resulting in a decline in CO, followed by the compensatory mechanisms previously discussed. This includes activation of neurohormonal pathways with pathological consequences including the RAAS, SNS, endothelin, and vasopressin, and those with counterregulatory properties such as the natriuretic peptides and nitric oxide. This model currently guides our therapy for chronic HF in terms of preventing disease progression and mortality.

Angiotensin II Angiotensin II is a key neurohormone in the pathophysiology of HF. The vasoconstrictive effects of angiotensin II lead to an increase in systemic vascular resistance (SVR) and blood pressure. The resulting increase in afterload contributes to an increase in myocardial oxygen demand and opposes the desired increase in SV. In the kidneys, angiotensin II enhances renal function acutely by raising intraglomerular pressure through constriction of the efferent arterioles.⁶ However, the increase in glomerular filtration pressure may be offset by a reduction in renal perfusion secondary to angiotensin II's influence over the release of other vasoactive neurohormones such as vasopressin and endothelin-1 (ET-1). Angiotensin II also potentiates the release of aldosterone from the adrenal glands and norepinephrine from adrenergic nerve terminals. Additionally, angiotensin II induces vascular hypertrophy and remodeling in both cardiac and renal cells. Clinical

studies show that blocking the effects of the RAAS in HF is associated with improved cardiac function and prolonged survival. Thus, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are the cornerstone of HF treatment.

Aldosterone Aldosterone's contribution to HF pathophysiology is also multifaceted. Renally, aldosterone causes sodium and water retention in an attempt to enhance intravascular volume and CO. This adaptive mechanism has deleterious consequences because excessive sodium and water retention worsen the already elevated ventricular filling pressures. Aldosterone also contributes to electrolyte abnormalities seen in HF patients. Hypokalemia and hypomagnesemia contribute to the increased risk of arrhythmias. In addition, evidence supports the role of aldosterone as an etiological factor for myocardial fibrosis and cardiac remodeling by causing increased extracellular matrix collagen deposition and cardiac fibrosis.⁶ Aldosterone potentially contributes to disease progression via sympathetic potentiation and ventricular remodeling. In addition, the combination of these multiple effects is likely responsible for the increased risk of sudden cardiac death attributed to aldosterone. As elevated aldosterone concentrations have been associated with a poorer prognosis in HF, its blockade has become an important therapeutic target for improvement of long-term prognosis.

Norepinephrine Norepinephrine is a classic marker for SNS activation. It plays an adaptive role in the failing heart by stimulating HR and myocardial contractility to augment CO and by producing vasoconstriction to maintain organ perfusion. However, excess levels are directly cardiotoxic. In addition, sympathetic activation increases the risk for arrhythmias, ischemia, and myocyte cell death through increased myocardial workload and accelerated **apoptosis** (i.e., programmed cell death). Ventricular hypertrophy and remodeling are also influenced by norepinephrine.⁸

Plasma norepinephrine concentrations are elevated proportionally to HF severity, with highest levels correlating to the poorest prognosis. Several mechanisms relate to diminished responsiveness to catecholamines (e.g., norepinephrine) as cardiac function declines.⁶ Adrenergic receptor desensitization and **downregulation** (decreased receptor number and postreceptor responses and signaling) occurs under sustained sympathetic stimulation. The desensitization contributes to further release of norepinephrine.⁵ β -Adrenergic blocking agents, although intrinsically negatively inotropic, have become essential therapy for chronic HF.

Endothelin ET-1, one of the most potent physiological vasoconstrictors, is an important contributor to HF pathophysiology.⁹ ET-1 binds to two G-protein coupled receptors, endothelin-A (ET-A) and endothelin-B (ET-B). ET-A receptors mediate vasoconstriction and are prevalent in vascular smooth muscle and cardiac cells. ET-B receptors are expressed on the endothelium and in vascular smooth muscle, and receptor stimulation mediates vasodilation. Levels of ET-1 correlate with HF functional class and mortality.

Arginine Vasopressin Higher vasopressin concentrations are linked to dilutional hyponatremia and a poor prognosis in HF. Vasopressin exerts its effects through vasopressin type 1a (V_{1a}) and vasopressin type 2 (V_2) receptors.^{5,7} Vasopressin type 1a stimulation leads to vasoconstriction, whereas actions on the V_2 receptor cause free water retention through aquaporin channels in the collecting duct. Vasopressin increases preload, afterload, and myocardial oxygen demand in the failing heart.

Counterregulatory Hormones (Natriuretic Peptides, Bradykinin, and Nitric Oxide) Atrial natriuretic peptide (ANP) and B-type (formerly brain) natriuretic peptide (BNP) are endogenous neurohormones that regulate sodium and water balance. Natriuretic peptides decrease sodium reabsorption in the collecting duct of the kidney.¹⁰ Natriuretic peptides also cause vasodilation through the cyclic guanosine monophosphate (cGMP) pathway. Atrial natriuretic peptide is synthesized and stored in the atria, while BNP is produced mainly in the ventricles. Release of ANP and BNP is stimulated by increased cardiac chamber wall stretch usually indicative of volume load. Higher concentrations of natriuretic peptides correlate with a more severe HF functional class and prognosis. BNP is sensitive to volume status; thus the plasma concentration can be used as a diagnostic marker in HF.¹⁰

Bradykinin is part of the kallikrein-kinin system, which shares a link to the RAAS through ACE. Bradykinin is a vasodilatory peptide that is released in response to a variety of stimuli, including neurohormonal and inflammatory mediators known to be activated in HF.⁹ As a consequence, bradykinin levels are elevated in HF patients and thought to partially antagonize the vasoconstrictive peptides.

Nitric oxide, a vasodilatory hormone released by the endothelium, is found in higher concentrations in HF patients and provides two main benefits in HF: vasodilation and neurohormonal antagonism of endothelin.⁹ Nitric oxide's production is affected by the enzyme inducible nitric oxide synthetase (iNOS), which is upregulated in the setting of HF, likely due to increased levels of angiotensin II, norepinephrine, and multiple cytokines. In HF, the physiological response to nitric oxide appears to be blunted, which contributes to the imbalance between vasoconstriction and vasodilation.

► **Cardiorenal Model**

There is growing evidence of a link between renal disease and HF.⁸ Renal insufficiency is present in one-third of HF patients and is associated with a worse prognosis. In hospitalized HF patients, the presence of renal insufficiency is associated with longer lengths of stay, increased in-hospital morbidity and mortality, and detrimental neurohormonal alterations. Conversely, renal dysfunction is a common complication of HF or results from its treatment. Renal failure is also a common cause for HF decompensation.

► **Proinflammatory Cytokines**

Inflammatory cytokines have been implicated in the pathophysiology of HF.⁹ Several proinflammatory (e.g.,

tumor necrosis factor [TNF]- α , interleukin-1, interleukin-6, and interferon- γ) and anti-inflammatory cytokines (e.g., interleukin-10) are overexpressed in the failing heart. The most is known about TNF- α , a pleiotropic cytokine that acts as a negative inotrope, stimulates cardiac cell apoptosis, uncouples β -adrenergic receptors from adenylyl cyclase, and is related to **cardiac cachexia**. The exact role of cytokines and inflammation in HF pathophysiology continues to be studied.

Precipitating and Exacerbating Factors in Heart Failure

HF patients exist in one of two clinical states. When a patient's volume status and symptoms are stable, their HF condition is said to be "compensated." In situations of volume overload or other worsening symptoms, the patient is considered "decompensated." Acute decompensation can be precipitated by numerous etiologies that can be grouped into cardiac, metabolic, or patient-related causes (Table 6-3).⁵

3 *The clinician must identify potential reversible causes of HF exacerbations including prescription and nonprescription drug therapies, dietary indiscretions, and medication nonadherence.* Nonadherence with dietary restrictions or chronic HF medications deserves special attention because it is the most common cause of acute decompensation and can be prevented. As such, an accurate history regarding diet, food choices, and the patient's knowledge regarding sodium and fluid intake (including alcohol) is valuable in assessing dietary indiscretion. Nonadherence with medical recommendations such as laboratory and other appointment follow-up can also be indicative of nonadherence with diet or medications.

Table 6-3

Exacerbating or Precipitating Factors in Heart Failure

Cardiac	Metabolic	Patient-Related
Acute ischemia	Anemia	Dietary/fluid nonadherence
Arrhythmia	Hyperthyroidism/ thyrotoxicosis	HF therapy nonadherence
Endocarditis	Infection	Use of cardiotoxins (cocaine, chronic alcohol, amphetamines, sympathomimetics)
Myocarditis	Pregnancy	Offending medications (NSAIDs, COX-2 inhibitors, steroids, lithium, β -blockers, calcium channel blockers, antiarrhythmics, alcohol, thiazolidinediones)
Pulmonary embolus	Worsening renal function	
Uncontrolled hypertension		
Valvular disorders		

COX-2, cyclooxygenase-2; HF, heart failure; NSAID, nonsteroidal anti-inflammatory drug.

CLINICAL PRESENTATION AND DIAGNOSIS OF CHRONIC HEART FAILURE

In low-output HF, symptoms are generally related to either congestion behind the failing ventricle(s), or hypoperfusion (decreased tissue blood supply), or both. For example, a failing left ventricle causes fluid to back up in the lungs, and a patient with right ventricular failure would exhibit systemic symptoms of congestion. Congestion is the most common symptom in HF, followed by symptoms related to decreased perfusion to peripheral tissues including decreased renal output, mental confusion, and cold extremities. Activation of the compensatory mechanisms occurs in an effort to increase CO and preserve blood flow to vital organs. However, the increase in preload and afterload in the setting of a failing ventricle leads to elevated filling pressures and further impairment of cardiac function, which manifests as systemic and/or pulmonary congestion. It is important to remember that congestion develops behind the failing ventricle, caused by the inability of that ventricle to eject the blood that it receives from the atria and venous return. As such, signs and symptoms may be classified as left sided or right sided.

4 *Symptoms of left-sided HF include dyspnea, orthopnea, and paroxysmal nocturnal dyspnea (PND), whereas symptoms of right-sided HF include fluid retention, GI bloating, and fatigue.* Although most patients initially have left ventricular failure (LVF; pulmonary congestion), the ventricles share a septal wall, and because LVF increases the workload of the right ventricle, both ventricles eventually fail and contribute to the HF syndrome. Because of the complex nature of this syndrome, it has become exceedingly more difficult to attribute a specific sign or symptom as caused by either right ventricular failure (RVF; systemic congestion) or LVF. Therefore, the numerous signs and symptoms associated with this disorder are collectively attributed to HF rather than to dysfunction of a specific ventricle.

General Signs and Symptoms

Hypoperfusion of skeletal muscles leads to fatigue, weakness, and exercise intolerance. Decreased perfusion of the central nervous system (CNS) is related to confusion, hallucinations, insomnia, and lethargy. Peripheral vasoconstriction due to SNS activity causes pallor, cool extremities, and cyanosis of the digits. Tachycardia is also common in these patients and may reflect increased SNS activity. Patients often exhibit polyuria and nocturia. Polyuria is a result of increased release of natriuretic peptides caused by volume overload. Nocturia occurs due to increased renal perfusion as a consequence of reduced SNS renal vasoconstrictive effects at night. In chronic severe HF, unintentional weight loss can occur that leads to a syndrome of cardiac cachexia. Cardiac cachexia can be defined as a nonedematous weight loss greater than 6% of the previous normal weight over a period of at least 6 months. HF prognosis worsens considerably once cardiac cachexia has been diagnosed, regardless of HF severity. This results from several factors including loss of appetite,

Clinical Presentation and Diagnosis of Chronic Heart Failure

General

Patient presentation may range from asymptomatic to cardiogenic shock.

Symptoms

- Dyspnea, particularly on exertion
- Orthopnea
- Shortness of breath (SOB)
- Paroxysmal nocturnal dyspnea
- Exercise intolerance
- Tachypnea
- Cough
- Fatigue
- **Nocturia** and/or **polyuria**
- Hemoptysis
- Abdominal pain
- Anorexia
- Nausea
- Bloating
- Ascites
- Mental status changes
- Weakness
- Lethargy

Signs

- Pulmonary rales
- Pulmonary edema
- S₃ gallop
- Pleural effusion

Cheyne-Stokes respiration

- Tachycardia
- Cardiomegaly
- Peripheral edema (e.g., pedal edema, which is swelling of feet and ankles)
- Jugular venous distension (JVD)
- **Hepatojugular reflux** (HJR)
- Hepatomegaly
- Cyanosis of the digits
- Pallor or cool extremities

Laboratory Tests

- BNP greater than 100 pg/mL (greater than 100 ng/L or 28.9 pmol/L) or N-terminal proBNP (NT-proBNP) greater than 300 pg/mL (greater than 300 ng/L or greater than 35.4 pmol/L)
- Electrocardiogram (ECG): May be normal or could show numerous abnormalities including acute ST-T-wave changes from myocardial ischemia, atrial fibrillation, bradycardia, and LV hypertrophy.
- Serum creatinine: May be increased owing to hypoperfusion; preexisting renal dysfunction can contribute to volume overload.
- Complete blood count: Useful to determine if HF is due to reduced oxygen-carrying capacity.
- Chest x-ray: Useful for detection of cardiac enlargement, pulmonary edema, and pleural effusions.
- Echocardiogram: Used to assess LV size, valve function, pericardial effusion, wall motion abnormalities, and ejection fraction.

malabsorption due to GI edema, elevated metabolic rate, and elevated levels of norepinephrine and proinflammatory cytokines. Absorption of fats is especially affected, leading to deficiencies of fat-soluble vitamins.

Patients can experience a variety of symptoms related to buildup of fluid in the lungs. Dyspnea, or shortness of breath, can result from pulmonary congestion or systemic hypoperfusion due to LVF. Exertional dyspnea occurs when patients describe breathlessness induced by physical activity or a lower level of activity than previously known to cause breathlessness. Patients often state that activities such as stair climbing, carrying groceries, or walking a particular distance cause shortness of breath. Severity of HF is inversely proportional to the amount of activity required to produce dyspnea. In severe HF, dyspnea is present even at rest.

Orthopnea is dyspnea that is positional. Orthopnea is present if a patient is unable to breathe while lying flat on

a bed (i.e., in the recumbent position). It manifests within minutes of a patient lying down and is relieved immediately when the patient sits upright. Patients can relieve orthopnea by elevating their head and shoulders with pillows. The practitioner should inquire as to the number of pillows needed to prevent dyspnea as a marker of worsening HF. PND occurs when patients awaken suddenly with a feeling of breathlessness and suffocation. PND is caused by increased venous return and mobilization of interstitial fluid from the extremities leading to alveolar edema, and it usually occurs within 1 to 4 hours of sleep. In contrast to orthopnea, PND is not relieved immediately by sitting upright and often takes up to 30 minutes for symptoms to subside.

Pulmonary congestion may also cause a nonproductive cough that occurs at night or with exertion. Cheyne-Stokes respiration, or periodic breathing, is also common in advanced HF. It is usually associated with low-output states and may be

perceived by the patient as either severe dyspnea or transient cessation of breathing. In cases of pulmonary edema, the most severe form of pulmonary congestion, patients may produce a pink frothy sputum and experience extreme breathlessness and anxiety due to feelings of suffocation and drowning. If not treated aggressively, patients can become cyanotic and acidotic. Severe pulmonary edema can progress to respiratory failure, necessitating mechanical ventilation.

Systemic venous congestion results mainly from right ventricular failure. A clinically validated assessment of the jugular venous pressure (JVP) is performed by examining the right internal jugular vein for distention or elevation of the pulsation while reclining at a 45-degree angle. A JVP more than 4 cm above the sternal angle is indicative of elevated right atrial pressure. JVP may be normal at rest, but if application of pressure to the abdomen can elicit a sustained elevation of JVP, this is defined as hepatjugular reflux (HJR). A positive finding of HJR indicates hepatic congestion and results from displacement of volume from the abdomen into the jugular vein because the right atrium is unable to accept this additional blood. Hepatic congestion can cause abnormalities in liver function, which can be evident in liver function tests and/or clotting times. Development of hepatomegaly occurs infrequently and is caused by long-term systemic venous congestion. Intestinal or abdominal congestion can also be present, but it usually does not lead to characteristic signs unless overt ascites is evident. In advanced RVF, evidence of pulmonary hypertension may be present (e.g., right ventricular heave).

The most recognized finding of systemic congestion is peripheral edema. It usually occurs in dependent areas of the body, such as the ankles (pedal edema) for ambulatory patients or the sacral region for bedridden patients. Weight gain often precedes signs of overt peripheral edema. Therefore, it is crucial for patients to weigh themselves daily even in the absence of symptoms to assess fluid status.

Patients may complain of swelling of their feet and ankles, which can extend up to their calves or thighs. Abdominal congestion may cause a bloated feeling, abdominal pain, early satiety, nausea, anorexia, and constipation. Often patients may have difficulty fitting into their shoes or pants due to edema.

► Patient History

A thorough history is crucial to identify cardiac and noncardiac disorders or behaviors that may lead to or accelerate the development of HF. Past medical history, family history, and social history are important for identifying comorbid illnesses that are risk factors for the development of HF or underlying etiological factors. A complete medication history (including prescription and nonprescription drugs, herbal therapy, and vitamin supplements) should be obtained each time a patient is seen to evaluate adherence, to assess appropriateness of therapy, to eliminate drugs that may be harmful in HF (Table 6-4), and to determine additional monitoring requirements.⁵ For newly diagnosed HF, previous use of chemotherapeutic agents as well as current or past use

Table 6-4

Drugs That May Precipitate or Exacerbate Heart Failure

Agents Causing Negative Inotropic Effect

Antiarrhythmics (e.g., disopyramide, flecainide, and others)
 β-Blockers (e.g., propranolol, metoprolol, atenolol, and others)
 Calcium channel blockers (e.g., verapamil and others)
 Itraconazole
 Terbinafine

Cardiotoxic Agents

Doxorubicin
 Daunomycin
 Cyclophosphamide

Agents Causing Sodium and Water Retention

Nonsteroidal anti-inflammatory drugs
 COX-2 inhibitors
 Glucocorticoids
 Androgens
 Estrogens
 Salicylates (high dose)
 Sodium-containing drugs (e.g., carbenicillin disodium, ticarcillin disodium)
 Thiazolidinediones (e.g., pioglitazone)

COX-2, cyclooxygenase-2.

Adapted from Parker RB, Cavallari LH. Systolic heart failure. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A pathophysiologic approach*, 8th ed. New York, NY: McGraw-Hill, 2011:137–172.

of alcohol and illicit drugs should be assessed. In addition, for patients with a known history of HF, questions related to symptomatology and exercise tolerance are essential for assessing any changes in clinical status that may warrant further evaluation or adjustment of the medication regimen.

Patient Encounter Part 1

DG is a 68-year-old man with a history of known coronary artery disease and type 2 diabetes mellitus who presents for a belated follow-up clinic visit (his last visit was 2 years ago). His most bothersome complaint is SOB at night when lying down flat; he has to sleep on three pillows to get adequate rest and sometimes even that does not help. Although he used to be able to walk a few blocks and two to three flights of stairs comfortably before getting breathless, he has had increasing symptoms and has now progressed to SOB with any walking and while cooking and getting dressed. He also notes his ankles are always swollen and his shoes no longer fit; therefore he only wears slippers. Additionally, his appetite is decreased, and he often feels bloated.

What information is suggestive of a diagnosis of HF?

What additional information do you need to know before creating a treatment plan for DG?

Heart Failure Classification

There are two common systems for categorizing patients with HF. The New York Heart Association (NYHA) Functional Classification (FC) system is based on the patient's activity level and exercise tolerance. It divides patients into one of four classes, with functional class I patients exhibiting no symptoms or limitations of daily activities, and functional class IV patients who are symptomatic at rest (Table 6–5). The NYHA FC system reflects a subjective assessment by a healthcare provider and can change frequently over short periods of time. Functional class correlates poorly with EF; however, EF is one of the strongest predictors of prognosis. In general, anticipated survival declines in conjunction with a decline in functional ability.

The American College of Cardiology/American Heart Association (ACC/AHA) have proposed another system based on the development and progression of the disease. Instead of classifications, patients are placed into stages A through D (Table 6–5).¹¹ Because the staging system is related to development and progression of HF, it also proposes management strategies for each stage including

risk factor modification. The staging system is meant to complement the NYHA FC system; however, patients can move between NYHA functional classes as symptoms improve with treatment, whereas HF staging does not allow for patients to move to a lower stage (e.g., patients cannot be categorized as stage C and move to stage B after treatment). Currently, patients are categorized based on both systems. Functional classification and staging are useful from a clinician's perspective, allowing for a longitudinal assessment of a patient's risk and progress, requirements for nonpharmacologic interventions, response to medications, and overall prognosis.

TREATMENT OF CHRONIC HEART FAILURE

Desired Therapeutic Outcomes

- There is no cure for HF. **5** *The general therapeutic management goals for chronic HF include preventing the onset of clinical symptoms or reducing symptoms, preventing or reducing hospitalizations, slowing progression of the disease, improving quality of life, and prolonging survival.* The ACC/AHA staging system described earlier provides a guide for application of these goals based on the clinical progression of HF for a given patient. The goals are additive as one moves from stage A to stage D.^{1,11} For stage A, risk factor management is the primary goal. Stage B includes the addition of pharmacologic therapies known to slow the progression of the disease in an attempt to prevent the onset of clinical symptoms. Stage C involves the use of additional therapies aimed at controlling symptoms and decreasing morbidity. Finally, in stage D, the goals shift toward quality-of-life related issues. Only with aggressive management throughout all the stages of the disease will the ultimate goal of improving survival be realized. The attainment of these goals is based on designing a therapeutic approach that encompasses strategies aimed at control and treatment of contributing disorders, nonpharmacologic interventions, and optimal use of pharmacologic therapies.^{12,13}

Table 6–5

New York Heart Association (NYHA) Functional Classification and American College of Cardiology/American Heart Association (ACC/AHA) Staging

NYHA Functional Class	ACC/AHA Stage	Description
N/A	A	Patients at high risk for heart failure but without structural heart disease or symptoms of heart failure.
I	B	Patients with cardiac disease but without limitations of physical activity. Ordinary physical activity does not cause undue fatigue, dyspnea, or palpitation.
II	C	Patients with cardiac disease that results in slight limitations of physical activity. Ordinary physical activity results in fatigue, palpitations, dyspnea, or angina.
III	C	Patients with cardiac disease that results in marked limitation of physical activity. Although patients are comfortable at rest, less than ordinary activity will lead to symptoms.
IV	C, D	Patients with cardiac disease that results in an inability to carry on physical activity without discomfort. Symptoms of heart failure are present at rest. With any physical activity, increased discomfort is experienced. Stage D refers to end-stage heart failure patients.

Control and Treatment of Contributing Disorders

All causes of HF must be investigated to determine the etiology of cardiac dysfunction in a given patient. Because the most common etiology of HF in the United States is ischemic heart disease, coronary angiography is warranted in most patients with a history suggestive of underlying CAD. Revascularization of those with significant CAD may help restore some cardiac function in patients with reversible ischemic defects. Aggressive control of hypertension, diabetes, and obesity is also essential because each of these conditions can cause further cardiac damage. Surgical repair of valvular disease or congenital malformations may be warranted if detected. Clinical HF partly depends on metabolic processes, so correction of imbalances such as thyroid disease, anemia,

Patient Encounter Part 2

DG's Medical History, Physical Examination, and Diagnostic Tests

PMH

Hypertension × 20 years

Type 2 diabetes mellitus × 15 years

Coronary artery disease × 10 years (MIs in 1999 and 2002)

Tobacco use

History of migraines × 40 years

Allergies

No known drug allergies

Meds

Verapamil SR 360 mg once daily

Nitroglycerin 0.4 mg sublingual (SL) as needed (last use yesterday after showering)

Glipizide 10 mg twice daily for diabetes

Pioglitazone 15 mg daily for diabetes

Ibuprofen 600 mg twice daily as needed for headaches

Vitamin B₁₂ once daily

Multivitamin daily

Aspirin 81 mg once daily

FH

Significant for early heart disease in father (MI at age 53)

SH

He is disabled from a previous accident; he is married, has three children, and runs his own business; he drinks three glasses of wine with dinner and smokes one to two packs of cigarettes per day.

PE

Blood pressure (BP) 146/70 mm Hg, pulse 60 bpm and regular, respiratory rate 16/minute, Ht 5'8" (173 cm), Wt 251 lb (114 kg), body mass index (BMI): 38.2 kg/m²

Lungs are clear to auscultation with a prolonged expiratory phase; rales are present bilaterally

CV: Regular rate and rhythm with normal S₁ and S₂; there is an S₃ and a soft S₄ present; there is a 2/6 systolic ejection murmur heard best at the left lower sternal border; point of maximal impulse is within normal limits at the midclavicular line; there is no JVD

Abd: Soft, nontender, and bowel sounds are present; 2+ pitting edema of extremities extending to below the knees is observed

Chest x-ray: Bilateral pleural effusions and cardiomegaly

Echocardiogram: EF = 30% (0.30)

Laboratory Values

Hct: 41.1% (0.411)

WBC: $5.3 \times 10^3/\mu\text{L}$ ($5.3 \times 10^9/\text{L}$)

Sodium: 132 mEq/L (132 mmol/L)

Potassium: 3.2 mEq/L (3.2 mmol/L)

Bicarb: 30 mEq/L (30 mmol/L)

Chloride: 90 mEq/L (90 mmol/L)

Magnesium: 1.5 mEq/L (0.75 mmol/L)

Fasting blood glucose: 120 mg/dL (6.7 mmol/L)

Uric acid: 8 mg/dL (476 $\mu\text{mol/L}$)

Blood urea nitrogen (BUN): 40 mg/dL (14.3 mmol/L)

SCr: 0.8 mg/dL (71 $\mu\text{mol/L}$)

Alk Phos: 120 IU/L (2.0 $\mu\text{Kat/L}$)

Aspartate aminotransferase: 100 IU/L (1.67 $\mu\text{Kat/L}$)

What other laboratory or other diagnostic tests are required for the assessment of DG's condition?

How would you classify DG's NYHA functional class and ACC/AHA HF stage?

Identify exacerbating or precipitating factors that may worsen DG's HF.

What are your treatment goals for DG?

and nutritional deficiencies is required. Other more rare causes such as autoimmune disorders or acquired illnesses may have specific treatments. Identifying and discontinuing medications that can exacerbate HF is also an important intervention.

Nonpharmacologic Interventions

- It is imperative that patients recognize the role of self-management in HF. 6 *Nonpharmacologic treatment involves dietary modifications such as sodium and fluid restriction, risk factor reduction including smoking cessation, timely immunizations, and supervised regular physical activity.*

Patient education regarding monitoring symptoms, dietary and medication adherence, exercise and physical fitness, risk factor reduction, and immunizations are important for the prevention of AHF exacerbations.

Patients should be encouraged to become involved in their own care through several avenues, the first of which is self-monitoring. Home monitoring should include daily assessment of weight and exercise tolerance. Daily weights should be done first thing in the morning upon arising and before any food intake to maintain consistency. Patients should record their weight daily in a journal and bring this log to each clinic or office visit. Changes in weight can indicate fluid retention and congestion prior to onset of

peripheral or pulmonary symptoms. Individuals who have an increase of 2 to 3 pounds (0.91 to 1.36 kg) in a single day or 5 pounds (2.27 kg) over 5 days should alert their HF care provider. Some patients may be educated about self-adjusting diuretic doses based on daily weights. In addition to weight changes, a marked decline in exercise tolerance should also be reported to the HF care provider.

Nonadherence is an important issue because it relates to acute exacerbations of HF. Ensuring an understanding of the importance of each medication used to treat HF, proper administration, and potential adverse effects may improve adherence. Stressing the rationale for each medication is important, especially for NYHA FC I or ACC/AHA stage B patients who are asymptomatic yet started on drugs that may worsen symptoms initially. A clinician's involvement in emphasizing medication adherence, offering adherence suggestions such as optimal timing of medications or use of weekly pill containers, and providing intensive follow-up care has been shown to reduce AHF hospitalizations.

Dietary modifications in HF consist of initiation of an AHA step II diet as part of cardiac risk factor reduction, sodium restriction, and sometimes fluid restriction. Because sodium and water retention is a compensatory mechanism that contributes to volume overload in HF, salt and fluid restriction is often necessary to help avoid or minimize congestion. The normal American diet includes 3 to 6 g of sodium per day. Most patients with HF should limit salt intake to a maximum of 2 g/day. Patients should be educated to avoid cooking with salt and to limit intake of foods with high salt content, such as fried or processed food (lunch meats, soups, cheeses, salted snack foods, canned food, and some ethnic foods). Salt restriction can be challenging for many patients. The clinician should counsel to restrict salt slowly over time. Drastic dietary changes may lead to nonadherence due to an unpalatable diet. Substituting spices to flavor food is a useful recommendation. Salt substitutes should be used judiciously because many contain significant amounts of potassium that can increase the risk of hyperkalemia. Fluid restriction may not be necessary in many patients. When applicable, fluid intake is generally limited from all sources to less than 2 L/day.

Exercise, although discouraged when the patient is acutely decompensated to ease cardiac workload, is recommended when patients are stable. The heart is a muscle that requires activity to prevent atrophy. In addition, exercise improves peripheral muscle conditioning and efficiency, which may contribute to better exercise tolerance despite the low CO state. Regular low intensity, aerobic exercise that includes walking, swimming, or riding a bike is encouraged; heavy weight training is discouraged. The prescribed exercise regimen needs to be tailored to the individual's functional ability, and thus it is suggested that patients participate in cardiac rehabilitation programs, at least initially. It is important that patients not overexert themselves to fatigue or exertional dyspnea.

Modification of classic risk factors, such as tobacco and alcohol consumption, is important to minimize the potential for further aggravation of heart function. Data from observational studies suggest that patients with HF who

smoke have a mortality rate 40% higher than those who do not consume tobacco products.¹ All HF patients who smoke should be counseled on the importance of tobacco cessation and offered a referral to a cessation program. Patients with an alcoholic cardiomyopathy should abstain from alcohol. Whether all patients with other forms of HF should abstain from any alcohol intake remains controversial. Proponents of moderation of alcohol base their rationale on the potential cardioprotective effects. However, opponents to any alcohol intake point out that alcohol is cardiotoxic and should be avoided.

In general, it is suggested that patients remain up to date on standard immunizations. Patients with HF should be counseled to receive yearly influenza vaccinations. Additionally, a pneumococcal vaccine is recommended.

Pharmacologic Treatment

- In addition to determining therapeutic goals, the ACC/AHA staging system delineates specific therapy options based on disease progression.^{1,11} For patients in stage A, every effort is made to minimize the impact of diseases that can injure the heart. Antihypertensive and lipid-lowering therapies should be utilized when appropriate to decrease the risk for stroke, MI, and HF. ACE inhibitors should be considered in high-risk vascular disease patients. For stage B patients, the goal is to prevent or slow disease progression by interfering with neurohormonal pathways that lead to cardiac damage and mediate pathological remodeling. The goal is to prevent the onset of HF symptoms. The backbone of therapy in these patients includes ACE inhibitors or ARBs and β -blockers. In stage C patients with symptomatic LV systolic dysfunction (EF less than 40% [0.40]), the goals focus on alleviating fluid retention, minimizing disability, slowing disease progression, and reducing long-term risk for hospitalizations and death. Treatment entails a strategy that combines diuretics to control intravascular fluid balance with neurohormonal antagonists to minimize the effects of the RAAS and SNS. Digoxin may be added to improve symptoms. If a patient continues to exhibit evidence of disease progression, other therapies can be used. In some cases, these include the combination of ACE inhibitors and ARBs, although the evidence for this option is limited. Another option is combination of hydralazine and isosorbide dinitrate in African American patients. Patients with advanced stage D disease are offered more modest goals, such as improvement in quality of life. Enhancing quality of life is often achieved at the expense of expected survival. Treatment options include mechanical support, transplantation, and continuous use of IV vasoactive therapies, in addition to maintaining an optimal regimen of chronic oral medications.

► Diuretics

Diuretics have been the mainstay for HF symptom management for many years. **7** *Diuretics are used for relief of acute symptoms of congestion and maintenance of euolemia.* These agents interfere with sodium retention

by increasing urinary sodium and free water excretion. No prospective data exist on the effects of diuretics on patient outcomes.¹⁴ Therefore, the primary rationale for the use of diuretic therapy is to maintain euvolemia in symptomatic or stages C and D HF. Diuretic therapy is recommended for all patients with clinical evidence of fluid overload.^{15,16} In more mild HF, diuretics may be used on an as-needed basis. However, once the development of edema is persistent, regularly scheduled doses will be required.

Two types of diuretics are used for volume management in HF: thiazides and loop diuretics. Thiazide diuretics such as hydrochlorothiazide, chlorthalidone, and metolazone block sodium and chloride reabsorption in the distal convoluted tubule. Thiazides are weaker than loop diuretics in terms of effecting an increase in urine output and therefore are not utilized frequently as monotherapy in HF. They are optimally suited for patients with hypertension who have mild congestion. Additionally, the action of thiazides is limited in patients with renal insufficiency (creatinine clearance less than 30 mL/min [0.50 mL/s]) due to reduced secretion into their site of action. An exception is metolazone, which retains its potent action in patients with renal dysfunction. Metolazone is often used in combination with loop diuretics when patients exhibit diuretic resistance, defined as edema unresponsive to loop diuretics alone.

Loop diuretics are the most widely used diuretics in HF. These agents, including furosemide, bumetanide, and torsemide, exert their action at the thick ascending loop of Henle. Loop diuretics are not filtered through the glomerulus, but instead they undergo active transport into the tubular lumen via the organic acid pathway. As a result, drugs that compete for this active transport (e.g., probenecid and organic by-products of uremia) can lower efficacy of loop diuretics. Loop diuretics increase sodium and water excretion and induce a prostaglandin-mediated increase in renal blood flow that contributes to their natriuretic effect. Unlike thiazides, they retain their diuretic ability in patients with poor renal function. The various loop diuretics are equally effective when used at equipotent doses, although there are intrinsic differences in pharmacokinetics and pharmacodynamics (Table 6-6).⁵ The choice of which loop diuretic to use and the route of administration depends on clinical factors such as the presence of intestinal edema and rapidity of the desired effect. Oral diuretic efficacy may vary based on differing bioavailability, which is almost complete for torsemide and bumetanide but averages only 50% for furosemide. Therefore, oral torsemide can be considered an alternative to the IV route of administration for patients who do not respond to oral furosemide in the setting of profound edema. The onset of effect is slightly delayed after oral administration but occurs within a few minutes with IV dosing. Consequently, bioequivalent doses of IV furosemide are half the oral dose, whereas bumetanide and torsemide IV doses are generally equivalent to the oral doses.

In patients with evidence of mild to moderate volume overload, diuretics should be initiated at a low dose and titrated to achieve a weight loss of up to 2 pounds (0.91 kg) per day. Patients with severe volume overload should

Table 6-6

Loop Diuretics Used in Heart Failure

	Furosemide	Bumetanide	Torsemide
Usual daily dose (oral)	20–160 mg	0.5–4 mg	10–80 mg
Ceiling dose:			
Normal renal function	80–160 mg	1–2 mg	20–40 mg
CrCL 20–50 mL/min (0.33–0.83 mL/s)	160 mg	2 mg	40 mg
CrCL less than 20 mL/min (0.33 mL/s)	400 mg	8–10 mg	100 mg
Bioavailability	10–100% (average 50%)	80–90%	80–100%
Affected by food	Yes	Yes	No
Half-life	0.3–3.4 hours	0.3–1.5 hours	3–4 hours

CrCL, creatinine clearance.

From Parker RB, Cavallari LH. Systolic heart failure. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A pathophysiologic approach*, 8th ed. New York, NY: McGraw-Hill, 2011:152, with permission.

be managed in an inpatient setting. Once diuretic therapy is initiated, dosage adjustments are based on symptomatic improvement and daily body weight. Because body weight changes are a sensitive marker of fluid retention or loss, patients should continue to weigh themselves daily. Once a patient reaches a euvolemic state, diuretics may be cautiously tapered and then withdrawn in appropriate patients. In stable, educated, and adherent patients, another option is self-adjusted diuretic dosing. Based on daily body weight, patients may temporarily increase their diuretic regimen to reduce the incidence of overt edema. This also avoids overuse of diuretics and possible complications of overdiuresis such as hypotension, fatigue, and renal impairment.

The maximal response to diuretics is reduced in HF, creating a “ceiling dose” above which there is limited added benefit. This diuretic resistance is due to a compensatory increase in sodium reabsorption in the distal tubules, which decreases the effect of blocking sodium reabsorption in the loop of Henle.¹⁷ In addition, there is a simultaneous increase in the reabsorption of sodium from the proximal tubule, allowing less to reach the site of action for loop diuretics. Apart from increasing diuretic doses, strategies to improve diuretic efficacy include increasing the frequency of dosing to two or three times daily, utilizing a continuous infusion of a loop diuretic, and/or combining a loop diuretic with a thiazide diuretic.^{17,18} The latter strategy theoretically prevents sodium and water reabsorption at both the loop of Henle and the compensating distal convoluted tubule. Metolazone is used most often for this purpose because it retains its activity in settings of a low creatinine clearance. Metolazone can be dosed daily or as little as once weekly. This combination is usually maintained until the patient reaches his or her baseline weight. The clinician must use

metolazone cautiously because its potent activity predisposes a patient to metabolic abnormalities as outlined next.

Diuretics cause numerous adverse effects and metabolic abnormalities, with severity linked to diuretic potency. A particularly worrisome adverse effect in the setting of HF is hypokalemia. Low serum potassium can predispose patients to arrhythmias and sudden death. Hypomagnesemia often occurs concomitantly with diuretic-induced hypokalemia, and therefore both should be assessed and replaced in patients needing correction of hypokalemia. Magnesium is an essential cofactor for movement of potassium intracellularly to restore body stores. Patients taking diuretics are also at risk for renal insufficiency due to overdiuresis and reflex activation of the renin-angiotensin system. The potential reduction in renal blood flow and glomerular pressure is amplified by concomitant use of ACE inhibitors or ARBs.

► Neurohormonal Blocking Agents

8 Agents with proven benefits in improving symptoms, slowing disease progression, and improving survival in chronic HF target neurohormonal blockade. These include ACE inhibitors, ARBs, β -adrenergic blockers, and aldosterone antagonists.

• **Angiotensin-Converting Enzyme Inhibitors** ACE inhibitors are the cornerstone of treatment for HF. ACE inhibitors decrease neurohormonal activation by blocking the conversion of angiotensin I (AT_1) to angiotensin II (AT_2), a potent mediator of vasoconstriction and cardiac remodeling. The breakdown of bradykinin is also reduced. Bradykinin enhances the release of vasodilatory prostaglandins and histamines. These effects result in arterial and venous dilatation, and a decrease in myocardial workload through reduction of both preload and afterload. ACE inhibitors demonstrate favorable effects on cardiac hemodynamics, such as long-term increases in **cardiac index** (CI), stroke work index, and SV index, as well as significant reductions in LV filling pressure, SVR, mean arterial pressure, and HR.

There is extensive clinical experience with ACE inhibitors in systolic HF. Numerous clinical studies show ACE inhibitor therapy is associated with improvements in clinical symptoms, exercise tolerance, NYHA FC, LV size and function, and quality of life as compared with placebo.^{18–21} ACE inhibitors significantly reduce hospitalization rates and mortality regardless of underlying disease severity or etiology. ACE inhibitors are also effective in preventing HF development in high-risk patients. Studies in acute MI patients show a reduction in new-onset HF and death with ACE inhibitors whether they are initiated early (within 36 hours) or started later. In addition, ACE inhibition decreases the risk of HF hospitalization and death in patients with asymptomatic LV dysfunction. The exact mechanisms for decreased HF progression and mortality are postulated to involve both the hemodynamic improvement and the inhibition of angiotensin II's growth promoting and remodeling effects. All patients with documented LV systolic dysfunction, regardless of existing HF symptoms, should receive ACE inhibitors unless a contraindication or intolerance is present.

There is no evidence to suggest that one ACE inhibitor is preferred over another. ACE inhibitors should be initiated using low doses and titrated up to target doses over several weeks depending on tolerability (adverse effects and blood pressure). The ACC/AHA 2005 guidelines advocate using the doses that were proven to decrease mortality in clinical trials as the target doses (**Table 6–7**).¹ If the target dose cannot be attained in a given patient, the highest tolerated dose should be used chronically. Although there is incremental benefit with higher doses of ACE inhibitors, it is accepted that lower doses provide substantial if not most of the effect.²² Because ACE inhibitors are only one component of a mortality-reducing treatment plan in HF, targeting a high ACE inhibitor dose should be used cautiously to avoid a hypotensive effect that precludes starting a β -blocker or aldosterone antagonist.

Despite their clear benefits, ACE inhibitors are still underutilized in HF. One reason is undue concern or confusion regarding absolute versus relative contraindications for their use. Absolute contraindications include a history of angioedema, bilateral renal artery stenosis, and pregnancy. Relative contraindications include unilateral renal artery stenosis, renal insufficiency, hypotension, hyperkalemia, and cough. Relative contraindications provide a warning that close monitoring is required, but they do not necessarily preclude their use.

Clinicians are especially concerned about the use of ACE inhibitors in patients with renal insufficiency. It is important to recognize that ACE inhibitors can potentially contribute to the preservation or decline of renal function depending on the clinical scenario. Through preferential efferent arteriole vasodilation, ACE inhibitors can reduce intraglomerular pressure. Reduced glomerular pressures are renoprotective chronically; however, in situations of reduced or fixed renal blood flow, this leads to a reduction in filtration. In general, ACE inhibitors can be used in patients with serum creatinine less than 2.5 to 3 mg/dL (221 to 265 μ mol/L). In HF, their addition can result in improved renal function through an increase in CO and renal perfusion. Although a small increase in serum creatinine (less than 0.5 mg/dL [44 μ mol/L]) is possible with the addition of an ACE inhibitor, it is usually transient or becomes the patient's new serum creatinine baseline level. However, ACE inhibition can also worsen renal function because glomerular filtration is maintained in the setting of reduced CO through angiotensin II's constriction of the efferent arteriole. Patients most dependent on angiotensin II for maintenance of glomerular filtration pressure, and hence most susceptible to ACE inhibitor worsening of renal function, include those with hyponatremia, severely depressed LV function, or dehydration. The most common reason for creatinine elevation in a patient without a history of renal dysfunction is overdiuresis. Therefore, clinicians should consider decreasing or holding diuretic doses if an elevation in serum creatinine occurs concomitantly with a rise in blood urea nitrogen.

Hypotension occurs commonly at the initiation of therapy or with dosage increases but may happen anytime

Table 6-7

Dosing and Monitoring for Neurohormonal Blocking Agents

Drug	Initial Daily Dose	Target or Maximum Daily Dose	Monitoring
ACE Inhibitors^a			
Captopril	6.25 mg 3 times	50 mg 3 times	BP
Enalapril	2.5 mg twice	10–20 mg twice	Electrolytes (K ⁺ , BUN, SCr) at baseline, 2 weeks, and after dose titration, CBC periodically
Fosinopril	5–10 mg once	40 mg once	
Lisinopril	2.5–5 mg once	20–40 mg once	Adverse effects: cough, angioedema
Perindopril	2 mg once	8–16 mg once	
Quinapril	5 mg once	20 mg twice	
Ramipril	1.25–2.5 mg twice	5 mg twice	
Trandolapril	1 mg once	4 mg once	
Angiotensin Receptor Blockers^a			
Candesartan	4–8 mg once	32 mg once	BP
Losartan	25–50 mg once	50–100 mg once	Electrolytes (K ⁺ , BUN, SCr) at baseline, 2 weeks, and after dose titration, CBC periodically
Valsartan	20–40 mg once	160 mg twice	
Aldosterone Antagonists			
Spirolactone	12.5–25 mg once	25 mg once or twice	BP
Eplerenone	25 mg once	50 mg once	Electrolytes (K ⁺) at baseline and within 1 week of initiation and dose titration Adverse effects: gynecomastia or breast tenderness, menstrual changes, hirsutism
β-Blockers			
Bisoprolol	1.25 mg once	10 mg once	BP, HR baseline and after each dose titration, ECG Adverse effects: worsening HF symptoms (edema, SOB, fatigue), depression, sexual dysfunction
Carvedilol	3.125 mg twice	25 mg twice (50 mg twice for patients greater than 85 kg or 187 lbs)	
Metoprolol succinate	12.5–25 mg once	200 mg once	

^aUse lower dose listed in patients with renal failure.

ACE, angiotensin-converting enzyme; BP, blood pressure; BUN, blood urea nitrate; CBC, complete blood cell count; ECG, electrocardiogram; HF, heart failure; HR, heart rate; K⁺, potassium; SCr, serum creatinine; SOB, shortness of breath.

during therapy. Hypotension can manifest as dizziness, lightheadedness, presyncope, or syncope. The risk of hypotension due to possible volume depletion increases when ACE inhibitors are initiated or used concomitantly in patients on high diuretic doses. Therefore, in euvoletic patients, diuretic doses may often be decreased or withheld during ACE inhibitor dose titration. Initiating at a low dose and titrating slowly can also minimize hypotension. It may be advisable to initiate therapy with a short-acting ACE inhibitor, such as captopril, and subsequently switch to a longer-acting agent, such as lisinopril or enalapril, once the patient is stabilized.

Hyperkalemia results from reduced angiotensin II-stimulated aldosterone release. The risk of hyperkalemia with ACE inhibitors is also increased in HF due to a propensity for impaired renal function and additive effects with aldosterone antagonists. ACE inhibitor dose may need to be decreased or held if serum potassium increases above 5 mEq/L (5 mmol/L). Persistent hyperkalemia in the setting of renal insufficiency may preclude the use of an ACE inhibitor.

Cough is commonly seen with ACE inhibitors (5% to 15%) and may be related to accumulation of tissue bradykinins.⁵

It can be challenging to distinguish an ACE inhibitor-induced cough from cough caused by pulmonary congestion. A productive or wet cough usually signifies congestion, whereas a dry, hacking cough is more indicative of a drug-related etiology. If a cough is determined to be ACE inhibitor-induced, its severity should be evaluated before deciding on a course of action. If the cough is truly bothersome, a trial with a different ACE inhibitor or switching to an ARB is warranted.

Angiotensin Receptor Blockers Angiotensin receptor blockers (ARBs) selectively antagonize the effects of angiotensin II directly at the AT₁ receptor. AT₁ receptor stimulation is associated with vasoconstriction, release of aldosterone, and cellular growth promoting effects, whereas AT₂ stimulation causes vasodilation. By selectively blocking AT₁ but leaving AT₂ unaffected, ARBs block the detrimental AT₁ effects on cardiac function while allowing AT₂-mediated vasodilation and inhibition of ventricular remodeling. Angiotensin receptor blockers are considered an equally effective replacement for ACE inhibitors in patients who are intolerant or have a contraindication to an ACE inhibitor.

It was hoped that the more complete blockade of angiotensin II's AT₁ effects would confer greater long-term efficacy with ARBs compared with ACE inhibitors. However, prospective randomized trials suggest that the clinical efficacy of ARBs is similar to that of ACE inhibitors for reduction of hospitalizations for HF, sudden cardiac death, and all-cause mortality.^{23–25} Despite poorer suppression of AT₂, comparable efficacy of ACE inhibitors may be due to the additional effects on the kallikrein-kinin system. Although ARBs produce hemodynamic and neurohormonal effects similar to those of ACE inhibitors, they are considered second-line therapy due to the overwhelming clinical trial experience with ACE inhibitors.

Because the mechanism for long-term benefit appears different for ACE inhibitors and ARBs, the combination has been studied for additive benefits. One study evaluated the addition of the ARB candesartan versus placebo in HF patients with systolic dysfunction intolerant to an ACE inhibitor, or systolic dysfunction currently on ACE inhibitor therapy, or patients with preserved systolic function.²⁵ Candesartan reduced the combined incidence of cardiovascular death and hospitalization for HF in all three groups; the greatest benefit was noted in those not on an ACE inhibitor. Candesartan significantly decreased mortality compared with placebo when all three groups were combined. Based on this study, the addition of an ARB to ACE inhibitor therapy can be considered in patients with evidence of disease progression despite optimal ACE inhibitor therapy, although this strategy is still undergoing investigation.¹ This study also demonstrates the importance of having some form of angiotensin II antagonism as part of a treatment regimen.

Angiotensin receptor blockers show similar tolerability to ACE inhibitors with regard to hypotension and hyperkalemia, but they are less likely to induce cough because ARBs do not cause an accumulation of bradykinin. Angiotensin receptor blockers can be considered in patients with ACE inhibitor-induced angioedema, but they should be initiated cautiously because cross-reactivity has been reported. Many of the other considerations for the use of ARBs are similar to those of ACE inhibitors, including the need for monitoring renal function, blood pressure, and potassium. Contraindications are similar to those of ACE inhibitors. In patients truly intolerant or contraindicated to ACE inhibitors or ARBs, the combination of hydralazine and isosorbide dinitrate should be considered.

Hydralazine and Isosorbide Dinitrate Complementary hemodynamic actions originally led to the combination of nitrates with hydralazine. Nitrates reduce preload by causing primarily venous vasodilation through activating guanylate cyclase and a subsequent increase in cGMP in vascular smooth muscle. Hydralazine reduces afterload through direct arterial smooth muscle relaxation via an unknown mechanism. More recently, nitric oxide has been implicated in modulating numerous pathophysiological processes in the failing heart including inflammation, cardiac remodeling, and oxidative damage. Supplementation of nitric oxide

via administration of nitrates has also been proposed as a mechanism for benefit from this combination therapy. The beneficial effect of an external nitric oxide source may be more apparent in the African American population, which appears to be predisposed to having an imbalance in nitric oxide production. In addition, hydralazine may reduce the development of nitrate tolerance when nitrates are given chronically.

The combination of hydralazine and isosorbide dinitrate was the first therapy shown to improve long-term survival in patients with systolic HF, but it has largely been supplanted by angiotensin II antagonist therapy (ACE inhibitors and ARBs).^{26,27} Therefore, until recently, this combination therapy was reserved for patients intolerant to ACE inhibitors or ARBs secondary to renal impairment, angioedema, or hyperkalemia. New insight into the pathophysiological role of nitric oxide has reinvigorated research into this combination therapy.

The nitrate-hydralazine combination was first shown to improve survival compared with placebo.²⁶ Subsequently, the combination of isosorbide dinitrate 40 mg and hydralazine 75 mg, both given four times daily, was compared with the ACE inhibitor enalapril.²⁷ Enalapril produced a 28% greater decrease in mortality. Therefore, the combination is considered a third-line vasodilatory option for patients truly intolerant of ACE inhibitors and ARBs.

More recently, the value of adding the combination of isosorbide dinitrate 40 mg and hydralazine 75 mg three times daily to therapy including ACE inhibitors, β -blockers, digoxin, and diuretics was shown in a prospective randomized trial in African American patients.²⁸ **9** *Combination therapy with hydralazine and isosorbide dinitrate is an appropriate substitute for angiotensin II antagonism in those unable to tolerate an ACE inhibitor or ARB or as add-on therapy in African Americans.* The ACC/AHA HF guidelines now recommend considering the addition of isosorbide dinitrate and hydralazine in African Americans already on ACE inhibitors or ARBs.¹ Combination therapy with isosorbide dinitrate and hydralazine should be initiated and titrated as are other neurohormonal agents such as ACE inhibitors and β -blockers. Low doses are used to initiate therapy with subsequent titration of the dose toward target doses based on tolerability. Adverse effects such as hypotension and headache cause frequent discontinuations in patients taking this combination, and full doses often cannot be tolerated. Patients should be monitored for headache, hypotension, and tachycardia. Hydralazine is also associated with a dose-dependent risk for lupus.

The frequent dosing of isosorbide dinitrate (e.g., three to four times daily) is not conducive to patient adherence; therefore, a once-daily isosorbide mononitrate is commonly substituted for isosorbide dinitrate to simplify the dosing regimen. A nitrate-free interval is still required when using nitrates for HF.

β -Adrenergic Antagonists β -Adrenergic antagonists, or β -blockers, competitively block the influence of the SNS at β -adrenergic receptors. As recently as 15 to 20 years ago,

β -adrenergic blockers were thought to be detrimental in HF due to their negative inotropic actions, which could potentially worsen symptoms and cause acute decompensations. Since then, the benefits of inhibiting the SNS have been recognized as far outweighing the acute negative inotropic effects. Chronic β -blockade reduces ventricular mass, improves ventricular shape, and reduces LV end-systolic and diastolic volumes.^{6,8} β -Blockers also exhibit antiarrhythmic effects, slow or reverse catecholamine-induced ventricular remodeling, decrease myocyte death from catecholamine-induced necrosis or apoptosis, and prevent myocardial fetal gene expression. Consequently, β -blockers improve EF, reduce all-cause and HF-related hospitalizations, and decrease all-cause mortality in patients with systolic HF.^{29–33}

The ACC/AHA recommends that β -blockers be initiated in all patients with NYHA FC I to IV or ACC/AHA stages B through D HF if clinically stable.¹ To date, only three β -blockers have been shown to reduce mortality in systolic HF including the selective β_1 -antagonists bisoprolol and metoprolol succinate, and the nonselective β_1 -, β_2 -, and α_1 -antagonist carvedilol.^{29–33} The positive findings of β -blockers are not a class effect because bucindolol did not exhibit a beneficial effect on mortality when studied for HF, and there is limited information with propranolol and atenolol.

Although metoprolol and carvedilol are the most commonly used β -antagonists in HF, it is unknown whether one agent should be considered first line. To compare their relative effects on patient outcomes, one study compared immediate-release metoprolol tartrate to carvedilol in 3,000 patients with mild to severe HF.³³ Carvedilol lowered all-cause mortality significantly more than metoprolol tartrate. There are questions about the validity of using immediate-release metoprolol tartrate as the comparison agent, and the low average dose of metoprolol tartrate achieved in the study.

The key to utilizing β -blockers in systolic HF is initiation with low doses and slow titration to target doses over weeks to months. It is important that the β -blocker be initiated when a patient is clinically stable and euvolemic. Volume overload at the time of β -blocker initiation increases the risk for worsening symptoms. β -Blockade should begin with the lowest possible dose (Table 6–7), after which the dose may be doubled every 2 to 4 weeks depending on patient tolerability. β -Blockers may cause an acute decrease in left ventricular ejection fraction (LVEF) and short-term worsening of HF symptoms upon initiation and at each dosage titration. After each dose titration, if the patient experiences symptomatic hypotension, bradycardia, orthostasis, or worsening symptoms, further increases in dose should be withheld until the patient stabilizes. After stabilization, attempts to increase the dose should be reinstated. If mild congestion ensues as a result of the β -blocker, an increase in diuretic dose may be warranted. If moderate or severe symptoms of congestion occur, a reduction in β -blocker dose should be considered along with an increase in diuretic dose. Dose titration should continue until target clinical trial doses are achieved (Table 6–7) or until limited by repeated hemodynamic or symptomatic intolerance. Patient education

regarding the possibility of acutely worsening symptoms but improved long-term function and survival is essential to ensure adherence.

Apart from possible clinical differences between the β -blockers approved for HF, selection of a β -blocker may also be affected by pharmacologic differences. Carvedilol exhibits a more pronounced blood pressure lowering effect, and thus causes more frequent dizziness and hypotension as a consequence of its β_1 and α_1 -receptor blocking activities. Therefore, in patients predisposed to symptomatic hypotension, such as those with advanced LV dysfunction (LVEF less than 20% [0.20]) who normally exhibit low systolic blood pressures, metoprolol succinate may be the more desirable first-line β -blocker. In patients with uncontrolled hypertension, carvedilol may provide additional antihypertensive efficacy.

β -Blockers may be used by those with reactive airway disease or peripheral vascular disease but should be used with considerable caution or avoided if patients display active respiratory symptoms. Care must also be used in interpreting shortness of breath in these patients because the etiology could be either cardiac or pulmonary. A selective β_1 -blocker such as metoprolol is a reasonable option for patients with reactive airway disease. The risk versus benefit of using any β -blocker in peripheral vascular disease must be weighed based on the severity of the peripheral disease, and a selective β_1 -blocker is preferred.

Both metoprolol and carvedilol are metabolized by the liver through cytochrome P-450 (CYP450) 2D6 and undergo extensive first-pass metabolism. β -blockers should not be used in patients with severe hepatic failure. Bisoprolol is not as commonly used since it is not FDA approved for this use.

There is some debate regarding which class of agents should be initiated first in a patient with HF, namely ACE inhibitors or β -blockers. A recent study evaluated whether the order of initiation of these therapies affects all-cause mortality or hospitalization and found no difference but that more events occurred during the 6-month single-treatment phase part of the study.³⁴ These findings reinforce the importance of using both ACE inhibitors and β -blockers in the HF patient. As such, doses of the agent initiated first should not prohibit initiation of the second class of agents.

Aldosterone Antagonists Currently, the aldosterone antagonists available are spironolactone and eplerenone. Both agents are inhibitors of aldosterone that produce weak diuretic effects while sparing potassium concentrations. Eplerenone is selective for the mineralocorticoid receptor and hence does not exhibit the endocrine adverse effect profile commonly seen with spironolactone. The initial rationale for specifically targeting aldosterone for treatment of HF was based on the knowledge that ACE inhibitors do not suppress the chronic production and release of aldosterone. Aldosterone is a key pathological neurohormone that exerts multiple detrimental effects in HF. Similar to norepinephrine and angiotensin II, aldosterone levels are increased in HF and have been shown to correlate with disease severity and patient outcomes.

Each agent (spironolactone and eplerenone) has been studied in a defined population of patients with HF. One

study established efficacy with low-dose spironolactone in NYHA FC III and IV HF patients in reducing HF hospitalizations, improving functional class, reducing sudden cardiac death, and improving all-cause mortality.³⁵ Another study investigated the use of eplerenone in patients within 14 days of MI and LVEF less than 40% (0.40).³⁶ Eplerenone was found to decrease mortality as well as cardiovascular death and related hospitalization, mainly due to reducing occurrence of sudden cardiac death. Based on these two studies, the ACC/AHA guidelines recommend the addition of spironolactone be considered in NYHA FC III and IV (ACC/AHA stages C and D) patients, and eplerenone in directly post-MI patients with evidence of LV dysfunction.¹ A more recent study investigated the use of eplerenone in NYHA FC II HF patients. Eplerenone reduced death from cardiovascular causes and hospitalizations due to HF.³⁷ It is likely that updated HF treatment guidelines will include the use of aldosterone antagonists in patients with mild to moderate HF symptoms and a reduced EF who are maximized on ACE inhibitors and β -blockers.

The major risk related to aldosterone antagonists is hyperkalemia. Therefore, the decision for use of these agents should balance the benefit of decreasing death and hospitalization from HF and the potential risks of life-threatening hyperkalemia. Before and within 1 week of initiating therapy, two parameters must be assessed: serum potassium and creatinine clearance (or serum creatinine). Aldosterone antagonists should not be initiated in patients with potassium concentrations greater than 5.5 mEq/L (5.5 mmol/L). Likewise, these agents should not be given when creatinine clearance is less than 30 mL/minute (0.50 mL/s) or serum creatinine is greater than 2.5 mg/dL (221 μ mol/L).

In patients without contraindications, spironolactone is initiated at a dose of 12.5 to 25 mg daily, or occasionally on alternate days for patients with baseline renal insufficiency. Eplerenone is used at a dose of 25 mg daily, with the option to titrate up to 50 mg daily. Doses should be halved or switched to alternate-day dosing if creatinine clearance falls below 50 mL/min (0.83 mL/s). Potassium supplementation is often decreased or stopped after aldosterone antagonists are initiated, and patients should be counseled to avoid high-potassium foods. At any time after initiation of therapy, if potassium concentrations exceed 5.5 mEq/L (5.5 mmol/L), the dose of the aldosterone antagonist should be reduced or discontinued. In addition, worsening renal function dictates consideration for stopping the aldosterone antagonist. Other adverse effects observed mainly with spironolactone include gynecomastia for men and breast tenderness and menstrual irregularities for women. Gynecomastia leads to discontinuation in up to 10% of patients on spironolactone. Eplerenone is a CYP3 A4 substrate and should not be used concomitantly with strong inhibitors of 3A4.

► Digoxin

Digoxin has been used for several decades in the treatment of HF. Traditionally, it was considered useful for its positive inotropic effects, but more recently its benefits are thought

to be related to neurohormonal modulation. Digoxin exerts positive inotropic effects through binding to sodium- and potassium-activated adenosine triphosphate (ATP) pumps, leading to increased intracellular sodium concentrations and subsequently more available intracellular calcium during systole. The mechanism of digoxin's neurohormonal blocking effect is less well understood but may be related to restoration of baroreceptor sensitivity and reduced central sympathetic outflow.⁵

The exact role of digoxin in therapy remains controversial largely due to disagreement on the risk versus benefit of routinely using this drug in patients with systolic HF. Digoxin was shown to decrease HF-related hospitalizations but did not decrease HF progression or improve survival.³⁸ Moreover, digoxin was associated with an increased risk for concentration-related toxicity and numerous adverse effects. Post hoc study analyses demonstrated a clear relationship between digoxin plasma concentration and outcomes. Concentrations below 1.2 ng/mL (1.5 nmol/L) were associated with no apparent adverse effect on survival, whereas higher concentrations increased the relative risk of mortality.^{39,40}

Current recommendations are for the addition of digoxin for patients who remain symptomatic despite an optimal HF regimen consisting of an ACE inhibitor or ARB, β -blocker, and diuretic. In patients with concomitant atrial fibrillation, digoxin may be added to slow ventricular rate regardless of HF symptomatology.

Digoxin is initiated at a dose of 0.125 mg to 0.25 mg daily depending on age, renal function, weight, and risk for toxicity. The lower dose should be used if the patient satisfies any of the following criteria: older than 65 years, creatinine clearance less than 60 mL/min (1.0 mL/s), or ideal body weight less than 70 kg (154 lb). The 0.125-mg daily dose is adequate in most patients. Doses are halved or switched to alternate-day dosing in patients with moderate to severe renal failure. The desired concentration range for digoxin is 0.5 ng/mL to 1.2 ng/mL (0.6 nmol/L to 1.5 nmol/L), preferably with concentrations at or less than 0.8 ng/mL (1.0 nmol/L). Routine monitoring of serum drug concentrations is not required but recommended in those with changes in renal function, suspected toxicity, or after addition or subtraction of an interacting drug.

Digoxin toxicity may manifest as nonspecific findings such as fatigue or weakness and other CNS effects such as confusion, delirium, and psychosis. GI manifestations include nausea, vomiting, or anorexia, and visual disturbances may occur such as halos, photophobia, and color perception problems (red-green or yellow-green vision). Cardiac findings include numerous types of arrhythmias related to enhanced automaticity, slowed or accelerated conduction, or delayed after-depolarizations. These include ventricular tachycardia and fibrillation, atrioventricular nodal block, and sinus bradycardia. Risk of digoxin toxicity, in particular the cardiac manifestations, are increased with electrolyte disturbances such as hypokalemia, hypercalcemia, and hypomagnesemia. To reduce the proarrhythmic risk of digoxin, serum potassium and magnesium should be monitored closely and supplemented when appropriate to

ensure adequate concentrations (potassium greater than 4.0 mEq/L [4.0 mmol/L] and magnesium greater than 2.0 mEq/L [1.0 mmol/L]). In patients with life-threatening toxicity due to cardiac or other findings, administration of digoxin-specific Fab antibody fragments usually reverses adverse effects within an hour in most cases.

► Calcium Channel Blockers

Treatment with nondihydropyridine calcium channel blockers (diltiazem and verapamil) may worsen HF and increase the risk of death in patients with advanced LV systolic dysfunction due to their negative inotropic effects. Conversely, dihydropyridine calcium channel blockers, although negative inotropes in vitro, do not appear to decrease contractility in vivo. Amlodipine and felodipine are the two most extensively studied dihydropyridine calcium channel blockers for systolic HF.^{41,42} These two agents have not been shown to affect patient survival, either positively or negatively. As such, they are not routinely recommended as part of a standard HF regimen; however, amlodipine and felodipine can safely be used in HF patients to treat uncontrolled hypertension or angina once all other appropriate drugs are maximized.

► Antiplatelets and Anticoagulation

Patients with HF are at an increased risk of thromboembolic events secondary to a combination of hypercoagulability, relative stasis of blood, and endothelial dysfunction. However, the role of antiplatelets and anticoagulants remains debatable due to a lack of prospective clinical trials.

Aspirin is generally used in HF patients with an underlying ischemic etiology, a history of ischemic heart disease, or other compelling indications such as history of embolic stroke. Routine use in nonischemic cardiomyopathy patients is currently discouraged because of a lack of data supporting any long-term benefit, as well as the potential negative drug-drug interaction with ACE inhibitors and ARBs. If aspirin is indicated, the preference is to use a low dose (81 mg daily).⁴³

Current consensus recommendations support the use of warfarin in patients with reduced LV systolic dysfunction and a compelling indication such as atrial fibrillation or prosthetic heart valves.⁴⁴ In addition, warfarin is empirically used in patients with echocardiographic evidence of a mural thrombus or severely depressed (LVEF less than 20% [0.20]) LV function.⁴⁵ However, there are limited data supporting the use of empirical warfarin based on echocardiographic findings. Patients with HF often have difficulty maintaining a therapeutic international normalized ratio (INR) due to fluctuating volume status and varying drug absorption. Therefore, the benefit of using warfarin should be evaluated in the context of the risk for bleeding.

► Complementary and Alternative Medications

Complementary and alternative medications (CAMs) are treatment strategies not commonly used in Western medicine and are considered nutrition supplements by the FDA. Some patients with HF use CAM for heart problems, weight loss,

Patient Encounter Part 3

Based on the information presented and your problem-based assessment, create a care plan for DG's HF. Your plan should include:

- Nonpharmacologic treatment options.
- Acute and chronic treatment plans to address DG's symptoms and prevent disease deterioration.
- Monitoring plan for acute and chronic treatments.

anxiety, and arthritis. Fish oils, n-3 polyunsaturated fatty acids, or w-3 fatty acids were recently studied for HF and found to mildly decrease cardiovascular admissions and mortality without significant adverse effects. Fish oils are more commonly used for the treatment of hypertriglyceridemia. Their mechanism in HF is incompletely understood but postulated to involve decreased membrane excitability (thus reducing arrhythmias), decreased inflammation and platelet aggregation, and favorable changes in autonomic tone. Hawthorn is another CAM studied in HF and shown to increase exercise capacity and reduce HF symptoms. Its benefits are thought to be due to flavonoids that increase force of contraction and cardiac output. The ACC/AHA guidelines do not currently advocate the use of fish oils and hawthorn for HF. It is important to counsel patients to remain on their other HF medications if they decide to initiate a CAM, and to let their healthcare providers know when starting a new supplement. As with any therapy, it is important to monitor for adverse events and therapeutic outcomes.

Heart Failure with Preserved Left Ventricular Ejection Fraction

It is now recognized that a significant number of patients exhibiting HF symptoms have normal systolic function or preserved LVEF (40% to 60% [0.40 to 0.60]). It is believed the primary defect in these patients is impaired ventricular relaxation and filling, commonly referred to as HF with preserved ejection fraction (HFpEF). HF with preserved EF is more prevalent in older women and closely associated with hypertension or diabetes and, to a lesser extent, CAD and atrial fibrillation.⁴⁶ Morbidity in HFpEF is comparable with those with depressed EF because both are characterized by frequent, repeated hospitalizations.⁴⁶ However, HFpEF appears to be associated with slightly lower mortality. The diagnosis is based on findings of typical signs and symptoms of HF, in conjunction with echocardiographic evidence of abnormal diastolic function, absence of significant LV chamber dilation, and no valvular disease.

Unlike systolic HF, few prospective trials have evaluated the safety and efficacy of various cardiac medications in patients with HFpEF. The PEP-CHF (Perindopril in Elderly People with Chronic Heart Failure) study was the first major randomized controlled trial to evaluate the use of an ACE inhibitor in patients with HFpEF.⁴⁷ The study did not find

differences in mortality and hospitalizations between groups, but premature withdrawal of many patients after 1 year could have contributed to the neutral findings.⁴⁷ The Candesartan in Heart Failure Assessment of Reduction in Mortality and Morbidity (CHARM) study demonstrated that angiotensin receptor blockade with candesartan resulted in beneficial effects on HF morbidity in patients with preserved LVEF similar to those seen in depressed LV function.²⁵ However, the largest clinical trial in HFpEF, the I-PRESERVE (Irbesartan in Patients with Heart Failure and Preserved Ejection Fraction) study did not find a reduction in the primary composite outcome of death or hospitalizations.⁴⁸ In the absence of more landmark clinical studies, the current treatment approach for HFpEF is (a) correction or control of underlying etiologies (including optimal treatment of hypertension and CAD and maintenance of normal sinus rhythm); (b) reduction of cardiac filling pressures at rest and during exertion; and (c) increased diastolic filling time. Diuretics are frequently used to control congestion. Recent studies failed to show significant reductions in mortality or hospitalizations with the use of ARBs. β -Blockers and calcium channel blockers can theoretically improve ventricular relaxation through negative inotropic and chronotropic effects. Unlike in systolic HF, nondihydropyridine calcium channel blockers (diltiazem and verapamil) may be especially useful in improving diastolic function by limiting the availability of calcium that mediates contractility. A recent study did not find favorable effects with digoxin in patients with mild to moderate diastolic HF. Therefore, the role of digoxin for symptom management and HR control in these patients is not well established.

Special Populations and Patients with Concomitant Disorders

► Ethnic and Genetic Considerations

HF is more prevalent and associated with a worse prognosis in African Americans compared with the general population.¹ Unfortunately, deficiencies in disease prevention, detection, and access to treatment are well documented in minority populations. African Americans and other races are underrepresented in clinical trials, compromising the extrapolation of results from these studies to ethnic subpopulations. The influence of race on efficacy and safety of medications used in HF treatment has received additional attention with the advent of pharmacogenomics (the influence of genetics on drug response). The application of race and genetics to pharmacotherapeutic decision making for HF is in the early stages. However, these concepts are being applied to the use of hydralazine and isosorbide dinitrate in African American patients.²⁸ It is anticipated that further investigation will lead to better insight relating to the clinical applicability of genetic variations to drug responses.

► Peripartum Cardiomyopathy and Pregnancy

Peripartum cardiomyopathy (PPCM) is currently defined as clinical and echocardiographic evidence for new-onset HF occurring during pregnancy and up to 6 months after delivery,

with other etiologies excluded. Although PPCM is not well understood, it manifests in pregnant women of all ages, but the risk is elevated in women older than 30 years.⁴⁹ The true incidence of idiopathic PPCM is debatable, with reported rates for peripartum HF at 1 case per 100 to 4,000 deliveries.⁵⁰ The leading hypothesis for PPCM pathogenesis is myocarditis caused by a viral infection or an abnormal immune response to pregnancy. HF may persist after delivery but can be reversible (with partial or full recovery of cardiac function) in many cases.⁴⁹

The clinical presentation of peripartum HF is indistinguishable from that of other types of HF. Initial treatment is also similar, with the exception of ACE inhibitors and ARBs being contraindicated during the antepartum period. Treatment includes reducing preload by sodium restriction and diuretics, afterload reduction with vasodilators, and sometimes inotropic support with digoxin. Hydralazine is utilized frequently in pregnancy and classified as FDA pregnancy category C. Labetalol is used for acute parenteral control of blood pressure, but long-term β -blocker use corresponds with low birthweight infants. Management of the cardiomyopathy after delivery includes use of ACE inhibitors and β -blockers, although these treatment guidelines have been extrapolated from studies in patients with idiopathic dilated cardiomyopathy rather than specific trials in PPCM. Patients with PPCM also have a high rate of thromboembolism. Treatment options during pregnancy are limited to unfractionated heparin and low molecular weight heparin because warfarin is contraindicated. After delivery, anticoagulation is recommended in patients with LVEF less than 20% (0.20).⁵⁰

Outcome Evaluation of Chronic Heart Failure

- The evaluation of therapy is influenced by the ability of treatment to successfully reduce symptoms, improve quality of life, decrease frequency of hospitalizations for acute HF, reduce disease progression, and prolong survival (**Fig. 6-1**).
- The major outcome parameters focus on (a) volume status, (b) exercise tolerance, (c) overall symptoms/quality of life, (d) adverse drug reactions, and (e) disease progression and cardiac function. Assess quality of life by evaluating patients' ability to continue their activities of daily living.
- Assess symptoms of HF such as dyspnea on exertion, orthopnea, weight gain, and edema, and abdominal manifestations such as nausea, bloating, and loss of appetite.
- If diuretic therapy is warranted, monitor for therapeutic response by assessing weight loss and improvement of fluid retention, as well as exercise tolerance and presence of fatigue.
- Once therapy for preventing disease progression is initiated, monitoring for symptomatic improvement continues.
- It is important to keep in mind that patients' symptoms of HF can worsen with β -blockers, and it may take weeks or months before patients notice improvement.

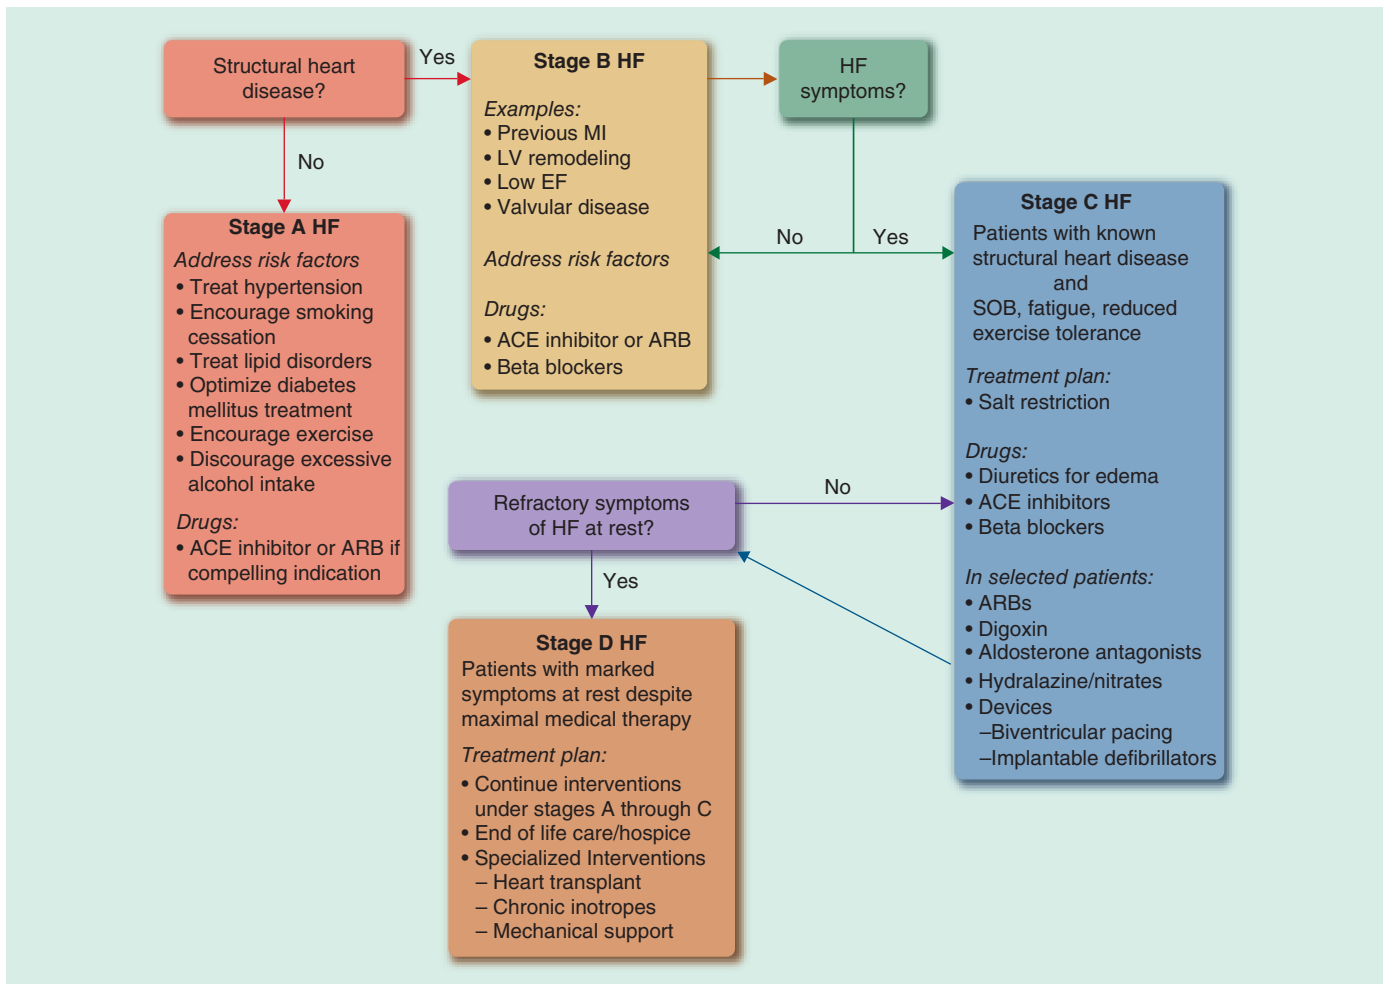

FIGURE 6-1. Treatment algorithm for chronic heart failure. (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; EF, ejection fraction; HF, heart failure; LV, left ventricular; MI, myocardial infarction; SOB, shortness of breath.) Table 6-5 describes the staging of heart failure.

- Monitor blood pressure to evaluate for hypotension caused by drug therapy.
- To assess for prevention of disease progression, practitioners may utilize serial echocardiograms every 6 months to assess cardiac function and evaluate the effects of drug therapy.
- Occasional exercise testing is conducted to ascertain disease prognosis or suitability for heart transplant. Even though these tests can demonstrate improvement in heart function and therefore slowed disease progression, patient symptoms may not improve.

ACUTE AND ADVANCED HEART FAILURE

Clinical Presentation and Diagnosis of Acute Heart Failure

Patients with acute heart failure (AHF) present with symptoms of worsening fluid retention or decreasing exercise tolerance and fatigue (typically worsening of symptoms presented in the

chronic HF clinical presentation text box). These symptoms reflect congestion behind the failing ventricle and/or hypoperfusion. Patients can be categorized into hemodynamic subsets based on assessment of physical signs and symptoms of congestion and/or hypoperfusion.⁵¹ Patients can be described as “wet” or “dry” depending on volume status, as well as “warm” or “cool” based on adequacy of tissue perfusion. “Wet” refers to patients with volume/fluid overload (e.g., edema and jugular venous distention [JVD]), whereas “dry” refers to euvolemic patients. “Warm” refers to patients with adequate CO to perfuse peripheral tissues (and hence the skin will be warm to touch), whereas “cool” refers to patients with evidence of hypoperfusion (skin cool to touch with diminished pulses). Additionally, invasive hemodynamic monitoring can be used to provide objective data for assessing volume status (pulmonary capillary wedge pressure [PCWP]) and perfusion (CO). A CI below 2.2 L/min/m² is consistent with hypoperfusion and reduced contractility, and a PCWP above 18 mm Hg (2.4 kPa) correlates with congestion and an elevated preload. The four possible hemodynamic subsets a patient may fall into are “warm and dry,” “warm and wet,” “cool and dry,” or “cool and wet.”

Clinical Presentation of Acute Heart Failure

Subset I (Warm and Dry)

- Cardiac index (CI) *greater than* 2.2 L/min/m², pulmonary capillary wedge pressure (PCWP) *less than* 18 mm Hg (2.4 kPa)
- Patients considered well compensated and perfused, without evidence of congestion
- No immediate interventions necessary except optimizing oral medications and monitoring

Subset II (Warm and Wet)

- CI *greater than* 2.2 L/min/m², PCWP *greater than* or equal to 18 mm Hg (2.4 kPa)
- Patients adequately perfused and display signs and symptoms of congestion
- Main goal is to reduce preload (PCWP) carefully with loop diuretics and vasodilators

Subset III (Cool and Dry)

- CI *less than* 2.2 L/min/m², PCWP *less than* 18 mm Hg (2.4 kPa)
- Patients are inadequately perfused and not congested
- Hypoperfusion leads to increased mortality, elevating death rates fourfold compared with those who are adequately perfused
- Treatment focuses on increasing CO with positive inotropic agents and/or replacing intravascular fluids
- Fluid replacement must be performed cautiously because patients can rapidly become congested

Subset IV (Cool and Wet)

- CI *less than* 2.2 L/min/m², PCWP *greater than* 18 mm Hg (2.4 kPa)
- Patients are inadequately perfused and congested
- Classified as the most complicated clinical presentation of AHF with the worst prognosis
- Most challenging to treat; therapy targets alleviating signs and symptoms of congestion by increasing CI as well as reducing PCWP while maintaining adequate mean arterial pressure
- Treatment involves a delicate balance between diuretics, vasodilators, and inotropic agents
- Use of vasopressors is sometimes necessary to maintain blood pressure

lifestyle factors can all precipitate AHF. The most common precipitating factors for acute decompensation and how they contribute pathophysiologically are listed in Table 6–3.

► Laboratory Assessment

Routine laboratory testing of patients with AHF includes electrolytes and blood glucose, as well as serum creatinine and blood urea nitrogen to assess renal function. Complete blood cell count is measured to determine if anemia or infection is present. Creatine kinase and/or troponin concentrations are used to diagnose ischemia, and hepatic transaminases are measured to assess hepatic congestion. Thyroid function tests are measured to assess hyperthyroidism or hypothyroidism as causes of AHF. A urinalysis is attained in patients with an unknown history of renal disease to rule out nephrotic syndrome. Lastly, a toxicology screen is obtained in patients in whom the use of illicit drugs is suspected.

Assays measuring BNP and its degradation product NT-proBNP are being used with greater frequency in clinical practice.¹⁰ B-type natriuretic peptide is synthesized, stored, and released from the ventricles in response to increased ventricular filling pressures. Hence plasma levels of BNP can be used as a marker for volume overload. The most widely accepted indication for BNP measurement is as an adjunctive aid for diagnosing a cardiac etiology for dyspnea.¹⁰

The current values for ruling out a cardiac etiology for dyspnea are a BNP less than 100 pg/mL (100 ng/L or 28.9 pmol/L) or an NT-proBNP less than 300 pg/mL (300 ng/L or 35.4 pmol/L). BNP measurements require cautious interpretation because numerous conditions can also elevate BNP concentrations. These include older age, renal dysfunction, pulmonary embolism, and chronic pulmonary disease. One group recommends age adjusted cut points for NT-proBNP as follows: 50 years old = 450 ng/mL, 50 to 75 years = 900 ng/mL, and greater than or equal to 75 years = 1800 ng/mL. Nesiritide, a recombinant BNP drug, has an identical structure to native BNP and will interfere with the commercial BNP assay, resulting in a falsely elevated level. Therefore, blood for BNP determination should be obtained 2 hours after the end of a nesiritide infusion, or alternatively the NT-proBNP assay should be utilized.

Other diagnostic tests should also be obtained in order to rule out precipitating factors (chest radiograph) and to evaluate cardiac function (electrocardiogram [ECG]).

Invasive hemodynamic monitoring in patients with HF entails placement of a right heart or pulmonary artery catheter (PAC). The catheter is inserted percutaneously through a central vein and advanced through the right side of the heart to the pulmonary artery. Inflation of a balloon proximal to the end port allows the catheter to “wedge,” yielding the PCWP, which estimates pressures in the left ventricle during diastole. Additionally, CO can be estimated and SVR calculated (Table 6–8).

There are no universally accepted guidelines dictating when invasive monitoring in HF is required, and invasive monitoring has not been shown to improve mortality or reduce hospitalizations in high-risk patients. Nonetheless, the

Clinical Assessment and Diagnosis

► Precipitating Factors

3 It is important for the clinician to identify the cause(s) of AHF in order to maximize treatment efficacy and reduce future disease exacerbations. Cardiovascular, metabolic, and

Table 6-8

Hemodynamic Monitoring: Normal Values

Hemodynamic Variable	Normal Value
Central venous (right atrial) pressure, mean	Less than 5 mm Hg ^a (0.67 kPa)
Right ventricular pressure	25/0 mm Hg ^a
Pulmonary artery pressure	25/10 mm Hg ^a
Pulmonary artery pressure, mean	Less than 18 mm Hg ^a (2.4 kPa)
Pulmonary artery occlusion pressure, mean	Less than 12 mm Hg ^a (1.60 kPa)
Systemic arterial pressure	120/80 mm Hg ^a
Mean arterial pressure	90–120 mm Hg ^a (12.0–16.0 kPa)
Cardiac index	2.8–4.2 L/min/m ^{2a}
Stroke volume index	30–65 mL/beat/m ^{2a} (0.030–0.065 L·beat ⁻¹ ·m ⁻²)
Systemic vascular resistance	900–1,400 dyn·s·m ⁻⁵ (90–140 MPa·s·m ⁻³)
Pulmonary vascular resistance	150–250 dyn·s·m ^{-5b} (15–25 MPa·s·m ⁻³)
Arterial oxygen content	20 mL/dL ^a (200 mL/L)
Mixed venous oxygen content	15 mL/dL ^a (150 mL/L)
Arteriovenous oxygen content difference	3–5 mL/dL ^a (30–50 mL/L)

^a1 mm Hg = 0.133 kPa; 1 mL/beat per square meter = 0.001 L·beat⁻¹·m⁻².

^b1 dyn·s·m⁻⁵ = 0.1 MPa·s·m⁻³; 1 mL/dL = 10 mL/L.

From Rodgers JE, Lee CR. Acute decompensated heart failure. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A pathophysiologic approach*, 8th ed. New York, NY: McGraw-Hill, 2011:196, with permission.

use of a PAC remains an essential component of management and monitoring of patients in cardiogenic shock; however, the use of inotropic agents does not mandate invasive monitoring. Invasive hemodynamic monitoring is most commonly used to aid in the assessment of hemodynamics when there is disagreement between signs and symptoms and clinical response. In addition, invasive monitoring is helpful in guiding ongoing therapy for AHF. Invasive monitoring offers the advantage of immediate hemodynamic assessment of an intervention, allowing for prompt adjustments. Risks with PACs include infection, bleeding, thrombosis, catheter malfunction, and ventricular ectopy.

TREATMENT OF ACUTE HEART FAILURE

Desired Therapeutic Outcomes

The goals of therapy for AHF are to (a) correct the underlying precipitating factor(s); (b) relieve the patient's symptoms; (c) improve hemodynamics; (d) optimize a chronic oral medication regimen; and (e) educate the patient, reinforcing adherence to lifestyle modifications and the drug regimen. The ultimate goal for a patient hospitalized for AHF is the return to a compensated HF state and discharge to the outpatient setting on oral medications. Only through

aggressive management to achieve all of these goals will a patient's prognosis be improved and future hospitalizations for acute decompensations be prevented.

Removal or control of precipitating factors is essential for an optimal response to pharmacologic therapy. Relief of symptoms should occur rapidly to minimize length of hospitalization. Although a rapid discharge from the hospital is desirable, a patient should not be discharged before ensuring that he or she is in a euvolemic, or nearly euvolemic, state with a body weight and functional capacity similar to before the acute decompensation. Oral agents such as β -blockers, ACE inhibitors or ARBs, and aldosterone antagonists should be initiated as soon as possible during the hospitalization. These chronic oral medications not only improve mortality and prevent readmissions, acutely they also contribute to improvement in hemodynamics. Patient education prior to discharge from the hospital is recommended to assist in minimizing adverse effects and nonadherence. Dissemination of written information, in addition to verbal information, is helpful for patient comprehension and retention. This can include therapy goals, lifestyle modifications, drug regimen, dosage information, and relevant adverse effects, as well as symptom and diary cards.

Pharmacologic Approaches to Treatment

- 10 *Treatment of AHF targets relief of congestion and optimization of CO utilizing oral or IV diuretics, IV vasodilators, and, when appropriate, inotropes, based on presenting hemodynamics. Current treatment strategies in AHF target improving hemodynamics while preserving organ function.* A specific treatment approach is formulated depending on the patient's symptoms (congestion versus hypoperfusion) and hemodynamic indices (CI and PCWP).^{52,53} If the patient primarily exhibits signs and symptoms of congestion, treatment entails use of diuretics as first-line agents to decrease PCWP. Additionally, IV vasodilators are added to provide rapid relief of congestion and additional reductions in PCWP. By reducing congestion in the heart, cardiac contractile function may improve, which results in an increase in SV and CO, and hence perfusion to vital organs. The patient's presenting blood pressure can also help guide the clinician on choice of diuretic, vasodilator, or both. For the patient with a systolic blood pressure of 120 to 160 mm Hg in the setting of progressive worsening of chronic HF with pulmonary and systemic congestion, aggressive diuresis can be beneficial. In the patient with systolic blood pressure greater than 160 mm Hg and abrupt onset of pulmonary congestion, IV vasodilators may be indicated in addition to diuretics. For patients primarily displaying symptoms of hypoperfusion, treatment relies on use of agents that increase cardiac contractility, known as positive inotropes. Some patients display both symptoms of congestion as well as hypoperfusion and thus require use of combination therapies. One of the current challenges to the treatment of AHF is achieving hemodynamic improvement without adversely affecting organ function. In the case of inotropes, the increased contractility occurs at the expense of an

Table 6-9

IV Diuretics Used to Treat Heart Failure–Related Fluid Retention

	Onset of Action (minutes)	Duration of Action (hours)	Relative Potency	Intermittent Bolus Dosing (mg)	Continuous Infusion Dosing (bolus/infusion)
Furosemide	2–5	6	40	20–200+	20–40/2.5–10
Torsemide	Less than 10	6–12	20	10–100	20/2–5
Bumetanide	2–3	4–6	0.5	1–10	1–4/0.5–1
Ethacrynic acid	5–15	2–7		0.5–1 mg/kg per dose up to 100 mg/dose	

increase in cardiac workload and proarrhythmia. In addition, high-dose diuretic therapy is associated with worsened renal function and possibly neurohormonal activation.

► Diuretics

Loop diuretics, including furosemide, bumetanide, and torsemide, are the diuretics of choice in the management of AHF. Furosemide is the most commonly used agent. Diuretics decrease preload by functional venodilation within 5 to 15 minutes of administration and subsequently by an increase in sodium and water excretion. This provides rapid improvement in symptoms of pulmonary congestion. Diuretics reduce PCWP but do not increase CI like positive inotropes and arterial vasodilators. Patients who have significant volume overload often have impaired absorption of oral loop diuretics because of intestinal edema or altered transit time. Therefore, doses are usually administered via IV boluses or continuous IV infusions, given either at the same dose as the home oral dose for those taking diuretics regularly or at lower doses for diuretic-naïve patients (Table 6-9). Higher doses may be required for patients with renal insufficiency due to decreased drug delivery to the site of action in the loop of Henle.

There is a paucity of clinical trial evidence comparing the benefit of diuretics with other therapies for symptom relief or long-term outcomes. Additionally, excessive preload reduction can lead to a decrease in CO resulting in reflex increase in sympathetic activation, renin release, and the expected consequences of vasoconstriction, tachycardia, and increased myocardial oxygen demand. Careful use of diuretics is recommended to avoid overdiuresis. Monitoring of serum electrolytes such as potassium, sodium, and magnesium is done frequently to identify and correct imbalances. Monitor serum creatinine and blood urea nitrogen daily at a minimum to assess volume depletion and renal function.

Occasionally, patients with HF do not respond to a diuretic, defined as failure to achieve a weight reduction of at least 0.5 kg (or negative net fluid balance of at least 500 mL) after several increasing bolus doses.¹⁷

Several strategies are used to overcome diuretic resistance. These include using larger oral doses, converting to IV dosing, or increasing the frequency of administration. A small study using low-dose continuous infusions of furosemide and torsemide have shown an increase in urine output compared

with intermittent bolus dosing, but newer evidence suggests there may be little difference between intermittent bolus dosing and continuous infusion strategies on symptom relief at 72 hours.^{54,55} Nonetheless, many regimens include a bolus dose followed by a maintenance infusion (Table 6-9).⁵⁶ Another useful strategy is to combine two diuretics with different sites of action within the nephron. The most common combination is the use of a loop diuretic with a thiazide diuretic such as metolazone. Combining diuretics should be used with caution due to an increased risk for cardiovascular collapse due to rapid intravascular volume depletion. Strict monitoring of electrolytes, vital signs, and fluid balance is warranted.

Finally, poor CO may contribute to diuretic resistance. In these patients, it may become necessary to add vasodilators or inotropes to enhance perfusion to the kidneys. Care must be taken because vasodilators can decrease renal blood flow despite increasing CO through dilation of central and peripheral vascular beds.

► Vasodilators

IV vasodilators cause a rapid decrease in arterial tone, resulting in a decrease in SVR and a subsequent increase in SV and CO. Additionally, vasodilators reduce ventricular filling pressures (PCWP) within 24 to 48 hours, reduce myocardial oxygen consumption, and decrease ventricular workload.

- Vasodilators are commonly used in patients presenting with AHF accompanied by moderate to severe congestion. This class includes nitroglycerin, nitroprusside, and nesiritide. Hemodynamic effects and dosages for these agents are included in Tables 6-10 and 6-11, respectively. Although vasodilators are generally safe and effective, identification of the proper patient for use is important to minimize the risk of significant hypotension. In addition, vasodilators are contraindicated in patients whose cardiac filling (and hence CO) depends on venous return or intravascular volume, as well as patients who present with shock.

Nitroglycerin Nitroglycerin acts as a source of nitric oxide, which induces smooth muscle relaxation in venous and arterial vascular beds. Nitroglycerin is primarily a venous vasodilator at lower doses, but it exerts potent arterial vasodilatory effects at higher doses. Thus, at lower doses, nitroglycerin causes decreases in preload (or filling pressures)

Table 6-10

Usual Hemodynamic Effects of Commonly Used IV Agents for Treatment of Acute or Severe Heart Failure

Drug	CO	PCWP	SVR	BP	HR
Diuretics	↑/↓/0	↓		↓	0
Nitroglycerin	↑	↓↓	↓	↓↓	↑/0
Nitroprusside	↑	↓↓↓	↓↓↓	↓↓↓	↑

Table 6-11

Usual Doses and Monitoring of Commonly Used Hemodynamic Medications

Drug	Dose	Monitoring Variables ^a
Dopamine	0.5–10 mcg/kg/min	BP, HR, urinary output and kidney function, ECG, extremity perfusion (higher doses only)
Dobutamine	2.5–20 mcg/kg/min	BP, HR, urinary output and function, ECG
Milrinone	0.375–0.75 mcg/kg/min	BP, HR, urinary output and function, ECG, changes in ischemic symptoms (e.g., chest pain), electrolytes
Nitroprusside	0.25–3 mcg/kg/min	BP, HR, liver and kidney function, blood cyanide and/or thiocyanate concentrations if toxicity suspected (nausea, vomiting, altered mental function)
Nitroglycerin	5–200+ mcg/kg/min	BP, HR, ECG, changes in ischemic symptoms
Nesiritide	Bolus: 2 mcg/kg; Infusion: 0.01 mcg/kg/min	BP, HR, urinary output and kidney function, blood BNP concentrations

^aIn addition to pulmonary capillary wedge pressure and cardiac output.

BNP, B-type natriuretic peptide; BP, blood pressure; ECG, electrocardiogram; HR, heart rate.

and improved coronary blood flow. At higher doses (greater than 100 mcg/min), additional reduction in preload is achieved, along with a decrease in afterload and subsequent increase in SV and CO. IV nitroglycerin is primarily used as a preload reducer for patients exhibiting pulmonary congestion or in combination with inotropes for congested patients with severely reduced CO.⁵²

Continuous infusions of nitroglycerin should be initiated at a dose of 5 to 10 mcg/min and increased every 5 to 10 minutes until symptomatic or hemodynamic improvement. Effective doses range from 35 to 200 mcg/min. The most

common adverse events reported are headache, dose-related hypotension, and tachycardia. A limitation to nitroglycerin's use is the development of tachyphylaxis, or tolerance to its effects, which can be evident within 12 hours after initiation of continuous infusion and necessitate additional titrations to higher doses.

Nitroprusside Nitroprusside, like nitroglycerin, causes the formation of nitric oxide and vascular smooth muscle relaxation. In contrast to nitroglycerin, nitroprusside is both a venous and arterial vasodilator regardless of dosage. Nitroprusside causes a pronounced decrease in PCWP, SVR, and blood pressure, with a modest increase in CO. Nitroprusside has been studied to a limited extent in AHF, and no studies have evaluated its effects on mortality.⁵² Nitroprusside is initiated at 0.1 to 0.25 mcg/kg/min, followed by dose adjustments in 0.1 to 0.2 mcg/kg/min increments if necessary to achieve desired effect. Because of its rapid onset of action and metabolism, nitroprusside is administered as a continuous infusion that is easy to titrate and provides predictable hemodynamic effects. Nitroprusside requires strict monitoring of blood pressure and HR. Nitroprusside's use is limited in AHF due to recommended hemodynamic monitoring with an arterial line and mandatory intensive care unit admission at many institutions. Abrupt withdrawal of therapy should be avoided because rebound neurohormonal activation may occur. Therefore, the dose should be tapered slowly. Nitroprusside has the potential to cause cyanide and thiocyanate toxicity, especially in patients with hepatic and renal insufficiency, respectively. Toxicity is most common with use longer than 3 days and with higher doses. Nitroprusside should be avoided in patients with active ischemia because its powerful afterload-reducing effects within the myocardium can “steal” coronary blood flow from myocardial segments that are supplied by epicardial vessels with high-grade lesions.

Nesiritide B-type natriuretic peptide is an endogenous neurohormone that is synthesized and released from the ventricles in response to chamber wall stretch or increased filling pressures. Recombinant BNP, or nesiritide, is the newest compound developed for AHF. Nesiritide binds to guanylate cyclase receptors in vascular smooth muscle and endothelial cells, causing an increase in cGMP concentrations leading to vasodilation (venous and arterial) and natriuresis. Nesiritide also antagonizes the effects of the RAAS and endothelin. Nesiritide reduces PCWP, right atrial pressure, and SVR. Consequently, it also increases SV and CO without affecting heart rate. Continuous infusions result in sustained effects for 24 hours without tachyphylaxis, although experience with its use beyond 72 hours is limited.

Nesiritide has been shown to improve symptoms of dyspnea and fatigue. In a randomized clinical trial,⁵⁷ nesiritide was found to significantly decrease PCWP more than nitroglycerin and placebo over 3 hours. Nesiritide improved patients' self-reported dyspnea scores compared with placebo at 3 hours, but there was no difference compared with nitroglycerin. In the Acute Study of Clinical Effectiveness of Nesiritide in Decompensated Heart Failure,⁵⁸ nesiritide

did not decrease death or rehospitalization for HF within 30 days. This is the largest prospective study in AHF to date, and it also shows that nesiritide does not worsen renal function or increase the risk for mortality, despite previous concerns regarding its association with elevations in serum creatinine.

Currently, nesiritide is indicated for patients with AHF exhibiting dyspnea at rest or with minimal activity. The recommended dose regimen is a bolus of 2 mcg/kg, followed by a continuous infusion for up to 24 hours of 0.01 mcg/kg/min. Because nesiritide's effects are predictable and sustained at the recommended dosage, titration of the infusion rate (maximum of 0.03 mcg/kg/min) is not commonly required nor is invasive hemodynamic monitoring. Nesiritide should be avoided in patients with systolic blood pressure less than 90 mm Hg. Although nesiritide's place in AHF therapy is not firmly defined, it can be used in combination with diuretics for patients presenting in moderate to severe decompensation, and it offers a unique mechanism of action. One potential disadvantage compared with other vasodilators is its longer half-life. If hypotension occurs, the effect can be prolonged (2 hours).

► Inotropic Agents

Currently available positive inotropic agents act via increasing intracellular cyclic adenosine monophosphate (cAMP) concentrations through different mechanisms. β -Agonists activate adenylate cyclase through stimulation of β -adrenergic receptors, which subsequently catalyzes the conversion of ATP to cAMP. In contrast, phosphodiesterase inhibitors reduce degradation of cAMP. The resulting elevation in cAMP levels leads to enhanced phospholipase activity, which then increases the rate and extent of calcium influx during systole, thereby enhancing contractility. Additionally, during diastole, cAMP promotes uptake of calcium by the sarcoplasmic reticulum, which improves cardiac relaxation. The inotropes approved for use in AHF are discussed in the following sections.

Dobutamine Dobutamine has historically been the inotrope of choice for AHF. As a synthetic catecholamine, it acts as an agonist mainly on β_1 - and β_2 -receptors and minimally on α_1 -receptors. The resulting hemodynamic effects are due to both receptor- and reflex-mediated activities. These effects include increased contractility and HR through β_1 - (and β_2 -) receptors and vasodilation through a relatively greater effect on β_2 - than α_1 -receptors. Dobutamine can increase, decrease, or cause little change in mean arterial pressure depending on whether the resulting increase in CO is enough to offset the modest vasodilation. Although dobutamine has a half-life of approximately 2 minutes, its positive hemodynamic effects can be observed for several days to months after administration. The use of dobutamine is supported by several small studies documenting improved hemodynamics, but large-scale clinical trials in AHF are lacking.⁵⁹

Dobutamine is initiated at a dose of 2.5 to 5 mcg/kg/min, which can be gradually titrated to 20 mcg/kg/min based on

clinical response. There are several practical considerations to dobutamine therapy in AHF. First, owing to its vasodilatory potential, monotherapy with dobutamine is reserved for patients with systolic blood pressures greater than 90 mm Hg. However, it is commonly used in combination with vasopressors in patients with lower systolic blood pressures. Second, due to downregulation of β_1 -receptors or uncoupling of β_2 -receptors from adenylate cyclase with prolonged exposure to dobutamine, attenuation of hemodynamic effects has been reported to occur as early as 48 hours after initiation of a continuous infusion, although tachyphylaxis is more evident with use spanning longer than 72 hours. Full sensitivity to dobutamine's effects can be restored 7 to 10 days after the drug is withdrawn. Third, many patients with AHF will be taking β -blockers chronically. Because of β -blockers' high affinity for β -receptors, the effectiveness of β -agonists such as dobutamine will be reduced. In patients on β -blocker therapy, it is recommended that consideration be given to the use of phosphodiesterase inhibitors such as milrinone, which do not depend on β -receptors for effect.^{60,61} Although commonly practiced, use of high doses of dobutamine to overcome the β -blockade should be discouraged because this negates any of the protective benefits of the β -blocker.

Dopamine Dopamine is most commonly reserved for patients with low systolic blood pressures and those approaching cardiogenic shock. Dopamine exerts its effects through direct stimulation of adrenergic receptors, as well as release of norepinephrine from adrenergic nerve terminals. Dopamine produces hemodynamic effects that differ based on dosing. At lower doses, dopamine stimulates dopamine type 1 (D1) receptors and thus increases renal perfusion. Positive inotropic effects are more pronounced at doses of 3 to 10 mcg/kg/min. Cardiac index is increased due to increased SV and HR. At doses higher than 10 mcg/kg/min, chronotropic and α_1 -mediated vasoconstriction effects are evident. This causes an increase in mean arterial pressure due to higher CI and SVR. The ultimate effect on cardiac hemodynamics will depend largely on the dosage prescribed and must be individually tailored to the patient's clinical status. Dopamine is generally associated with an increase in CO and blood pressure, with a concomitant increase in PCWP. Dopamine increases myocardial oxygen demand and may decrease coronary blood flow through vasoconstriction and increased wall tension. As with other inotropes, dopamine is associated with a risk for arrhythmias.

Phosphodiesterase Inhibitors Milrinone and inamrinone work by inhibiting phosphodiesterase III, the enzyme responsible for the breakdown of cAMP. The increase in cAMP levels leads to increased intracellular calcium concentrations and enhanced contractile force generation. Milrinone has replaced inamrinone as the phosphodiesterase inhibitor of choice due to the higher frequency of thrombocytopenia seen with inamrinone.

Milrinone has both positive inotropic and vasodilating properties and as such is referred to as an "inodilator." Its vasodilating activities are especially prominent on venous capacitance vessels and pulmonary vascular beds, although

a reduction in arterial tone is also noted. IV administration results in an increase in SV and CO, and usually only minor changes in heart rate. Milrinone also lowers PCWP through venodilation. Routine use of milrinone during acute decompensations in NYHA FC II to IV heart failure is not recommended, and milrinone use remains limited to patients who require inotropic support.⁶²

Dosing recommendations for milrinone include a loading dose of 50 mcg/kg, followed by an infusion beginning at 0.5 mcg/kg/min (range: 0.23 mcg/kg/min for patients with renal failure up to 0.75 mcg/kg/min). A loading dose is not necessary if immediate hemodynamic effects are not required or if patients have low systolic blood pressures (less than 90 mm Hg). Decreases in blood pressure during an infusion may necessitate dose reductions as well. Lower doses are also used in patients with renal insufficiency.

Milrinone is a good option for patients requiring an inotrope who are also chronically receiving β -blockers because the inotropic effects are achieved independent of β -adrenergic receptors. However, milrinone exhibits a long distribution and elimination half-life compared with β -agonists, thus requiring a loading dose when an immediate response is desired. Potential adverse effects include hypotension, arrhythmias, and, less commonly, thrombocytopenia. Additionally, milrinone has been associated with increased risk for death in some studies. Milrinone should not be used in patients in whom vasodilation is contraindicated.

Mechanical, Surgical, and Device Therapies

► Implantable Cardioverter Defibrillators

Implantable cardioverter defibrillators (ICDs) are the most effective modality for primary and secondary prevention of sudden cardiac death in patients with LV dysfunction. Studies universally demonstrate greater efficacy compared with antiarrhythmic therapy and a significant reduction in mortality compared with placebo.^{63–65} Recent studies have expanded the eligible patient populations beyond classic indications, such as prior MI and nonsustained ventricular tachycardia or nonsuppressible ventricular tachycardia during an electrophysiological study. A clear advantage of implanting ICDs in all symptomatic patients with LVEF less than 35% (0.35) regardless of etiology or other cardiac parameters has been demonstrated.⁶⁵ Because ICD implantation and follow-up is associated with a significant economic burden, the cost effectiveness of widespread ICD use continues to be debated. Defining subgroups that would derive the greatest benefit and determining the optimal ICD configuration will aid in improving the potential costs compared with benefits.

► Cardiac Resynchronization Therapy

Dyssynchronous contraction, as a reflection of intra- and interventricular conduction delays between chambers of the heart, is common in advanced HF patients. Dyssynchrony contributes to diminished cardiac function and unfavorable

myocardial energetics through altered filling times, valvular dysfunction, and wall motion defects. Cardiac resynchronization therapy (CRT) with biventricular pacing devices improves cardiac function, quality of life, and mortality in patients with NYHA FC III or IV heart failure, evidence of intraventricular conduction delay (QRS greater than 120 ms), depressed LV function (LVEF less than 35% [0.35]), and on an optimal pharmacologic regimen. A study also showed that the addition of an ICD to CRT with biventricular pacing further reduced hospitalizations and mortality.⁶⁶

► Intraaortic Balloon Counterpulsation

Intraaortic balloon counterpulsation (IABC) or intraaortic balloon pumps (IABPs) are one of the most widely used mechanical circulatory assistance devices for patients with cardiac failure who do not respond to standard therapies. An IABP is placed percutaneously into the femoral artery and advanced to the high descending thoracic aorta. Once in position, the balloon is programmed to inflate during diastole and deflate during systole. Two main beneficial mechanisms are (a) inflation during diastole increases aortic pressure and perfusion of the coronary arteries, and (b) deflation just prior to the aortic valve opening reduces arterial impedance (afterload). As such, IABC increases myocardial oxygen supply and decreases oxygen demand. This device has many indications, including cardiogenic shock, high-risk unstable angina in conjunction with percutaneous interventions, preoperative stabilization of high-risk patients prior to surgery, and in patients who cannot be weaned from cardiopulmonary bypass. Possible complications include infection, bleeding, thrombosis, limb ischemia, and device malfunction. The device is typically useful for short-term therapy due to the invasiveness of the device, the need for limb immobilization, and the requirement for anticoagulation.

► Ventricular Assist Device

The ventricular assist device (VAD) is a surgically implanted pump that reduces or replaces the work of the right, left, or both ventricles. VADs are currently indicated for short-term support in patients refractory to pharmacologic therapies, as long-term bridge therapy (a temporary transition treatment) in patients awaiting cardiac transplant, or in some instances as the destination therapy (treatment for patients in lieu of cardiac transplant for those who are not appropriate candidates for transplantation).¹ The most common complications are infection and thromboembolism. Other adverse effects include bleeding, air embolism, device failure, and multiorgan failure.

► Surgical Therapy

Heart transplantation represents the final option for refractory end-stage HF patients who have exhausted medical and device therapies. Heart transplantation is not a cure but should be considered a trade between a life-threatening syndrome and the risks associated with the

operation and long-term immunosuppression. Assessment of appropriate candidates includes comorbid illnesses, psychosocial behavior, available financial and social support, and patient willingness to adhere to lifelong therapy and close medical follow-up.¹ Overall, the transplant recipient's quality of life may be improved, but not all patients receive this benefit. Posttransplant survival continues to improve due to advances in immunosuppression, treatment and prevention of infection, and optimal management of patient comorbidities.

► Investigational Therapies

Clinical trials are currently investigating new agents for the treatment of AHF. These compounds offer unique mechanisms of action by targeting different neurohormonal receptors (vasopressin, endothelin, atrial natriuretic peptide, and adenosine) or through completely novel pharmacologic profiles (myosin ATPase agonists). Some agents or drug classes being studied include tolvaptan, a V₂-selective vasopressin antagonist; various ET-A selective and nonselective antagonists; and an adenosine-1 receptor agonist.

OUTCOME EVALUATION OF ACUTE HEART FAILURE

- Focus on (a) acute improvement of symptoms and hemodynamics due to IV therapies, (b) criteria for a safe discharge from the hospital, and (c) optimization of oral therapy.
- Initially, monitor patients for rapid relief of symptoms related to the chief complaint on admission. This includes improvement of dyspnea, oxygenation, fatigue, JVD, and other markers of congestion or distress.
- Monitor for adequate perfusion of vital organs through assessment of mental status, creatinine clearance, liver function tests, and a stable HR between 50 and 100 beats/min. Additionally, adequate skin and muscle blood perfusion and normal pH is desirable.
- Monitor changes in hemodynamic variables if available. CI should increase, with a goal to maintain it above 2.2 L/min/m². Pulmonary capillary wedge pressure should decrease in volume-overloaded patients to a goal of less than 18 mm Hg (2.4 kPa).

Patient Encounter Part 4

After 6 months, DG returns to the clinic complaining of extreme SOB with any activity, as well as at rest. He sleeps sitting up due to severe orthopnea, can only eat a few bites of a meal and then feels full and nauseous, and states he has gained 22 lb (10 kg) from his baseline weight. He is also profoundly dizzy when standing up from a chair and bending over. He states that he does not feel his furosemide therapy is working. He is admitted to the cardiology unit.

SH

DG admits to resuming smoking after quitting for 2 months; additionally, he has been eating out in restaurants more often in the past 2 weeks.

Meds

Lisinopril 10 mg once daily

Furosemide 80 mg twice daily

Glipizide 10 mg twice daily for diabetes

Metformin 1000 mg twice daily for diabetes

Nitroglycerin 0.4 mg sublingual (SL) as needed

Multivitamin daily

Aspirin 325 mg daily

VS: blood pressure 96/54 mm Hg, pulse 102 bpm and regular, respiratory rate 22/minute, temperature 37°C (98.6°F), Wt 271 lb (123 kg), BMI 41.2 kg/m²

Lungs: There are rales present bilaterally

CV: Regular rate and rhythm with normal S₁ and S₂; there is an S₃ and an S₄; a 4/6 systolic ejection murmur is present and heard best at the left lower sternal border; point of maximal impulse is displaced laterally; jugular veins are distended, JVP is 11 cm above sternal angle; a positive HJR is observed

Abd: Hard, tender, and bowel sounds are absent; 3+ pitting edema of extremities is observed

CXR: Bilateral pleural effusions and cardiomegaly

Echo: EF = 20% (0.20)

Pertinent labs

BNP 740 pg/mL (740 ng/L; 214 pmol/L), K: 4.2 mEq/L (4.2 mmol/L), BUN 64 mg/dL (23 mmol/L), SCr 2.4 mg/dL (212 μmol/L), Mg 1.8 mEq/L (0.90 mmol/L)

A pulmonary catheter is placed, revealing the following: PCWP 37 mm Hg (4.9 kPa); cardiac index 1.8 L/min/m²

What NYHA functional class, ACC/AHA stage, and hemodynamic subset is DG currently in?

What are your initial treatment goals?

What pharmacologic agents are appropriate to use at this time?

Identify a monitoring plan to assess for efficacy and toxicity of the recommended drug therapy.

Once DG's symptoms are improved, how would you optimize his oral medication therapy for HF?

Patient Care and Monitoring

1. Assess the severity and duration of the patient's symptoms including limitations in activity. Rule out potential exacerbating factors.
2. Obtain a thorough history of prescription, nonprescription, and herbal medication use. Is the patient taking any medications that can exacerbate HF?
3. Review available diagnostic information from the chest radiograph, ECG, and echocardiogram.
4. Review the patient's lifestyle habits including salt and alcohol intake, tobacco product use, and exercise routine.
5. If unknown, investigate the patient's underlying etiology of HF. Verify that comorbidities that lead to or worsen HF are optimally managed with appropriate drug therapy.
6. Educate the patient on lifestyle modifications such as salt restriction (maximum 2 to 4 g/day), fluid restriction if appropriate, limitation of alcohol, tobacco cessation, participation in a cardiac rehabilitation and exercise program, and proper immunizations such as the pneumococcal vaccine and yearly influenza vaccine.
7. Develop a treatment plan to alleviate symptoms and maintain euvolemia with diuretics. Daily weights to assess fluid retention are recommended.
8. Develop a medication regimen to slow the progression of HF with the use of neurohormonal blockers such as vasodilators (ACE inhibitors, ARBs, or hydralazine/ isosorbide dinitrate), β -blockers, and aldosterone antagonists. Utilize digoxin if the patient remains symptomatic despite optimization of the therapies just described.
 - Is the patient at goal or maximally tolerated doses of vasodilator and β -blocker therapy?
 - Are aldosterone antagonists utilized in appropriate patients with proper electrolyte and renal function monitoring?
9. Stress the importance of adherence to the therapeutic regimen and lifestyle changes for maintenance of a compensated state and slowing of disease progression.
10. Evaluate the patient for presence of adverse drug reactions, drug allergies, and drug interactions.
11. Provide patient education with regard to disease state and drug therapy, and reinforce self-monitoring for symptoms of HF that necessitate follow-up with a healthcare practitioner.

- Closely monitor blood pressures and renal function while decreasing preload with diuretics and vasodilators.
- Ensure patients are euvolemic or nearly euvolemic prior to discharge.
- Because oral therapies can both improve symptoms and prolong survival, optimizing outpatient HF management is a priority when preparing a patient for hospital discharge. Ensure that the patient's regimen includes a vasodilator, β -blocker, a diuretic at an adequate dose to maintain euvolemia, and digoxin or aldosterone antagonist if indicated.

BNP	B-type natriuretic peptide
BP	Blood pressure
bpm	Beats per minute
BUN	Blood urea nitrogen
CAD	Coronary artery disease
CAM	Complementary and alternative medication
cAMP	Cyclic adenosine monophosphate
CBC	Complete blood cell count
cGMP	Cyclic guanosine monophosphate
CHARM	Candesartan in Heart Failure Assessment of Reduction in Mortality and Morbidity
CI	Cardiac index
CNS	Central nervous system
CO	Cardiac output
COX-2	Cyclooxygenase-2
CrCL	Creatinine clearance
CRT	Cardiac resynchronization therapy
CYP450	Cytochrome P-450 isoenzyme
D1	Dopamine receptor type 1
ECG	Electrocardiogram
EF	Ejection fraction
ET-1	Endothelin-1
ET-A	Endothelin-A
ET-B	Endothelin-B
HF	Heart failure
HFpEF	Heart failure with preserved ejection fraction

Abbreviations Introduced in This Chapter

ACC/AHA	American College of Cardiology/American Heart Association
ACE	Angiotensin-converting enzyme
AHF	Acute heart failure
ANP	Atrial natriuretic peptide
ARB	Angiotensin receptor blocker
AT ₁	Angiotensin type 1
AT ₂	Angiotensin type 2
ATP	Adenosine triphosphate
BMI	Body mass index

HJR	Hepatojugular reflux
HR	Heart rate
IABC	Intraaortic balloon counterpulsation
IABP	Intraaortic balloon pump
ICD	Implantable cardioverter defibrillator
iNOS	Inducible nitric oxide synthetase
INR	International normalized ratio
I-PRESERVE	Irbesartan in Patients with Heart Failure and Preserved Ejection Fraction
JVD	Jugular venous distention
JVP	Jugular venous pressure
K	Potassium
LV	Left ventricular
LVEF	Left ventricular ejection fraction
LVF	Left ventricular failure
MI	Myocardial infarction
MVO ₂	Myocardial oxygen consumption
NSAID	Nonsteroidal anti-inflammatory drug
NT-proBNP	N-terminal proBNP
NYHA FC	New York Heart Association Functional Class
PAC	Pulmonary artery catheter
PCWP	Pulmonary capillary wedge pressure
PEP-CHF	Perindopril in Elderly People with Chronic Heart Failure
PND	Paroxysmal nocturnal dyspnea
PPCM	Peripartum cardiomyopathy
RAAS	Renin-angiotensin-aldosterone system
RVF	Right ventricular failure
SCr	Serum creatinine
SL	Sublingual
SNS	Sympathetic nervous system
SOB	Shortness of breath
SV	Stroke volume
SVR	Systemic vascular resistance
TNF- α	Tumor necrosis factor- α
V _{1a}	Vasopressin type 1a
V ₂	Vasopressin type 2
VAD	Ventricular assist device

Ischemic Heart Disease

Larisa H. Cavallari and Robert J. DiDomenico

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Identify risk factors for the development of ischemic heart disease.
2. Differentiate between the pathophysiology of chronic stable angina and acute coronary syndromes.
3. Recognize symptoms and diagnostic criteria of ischemic heart disease in a specific patient.
4. Identify treatment goals of ischemic heart disease, appropriate lifestyle modifications, and pharmacologic therapy to address each goal.
5. Design an appropriate therapeutic regimen for the management of ischemic heart disease based on patient-specific information.
6. Formulate a monitoring plan to assess effectiveness and adverse effects of an ischemic heart disease drug regimen.

KEY CONCEPTS

- 1 Ischemic heart disease results from an imbalance between myocardial oxygen demand and oxygen supply that is most often due to coronary atherosclerosis. Common clinical manifestations of ischemic heart disease include chronic stable angina and the acute coronary syndromes of unstable angina, non-ST-segment elevation myocardial infarction, and ST-segment elevation myocardial infarction.
- 2 Early detection and aggressive modification of risk factors are the primary strategies for delaying ischemic heart disease progression and preventing ischemic heart disease-related events including death.
- 3 Patients with chest pressure or heaviness that is provoked by activity and relieved with rest should be assessed for ischemic heart disease. Sharp pain is not a typical symptom of ischemic heart disease. Some patients may experience discomfort in the neck, jaw, shoulder, or arm rather than, or in addition to, the chest. Pain may be accompanied by nausea, vomiting, or diaphoresis.
- 4 The major goals for the treatment of ischemic heart disease are to prevent acute coronary syndrome and death, alleviate acute symptoms of myocardial ischemia, prevent recurrent symptoms of myocardial ischemia, prevent disease progression, reduce complications, and avoid or minimize adverse treatment effects.
- 5 Both 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins) and angiotensin-converting enzyme inhibitors are believed to provide vasculoprotective effects, and in addition to antiplatelet agents, they have been shown to reduce the risk of acute coronary events and death in patients with ischemic heart disease. Angiotensin receptor blockers may be used in patients who cannot tolerate angiotensin-converting enzyme inhibitors because of side effects (e.g., chronic cough). β -Blockers have been shown to decrease morbidity and improve survival in patients who have suffered a myocardial infarction.
- 6 Antiplatelet therapy with aspirin should be considered for all patients without contraindications, particularly in patients with a history of myocardial infarction. Clopidogrel may be considered in patients with allergies or intolerance to aspirin. In some patients, combination antiplatelet therapy with aspirin and P2Y₁₂ inhibitor may be used.
- 7 To control risk factors and prevent major adverse cardiac events, statin therapy should be considered in all patients with ischemic heart disease, particularly in those individuals with elevated low-density lipoprotein cholesterol. In the absence of contraindications, angiotensin-converting enzyme inhibitors are initiated in individuals with ischemic heart disease, diabetes mellitus, left ventricular dysfunction, or a history of myocardial infarction. Angiotensin receptor blockers may be used in patients who cannot tolerate angiotensin-converting enzyme inhibitors because of side effects.
- 8 All patients with a history of angina should have sublingual nitroglycerin tablets or spray to relieve acute

ischemic symptoms. Patients should be instructed to use one dose (tablet or spray) every 5 minutes until pain is relieved and to call 911 if pain is unimproved or worsens 5 minutes after the first dose.

- 9 β -Blockers are first-line therapy for preventing ischemic symptoms, particularly in patients with a history of myocardial infarction. Long-acting calcium channel blockers and long-acting nitrates may be added for refractory symptoms or substituted if a β -blocker is not tolerated.
- 10 Patients should be monitored to assess for drug effectiveness, adverse drug reactions, and potential drug–drug interactions. Patients should be assessed for adherence to their pharmacotherapeutic regimens and lifestyle modifications.

INTRODUCTION

Ischemic heart disease (IHD) is also called **coronary heart disease** (CHD) or **coronary artery disease** (CAD). The term *ischemic* refers to a decreased supply of oxygenated blood, in this case to the heart muscle. IHD is caused by the narrowing of one or more of the major coronary arteries that supply blood to the heart, most commonly by atherosclerotic plaques. Atherosclerotic plaques may impede coronary blood flow to the extent that cardiac tissue distal to the site of the coronary artery narrowing is deprived of sufficient oxygen in the face of increased oxygen demand. 1 *Ischemic heart disease results from an imbalance between myocardial oxygen*

supply and oxygen demand (Fig. 7-1). Common clinical manifestations of IHD include chronic stable angina and the acute coronary syndromes (ACS) of unstable angina, non-ST-segment elevation myocardial infarction (MI), and ST-segment elevation MI.

Angina pectoris, or simply **angina**, is the most common symptom of IHD. Angina is discomfort in the chest that occurs when the blood supply to the myocardium is compromised. Chronic stable angina is defined as a chronic occurrence of chest discomfort due to transient myocardial ischemia with physical exertion or other conditions that increase oxygen demand. The primary focus of this chapter is on the management of chronic stable angina. However, some information is also provided related to ACS, given the overlap between the two disease states. The American College of Cardiology and the American Heart Association have jointly published practice guidelines for the management of patients with chronic stable angina. Refer to these guidelines for further information.^{1,2}

EPIDEMIOLOGY AND ETIOLOGY

IHD affects over 16 million Americans and is the leading cause of death for both men and women in the United States.³ The incidence of IHD is higher in middle-aged men compared with women. However, the rate of IHD increases two- to threefold in women after menopause. Chronic stable angina is the initial manifestation of IHD in about 50% of patients, whereas unstable angina or MI is the first sign of IHD in other patients. Chronic stable angina is associated with considerable patient morbidity, with many

FIGURE 7-1. This illustration depicts the balance between myocardial oxygen supply and demand and the various factors that affect each. It should be noted that diastolic filling time is not an independent predictor of myocardial oxygen supply per se, but rather a determinant of coronary blood flow. On the left is myocardial oxygen supply and demand under normal circumstances. On the right is the mismatch between oxygen supply and demand in patients with ischemic heart disease. In patients without ischemic heart disease, coronary blood flow increases in response to increases in myocardial oxygen demand. However, in patients with ischemic heart disease, coronary blood flow cannot sufficiently increase (and may decrease) in response to increased oxygen demand resulting in angina. (Po_2 , partial pressure of oxygen.)

affected patients eventually requiring hospitalization for ACS. In addition, chronic stable angina has a major negative impact on health-related quality of life. Thus, in patients with chronic stable angina, it is important to optimize pharmacotherapy to reduce symptoms, improve quality of life, slow disease progression, and prevent ACS.

Conditions Associated with Angina

Figure 7-2 shows the anatomy of the coronary arteries. The major epicardial coronary arteries are the left main, left anterior descending, left circumflex, and right coronary arteries.

FIGURE 7-2. Coronary artery anatomy with sternocostal and diaphragmatic views. (Reproduced from Talbert RL. Ischemic heart disease. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. *Pharmacotherapy: A pathophysiologic approach*, 6th ed. New York, NY: McGraw-Hill, 2005:263, with permission.)

Organ System	Condition
Cardiac	Aortic dissection, aortic stenosis, coronary artery vasospasm, pericarditis, valvular heart disease, severe uncontrolled hypertension
Noncardiac	Anemia, anxiety disorders, carbon monoxide poisoning, chest wall trauma, cocaine use, esophageal reflux or spasm, generalized anxiety disorder, peptic ulcer, pleuritis, pneumonia, pneumothorax, pulmonary embolus, pulmonary hypertension, thyrotoxicosis

Atherosclerosis leading to obstructive lesions in one or more of the major coronary arteries or their principal branches is the major cause of angina. **Vasospasm** at the site of an atherosclerotic plaque may contribute to angina by further restricting blood supply to the distal myocardium. Less commonly, vasospasm in coronary arteries with no or minimal atherosclerotic disease can produce angina and even precipitate ACS. This type of vasospasm is referred to as variant or **Prinzmetal's angina**. Other nonatherosclerotic conditions that can cause angina-like symptoms are listed in **Table 7-1**. It is important to differentiate the etiology of chest discomfort because treatment varies depending on the underlying disease process.

Risk Factors

Factors that predispose an individual to IHD are listed in **Table 7-2**. Optimization of modifiable risk factors can significantly reduce the risk of MI.⁴ Hypertension, diabetes, **dyslipidemia**, and cigarette smoking are associated with endothelial damage and dysfunction and contribute to

Modifiable	Nonmodifiable
Cigarette smoking	Age 45 years or greater for men, age 55 years or greater for women
Dyslipidemia • Elevated LDL or total cholesterol • Reduced HDL cholesterol	Gender (men and postmenopausal women)
Diabetes mellitus	Family history of premature cardiovascular disease, defined as cardiovascular disease in a male first-degree relative (i.e., father or brother) younger than 55 years old or a female first-degree relative (i.e., mother or sister) younger than 65 years
Hypertension	
Physical inactivity	
Obesity (body mass index greater than or equal to 30 kg/m ²)	
Low daily fruit and vegetable consumption	
Alcohol overconsumption	

HDL, high-density lipoprotein; LDL, low-density lipoprotein.

atherosclerosis of the coronary arteries. The risk for IHD increases twofold for every 20 mm Hg increment in systolic blood pressure or 10 mm Hg increment in diastolic blood pressure and up to eightfold in the presence of diabetes.³ Physical inactivity and obesity independently increase the risk for IHD, in addition to predisposing individuals to hypertension, dyslipidemia, and diabetes.

Patients with multiple risk factors, particularly those with diabetes, are at the greatest risk for IHD. Although alternative definitions exist, **metabolic syndrome** is generally considered as a constellation of common cardiovascular risk factors including hypertension, abdominal obesity, dyslipidemia, and insulin resistance. Metabolic syndrome increases the risk of developing IHD and related complications by twofold.⁵ According to a joint statement from several large organizations, including the American Heart Association, patients must meet at least three of the following criteria for the diagnosis of metabolic syndrome:⁵

- Increased waist circumference (40 inches or greater or 102 cm or greater in men and 35 inches or greater or 89 cm or greater in women).
- Triglycerides of 150 mg/dL (1.70 mmol/L) or greater or active treatment to lower triglycerides.
- Low high-density lipoprotein (HDL) cholesterol (less than 40 mg/dL or 1.03 mmol/L in men and less than 50 mg/dL or 1.29 mmol/L in women) or active treatment to raise HDL cholesterol.
- Systolic blood pressure of 130 mm Hg or greater, diastolic blood pressure of 85 mm Hg or greater, or active treatment with antihypertensive therapy.
- Fasting blood glucose of 100 mg/dL (5.6 mmol/L) or greater or active treatment for diabetes.

2 *Early detection and aggressive modification of risk factors are among the primary strategies for delaying IHD progression and preventing IHD-related events including death.*

PATHOPHYSIOLOGY

The determinants of oxygen supply and demand are shown in Figure 7–1. Increases in heart rate, cardiac contractility, and left ventricular wall tension increase the rate of myocardial oxygen consumption (MVO_2). Ventricular wall tension is a function of blood pressure, left ventricular end-diastolic volume, and ventricular wall thickness. Physical exertion increases MVO_2 and commonly precipitates symptoms of angina in patients with significant coronary atherosclerosis.

Reductions in coronary blood flow (secondary to atherosclerotic plaques, vasospasm, or **thrombus** formation) and arterial oxygen content (secondary to hypoxia) decrease myocardial oxygen supply. Because the coronary arteries fill during diastole, decreases in diastolic filling time (e.g., tachycardia) can also reduce coronary perfusion and myocardial oxygen supply. In chronic stable angina, atherosclerotic plaques are the most common cause of

coronary artery narrowing and reductions in coronary blood flow. In contrast, in ACS, disruption of an atherosclerotic plaque with subsequent thrombus (blood clot) formation causes abrupt reductions in coronary blood flow and oxygen supply. Anemia, carbon monoxide poisoning, and cyanotic congenital heart disease are examples of conditions that reduce the oxygen-carrying capacity of the blood, potentially causing ischemia in the face of adequate coronary perfusion.

Coronary Atherosclerosis

The normal arterial wall is illustrated in panel A of **Figure 7–3**. The intima consists of a layer of endothelial cells that line the lumen of the artery and form a selective barrier between the vessel wall and blood contents. Vascular smooth muscle cells are found in the media. The vascular adventitia comprises the artery's outer layer. Atherosclerotic lesions form in the subendothelial space in the intimal layer.

Endothelial damage and dysfunction allow low-density lipoprotein (LDL) cholesterol and inflammatory cells (e.g., monocytes and T lymphocytes) to migrate from the plasma to the subendothelial space, as illustrated in Figure 12–5 in Chapter 12, “Dyslipidemias.” The process is initiated with monocyte-derived macrophages ingesting lipoproteins to form foam cells. Macrophages also secrete growth factors that promote smooth muscle cell migration from the media to the intima. The development of a fatty streak consisting of lipid-laden macrophages and smooth muscle cells is formed. The fatty streak is the earliest type of atherosclerotic lesion.

The fatty streak enlarges as foam cells, smooth muscle cells, and necrotic debris accumulate in the subendothelial space. A collagen matrix forms a fibrous cap that covers the lipid core of the lesion to establish an atherosclerotic plaque. The atherosclerotic plaque may progress until it protrudes into the artery lumen and impedes blood flow. When the plaque occludes 70% or more of a major coronary artery or 50% or more of the left main coronary artery, the patient may experience angina during activities that increase myocardial oxygen demand.

Compared with men, women with angina are less likely to have obstructive CAD of the major epicardial arteries and more likely to present with microvascular disease. Microvascular angina, also called cardiac syndrome X, refers to disease of the smaller coronary vessels causing typical angina in the absence of obstructive CAD of the epicardial arteries. Endothelial dysfunction and reduced smooth muscle relaxation, resulting in reduced vasodilation and enhanced vasoconstriction, are proposed to contribute to microvascular disease.⁶

Stable versus Unstable Atherosclerotic Plaques

- The hallmark feature in the pathophysiology of chronic stable angina is an established atherosclerotic plaque in one or more of the major coronary arteries that impedes coronary

FIGURE 7-3. Pathophysiology of chronic stable angina versus acute coronary syndromes. Panel **A** depicts the cross-section of a normal coronary artery. Panel **B** depicts the cross-section of a coronary artery with a stable atherosclerotic plaque. Note that the lipid core is relatively small in size and the fibrous cap is made up of several layers of smooth muscle cells. Panel **C** depicts an unstable atherosclerotic plaque with a larger lipid core, and a thin fibrous cap composed of a single layer of smooth muscle cells with a fissure or rupture. Panel **D** depicts platelet adhesion in response to the fissured plaque. Platelet activation may ensue, leading to platelet aggregation as fibrinogen binds platelets to one another to form a mesh-like occlusion in the coronary lumen (Panel **E**). At this stage, patients may experience symptoms of acute coronary syndrome. If endogenous anticoagulant proteins fail to halt this process, platelet aggregation continues and fibrinogen is converted to fibrin, resulting in an occlusive thrombus (Panel **F**).

blood flow to the extent that myocardial oxygen supply can no longer meet increases in myocardial oxygen demand. In contrast, the hallmark feature in the pathophysiology of ACS is atherosclerotic plaque rupture with subsequent thrombus formation. Plaque rupture refers to fissuring of the fibrous cap and exposure of the plaque contents to

elements in the blood. Plaque composition, rather than the degree of coronary stenosis, determines the stability of the plaque and the likelihood of rupture and ACS. As depicted in Figure 7-3B, a stable lesion characteristic of chronic stable angina consists of a small lipid core surrounded by a thick fibrous cap that protects the lesion from the shear stress of

blood flow. In contrast, an unstable plaque consists of a thin, weak cap covering a large lipid-rich core that renders the plaque vulnerable to rupture (Fig. 7-3C). The transformation of a stable plaque into an unstable plaque involves the degradation of the fibrous cap by substances released from macrophages and other inflammatory cells. Following plaque rupture, platelets adhere to the site of rupture, aggregate, and generate thrombin and a fibrin clot (Fig. 7-3D, E, and F). Coronary thrombi extend into the vessel lumen, where they

either partially or completely occlude blood flow, potentially resulting in unstable angina or MI.

An unstable plaque often produces minimal occlusion of the coronary vessel, and the patient remains asymptomatic until the plaque ruptures. In fact, many acute coronary syndromes arise from vulnerable plaques that occlude less than 50% of the coronary lumen.⁷ As a result, unstable angina or MI is the initial manifestation of IHD in about one-half of affected patients.

Clinical Presentation and Diagnosis of Ischemic Heart Disease

General

- Patients with chronic stable angina will generally be in no acute distress. In patients presenting in acute distress, the clinician should be suspicious of ACS.

Symptoms of Angina Pectoris

- The five components commonly used to characterize chest pain are quality, location, and duration of pain; factors that provoke pain; and factors that relieve pain.
- Patients typically describe pain as a sensation of pressure, heaviness, tightness, or squeezing in the anterior chest area. Sharp pain is not a typical symptom of IHD.
- Pain may radiate to the neck, jaw, shoulder, back, or arm.
- Pain may be accompanied by dyspnea, nausea, vomiting, or **diaphoresis**.
- Pain typically persists for several minutes.
- Symptoms are often provoked by exertion (e.g., walking, climbing stairs, and doing yard or housework) or emotional stress and relieved within minutes by rest or sublingual nitroglycerin. Other precipitating factors include exposure to cold temperatures and heavy meals. Pain that occurs at rest (without provocation) or that is prolonged and unrelieved by sublingual nitroglycerin is indicative of an ACS.
- Some patients, most commonly women and patients with diabetes, may present with atypical symptoms including indigestion, gastric fullness, back pain, and shortness of breath. Patients with diabetes and the elderly may experience associated symptoms, such as dyspnea, diaphoresis, nausea, fatigue, and dizziness, without having any of the classic chest pain symptoms.
- In some cases, ischemia may not produce any symptoms and is termed “silent ischemia.”

Signs

- Findings on the physical examination are often normal in patients with chronic stable angina. However, during episodes of ischemia, patients may present with abnormal heart sounds, such as paradoxical splitting of the second heart sound, a third heart sound, or a loud fourth heart sound.

Laboratory Tests

- Cardiac enzymes (creatinine kinase [CK], CK-MB fraction, troponin I, and troponin T) are elevated in MI (ST-segment elevation MI and non-ST-segment elevation MI), but normal in chronic stable angina and unstable angina.
- Hemoglobin, fasting glucose, and fasting lipid profile should be determined for assessing cardiovascular risk factors and establishing the differential diagnosis.

Other Diagnostic Tests

- A 12-lead ECG recorded during rest is often normal in patients with chronic stable angina in the absence of active ischemia. Significant Q waves indicate prior MI. ST-segment or T-wave changes in two or more contiguous leads during symptoms of angina support the diagnosis of IHD. ST-segment depression or T-wave inversion may be observed in chronic stable angina, unstable angina, and non-ST-segment elevation MI, whereas ST-segment elevation occurs with ST-segment elevation MI and Prinzmetal's (variant) angina.
- Treadmill or bicycle exercise ECG, commonly referred to as a “stress test,” is considered positive for IHD if the ECG shows at least a 1-mm deviation of the ST-segment (depression or elevation).
- Wall motion abnormalities or left ventricular dilation with stress echocardiography are indicative of IHD.
- Stress myocardial perfusion imaging with the radionuclides technetium-99m sestamibi or thallium-201 allows for the identification of multivessel disease and assessment of myocardial viability.
- Coronary angiography detects the location and degree of coronary atherosclerosis and is used to evaluate the potential benefit from revascularization procedures. Stenosis of at least 70% of the diameter of at least one of the major epicardial arteries on coronary angiography is indicative of significant IHD.
- Coronary angiography may be normal in patients with microvascular angina.

Coronary Artery Vasospasm

Prinzmetal's or variant angina results from spasm (or vasoconstriction) of a coronary artery in the absence of significant atherosclerosis. Variant angina usually occurs at rest, especially in the early morning hours. Although vasospasm is generally transient, in some instances vasospasm may persist long enough to infarct the myocardium. Patients with variant angina are typically younger than those with chronic stable angina and often do not possess the classic risk factors for IHD. The cause of variant angina is unclear but appears to involve vagal withdrawal, endothelial dysfunction, and paradoxical response to agents that normally cause vasodilation. Precipitants of variant angina include cigarette smoking, cocaine or amphetamine use, hyperventilation, and exposure to cold temperatures. The management of variant angina differs from that of classic angina, and thus it is important to distinguish between the two.

CLINICAL PRESENTATION AND DIAGNOSIS

History

The evaluation of a patient with suspected IHD begins with a detailed history of symptoms. **3** *The classic presentation of angina is described in the Clinical Presentation and Diagnosis box.* Chronic stable angina should be distinguished from unstable angina because the latter is associated with a greater risk for MI and death and requires more aggressive treatment. Because the pathophysiology of chronic stable angina is due primarily to increases in oxygen demand, rather than acute changes in oxygen supply, symptoms are typically reproducible when provoked by exertion, exercise, or stress. Specifically, a patient with angina secondary to significant coronary atherosclerosis generally experiences a similar pattern of chest, arm, or neck discomfort (i.e., same quality, location, and accompanying symptoms) with a similar level of exertion. The exception may be a patient with coronary artery vasospasm, in whom symptoms may be more variable and unpredictable. In contrast to chronic stable angina, ACS is due to an acute decrease in coronary blood flow leading to an insufficient oxygen supply. Consequently, ACS is marked by prolonged symptoms, symptoms that occur at rest, or an escalation in the frequency or severity of angina over a short period of time. The presentation of unstable angina is described in [Table 7-3](#).⁸

The Canadian Cardiovascular Society Classification System

The Canadian Cardiovascular Society Classification System ([Table 7-4](#)) is commonly used to assess the degree of disability resulting from IHD.⁹ Patients are categorized into one of four classes depending on the extent of activity that produces angina. Grouping patients according to this or a similar method is commonly used to assess changes in IHD severity over time and the effectiveness of pharmacologic therapy.

Table 7-3

Presentations of Acute Coronary Syndromes⁸

- Angina at rest that is prolonged in duration, usually lasting over 20 minutes.
- Angina of recent onset (within 2 months) that markedly limits usual activity.
- Angina that increases in severity (i.e., by Canadian Cardiovascular Society Classification System Class of one level or greater), frequency, or duration, or that occurs with less provocation over a short time period (i.e., within 2 months).

Table 7-4

The Canadian Cardiovascular Society Classification System of Angina

Class	Description
I	Able to perform ordinary physical activity (e.g., walking and climbing stairs) without symptoms. Strenuous, rapid, or prolonged exertion causes symptoms.
II	Symptoms slightly limit ordinary physical activity. Walking rapidly or for more than two blocks, climbing stairs rapidly, or climbing more than one flight of stairs causes symptoms.
III	Symptoms markedly limit ordinary physical activity. Walking less than two blocks or climbing one flight of stairs causes symptoms.
IV	Angina may occur at rest. Any physical activity causes symptoms.

Patient Encounter Part 1

DF is a 49-year-old African American man with a history of hypertension, diabetes, and dyslipidemia who presents to your clinic complaining of chest pain that occurred several times over the past few weeks. DF describes his chest pain as "a heaviness." He states that the discomfort first occurred while he was carrying groceries up to his third-floor apartment. Later, he experienced the same heavy sensation while raking leaves and again while carrying some boxes. The pain was located in the substernal area and radiated to his neck. The pain resolved after about 5 minutes of rest.

What information is suggestive of angina?

What tests would be beneficial in establishing a diagnosis?

What additional information do you need to create a treatment plan for this patient?

Physical Findings and Laboratory Analysis

A thorough medical history, physical examination, and laboratory analysis are necessary to ascertain cardiovascular risk factors and to exclude nonischemic and noncardiac

conditions that could cause angina-like symptoms. Laboratory analyses should assess for glycemic control (i.e., fasting glucose, glycated hemoglobin), fasting lipids, hemoglobin, and organ function (i.e., blood urea nitrogen, creatinine, liver function tests, thyroid function tests). Additionally, serial measurements of cardiac enzymes (usually three measurements within 12 hours) are used to exclude the diagnosis of an acute MI. Cardiac findings on the physical examination are often normal in patients with chronic stable angina. However, findings such as **carotid bruits** or abnormal peripheral pulses would indicate atherosclerosis in other vessel systems and raise the suspicion for IHD.

Diagnostic Tests

A resting electrocardiogram (ECG) is indicated in all patients with angina-like symptoms. A 12-lead ECG should be done in patients with new or worsening symptoms of ischemia. Patients with characteristic chest discomfort, accompanied by ST-segment elevation in two or more contiguous leads, or a new bundle branch block, are diagnosed with an ST-segment elevation MI and are at the highest risk of death. These patients are treated as a medical emergency, often requiring percutaneous coronary interventions or pharmacologic therapies to achieve reperfusion of the occluded artery and restore blood flow to the myocardium. In patients without ST-segment elevation, troponin is the preferred biomarker to distinguish between unstable angina and non-ST-segment elevation MI in patients hospitalized for ACS.

“Stress” testing with either exercise or pharmacologic stressors increases myocardial oxygen demand and is commonly used to evaluate the patient with suspected IHD. Approximately 50% of patients with IHD who have a normal ECG at rest will develop ECG changes with exercise on a treadmill (most commonly) or bicycle ergometer. Dobutamine is a pharmacologic stressor used in patients who are unable to exercise. Dobutamine increases oxygen demand by stimulating the β_1 -receptor, leading to increases in heart rate and contractility. Dobutamine is commonly used with echocardiography (referred to as dobutamine stress echocardiography) to identify stress-induced wall motion abnormalities indicative of coronary disease.

Adenosine, dipyridamole, dobutamine, or regadenoson are commonly combined with radionuclide myocardial perfusion imaging (nuclear imaging studies). Adenosine, dipyridamole, and regadenoson are coronary vasodilators that increase coronary blood flow in vessels free of disease but not in diseased vessels. An IV radioactive tracer is used to detect areas of the heart that receive less blood after adenosine, dipyridamole, or regadenoson administration, indicating a myocardial perfusion defect and coronary disease. Positive emission tomography is an alternative to conventional myocardial perfusion imaging that may be preferred in obese patients. This technique involves administration of a radioactive tracer that emits γ rays captured by a scanner to allow for assessment of myocardial perfusion and viability.

Coronary artery calcium scoring via computed tomography (CT), also known as electron beam CT (EBCT) or “ultra-fast CT,” may be performed as a noninvasive means to assess for CAD. Calcium deposits within the coronary arteries that are indicative of CAD are detected on CT. A calcium score is calculated, and the risk for IHD-related events is estimated.

Coronary angiography (also referred to as a cardiac catheterization or “cardiac cath”) is considered the gold standard for the diagnosis of IHD. Coronary angiography is indicated when stress testing results are abnormal or symptoms of angina are poorly controlled. Angiography involves catheter insertion into either the femoral or radial artery and advancement into the aorta and into the coronary arteries. Contrast medium is injected through the catheter into the coronary arteries allowing visualization of the coronary anatomy by fluoroscopy and identification of significant lesions of the coronary arteries. Contrast medium must be used cautiously in patients with preexisting renal disease (especially in those with diabetes) to avoid contrast-induced nephropathy. Judicious hydration may be warranted to reduce the direct toxic effects of contrast medium. The use of low ionic contrast solutions may be used to prevent damage to the kidneys.

TREATMENT

Desired Outcomes

Once the diagnosis of IHD is established in a patient, the clinician should provide counseling on lifestyle modifications, institute appropriate pharmacologic therapy, and evaluate the need for surgical revascularization. Optimal medical therapy is essential for managing patients with IHD.

4 The major goals for the treatment of IHD are to:

- Prevent acute coronary syndrome and death
- Alleviate acute symptoms of myocardial ischemia
- Prevent recurrent symptoms of myocardial ischemia
- Prevent progression of the disease
- Reduce complications of IHD
- Avoid or minimize adverse treatment effects

The treatment approach to address these goals is illustrated in **Figure 7-4**.

General Approach to Treatment

The primary strategies for preventing ACS and death are to:

- Aggressively modify cardiovascular risk factors
- Slow the progression of coronary atherosclerosis
- Stabilize existing atherosclerotic plaques

The treatment algorithm in **Figure 7-5** summarizes the appropriate management of IHD. Risk factor modification is accomplished through lifestyle changes and pharmacologic therapy. 5 Both 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (HMG-CoA reductase inhibitors or

Patient Encounter Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH

Hypertension, diagnosed 10 years ago
 Diabetes, diagnosed 10 years ago
 Dyslipidemia, diagnosed 8 years ago
 Seasonal allergies, diagnosed ~25 years ago
 Osteoarthritis

FH

Father with coronary artery disease, had a myocardial infarction at age 50 years
 Two siblings each with coronary artery disease diagnosed in their 40s
 Mother alive and well

SH

Quit smoking 5 years ago.
 Denies alcohol or illicit drug use
 No regular exercise program

Meds

- Amlodipine 5 mg PO once daily
- Metformin 500 mg PO twice daily
- Pravastatin 20 mg PO at bedtime (has not taken in several months)
- Desloratadine/pseudoephedrine 2.5 mg/120 mg PO twice daily
- Ibuprofen 400 mg twice daily as needed (uses most days)

Allergies: NKDA

PE

VS: Blood pressure = 164/90 mm Hg
 Heart rate = 94 beats/min, respirations = 20
 Temperature = 37°C (98.6°F)
 Height = 5'10" (178 cm), weight = 360 lb (163.6 kg)

Cardiovascular: Regular rate and rhythm, normal S_1 and S_2 , no S_3 or S_4 ; no murmurs, rubs, gallops

Lungs: Clear to auscultation and percussion

Abd: Nontender, nondistended, + bowel sounds

Ext: 1+ lower extremity edema to the ankles bilaterally

Labs

Fasting lipid profile: total cholesterol 196 mg/dL (5.07 mmol/L), HDL cholesterol 27 mg/dL (0.70 mmol/L), LDL cholesterol 127 mg/dL (3.28 mmol/L), triglycerides 211 mg/dL (2.38 mmol/L); fasting glucose 178 mg/dl (9.9 mmol/L); other labs within normal limits

Exercise treadmill test: Positive for ischemia

Identify DF's risk factors for ischemic heart disease.

How might DF's current drug regimen adversely affect his ischemic heart disease?

What therapeutic alternatives are available to manage DF's ischemic heart disease?

How does this patient's ancestry influence drug therapy decisions?

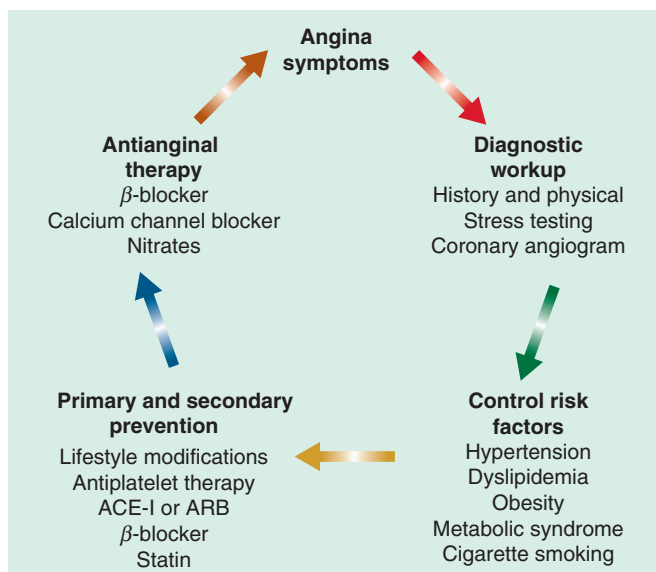

FIGURE 7-4. General treatment strategies for angina follow in clockwise fashion from the top center. (ACE-I, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker.)

statins) and angiotensin-converting enzyme (ACE) inhibitors are believed to provide vasculoprotective effects (properties that are generally protective of the vasculature that may include anti-inflammatory effects, antiplatelet effects, improvement in endothelial function, and improvement in arterial compliance and tone), and, in addition to aspirin, have been shown to reduce the risk of acute coronary events as well as mortality in patients with IHD. In select patients with IHD (following hospitalization for ACS ± **percutaneous coronary intervention [PCI]** and/or following intracoronary stent placement), dual antiplatelet therapy with aspirin and a P2Y₁₂ antagonist has also been shown to reduce ischemic events. Angiotensin receptor blockers (ARBs) may be used in patients who cannot tolerate ACE inhibitors because of side effects (e.g., chronic cough). β -Blockers have been shown to decrease morbidity and improve survival in patients who have suffered an MI.

Therapies to alleviate and prevent angina are aimed at improving the balance between myocardial oxygen demand and supply. Because angina usually results from increased myocardial oxygen demand in the face of a relatively fixed reduction in oxygen supply, drug treatment is primarily aimed at reducing oxygen demand. Short-acting nitrates are indicated to acutely relieve angina. β -Blockers, calcium

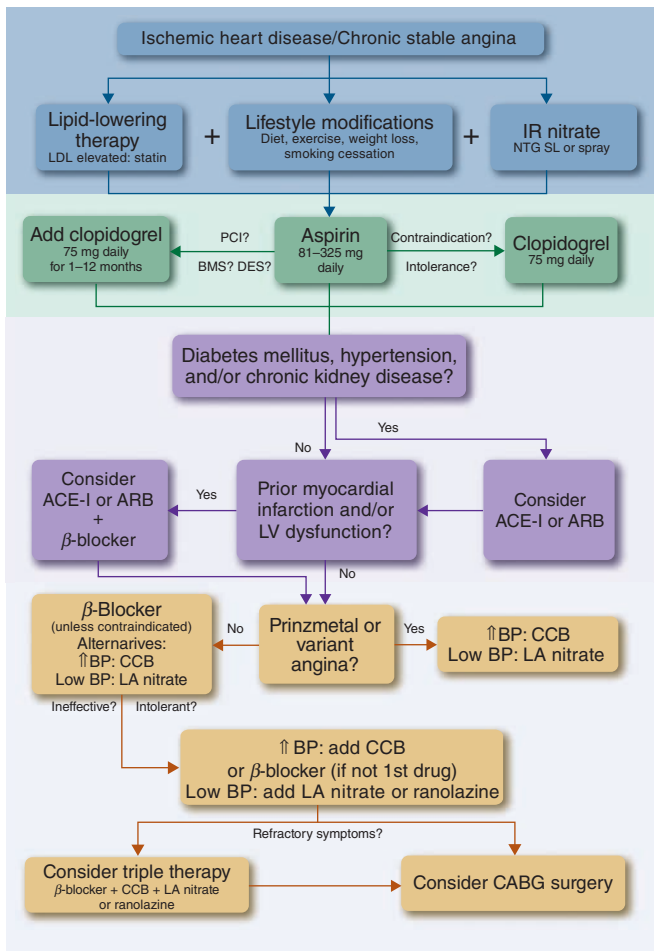

FIGURE 7-5. The treatment algorithm for ischemic heart disease. It begins at the top (blue section), which suggests risk factor modifications as the first treatment modality. Moving down to the green section, appropriate antiplatelet therapy is selected. The purple section identifies patients at high risk for major adverse cardiac events and suggests appropriate drug therapy to decrease cardiovascular risk. The yellow section at the bottom recommends appropriate antianginal therapy. *The minimum duration of clopidogrel therapy following intracoronary stent placement is as follows: at least 1 month for bare metal stents and at least 12 months for drug-eluting stents. (ACE-I, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BMS, bare metal stent; BP, blood pressure; CABG, coronary artery bypass graft; CCB, calcium channel blocker; DES, drug-eluting stent; HR, heart rate; IR, immediate release; LA, long acting; LDL, low-density lipoprotein; LV, left ventricular; NTG, nitroglycerin; PCI, percutaneous coronary intervention; SL, sublingual.)

channel blockers (CCBs), and long-acting nitrates are traditionally used to reduce the frequency of angina and improve exercise tolerance. In most patients with IHD, the most effective treatments to improve myocardial oxygen supply are invasive mechanical interventions, PCI, and

coronary artery bypass graft (CABG) surgery, which are described later in the chapter in the section on interventional approaches. These interventional approaches are reserved for patients with symptoms despite optimal medical therapy and lifestyle modifications and those hospitalized for ACS.

Adverse treatment effects can be averted by avoiding drug interactions and the use of drugs that may have unfavorable effects on comorbid diseases. For example, β -blockers may exacerbate preexisting bronchospasm. β -Blockers are not absolutely contraindicated in bronchospastic disease but should be avoided in patients with poorly controlled symptoms. Although patients often require combination anti-anginal therapy, there is a potential pharmacodynamic drug interaction with the concurrent use of β -blockers and nondihydropyridine CCBs. Because both drug classes slow electrical conduction through the atrioventricular (AV) node, serious bradycardia or heart block may result with their concomitant use. Appropriate drug dosing and monitoring also reduces the risk for adverse treatment effects. Drugs should be initiated in low doses, with careful up-titration as necessary to control symptoms of angina and cardiovascular risk factors.

Lifestyle Modifications

- Lifestyle modifications including smoking cessation, avoidance of secondhand smoke, dietary modifications, increased physical activity, and weight loss reduce cardiovascular risk factors, slow the progression of IHD, and decrease the risk for IHD-related complications. Cigarette smoking is the single most preventable cause of IHD and IHD-related death. Smoking may also attenuate the antianginal effects of drug therapy. The clinician should ascertain smoking status for the patient and family members on the patient's initial clinic visit. For patients and/or family members who smoke, clinicians should provide counseling on the importance of smoking cessation at each subsequent visit and referral to special smoking cessation programs. There are several pharmacologic aids for smoking cessation. Transdermal nicotine replacement therapy and bupropion have been studied in patients with IHD and appear safe.^{10,11} The safety of varenicline, a partial nicotine receptor agonist, has been questioned due to reports of psychiatric symptoms and suicidal ideation.¹² Thus the potential benefits and risks of the drug should be carefully considered and discussed with the patient before prescribing varenicline for smoking cessation. Weight loss, through caloric restriction and increased physical activity, should be encouraged in patients who have a body mass index greater than 25 kg/m². Dietary modification is important for risk factor management, and dietary counseling should be provided to all patients with newly diagnosed angina regardless of weight. The American Heart Association recommends a diet that includes a variety of fruits, vegetables, grains, low-fat or nonfat dairy products, fish, legumes, poultry, and lean meats.¹³ Fatty fish, such as salmon and herring, are high in ω -3 polyunsaturated fatty acids, which have been shown

to reduce triglyceride concentrations at daily doses of 3 g or more, slow atherosclerotic plaque progression, and may have cardiovascular protective effects.¹⁴ Specific dietary recommendations for patients with IHD should include the following:^{2,13}

- Limit fat intake to less than 30% of total caloric consumption.
- Limit cholesterol intake to less than 200 mg/day.
- Limit consumption of saturated fat and trans unsaturated fat found in fatty meats, full-fat dairy products, and hydrogenated vegetable oils to less than 7% of total calories.
- Consume approximately 1 g of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) per day in the form of fatty fish or fish oil capsules.
- Consume at least six servings of grains, five servings of fruits and vegetables, and two servings of nonfat or low-fat dairy products per day.
- Consider plant stanol/sterols (2 g/day) and/or viscous fiber (over 10 g/day) to lower LDL cholesterol. It is recommended that patients with diabetes consume 14 g of fiber for every 1,000 kcal (4,200 kJ) consumed.
- Limit daily sodium intake to 2.4 g (6 g of salt) for blood pressure control.

Exercise facilitates both weight loss and blood pressure reduction. In addition, regular exercise improves functional capacity and symptoms in chronic stable angina.¹ Guidelines recommend moderate intensity aerobic activity, such as brisk walking, ideally for 30 to 60 minutes every day.² Medically supervised cardiac rehabilitation programs are recommended for high-risk patients.

Interventional Approaches

► Percutaneous Coronary Intervention

When optimal medical therapy fails (e.g., hospitalization for ACS) or if extensive coronary atherosclerosis is present, PCI is often performed to restore coronary blood flow and relieve symptoms. However, there is no reduction in major adverse cardiac events or mortality with PCI compared with optimal medical therapy alone in patients with stable IHD.¹⁵ Thus optimal medical therapy is the preferred initial strategy for patients with stable IHD. Proceeding to PCI is appropriate for patients with one or more critical coronary stenoses (i.e., greater than 70% occlusion of the coronary lumen) detected during coronary angiography whose symptoms are unstable and/or persist despite optimal medical therapy. Several catheter-based interventions may be used during PCI, including:

- Percutaneous transluminal coronary angioplasty (PTCA)
- Intracoronary bare metal stent placement
- Intracoronary drug-eluting stent placement
- Rotational atherectomy

During PCI, a catheter is advanced into the blocked coronary artery, as described for cardiac catheterization. If PTCA (i.e., balloon angioplasty) is performed, a balloon at the end of the catheter is inflated inside the artery at the site of the critical stenosis. When inflated, this balloon catheter displaces the atherosclerotic plaque out of the lumen of the artery, restoring normal myocardial blood flow. Most PCI procedures involve the placement of a small mesh wire stent (similar in size and shape to the spring at the tip of a ballpoint pen) at the site of angioplasty. Coronary stenting involves use of a special balloon catheter containing the stent. When the balloon is inflated, the stent is deployed in the wall of the coronary artery, forming a sort of bridge or scaffold to maintain normal coronary blood flow. Either a bare metal stent or a drug-eluting stent may be used. Drug-eluting stents are impregnated with low concentrations of an antiproliferative drug (paclitaxel, everolimus, sirolimus, or zotarolimus), which is released locally over a period of weeks to inhibit **restenosis** or re-narrowing of the coronary artery after PCI. An observational study demonstrated a significant reduction in all-cause mortality over a 4.5-year interval among patients who received a drug-eluting stent compared to those with a bare metal stent.¹⁶ Stents are thrombogenic, especially until they become endothelialized (covered in endothelial cells like a normal coronary artery). Dual antiplatelet therapy (discussed later) is required until the stent becomes endothelialized, generally a period of 6 to 12 months, and, in some cases indefinitely following stent placement to reduce the risk for stent thrombosis, MI, or death. Lastly, rotational atherectomy may be performed wherein a special catheter is used to essentially cut away the atherosclerotic plaque, restoring coronary blood flow.

► Coronary Artery Bypass Graft Surgery

As an alternative to PCI, CABG surgery, or open-heart surgery, may be performed if the patient is found to have extensive coronary atherosclerosis (generally greater than 70% occlusion of three or more coronary arteries) or is refractory to optimal medical treatment. In the former case, CABG surgery has been shown to reduce the need for revascularization, but not death, compared with PCI.¹⁷ During CABG surgery, veins from the leg (i.e., saphenous veins) or arteries from the arm (i.e., radial artery) or chest wall (i.e., internal mammary arteries) are surgically removed. In the case of venous or radial artery conduits, one end of the removed blood vessel is attached to the aorta, and the other end is attached to the coronary artery distal to the atherosclerotic plaque. However, when internal mammary arteries are used, the distal end of the artery is detached from the chest wall and anastomosed to the coronary artery distal to the plaque. A median sternotomy, in which an incision the length of the sternum is made, is commonly required to gain access to the thoracic cavity and expose the heart. As the “new” blood vessels are being engrafted, the patient is typically placed on cardiopulmonary bypass (i.e., heart-lung

machine) to maintain appropriate myocardial and systemic perfusion. Alternative surgical approaches for advanced IHD may be used in some settings including “off-pump” CABG (cardiopulmonary bypass is not required) and minimally invasive CABG (i.e., thorascopic surgery), although these techniques are not the norm. Because of the extremely invasive nature of this surgery, CABG surgery is generally reserved for patients with extensive coronary disease or as a treatment of last resort in patients with symptoms refractory to medical therapy.

Pharmacologic Therapy

► Pharmacotherapy to Prevent Acute Coronary Syndromes and Death

- **Control of Risk Factors** A major component of any IHD treatment plan, which is often underutilized, is control of modifiable risk factors, including dyslipidemia, hypertension, and diabetes. Treatment strategies for dyslipidemia and hypertension in the patient with IHD are summarized in the following paragraphs. Visit chapters in this textbook on the management of hypertension (Chapter 5) and dyslipidemias (Chapter 12) for further information.

Because lipoprotein metabolism and the pathophysiology of atherosclerosis are closely linked, treatment of dyslipidemias is critical for both primary and secondary prevention of IHD-related cardiac events. In 2004 the Adult Treatment Panel III of the National Cholesterol Education Program updated the guidelines for the management of dyslipidemia and recommended a LDL cholesterol goal of less than 100 mg/dL (2.59 mmol/L) for patients with documented IHD or IHD risk equivalents such as diabetes or other vascular disease.¹⁸ Since the publication of these guidelines, new evidence from several primary and secondary prevention trials suggests there are additional clinical benefits from further reduction in LDL cholesterol (e.g., LDL cholesterol less than 70 mg/dL [1.81 mmol/L]).¹⁹ In response to this evidence, more aggressive cholesterol-lowering goals were established for patients at *high risk* for developing IHD-related events, including those with diabetes or known cardiovascular disease. The following modifications were made to national treatment guidelines^{19,20}:

- In addition to lifestyle modifications, statins or other LDL-lowering therapy are indicated for patients with cardiovascular disease, diabetes, and multiple cardiovascular risk factors, regardless of baseline LDL cholesterol.
- Intensity of LDL-lowering therapy should be sufficient to decrease LDL cholesterol by 30% to 40%.
- Goal LDL cholesterol in patients with known clinical cardiovascular disease, recent hospitalization for ACS, or diabetes plus one or more cardiovascular risk factors is less than 70 mg/dL (1.81 mmol/L).

Like dyslipidemia, hypertension is a major, modifiable risk factor for the development of IHD and related complications. Unfortunately, awareness, treatment, and

control of blood pressure are suboptimal.⁴ Aggressive identification and control of hypertension is warranted in patients with IHD to minimize the risk of major adverse cardiac events. The American Heart Association recommends a goal blood pressure in patients with IHD of less than 130/80 mm Hg.²¹ Because of their cardioprotective benefits, β -blockers and ACE inhibitors (or ARBs in ACE inhibitor-intolerant patients), either alone or in combination, are appropriate for most patients with both hypertension and IHD.

Antiplatelet Agents Platelets play a major role in the pathophysiology of ACS. Thromboxane is a potent platelet activator. Aspirin inhibits cyclooxygenase, an enzyme responsible for the production of thromboxane, thereby inhibiting platelet activation and aggregation. In patients with stable or unstable angina, aspirin has been consistently shown to reduce the risk of major adverse cardiac events, particularly MI.²² **6** *Antiplatelet therapy with aspirin should be considered for all patients without contraindications, particularly in patients with a history of myocardial infarction. Aspirin doses of 75 to 162 mg daily are recommended in patients with or at risk for IHD.^{2,22} If aspirin is contraindicated (e.g., aspirin allergy) or is not tolerated by the patient, an alternative antiplatelet agent such as clopidogrel should be considered.*

Binding of adenosine diphosphate to the P2Y₁₂ receptors on platelets activates glycoprotein IIb/IIIa receptors leading to platelet aggregation and thrombus formation. **6** *Inhibition of the P2Y₁₂ receptor with either a thienopyridine (ticlopidine, clopidogrel, prasugrel) or ticagrelor prevents platelet aggregation and is indicated in combination with aspirin in select patients with IHD.* Dual antiplatelet therapy with aspirin and a P2Y₁₂ inhibitor is recommended following hospitalization for ACS and/or PCI with stent placement to prevent ischemic events, although indications for specific drugs differ slightly (see later). Following stent placement, prolonged treatment with dual antiplatelet therapy (often greater than or equal to 12 months) is often necessary to prevent in-stent thrombosis prior to stent endothelialization. Historically, ticlopidine was the P2Y₁₂ inhibitor used in combination with aspirin. Clopidogrel, prasugrel, and ticagrelor have replaced ticlopidine due to the hematological toxicities (leucopenia) associated with ticlopidine and the growing body of evidence supporting the use of the other P2Y₁₂ inhibitors.

Clopidogrel is a prodrug that must be converted via a two-step process to its active thiol metabolite. The CYP2C19 enzyme is involved in both steps of the biotransformation. Individuals with reduced CYP2C19 activity, either from inherited deficiencies of CYP2C19 or use of CYP2C19 inhibitors (e.g., proton pump inhibitors), may produce less of the active thiol metabolite. These individuals are at increased risk for stent thrombosis and adverse cardiovascular events during clopidogrel treatment compared with those with “normal” CYP2C19 activity.²³ The clopidogrel labeling now warns of reduced effectiveness in CYP2C19 poor metabolizers. Poor metabolizers carry two dysfunctional CYP2C19 gene alleles and may be identified through genotyping.

The *CYP2C19**2 and *CYP2C19**3 alleles are the most common alleles leading to reduced *CYP2C19* activity.

Prasugrel is a thienopyridine that also requires biotransformation to its active metabolite. However, unlike clopidogrel, *CYP2C19* deficiency does not appear to alter its effectiveness. Ticagrelor is a direct-acting P2Y₁₂ inhibitor that does not require biotransformation to exert its antiplatelet effects and is unaffected by *CYP2C19* activity.²⁴ Thus prasugrel or ticagrelor may be suitable alternatives to clopidogrel, depending on the indication, when reduced *CYP2C19* activity is suspected.

Antiproliferative drugs in drug-eluting stents delay endothelialization, and thus a longer period of dual antiplatelet therapy is recommended for drug-eluting stents compared with bare metal stents to prevent thrombosis. Guidelines advocate dual antiplatelet therapy for 12 months after stent placement.²⁵ The duration of dual antiplatelet therapy may be abbreviated in select patients with bare metal stents (i.e., high risk for bleeding, history of nonadherence, need for invasive procedures or major surgery), whereas some data support indefinite use of combination antiplatelet therapy following stent placement. Because of the risk for stent thrombosis with premature discontinuation of dual antiplatelet therapy, it is imperative for clinicians to educate patients on this risk and the need for continuation of combination antiplatelet therapy for the recommended duration.

Clopidogrel, prasugrel, and ticagrelor are all indicated in combination with aspirin for at least 1 year in patients with ACS who undergo PCI. Unlike prasugrel, both clopidogrel and ticagrelor are indicated in combination with aspirin in ACS patients regardless of whether PCI is performed. In this population, combination therapy with aspirin and either clopidogrel or ticagrelor more effectively reduces the risk of death, MI, and stroke compared with aspirin alone even in patients who were managed medically (e.g., in the absence of PCI).^{26–28} When used in combination with aspirin in patients with ACS (with or without PCI), both prasugrel and ticagrelor may provide greater protection against cardiovascular events after stent placement compared with clopidogrel, but at the cost of an increased risk for bleeding.^{28,29} For more information regarding the use of dual antiplatelet therapy in the setting of ACS, see Chapter 8.

Statins Statins are the preferred drugs to achieve LDL cholesterol goals based on their potency in lowering LDL cholesterol and efficacy in preventing cardiac events. Specifically, over the last decade, several studies in tens of thousands of patients have revealed that lowering cholesterol with statins is effective for both primary and secondary prevention of IHD-related events.¹⁹ Statins shown to decrease morbidity and mortality associated with IHD include lovastatin, simvastatin, pravastatin, and atorvastatin. A meta-analysis showed the risk of major adverse cardiac events is reduced by 21% with the use of statins in patients at high risk for IHD-related events.³⁰

Several studies have investigated whether statins possess pharmacologic properties in addition to their LDL cholesterol-lowering effect that may confer additional

benefits in IHD.³¹ These studies were prompted by evidence that patients with “normal” LDL cholesterol derived benefit from statins. Statins have been shown to modulate the following characteristics thought to stabilize atherosclerotic plaques and contribute to the cardiovascular risk reduction seen with these drugs:

- Shift LDL cholesterol particle size from predominantly small, dense, highly atherogenic particles to larger, less atherogenic particles.
- Improve endothelial function leading to more effective vasoactive response of the coronary arteries.
- Prevent or inhibit inflammation by lowering C-reactive protein and other inflammatory mediators thought to be involved in atherosclerosis.
- Possibly improve atherosclerotic plaque stability.

7 *In summary, to control risk factors and prevent major adverse cardiac events, statin therapy should be considered in all patients with ischemic heart disease, particularly in those with elevated low-density lipoprotein cholesterol or diabetes.* Statins are potent lipid-lowering agents, possess non-lipid-lowering effects that may provide additional benefit to patients with IHD, and have been shown to reduce morbidity and mortality in patients with IHD. Based on these benefits, statins are generally considered the drugs of choice in patients with dyslipidemias. Moreover, based on evidence that statins improve outcomes in patients with IHD and “normal” LDL cholesterol concentration, statins should be considered in all patients with IHD at high risk of major adverse cardiac events, regardless of baseline LDL cholesterol.

ACE Inhibitors and Angiotensin Receptor Blockers

Angiotensin II, a neurohormone produced primarily in the kidney, is a potent vasoconstrictor and stimulates the production of aldosterone. Together, angiotensin II and aldosterone increase blood pressure and sodium and water retention (increasing ventricular wall tension), cause endothelial dysfunction, promote blood clot formation, and cause myocardial fibrosis.

ACE inhibitors decrease angiotensin II production and have consistently been shown to decrease morbidity and mortality in patients with heart failure or a history of MI.^{32,33} In addition, there is evidence that ACE inhibitors reduce the risk of vascular events in patients with chronic stable angina or risk factors for IHD.^{34,35} Specifically, in nearly 10,000 patients with vascular disease (including IHD) or risk factors for vascular disease, such as diabetes, ramipril reduced the risk of death, acute MI, and stroke by 22% compared with placebo after an average of 5 years of treatment.³⁴ Similar results have been demonstrated with perindopril in patients with IHD.³⁵

7 *In the absence of contraindications, ACE inhibitors should be considered in all patients with IHD, particularly those individuals who also have hypertension, diabetes mellitus, chronic kidney disease, left ventricular dysfunction, history of myocardial infarction, or any combination of these.² Additionally, ACE inhibitors should also be considered in*

patients at high risk for developing IHD based on findings from the studies summarized above. Angiotensin receptor blockers may be used in patients with indications for ACE inhibitors but who cannot tolerate them due to side effects (e.g., chronic cough). Angiotensin receptor blockers also antagonize the effects of angiotensin II. In one large trial, valsartan was as effective as captopril at reducing morbidity and mortality in post-MI patients.³² However, there are far more data supporting the use of ACE inhibitors in IHD. Therefore, ACE inhibitors should remain first line in patients with a history of MI, diabetes, chronic kidney disease, or left ventricular dysfunction. The ACE inhibitors and ARBs with indications for patients with or at risk for IHD or IHD-related complications are listed in [Table 7-5](#).

Side effects with ACE inhibitors and ARBs include hyperkalemia, deterioration in renal function, and angioedema. Serum potassium increases are secondary to aldosterone inhibition and are more likely in the presence of preexisting renal impairment, diabetes, or concomitant therapy with nonsteroidal anti-inflammatory drugs (NSAIDs), potassium supplements, or potassium-sparing diuretics. Reductions in glomerular filtration may occur during ACE inhibitor or ARB initiation or up-titration due to inhibition of angiotensin II-mediated vasoconstriction of the efferent arteriole. This type of renal impairment is usually temporary and more common in patients with preexisting renal dysfunction or unilateral renal artery stenosis. Bilateral renal artery stenosis is a contraindication for ACE inhibitors and ARBs

because of the risk for overt renal failure. Angioedema is a potentially life-threatening adverse effect that occurs in less than 1% of ACE inhibitor-treated white patients but up to 8% of African Americans. Angioedema may also occur with the administration of ARBs. Substitution of an ARB for an ACE inhibitor is appropriate for patients who develop a persistent cough with ACE inhibitor therapy because this cough is related to the accumulation of bradykinin secondary to ACE inhibition. Both ACE inhibitors and ARBs can cause fetal injury and death and are contraindicated in pregnancy.

► Nitroglycerin to Relieve Acute Symptoms

- Short-acting nitrates are first-line treatment to terminate acute episodes of angina. **8** All patients with a history of angina should have sublingual nitroglycerin tablets or spray to relieve acute ischemic symptoms. Nitrates undergo biotransformation to nitric oxide. Nitric oxide activates smooth muscle guanylate cyclase, leading to increased intracellular concentrations of cyclic guanosine monophosphate, release of calcium from the muscle cell, and ultimately, to smooth muscle relaxation. Nitrates primarily cause venodilation, leading to reductions in **preload**. The resultant decrease in ventricular volume and wall tension leads to a reduction in myocardial oxygen demand. In higher doses, nitrates cause arterial dilation and reduce afterload and blood pressure. In addition to reducing oxygen demand, nitrates increase myocardial oxygen supply by dilating the epicardial coronary arteries and collateral vessels, as well as relieving vasospasm.

Short-acting nitrates are available in tablet and spray formulations for sublingual administration. Sublingual nitroglycerin tablets are well absorbed across the oral mucosa and produce an antianginal effect within 1 to 3 minutes and are less expensive than the spray. However, the spray is preferred for patients who have difficulty opening the tablet container or produce insufficient saliva for rapid dissolution of sublingual tablets. **8** At the onset of an angina attack, a 0.3 to 0.4 mg dose of nitroglycerin (tablet or spray) should be administered sublingually, and repeated every 5 minutes up to three times or until symptoms resolve. Standing enhances venous pooling and may contribute to hypotension, dizziness, or lightheadedness. Sublingual nitroglycerin may be used to prevent effort-induced angina (i.e., angina that occurs with exertion). In this case, the patient should use sublingual nitroglycerin 2 to 5 minutes prior to an activity known to cause angina, with the effects persisting for approximately 30 minutes. Isosorbide dinitrate, also available in a sublingual form, has a longer half-life with antianginal effects lasting up to 2 hours. The use of short-acting nitrates alone, without concomitant long-acting antianginal therapy, may be acceptable for patients who experience angina symptoms once every few days. However, for patients with more frequent attacks, long-acting antianginal therapy with β -blockers, CCBs, or long-acting nitrates is recommended.

The use of nitrates within 24 to 48 hours of a phosphodiesterase type 5 inhibitor (e.g. sildenafil, vardenafil, and tadalafil), commonly prescribed for erectile dysfunction,

Table 7-5

Doses of Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers Indicated in Ischemic Heart Disease

Drug	Indications	Usual Dosage in IHD ^a
Angiotensin-converting enzyme inhibitors		
Captopril	HTN, HF, post-MI, diabetic nephropathy	6.25–50 mg 3 times daily
Enalapril	HTN, HF	2.5–40 mg daily in 1–2 divided doses
Fosinopril	HTN, HF	10–80 mg daily in 1–2 divided doses
Lisinopril	HTN, HF, post-MI	2.5–40 mg daily
Perindopril	HTN, IHD	4–8 mg daily
Quinapril	HTN, HF, post-MI	5–20 mg twice daily
Ramipril	HTN, high-risk for IHD, HF, post-MI	2.5–10 mg daily in 1–2 divided doses
Trandolapril	HTN, HF, post-MI	1–4 mg daily
Angiotensin receptor blockers		
Candesartan	HTN, HF	4–32 mg daily
Valsartan	HTN, HF, post-MI	80–320 mg daily in 1–2 divided doses
Telmisartan	HTN, high-risk for IHD	20–80 mg daily

HF, heart failure; HTN, hypertension; IHD, ischemic heart disease; MI, myocardial infarction.

^aReduce initial dose and gradually titrate upward as tolerated in renal impairment.

is contraindicated. Phosphodiesterase degrades cyclic guanosine monophosphate (cGMP), which is responsible for the vasodilatory effects of nitrates. Concomitant use of nitrates and phosphodiesterase type 5 inhibitors enhances cGMP-mediated vasodilation and can result in serious hypotension, decreased coronary perfusion, and even death. All patients with IHD should receive a prescription for sublingual nitrates and education regarding their use. Points to emphasize when counseling a patient on nitroglycerin use include:

- The seated position is generally preferred when using nitroglycerin because the drug may cause dizziness.
- Call 911 if symptoms are unimproved or worsen 5 minutes after the first dose.
- Keep nitroglycerin tablets in the original glass container and close the cap tightly after use.
- Nitroglycerin should not be stored in the same container as other medications because this may reduce nitroglycerin's effectiveness.
- Repeated use of nitroglycerin is not harmful or addictive and does not result in any long-term side effects. Patients should not hesitate to use nitroglycerin whenever needed.
- Nitroglycerin should not be used within 24 hours of taking sildenafil or vardenafil or within 48 hours of taking tadalafil because of the potential for life-threatening hypotension.

► Pharmacotherapy to Prevent Recurrent Ischemic Symptoms

The overall goal of antianginal therapy is to allow patients with IHD to resume normal activities without symptoms of angina and to experience minimal to no adverse drug effects. The drugs traditionally used to prevent ischemic symptoms are β -blockers, CCBs, and nitrates. These drugs exert their antianginal effects by improving the balance between myocardial oxygen supply and demand, with specific effects listed in **Table 7-6**. β -Blockers, CCBs, and nitrates decrease the frequency of angina and delay the onset of angina during exercise. However, there is no evidence that any of these agents prevent ACS or improve survival in patients with chronic stable angina. Ranolazine, a newer molecular entity whose mechanism of action is unknown, is indicated for the treatment of chronic stable angina. Combination therapy with two or three antianginal drugs is often needed.

β -Blockers Stimulation of the β_1 - and β_2 -adrenergic receptors in the heart increases heart rate and cardiac contractility. β -Blockers antagonize β_1 - and β_2 -adrenergic receptors, reducing heart rate and cardiac contractility, and decreasing myocardial oxygen demand. β -Blockers may also reduce oxygen demand by lowering blood pressure and ventricular wall tension through inhibition of renin release from juxtaglomerular cells. By slowing heart rate, β -blockers prolong diastole, thus increasing coronary blood flow. However, with marked reductions in heart rate, β -blockers may actually increase ventricular wall tension. This is because

Table 7-6

Effects of Antianginal Medications on Myocardial Oxygen Demand and Supply

Antianginal Agent	Oxygen Demand			
	Heart Rate	Wall Tension	Cardiac Contractility	Oxygen Supply
β -Blockers	↓	↔ or ↑	↓	↔
Calcium channel blockers				
Verapamil, diltiazem	↓	↓	↓	↑
Dihydropyridines	↔ or ↑	↓	↓	↑
Nitrates	↑	↓	↔	↑
Ranolazine ^a	↔	↓	↔	↔

^aThe exact mechanism of the antiischemic effects of ranolazine is not known.

↓ decreases; ↔, no change; ↑, increases.

slower heart rates allow the ventricle more time to fill during diastole, leading to increased left ventricular volume, end diastolic pressure, and wall tension. However, the net effect of β -blockade is usually a reduction in myocardial oxygen demand. β -Blockers do not improve myocardial oxygen supply.

β -Blockers with intrinsic sympathomimetic activity (e.g., acebutolol, pindolol, and penbutolol) have partial β -agonist effects and cause lesser reductions in heart rate at rest. As a result, β -blockers with intrinsic sympathomimetic activity may produce lesser reductions in myocardial oxygen demand and should be avoided in patients with IHD. Other β -blockers appear equally effective at controlling symptoms of angina. The properties and recommended doses of various β -blockers used to prevent angina are summarized in **Table 7-7**. The frequency of dosing and drug cost should be taken into consideration when choosing a particular drug. Agents that can be dosed once or twice daily are preferred. Most β -blockers are available in inexpensive generic versions. β -Blockers should be initiated in doses at the lower end of the usual dosing range, with titration according to symptom and hemodynamic response. The β -blocker dose is commonly titrated to achieve the following:

- Resting heart rate between 55 and 60 beats/min.
- Maximum heart rate with exercise of 100 beats/min or less or 20 beats/min above the resting heart rate.

9 β -Blockers are first-line therapy for preventing ischemic symptoms, particularly in patients with a history of myocardial infarction. In the absence of contraindications, β -blockers are the preferred antianginal therapy because of their potential cardioprotective effects. Specifically, β -blockers possessing membrane stabilizing properties may prevent cardiac arrhythmias by decreasing the rate of spontaneous depolarization of ectopic pacemakers. Secondly, although the long-term effects of β -blockers on morbidity and mortality in patients with chronic stable angina are largely unknown,

Table 7-7

Properties and Dosing of β -Blockers in Ischemic Heart Disease

Drug	Receptor Affinity	Usual Dose Range	Dose Adjust in Hepatic Impairment	Dose Adjust in Renal Impairment
Atenolol	β_1 -Selective	25–200 mg once daily	No	Yes
Betaxolol	β_1 -Selective	5–20 mg once daily	No	Yes
Bisoprolol	β_1 -Selective	2.5–10 mg once daily	Yes	Yes
Carvedilol	α_1 , β_1 , and β_2	3.125–25 mg twice daily	Avoid in severe impairment	No
Carvedilol phosphate	α_1 , β_1 , and β_2	10–80 mg once daily	Avoid in severe impairment	No
Labetalol	α_1 , β_1 , and β_2	100–400 mg twice daily	Yes	No
Metoprolol	β_1 -Selective	50–200 mg twice daily (once daily for extended release)	Yes	No
Nadolol	β_1 and β_2	40–120 mg once daily	No	Yes
Propranolol	β_1 and β_2	20–120 mg twice daily (60–240 mg once daily for long-acting formulation)	Yes	No
Timolol	β_1 and β_2	10–20 mg twice daily	Yes	Yes

certain β -blockers have been shown to decrease the risk for reinfarction and improve survival in patients who have suffered an MI.^{36,37} Specific β -blockers associated with mortality reductions in clinical trials include metoprolol, propranolol, and carvedilol. In a meta-analysis of 82 clinical trials investigating the use of β -blockers in patients following MI, the relative risk of death was reduced by 23% in patients treated with β -blockers compared with control subjects.³⁷ Long-term therapy (for at least 6 months) was associated with a greater mortality benefit compared with short-term β -blockade (6 weeks or less).

β -Blockers are contraindicated in patients with severe bradycardia (heart rate less than 50 beats/min) or AV conduction defects in the absence of a pacemaker. β -Blockers should be used with particular caution in combination with other agents that depress AV conduction (e.g., digoxin, verapamil, and diltiazem) because of the increased risk for bradycardia and heart block. Relative contraindications include asthma, bronchospastic disease, and severe depression. β_1 -Selective blockers are preferred in patients with asthma or chronic obstructive pulmonary disease. However, selectivity is dose dependent, and β_1 -selective agents may induce bronchospasm in higher doses.

There are several precautions to consider with the use of β -blockers in patients with diabetes or heart failure. All β -blockers may mask the tachycardia and tremor (but not sweating) that commonly accompany episodes of hypoglycemia in diabetes. In addition, nonselective β -blockers may alter glucose metabolism and slow recovery from hypoglycemia in insulin-dependent diabetes. β_1 -Selective agents are preferred because they are less likely to prolong recovery from hypoglycemia. Importantly, β -blockers should not be avoided in patients with IHD and diabetes, particularly in patients with a history of MI who are at high risk for recurrent cardiovascular events. β -Blockers are negative inotropes (i.e., they decrease cardiac contractility). Cardiac contractility is impaired in patients with left ventricular dysfunction. Therefore, β -blockers may worsen symptoms of acute heart failure in patients with left

ventricular dysfunction (i.e., ejection fraction less than 40% [0.40]) and should be delayed until the patient has stabilized. β -blockers are indicated in patients with heart failure whose acute symptoms have resolved and who are euvoletic. Research has indicated that treatment with β -blockers is associated with a reduction in morbidity and mortality in this population. In particular, when used for the management of IHD in a patient with heart failure, β -blockers should be initiated in very low doses with slow up-titration to avoid worsening heart failure symptoms.

Other potential adverse effects from β -blockers include fatigue, sleep disturbances, malaise, depression, and sexual dysfunction. Abrupt β -blocker withdrawal may increase the frequency and severity of angina, possibly because of increased receptor sensitivity to catecholamines after long-term β -blockade. If the decision is made to stop β -blocker therapy, the dose should be tapered over several days to weeks to avoid exacerbating angina.

Calcium Channel Blockers Calcium channel blockers (CCBs) inhibit calcium entry into vascular smooth muscle and cardiac cells, resulting in the inhibition of the calcium-dependent process leading to muscle contraction. Inhibition of calcium entry into the vascular smooth muscle cells leads to systemic vasodilation and reductions in afterload. Inhibition of calcium entry into the cardiac cells leads to reductions in cardiac contractility. Thus CCBs reduce myocardial oxygen demand by lowering both wall tension (through reductions in afterload) and cardiac contractility. The nondihydropyridine CCBs, verapamil and diltiazem, further decrease myocardial oxygen demand by slowing cardiac sinoatrial and atrioventricular (AV) nodal conduction and lowering heart rate. Because of their negative **chronotropic** effects, verapamil and diltiazem are generally more effective antianginal agents than the dihydropyridine CCBs. In contrast, dihydropyridine CCBs, nifedipine in particular, inhibits calcium in the vasculature, and they are potent vasodilators that can cause baroreflex-mediated increases in sympathetic tone and heart rate.

In addition to decreasing myocardial oxygen demand, all CCBs increase myocardial oxygen supply by dilating coronary arteries, thus increasing coronary blood flow and relieving vasospasm.

In randomized controlled clinical trials, CCBs were as effective as β -blockers at preventing ischemic symptoms. **9** *Calcium channel blockers are recommended as alternative treatment in IHD when β -blockers are contraindicated or not tolerated. In addition, CCBs may be used in combination with β -blockers when initial treatment is unsuccessful.* The combination of a β -blocker and a dihydropyridine CCB may improve symptoms better than either drug used alone.³⁸ However, the combination of a β -blocker with either verapamil or diltiazem should be used with extreme caution because both drugs decrease AV nodal conduction, increasing the risk for severe bradycardia or AV block when used together. If combination therapy is warranted, a long-acting dihydropyridine CCB is preferred. β -Blockers will prevent reflex increases in sympathetic tone and heart rate with the use of CCBs with potent vasodilatory effects. For patients with variable and unpredictable occurrences of angina, indicating possible coronary vasospasm, CCBs may be more effective than β -blockers in preventing angina episodes. The dosing of CCBs in IHD is described in [Table 7-8](#).

Verapamil and diltiazem are contraindicated in patients with bradycardia and preexisting conduction disease in the absence of a pacemaker. As previously noted, verapamil and diltiazem should be used with particular caution in combination with other drugs that depress AV nodal conduction (e.g., β -blockers and digoxin). Because of their negative **inotropic** effects, CCBs may cause or exacerbate heart failure in patients with preexisting left ventricular systolic dysfunction and should be avoided in this population. The exceptions are amlodipine and felodipine that have less negative inotropic effects compared with other CCBs and appear to be safe in patients with left ventricular

Table 7-8	
Dosing of Calcium Channel Blockers in Ischemic Heart Disease	
Drug	Usual Dose Range
Nondihydropyridines	
Diltiazem, extended release	120–360 mg once daily; consider dose adjustment in hepatic dysfunction
Verapamil, extended release	180–480 mg once daily; use initial dose of 120 mg in hepatic dysfunction
Dihydropyridines	
Amlodipine	5–10 mg once daily
Felodipine	5–10 mg once daily; use initial dose of 2.5 mg once daily in hepatic dysfunction
Nifedipine, extended release	30–90 mg once daily; dose adjust and monitor closely in hepatic dysfunction
Nicardipine	20–40 mg three times daily; dose twice daily in hepatic dysfunction and up-titrate slowly in both hepatic and renal dysfunction

Table 7-9	
Nitrate Formulations and Dosing for Chronic Use	
Formulation	Dose
Oral	
Nitroglycerin extended-release capsules	2.5 mg 3 times daily initially, with up-titration according to symptoms and tolerance; allow a 10- to 12-hour nitrate-free interval
Isosorbide dinitrate tablets	5–20 mg 2–3 times daily, with a daily nitrate-free interval of at least 14 hours (e.g., dose at 7 AM, noon, and 5 PM)
Isosorbide dinitrate slow-release capsules	40 mg 1–2 times daily, with a daily nitrate-free interval of at least 18 hours (e.g., dose at 8 AM and 2 PM)
Isosorbide mononitrate tablets	5–20 mg 2 times daily initially, with up-titration according to symptoms and tolerance; doses should be taken 7 hours apart (e.g., 8 AM and 3 PM)
Isosorbide mononitrate extended-release tablets	30–120 mg once daily
Transdermal	
Nitroglycerin extended-release film	0.2–0.8 mg/hour, on for 12–14 hours, off for 10–12 hours

- systolic dysfunction.^{39,40} Finally, there is some evidence that short-acting CCBs (particularly short-acting nifedipine and nicardipine) may increase the risk of cardiovascular events.⁴¹ Therefore, short-acting agents should be avoided in the management of IHD.

Long-Acting Nitrates Nitrate products are available in both oral and transdermal formulations for chronic use. Commonly used products are listed in [Table 7-9](#). All long-acting nitrate products produce effects within 30 to 60 minutes and are equally effective at preventing the recurrence of angina when used appropriately.

The major limitation of nitrate therapy is the development of tolerance with continuous use. The loss of antianginal effects may occur within the first 24 hours of continuous nitrate therapy. Although the cause of tolerance is unclear, several mechanisms have been proposed, including the generation of free radicals that degrade nitric oxide. The most effective method to avoid tolerance and maintain the antianginal efficacy of nitrates is to allow a daily nitrate-free interval of at least 8 to 12 hours. Nitrates do not provide protection from ischemia during the nitrate-free period. Therefore, the nitrate-free interval should occur when the patient is least likely to experience angina. Generally, angina is less common during the nighttime hours when the patient is sleeping and myocardial oxygen demand is reduced. Thus it is common to dose long-acting nitrates so that the nitrate-free interval begins in the evening. For example, isosorbide dinitrate is typically dosed on awakening and again 6 to 7 hours later.

- Monotherapy with nitrates for the prevention of ischemia should generally be avoided for a couple of reasons. First, reflex increases in sympathetic activity and heart rate, with resultant increases in myocardial oxygen demand, may

occur secondary to nitrate-induced venodilation. Second, patients are unprotected from ischemia during the nitrate-free interval. β -Blockers and CCBs are dosed to provide 24-hour protection from ischemia. **9** *Treatment with long-acting nitrates should be added to baseline therapy with either a β -blocker or CCB or a combination of the two.* β -Blockers attenuate the increase in sympathetic tone and heart rate that occurs during nitrate therapy. In turn, nitrates attenuate the increase in wall tension during β -blocker therapy. As a result, the combination of β -blockers and nitrates is particularly effective at preventing angina and provides greater protection from ischemia than therapy with either agent alone. Monotherapy with nitrates may be appropriate in patients who have low blood pressure at baseline or who experience symptomatic hypotension with low doses of β -blockers or CCBs.

Common adverse effects of nitrates include postural hypotension, dizziness, flushing, and headache secondary to venodilation. Headache often resolves with continued therapy and may be treated with acetaminophen. Hypotension is generally of no serious consequence. However, in patients with hypertrophic obstructive cardiomyopathy or severe aortic valve stenosis, nitroglycerin may cause serious hypotension and syncope. Therefore, long-acting nitrates are relatively contraindicated in these conditions. Because life-threatening hypotension may occur with concomitant use of nitrates and phosphodiesterase type 5 inhibitors, nitrates should not be used within 24 hours of taking sildenafil or vardenafil or within 48 hours of taking tadalafil. Skin erythema and inflammation may occur with transdermal nitroglycerin administration and may be minimized by rotating the application site.

Ranolazine Ranolazine is an antiischemic agent indicated for the management of chronic angina. The mechanism of action is unclear, but it is believed to inhibit the late inward sodium current during the plateau phase of the cardiac action potential. Under ischemic conditions, excess sodium may enter the myocardial cell during systole. The resultant intracellular sodium overload leads to intracellular calcium accumulation (calcium overload) through a sodium/calcium exchange mechanism. Calcium overload results in increases in left ventricular wall tension and myocardial oxygen consumption. By reducing intracellular sodium concentrations in ischemic myocytes, ranolazine decreases intracellular calcium overload, left ventricular wall tension, and myocardial oxygen consumption.

In clinical trials, ranolazine reduced angina and increased exercise capacity when added to other antianginal therapy, with no effect on major cardiovascular events.^{42,43} Ranolazine has minimal effects on heart rate or blood pressure; thus it may be an option in IHD patients with low baseline blood pressure or heart rate. Ranolazine is indicated as a first-line treatment for chronic stable angina. However, it is often reserved for patients with angina that is refractory to traditional antianginal medications due to its excessive cost and small risk for dose-related prolongation of the QT interval. When used at recommended doses, the mean prolongation of QT interval is minimal (2.6 ms).⁴² However,

Table 7-10

Contraindications and Precautions with Ranolazine

Contraindications	Precautions
Liver cirrhosis increases ranolazine plasma concentrations by 30% to 80% resulting in increased risk for QT interval prolongation	Treatment with moderate CYP3A4 inhibitors including diltiazem, verapamil, grapefruit juice, erythromycin, and fluconazole increases ranolazine plasma concentrations (twofold with diltiazem and verapamil)
Treatment with potent CYP3A4 inhibitors, including ketoconazole, clarithromycin, and nelfinavir increases ranolazine concentrations (3.2-fold with ketoconazole)	Preexisting QT prolongation, history of torsades de pointes, or treatment with other QT-prolonging drugs
Treatment with CYP3A4 inducers including rifampin, phenobarbital, phenytoin, carbamazepine, and St. John's wort may significantly decrease the efficacy of ranolazine (by 95% with rifampin)	Uncorrected hypokalemia
	Treatment with a p-glycoprotein inhibitor, such as cyclosporine, may increase ranolazine absorption
	Ranolazine may increase bioavailability of p-glycoprotein substrates (increases digoxin plasma concentrations by 1.5-fold)
	Ranolazine may cause syncope; use caution when driving or operating machinery
	Ranolazine may cause reduced metabolism of CYP2D6 substrates
	Up to a 50% increase in ranolazine plasma concentration has been observed in renal impairment

the risk for QT interval prolongation is elevated in patients with hepatic impairment or taking other medications with the potential to prolong the QT interval. Ranolazine should be started at a dose of 500 mg twice daily and increased to 1000 mg twice daily if needed for symptom relief. Higher doses are poorly tolerated and should be avoided. Contraindications to ranolazine are shown in **Table 7-10**. Common adverse effects with ranolazine include dizziness, constipation, headache, and nausea. Syncope may occur infrequently. Ranolazine is a CYP3A4 substrate, weak CYP2D6 substrate, CYP2D6 inhibitor, and both an inhibitor and substrate of p-glycoprotein. Concomitant use of ranolazine with potent CYP3A4 inhibitors (e.g., ketoconazole, clarithromycin, and nelfinavir) or inducers (e.g., rifampin) is contraindicated. The use of ranolazine is contraindicated in patients with significant hepatic disease. The ranolazine dose should be limited to 500 mg twice daily when combined with moderate CYP3A4 inhibitors including diltiazem and verapamil. Ranolazine should be used cautiously with p-glycoprotein inhibitors (e.g., cyclosporine) and substrates (e.g., digoxin).

► **Pharmacotherapy with No Benefit or Potentially Harmful Effects**

Hormone Replacement Therapy Hormone replacement therapy (HRT) has favorable effects on lipoprotein cholesterol concentrations. Data from several observational studies

suggested that HRT might reduce the risk of cardiovascular events in women with IHD. However, subsequent randomized controlled clinical trials failed to demonstrate a reduction in the risk for IHD or cardiovascular events with HRT in postmenopausal women.^{44,45} In fact, HRT appeared to be harmful in this patient population, increasing the risk of thromboembolic events and breast cancer. Current guidelines recommend against the use of HRT to reduce cardiovascular risk.¹ Furthermore, the clinician should consider discontinuing HRT therapy in women who suffer an acute coronary event while receiving such therapy.

Antioxidants Oxidization of LDL-cholesterol is believed to play a significant role in the atherosclerotic process. The antioxidant vitamins, vitamin E, vitamin C, and β -carotene, protect LDL cholesterol from oxidation. Evidence from observational and animal studies suggests that an increased intake of antioxidant vitamins might inhibit the formation of atherosclerotic lesions and decrease the risk for cardiovascular events.⁴⁶ However, randomized prospective studies have not substantiated the findings from earlier studies and found no beneficial effect of vitamin E, vitamin C, or β -carotene on cardiovascular outcomes in patients with IHD or IHD risk factors.^{47,48} Based on this evidence, current guidelines do not recommend supplementation with vitamin E or other antioxidants for the purpose of preventing cardiovascular events.

Folic Acid Elevated homocysteine concentrations have been associated with an increased risk for cardiovascular disease in both epidemiologic and clinical studies.⁴⁹ Although folic acid and vitamin B supplementation are effective at reducing homocysteine levels, neither treatment reduces cardiovascular events.⁴⁹ Based on available evidence, the use of folate or vitamin B supplementation for the prevention of cardiovascular events in patients with preexisting IHD or at risk for IHD is not recommended.

Herbal Supplements Herbal products are widely used for their purported cardiovascular benefits; examples of such products include danshen, dong quai, feverfew, garlic, hawthorn, and hellebore. However, strong evidence supporting their benefits in cardiovascular disease is generally lacking. Although small randomized controlled trials have shown benefits with some herbal supplements, the potential for drug interactions and the lack of product standardization limits the products' usefulness in clinical practice. Safety with herbal supplements in patients with IHD is a major concern. Numerous case reports of adverse cardiovascular events, including stroke, MI, and lethal cardiac arrhythmias with ephedra-based products (e.g., Ma huang), led the FDA to ban ephedra-containing products in 2004. However, other herbal supplements with potentially serious adverse cardiovascular effects remain easily accessible to the consumer. Some herbal supplements may interact with antiplatelet and antithrombotic therapy and increase bleeding risk. Dietary supplements purported to enhance sexual performance may contain phosphodiesterase-like chemicals and increase risk for serious hypotension with nitroglycerin. Other agents may reduce the effectiveness of antianginal medications, such

Patient Encounter Part 3: Creating a Care Plan

Based on the information presented, create a specific plan for the management of DF's ischemic heart disease. Your plan should include (a) the goals of therapy, (b) specific nonpharmacologic and pharmacologic interventions to address these goals, and (c) a plan for follow-up to assess drug tolerance and whether the therapeutic goals have been achieved.

as St. John's wort with ranolazine. Thus it is important to assess the use of herbal products in patients with IHD and to counsel patients about the potential for drug interactions and adverse events with herbal therapies.

Cyclooxygenase-2 Inhibitors and Nonsteroidal Anti-inflammatory Drugs Data suggest that cyclooxygenase-2 (COX-2) inhibitors and nonselective NSAIDs may increase the risk for MI and stroke.⁵⁰ The cardiovascular risk with COX-2 inhibitors and NSAIDs may be greatest in patients with a history of, or with risk factors for, cardiovascular disease. The COX-2 inhibitors rofecoxib and valdecoxib were withdrawn from the market in recent years because of safety concerns. The FDA requested the manufacturers of other COX-2 and nonselective NSAIDs (prescription and over-the-counter) to include information about the potential adverse cardiovascular effects of these drugs in their product labeling. The American Heart Association recommends that the use of COX-2 inhibitors be limited to low-dose, short-term therapy in patients for whom there is no appropriate alternative.⁵⁰ Patients with cardiovascular disease should consult a clinician before using over-the-counter NSAIDs.

SPECIAL POPULATIONS

Variant Angina

Vasospasm as the sole etiology of angina (Prinzmetal's or variant angina) is relatively uncommon. As a result, treatment options are not well studied. Nevertheless, based on the pharmacology of available drugs, several recommendations can be made. First, β -blockers should be avoided in patients with variant angina because of their potential to worsen vasospasm due to unopposed α -adrenergic receptor stimulation. In contrast, both CCBs and nitrates are effective in relieving vasospasm and are preferred in the management of variant angina. Nitrates have several limitations, outlined earlier, most notably, the need for an 8- to 12-hour nitrate-free interval. Therefore, the role of monotherapy with long-acting nitrates as prophylaxis for anginal attacks due to vasospasm is limited. However, immediate-release nitroglycerin is effective at terminating acute anginal attacks due to vasospasm. Therefore, all patients diagnosed with variant angina should be prescribed immediate-release nitroglycerin. CCBs are effective for monotherapy of variant angina. Because short-acting CCBs have been associated with increased risk of adverse cardiac

events, they should be avoided.⁴¹ Long-acting nitrates may be added to CCB therapy if needed.

Microvascular Angina

There are limited data on optimal therapy in patients with microvascular disease. Both ACE inhibitors and statins may produce beneficial effects on endothelial function and improve microvascular angina.⁶ Short-acting nitrates remain the treatment of choice for relieving acute symptoms, although they may be less effective in microvascular disease. Similar to obstructive CAD, β -blockers are first line to control symptoms of angina in patients with microvascular disease and may be more effective than CCBs and long-acting nitrates in this setting.⁶ Ranolazine may also produce favorable antianginal effects for patients with continued symptoms.

Elderly Patients with IHD

Elderly patients are more likely than younger patients to have other comorbidities that may influence drug selection for the treatment of angina. As a result, polypharmacy is more common in elderly patients, increasing the risk of drug–drug interactions, and perhaps decreasing medication adherence. Additionally, elderly patients are often more susceptible to adverse effects of antianginal therapies, particularly the negative chronotropic and inotropic effects of β -blockers and CCBs. Therefore, drugs should be initiated in low doses with close monitoring of elderly patients with IHD.

Acute Coronary Syndromes

The management of ACS is discussed in further detail in Chapter 8, “Acute Coronary Syndromes.” It is important to educate patients with IHD on the signs of ACS and the steps to take if signs or symptoms occur. Importantly, patients should be instructed to seek emergent care if symptoms of angina last longer than 20 to 30 minutes, do not improve after 5 minutes of using sublingual nitroglycerin, or worsen after 5 minutes of using sublingual nitroglycerin. In patients with a history of ACS, it is crucial to select appropriate pharmacotherapy to prevent recurrent ACS and death. Appropriate pharmacotherapy for patients with a history of ACS includes aspirin (perhaps in combination with clopidogrel), ACE inhibitors or ARBs, β -blockers, and statins. In addition, determining appropriate goals and instituting appropriate therapy to meet the goals for cardiovascular risk factors (e.g., dyslipidemia, hypertension, and diabetes) is critical.

OUTCOME EVALUATION

Assessing for Drug Effectiveness and Safety

- **10** *Monitor symptoms of angina at baseline and at each clinic visit for patients with IHD to assess the effectiveness of antianginal therapy. In particular, assess the frequency and intensity of anginal symptoms. Determining the frequency of sublingual nitroglycerin use is helpful in making this assessment. If angina is occurring with*

increasing frequency or intensity, adjust antianginal therapy and refer the patient for additional diagnostic testing (e.g., coronary angiography) and possibly, coronary intervention (e.g., PCI or CABG surgery), if indicated.

- Assess the patient for IHD-related complications, such as heart failure. The presence of new comorbidities may indicate worsening IHD requiring additional workup or pharmacologic therapy.
- **10** *Routinely monitor hemodynamic parameters to assess drug tolerance. Assess blood pressure at baseline, after drug initiation and after dose titration. Blood pressure should be monitored periodically in patients treated with β -blockers, CCBs, nitrates, ACE inhibitors, and/or ARBs.*
- Blood pressure reduction may be particularly pronounced after initiation and dose titration of β -blockers that also possess α -blocking effects (e.g., labetalol and carvedilol).
- Because of the potential for postural hypotension, warn patients that dizziness, presyncope, and even syncope may result from abrupt changes in body position during initiation or up-titration of drugs with α -blocking effects.
- **10** *Closely monitor heart rate in patients treated with drugs that have negative chronotropic effects (e.g., β -blockers, verapamil, or diltiazem) or drugs that may cause reflex tachycardia (e.g., nitrates or dihydropyridine CCBs).*
- Treatment with β -blockers, verapamil, or diltiazem can usually be continued in patients with asymptomatic bradycardia. However, reduce or discontinue treatment with these agents in patients who develop symptomatic bradycardia or serious conduction abnormalities.
- Regularly assess control of existing risk factors and the presence of new risk factors for IHD. Routine screening for the presence of metabolic syndrome will help in assessing the control of known major risk factors and identifying new risk factors. If new risk factors are identified and/or the presence of metabolic syndrome is detected, modify the pharmacotherapy regimen, as discussed previously, to control these risk factors and lower the risk of IHD and IHD-related adverse events.
- **10** *In patients treated with ACE inhibitors and/or ARBs, routinely monitor renal function and potassium levels at baseline, after drug initiation and post dose titration, and periodically thereafter. This is particularly important when using these therapies in patients with preexisting renal impairment or diabetes because they may be more susceptible to these adverse events.*

Duration of Therapy

- Drugs that modify platelet activity, lipoprotein concentrations, and neurohormonal systems reduce the risk for coronary events and death. However, these therapies do not cure IHD.
- Treatment with antiplatelet (aspirin or clopidogrel), lipid-lowering, and neurohormonal-modifying therapy for IHD is generally lifelong. Similarly, antianginal therapy with a β -blocker, CCB, and/or nitrate is usually long term.

- A patient with severe symptoms managed with combination antianginal drugs who undergoes successful coronary revascularization may be able to reduce antianginal therapy. However, treatment with at least one agent that improves the balance between myocardial oxygen demand and supply is usually warranted.

Patient Care and Monitoring

1. Assess the patient's symptoms to determine whether the patient should be evaluated by a physician.
 - Determine the quality, location, and duration of pain.
 - Determine factors that provoke and relieve pain.
 - Are symptoms characteristic of angina?
2. Identify risk factors for IHD.
 - Are there any modifiable risk factors?
3. Obtain a thorough history of prescription drug, nonprescription drug, and herbal product use.
 - Is the patient taking any medications/supplements that may exacerbate angina or interact with antianginal drug therapy?
4. Educate the patient on lifestyle modifications to control risk factors for IHD.
5. Is the patient taking appropriate drug therapy to prevent ACS and death? If not, why?
6. Is the patient taking appropriate antianginal therapy? If not, why?
7. Develop a plan to assess effectiveness of antiischemic therapy after 1 to 2 weeks.
8. Evaluate the patient to assess for adverse drug reactions, drug intolerance, and drug interactions.
9. Stress the importance of adherence with the therapeutic regimen including lifestyle modifications.
10. Provide patient education regarding disease state, lifestyle modifications, and drug therapy:
 - What are the consequences of untreated IHD?
 - What lifestyle modifications should the patient follow?
 - When should the patient take his or her medications?
 - What potential adverse drug effects may occur?
 - Teach the patient how to monitor heart rate and blood pressure to assess tolerance to antianginal therapy.
 - Which drugs may interact with therapy or worsen IHD?
 - What should the patient do when chest pain or its equivalent occurs?
 - When should the patient seek emergent care?

Abbreviations Introduced in This Chapter

ACE	Angiotensin-converting enzyme
ACE-I	Angiotensin-converting enzyme inhibitor
ACS	Acute coronary syndrome
ARB	Angiotensin receptor blocker
AV	Atrioventricular
BMS	Bare metal stent
BP	Blood pressure
CABG	Coronary artery bypass graft
CAD	Coronary artery disease
CCB	Calcium channel blocker
cGMP	Cyclic guanosine monophosphate
CHD	Coronary heart disease
CK	Creatine kinase
CK-MB	Creatine kinase, MB fraction
COX-2	Cyclooxygenase-2
CT	Computed tomography
DES	Drug-eluting stent
DHA	Docosahexaenoic acid
EBCT	Electron beam computer tomography
ECG	Electrocardiogram
EPA	Eicosapentaenoic acid
HDL	High-density lipoprotein
HF	Heart failure
HMG-CoA	3-hydroxy-3-methylglutaryl coenzyme A
HR	Heart rate
HRT	Hormone replacement therapy
HTN	Hypertension
IHD	Ischemic heart disease
IR	Immediate release
LA	Long acting
LV	Left ventricular
LDL	Low-density lipoprotein
MI	Myocardial infarction
MVO ₂	Myocardial oxygen consumption
NSAID	Nonsteroidal anti-inflammatory drug
NTG	Nitroglycerin
PCI	Percutaneous coronary intervention
Po ₂	Partial pressure of oxygen
PTCA	Percutaneous transluminal coronary angioplasty
SL	Sublingual

Acute Coronary Syndromes

Sarah A. Spinler and Simon de Denus

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Define the role of atherosclerotic plaque, platelets, and the coagulation system in an acute coronary syndrome (ACS).
2. List key electrocardiogram (ECG) and clinical features identifying a patient with non-ST-segment elevation (NSTEMI) ACS who is at high risk of myocardial infarction (MI) or death.
3. Devise a pharmacotherapy treatment plan for a patient undergoing primary percutaneous coronary intervention (PCI) in ST-segment elevation (STEMI) MI and NSTEMI ACS given patient-specific data.
4. Compare and contrast the pharmacokinetics, antiplatelet effects, adverse effects, and drug–drug interactions between clopidogrel, prasugrel, and ticagrelor.
5. Devise a pharmacotherapy treatment plan for a patient with NSTEMI ACS given patient-specific data.
6. Develop a pharmacotherapy and risk-factor modification treatment plan for secondary prevention of coronary heart disease events in a patient following MI.
7. Identify the characteristics of patients who are ideal candidates for mineralocorticoid receptor antagonist therapy following MI.
8. Formulate a treatment and monitoring plan for a patient with STEMI or NSTEMI ACS.
9. List the quality performance measures of care for MI.

KEY CONCEPTS

- 1 The cause of an acute coronary syndrome (ACS) is the rupture of an atherosclerotic plaque with subsequent platelet adherence, activation, and aggregation, and the activation of the clotting cascade. Ultimately, a clot forms composed of fibrin and platelets.
- 2 The American College of Cardiology Foundation (ACCF), American Heart Association (AHA), and Society for Cardiovascular Angiography and Interventions (SCAI) recommend strategies, or guidelines, for ACS patient care for ST-segment elevation (STEMI) myocardial infarction (MI) and non-ST-segment elevation (NSTEMI) ACS, including guidelines for patients undergoing percutaneous coronary intervention (PCI).
- 3 Patients with ischemic chest discomfort and suspected ACS are risk stratified based on a 12-lead electrocardiogram (ECG), past medical history, and results of the troponin and creatine kinase (CK) myocardial band (MB) tests. The diagnosis of myocardial infarction (MI) is confirmed based on the results of the CK MB and troponin biochemical marker tests.
- 4 Early reperfusion therapy with primary PCI of the infarct artery is the recommended therapy for patients presenting with STEMI within 12 hours of symptom onset.
- 5 The most recent PCI ACCF/AHA/SCAI clinical practice guidelines recommend coronary angiography with either PCI or coronary artery bypass graft (CABG) surgery revascularization as an early treatment (early invasive strategy) for patients with NSTEMI ACS at an elevated risk for death or MI, including those with a high risk score or patients with refractory angina, acute heart failure, other symptoms of cardiogenic shock, or arrhythmias.
- 6 In addition to reperfusion therapy, other early pharmacotherapy that all patients with STEMI and without contraindications should receive within the first day of hospitalization, and preferably in the emergency department, are intranasal oxygen (if oxygen saturation is low), sublingual (SL) nitroglycerin (NTG), aspirin (ASA), a P2Y₁₂ inhibitor (clopidogrel, prasugrel, or ticagrelor depending on reperfusion strategy), and anticoagulation with bivalirudin, unfractionated heparin (UFH), or enoxaparin (agent dependent on reperfusion

strategy). A glycoprotein (GP) IIb/IIIa inhibitor should be administered with UFH for patients undergoing primary PCI. IV β -blockers and IV NTG should be given in selected patients. Oral β -blockers should be initiated within the first day in patients without cardiogenic shock.

- 7 In the absence of contraindications, all patients with NSTEMI ACS should be treated in the emergency department with intranasal oxygen (if oxygen saturation is low), SL NTG, ASA, and an anticoagulant, either UFH, enoxaparin, fondaparinux or bivalirudin. High-risk patients should proceed to early angiography and may receive a GP IIb/IIIa inhibitor. A P2Y₁₂ inhibitor (selection of agent and timing of initiation dependent upon selection of an interventional approach involving PCI or CABG surgery versus a noninterventional approach with medical management alone) should be administered to all patients. IV β -blockers and IV NTG should be given in selected patients. Oral β -blockers should be initiated within the first day in patients without cardiogenic shock.
- 8 Secondary prevention guidelines from the ACCF/AHA suggest that following MI from either STE MI or NSTEMI ACS, all patients, in the absence of contraindications, should receive indefinite treatment with ASA, a β -blocker, and an angiotensin-converting enzyme (ACE) inhibitor for secondary prevention of death, stroke, or recurrent infarction. Most patients will receive a statin to reduce low-density lipoprotein cholesterol to less than 100 mg/dL (2.59 mmol/L) and ideally to less than 70 mg/dL (1.81 mmol/L). A P2Y₁₂ inhibitor should be continued for at least 12 months for patients undergoing PCI and for patients with NSTEMI ACS receiving a medical management strategy of treatment. Clopidogrel should be continued for at least 14 days in patients with STE MI not undergoing PCI. An angiotensin II receptor blocker and a mineralocorticoid receptor antagonist should be given to selected patients. For all patients with ACS, treatment and control of modifiable risk factors such as hypertension (HTN), dyslipidemia, obesity, smoking, and diabetes mellitus are essential.
- 9 To determine the efficacy of nonpharmacologic treatments and pharmacotherapy, monitor patients for relief of ischemic discomfort, return of ECG changes to baseline, and absence or resolution of heart failure signs and symptoms. The most common adverse effects from pharmacotherapy of ACS are bleeding and hypotension.

INTRODUCTION

Cardiovascular disease (CVD) is the leading cause of death in the United States and one of the major causes of death worldwide. **Acute coronary syndromes** (ACSs), including unstable angina (UA) and myocardial **infarction** (MI), are a form of coronary heart disease (CHD) that comprises the most common cause of CVD death. 1 *The cause of an ACS is primarily the rupture of an atherosclerotic plaque with subsequent platelet adherence, activation, and aggregation, and the activation of the clotting cascade. Ultimately, a clot*

forms composed of fibrin and platelets. 2 *The American Heart Association (AHA) and the American College of Cardiology Foundation (ACCF) recommend strategies, or guidelines, for ACS patient care for **ST-segment elevation** (STE) and **non-ST-segment elevation** (NSTEMI) ACS. In collaboration with the Society for Cardiovascular Angiography and Interventions (SCAI), the ACCF and AHA issue joint guidelines for **percutaneous coronary intervention** (PCI), including PCI in the setting of ACS. These practice guidelines are based on a review of available clinical evidence, have graded recommendations based on evidence and expert opinion, and are updated periodically. These guidelines form the cornerstone for quality care of the ACS patient.* 2-8

EPIDEMIOLOGY

Each year, more than 1.1 million Americans experience an ACS, and 150,000 die of an MI.¹ In the United States, more than 7 million living persons have survived an MI.¹

CVDs are the leading cause of hospitalization in the United States, resulting in about 6.2 million hospital discharges per year. Each year, there are more than 1.3 million MIs, and one in six deaths is secondary to CHD.¹

The proportion of patients with MI presenting with STE MI compared with NSTEMI MI decreased from approximately 80% in the early 1990s to 30% currently.¹ This may be secondary to the use of the more sensitive biomarker troponin (increasing the diagnosis of MI in the NSTEMI ACS group), greater use of antecedent revascularization procedures, decreased reinfarction from enhanced medical therapy after an initial event, or prevention of progression of unstable angina to MI through more effective anticoagulant and antiplatelet therapy.

According to data from the National Registry of Myocardial Infarction, in-hospital mortality has decreased by more than 20% during the past 20 years. Improvements in care that may have contributed to this mortality reduction include greater use of guideline-recommended drugs (e.g., aspirin [ASA], β -blockers, angiotensin-converting enzyme [ACE] inhibitors and angiotensin receptor blockers [ARBs], statins, clopidogrel); reductions in the median door-to-needle time for administering fibrinolytics and in the corresponding door-to-balloon time for primary PCI; and increased use of early coronary angiography and PCI for high-risk patients with NSTEMI ACS.¹

In patients with STE MI, in-hospital death rates are approximately 3% in patients receiving primary PCI, 7% for patients who are treated with fibrinolytics and 16% for patients who do not receive reperfusion therapy. In patients with NSTEMI MI, in-hospital mortality is less than 5%. At 6 months and 1 year, mortality and reinfarction rates are similar between STE and NSTEMI MI.^{9,10} Other than persistent ST-segment changes and troponin, other predictors of in-hospital mortality include older age, elevated serum creatinine, tachycardia, and heart failure (HF).¹¹

CHD is the leading cause of premature, chronic disability in the United States. The risks of CHD events, such as death, recurrent MI, and stroke, are higher for patients with established CHD and a history of MI than for patients with no known CHD. The cost of CHD is high, with estimated direct

and indirect costs of more than \$177 billion.¹⁰ The estimated cost of hospitalization for MI is \$14,000, and the median length of hospital stay is 3.2 days.¹² Risk-standardized hospital mortality for MI as well as 30-day hospital readmission rates following MI and PCI are quality performance measures and Outcome of Care Measures that are publicly reportable by the Center for Medicare and Medicaid Services.¹² The Patient Protection and Affordable Care Act of 2010 links quality performance measures to hospital reimbursement.

ETIOLOGY

Endothelial dysfunction, inflammation, and the formation of fatty streaks contribute to the formation of atherosclerotic coronary artery plaques, the underlying cause of coronary artery disease (CAD).¹³ **1** *The predominant cause of ACS in more than 90% of patients is atheromatous plaque rupture, fissuring, or erosion of an unstable atherosclerotic plaque that*

*occludes less than 50% of the coronary lumen prior to the event, rather than a more stable 70% to 90% stenosis of the coronary artery.*¹⁴ Stable stenoses are characteristic of stable angina.

PATHOPHYSIOLOGY

Spectrum of ACSs

ACSs include all clinical syndromes compatible with acute MI resulting from an imbalance between myocardial oxygen demand and supply. In contrast to stable angina, an ACS results primarily from diminished myocardial blood flow secondary to an occlusive or partially occlusive coronary artery thrombus. ACSs are classified according to electrocardiogram (ECG) changes into STE MI or NSTEMI ACS (NSTEMI and UA) (**Fig. 8-1**).¹⁵ An STE MI, formerly known as Q-wave or transmural MI, typically results in an injury that transects the thickness of the myocardial wall. Following an STE MI, pathological Q waves are frequently

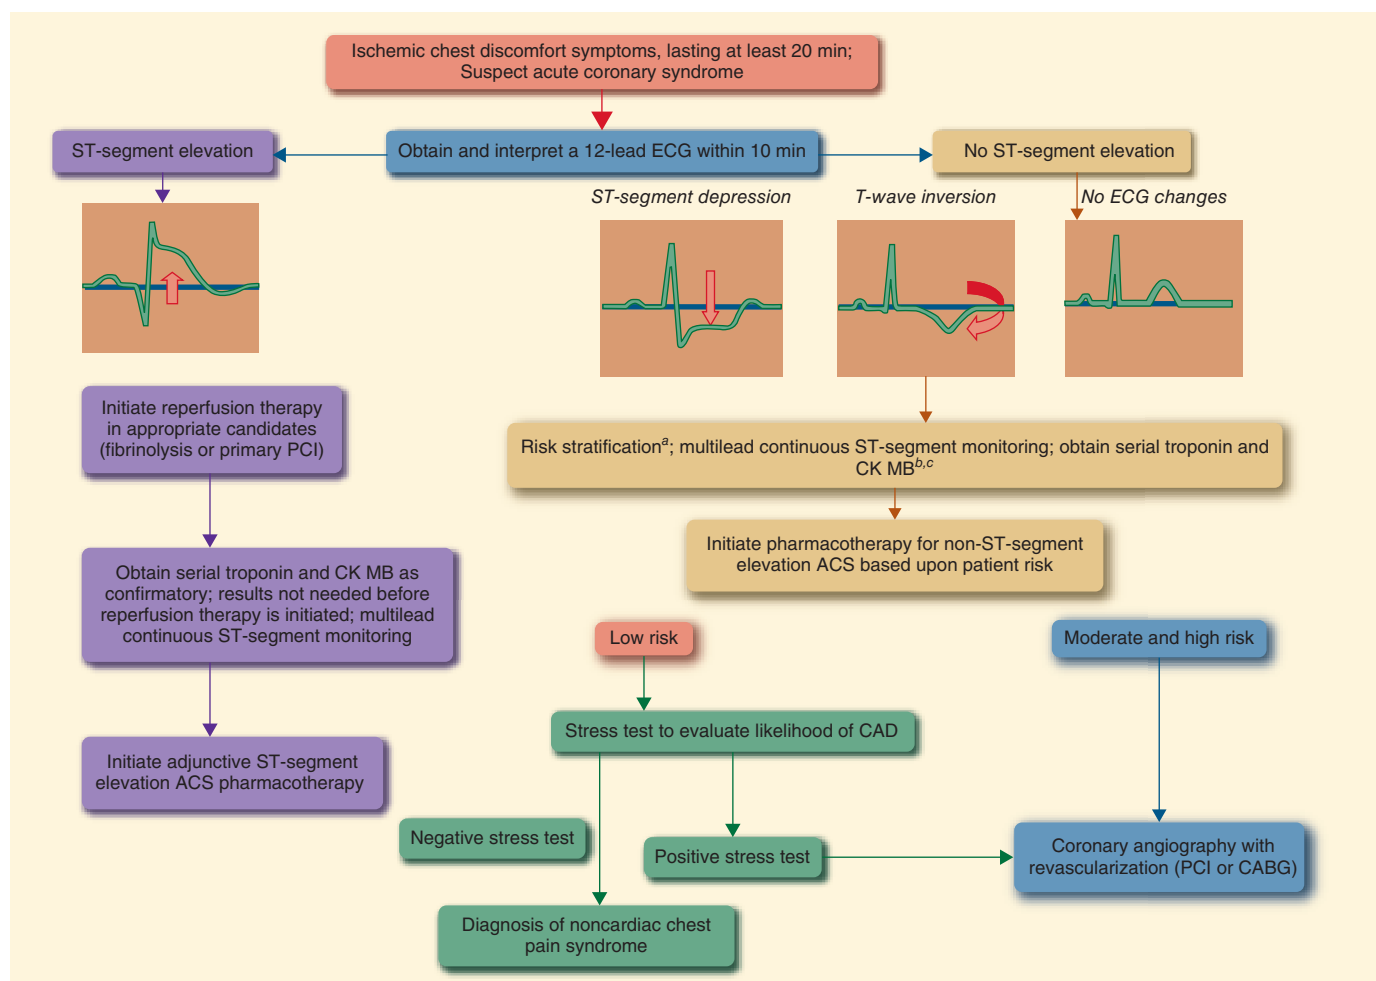

FIGURE 8-1. Evaluation of the acute coronary syndrome patient. ^aAs described in Table 8-1. ^b“Positive”: Above the myocardial infarction decision limit. ^c“Negative”: Below the myocardial infarction decision limit. (ACS, acute coronary syndrome; CABG, coronary artery bypass graft; CAD, coronary artery disease; CK MB, creatine kinase myocardial band; ECG, electrocardiogram; PCI, percutaneous coronary intervention.) (Modified with permission from Spinler SA. Evolution of antithrombotic therapy used in acute coronary syndromes. In: Richardson MM, Chant C, Cheng JWM, et al., eds. Pharmacotherapy self-assessment program, 7th ed. Book 1: Cardiology. Lenexa, KS: American College of Clinical Pharmacy, 2010.)

seen on the ECG, indicating transmural MI, whereas such an ECG manifestation is seen less commonly in patients with NSTEMI.⁵ Non-ST-segment elevation MI, formerly known as non-Q-wave or nontransmural MI, is limited to the subendocardial myocardium. Patients in this case do not usually develop a pathological Q wave on the ECG. Moreover, an NSTEMI is smaller and not as extensive as an STEMI. Non-ST-segment elevation MI differs from UA in that ischemia is severe enough to produce myocardial necrosis resulting in the release of a detectable amount of biomarkers, mainly **troponins T or I**, but also **creatinase kinase (CK-myocardial band (MB))**, from the necrotic myocytes in the bloodstream. The clinical significance of serum markers is discussed in greater detail in later sections of this chapter.

Plaque Rupture and Clot Formation

- Following plaque rupture, a clot (a partially or completely occlusive thrombus) forms on top of the ruptured plaque. The thrombogenic contents of the plaque are exposed to blood elements. Exposure of collagen and tissue factor induce platelet adhesion and activation, which promote the release of platelet-derived vasoactive substances including adenosine diphosphate (ADP) and thromboxane A₂ (TXA₂).¹³ These produce vasoconstriction and potentiate platelet activation. Furthermore, during platelet activation, a change in the conformation in the glycoprotein (GP) IIb/IIIa surface receptors of platelets occurs that cross-links platelets to each other through fibrinogen bridges. This is considered the final common pathway of platelet aggregation. Inclusion of platelets gives the clot a white appearance. Simultaneously, the extrinsic coagulation cascade pathway is activated as a result of exposure of blood components to the thrombogenic lipid core and disrupted endothelium, which are rich in tissue factor. This leads to the production of thrombin (factor IIa), which converts fibrinogen to fibrin through enzymatic activity. Fibrin stabilizes the clot and traps red blood cells, which gives the clot a red appearance. Therefore, the clot is composed of cross-linked platelets and fibrin strands.^{14,16}

Ventricular Remodeling Following an Acute MI

Ventricular remodeling is a process that occurs in several cardiovascular conditions including HF and following an MI. It is characterized by left ventricular dilation and reduced pumping function of the left ventricle, leading to cardiac failure.¹⁷ Because HF represents one of the principal causes of mortality and morbidity following an MI, preventing ventricular remodeling is an important therapeutic goal.

Angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), β -blockers, and mineralocorticoid receptor antagonists are all agents that slow down or reverse ventricular remodeling through inhibition of the renin-angiotensin aldosterone system and/or through improvement in hemodynamics (decreasing preload or afterload).¹⁷ These agents also improve survival and are discussed in more detail in subsequent sections of this chapter.

Complications

This chapter focuses on management of the uncomplicated ACS patient. However, it is important for clinicians to recognize complications of MI because MI is associated with increased mortality. The most serious complication of MI is cardiogenic shock, occurring in approximately 5% to 6% of hospitalized patients presenting with STEMI.¹⁸ Mortality in cardiogenic shock patients with MI is high, approaching 60%.¹⁹ Other complications that may result from MI are HF, valvular dysfunction, bradycardia, heart block, pericarditis, stroke secondary to left ventricular thrombus embolization, venous thromboembolism, left ventricular free wall rupture, and ventricular and atrial tachyarrhythmias.²⁰ In fact, more than a quarter of MI patients die, presumably from ventricular fibrillation, prior to reaching the hospital.¹

Symptoms and Physical Examination Findings

The classic symptom of an ACS is midline anterior anginal chest discomfort, most often occurring when an individual is at rest, as a severe new onset, or as an increasing angina that is at least 20 minutes in duration. The chest discomfort may radiate to the shoulder, down the left arm, and to the back or to the jaw. Associated symptoms that may accompany the chest discomfort include nausea, vomiting, **diaphoresis**, or shortness of breath. Although similar to stable angina, the duration may be longer and the intensity greater. All healthcare professionals should review these warning symptoms with patients at high risk for CHD. On physical examination, no specific features are indicative of ACS.

12-Lead ECG

- There are key features of a 12-lead ECG that identify and risk-stratify a patient with an ACS. Within 10 minutes of presentation to an emergency department with symptoms of ischemic chest discomfort, a 12-lead ECG should be obtained and interpreted. When possible, a 12-lead ECG should be performed by emergency medical system providers in order to reduce the delay until myocardial reperfusion. If available, a prior 12-lead ECG should be reviewed to identify whether or not the findings on the current ECG are new or old, with new findings being more indicative of an ACS. Key findings on review of a 12-lead ECG that indicate myocardial ischemia or infarction are STE, ST-segment depression, and T-wave inversion (Fig. 8-1).¹⁵ ST-segment and/or T-wave changes in certain groupings of leads help to identify the location of the coronary artery that is the cause of the ischemia or infarction. In addition, the appearance of a new left bundle-branch block accompanied by chest discomfort is highly specific for acute MI. About one-half of patients diagnosed with MI present with STE on their ECG, with the remainder having ST-segment depression, T-wave inversion, or, in some instances, no ECG changes. Some parts of the heart are more “electrically silent” than others, and myocardial ischemia may not be detected on a surface ECG. Therefore, it is important to review findings from the ECG in conjunction

Clinical Presentation and Diagnosis of ACSs

General

- The patient is typically in acute distress and may develop or present with acute heart failure, cardiogenic shock, or cardiac arrest.

Symptoms

- The classic symptom of ACS is midline anterior chest discomfort. Accompanying symptoms may include arm, back, or jaw pain, nausea, vomiting, or shortness of breath.
- Patients less likely to present with classic symptoms include elderly patients, diabetic patients, and women.

Signs

- No signs are classic for ACS.
- Patients with ACS may present with signs of acute heart failure including jugular venous distention and an S_3 sound on auscultation.
- Patients may also present with arrhythmias and therefore may have tachycardia, bradycardia, or heart block.

Laboratory Tests

- Troponin I or T and CK-MB are measured at the time of first assessment and repeated at least once, 6 to 9 hours later to ascertain heart muscle damage, confirmatory for the diagnosis of infarction. For patients with non-ST-segment elevation ACS, an elevated troponin is diagnostic for MI, defining a NSTEMI. Patients presenting with suspected NSTEMI ACS who do not have an MI undergo further diagnostic testing to determine whether or not they have unstable angina or do not have ACS.
- Blood chemistry tests are performed with particular attention given to potassium and magnesium, which may affect heart rhythm.

- Serum creatinine is measured and creatinine clearance is used to identify patients who may need dosing adjustments for some medications, as well as those who are at high risk of morbidity and mortality.
- Baseline complete blood count (CBC) and coagulation tests (activated partial thromboplastin time [aPTT] and international normalized ratio [INR]) should be obtained because most patients will receive antithrombotic therapy that increases the risk for bleeding.
- Fasting lipid panel (optional).

Other Diagnostic Tests

- The 12-lead ECG is the first step in management. Patients are risk stratified into two groups: ST-segment elevation ACS and suspected non-ST-segment elevation ACS.
- High-risk ACS patients and those with recurrent chest discomfort will undergo coronary angiography via a left heart catheterization and injection of contrast dye into the coronary arteries to determine the presence and extent of coronary artery stenosis.
- During hospitalization, a measurement of left ventricular function, such as an echocardiogram, is performed to identify patients with low ejection fractions (less than 40%) who are at high risk of death following hospital discharge.
- Selected low-risk patients may undergo early stress testing.

With permission from Spinler SA, de Denu S. Acute coronary syndromes. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011:244.

with biochemical markers of myocardial necrosis, such as troponin I or T, and other risk factors for CHD to determine the patient's risk for experiencing a new MI or having other complications.

Biochemical Markers/Cardiac Enzymes

Biochemical markers of myocardial cell death are important for confirming the diagnosis of MI. **3** *The diagnosis of MI is confirmed when the following conditions are met in a clinical setting consistent with myocardial ischemia: "Detection of a rise and/or fall of cardiac biomarkers (troponin preferred) with at least one value above the 99th percentile of the upper reference limit together with evidence of myocardial ischemia as recognized by at least one of the following: (a) symptoms of ischemia; (b) ECG changes of new ischemia or development of pathological Q waves; or (c) imaging evidence of new loss of viable myocardium or*

new regional wall motion abnormality."²¹ Typically, a blood sample is obtained once in the emergency department, then 6 to 9 hours later, and in patients at a high suspicion of MI but in whom previous measurements did not reveal elevations in biomarkers, 12 to 24 hours after. A single measurement of a biochemical marker is not adequate to exclude a diagnosis of MI, as up to 15% of values that were initially below the level of detection (a "negative" test) rise to the level of detection (a "positive" test) in subsequent hours. While troponins and CK-MB appear in the blood within 6 hours of infarction, troponins stay elevated for up to 10 days while CK-MB returns to normal values within 48 hours. Hence, traditionally, CK-MB was used to detect reinfarction. However, more recent data have suggested that troponins provide similar information to CK-MB in such a situation that has led to the use of troponins in this setting as well. Current guidelines suggest that, in patients in whom a recurrent MI is suspected, a cardiac biomarker should be

immediately measured, followed by a second measurement 3 to 6 hours later. A recurrent MI is diagnosed when there is an increase of at least 20% in the second measurement of the biomarker, if this value exceeds the 99th percentile of the upper reference limit.²¹

Risk Stratification

Patient symptoms, past medical history, ECG, and biomarkers, particularly troponins, are utilized to stratify patients into low, medium, or high risk of death, MI, or likelihood of failing pharmacotherapy and needing urgent coronary angiography and PCI (Table 8-1). Initial treatment according to risk

stratification is depicted in Figure 8-1.⁴ Patients with STE MI are at the highest risk of death. Initial treatment of STE MI should proceed without evaluation of the troponins because these patients have a greater than 97% chance of having an MI subsequently diagnosed with biochemical markers. The ACCF/AHA define a target time to initiate reperfusion treatment as within 30 minutes of hospital presentation for fibrinolytics (e.g., streptokinase, alteplase, reteplase, and tenecteplase) and within 90 minutes or less from presentation for primary PCI.⁸ The sooner the infarct-related coronary artery is opened for these patients, the lower their mortality and the greater the amount of myocardium that is preserved.^{22,23} Although all patients should be evaluated

Table 8-1

Risk Stratification for Acute Coronary Syndromes⁵

TIMI Risk Score for NSTEMI ACSs

One point is assigned for each of the seven medical history and clinical presentation findings. The point total is calculated, and the patient is assigned a risk for experiencing the composite endpoint of death, myocardial infarction, or urgent need for revascularization as follows:

- Age 65 years or older
- Three or more CHD risk factors: smoking, hypercholesterolemia, hypertension, diabetes mellitus, family history of premature CHD death/events
- Known CAD (50% or greater stenosis of at least one major coronary artery on coronary angiogram)
- Aspirin use within the past 7 days
- Two or more episodes of chest discomfort within the past 24 hours
- ST-segment depression 0.5 mm or greater
- Positive biochemical marker for infarction

Patient Encounter 1, Part 1

RR is a 65-year-old, 85-kg (187-lb) woman who developed chest heaviness/tightness at 10:15 hours while at her place of employment. Local paramedics were summoned and she was given three 0.4-mg sublingual nitroglycerin tablets by mouth, 325 mg ASA by mouth, and morphine 2-mg IV push without relief of chest discomfort. RR presented to the hospital at 11:00 hours. The hospital has a cardiac catheterization laboratory and primary PCI was selected as a treatment strategy for STE MI.

PMH: Hypertension (HTN) for 18 years; dyslipidemia for 6 years; transient ischemic attack 2 years ago

FH: Father with stroke at age 65; mother with HTN; no siblings

SH: Smoked one pack per day for 30 years, quit 6 years ago

Allergies: NKDA

Meds: Amlodipine 10 mg by mouth once daily; enalapril 5 mg by mouth once daily; ASA 325 mg by mouth once daily; simvastatin 20 mg by mouth once daily at bedtime

ROS: 10/10 chest discomfort/squeezing

PE:

HEENT: Normocephalic atraumatic

CV: Regular rate and rhythm S_1 , S_2 , $-S_3$, $-S_4$, no murmurs or rubs

VS: BP 110/70 mm Hg; HR 98 bpm; T 37°C (98.6°F)

Lungs: Clear to auscultation and percussion

Abd: Nontender, nondistended

GI: Normal bowel sounds

GU: Stool guaiac negative

Exts: No bruits, pulses 2+, femoral pulse present, good range of motion

Neuro: Alert and oriented $\times 3$, cranial nerves intact

Labs: Sodium 138 mEq/L (138 mmol/L), potassium 4.2 mEq/L (4.2 mmol/L), chloride 105 mEq/L (105 mmol/L), bicarbonate 24 mEq/L (24 mmol/L), SCr 1.0 mg/dL (88 μ mol/L), glucose 95 mg/dL (5.3 mmol/L), WBC $9.9 \times 10^3/\text{mm}^3$ ($9.9 \times 10^9/\text{L}$), hemoglobin 15.7 g/dL (157 g/L or 9.7 mmol/L), hematocrit 47% (0.47), platelets $220 \times 10^3/\text{mm}^3$ ($220 \times 10^9/\text{L}$), troponin I 1.8 ng/mL (1.8 mcg/L), oxygen saturation 99% (0.99) on room air

ECG: Normal sinus rhythm, PR 0.16 seconds, QRS 0.08 seconds, QTc 0.38 seconds, occasional polymorphic premature ventricular contractions, 3 mm ST-segment elevation anterior leads

CXR: No active disease

Echo: Anterior wall dyskinesis, LVEF 45% (0.45)

What information is suggestive of acute MI?

Are any complications of MI present?

Patient Encounter 1, Part 2

Identify your acute treatment goals for RR.

What adjunctive pharmacotherapy should be administered to RR in the emergency department prior to proceeding to the cardiac catheterization laboratory?

What additional pharmacotherapy should be initiated on the first day of RR's hospitalization following successful PCI/intracoronary stenting?

for reperfusion therapy, not all patients may be eligible. Indications and contraindications for fibrinolytic therapy are described in the treatment section of this chapter. Less than 25% of hospitals in the United States are equipped to perform primary PCI. If patients are not eligible for reperfusion therapy, additional pharmacotherapy for STE patients should be initiated in the emergency department and the patient transferred to a coronary intensive care unit. The typical length of stay for a patient with uncomplicated STE MI is less than 4 days.²⁴

Risk-stratification of the patient with NSTEMI ACS is more complex because in-hospital outcomes for this group of patients varies with reported rates of death of 0% to 12%, reinfarction rates of 0% to 3%, and recurrent severe ischemia rates of 5% to 20%.²² Not all patients presenting with suspected NSTEMI ACS have CAD. Some eventually are diagnosed with nonischemic chest discomfort. In general, among NSTEMI patients, those with ST-segment depression (Fig. 8-1)¹⁵ and/or elevated biomarkers are at higher risk of death or recurrent infarction.

TREATMENT

Desired Outcomes

Short-term desired outcomes in a patient with ACS are (a) early restoration of blood flow to the infarct-related artery to prevent infarct expansion (in the case of MI) or prevent complete occlusion and MI (in UA); (b) prevention of death and other MI complications; (c) prevention of coronary artery reocclusion; and as evidence of restoration of coronary artery blood flow; (d) relief of ischemic chest discomfort; and (e) resolution of ST-segment and T-wave changes on the ECG.

Long-term desired outcomes are control of cardiovascular (CV) risk factors, prevention of additional CV events, including reinfarction, stroke, and HF, and improvement in quality of life.

General Approach to Treatment

Selecting evidence-based therapies described in the ACCF/AHA guidelines for patients without contraindications result in lower mortality.²⁵⁻²⁷ General treatment measures for all STE MI and high- and intermediate-risk NSTEMI ACS patients include admission to hospital, oxygen administration (if oxygen saturation is low, less than 90% [0.90]), continuous

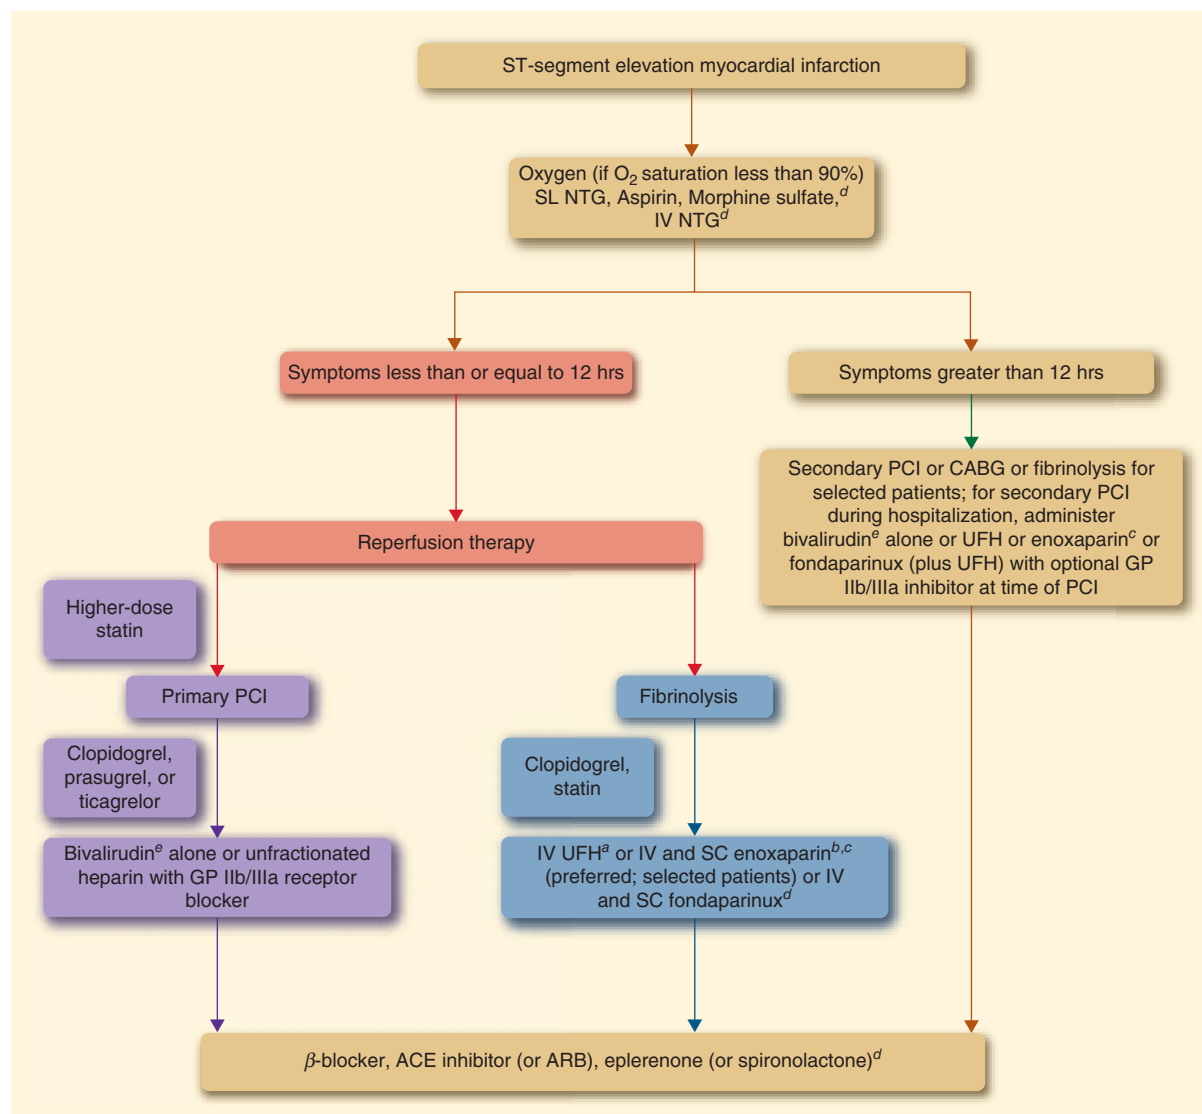

FIGURE 8-2. Initial pharmacotherapy for ST-segment elevation myocardial infarction. ^aFor at least 48 hours. ^bSee Table 8-2 for dosing and specific types of patients who should not receive enoxaparin. ^cFor the duration of hospitalization, up to 8 days. ^dFor selected patients, see Table 8-2. ^eIf pretreated with UFH, stop UFH infusion for 30 minutes prior to administration of bivalirudin (bolus plus infusion). (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; CABG, coronary artery bypass graft surgery; GP, glycoprotein; NTG, nitroglycerin; PCI, percutaneous coronary intervention; SC, subcutaneous; SL, sublingual; UFH, unfractionated heparin.) (Modified with permission from Spinler SA. Evolution of antithrombotic therapy used in acute coronary syndromes. In: Richardson MM, Chant C, Cheng JWM, et al., eds. Pharmacotherapy self-assessment program, 7th ed. Book 1: Cardiology. Lenexa, KS: American College of Clinical Pharmacy, 2010.)

multilead ST-segment monitoring for arrhythmias and ischemia, frequent measurement of vital signs, bed rest for 12 hours in hemodynamically stable patients, avoidance of the Valsalva maneuver (prescribe stool softeners routinely), and pain relief (Figs. 8-2 and 8-3).^{2-8,28}

Because risk varies and resources are limited, it is important to triage and treat patients according to their risk category. Initial approaches to treatment of STE MI and NSTEMI ACS patients are outlined in Figure 8-1. Patients with STE are at high risk of death, and efforts to reestablish coronary perfusion, as well as adjunctive pharmacotherapy, should be initiated immediately.

Features identifying low-, moderate-, and high-risk NSTEMI ACS patients are described in Table 8-1.^{29,30}

Nonpharmacologic Therapy

► Primary PCI for STE MIs

4 Early reperfusion therapy with primary PCI of the infarct artery within 90 minutes from time of hospital presentation is the reperfusion treatment of choice for patients presenting with STE MI who present within 12 hours of symptom onset^{3,8} (Fig. 8-2). For primary PCI, the patient is taken from the emergency department to the cardiac catheterization laboratory and undergoes coronary angiography with either balloon angioplasty or placement of a bare metal or drug-eluting intracoronary stent in the artery associated with the infarct. About 62% of patients with STE MI are treated with

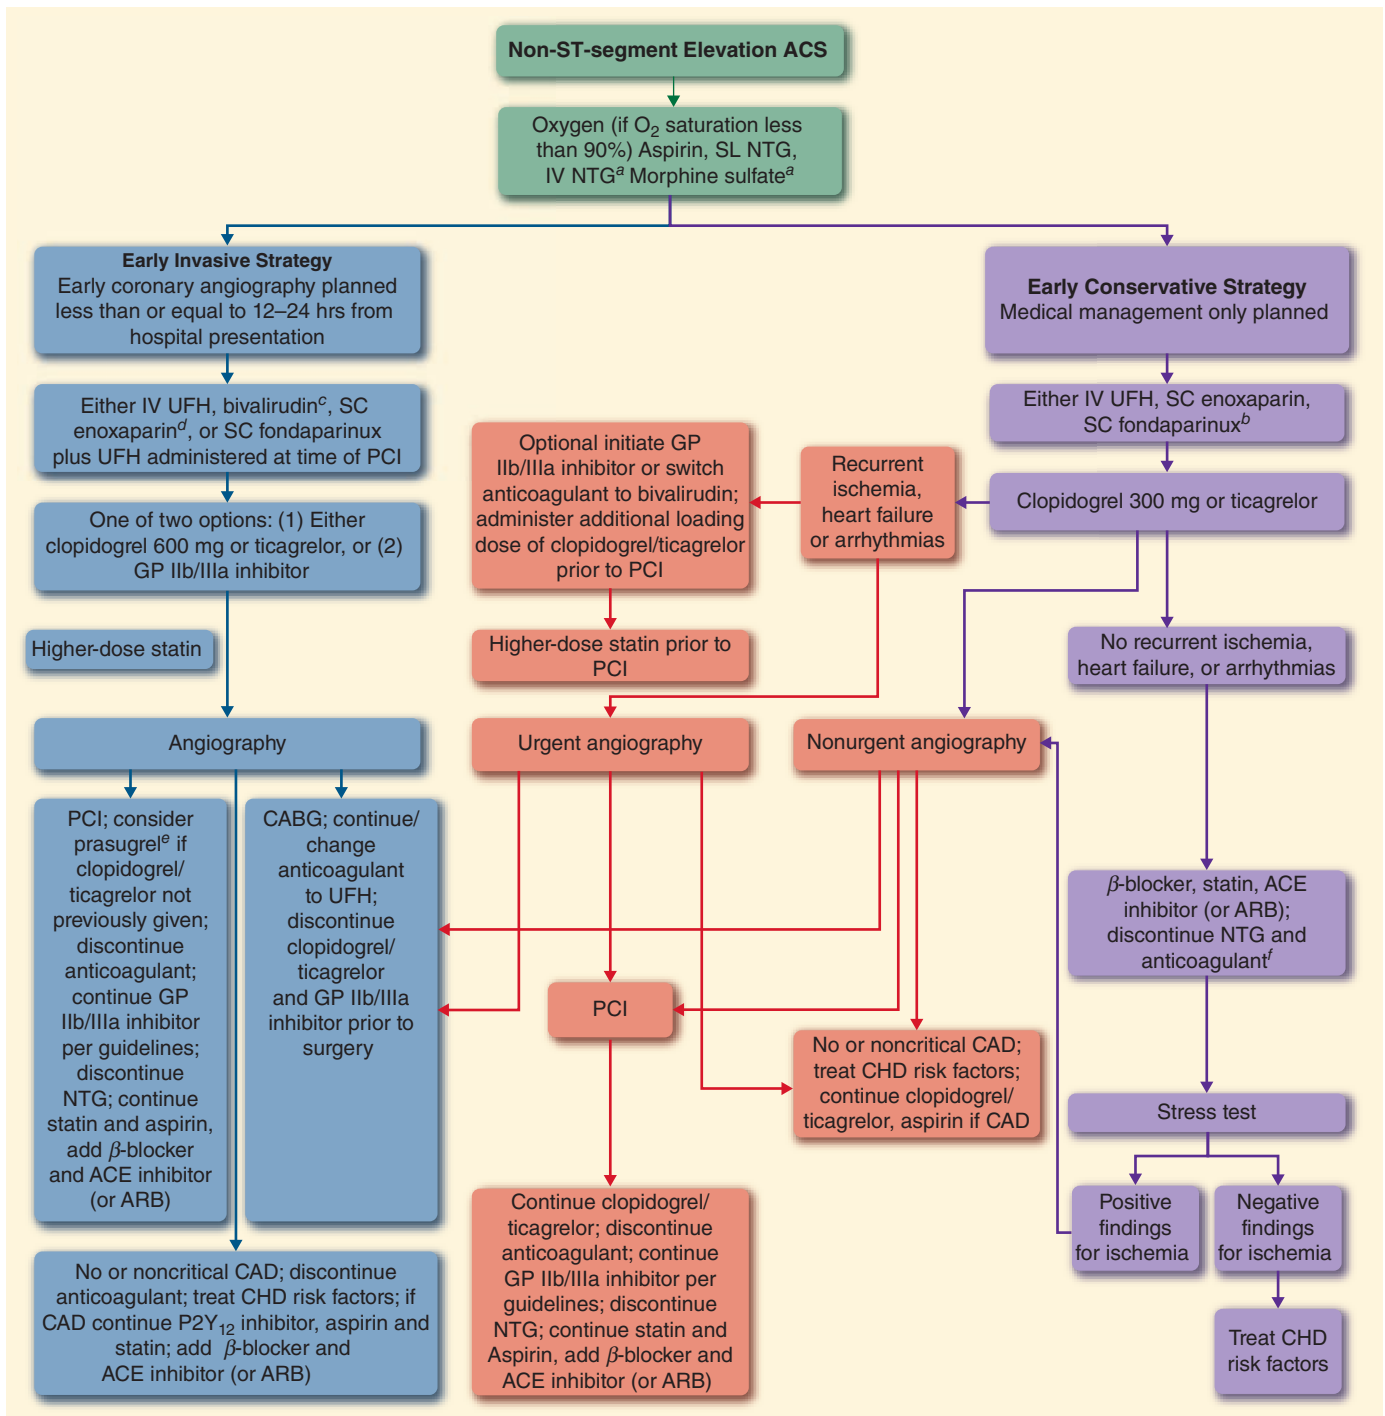

FIGURE 8-3. Initial pharmacotherapy for non-ST-segment elevation ACS. ^aFor selected patients, see Table 8-2. ^bPreferred in patients at high risk for bleeding. ^cIf pretreated with UFH, stop UFH infusion for 30 minutes prior to administration of bivalirudin bolus plus infusion. ^dMay require IV supplemental dose of enoxaparin; see Table 8-2. ^eDo not use if prior history of stroke/transient ischemic attack (TIA), age older than 75 years, or body weight less than or equal to 60 kg. ^fSC enoxaparin or UFH can be continued at a lower dose for venous thromboembolism prophylaxis. (ACS, acute coronary syndrome; ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; CABG, coronary artery bypass graft; CAD, coronary artery disease; CHD, coronary heart disease; GP, glycoprotein; NTG, nitroglycerin; PCI, percutaneous coronary intervention; SC, subcutaneous; SL, sublingual; UFH, unfractionated heparin.)

primary PCI; 18% are treated with fibrinolytics. Results from a meta-analysis of trials comparing fibrinolysis with primary PCI indicate a lower mortality rate with primary PCI.³¹ One reason for the superiority of primary PCI compared with

fibrinolysis is that more than 90% of occluded infarct-related coronary arteries are opened with primary PCI compared with fewer than 60% of coronary arteries opened with currently available fibrinolytics.^{4,5} In addition, intracranial

hemorrhage and major bleeding risks from primary PCI are lower than the risks of severe bleeding events following fibrinolysis. An invasive strategy of primary PCI is generally preferred in patients presenting to institutions with skilled interventional cardiologists and a catheterization laboratory immediately available, in patients in cardiogenic shock, those with contraindications to fibrinolytics, and those with continuing symptoms 12 to 24 hours after symptom onset.⁸ A quality performance measure (quality performance measures are measures of quality healthcare developed from practice guidelines and intended to permit the quality of patient care to be assessed, compared between institutions and over time, and ultimately, improved) in the care of MI patients with STE MI is the time from first medical contact to the time the occluded artery is opened with PCI. This “door-to-primary PCI” time should be equal to or less than 90 minutes.^{4,32} Efforts to improve system-wide rapid triage of patients with STE MI, such as participation in the Door to Balloon Time Alliance and Get with the Guidelines (GWTG) educational programs within health systems have resulted in shorter primary PCI times in the United States. In 2010 the median door-to-primary PCI time was 64 minutes, decreasing from a median of 96 minutes in 2005.³³ In 2005, 44% of patients treated with primary PCI had door-to-primary PCI times of less than 90 minutes; in 2010 this percentage had increased to 94%.³³ Unfortunately, most hospitals do not have interventional cardiology services capable of performing primary PCI 24 hours a day.

Patients presenting to facilities that do not have interventional cardiology services can be transferred to such facilities when a transfer protocol that minimizes transfer delays has been established between the institutions and if primary PCI can be performed within the first 120 minutes of medical contact. PCI during hospitalization for STE MI may also be appropriate in other patients following STE MI, such as those in whom fibrinolysis is not successful, those presenting later in cardiogenic shock, those with life-threatening ventricular arrhythmias, and those with persistent rest ischemia or signs of ischemia on stress testing following MI.^{4,5}

► PCI in NSTEMI ACSs

5 *The most recent PCI ACCF/AHA/SCAI clinical practice guidelines recommend coronary angiography with either PCI or coronary artery bypass graft (CABG) surgery revascularization as an early treatment (early invasive strategy) for patients with NSTEMI ACS at an elevated risk for death or MI, including those with a high risk score (Table 8-1) or patients with refractory angina, acute HF, other symptoms of cardiogenic shock, or arrhythmias (Fig. 8-3).⁸ Several clinical trials support an “invasive” interventional strategy with early angiography and PCI or CABG versus a “conservative medical management” strategy, whereby coronary angiography with revascularization is reserved for patients with symptoms refractory to pharmacotherapy and patients with signs of ischemia on stress testing.^{5,34} An early invasive approach results in a lower rate of refractory angina during hospital*

admission and over the first year, as well as a lower frequency of MI at 5 years, but an increased frequency of minor bleeding is related to the procedure.³⁵ An early invasive strategy is also less costly than the conservative medical stabilization approach.³⁴ Mortality is not reduced by an early invasive approach in patients with NSTEMI ACS.³⁴

All patients undergoing PCI should receive low-dose aspirin (ASA) therapy indefinitely. A P2Y₁₂ inhibitor antiplatelet (clopidogrel, prasugrel, or ticagrelor) should be administered concomitantly with ASA for at least 12 months following PCI for a patient with ACS (Table 8-2).²⁻⁸ Earlier discontinuation of the P2Y₁₂ inhibitor should be considered if the risk of bleeding outweighs the anticipated benefit in reduction in risk of death, MI, or stroke as well as stent thrombosis.⁸ A longer duration of P2Y₁₂ inhibitor therapy may be considered for patients receiving a drug-eluting stent because the risk of stent thrombosis is greater upon cessation of dual antiplatelet therapy.⁸ Drug-eluting stents reduce the rate of smooth muscle cell growth causing stent restenosis. However, there is a delay in endothelial cell regrowth at the site of the stent that places the patient at higher risk of thrombotic events following PCI. Therefore, dual antiplatelet therapy is indicated for a longer period of time following PCI with a drug-eluting stent. Trials are ongoing evaluating the need for an extended duration (greater than 12 months) of P2Y₁₂ inhibitor therapy following PCI. Regardless of whether or not a patient with NSTEMI ACS receives a stent, the preferred duration P2Y₁₂ therapy is at least a year.²

Additional Testing and Risk Stratification

For patients with NSTEMI ACS, an initial conservative strategy is recommended for patients with a low risk score, normal ECGs, and negative troponin tests who are without recurrence of chest discomfort (Fig. 8-3).⁶

At some point during hospitalization but prior to discharge, patients with MI should have their left ventricular function (LVF) evaluated for risk stratification.^{4,32} The most common way LVF is measured is using an echocardiogram to calculate the patient’s left ventricular ejection fraction (LVEF). Left ventricular function is the single best predictor of mortality following MI. Patients with LVEFs less than 40% (0.40) are at highest risk of death. Patients with ventricular fibrillation or sustained ventricular tachycardia occurring more than 2 days following MI and those with LVEF less than 30% (0.30; measured at least 1 month after STE MI and 3 months after coronary artery revascularization with either PCI or CABG) benefit from placement of an implantable cardioverter defibrillator (ICD).³⁶

Predischarge from the hospital, stress testing (Fig. 8-3) is indicated in patients with NSTEMI ACS where an initial conservative strategy is selected and for patients with STE MI where primary PCI was not performed and there has been no recurrent ischemia.^{6,8} Following the stress test, patients deemed not at low risk should undergo left heart catheterization with coronary angiography and revascularization as indicated by the results.⁶ Patients

Table 8-2

Evidence-Based Pharmacotherapy for ST-Segment Elevation Myocardial Infarction and Non-ST-Segment Elevation Acute Coronary Syndrome^{2-8,46}

Drug	Clinical Condition and ACCF/AHA/SCAI Guideline Recommendation ^a	Contraindications ^b	Dose and Duration of Therapy
Aspirin	STE MI, class I recommendation for all patients. NSTE ACS, class I recommendation for all patients.	Hypersensitivity, active bleeding, severe bleeding risk	160–325 mg orally once on hospital day 1. 75–162 mg once daily orally starting hospital day 2 and continued indefinitely in all patients. Limit dose to less than 100 mg if using ticagrelor.
Clopidogrel	NSTE ACS, class I recommendation added to aspirin. STE MI, class I recommendation added to aspirin. PCI in STE and NSTE ACS, class I recommendation. In patients with aspirin allergy, class I recommendation.	Hypersensitivity, active bleeding, severe bleeding risk	300 mg (class I recommendation) to 600 mg (class IIa recommendation) oral loading dose on hospital day 1 followed by a maintenance dose of 75 mg once daily starting on hospital day 2 in patients with NSTE ACS. 300 mg oral loading dose followed by 75 mg orally daily in patients receiving a fibrinolytic or who do not receive reperfusion therapy with a STE MI, avoid loading dose in patients 75 years or older. 600 mg (class I recommendation) loading dose before or when PCI performed (unless within 24 hours of fibrinolytic therapy, a dose of 300 mg should be given). Discontinue at least 5 days before CABG surgery if bleeding risk outweighs benefit (class I recommendation). Administer indefinitely in patients with aspirin allergy (class I recommendation). Continue for at least 12 months (class I recommendation) and possibly beyond 12 months (class IIb recommendation) in patients with ACS managed with PCI/stent. In patients with NSTE ACS treated medically, administer for 1 month and ideally for 1 year (class I recommendation). In patients receiving a fibrinolytic or who do not receive reperfusion therapy, administer for at least 14 days (class I recommendation) and up to 1 year (class IIa recommendation). Genetic testing might be considered to identify patients at high risk of poor response (class IIb recommendation). In these patients, an alternative P2Y ₁₂ inhibitor might be considered (class IIb recommendation). The routine use of genetic testing is not recommended (class III recommendation).
Prasugrel	PCI in STE and NSTE ACS, added to aspirin, class I recommendation.	Active bleeding, prior stroke or TIA	Initiate in patients with known coronary artery anatomy only (so as to avoid use in patients needing CABG surgery; class I recommendation). Give no later than 1 hour after PCI. Patients who have history of prior stroke or TIA or are 75 years of age or more or weigh less than 60 kg (132 lb) have higher risk of bleeding and no added benefit compared with clopidogrel. 60 mg oral loading dose followed by 10 mg once daily for patients weighing 60 kg (132 lb) or more. 60-mg oral loading dose followed by 5 mg once daily in patients weighing less than 60 kg (132 lb) (based on limited data). Discontinue at least 7 days prior to CABG surgery if bleeding risk outweighs benefit (class I recommendation). Continue for at least 12 months (class I recommendation) and possibly beyond 12 months (class IIb recommendation) in patients with ACS managed with PCI/stent.

(Continued)

Table 8-2

Evidence-Based Pharmacotherapy for ST-Segment Elevation Myocardial Infarction and Non-ST-Segment Elevation Acute Coronary Syndrome^{2-8,46} (Continued)

Drug	Clinical Condition and ACCF/AHA/SCAI Guideline Recommendation ^a	Contraindications ^b	Dose and Duration of Therapy
Ticagrelor	PCI in STE and NSTEMI ACS, added to aspirin, class I recommendation.	Active bleeding	180 mg (class I recommendation) oral loading dose in patients undergoing PCI, followed by 90 mg twice daily for at least 12 months (class I recommendation) and possibly beyond 12 months (class IIb recommendation) in patients with ACS managed with PCI/stent. Although not included in 2011 NSTEMI ACS guidelines, may also be used in medically managed patients with NSTEMI ACS. Current data are too limited to recommend use in patients with STE MI not undergoing primary PCI. Discontinue at least 5 days prior to CABG surgery if bleeding risk outweighs benefit (class I recommendation).
Unfractionated heparin	STE MI, class I recommendation in patients undergoing PCI and for those patients treated with fibrinolytics; class IIa recommendation for patients not treated with fibrinolytic therapy. NSTEMI ACS, class I recommendation in combination with antiplatelet therapy for conservative or invasive approach PCI, class I recommendation (NSTEMI ACS and STE MI).	Active bleeding, history of heparin-induced thrombocytopenia, severe bleeding risk, recent stroke	For STE MI with fibrinolytics, administer 60 Units/kg IV bolus (maximum 4000 Units) heparin followed by a constant IV infusion at 12 Units/kg/hr (maximum 1000 Units/hr). For STE MI primary PCI, administer 50–70 Units/kg IV bolus if a GP IIb/IIIa inhibitor planned; 70–100 Units/kg IV bolus if no GP IIb/IIIa inhibitor planned and supplement with IV bolus doses to maintain target ACT. For NSTEMI ACS, administer 60 Units/kg IV bolus (maximum 4000 Units) followed by a constant IV infusion at 12 Units/kg/hr (maximum 1000 Units/hr). Titrated to maintain an aPTT of 1.5 to 2.0 times control (approximately 50–70 seconds) for STE MI with fibrinolytics and for NSTEMI ACS. Titrated to ACT of 250–350 seconds for primary PCI without a GP IIb/IIIa inhibitor and 200–250 seconds in patients given a concomitant GP IIb/IIIa inhibitor. The first aPTT should be measured at 4–6 hours for NSTEMI ACS and STE ACS in patients not treated with fibrinolytics or undergoing primary PCI. The first aPTT should be measured at 3 hours in patients with STE ACS who are treated with fibrinolytics. Continue for 48 hours or until the end of PCI.
Enoxaparin	STE MI class I recommendation in patients receiving fibrinolytics and class IIa for patients not undergoing reperfusion therapy. NSTEMI ACS, class I recommendation in combination with aspirin for conservative or invasive approach. For PCI, class IIa recommendation as an alternative to UFH in patients with NSTEMI ACS. For primary PCI in STE MI, class IIb recommendation as an alternative to UFH.	Active bleeding, history of heparin-induced thrombocytopenia, severe bleeding risk, recent stroke, avoid enoxaparin if CrCl less than 15 mL/min (less than 0.25 mL/s), avoid if CABG surgery planned	Enoxaparin 1 mg/kg SC every 12 hours for patients with NSTEMI ACS (CrCl greater than or equal to 30 mL/min [greater than or equal to 0.50 mL/s]). Enoxaparin 1 mg/kg SC every 24 hours (CrCl 15–29 mL/min [0.25–0.49 mL/s]) for NSTEMI ACS or STE MI. For all patients undergoing PCI following initiation of SC enoxaparin for NSTEMI ACS, a supplemental 0.3 mg/kg IV dose of enoxaparin should be administered at the time of PCI if the last dose of SC enoxaparin was given 8–12 hours prior to PCI or who received less than two therapeutic SC doses.

Bivalirudin	NSTE ACS class I recommendation for invasive strategy. PCI in STE MI (Class I recommendation).	Active bleeding, severe bleeding risk	<p>For patients with STE MI receiving fibrinolytics:</p> <ul style="list-style-type: none"> • Age less than 75 years: Administer enoxaparin 30 mg IV bolus followed immediately by 1 mg/kg. • SC every 12 hours (first two doses administer maximum of 100 mg for patients weighing more than 100 kg). • Age greater than or equal to 75 years: Administer enoxaparin 0.75 mg/kg SC every 12 hours (first two doses administer maximum of 75 mg for patients weighing more than 75 kg). <p>Continue throughout hospitalization or up to 8 days for STE MI. Continue for 24–48 hours for NSTE ACS or until the end of PCI for NSTE MI. Discontinue at least 12–24 hours after CABG surgery.</p> <p>For NSTE ACS, administer 0.1 mg/kg IV bolus followed by 0.25 mg/kg/hr infusion. For PCI in NSTE ACS, administer a second bolus of 0.5 mg/kg IV and increase infusion rate to 1.75 mg/kg/hr. For PCI in STE MI, administer 0.75 mg/kg IV bolus followed by 1.75 mg/kg/hr infusion. If prior UFH given, discontinue UFH and wait 30 minutes before initiating bivalirudin. Dosage adjustment for renal failure: None required in the HORIZONS-AMI trial. Discontinue at end of PCI or continue at 0.25 mg/kg/hr if prolonged anticoagulation necessary. Lower bleeding rates are mitigated when administered with a glycoprotein IIb/IIIa inhibitor. Clopidogrel should be administered at least 6 hours before if a glycoprotein IIb/IIIa inhibitor is not used. Discontinue at least 3 hours prior to CABG surgery.</p>
Fondaparinux	STE MI class I recommendation receiving fibrinolytics and IIa for patients not undergoing reperfusion therapy. NSTE ACS class I recommendation for invasive or conservative approach. Class III as sole agent in PCI.	Active bleeding, severe bleeding risk, SCr greater than or equal to 3.0 mg/dL (greater than or equal to 265 µmol/L) or CrCl less than 30 mL/min (less than 0.50 mL/s)	<p>For STE MI, 2.5 mg IV bolus followed by 2.5 mg SC once daily starting on hospital day 2. For NSTE ACS, 2.5 mg SC once daily. Continue until hospital discharge or up to 8 days. For PCI, give additional 85 Units/kg IV without and 60 Units/kg IV with GP IIb/IIIa inhibitor. Discontinue at least 24 hours prior to CABG surgery.</p>
Fibrinolytic therapy	STE MI, class I recommendation for patients presenting within 12 hours following the onset of symptoms, class IIa in patients presenting between 12 and 24 hours following the onset of symptoms with continuing signs of ischemia. NSTE ACS, class III recommendation.	Any prior intracranial hemorrhage, known structural cerebrovascular lesions, such as an arterial venous malformation, known intracranial malignant neoplasm, ischemic stroke within 3 months, active bleeding (excluding menses), significant closed head or facial trauma within 3 months	<p>Streptokinase: 1.5 MU IV over 60 minutes. Alteplase: 15 mg IV bolus followed by 0.75 mg/kg IV over 30 minutes (maximum 50 mg) followed by 0.5 mg/kg (max 35 mg) over 60 minutes (maximum dose 100 mg). Retepase: 10 Units IV × 2, 30 minutes apart. Tenecteplase:</p> <ul style="list-style-type: none"> • Less than 60 kg (less than 132 lb), 30 mg IV bolus • 60–69.9 kg (132–153 lb), 35 mg IV bolus • 70–80 kg (154–176 lb), 40 mg IV bolus

Table 8-2

Evidence-Based Pharmacotherapy for ST-Segment Elevation Myocardial Infarction and Non-ST-Segment Elevation Acute Coronary Syndrome^{2-8,46} (Continued)

Drug	Clinical Condition and ACCF/AHA/SCAI Guideline Recommendation ^a	Contraindications ^b	Dose and Duration of Therapy		
Glycoprotein IIb/IIIa receptor	<p>NSTE ACS PCI, class I recommendation for abciximab, high-bolus dose tirofiban or double-bolus eptifibatide at the time of PCI in high-risk patients already receiving aspirin and not pretreated with a P2Y₁₂ inhibitor and not receiving bivalirudin as the anticoagulant; class IIa at the time of PCI for high-risk patients already receiving aspirin and pretreated with a P2Y₁₂ inhibitor; class IIb for upstream use in high-risk patients already receiving aspirin and pretreated with a P2Y₁₂ inhibitor and not receiving bivalirudin as the anticoagulant; class I for upstream use in addition to aspirin without P2Y₁₂ inhibitor pretreatment for moderate- to high-risk patients.</p> <p>NSTE ACS for patients not undergoing PCI (conservative medical management), class IIb recommendation.</p> <p>STE MI primary PCI, class IIa recommendation for abciximab, high-bolus dose tirofiban or double-bolus eptifibatide.</p>	Active bleeding, thrombocytopenia, prior stroke, renal dialysis (eptifibatide)	Drug	Dose	Dosing adjustment for CKD
			Abciximab	0.25 mg/kg IV bolus followed by 0.125 mcg/kg/min (maximum 10 mcg/min) for 12 hours	None
			Eptifibatide	180 mcg/kg IV bolus × 2, 10 minutes apart with an infusion of 2 mcg/kg/min for 18–24 hours after PCI	Reduce maintenance infusion to 1 mcg/kg/min for CrCl less than 50 mL/min (less than 0.83 mL/s); contraindicated if patient dependent on dialysis. Patients weighing 121 kg (266 lb) or more should receive a maximum infusion rate of 22.6 mg per bolus and a maximum rate of 15 mg/hr
			Tirofiban	25mcg/kg IV bolus followed by an infusion of 0.1 mcg/kg/min for up to 18 hours	Reduce maintenance infusion to 0.05 mcg/kg/min for patients with CrCl less than 30 mL/min (less than 0.05 mL/s)
Nitroglycerin	STE MI and NSTE ACS, class I recommendation in patients with ongoing ischemic discomfort, control of hypertension or management of pulmonary congestion.	Hypotension, sildenafil or vardenafil within 24 hours or tadalafil within 48 hours	<p>0.4 mg SL, repeated every 5 minutes × 3 doses.</p> <p>5 to 10 mcg/min IV infusion titrated up to 75–100 mcg/min until relief of symptoms or limiting side effects (headache) with a systolic blood pressure less than 90 mm Hg or more than 30% below starting mean arterial pressure levels if significant hypertension is present. Topical patches or oral nitrates are acceptable alternatives for patients without ongoing or refractory symptoms.</p> <p>Continue IV infusion for 24–48 hours.</p>		

β-Blockers ^c	STE MI and NSTEMI ACS, class I recommendation for oral β-blockers in all patients without contraindications in the first 24 hours, class IIa for IV β-blockers in hypertensive patients.	PR ECG segment greater than 0.24 seconds, second-degree or third-degree atrioventricular heart block, heart rate less than 60 beats/min, systolic blood pressure less than 90 mm Hg, shock, left ventricular failure with congestive heart failure, severe reactive airway disease	Target resting heart rate of 50–60 beats/min. Metoprolol 5 mg slow IV push (over 1–2 min), repeated every 5 min for a total of 15 mg followed in 1–2 hours by 25–50 mg orally every 6 hours; if a very conservative regimen is desired, initial doses can be reduced to 1–2 mg. Propranolol 0.5–1 mg IV dose followed in 1–2 hours by 40–80 mg orally every 6–8 hours. Atenolol 5 mg IV dose followed in 5 min by a second 5 mg IV dose for a total of 10 mg followed in 1–2 hours by 50–100 mg orally once daily. Alternatively, initial IV therapy can be omitted. Continue oral β-blocker indefinitely.		
Calcium channel blockers	STE MI class IIa recommendation and NSTEMI ACS class I recommendation for patients with ongoing ischemia who are already taking adequate doses of nitrates and β-blockers or in patients with contraindications to or intolerance to β-blockers (diltiazem or verapamil preferred during initial presentation). NSTEMI ACS, class IIb recommendation for diltiazem for patients with AMI.	Pulmonary edema, evidence of left ventricular dysfunction, systolic blood pressure less than 100 mm Hg, PR ECG segment greater than 0.24 seconds second- or third-degree atrioventricular heart block for verapamil or diltiazem, pulse rate less than 60 beats/min for diltiazem or verapamil	Diltiazem 120–360 mg sustained release orally once daily. Verapamil 180–480 mg sustained release orally once daily. Amlodipine 5–10 mg orally once daily. Continue indefinitely if contraindication to oral β-blocker persists.		
ACE inhibitors	NSTEMI ACS and STE MI, class I recommendation for patients with heart failure, left ventricular dysfunction and EF less than or equal to 40%, type 2 diabetes mellitus or CKD in the absence of contraindications. Consider in all patients with CAD (class I recommendation, class IIa in low-risk patients). Indicated indefinitely for all patients with EF less than 40% (class I recommendation).	Systolic blood pressure less than 100 mm Hg, history of intolerance to an ACE inhibitor, bilateral renal artery stenosis, serum potassium more than 5.5 mEq/L (greater than 5.5 mmol/L), acute renal failure, pregnancy	Drug	Initial Dose (mg)	Target Dose (mg)
			Captopril	6.25–12.5	50 twice daily orally to 50 three times daily
			Enalapril	2.5–5.0	10 twice daily orally
			Lisinopril	2.5–5.0	10–20 once daily orally
			Ramipril	1.25–2.5	5 twice daily or 10 once daily orally
			Trandolapril	1.0	4 once daily orally
Angiotensin receptor blockers	NSTEMI and STE MI, class I recommendation in patients with clinical signs of heart failure or left ventricular EF less than 40% and intolerant of an ACE inhibitor, class IIa recommendation in patients with clinical signs of heart failure or EF less than 40% and no documentation of ACE inhibitor intolerance. Class I in other ACE inhibitor-intolerant patients with hypertension.	Systolic blood pressure less than 100 mm Hg, bilateral renal artery stenosis, serum potassium more than 5.5 mEq/L (greater than 5.5 mmol/L), acute renal failure, pregnancy	Drug	Initial Dose (mg)	Target Dose (mg)
			Candesartan	4–8	32 once daily orally
			Valsartan	40	160 twice daily orally
			Losartan	12.5–25	150 daily
			Continue indefinitely.

Table 8-2

Evidence-Based Pharmacotherapy for ST-Segment Elevation Myocardial Infarction and Non-ST-Segment Elevation Acute Coronary Syndrome^{2-8,46} (Continued)

Drug	Clinical Condition and ACCF/AHA/SCAI Guideline Recommendation ^a	Contraindications ^b	Dose and Duration of Therapy		
Aldosterone antagonists	NSTE MI and STE MI class I recommendation in patients with EF less than or equal to 40% and either diabetes mellitus or heart failure symptoms who are already receiving an ACE inhibitor.	Hypotension, hyperkalemia, serum potassium greater than 5.0 mEq/L (greater than 5 mmol/L), SCr greater than 2.5 mg/dL (221 μmol/L) and/or CrCl less than 30 mL/min (less than 0.50 mL/s)	Drug	Initial Dose (mg)	Maximum Dose (mg)
			Eplerenone	25	50 once daily orally
			Spironolactone	12.5	25–50 once daily orally
			Continue indefinitely.		
Morphine sulfate	STE and NSTE ACS, class I recommendation for patients whose symptoms are not relieved after three serial SL nitroglycerin tablets or whose symptoms recur with adequate antiischemic therapy.	Hypotension, respiratory depression, confusion, obtundation	2–4 mg IV bolus dose. May be repeated every 5–15 minutes as needed to relieve symptoms and maintain patient comfort.		

^aClass I recommendations are conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective.

Class II recommendations are those conditions for which there is conflicting evidence and/or divergence of opinion about the usefulness/efficacy of a procedure or treatment. For Class IIa recommendations, the weight of the evidence/opinion is in favor of usefulness/efficacy. Class IIb recommendations are those for which usefulness/efficacy is less well established by evidence/opinion. Class III recommendations are those where the procedure or treatment is not useful and may be harmful.

^bAllergy or prior intolerance contraindication for all categories of drugs listed in this chart.

^cChoice of the specific agent is not as important as ensuring that appropriate candidates receive this therapy. If there are concerns about patient intolerance due to existing pulmonary disease, especially asthma, selection should favor a short-acting agent, such as metoprolol or the ultra short-acting agent, esmolol. Mild wheezing or a history of chronic obstructive pulmonary disease should prompt a trial of a short-acting agent at a reduced dose (e.g., 2.5 mg IV metoprolol, 12.5 mg oral metoprolol, or 25 mcg/kg/min esmolol as initial doses) rather than complete avoidance of β-blocker therapy.

with NSTEMI ACS at low risk for recurrent CHD events following stress testing should be given ASA indefinitely and clopidogrel for a minimum of 1 month and ideally 12 months following hospital discharge in addition to other pharmacotherapy described later.⁶ Patients with STEMI at low risk for recurrent CHD events should receive ASA indefinitely and clopidogrel for at least 14 days in addition to other pharmacotherapy described later (Fig. 8–2).³

Early Pharmacologic Therapy for STEMI

- Pharmacotherapy for early treatment of ACS is outlined in Fig. 8–2 and Table 8–2.^{2–8} **6** According to the ACCF/AHA STEMI practice guidelines, in addition to reperfusion therapy, other early pharmacotherapy that all patients with STEMI and without contraindications should receive within the first day of hospitalization, and preferably in the emergency department, are intranasal oxygen (if oxygen saturation is low), sublingual (SL) nitroglycerin (NTG), ASA, a P2Y₁₂ inhibitor (clopidogrel, prasugrel, or ticagrelor depending on reperfusion strategy), and anticoagulation with bivalirudin, unfractionated heparin (UFH), or enoxaparin (agent dependent on reperfusion strategy). A GP IIb/IIIa inhibitor should be administered with UFH for patients undergoing primary PCI. IV β -blockers and IV NTG should be given in selected patients. Oral β -blockers should be initiated within the first day in patients without cardiogenic shock^{2–4,8} Morphine is administered to patients with refractory angina as an analgesic and a venodilator that lowers preload. These agents should be administered early while the patient is still in the emergency department. Dosing and contraindications for SL and IV NTG, ASA, clopidogrel, β -blockers, anticoagulants, and fibrinolytics are listed in Table 8–2.^{2–4,8}

► Fibrinolytic Therapy

- Administration of a fibrinolytic agent is indicated in patients with STEMI who present to the hospital within 12 hours of the onset of chest discomfort, have at least a 1-mm STEMI in two or more contiguous ECG leads, and are not able to undergo primary PCI within 90 minutes of medical contact.⁴ The mortality benefit of fibrinolysis is highest with early administration and diminishes after 12 hours. The use of fibrinolytics between 12 and 24 hours after symptom onset should be limited to patients with ongoing ischemia. Fibrinolytic therapy is preferred over primary PCI where there is no cardiac catheterization laboratory or there would be a delay in “door-to-primary PCI” of more than 90 minutes (of first medical contact) within the institution or 120 minutes (of first medical contact) if the patient is transferred. Indications and contraindications for fibrinolysis are listed in Table 8–3.² It is not necessary to obtain the results of biochemical markers before initiating fibrinolytic therapy. Because administration of fibrinolytics result in clot lysis, patients who are at high risk of major bleeding (including intracranial hemorrhage) presenting with an absolute contraindication should not receive fibrinolytic therapy; primary PCI is preferred. In patients who have a

Patient Encounter 2, Part 1

SD is a 66-year-old, 90-kg (198-lb) man who presents to the emergency department by ambulance complaining of 3 hours of continuous chest pressure that started while walking his dog. SD developed substernal chest pain about 15 minutes after walking. He stopped and rested but the chest pain did not resolve. He returned home and called 911. Local paramedics were summoned, and he was given three 0.4 mg sublingual nitroglycerin tablets by mouth, 325 mg ASA by mouth, and morphine 2 mg IV push without relief of chest discomfort. An early invasive strategy is selected.

PMH: HTN for 5 years; type 2 diabetes mellitus (DM) for 5 years; dyslipidemia for 2 years

FH: Father with myocardial infarction at age 75; mother and sister alive with type 2 DM

SH: Nonsmoker

Allergies: NKDA

Meds: Metformin 1,000 mg by mouth twice daily; ASA 325 mg by mouth once daily; lisinopril 20 mg by mouth once daily; simvastatin 20 mg by mouth once daily

ROS: 10/10 chest pressure/squeezing

PE:

HEENT: Normocephalic atraumatic

CV: Regular rate and rhythm S₁, S₂, –S₃, –S₄, no murmurs or rubs

VS: BP 150/92; HR 88 bpm; T 37°C (98.6°F)

Lungs: Clear to auscultation and percussion

Abd: Nontender, nondistended

GI: Normal bowel sounds

GU: Stool guaiac negative

Exts: No bruits, pulses 2+, femoral pulse present, good range of motion

Neuro: Alert and oriented $\times 3$, cranial nerves intact

Labs: Sodium 136 mEq/L (136 mmol/L), potassium 4.0 mEq/L (4.0 mmol/L), chloride 105 mEq/L (105 mmol/L), bicarbonate 22 mEq/L (22 mmol/L), SCr 1.0 mg/dL (88 μ mol/L), glucose 160 mg/dL (8.9 mmol/L), WBC $6.9 \times 10^3/\text{mm}^3$ ($6.9 \times 10^9/\text{L}$), hemoglobin 14.7 g/dL (147 g/L or 9.1 mmol/L), hematocrit 42% (0.42), platelets $320 \times 10^3/\text{mm}^3$ ($320 \times 10^9/\text{L}$), troponin I 1.0 ng/mL (1.0 mcg/L), oxygen saturation 99% (0.99) on room air

ECG: Normal sinus rhythm, PR 0.16 seconds, QRS 0.08 seconds, QT_c 0.38 seconds, 1 mm ST-segment depression anterior leads

CXR: Normal

Echo: Anterior wall dyskinesis, LVEF 55% (0.55)

What information is suggestive of acute MI?

Table 8-3

Indications and Contraindications to Fibrinolytic Therapy per ACC/AHA Guidelines for Management of Patients with ST-Segment Elevation Myocardial Infarction⁴

Indications

1. Ischemic chest discomfort at least 20 minutes in duration but 12 hours or less since symptom onset
and
ST-segment elevation of at least 1 mm in height in two or more contiguous leads, or new or presumed new left bundle-branch block
2. Ongoing ischemic chest discomfort at least 20 minutes in duration 12–24 hours since symptom onset
and
ST-segment elevation of at least 1 mm in height in two or more contiguous leads

Absolute Contraindications

- Active internal bleeding (not including menses)
- Previous intracranial hemorrhage at any time; ischemic stroke within 3 months
- Known intracranial neoplasm
- Known structural vascular lesion (e.g., arteriovenous malformation)
- Suspected aortic dissection
- Significant closed head or facial trauma within 3 months

ACC, American College of Cardiology; AHA, American Heart Association

contraindication to fibrinolytics and PCI, or who do not have access to a facility that can perform PCIs, treatment with an anticoagulant (other than UFH) for up to 8 days can be administered.

In patients with symptoms lasting less than 6 hours, a more fibrin-specific agent such as alteplase, reteplase, or tenecteplase is preferred over a nonfibrin-specific agent such as streptokinase.² Fibrin-specific fibrinolytics open a greater percentage of infarcted arteries. In a large clinical trial, administration of alteplase reduced mortality by 1% (absolute reduction) and cost about \$30,000 per year of life saved compared with streptokinase.³⁷ Two other trials compared alteplase with reteplase and alteplase with tenecteplase and found similar mortality between agents.^{38,39} Therefore, alteplase, reteplase, or tenecteplase is acceptable as a first-line agent. Intracranial hemorrhage (ICH) and major bleeding are the most serious side effects of fibrinolytic agents. The risk of ICH is higher with fibrin-specific agents than with streptokinase.²² However, the risk of systemic bleeding other than ICH is higher with streptokinase than with other more fibrin-specific agents and was higher with alteplase versus tenecteplase in one study.^{22,37,39}

As mentioned previously, less than 20% of patients with STE MI receive fibrinolysis compared with more than 60% receiving primary PCI. However, 17% of eligible patients receive neither primary PCI nor fibrinolysis despite being eligible. The primary reason for lack of reperfusion therapy is

that most patients present more than 12 hours after the time of symptom onset. The percentage of eligible patients who receive reperfusion therapy is a quality performance measure of care in patients with MI.³² The “door-to-needle time,” the time from hospital presentation to start of fibrinolytic therapy, is another quality performance measure.³² The ACCF/AHA guidelines recommend a “door-to-needle time” of less than 30 minutes from the time of hospital presentation until start of fibrinolytic therapy.⁴ The median administration time in the United States in 2006 was 29 minutes, with only 50% of patients meeting the quality performance target of less than 30 minutes.⁴⁰ All hospitals should have protocols addressing fibrinolysis eligibility, dosing, and monitoring.

► Aspirin

ASA is the preferred antiplatelet agent in the treatment of all ACS.^{4,8} ASA administration to all patients who do not have contraindications to ASA therapy within 24 hours before or after hospital arrival is a quality performance measure for MI.^{4,32} The antiplatelet effects of ASA are mediated by inhibiting the synthesis of thromboxane A₂ (TXA₂) through an irreversible inhibition of platelet cyclooxygenase-1. In patients undergoing PCI, ASA prevents acute thrombotic occlusion during the procedure. In patients receiving fibrinolytics, ASA reduces mortality, and its effects are additive to fibrinolysis alone.^{4,41} Additionally, in patients undergoing PCI, ASA, in addition to a P2Y₁₂ inhibitor, reduces the risk of stent thrombosis.

- In patients experiencing an ACS, an initial dose equal to or greater than 160 mg nonenteric ASA is necessary to achieve a rapid platelet inhibition.^{42,43} Current guidelines for STE MI recommend an initial ASA dose of 162 to 325 mg (Table 8-2).⁴ This first dose can be chewed in order to achieve high blood concentrations and platelet inhibition rapidly.
- Preferably, patients undergoing PCI not previously taking ASA should receive 325 mg nonenteric-coated ASA.⁸ The notion of chewing ASA came from the use of an enteric-coated formulation of ASA in the Second International Study of Infarct Survival (ISIS-2) trial in order to break the enteric coating to ensure more rapid effect.⁴³ Current data suggest that although an initial dose 160 to 325 mg is required, long-term therapy with doses of 75 to 150 mg daily are as effective
- as higher doses, and therefore a daily maintenance dose of 75 to 162 mg is recommended in most patients to inhibit the 10% of the total platelet pool that is regenerated daily.^{4,44-46}
- Because of increased bleeding risk in patients receiving ASA plus a P2Y₁₂ inhibitor compared with ASA alone, low-dose ASA (81 mg daily) is preferred following PCI.⁸ In a large ($n = 25,086$) randomized trial, high-dose ASA, 300 to 325 mg daily, had similar frequency of CV death, MI, or stroke as well as major bleeding compared to low-dose ASA in the first 30 days following ACS presentation.⁴⁷ Minor bleeding and GI bleeding were less frequent with low-dose ASA. In this trial, patients undergoing PCI during hospitalization had a lower frequency of death, MI, or stroke, but major bleeding was increased with high-dose ASA.⁴⁸ In PLATO (the Study of Platelet Inhibition and Patient Outcomes), a

randomized double-blind clinical trial comparing ticagrelor with clopidogrel in patients receiving ASA, a post hoc analysis suggested that maintenance doses of ASA above 100 mg daily reduced the effectiveness of ticagrelor.⁴⁹ Low-dose ASA should be continued indefinitely.⁴⁶

Nonsteroidal anti-inflammatory agents other than ASA, as well as cyclooxygenase-2 (COX-2) selective anti-inflammatory agents, should be discontinued at the time of STE MI secondary to increased risk of death, reinfarction, HF, and myocardial rupture.³

The most frequent side effects of ASA are dyspepsia and nausea. Patients should be counseled about the risk of bleeding, especially GI bleeding, with ASA.

► Platelet P2Y₁₂ Inhibitors

Clopidogrel, prasugrel, and ticagrelor block a subtype of ADP receptor, the P2Y₁₂ receptor, on platelets, preventing the binding of ADP to the receptor and subsequent expression of platelet GP IIb/IIIa receptors, reducing platelet activation and aggregation. Both clopidogrel and prasugrel are thienopyridine and prodrugs that are converted to an active metabolite by a variety of cytochrome CYP450 isoenzymes (Table 8-4).⁵⁰⁻⁵²

Both of these agents bind irreversibly to P2Y₁₂ receptor. Ticagrelor, which is not a thienopyridine, is a reversible, noncompetitive P2Y₁₂ receptor inhibitor. Ticagrelor parent compound has antiplatelet effects and is also metabolized primarily by CYP3A to an active metabolite producing its antiplatelet effects.

Both prasugrel and ticagrelor are more potent ADP inhibitors than clopidogrel. Prasugrel has the fewest significant drug-drug interactions. The production of clopidogrel's active metabolite and consequently its antiplatelet effect is reduced by moderate and strong inhibitors of CYP2C19, whereas ticagrelor's concentration is reduced by strong inhibitors of CYP3A. Labeled drug interactions are described in Table 8-4. A more detailed discussion of the interaction between clopidogrel and proton pump inhibitors may be found in Chapter 7, "Ischemic Heart Disease."

A considerable amount of data support that genetic variations in the gene coding for *CYP2C19* significantly modulate the antiplatelet effects of clopidogrel. Specifically, carriers of reduced-function allele (i.e., *2 or *3) are not able to convert clopidogrel to its active metabolite to the extent of carriers of the wild-type allele. This results in decreased antiplatelet effects,⁵³ as well as higher rates of CV events, especially stent thrombosis and MI around the time of PCI.⁵⁴ Prasugrel is not as dependent on *CYP2C19* genotype for its conversion to the active metabolite and has a lower frequency of poor antiplatelet responsiveness.⁵⁵ Moreover, current data suggest the benefit of prasugrel compared with clopidogrel may only be apparent in carriers of these reduced function alleles,⁵⁵ whereas the benefits of ticagrelor over clopidogrel may be unrelated to *CYP2C19*.⁵⁶ Hence ticagrelor or prasugrel may be considered preferred agents in carriers of *CYP2C19* reduced function alleles.

Although the product labeling for clopidogrel suggests that genetic testing and alternative therapy should be selected

for patients that are *CYP2C19* poor metabolizers,⁵⁰ the most recent clinical practice guidelines of the ACCF/AHA/SCAI have not endorsed routine genotyping to guide the prescription of P2Y₁₂ inhibitors because no prospective randomized clinical study has demonstrated the benefit of such a genotype-based prescribing approach.⁸

Administration of a P2Y₁₂ receptor inhibitor, in addition to ASA, is recommended for all patients with STE MI.^{2-4,8} For STE MI undergoing primary PCI, clopidogrel, prasugrel, or ticagrelor, in addition to ASA, should be administered to prevent subacute stent thrombosis and longer-term CV events (Table 8-2).^{2,8} Although not FDA approved, a clopidogrel loading dose of 600 mg is recommended over administration of 300 mg for patients undergoing PCI. A systematic review and meta-analysis of randomized and nonrandomized trials in more than 25,000 patients demonstrated a reduction in CV ischemic events with a loading dose of 600 mg compared with 300 mg in patients undergoing PCI.⁵⁷

In the most recent ACCF/AHA/SCAI PCI practice guidelines, no preference is given for one agent over the other. Nevertheless, clinical trials comparing these agents have highlighted distinct clinical differences between these antiplatelet agents.

A large randomized double-blind study demonstrated that, compared with clopidogrel, the addition of prasugrel to ASA for patients undergoing PCI in the setting of STE MI or NSTEMI significantly reduced risk of CV death or MI by 19% (9.9% versus 12.1%), as well as MI and stent thrombosis, but increased the risk of major bleeding (not ICH) by 32% (2.4% versus 1.8%).⁵⁸ Patients with a history of prior stroke or transient ischemic attack (TIA) had an increased risk of ICH and no net clinical benefit from prasugrel, and the product label lists prior stroke or TIA as a contraindication to prasugrel.⁵¹ Patients older than 75 years and those weighing less than 60 kg (132 lb) are at increased risk of bleeding with prasugrel compared with clopidogrel.⁵¹ Two subgroups of patients do not have an increased bleeding risk with prasugrel compared with clopidogrel and have even greater benefit, namely patients undergoing primary PCI for STE MI and those patients with a history of diabetes mellitus (DM).^{59,60}

PLATO compared ticagrelor with clopidogrel in patients receiving ASA and presenting with either STE MI or NSTEMI ACS and undergoing an intended interventional management strategy with PCI or conservative noninterventional management strategy with medical therapy alone. In this trial, ticagrelor significantly reduced the rate of CV death, MI, stroke, and stent thrombosis compared with clopidogrel.⁶¹ Although no increase in study-defined major bleeding was noted with ticagrelor, the frequency of non-CABG major bleeding was increased compared with clopidogrel. As with the prasugrel trial previously described, several subgroups of patients enrolled in this trial had particular benefit with ticagrelor, including those with an intended invasive approach, those with an intended noninvasive approach, patients with STE MI primary PCI, and patients with DM.⁶²⁻⁶⁵ Therefore, both of the more potent P2Y₁₂ inhibitors are more efficacious than clopidogrel but may also be associated with an increased risk of bleeding. No large randomized trial has directly

Table 8-4

Pharmacokinetics of Clopidogrel, Prasugrel, and Ticagrelor⁵⁰⁻⁵²

	Clopidogrel	Prasugrel	Ticagrelor
Pharmacologic class	Thienopyridine	Thienopyridine	Cyclopentyl triazolopyrimidine
ADP receptor binding	Irreversible	Irreversible	Reversible
Absorption and metabolism	Prodrug Inactive metabolite SR266334 Active metabolite R-130946 Metabolism to R-130946 is primarily by CYP2C19, with lesser contributions from CYP3A4, 2B6, and 1A2 Exposure to the active metabolite is affected by CYP 2C19 and possible ATP-binding cassette B1 (ABCB1) transporter (also called P-glycoprotein) polymorphisms Rapid conversion of the parent drug to active metabolite (mean time to peak plasma concentration of active metabolite approximately 1 hour)	Prodrug Active metabolite R-138727 Metabolism to R-138727 is primarily via CYP 3A4 and CYP 2B6 Exposure to the active metabolite is not affected by CYP 2C19 polymorphisms Rapid conversion of the parent drug to active metabolite (median time to peak plasma concentration of active metabolite approximately 30 minutes)	Active moiety, bioavailability 36% Active metabolite AR-C124910XX approximately 30% to 40% activity of parent compound Metabolism is primarily via CYP 3A4/5 Exposure to the active metabolite is not affected by CYP 2C19 polymorphisms Rapid conversion of the parent drug to active metabolite (median time to peak plasma concentration of active metabolite 2.5 hours)
Food effect	One report in healthy volunteers of bioavailability of inactive metabolite concentrations unaffected by food; one report in healthy volunteers of clopidogrel t_{max} delayed by 1.5 hours, C_{max} increased sixfold and bioavailability increased ninefold	Fasting administration preferred; C_{max} is reduced by 49% and t_{max} delayed 0.5–1.5 hours when administered with high-fat, high-calorie meal, although AUC is unaffected	May be taken with or without food; no effect on C_{max} and 21% increase in AUC when administered with high-fat, high-calorie meal. Decrease in C_{max} by 22% and no effect on AUC of active metabolite when administered with high-fat, high-calorie meal
Disposition	Linear pharmacokinetics at doses of 50–150 mg	Linear pharmacokinetics at doses up to 75 mg	Linear pharmacokinetics at doses up to 600 mg daily
Elimination	Elimination half-life of active metabolite is approximately 30 minutes after a 75-mg dose Excretion is 50% urinary and 46% fecal	Median elimination half-life of the active metabolite approximately 7.4 hours Excretion is primarily urinary (approximately 70%); fecal excretion less than 30%	Median elimination half-life of the parent compound is approximately 7 hours and active metabolite approximately 9 hours Excretion is primarily metabolism (84%); fecal excretion 58%, urinary excretion 26%
Labeled drug interactions and suggested management of interaction	Enhanced bleeding with NSAIDs; avoid use Enhanced bleeding with warfarin; monitor carefully for bleeding; target INR to 2.0–2.5 for most indications Avoid use with moderate or strong CYP2C19 inhibitors (e.g., omeprazole, esomeprazole, chloramphenicol, cimetidine, efavirenz, etravirine, felbamate, fluoxetine, fluconazole, fluvoxamine, isoniazid, oxcarbazepine, ketoconazole, voriconazole); select alternative noninteracting P2Y ₁₂ inhibitor or alternative noninteracting drug	Enhanced bleeding with warfarin and NSAIDs, avoid use	Enhanced bleeding with warfarin and NSAIDs Use aspirin doses less than or equal to 100 mg daily Avoid use with strong CYP3A inhibitors (atazanavir, clarithromycin, indinavir, itraconazole, nefazodone, nelfinavir, ketoconazole, ritonavir, saquinavir, telithromycin, voriconazole) Avoid use with potent CYP3A inducers (carbamazepine, dexamethasone, phenobarbital, phenytoin, rifampin) Avoid simvastatin and lovastatin doses more than 40 mg daily (ticagrelor inhibits CYP3A4 and increases statin concentration) Monitor digoxin serum concentrations with any change in ticagrelor dose (ticagrelor inhibits P-glycoprotein)

ADP, adenosine diphosphate; ATP, adenosine triphosphate; AUC, area under the curve; CYP, cytochrome P450; INR, international normalized ratio; NSAIDs, nonsteroidal anti-inflammatory drugs.

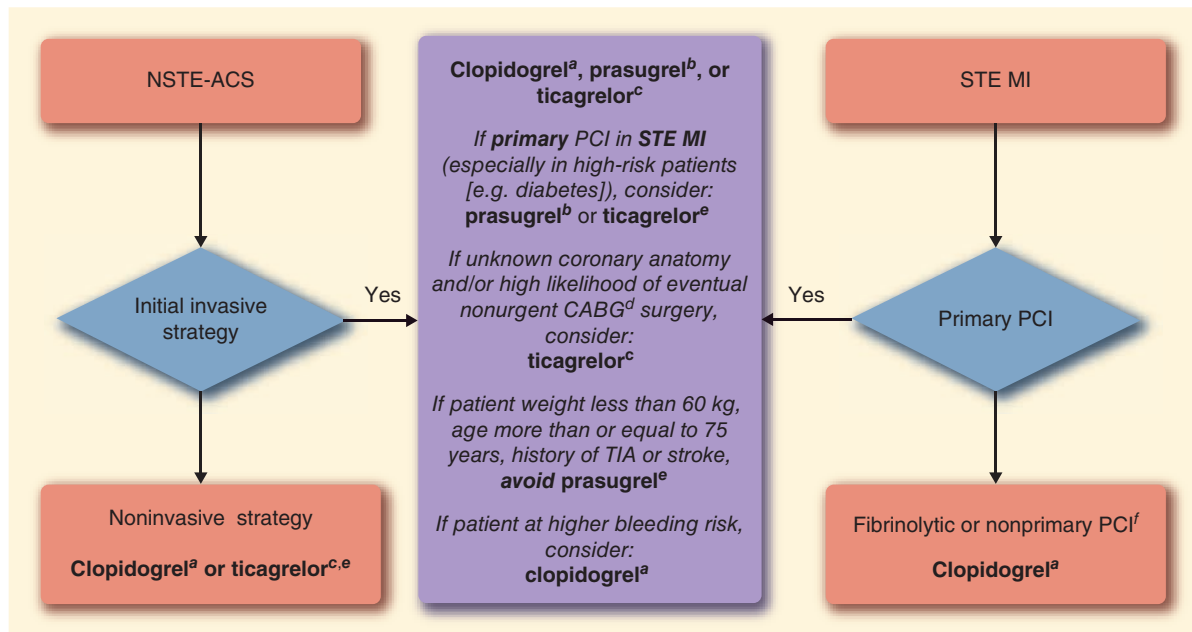

FIGURE 8-4. Proposed use of P2Y₁₂ inhibitors. ^aDo not use clopidogrel in patients with active pathological bleeding; consider alternative P2Y₁₂ receptor inhibitor if documented clopidogrel ineffectiveness (e.g., poor metabolism, stent thrombosis during clopidogrel therapy) or drug–drug interactions (e.g., avoid moderate and strong CYP2C19 inhibitors); clopidogrel should be held for at least 5 days before CABG surgery, if the surgery can be delayed. ^bDo not use prasugrel in patients with active pathological bleeding or a history of transient ischemic attack or stroke; if a patient subsequently goes on to receive CABG surgery, the drug should be held for at least 7 days if the surgery can be delayed. ^cDo not use ticagrelor in patients with active pathological bleeding or a history of intracranial hemorrhage, or in patients planned to undergo urgent CABG surgery; concomitant maintenance aspirin dose above 100 mg should be avoided; dose of ticagrelor should be held for 5 days before CABG surgery if the surgery can be delayed; when selecting this agent consider patient compliance (dosed twice daily), unique adverse effects (e.g., dyspnea), and potential drug–drug interactions (e.g., avoid strong CYP3A inhibitors/inducers). ^dPrior to diagnostic angiography, it is difficult to determine the likelihood that an individual patient will receive CABG surgery; notable variables that predict this occurrence include previous CABG, male gender, previous heart failure, presence of diabetes, previous percutaneous coronary intervention, among others. ^eRecommendation based on subgroup analysis. ^fAt this time, there is insufficient data to support ticagrelor or prasugrel in the “fibrinolytic or nonprimary PCI” patient group. (ACS, acute coronary syndrome; CABG, coronary artery bypass surgery; MI, myocardial infarction; NSTE, non-ST-segment elevation; PCI, percutaneous coronary intervention; STE, ST-segment elevation; TIA, transient ischemic attack.) (Adapted from Crouch MA, Colucci VJ, Howard PA, Spinler SA. P2Y₁₂ receptor inhibitors: Integrating ticagrelor into the management of acute coronary syndrome. *Ann Pharmacother* 2011;45:1151–1156, with permission.)

compared ticagrelor and prasugrel. **Figure 8-4** outlines the role of the newer P2Y₁₂ inhibitors in ACS compared with clopidogrel.⁶⁶

Although a modest benefit of using a 7-day course of clopidogrel 150 mg compared to 75 mg daily has been suggested, it is also associated with a higher risk of major bleeding.⁴⁷ While mentioned in STE MI practice guidelines,^{2,8} such a regimen is not used routinely in practice with the availability of the more potent agents, prasugrel and ticagrelor.

The recommended duration of P2Y₁₂ inhibitors for a patient undergoing PCI for ACS, either STE MI or NSTE ACS, is at least 12 months for patients receiving either a bare metal or a drug-eluting stent.⁸ The benefit of prolonging treatment beyond 12 months is uncertain.⁸ Nonadherence to P2Y₁₂ inhibitors is a major risk factor for stent thrombosis, and hence the likelihood of adherence to dual antiplatelet

therapy (ASA and a P2Y₁₂ inhibitor) should be assessed prior to angiography.⁸ The use of a bare metal stent over a drug-eluting stent should be considered in patients who are anticipated to be nonadherent to 12 months of dual antiplatelet therapy.⁸

To minimize the risk of CV events, elective noncardiac surgery should be delayed to more than 4 to 6 weeks after angioplasty or bare metal stent implantation, or 12 months after drug-eluting stent implantation if the discontinuation of the P2Y₁₂ inhibitor is required.⁸ If CABG surgery is planned, clopidogrel and ticagrelor should be withheld preferably for 5 days, and prasugrel at least 7 days, to reduce the risk of postoperative bleeding, unless the need for revascularization outweighs the bleeding risk.⁸

Although a variety of blood tests can assess functional platelet aggregation inhibition to P2Y₁₂ inhibitors, especially

clopidogrel, there is no one gold standard test. Moreover, while using higher maintenance doses of clopidogrel (150 mg daily) in patients with a high level of on-treatment platelet aggregation (low platelet aggregation inhibition) improves platelet aggregation inhibition, it does not result in improved clinical outcomes.⁶⁷ Therefore, the most recent PCI practice guidelines do not recommend routine platelet aggregation testing to determine P2Y₁₂ inhibitor strategy.⁸

The most frequent side effects of clopidogrel and prasugrel are nausea, vomiting, and diarrhea, which occur in approximately 2% to 5% of patients.^{50,51} Rarely, thrombotic thrombocytopenic purpura (TTP) has been reported with clopidogrel.⁵⁰ In addition to nausea (4%) and diarrhea (3%), use of ticagrelor is associated with dyspnea (14%) and, rarely, ventricular pauses and bradyarrhythmias. Patients at risk of bradycardia were excluded from PLATO.⁵² Small nonclinically significant increases in serum creatinine and serum uric acid have also been reported with ticagrelor.⁵²

In patients receiving fibrinolysis, early therapy with clopidogrel 75 mg once daily administered during hospitalization and up to 28 days (mean: 14 days) in patients with STE MI reduced mortality and reinfarction in patients treated with fibrinolytics without increasing the risk of major bleeding.^{3,68,69} In adult patients younger than 75 years receiving fibrinolytics, the first dose of clopidogrel can be a 300-mg loading dose.^{3,69} Although prasugrel and ticagrelor have been studied in the setting of PCI, no studies have evaluated their use when added to both ASA and a fibrinolytic.

Clopidogrel is currently the ACCF/AHA guideline-preferred P2Y₁₂ inhibitor added to ASA and should be continued for at least 14 days (and up to 1 year) for patients presenting with STE MI who do not undergo reperfusion therapy with either primary PCI or fibrinolysis.^{3,68} However, recent subgroup analysis from PLATO suggests that ticagrelor may also be an option in medically managed patients with ACS because the frequency of CV death, MI, or stroke as well as mortality was lower in ticagrelor-treated patients compared with those receiving clopidogrel (Fig. 8-4).^{62,66} Ticagrelor use was not associated with a higher bleeding rate compared with clopidogrel.⁶²

► Glycoprotein IIb/IIIa Receptor Inhibitors

GP IIb/IIIa receptor inhibitors block the final common pathway of platelet aggregation, namely cross-linking of platelets by fibrinogen bridges between the GP IIb and IIIa receptors on the platelet surface. In patients with STE MI undergoing primary PCI who are treated with UFH, either abciximab (IV or intracoronary administration), eptifibatid or tirofiban may be administered.⁸ Routine use of a GP IIb/IIIa receptor inhibitor is not recommended in patients who have received fibrinolytics or in those receiving bivalirudin secondary to increased bleeding risk. GP IIb/IIIa inhibitors should not be administered for medical management of the patient with STE MI who will not be undergoing PCI.⁸ A meta-analysis of STE MI primary PCI trials demonstrated no reduction in mortality or 30-day reinfarction but increased

risk of major bleeding with GP IIb/IIIa inhibitors compared with control.⁷⁰ Although there are more clinical trial data with abciximab for primary PCI compared with the small molecule GP IIb/IIIa inhibitors eptifibatid and tirofiban, the small molecule agents are used more commonly in clinical practice. A meta-analysis found no difference in efficacy and safety between abciximab and the small molecular GP IIb/IIIa inhibitors.⁷¹

Dosing and contraindications for GP IIb/IIIa inhibitors are described in Table 8-2.¹² Bleeding is the most significant adverse effect associated with administration of GP IIb/IIIa inhibitors. GP IIb/IIIa inhibitors should not be administered to patients with a prior history of hemorrhagic stroke or recent ischemic stroke. The risk of bleeding is increased in patients with chronic kidney disease. Eptifibatid is contraindicated in patients dependent on dialysis and requires a reduced infusion dose in patients with creatinine clearance (CrCl) less than 50 mL/min (0.83 mL/s).⁷² The STE MI PCI guideline-recommended dosing for tirofiban is not a FDA-approved regimen but one that has been studied in more contemporary clinical trials.^{8,73} The dose of tirofiban should be halved in patients with CrCl less than 30 mL/min (0.50 mL/s).⁷⁴ No dosage adjustment for renal function is necessary for abciximab. An immune-mediated thrombocytopenia occurs in approximately 5% of patients with abciximab and less than 1% of patients receiving eptifibatid or tirofiban.⁷⁵

► Anticoagulants

Options for anticoagulant therapy for patients with STE MI are outlined in Figure 8-2 and Table 8-2.^{2-4,8} For patients undergoing primary PCI, either UFH or bivalirudin is preferred, whereas for fibrinolysis, enoxaparin is preferred.^{2,3} For patients undergoing PCI, anticoagulation is discontinued immediately following the PCI procedures. In patients receiving enoxaparin plus a fibrinolytic, enoxaparin is continued for the duration of hospitalization, up to 8 days.³ In patients who do not undergo reperfusion therapy, it is reasonable to administer anticoagulant therapy for up to 48 hours for UFH or for the duration of hospitalization for enoxaparin.^{3,4}

Unfractionated heparin has been the traditional anticoagulant administered to patients with STE MI to prevent reocclusion of an infarct artery for more than 50 years. The results of a meta-analysis of more than 7,500 patients suggests that low molecular weight heparins (LMWHs) reduce both mortality and reinfarction compared with placebo in patients treated with fibrinolytics and ASA.⁷⁶ In a randomized open-label clinical trial of primary PCI for STE MI, bivalirudin, a direct thrombin inhibitor, significantly reduced the frequency of CV mortality by 45% (2.9% versus 5.1%) and all-cause mortality by 25% (5.9% versus 7.7%) at 3 years of follow-up while lowering the risk of in-hospital major bleeding events by 40% (4.9% versus 8.3%) compared with UFH plus a GP IIb/IIIa inhibitor (abciximab, eptifibatid, or tirofiban).^{77,78} Therefore bivalirudin has

similar or greater efficacy but better safety than UFH in the setting of primary PCI.

In patients with STE MI treated with fibrinolytics, enoxaparin, administered for a median of 7 days, has shown a reduction in the risk of death or non-fatal MI but increased bleeding risk compared with UFH administered for a median of 2 days in a large randomized clinical trial.⁷⁹ Enoxaparin dosing is adjusted for body weight and renal function, and when administered in combination with fibrinolysis, it has special dosing requirements for older patients and those weighing more than 100 kg (Table 8–2).

Besides bleeding, the most serious adverse effect of UFH and enoxaparin is **heparin-induced thrombocytopenia**. ACS registry data indicate, however, that the frequency of heparin-induced thrombocytopenia is rare (less than 0.5%).⁸⁰ Bivalirudin would be a preferred anticoagulant for patients with a history of heparin-induced thrombocytopenia undergoing PCI.⁸

► Nitrates

- One SL NTG tablet should be administered every 5 minutes for up to three doses to relieve myocardial ischemia. If patients have been previously prescribed SL NTG and ischemic chest discomfort persists for more than 5 minutes after the first dose, the patient should be instructed to contact emergency medical services before self-administering subsequent doses
- to activate emergency care sooner. IV NTG should then be initiated in all patients with an ACS who have persistent ischemia, HF, or uncontrolled high blood pressure (BP) in the absence of contraindications.⁴ IV NTG should be continued for approximately 24 hours after ischemia is relieved (Table 8–2). Nitrates promote the release of nitric oxide from the endothelium, which results in venous and arterial vasodilation. Venodilation lowers preload and myocardial oxygen demand. Arterial vasodilation may lower BP, thus reducing myocardial oxygen demand. Arterial vasodilation also relieves coronary artery vasospasm, dilating coronary arteries to improve myocardial blood flow and oxygenation. Although used to treat ACS, nitrates have been suggested to play a limited role in the treatment of ACS patients because two large randomized clinical trials failed to show a mortality benefit for IV nitrate therapy followed by oral nitrate therapy in acute MI.^{81,82} The most significant adverse effects of nitrates are tachycardia, flushing, headache, and hypotension. Nitrate administration is contraindicated in patients who have received oral phosphodiesterase-5 inhibitors, such as sildenafil and vardenafil, within the past 24 hours, and tadalafil within the past 48 hours.⁴

► β -Blockers

- A β -blocker should be administered early in the care of patients with STE MI and continued indefinitely. In ACS, the benefit of β -blockers results mainly from the competitive blockade of β_1 -adrenergic receptors located on the myocardium. β_1 -blockade produces a reduction in heart

rate, myocardial contractility, and BP, decreasing myocardial oxygen demand. In addition, the reduction in heart rate increases diastolic time, thus improving ventricular filling and coronary artery perfusion. As a result of these effects, β -blockers reduce the risk for recurrent ischemia, infarct size, risk of reinfarction, and occurrence of ventricular arrhythmias in the hours and days following MI.

Landmark clinical trials have established the role of early β -blocker therapy in reducing MI mortality. Most of these trials were performed in the 1970s and 1980s before routine use of early reperfusion therapy.^{83,84} However, data regarding the acute benefit of β -blockers in MI in the reperfusion era are derived mainly from a recently reported large clinical trial which suggests that although initiating IV followed by oral β -blockers early in the course of STE MI was associated with a lower risk of reinfarction or ventricular fibrillation, there may be an early risk of cardiogenic shock, especially in patients presenting with pulmonary congestion or systolic blood pressure less than 120 mm Hg.⁸⁵ Therefore, initiation of β -blockers, particularly when administered IV, should be limited to patients who are hemodynamically stable and who do not demonstrate any signs or symptoms of acute HF.³ Careful assessment for signs of hypotension and HF should be performed following β -blocker initiation and prior to any dose titration. Patients already taking β -blockers can continue taking them.³ The Joint Commission has retired the “Beta Blocker at Hospital Arrival” Core Measure and is no longer requiring hospital reporting of this measure.

The most serious side effects of β -blocker administration early in ACS are hypotension, acute HF, bradycardia, and heart block. Although initial acute administration of β -blockers is not appropriate for patients who present with acute HF, initiation of β -blockers may be attempted before hospital discharge in most patients following treatment of acute HF. β -blockers are continued indefinitely.⁴

► Calcium Channel Blockers

Calcium channel blockers in the setting of STE MI are used for relief of ischemic symptoms in patients who have certain contraindications to β -blockers. Current data suggest little benefit on clinical outcomes beyond symptom relief for calcium channel blockers in the setting of ACS.⁴ Therefore, calcium channel blockers should be avoided in the acute management of all ACSs unless there is a clear symptomatic need or a contraindication to β -blockers. Agent selection is based on presenting heart rate and left ventricular dysfunction (diltiazem and verapamil are contraindicated in patients with bradycardia, heart block, or systolic HF). Nifedipine should be avoided because it has demonstrated reflex sympathetic activation, tachycardia, and worsened myocardial ischemia.⁴ Dosing and contraindications are described in Table 8–2.

Early Pharmacotherapy for NSTEMI ACSs

- In general, early pharmacotherapy of NSTEMI ACS (Fig. 8–3) is similar to that of STE MI. **7** *In the absence of contraindications,*

Patient Encounter 2, Part 2

Is reperfusion therapy with fibrinolysis indicated at this time for patient SD?

What adjunctive pharmacotherapy should be administered to SD in the emergency department?

What additional pharmacotherapy should be initiated on the first day of SD's hospitalization following successful reperfusion with PCI?

all patients with NSTEMI ACS should be treated in the emergency department with intranasal oxygen (if oxygen saturation is low), SL NTG, ASA, and an anticoagulant: UFH, enoxaparin, fondaparinux, or bivalirudin. High-risk patients should proceed to early angiography and may receive a GP IIb/IIIa inhibitor. A P2Y₁₂ inhibitor (selection of agent and timing of initiation dependent on selection of an interventional approach involving PCI or CABG surgery versus a noninterventional approach with medical management alone) should be administered to all patients. IV β -blockers and IV NTG should be given in selected patients. Oral β -blockers should be initiated within the first day in patients without cardiogenic shock.^{5,6,8} Morphine is also administered to patients with refractory angina as described previously. These agents should be administered early while the patient is still in the emergency department. Fibrinolytic therapy is never administered. Dosing and contraindications for SL and IV NTG (for selected patients), ASA, P2Y₁₂ inhibitors, β -blockers, and anticoagulants are listed in Table 8–2.

► Fibrinolytic Therapy

Fibrinolytic therapy is not indicated in any patient with NSTEMI ACS because increased mortality has been reported with fibrinolytics compared with controls in clinical trials in which fibrinolytics have been administered to patients with NSTEMI ACS (patients with normal or ST-segment depression ECGs).

► Aspirin

ASA reduces the risk of death or developing MI by about 50% (compared with no antiplatelet therapy) in patients with NSTEMI ACS.⁸⁶ Therefore, ASA remains the cornerstone of early treatment for all ACS. Dosing of ASA for NSTEMI ACS is the same as that for STEMI (Table 8–2). Low-dose ASA is continued indefinitely.

► Anticoagulants

The choice of anticoagulant for a patient with NSTEMI ACS is guided by risk stratification and initial treatment strategy, either an early invasive approach with early coronary angiography and PCI or an early conservative strategy with angiography in selected patients guided by relief of symptoms

and stress testing (Fig. 8–3). For patients treated by an early invasive strategy, UFH, enoxaparin, or bivalirudin should be administered.⁶ In a large open-label, randomized clinical trial evaluating bivalirudin versus UFH or enoxaparin plus a GP IIb/IIIa inhibitor (abciximab, eptifibatide, or tirofiban) in moderate- and high-risk patients with NSTEMI ACS undergoing an early invasive strategy, bivalirudin demonstrated similar efficacy in preventing CV ischemic events but a lower bleeding rate.⁸⁷ Similarly, in a recent smaller randomized trial specifically comparing abciximab plus UFH with bivalirudin for patients with NSTEMI MI undergoing PCI, no differences in clinical outcomes but a lower bleeding risk with bivalirudin was observed.⁸⁸

In patients in whom an initial conservative strategy is planned (i.e., they are not anticipated to receive angiography and revascularization), enoxaparin, UFH, or low-dose fondaparinux is recommended.⁶ UFH and LMWH when added to ASA reduce the frequency of death or MI in patients presenting with NSTEMI ACS compared with control/placebo in patients primarily managed with a conservative strategy.^{89,90} Compared with enoxaparin, fondaparinux showed similar ischemic outcomes with a lower bleeding rate in a large randomized trial of patients with NSTEMI ACS primarily managed with a conservative strategy.⁹¹ For patients presenting with NSTEMI ACS in whom clinicians suspect a high risk for bleeding while receiving an anticoagulant, fondaparinux is the preferred anticoagulant recommended by the ACCF/AHA NSTEMI ACS guidelines.⁶ Bivalirudin has not been studied for initial therapy in this setting. If fondaparinux is chosen for a patient initially receiving a conservative strategy who subsequently undergoes angiography and PCI, it should be administered in combination with UFH (and not as the sole anticoagulant) because the dose of fondaparinux studied appears too low to prevent thrombotic events during PCI.⁶ Neither fondaparinux or bivalirudin are FDA approved for NSTEMI ACS despite being recommended by the ACCF/AHA NSTEMI ACS guidelines. Guideline-recommended dosing and contraindications are described in Table 8–2.

Therapy should be continued for at least 48 hours for UFH, until the patient is discharged from the hospital (or 8 days, whichever is shorter) for either enoxaparin or fondaparinux, and until the end of PCI or angiography procedure (or up to 72 hours following PCI) for bivalirudin.² UFH is the preferred anticoagulant following angiography in patients subsequently undergoing CABG during the same hospitalization because it has a short duration of action following discontinuation when the patient is proceeding to surgery.⁷ Because enoxaparin is eliminated renally and patients with renal insufficiency generally have been excluded from clinical trials, some practice protocols recommend UFH for patients with CrCl rates of less than 30 mL/min (0.50 mL/s) based on total patient body weight using the Cockcroft-Gault equation.⁷ Although recommendations for dosing adjustment of enoxaparin in patients with CrCl between 10 and 30 mL/min (0.17 and 0.50 mL/s) are listed in the product manufacturer's label, the safety and efficacy

of enoxaparin in this patient population remain vastly understudied. Administration of enoxaparin should be avoided in dialysis patients with ACS. It is unclear whether or not bivalirudin requires dose adjustment for patients with significant renal dysfunction. Although bivalirudin is eliminated renally, the duration of infusion in recent trials has been short (several hours only), and therefore the actual need for dosing adjustment is unlikely. Practice guidelines recommend manufacturer's suggesting dosing adjustment for patients with chronic kidney disease.⁸ Patients with serum creatinine (SCr) greater than 3.0 mg/dL (265 μmol/L) were excluded from ACS trials with fondaparinux, and the product label states that fondaparinux is contraindicated in patients with CrCl less than 30 mL/min (0.50 mL/s) and in patients weighing less than 50 kg (110 lb).

UFH is monitored and the dose adjusted to a target activated partial thromboplastin time (aPTT), whereas enoxaparin is administered by a fixed actual body weight-based dose without routine monitoring of antifactor Xa levels. Some experts recommend antifactor Xa monitoring for LMWHs in patients with renal impairment during prolonged courses of administration of more than several days. No monitoring of coagulation is recommended for bivalirudin and fondaparinux.

► P2Y₁₂ Inhibitors

- Figure 8–4 delineates the role of different P2Y₁₂ inhibitors in ACS. For patients with NSTEMI ACS where an initial invasive management strategy is selected, two initial options for dual antiplatelet therapy are described by the practice guidelines depending on choice of P2Y₁₂ inhibitor. In addition to ASA administered either prehospital or in the emergency department, either

1. Early use of clopidogrel⁶ or ticagrelor⁶⁶ (in the emergency department), or
2. Double bolus dose eptifibatide or high-dose tirofiban administered at the time of PCI (bivalirudin should not be administered as the anticoagulant in this option)⁶

- Subsequent antiplatelet therapy following PCI is selected based on the coronary anatomy at the time of angiography. For patients undergoing PCI initially treated with regimen 1 above, a GP IIb/IIIa inhibitor (abciximab, eptifibatide, or tirofiban) can be added and then clopidogrel continued with low-dose aspirin. For patients undergoing PCI initially treated with option 2, clopidogrel, prasugrel, or ticagrelor can be selected following PCI (within 1 hour following PCI) and the P2Y₁₂ inhibitor continued with low-dose ASA. In a subgroup of patients undergoing PCI enrolled in a large clinical trial evaluating clopidogrel versus placebo added to ASA in patients with NSTEMI ACS, clopidogrel reduced the frequency of death or MI by 30%.⁹² In the large pivotal trials of prasugrel versus clopidogrel and ticagrelor versus clopidogrel (PLATO), no added benefit of the newer P2Y₁₂ inhibitors was observed in the subgroup of patients with NSTEMI ACS undergoing PCI.^{58,61} Following PCI in ACS, dual oral antiplatelet therapy is continued for at least 12 months.⁶

For patients receiving an initial conservative treatment strategy, the 2011 ACCF/AHA NSTEMI ACS guidelines recommend early administration of clopidogrel (a 300-mg loading dose followed by 75 mg daily) in addition to ASA. The subgroup of medically managed patients in a large trial of clopidogrel in patients with NSTEMI ACS demonstrated a 20% reduction in the risk of CV death, MI, or stroke compared with aspirin alone, a benefit similar to that seen in patients undergoing PCI.⁹³ Ticagrelor is an alternative in medically managed patients as described in the section “Early Pharmacotherapy for STE MI.”^{62,66} Dual antiplatelet therapy is continued for at least 1 month and ideally for 1 year.

Specific dosing and contraindications of the P2Y₁₂ inhibitors are described in Table 8–2.

► Glycoprotein IIb/IIIa Receptor Inhibitors

- The role of GP IIb/IIIa inhibitors in NSTEMI ACS is diminishing as P2Y₁₂ inhibitors are used earlier in therapy, and bivalirudin is selected more commonly as the anticoagulant in patients receiving an early intervention approach. See the preceding section (P2Y₁₂ inhibitors) that includes the selection and timing of GP IIb/IIIa inhibitors in patients with NSTEMI ACS undergoing PCI.^{6,8} Routine administration of eptifibatide (added to aspirin and clopidogrel) prior to angiography and PCI (i.e., “upstream” use) in NSTEMI ACS does not reduce ischemic events and increases bleeding risk.⁹⁴ Therefore, the two antiplatelet initial therapy options, described in the previous section, are preferred.⁶

For low-risk patients where a conservative management strategy is selected, there is no role for routine GP IIb/IIIa inhibitors because the bleeding risk exceeds the benefit.⁶ For patients in whom an initial conservative strategy was selected but who experience recurrent ischemia (chest discomfort and ECG changes), HF, or arrhythmias after initial medical therapy necessitating a change in strategy to angiography and revascularization, a GP IIb/IIIa inhibitor may be added to ASA and clopidogrel prior to the angiogram.⁶

Doses and contraindications to GP IIb/IIIa receptor inhibitors are described in Table 8–2.

► Nitrates

- SL NTG followed by IV NTG should be administered to patients with NSTEMI ACS and ongoing ischemia, HF, or uncontrolled high BP (Table 8–2). The mechanism of action, dosing, contraindications, and adverse effects are the same as those described in the section on early pharmacologic therapy for STE MI. IV NTG is typically continued for approximately 24 hours following ischemia relief.

► β-Blockers

- The use of β-blockers in NSTEMI ACS is similar to STE MI in that oral β-blockers should be initiated within 24 hours of hospital admission to all patients in the absence of contraindications. Benefits of β-blockers in this patient

group are assumed to be similar to those seen in patients with STE MI. β -Blockers are continued indefinitely. The prescription of a β -blocker at hospital discharge used to be reported as a quality measure.

► Calcium Channel Blockers

As described in the previous section, calcium channel blockers should not be administered to most patients with ACS. Their role is a second-line treatment for patients with certain contraindications to β -blockers and those with continued ischemia despite β -blocker and nitrate therapy. Administration of amlodipine, diltiazem, or verapamil is preferred.⁵

Secondary Prevention Following MI

The long-term goals following MI are to (a) control modifiable CHD risk factors; (b) prevent the development of HF; (c) prevent recurrent MI and stroke; (d) prevent death, including sudden cardiac death; and (e) prevent stent thrombosis following PCI. Pharmacotherapy, which has been proven to decrease mortality, HF, reinfarction or stroke, and stent thrombosis, should be initiated prior to hospital discharge for secondary prevention. **8** *Secondary prevention guidelines from the ACCF/AHA suggest that following MI, from either STE MI or NSTEMI ACS, all patients, in the absence of contraindications, should receive indefinite treatment with ASA, a β -blocker, and an angiotensin-converting enzyme (ACE) inhibitor for secondary prevention of death, stroke, or recurrent infarction.⁴⁶ Most patients will receive a statin to reduce low-density lipoprotein cholesterol to less than 100 mg/dL (2.59 mmol/L) and ideally to less than 70 mg/dL (1.81 mmol/L). A P2Y₁₂ inhibitor should be continued for at least 12 months for patients undergoing PCI and for patients with NSTEMI ACS receiving a medical management strategy of treatment.^{3,6} Clopidogrel should be continued for at least 14 days in patients with STE MI not undergoing PCI.⁸ An angiotensin II receptor blocker (ARB) and a mineralocorticoid receptor antagonist should be given to selected patients as discussed in greater detail later in the chapter.⁴⁶ For all patient with ACS, treatment and control of modifiable risk factors such as hypertension (HTN), dyslipidemia, obesity, smoking, and DM are essential.⁴⁶ Dosing and contraindications are described in detail in Table 8–2. Benefits and adverse effects of long-term treatment with these medications are discussed in more detail later. Use of ICDs for the prevention of sudden cardiac death following MI in patients with diminished LVEF and nonsustained ventricular arrhythmias is discussed in more detail in Chapter 9, “Arrhythmias.”*

► Aspirin

ASA decreases the risk of death, recurrent infarction, and stroke following MI. All patients should receive ASA indefinitely; those patients with a contraindication to ASA should receive clopidogrel.⁴⁶ The risk of major bleeding

from chronic ASA therapy is approximately 2% and is dose related. Higher doses of ASA, 160 to 325 mg, are not more effective than ASA doses of 75 to 81 mg but have higher rates of bleeding.⁹⁵ Therefore, chronic doses of ASA should not exceed 81 mg.^{8,46}

► P2Y₁₂ Inhibitors

For patients with either STE MI or NSTEMI ACS, clopidogrel decreases the risk of CV events and stent thrombosis compared with placebo. Compared with clopidogrel, either prasugrel or ticagrelor lowers the risk of CV death, MI, or stroke by an additional 20% to 30% depending on the patient population studied. The frequency of stent thrombosis following PCI is also lower with prasugrel or ticagrelor compared with clopidogrel. However, the rate of non-CABG surgery-associated bleeding is higher with both prasugrel and ticagrelor compared with clopidogrel. The ACCF/AHA/SCAI PCI guidelines recommend that for patients with ACS, a P2Y₁₂ inhibitor should be continued for at least 12 months following PCI. For medically managed patients with STE MI, clopidogrel should be continued for at least 14 days and up to 1 year.³ For medically managed NSTEMI ACS patients, clopidogrel should be continued at least 1 month and ideally up to 1 year.⁶ Ticagrelor has also been studied for medical management of ACS and may be considered an option, although currently it is not a recommended therapy in ACCF/AHA guideline because these guidelines were published prior to the availability of ticagrelor in the United States.⁶²

The combination of clopidogrel and aspirin increases the risk of major bleeding by approximately 50% and minor bleeding by approximately 40% but not fatal bleeding compared with a single agent alone.⁹⁶ Oral antiplatelet agents are the third leading cause of adverse drug reaction-associated hospital admissions after emergency department visits among seniors.⁹⁷ Therefore, patients should be counseled on the risks and sites of potential bleeding and should be told to seek medical care immediately if significant bleeding is noticed.

► β -Blockers, Nitrates, and Calcium Channel Blockers

- Current treatment guidelines recommend that following an ACS, patients should receive a β -blocker indefinitely^{3,6} whether they have residual symptoms of angina or not.⁹⁸ Overwhelming data support the use of β -blockers in patients with a previous MI. Currently, there are no data to support the superiority of one β -blocker over another in the absence of HF.
- Although β -blockers should be avoided in patients with decompensated HF from left ventricular systolic dysfunction complicating an MI, clinical trial data suggest it is safe to initiate β -blockers prior to hospital discharge in these patients once HF symptoms have resolved.⁹⁹ These patients may actually benefit more than those without left ventricular dysfunction.¹⁰⁰ In patients who cannot tolerate or have a

contraindication to a β -blocker, a calcium channel blocker can be used to prevent anginal symptoms but should not be used routinely in the absence of such symptoms.⁴

Finally, all patients should be prescribed short-acting sublingual NTG or lingual NTG spray to relieve any anginal symptoms when necessary and instructed on its use.^{4,6} Chronic long-acting nitrate therapy has not been shown to reduce CHD events following MI. Therefore, IV NTG is not routinely followed by chronic, long-acting oral nitrate therapy in ACS patients who have undergone revascularization, unless the patient has chronic stable angina or significant coronary stenoses that were not revascularized.¹⁰¹

► ACE Inhibitors and ARBs

ACE inhibitors should be initiated in all patients following MI to reduce mortality, decrease reinfarction, and prevent the development of HF.^{3,6,46} The benefit of ACE inhibitors in patients with MI most likely comes from their ability to prevent cardiac remodeling. The largest reduction in mortality is observed in patients with left ventricular dysfunction (low LVEF) or HF symptoms. Early initiation (within 24 hours) of an oral ACE inhibitor appears to be crucial during an acute MI because 40% of the 30-day survival benefit is observed during the first day, 45% from days 2 to 7, and approximately 15% from days 8 to 30.¹⁰² However, current data do not support the early administration of IV ACE inhibitors in patients experiencing an MI because mortality may be increased.¹⁰³ Administration of ACE inhibitors should be continued indefinitely. Hypotension should be avoided because coronary artery filling may be compromised. Additional trials suggest that most patients with CAD, not just ACS or HF patients, benefit from ACE inhibitors. Therefore, ACE inhibitors should be considered in all patients following an ACS in the absence of a contraindication.

Many patients cannot tolerate chronic ACE inhibitor therapy secondary to adverse effects. The ARBs candesartan, valsartan, and losartan have been documented in trials to improve clinical outcomes in patients with HF.^{104,105} Therefore, either an ACE inhibitor or candesartan, valsartan or losartan are acceptable choices for chronic therapy for patients who have a low LVEF and HF following MI.

Besides hypotension, the most frequent adverse reaction to an ACE inhibitor is cough, which may occur in up to 30% of patients. Patients with an ACE inhibitor cough and either clinical signs of HF or LVEF less than 40% (0.40) may be prescribed an ARB.⁴⁶ Other, less common but more serious adverse effects of ACE inhibitors and ARBs include acute renal failure, hyperkalemia, and angioedema.

► Mineralocorticoid Receptor Antagonists

To reduce mortality, administration of a mineralocorticoid receptor antagonist, either eplerenone or spironolactone, should be considered within the first 2 weeks following MI in all patients who are already receiving an ACE inhibitor (or ARB) and a β -blocker and have an LVEF equal to or less than 40% (0.40) and either HF

symptoms or DM.⁴⁶ Aldosterone plays an important role in HF and in MI because it promotes vascular and myocardial fibrosis, endothelial dysfunction, HTN, left ventricular hypertrophy, sodium retention, potassium and magnesium loss, and arrhythmias. Mineralocorticoid receptor antagonists have been shown in experimental and human studies to attenuate these adverse effects.¹⁰⁶ Spironolactone decreases all-cause mortality in patients with stable severe HF.¹⁰⁷

Eplerenone, like spironolactone, is an aldosterone antagonist that blocks the mineralocorticoid receptor. In contrast to spironolactone, eplerenone has no effect on the progesterone or androgen receptor, thereby minimizing the risk of gynecomastia, sexual dysfunction, and menstrual irregularities. In a large clinical trial,¹⁰⁸ eplerenone significantly reduced mortality as well as hospitalization for HF in post-MI patients with an LVEF less than 40% (0.40) and symptoms of HF at any time during hospitalization. Eplerenone has also been demonstrated to reduce mortality in patients with mild systolic HF.¹⁰⁹ The risk of hyperkalemia, however, was increased in both these studies.

Therefore, patients with a SCr greater than 2.5 mg/dL (221 μ mol/L) or CrCl less than 50 mL/min (0.83 mL/s) or serum potassium concentration of greater than 5.0 mmol/L (5.0 mEq/L) should not receive eplerenone (in addition to either an ACE inhibitor or ARB). Currently, there are no data to support that the more selective, more expensive eplerenone is superior to, or should be preferred to, the less expensive generic spironolactone unless a patient has experienced gynecomastia, breast pain, or impotence while receiving spironolactone. Finally, it should be noted that hyperkalemia is just as likely to appear with both of these agents, and it is more common in patients receiving concomitant ACE inhibitors.

► Lipid-Lowering Agents

Following MI, statins reduce total mortality, CV mortality, and stroke. According to the National Cholesterol Education Program (NCEP) Adult Treatment Panel recommendations, all patients with CAD should receive dietary counseling and pharmacologic therapy in order to reach a low-density lipoprotein (LDL) cholesterol of less than 100 mg/dL (2.59 mmol/L), with statins the preferred agents to lower LDL cholesterol.¹¹⁰ Results from landmark clinical trials have unequivocally demonstrated the value of statins in secondary prevention following MI. A meta-analysis of randomized controlled clinical trials in almost 18,000 patients with recent ACS (less than 14 days) found that statin therapy reduces mortality by 19%, with benefits observed after approximately 4 months of treatment.¹¹¹ Although the primary effect of statins is to decrease LDL cholesterol, statins are believed to produce many non-lipid-lowering or “pleiotropic” effects such as anti-inflammatory and antithrombotic properties. Additional recommendations from the NCEP give an optional LDL cholesterol goal of less than 70 mg/dL (1.81 mmol/L).¹¹² The current evidence indicates that

higher-dose statin therapy, such as atorvastatin 40 to 80 mg daily and rosuvastatin 10 to 20 mg daily, produces greater reduction in CV events such as MI, ischemic stroke, and revascularization than less intensive statin regimens (such as simvastatin 20 to 40 mg daily).¹¹³ Moreover, the administration of high-dose statins prior to PCI may reduce the risk of periprocedural MI, and hence statins should be initiated as early as possible in ACS.⁸

A fibrate derivative, niacin, or fish oil may be considered in patients with an elevated non-high-density lipoprotein cholesterol level despite maximally tolerated statin therapy, although the benefits of this management strategy remain largely unproven.⁴⁶ In a large randomized trial of men with established CAD and low levels of high-density lipoprotein (HDL) cholesterol, the use of gemfibrozil (600 mg twice daily, alone and not added to a statin) significantly decreased the risk of nonfatal MI or death from coronary causes.¹¹⁴ Studies with fenofibrate and niacin have produced less definitive results.^{115,116}

► Other Modifiable Risk Factors

Smoking cessation, managing HTN, weight loss, exercise, and tight glucose control for patients with DM, in addition to treatment of dyslipidemia, are important treatments for secondary prevention of CHD events.⁴⁶ Referral to a comprehensive CV risk reduction program for cardiac rehabilitation is recommended.⁴⁶ The use of nicotine patches or gum, or of bupropion alone or in combination with nicotine patches, should be considered in appropriate patients.³ HTN should be strictly controlled according to published guidelines.⁴⁶ Patients who are overweight should be educated on the importance of regular exercise, healthy eating habits, and reaching and maintaining an ideal weight. Moderate-intensity aerobic exercise for at least 30 minutes, 7 days per week (minimum 5 days per week) is recommended.⁴⁶ The goal body mass index is less than 25 kg/m². Finally, because patients with DM have up to a fourfold increased mortality risk compared with patients without DM, the importance of blood glucose control, as well as other CHD risk factor modifications, cannot be overstated.⁴⁶

Patient Encounter 1, Part 3

Identify the long-term treatment goals for RR.

What additional pharmacotherapy should be initiated prior to hospital discharge?

Create a care plan for RR for hospital discharge that includes pharmacotherapy, desired treatment outcomes, and monitoring for efficacy and adverse effects.

Patient Encounter 2, Part 3

Patient SD undergoes coronary angiography and PCI with a drug-eluting stent placed for a 90% stenosis in his left anterior descending coronary artery on hospital day 1.

Identify the long-term treatment goals for SD.

What additional pharmacotherapy should be initiated prior to hospital discharge?

Create a care plan for SD for hospital discharge that includes pharmacotherapy, desired treatment outcomes, and monitoring for efficacy and adverse effects.

OUTCOME EVALUATION

- **9** To determine the efficacy of nonpharmacologic and pharmacotherapy for both STE and NSTEMI ACS, monitor patients for (a) relief of ischemic discomfort; (b) return of ECG changes to baseline; and (c) absence or resolution of HF signs and symptoms.
- Monitoring parameters for recognition and prevention of adverse effects from ACS pharmacotherapy are described in **Table 8–5**. **9** In general, the most common adverse reactions from ACS therapies are hypotension and bleeding. To treat for bleeding and hypotension, discontinue the offending agent(s) until symptoms resolve. Severe bleeding resulting in hypotension secondary to hypovolemia may require blood transfusion.
- Because poor medication adherence of secondary prevention medications following MI leads to worsened CV outcomes, patients should receive medication counseling (including counseling prior to hospital discharge) and be monitored for medication persistence.^{8,117} Counseling should include assessment of health literacy level, assessment of barriers to adherence, assessment of access to medications, written and verbal instructions about the purpose of each medication, changes to previous medication regimen, optimal time to take each medication, new allergies or medication intolerances, need for timely prescription fill after discharge, anticipated duration of therapy, consequences of nonadherence, common and/or serious adverse reactions that may develop, drug–drug and drug–food interactions, and an assessment of instruction understanding).
- Process of care quality performance measures for MI endorsed by the AHA and Centers for Medicare and Medicaid Services are described in **Table 8–6**.^{32,118}

Table 8-5

Therapeutic Drug Monitoring for Adverse Effects of Pharmacotherapy for Acute Coronary Syndromes

Drug	Adverse Effects	Monitoring
Aspirin	Dyspepsia, bleeding, gastritis	Clinical signs of bleeding ^a ; GI upset; baseline CBC and platelet count; CBC platelet count every 6 months
Clopidogrel and prasugrel	Bleeding, diarrhea, rash, TTP (rare)	Clinical signs of bleeding ^a ; baseline CBC and platelet count; CBC and platelet count every 6 months following hospital discharge
Ticagrelor	Bleeding, dyspnea, diarrhea, rash, elevated SCr, elevated serum uric acid	Clinical signs of bleeding ^a ; baseline CBC and platelet count; CBC and platelet count every 6 months following hospital discharge
Unfractionated heparin	Bleeding, heparin-induced thrombocytopenia	Clinical signs of bleeding ^a ; baseline aPTT, INR, CBC, and platelet count; aPTT every 6 hours until target then every 24 hours; daily CBC; platelet count every 2–3 days from days 4 to 14 until heparin is stopped (minimum, preferably every day)
Enoxaparin	Bleeding, heparin-induced thrombocytopenia	Clinical signs of bleeding ^a ; baseline SCr, aPTT, INR, CBC, and platelet count; daily CBC, no routine platelet count monitoring unless recent UFH (less than 100 days) then baseline and within 24 hours; daily CBC and SCr
Fondaparinux	Bleeding	Clinical signs of bleeding ^a ; baseline SCr, aPTT, INR, CBC, and platelet count; daily CBC and SCr
Bivalirudin	Bleeding	Clinical signs of bleeding ^a ; baseline SCr, aPTT, INR, CBC, and platelet count
Fibrinolytics	Bleeding, especially intracranial hemorrhage	Clinical signs of bleeding ^a ; baseline aPTT, INR, CBC, and platelet count; mental status every 2 hours for signs of intracranial hemorrhage; daily CBC
Glycoprotein IIb/IIIa receptor inhibitors	Bleeding, acute profound thrombocytopenia	Clinical signs of bleeding ^a ; baseline SCr (for eptifibatide and tirofiban), CBC, and platelet count; platelet count at 4 hours after initiation; daily CBC (and SCr for eptifibatide and tirofiban)
IV nitrates	Hypotension, flushing, headache, tachycardia	BP and HR every 2 hours
β -Blockers	Hypotension, bradycardia, heart block, bronchospasm, acute heart failure, fatigue, depression, sexual dysfunction	BP, RR, HR, 12-lead ECG, and clinical signs of heart failure every 5 minutes during bolus IV dosing; BP, RR, HR, and clinical signs of heart failure every shift during oral administration during hospitalization, then BP and HR every 6 months following hospital discharge
Diltiazem and verapamil	Hypotension, bradycardia, heart block, heart failure, gingival hyperplasia	BP and HR every shift during oral administration during hospitalization, then every 6 months following hospital discharge; dental examination and teeth cleaning every 6 months
Amlodipine	Hypotension, dependent peripheral edema, gingival hyperplasia	BP every shift during oral administration during hospitalization, then every 6 months following hospital discharge; dental examination and teeth cleaning every 6 months
Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs)	Hypotension, cough (with ACE inhibitors), hyperkalemia, prerenal azotemia, acute renal failure, angioedema (ACE inhibitors more so than ARBs)	BP every 4 hours \times 3 for first dose, then every shift during oral administration during hospitalization, then once every 6 months following hospital discharge; baseline SCr and potassium; daily SCr and potassium while hospitalized, then every 6 months (or 1–2 weeks after each outpatient dose titration); closer monitoring required in selected patients using spironolactone or eplerenone or if renal insufficiency; counsel patient on throat, tongue, and facial swelling
Mineralocorticoid receptor antagonists	Hypotension, hyperkalemia, increased SCr	BP and HR every shift during oral administration during hospitalization, then once every 6 months; baseline SCr and serum potassium concentration; SCr and potassium at 48 hours, at 7 days, then monthly for 3 months, then every 3 months thereafter following hospital discharge
Morphine	Hypotension, respiratory depression	BP and RR 5 minutes after each bolus dose
Statins	GI upset, myopathy, hepatotoxicity	Liver function tests at baseline, at 6 weeks following initiation, and after titration to highest dose, then annually thereafter; counsel patient on myalgia; consider creatinine kinase at baseline if adding a fibrate or niacin

^aClinical signs of bleeding include bloody stools, melena, hematuria, hematemesis, bruising, and oozing from arterial or venous puncture sites.

ACE, angiotensin-converting enzyme; aPTT, activated partial thromboplastin time; ARB, angiotensin receptor blocker; BP, blood pressure; CBC, complete blood count; ECG, electrocardiogram; HR, heart rate; INR, international normalized ratio; RR, respiratory rate; SCr, serum creatinine, TTP, thrombotic thrombocytopenic purpura.

Table 8–6

Process of Care Quality Performance Measures for Myocardial Infarction^{32,118}

- Median time to initial ECG (desired less than or equal to 10 minutes)^a
- Aspirin at hospital arrival.^{a,b}
- Fibrinolytic medication within 30 minutes of hospital arrival for STE MI (“door-to-needle” time)^{a,b}
- Median time to fibrinolysis^a
- PCI received within 90 minutes of hospital arrival for STE MI^{a,b}
- Median time to transfer to another facility for PCI (“door in door out time” desired is less than or equal to 30 minutes)^{a,b}
- Percentage of eligible patients with STE MI receiving reperfusion therapy with either fibrinolytics or PCI^b
- Aspirin at hospital discharge^{a,b}
- ACE Inhibitor or ARB for systolic dysfunction at hospital discharge^{a,b}
- β -Blocker at hospital discharge^{a,b}
- Smoking cessation advice/counseling^{a,b}
- Statin at hospital discharge^b
- Evaluation of LV function^b
- Cardiac rehabilitation referral^b

^a2010 Center for Medicare and Medicaid Services process of care measures for myocardial infarction.

^bAmerican Heart Association 2008 myocardial infarction performance measure.

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; ECG, electrocardiogram; LV, left ventricular; MI, myocardial infarction; PCI, percutaneous coronary intervention; STE, ST-segment elevation.

Patient Care and Monitoring

For patients in acute distress and ACS is suspected:

- Follow recommendations in Figures 8–1 and 8–2 and Table 8–2. Also incorporate into your plan the recommendations detailed below under “For patients diagnosed with ACS.”

For patients diagnosed with ACS:

1. Review patient’s medical record to determine indications for each medication.
2. Review patient’s medical record to determine contraindications for each medication. For ASA, β -blockers, ACE inhibitors, and ARBs, document contraindications in patient’s medical record.
3. Review doses of medications for appropriateness. Titration toward target doses of ACE inhibitors and β -blockers should be in progress. Evaluate if the dose of ASA may be reduced to less than 100 mg if no recent stent.
4. Interview the patient to assess health literacy, prescription medications, and complementary or alternative medication use.
5. Evaluate the patient’s medical record and medication history, and conduct a patient interview to assess for the presence of drug allergies, adverse drug reactions, drug interactions, and medication adherence.
6. Educate the patient and evaluate their success with lifestyle modifications including smoking cessation,

diet, weight loss, and exercise. For patients with DM, appropriate blood glucose control should be emphasized.

7. Provide patient education with regard to CAD, MI, indications for medications, and potential adverse effects and drug interactions.
 - What is CAD?
 - How can the progression of CAD and MI be prevented?
 - How does each medication benefit the patient?
 - Why is adherence important?
 - What potential adverse effects may occur?
 - What potential drug interactions may occur?
 - Warning signs to report to the physician or emergency medical services include chest squeezing, burning, or pain; jaw pain; pain radiation down the arm; bleeding; and loss of consciousness.
 - Dial 911 if there is no chest discomfort relief after one SL NTG tablet.
 - Important to train caregiver or relative to administer cardiopulmonary resuscitation (CPR).
8. Document smoking cessation counseling and patient receipt of discharge instructions in the patient’s medical record.

Abbreviations Introduced in This Chapter

ABCB1	ATP-binding cassette B1
ACC	American College of Cardiology
ACCF	American College of Cardiology Foundation
ACE	Angiotensin-converting enzyme
ACS	Acute coronary syndrome
ACT	Activated clotting time
ADP	Adenosine diphosphate
AHA	American Heart Association
AMI	Acute myocardial infarction
aPTT	Activated partial thromboplastin time
ARB	Angiotensin receptor blocker
ASA	Aspirin
ATP	Adenosine triphosphate
AUC	Area under the curve
BP	Blood pressure
CABG	Coronary artery bypass graft (surgery)
CAD	Coronary artery disease
CBC	Complete blood count
CHD	Coronary heart disease
CK	Creatine kinase
CKD	Chronic kidney disease
COX-2	Cyclooxygenase-2
CPR	Cardiopulmonary resuscitation
CrCl	Creatinine clearance
CV	Cardiovascular
CVD	Cardiovascular disease
CYP	Cytochrome P450
DM	Diabetes mellitus
ECG	Electrocardiogram
EF	Ejection fraction
GP	Glycoprotein
GRACE	Global Registry of Acute Coronary Events
GWTG	Get With the Guidelines
HDL	High-density lipoprotein
HF	Heart failure
HORIZONS-AMI	Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction
HR	Heart rate
HTN	Hypertension
ICD	Implantable cardioverter defibrillator
ICH	Intracranial hemorrhage
INR	International normalized ratio
ISIS-2	Second International Study of Infarct Survival
LDL	Low-density lipoprotein
LMWH	Low molecular weight heparin
LVEF	Left ventricular ejection fraction
LVF	Left ventricular function
MB	Myocardial band
MI	Myocardial infarction

NCEP	National Cholesterol Education Program
NSAID	Nonsteroidal anti-inflammatory drug
NSTE	Non-ST-segment elevation
NTG	Nitroglycerin
PCI	Percutaneous coronary intervention
PLATO	Study of Platelet Inhibition and Patient Outcomes
RR	Respiratory rate
SCAI	Society for Cardiovascular Angiography and Interventions
SCr	Serum creatinine
SC	Subcutaneous
SL	Sublingual
STE	ST-Segment elevation
TIA	Transient ischemic attack
TIMI	Thrombolysis in myocardial infarction
TTP	Thrombotic thrombocytopenia purpura
TXA ₂	Thromboxane A ₂
UA	Unstable angina
UFH	Unfractionated heparin

9 Arrhythmias

James E. Tisdale

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Describe the phases of the cardiac action potential, compare and contrast the cellular ionic changes corresponding to each phase, and explain the relationship between the cardiac action potential and the electrocardiogram (ECG).
2. Describe the modified Vaughan Williams classification of antiarrhythmic drugs, and compare and contrast the effects of available antiarrhythmic drugs on ventricular conduction velocity, refractory period, automaticity, and inhibition of ion flux through specific myocardial ion channels.
3. Compare and contrast the risk factors for and the features, mechanisms, etiologies, symptoms, and goals of therapy of (a) sinus bradycardia, (b) atrioventricular (AV) nodal blockade, (c) atrial fibrillation (AF), (d) paroxysmal supraventricular tachycardia (PSVT), (e) ventricular premature depolarizations (VPDs), (f) ventricular tachycardia (VT, including torsades de pointes), and (g) ventricular fibrillation (VF).
4. Compare and contrast appropriate nonpharmacologic and pharmacologic treatment options for sinus bradycardia and AV nodal blockade.
5. Compare and contrast the mechanisms of action of drugs used for ventricular rate control, conversion to sinus rhythm and maintenance of sinus rhythm in patients with AF, and explain the importance of anticoagulation for patients with AF.
6. Discuss nonpharmacologic methods for termination of PSVT, and compare and contrast the mechanisms of action of drugs used for acute termination of PSVT.
7. Compare and contrast the role of drug therapy versus nonpharmacologic therapy for long-term prevention of recurrence of PSVT.
8. Describe the role of drug therapy for management of asymptomatic and symptomatic VPDs.
9. Compare and contrast the mechanisms of action of drugs used for the treatment of acute episodes of VT (including torsades de pointes), and describe options and indications for nonpharmacologic treatment of VT and VF.
10. Design individualized drug therapy treatment plans for patients with (a) sinus bradycardia, (b) AV nodal blockade, (c) AF, (d) PSVT, (e) VPDs, (f) VT (including torsades de pointes), and (g) VF.

KEY CONCEPTS

- 1 Cardiac arrhythmias may be caused by abnormal impulse formation (automaticity), abnormal impulse conduction (reentry), or both.
- 2 Numerous drugs (β -blockers, diltiazem, verapamil, digoxin, dronedarone, and amiodarone) can cause bradyarrhythmias (sinus bradycardia and/or atrioventricular [AV] nodal blockade).
- 3 Individualized goals of treatment for atrial fibrillation (AF) include (a) ventricular rate control with drugs that inhibit AV nodal conduction, (b) restoration of sinus rhythm with direct current cardioversion or antiarrhythmic drugs (commonly referred to as “cardioversion” or “conversion to sinus rhythm”), (c) maintenance of sinus rhythm/reduction in the frequency of episodes, and (d) prevention of stroke.
- 4 Antiarrhythmic drug therapy for maintenance of sinus rhythm/reduction in frequency of episodes of AF should be initiated only in patients in whom symptoms persist despite maximal tolerated doses of appropriate drugs for ventricular rate control.
- 5 Most patients with AF require therapy with dabigatran or warfarin for stroke prevention; in some patients with

no additional risk factors for stroke, anticoagulation may not be necessary.

- 6 Adenosine is the drug of choice for termination of paroxysmal supraventricular tachycardia.
- 7 Asymptomatic ventricular premature depolarizations (VPDs) should not be treated with antiarrhythmic drug therapy.
- 8 Implantable cardioverter defibrillators are more effective than antiarrhythmic drugs for reduction in the risk of sudden cardiac death due to ventricular tachycardia (VT) or ventricular fibrillation (VF).
- 9 The purpose of drug therapy for VF is facilitation of electrical defibrillation; in the absence of electrical defibrillation, drug therapy alone will not terminate VF.
- 10 Drugs with the potential to cause QT interval prolongation and torsades de pointes should be avoided or used with extreme caution in patients with other risk factors for torsades de pointes.

NORMAL AND ABNORMAL CARDIAC CONDUCTION AND ELECTROPHYSIOLOGY

The heart functions via both mechanical and electrical activity. The mechanical activity of the heart refers to atrial and ventricular contraction, the mechanism by which blood is delivered to tissues. When circulated blood returns to the heart via the venous circulation, the blood enters the right atrium. Right atrial contraction and changes in right ventricular pressure result in delivery of blood to the right ventricle through the tricuspid valve. Right ventricular contraction pumps blood through the pulmonary valve through the pulmonary arteries to the lungs, where the blood becomes oxygenated. The blood then flows through the pulmonary veins into the left atrium. Left atrial contraction and changes in left ventricular (LV) pressure result in delivery of blood through the mitral valve into the left ventricle. Contraction of the left ventricle results in pumping of blood through the aortic valve and to the tissues of the body.

The mechanical activity of the heart (contraction of the atria and ventricles) occurs as a result of the electrical activity of the heart. The heart possesses an intrinsic electrical conduction system (Fig. 9–1).¹ Normal myocardial contraction cannot occur without proper and normal function of the heart's electrical conduction system. Depolarization of the atria results in atrial contraction, and ventricular depolarization is followed by ventricular contraction. Malfunction of the heart's electrical conduction system may result in dysfunctional atrial and/or ventricular contraction and may reduce cardiac output.

The Cardiac Conduction System

Under normal circumstances, the sinoatrial (SA) node (also known as the sinus node), located in the upper portion of the right atrium, serves as the **pacemaker** of the heart and generates

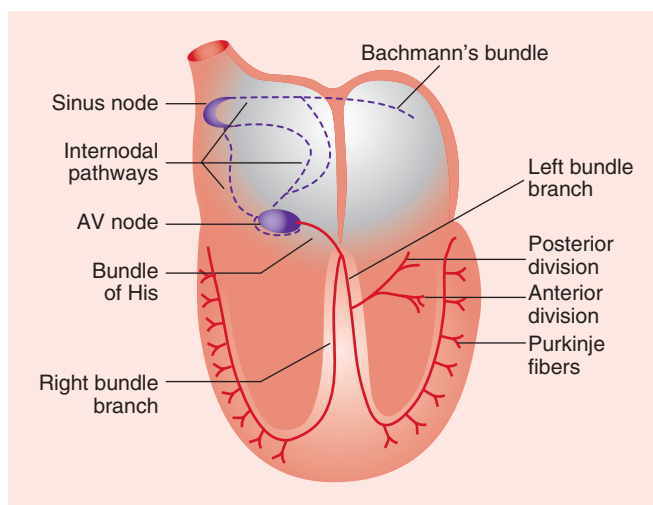

FIGURE 9-1. The cardiac conduction system. (AV, atrioventricular.)

the electrical impulses that subsequently result in atrial and **ventricular depolarization** (Fig. 9–1).¹ The SA node serves as the heart's dominant pacemaker because it has the greatest degree of **automaticity**, which is defined as the ability of a cardiac fiber or tissue to initiate depolarizations spontaneously. In adults at rest, the normal intrinsic depolarization rate of the SA node is 60 to 100 per minute. Other cardiac fibers also possess the property of automaticity, but normally the intrinsic depolarization rates are slower than that of the SA node. For example, the normal intrinsic depolarization rate of the atrioventricular (AV) node is 40 to 60 per minute; that of the ventricular tissue is 30 to 40 per minute. Therefore, because of greater automaticity, the SA node normally serves as the pacemaker of the heart. However, if the SA node fails to generate depolarizations at a rate faster than that of the AV node, the AV node may take over as the pacemaker. Similarly, if the SA node and AV node fail to generate depolarizations at a rate greater than 30 to 40 per minute, ventricular tissue may take over as the pacemaker.

Following initiation of the electrical impulse from the SA node, the impulse travels through the internodal pathways of the specialized atrial conduction system and Bachmann's bundle (Fig. 9–1).¹ The atrial conducting fibers do not traverse the entire breadth of the left and right atria; impulse conduction occurs across the internodal pathways, and when the impulse reaches the end of Bachmann's bundle, atrial depolarization spreads as a wave, conceptually similar to that which occurs upon throwing a pebble into water. As the impulse is conducted across the atria, each depolarized cell excites and depolarizes the surrounding connected cells, until both atria have been completely depolarized. Atrial contraction follows normal atrial depolarization.

Following atrial depolarization, impulses are conducted through the AV node, located in the lower right atrium (Fig. 9–1).¹ The impulse then enters the bundle of His and is conducted through the ventricular conduction system, consisting of the left and right bundle branches. The left ventricle requires a larger conduction system than the right

ventricle due to its larger mass; therefore, the left bundle branch bifurcates into the left anterior and posterior divisions (also commonly known as “fascicles”). The bundle branches further divide into the **Purkinje fibers** through which impulse conduction results in ventricular depolarization, initiating ventricular contraction.

The Ventricular Action Potential

- The ventricular **action potential** is depicted in **Figure 9-2**. Cardiac myocyte resting membrane potential is usually -70 to -90 mV, due to the action of the sodium-potassium adenosine triphosphatase (ATPase) pump, which maintains relatively high extracellular sodium concentrations and relatively low extracellular potassium concentrations. During each action potential cycle, the potential of the membrane slowly increases to a threshold potential due to a slow influx of sodium into the cell, raising the threshold to -60 to -80 mV. When the membrane potential reaches this threshold, the fast sodium channels open, allowing sodium ions to rapidly enter the cell. This rapid influx of positive ions creates a vertical upstroke of the action potential, such that the potential reaches 20 to 30 mV. This is phase 0, which represents ventricular depolarization. At this point, the fast sodium channels become inactivated, and ventricular repolarization begins, consisting of phases 1 through 3 of the action potential. Phase 1 repolarization occurs primarily as a result of an efflux of potassium ions (Fig. 9-2). During phase 2, potassium ions continue to exit the cell, but the membrane potential is balanced by an influx of calcium and sodium ions, transported through slow calcium and slow sodium channels, resulting in a plateau. During phase 3, the efflux of potassium ions greatly exceeds calcium and sodium

influx, resulting in the major component of ventricular repolarization. During phase 4, sodium ions gradually enter the cell increasing the threshold again to -60 to -80 mV and initiating another action potential. An understanding of the ionic fluxes that are responsible for each phase of the action potential facilitates understanding of the effects of specific drugs on the action potential. For example, drugs that primarily inhibit ion flux through sodium channels influence phase 0 (ventricular depolarization), whereas drugs that primarily inhibit ion flux through potassium channels influence the repolarization phases, particularly phase 3.

The Electrocardiogram

The **electrocardiogram** (ECG) is a noninvasive means of measuring the electrical activity of the heart. The relationship between the ventricular action potential and the ECG is depicted in Figure 9-2. The P wave on the ECG represents atrial depolarization (atrial depolarization is not depicted in the action potential shown in Fig. 9-2, which shows only the ventricular action potential). Phase 0 of the action potential corresponds to the QRS complex; therefore, the QRS complex on the ECG is a noninvasive representation of ventricular depolarization. The T wave on the ECG corresponds to phase 3 ventricular repolarization. The interval from the beginning of the Q wave to the end of the T wave, known as the QT interval, is used as a noninvasive marker of ventricular repolarization time. Atrial repolarization is not visible on the ECG because it occurs during ventricular depolarization and is obscured by the QRS complex.

Several intervals and durations are routinely measured on the ECG. The PR interval represents the time of conduction of impulses from the atria to the ventricles through the

FIGURE 9-2. The ventricular action potential depicting the flow of specific ions responsible for each phase. The specific phases of the action potential that correspond to the absolute and relative refractory periods are portrayed, and the relationship between phases of the action potential and the electrocardiogram (ECG) are shown. (Ca, calcium; K, potassium; Na, sodium.)

AV node; the normal PR interval in adults is 0.12 to 0.2 seconds. The QRS duration represents the time required for ventricular depolarization, which is normally 0.08 to 0.12 seconds in adults. The QT interval, measuring 0.32 to 0.4 seconds, represents the time required for ventricular repolarization. The QT interval varies with heart rate—the faster the heart rate, the shorter the QT interval, and vice versa. Therefore, the QT interval is corrected for heart rate using Bazett's equation,² which is:

$$QT_c = \frac{QT}{\sqrt{RR}}$$

where QT_c is the QT interval corrected for heart rate, and RR is the interval from the onset of one QRS complex to the onset of the next QRS complex, measured in seconds (i.e., the heart rate, expressed in different terminology). The normal QT_c interval in adults is 0.36 to 0.47 seconds in men and 0.36 to 0.48 seconds in women.³

Refractory Periods

After an electrical impulse is initiated and conducted, there is a period of time during which cells and fibers cannot be depolarized again. This period of time is referred to as the absolute **refractory period** (Fig. 9–2) and corresponds to phases 1, 2, and approximately a third of phase 3 repolarization of the action potential. The absolute refractory period also corresponds to the period from the Q wave to approximately the first half of the T wave on the ECG (Fig. 9–2). During this period, if there is a premature stimulus for an electrical impulse, this impulse cannot be conducted because the tissue is absolutely refractory. However, there is a period of time following the absolute refractory period during which a premature electrical stimulus can be conducted and is often conducted abnormally. This period of time is called the relative refractory period (Fig. 9–2). The relative refractory period corresponds roughly to the latter two-thirds of phase 3 repolarization on the action potential and to the latter half of the T wave on the ECG. If a new (premature) electrical stimulus is initiated during the relative refractory period, it can be conducted abnormally, potentially resulting in an arrhythmia.

Mechanisms of Cardiac Arrhythmias

① *In general, cardiac arrhythmias are caused by (a) abnormal impulse formation, (b) abnormal impulse conduction, or (c) both.*

► Abnormal Impulse Initiation

Abnormal initiation of electrical impulses occurs as a result of abnormal automaticity. If the automaticity of the SA node decreases, this results in a decreased rate of impulse generation and a slow heart rate (sinus bradycardia). Conversely, if the automaticity of the SA node increases, this results in an increased rate of generation of impulses and a rapid heart rate (sinus tachycardia). If other cardiac fibers become abnormally automatic, such that the rate of

initiation of spontaneous impulses exceeds that of the SA node, or premature impulses are generated, other types of tachyarrhythmias may occur. Many cardiac fibers possess the capability for automaticity including the atrial tissue, the AV node, the Purkinje fibers, and the ventricular tissue. In addition, fibers with the capability of initiating and conducting electrical impulses are present in the pulmonary veins. Abnormal atrial automaticity may result in premature atrial contractions or may precipitate atrial tachycardia or atrial fibrillation (AF); abnormal AV nodal automaticity may result in “junctional tachycardia” (the AV node is also sometimes referred to as the AV junction). Abnormal automaticity in the ventricles may result in ventricular premature depolarizations (VPDs) or may precipitate ventricular tachycardia (VT) or ventricular fibrillation (VF). In addition, abnormal automaticity originating from the pulmonary veins is a precipitant of AF.

Automaticity of cardiac fibers is controlled in part by activity of the sympathetic and parasympathetic nervous systems. Enhanced activity of the sympathetic nervous system may result in increased automaticity of the SA node or other automatic cardiac fibers. Enhanced activity of the parasympathetic nervous system tends to suppress automaticity; conversely, inhibition of activity of the parasympathetic nervous system increases automaticity. Other factors may lead to abnormal increases in automaticity of extra-SA nodal tissues, including hypoxia, atrial or ventricular stretch (as might occur following long-standing hypertension or during and after the development of heart failure), and electrolyte abnormalities such as hypokalemia or hypomagnesemia.

► Abnormal Impulse Conduction

The mechanism of abnormal impulse conduction is traditionally referred to as **reentry**. ① *Reentry is often initiated as a result of an abnormal premature electrical impulse (abnormal automaticity); therefore, in these situations, the mechanism of the arrhythmia is both abnormal impulse formation (automaticity) and abnormal impulse conduction (reentry).* For reentry to occur, three conditions must be present. There must be (a) at least two pathways down which an electrical impulse may travel (which is the case in most cardiac fibers); (b) a “unidirectional block” in one of the conduction pathways (this “unidirectional block” reflects prolonged refractoriness in this pathway, or increased “dispersion of refractoriness,” defined as substantial variation in refractory periods between cardiac fibers); and (c) slowing of the velocity of impulse conduction down the other conduction pathway.

The process of reentry is depicted in **Figure 9–3**.⁴ Under normal circumstances, when a premature impulse is initiated, it cannot be conducted in either direction down either pathway because the tissue is in its absolute refractory period from the previous impulse. A premature impulse may be conducted down both pathways if it is only slightly premature and arrives after the tissue is no longer refractory. However, when refractoriness is prolonged down

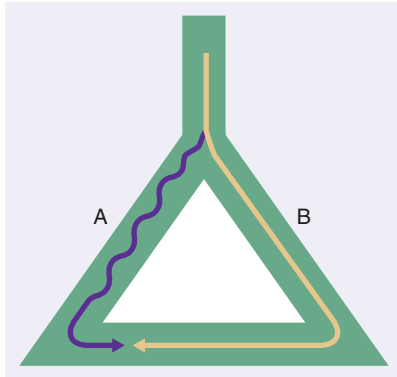

FIGURE 9-3. The process of initiation of reentry. There are two pathways for impulse conduction, slowed impulse conduction down pathway A and a longer refractory period in pathway B. A precisely timed premature impulse usually initiates reentry; the premature impulse cannot be conducted down pathway B because the tissue is still in the absolute refractory period from the previous, normal impulse. However, because of dispersion of refractoriness (i.e., different refractory periods down the two pathways), the impulse can be conducted down pathway A. Because conduction down pathway A is slowed, by the time the impulse reaches pathway B in a retrograde direction, the impulse can be conducted retrogradely up the pathway because the pathway is now beyond its refractory period from the previous impulse. This creates reentry, in which the impulse continuously and repeatedly travels in a circular fashion around the loop.

one of the pathways, a precisely timed premature beat may be conducted down one pathway but cannot be conducted in either direction in the pathway with prolonged refractoriness because the tissue is still in its absolute refractory period (Fig. 9-3).⁴ When the third condition for reentry is present, that is, when the velocity of impulse conduction in one is slowed, the impulse traveling forward down the other pathway still cannot be conducted. However, because the impulse in one is traveling more slowly than normal, by the time it circles around and travels upward along the other pathway, sufficient time has passed so the pathway is no longer in its absolute refractory period, and now the impulse may travel upward in that pathway. In other words, the electrical impulse “reenters” a previously stimulated pathway in the reverse (retrograde) direction. This results in circular movement of electrical impulses; as the impulse travels in this circular fashion, it excites each cell around it, and if the impulse is traveling at a rate faster than the intrinsic rate of the SA node, a tachycardia occurs in the tissue in question. Reentry may occur in numerous tissues, including the atria, the AV node, and the ventricles.

Prolonged refractoriness and/or slowed impulse conduction velocity may be present in cardiac tissues for a variety of reasons. Myocardial ischemia may alter ventricular refractory periods or impulse conduction velocity, facilitating ventricular reentry. In patients with past myocardial infarction, the

infarcted myocardium is dead and cannot conduct impulses. However, there is typically a border zone of tissue that is damaged and in which refractory periods and conduction velocity are often deranged, facilitating ventricular reentry. In patients with left atrial or LV hypertrophy as a result of long-standing hypertension, refractory periods and conduction velocity are often perturbed. In patients with heart failure due to LV dysfunction, ventricular refractoriness and conduction velocity are often altered due to LV hypertrophy, collagen deposition, and other anatomical and structural changes.

Vaughan Williams Classification of Antiarrhythmic Drugs

- The Vaughan Williams classification of antiarrhythmic drugs, first described in 1970⁵ and subsequently further expanded,^{6,7} is presented in [Table 9-1](#). This classification is based on the effects of specific drugs on ventricular conduction velocity, repolarization/refractoriness, and automaticity. Class I drugs, which are the sodium channel blocking agents, primarily inhibit ventricular automaticity and slow conduction velocity. However, due to differences in the potency of the drugs to slow conduction velocity, the class I drugs are subdivided into class IA, IB, and IC. The class IC drugs have the greatest potency for slowing ventricular conduction, the class IA drugs have intermediate potency, and the class IB drugs have the lowest potency, with minimal effects on conduction velocity at normal heart rates. Class II drugs are the adrenergic β -receptor inhibitors (β -blockers), class III drugs are those that inhibit ventricular repolarization or prolong refractoriness, and class IV drugs are the calcium channel blockers (CCBs) diltiazem and verapamil.

The Vaughan Williams classification of antiarrhythmic drugs has been criticized for a number of reasons. The classification is based on the effects of drugs on normal, rather than diseased, myocardium. In addition, many of the drugs may be placed into more than one class. For example, the class IA drugs prolong repolarization/refractoriness, either via the parent drug^{8,9} or an active metabolite,¹⁰ and therefore they may also be placed in class III. Sotalol is also a β -blocker and therefore fits into class II. Amiodarone inhibits sodium and potassium conductance, is a noncompetitive inhibitor of β -receptors, and inhibits calcium channels, and therefore it may be placed into any of the four classes. For this reason, drugs within each class cannot be considered “interchangeable.” Nonetheless, despite attempts to develop mechanism-based classifications that better distinguish the actions of antiarrhythmic drugs,¹¹ the Vaughan Williams classification continues to be widely used because of its simplicity and the fact that it is relatively easy to remember and understand.

CARDIAC ARRHYTHMIAS

In general, cardiac arrhythmias are classified into two broad categories: supraventricular (those occurring above the ventricles) and ventricular (those occurring in the ventricles).

Table 9-1

Vaughan Williams Classification of Antiarrhythmic Agents^a

Class	Drug	Conduction Velocity ^b	Repolarization/Refractoriness ^b	Automaticity ^b
IA	Quinidine	↓	↑	↓
	Procainamide			
IB	Disopyramide			
	Lidocaine	0/↓	↓/0	↓
IC	Mexiletine			
	Flecainide	↓↓	0	↓
II	Propafenone			
	β-Blockers ^c	0	0	0
	Acebutolol			
	Atenolol			
	Betaxolol			
	Bisoprolol			
	Carteolol			
	Carvedilol ^d			
	Esmolol			
	Labetalol ^d			
	Metoprolol			
	Nadolol			
	Nebivolol			
	Penbutolol			
	Pindolol			
	Propranolol			
Timolol				
III	Amiodarone ^e	0	↑	0
	Dofetilide			
	Dronedarone ^e			
	Ibutilide			
	Sotalol			
IV	CCBs ^c	0	0	0
	Diltiazem			
	Verapamil			

CCB, calcium channel blocker; ↑, increase/prolong; ↓, decrease; 0, no effect; 0/↓, does not change or may decrease; ↓/0, decreases or does not change.

^aAdenosine and digoxin are agents used for the management of arrhythmias that do not fit into the Vaughan Williams classification.

^bIn ventricular tissue only; effects may differ in atria, sinus node, or atrioventricular node.

^cSlow conduction, prolong refractory period, and reduce automaticity in sinoatrial node and AV node tissue but generally not in the ventricles.

^dCombined α - and β -blockers.

^eAmiodarone and dronedarone also slow conduction velocity and inhibit automaticity.

The names of specific arrhythmias are generally composed of two words; the first word indicates the location of the electrophysiological abnormality resulting in the arrhythmia (sinus, AV node, atrial, or ventricular), and the second word describes the arrhythmia in terms of whether it is abnormally slow (bradycardia) or fast (tachycardia), or the type of arrhythmia (block, fibrillation, or flutter).

SUPRAVENTRICULAR ARRHYTHMIAS

Sinus Bradycardia

Sinus bradycardia, an arrhythmia that originates in the SA node, is defined by a sinus rate less than 60 beats per minute (bpm).¹²

► Epidemiology and Etiology

Many individuals, particularly those who engage in regular vigorous exercise, have resting heart rates less than 60 bpm. For those individuals, sinus bradycardia is normal and healthy, and it does not require evaluation or treatment. However, some individuals may develop symptomatic sinus node dysfunction. In the absence of correctable underlying causes, idiopathic sinus node dysfunction is referred to as **sick sinus syndrome**¹² and occurs with greater frequency in association with advancing age. The prevalence of sick sinus syndrome is approximately 1 in 600 individuals older than 65 years.¹²

Sick sinus syndrome leading to sinus bradycardia may be caused by degenerative changes in the sinus node that occur

Clinical Presentation and Diagnosis of Sinus Bradycardia

Symptoms

- Many patients are asymptomatic, particularly those with normal resting heart rates less than 60 bpm as a result of physical fitness due to regular vigorous exercise
- Susceptible patients may develop symptoms, depending on the degree of heart rate lowering
- Symptoms of bradyarrhythmias include dizziness, fatigue, light-headedness, syncope, chest pain (in patients with underlying coronary artery disease [CAD]), and shortness of breath and other symptoms of heart failure (in patients with underlying left ventricular dysfunction)

Diagnosis

- Cannot be made on the basis of symptoms alone because the symptoms of all bradyarrhythmias are similar

- History of present illness, presenting symptoms, and 12-lead ECG that reveals sinus bradycardia
- Assess possible correctable etiologies, including myocardial ischemia, serum potassium concentration (for hyperkalemia), thyroid function tests (for hypothyroidism)
- Determine whether patient is taking any drugs known to cause sinus bradycardia. If the patient is currently taking digoxin, determine the serum digoxin concentration and ascertain whether it is supratherapeutic (greater than 2 ng/mL [2.6 nmol/L])

Table 9-2

Etiologies of Sinus Bradycardia^{12,13}

Idiopathic (“sick sinus syndrome”)	
Myocardial ischemia	
Carotid sinus hypersensitivity	
Neurocardiac syncope	
Electrolyte abnormalities: hypokalemia or hyperkalemia	
Hypothyroidism	
Hypothermia	
Amyloidosis	
Sarcoidosis	
Systemic lupus erythematosus	
Scleroderma	
Sleep apnea	
Drugs:	
Adenosine	Fluoxetine
Amiodarone	Halothane
β-Blockers	Isradipine
Cisplatin	Ketamine
Citalopram	Neostigmine
Clonidine	Nicardipine
Cocaine	Nitroglycerin
Dexmedetomidine	Paclitaxel
Digoxin	Propafenone
Diltiazem	Propofol
Dipyridamole	Remifentanil
Disopyramide	Sotalol
Donepezil	Succinylcholine
Dronedarone	Thalidomide
Flecainide	Verapamil

► Treatment

- **Desired Outcomes** The desired outcomes of treatment are to restore normal heart rate and alleviate patient symptoms.

Pharmacologic Therapy

Treatment of sinus bradycardia is only necessary in patients who become symptomatic. **2** *If the patient is taking any medication(s) that may cause sinus bradycardia, the drug(s) should be discontinued whenever possible.* If the patient remains in sinus bradycardia after discontinuation of the drug(s) and after five half-lives of the drug(s) have elapsed, then the drugs(s) can usually be excluded as the etiology of the arrhythmia. In certain circumstances, however, discontinuation of the medication(s) may be undesirable, even if it may be the cause of symptomatic sinus bradycardia. For example, if the patient has a history of myocardial infarction or heart failure, discontinuation of a β-blocker may be necessary in the short term but undesirable in the long term because β-blockers have been shown to reduce mortality and prolong life in patients with those diseases, and the benefits of therapy with β-blockers outweigh the risks associated with sinus bradycardia. In these patients, clinicians and patients may elect to implant a permanent pacemaker to allow the patient to continue therapy with β-blockers.

- Acute treatment of the symptomatic and/or hemodynamically unstable patient with sinus bradycardia includes administration of the anticholinergic drug atropine, which should be given in doses of 0.5 mg IV every 3 to 5 minutes. The maximum recommended total dose of atropine is 3 mg.¹⁴ Atropine is generally used as a method of achieving acute symptom control while awaiting placement of a transcutaneous or transvenous pacemaker. Where necessary, transcutaneous pacing can be initiated during atropine administration. Atropine should be used cautiously in patients with myocardial ischemia or infarction because increasing heart rate and myocardial oxygen demand may aggravate ischemia or extend the infarct.¹⁴

with advancing age. **2** *However, there are other possible etiologies of sinus bradycardia, including drugs (Table 9-2).*¹³

► Pathophysiology

Sick sinus syndrome leading to sinus bradycardia occurs as a result of fibrotic tissue in the SA node, which replaces normal SA node tissue.¹²

In patients with hemodynamically unstable sinus bradycardia who do not respond to atropine, transcutaneous pacing may be initiated. In patients with hemodynamically unstable or severely symptomatic sinus bradycardia that is unresponsive to atropine and in whom temporary or **transvenous pacing** is not available or is ineffective, or while awaiting placement of a pacemaker, dopamine (2 to 10 mcg/kg/min, titrate to response), epinephrine (2 to 10 mcg/min, titrate to response), or isoproterenol (2 to 10 mcg/min, titrate to response) may be administered to increase heart rate.¹⁴

In patients with sinus bradycardia due to underlying correctable disorders (such as electrolyte abnormalities or hypothyroidism), management consists of correcting those disorders.

- **Nonpharmacologic Therapy** Long-term management of patients with sick sinus syndrome requires implantation of a permanent pacemaker.¹²

► **Outcome Evaluation**

- Monitor the patient's heart rate and alleviation of symptoms.
- Monitor for adverse effects of medications such as atropine (dry mouth, mydriasis, urinary retention, and tachycardia).

AV Nodal Blockade

- AV nodal blockade occurs when conduction of electrical impulses through the AV node is impaired to varying degrees. AV nodal blockade is classified into three categories. First-degree AV block is defined simply as prolongation of the PR interval to greater than 0.2 seconds. During first-degree AV block, all impulses initiated by the SA node that have resulted in atrial depolarization are conducted through the AV node; the abnormality is simply that the impulses are conducted more slowly than normal, resulting in prolongation of the PR interval.¹⁵ Second-degree AV block is further distinguished into two types: **Mobitz type I** (also known as Wenckebach) and **Mobitz type II**. In both types of second-degree AV block, some of the impulses initiated by the SA node are not conducted through the AV node. This often occurs in a regular pattern; for example, every third or fourth impulse generated by the SA node may not be conducted. During third-degree AV block, which is also referred to as “complete heart block,” none of the impulses generated by the SA node are conducted through the AV node. This results in “AV dissociation,” during which the atria continue to depolarize normally as a result of normal impulses initiated by the SA node; however, the ventricles initiate their own depolarizations because no SA node-generated impulses are conducted to the ventricles. Therefore, on the ECG, there is no relationship between the P waves and the QRS complexes.

► **Epidemiology and Etiology**

- The overall incidence of AV nodal blockade is unknown. AV nodal blockade may be caused by degenerative changes in

Table 9-3

Etiologies of AV Nodal Blockade^{12,13,15}

Idiopathic degeneration of the AV node	
Myocardial ischemia or infarction	
Neurocardiac syncope	
Carotid sinus hypersensitivity	
Electrolyte abnormalities: hypokalemia or hyperkalemia	
Hypothyroidism	
Hypothermia	
Infectious diseases: Chagas' disease or endocarditis	
Amyloidosis	
Sarcoidosis	
Systemic lupus erythematosus	
Scleroderma	
Sleep apnea	
Drugs:	
Adenosine	Hydroxychloroquine
Amiodarone	Paclitaxel
β-Blockers	Phenylpropanolamine
Bupivacaine	Propafenone
Carbamazepine	Propofol
Chloroquine	Sotalol
Digoxin	Thioridazine
Diltiazem	Tricyclic antidepressants
Dronedarone	Verapamil
Flecainide	

AV, atrioventricular.

the AV node. 2 In addition, there are many other possible etiologies of AV nodal blockade including drugs (Table 9-3).^{12,13}

► **Pathophysiology**

First-degree AV nodal blockade occurs due to inhibition of conduction within the upper portion of the node.¹⁵ Mobitz type I second-degree AV nodal blockade occurs as a result of inhibition of conduction further down within the node.^{12,15} Mobitz type II second-degree AV nodal blockade is caused by inhibition of conduction within or below the level of the bundle of His.^{12,15} Third-degree AV nodal blockade may be a result of inhibition of conduction either within the AV node or within the bundle of His or the His-Purkinje system.^{12,15} AV block may occur as a result of age-related AV node degeneration.

► **Treatment**

- **Desired Outcomes** The desired outcomes of treatment are to restore normal sinus rhythm and alleviate patient symptoms.

Pharmacologic Therapy Treatment of first-degree AV nodal blockade is rarely necessary because symptoms rarely occur. However, the ECGs of patients with first-degree AV nodal blockade should be monitored to assess the possibility of progression of first-degree AV nodal blockade to second- or third-degree block. Second- or third-degree AV nodal blockade requires treatment because bradycardia often results in symptoms. If the patient is taking any medication(s) that may cause AV nodal blockade, the drug(s) should be discontinued whenever possible. If the patient's rhythm still exhibits AV

Clinical Presentation and Diagnosis of AV Nodal Blockade

Symptoms

- First-degree AV nodal blockade is rarely symptomatic because it rarely results in bradycardia
- Second-degree AV nodal blockade may cause bradycardia because not all impulses generated by the SA node are conducted through the AV node to the ventricles
- In third-degree AV nodal blockade, or complete heart block, the heart rate is usually 30 to 40 bpm, resulting in symptoms
- Symptoms of bradyarrhythmias such as second- or third-degree AV block consist of dizziness, fatigue, light-headedness, syncope, chest pain (in patients with underlying CAD), and shortness of breath and other symptoms of heart failure (in patients with underlying left ventricular dysfunction)

Diagnosis

- Made on the basis of patient presentation, including history of present illness and presenting symptoms, as well as a 12-lead ECG that reveals AV nodal blockade
- Assess potentially correctable etiologies, including myocardial ischemia, serum potassium concentration (for hyperkalemia), and thyroid function tests (for hypothyroidism)
- Determine whether the patient is taking any drugs known to cause AV block
- If the patient is currently taking digoxin, determine the serum digoxin concentration and ascertain whether it is supratherapeutic (greater than 2 ng/mL [2.6 nmol/L])

nodal blockade after discontinuing the medication(s) and after five half-lives of the drug(s) have elapsed, then the drug(s) can usually be excluded as the etiology of the arrhythmia. However, in certain circumstances, discontinuation of a medication that is inducing AV nodal blockade may be undesirable. For example, if the patient has a history of myocardial infarction or heart failure, discontinuation of a β -blocker is undesirable because β -blockers have been shown to reduce mortality and prolong life in patients with those diseases, and the benefits of therapy with β -blockers outweigh the risks associated with AV nodal blockade. In these patients, clinicians and patients may elect to implant a permanent pacemaker in order to allow the patient to continue therapy with β -blockers.

Acute treatment of patients with second- or third-degree AV nodal blockade consists primarily of administration of atropine, which may be administered in the same doses as recommended for the management of sinus bradycardia. In patients with hemodynamically unstable or severely symptomatic AV nodal blockade that is unresponsive to atropine and in whom temporary or transvenous pacing is not available or is ineffective, epinephrine (2 to 10 mcg/min, titrate to response) and/or dopamine (2 to 10 mcg/kg/min) may be administered.¹⁴

In patients with second- or third-degree AV block due to underlying correctable disorders (such as electrolyte abnormalities or hypothyroidism), management consists of correcting those disorders.

Nonpharmacologic Therapy Long-term management of patients with second- or third-degree AV nodal blockade due to idiopathic degeneration of the AV node requires implantation of a permanent pacemaker.¹²

Outcome Evaluation

- Monitor the patient for termination of AV nodal blockade and restoration of normal sinus rhythm, heart rate, and alleviation of symptoms.

- If atropine is administered, monitor the patient for adverse effects including dry mouth, mydriasis, urinary retention, and tachycardia.

Atrial Fibrillation

AF is the most common arrhythmia encountered in clinical practice. It is important for clinicians to understand AF because it is associated with substantial morbidity and mortality and because many strategies for drug therapy are available. Drugs used to treat AF often have a narrow therapeutic index and a broad adverse-effect profile.

Epidemiology and Etiology

Approximately 2.2 million Americans have AF. The prevalence of AF increases with advancing age; roughly 8% of patients between the ages of 80 and 89 years have AF.¹⁶ Similarly, the incidence of AF increases with age, and it occurs more commonly in men than in women.¹⁶

Etiologies of AF are presented in [Table 9-4](#). The common feature of the majority of etiologies of AF is the development of left atrial hypertrophy. Hypertension may be the most important risk factor for development of AF. However, AF also occurs commonly in patients with CAD. In addition, heart failure is increasingly recognized as a cause of AF; approximately 25% to 30% of patients with New York Heart Association (NYHA) class III heart failure have AF,¹⁷ and the arrhythmia is present in as many as 50% of patients with NYHA class IV heart failure.¹⁸

Drug-induced AF is relatively uncommon but has been reported ([Table 9-4](#)).¹³ Acute ingestion of large amounts of alcohol may cause AF; this phenomenon has been referred to as the “holiday heart” syndrome.¹⁹ In addition, recent reports have associated use of the bisphosphonate drugs zoledronic acid²⁰ and alendronate²¹ with new-onset serious AF. The potential relationship between bisphosphonate use and new-onset AF requires further study.

Clinical Presentation and Diagnosis of AF

Symptoms

- Approximately 20% to 30% of patients with AF remain asymptomatic
- Symptoms typical of tachyarrhythmias such as AF include palpitations, dizziness, light-headedness, shortness of breath, chest pain (if underlying CAD is present), near-syncope, and syncope. Patients commonly complain of palpitations; often the complaint is “I can feel my heart beating fast” or “I can feel my heart fluttering” or “It feels like my heart is going to beat out of my chest”
- Other symptoms depend on the degree to which cardiac output is diminished, which in turn depends on the

ventricular rate and the degree to which **stroke volume** is reduced by the rapidly beating heart

- In some patients, the first symptom of AF is stroke

Diagnosis

- Because the symptoms of all tachyarrhythmias depend on heart rate and are therefore essentially the same, the diagnosis depends on the presence of AF on the ECG
- AF is characterized on ECG by an absence of P waves, an undulating baseline that represents chaotic atrial electrical activity, and an irregularly irregular rhythm, meaning that the intervals between the R waves are irregular and there is no pattern to the irregularity

Table 9–4

Etiologies of AF^{13,20,21,25}

Hypertension
Coronary artery disease
Heart failure
Diabetes
Hyperthyroidism
Rheumatic heart disease
Diseases of the heart valves:
Mitral stenosis or regurgitation
Mitral valve prolapse
Acute myocardial infarction
Pericarditis
Amyloidosis
Myocarditis
Pulmonary embolism
Idiopathic (“lone” AF)
Familial AF
Thoracic surgery:
Coronary artery bypass graft surgery
Pulmonary resection
Thoracoabdominal esophagectomy
Drugs:
Adenosine
Albuterol
Alcohol
Alendronate
Dobutamine
Enoximone
Ipratropium bromide
Methylprednisolone
Milrinone
Mitoxantrone
Paclitaxel
Propafenone
Theophylline
Verapamil
Zoledronic acid

AF, atrial fibrillation.

► Pathophysiology

1 AF may be caused by both abnormal impulse formation and abnormal impulse conduction. Traditionally, AF was

believed to be initiated by premature impulses initiated in the atria. However, it is now understood that in many patients AF is triggered by electrical impulses generated within the pulmonary veins.²² These impulses initiate the process of reentry within the atria, and AF is believed to be sustained by multiple reentrant wavelets operating simultaneously within the atria. Some believe that, at least in some patients, the increased automaticity in the pulmonary veins may be the sole mechanism of AF and that the multiple reentrant wavelet hypothesis may be incorrect. However, the concept of multiple simultaneous reentrant wavelets remains the predominant hypothesis regarding the mechanism of AF.²³

AF leads to electrical remodeling of the atria. Episodes of AF that are of longer duration and episodes that occur with increasing frequency result in progressive shortening of atrial refractory periods, further potentiating the reentrant circuits in the atria.²⁴ Therefore, it is often said that “atrial fibrillation begets atrial fibrillation”; that is, AF causes atrial electrophysiologic alterations that promote further AF.^{23,24} AF is associated with chaotic, disorganized atrial electrical activity, resulting in no completed atrial depolarizations and therefore no atrial contraction.

A substantial amount of the atrial electrical activity occurring during AF may be conducted through the AV node into the ventricles, resulting in ventricular rates ranging from 100 to 200 bpm.

AF occurs in specific patterns: first detected, **paroxysmal**, persistent, or permanent (**Fig. 9–4**).²⁵ Patients with paroxysmal AF have episodes that begin suddenly and spontaneously, last minutes to hours, or rarely as long as 7 days, and terminate suddenly and spontaneously. Some patients with paroxysmal AF have episodes that do not terminate spontaneously; episodes that last greater than 7 days are termed persistent AF. Approximately 18% to 30% of patients with AF progress to the point of permanent AF; these patients are subsequently never in normal sinus rhythm but rather are always in AF.

AF is associated with substantial morbidity and mortality. This arrhythmia is associated with a risk of ischemic stroke of approximately 5% per year.²⁵ The risk of stroke is increased

Patient Encounter Part 1

DT is a 62-year-old man who presents to the emergency department (ED) complaining that he can “feel my heart beating fast.” He states that this started several hours ago, and he waited to see if it would stop, but it has not. He also complains of feeling dizzy and nearly passing out. His pulse is irregularly irregular, with a rate of 130 bpm.

His physical examination is completely normal and no focal neurological deficits are observed.

What information is suggestive of AF?

What additional information do you need in order to develop a treatment plan?

FIGURE 9-4. Patterns of atrial fibrillation. ^aEpisodes that generally last 7 days or less (most less than 24 hours). ^bEpisodes that usually last 7 days. ^cCardioversion failed or not attempted. ^dEither paroxysmal or persistent atrial fibrillation may be recurrent. (From Fuster V, Rydén LE, Cannom DS, et al. 2011 ACCF/AHA/HRS focused updates incorporated into the ACC/AHA/ESC 2006 guidelines for the management of patients with atrial fibrillation: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines and the European Society of Cardiology Committee for Practice Guidelines. *J Am Coll Cardiol* 2011;57:e101–198.)

two- to sevenfold in patients with AF compared with patients without this arrhythmia.²⁵ AF is the cause of roughly one of every six strokes. During AF, atrial contraction is absent. Due to the fact that atrial contraction is responsible for approximately 30% of left ventricular filling, this blood that is not ejected from the left atrium to the left ventricle pools in the atrium, particularly in the left atrial appendage. Blood pooling facilitates the formation of a thrombus, which subsequently may travel through the mitral valve into the left ventricle and may be ejected during ventricular contraction. The thrombus then may travel through a carotid artery into the brain, resulting in an ischemic stroke.

AF may lead to the development of heart failure as a result of tachycardia-induced cardiomyopathy.²⁶ AF increases the

risk of mortality approximately twofold compared with patients without AF²⁵; the causes of death are likely stroke or heart failure.

► Treatment

- **Desired Outcomes** **3** *The goals of individualized therapy for AF are (a) ventricular rate control, (b) termination of AF and restoration of sinus rhythm (commonly referred to as “cardioversion” or “conversion to sinus rhythm”), (c) maintenance of sinus rhythm, or reduction in the frequency of episodes of paroxysmal AF, and/or (d) prevention of stroke.* These goals of therapy do not necessarily apply to all patients; the specific goal(s) that apply depend on the patient’s AF pattern (**Table 9–5**).

- **Hemodynamically Unstable AF** For patients who present with an episode of AF that is hemodynamically unstable, emergent conversion to sinus rhythm is necessary using **direct current cardioversion** (DCC). Hemodynamic instability may be defined as the presence of any one of the following¹⁴: (a) patient has acutely altered mental status, (b) hypotension (systolic blood pressure less than 90 mm Hg) or other signs of shock, (c) ischemic chest discomfort, and/or (d) acute heart failure.

- DCC is the process of administering a synchronized electrical shock to the chest. The purpose of DCC is to simultaneously depolarize all of the myocardial cells, resulting in interruption and termination of the multiple reentrant circuits and restoration of normal sinus rhythm. The recommended initial energy level for conversion of AF to sinus rhythm is 120 to 200 joules (J) for biphasic shocks or 200 J for monophasic shocks. If the DCC attempt is unsuccessful, the DCC energy should be increased in a stepwise fashion.¹⁴

Patient Encounter Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH: Hypertension × 15 years

Meds: Aspirin 81 mg once daily; hydrochlorothiazide 25 mg orally once daily; lisinopril 20 mg orally once daily

PE:

Ht 5 ft.10 in. (178 cm), wt 80 kg (176 lb), BP 100/60 mm Hg, P 130 bpm, RR 18/min; remainder of physical examination noncontributory

Labs: All within normal limits

CXR: No pulmonary edema

ECG: Atrial fibrillation

What is your assessment of DT’s condition?

What are your treatment goals?

What pharmacologic or nonpharmacologic alternatives are available for each treatment goal?

Table 9-5

Treatment Goals According to AF Pattern

First Detected Episode	Paroxysmal AF	Persistent AF	Permanent AF
Ventricular rate control Stroke prevention Conversion to sinus rhythm	Ventricular rate control Stroke prevention Maintenance of sinus rhythm <i>if ventricular rate control is not sufficient to control symptoms</i>	Ventricular rate control Stroke prevention Conversion to sinus rhythm	Ventricular rate control Stroke prevention

AF, atrial fibrillation.

Delivery of the shock is synchronized to the ECG by the cardioverter machine, such that the electrical charge is not delivered during the latter portion of the T wave (i.e., the relative refractory period), to avoid delivering an electrical impulse that may be conducted abnormally, which may result in a life-threatening ventricular arrhythmia.

The remainder of this section is devoted to management of hemodynamically stable AF. The specific goals of therapy that apply to patients in each AF pattern are presented in Table 9-5.

► Pharmacologic Therapy

Ventricular Rate Control Ventricular rate control can be achieved by inhibiting the proportion of electrical impulses

conducted from the atria to the ventricles through the AV node. Therefore, drugs that are effective for ventricular rate control are those that inhibit AV nodal impulse conduction: β -blockers, diltiazem, verapamil, digoxin, and amiodarone (Tables 9-6 and 9-7).

In patients who present with their first detected episode of AF, or for those who present with an episode of persistent AF, ventricular rate control is usually initially achieved using IV drugs. A decision algorithm for selecting a specific drug for acute ventricular rate control is presented in Figure 9-5.^{25,27} In general, an IV CCB or β -blocker is preferred for ventricular rate control in patients with normal LV function because ventricular rate control can often be achieved within several minutes. In patients with heart failure due to LV dysfunction, IV digoxin or amiodarone is preferred because diltiazem

Table 9-6

Drugs for Ventricular Rate Control in AF

Drug	Mechanism of Action	Loading Dose	Daily Dose	Drug Interactions
Amiodarone	β -Blocker CCB	150 mg IV over 10 minutes	0.5–1 mg/min IV continuous infusion 200 mg orally once daily	Inhibits clearance of digoxin, warfarin, and other drugs
β -Blockers ^a	Inhibit AV nodal conduction by slowing AV nodal conduction and prolonging AV nodal refractoriness	Esmolol 500 mcg/kg IV over 1 minute Propranolol 0.15 mg/kg IV Metoprolol 2.5–5 mg IV \times 2–3 doses	Esmolol 60–200 mcg/kg/min continuous IV infusion Propranolol 80–240 mg/day orally in divided doses Metoprolol 25–100 mg orally twice daily	
Diltiazem	Inhibits AV nodal conduction by slowing AV nodal conduction and prolonging AV nodal refractoriness	0.25 mg/kg IV load over 2 minutes. Additional 0.35 mg/kg in 15 minutes if needed	Continuous infusion of 5–15 mg/h 120–360 mg orally daily in divided doses	Inhibits elimination of cyclosporine
Verapamil	Inhibits AV nodal conduction by slowing AV nodal conduction and prolonging AV nodal refractoriness	0.075–0.15 mg/kg IV over 2 minutes. May repeat every 15–30 minutes to total dose of 20–30 mg	120–360 mg orally daily in divided doses	Inhibits digoxin elimination
Digoxin	Inhibits AV nodal conduction by (a) vagal stimulation by (b) directly slowing AV nodal conduction, and (c) prolonging AV nodal refractoriness	0.25 mg IV every 2 hours, up to 1.5 mg	0.125–0.375 mg orally once daily	Amiodarone, verapamil, inhibit digoxin elimination

AF, atrial fibrillation; AV, atrioventricular; CCB, calcium channel blocker.

^aAlthough oral β -blockers are important agents for mortality reduction in patients with heart failure, IV β -blockers should be avoided due to the potential for heart failure exacerbation.

Table 9-7

Adverse Effects of Drugs Used to Treat Arrhythmias

Drug	Adverse Effects
Adenosine	Chest pain, flushing, shortness of breath, sinus bradycardia/AV block
Amiodarone	IV: Hypotension, sinus bradycardia Oral: Blue-gray skin discoloration, photosensitivity, corneal microdeposits, pulmonary fibrosis, hepatotoxicity, sinus bradycardia, hypo- or hyperthyroidism, peripheral neuropathy, weakness, AV block
Atropine	Tachycardia, urinary retention, blurred vision, dry mouth, mydriasis
Digoxin	Nausea, vomiting, anorexia, green-yellow halos around objects, ventricular arrhythmias
Diltiazem	Hypotension, sinus bradycardia, heart failure exacerbation, AV block
Dofetilide	Torsades de pointes
Dronedarone	Diarrhea, asthenia, nausea and vomiting, abdominal pain, bradycardia, GI distress, hepatotoxicity
Esmolol	Hypotension, sinus bradycardia, AV block, heart failure exacerbation
Flecainide	Dizziness, blurred vision, heart failure exacerbation
Ibutilide	Torsades de pointes
Metoprolol	Hypotension, sinus bradycardia, AV block, fatigue, heart failure exacerbation ^a
Mexiletine	Nausea, vomiting, GI distress, tremor, dizziness, fatigue, seizures (if dose too high)
Procainamide	Hypotension, torsades de pointes
Propafenone	Dizziness, blurred vision
Propranolol	Hypotension, bradycardia, AV block, heart failure exacerbation ^a
Sotalol	Sinus bradycardia, AV block, fatigue, torsades de pointes
Verapamil	Hypotension, heart failure exacerbation, bradycardia, AV block, constipation (oral)

AV, atrioventricular.

^aAssociated with IV administration, inappropriately high oral doses at initiation of therapy, or overly aggressive and rapid dose titration.

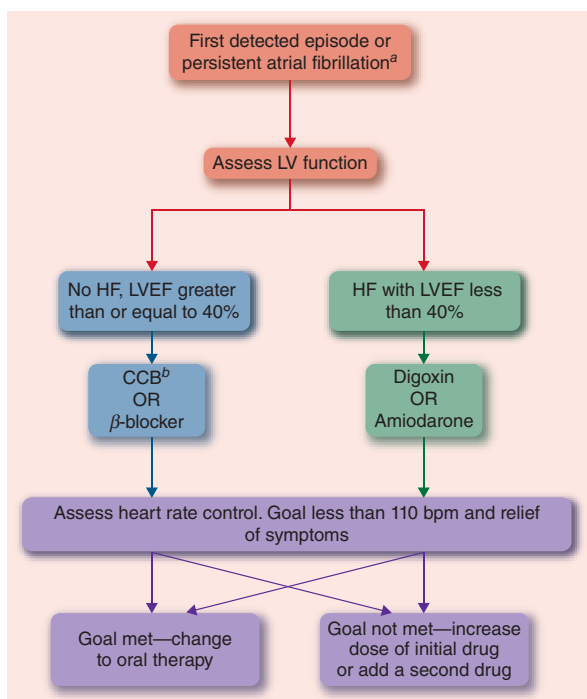

FIGURE 9-5. Decision algorithm for ventricular rate control using IV drug therapy for patients presenting with the first detected episode or an episode of persistent atrial fibrillation that is hemodynamically stable. ^aDrugs administered IV. ^bDiltiazem is generally preferred over verapamil because of a lower risk of severe hypotension. (β-Blocker, esmolol, metoprolol, or propranolol; bpm, beats per minute; CCB, calcium channel blocker [diltiazem or verapamil]; HF, heart failure; LV, left ventricular; LVEF, left ventricular ejection fraction; LVEF of 40% can also be expressed as 0.40.)

and verapamil are associated with negative inotropic effects and may exacerbate heart failure.^{25,28} Similarly, although oral β-blockers are indicated in patients with heart failure due to LV dysfunction, IV β-blockers are generally avoided due to the potential for acutely exacerbating heart failure.

A decision strategy for long-term rate control with oral medications in patients with paroxysmal or permanent AF is presented in **Figure 9-6**.^{25,27} In general, although digoxin is effective for ventricular rate control in patients at rest, it is less effective than CCBs or β-blockers for ventricular rate control in patients undergoing physical activity including activities of daily living. This is likely because activation of the sympathetic nervous system during exercise and activity overwhelms the stimulating effect of digoxin on the parasympathetic nervous system. Therefore, in patients with normal LV function, CCBs or β-blockers are preferred for long-term ventricular rate control. Diltiazem may be preferable to verapamil in older patients due to a lower incidence of constipation. However, in patients with heart failure, oral diltiazem and verapamil are contraindicated as a result of their negative inotropic activity and propensity to exacerbate heart failure. Therefore, the options in this population are β-blockers or digoxin. Most patients with heart failure should be receiving therapy with an oral β-blocker with the goal of achieving mortality risk reduction. In patients with heart failure who develop rapid AF while receiving therapy with β-blockers, digoxin should be administered for purposes of ventricular rate control. Fortunately, studies have found the combination of digoxin and β-blockers to be effective for ventricular rate control, likely as a result of β-blocker-induced attenuation of the inhibitory effects of the sympathetic nervous system on the efficacy of digoxin.

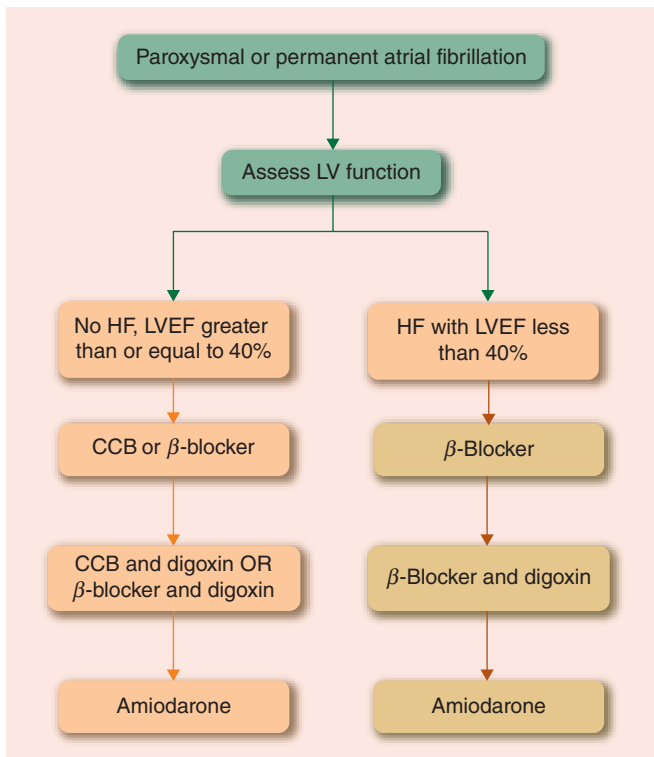

FIGURE 9-6. Decision algorithm for long-term ventricular rate control with oral drug therapy for patients with paroxysmal or permanent atrial fibrillation. With each therapy/dose change, assess heart rate control. Goal less than 100 bpm or reduction of heart rate by more than 20% with symptom relief. If goal is not met, move to next step in algorithm. (bpm, beats per minute; CCB, calcium channel blocker [diltiazem or verapamil]; HF, heart failure; LV, left ventricular function; LVEF, left ventricular ejection fraction; LVEF of 40% can also be expressed as 0.40.)

Conversion to Sinus Rhythm Termination of AF in hemodynamically stable patients may be performed using antiarrhythmic drug therapy or elective DCC. Drugs that may be used for conversion to sinus rhythm are presented in [Table 9-8](#); these agents slow atrial conduction velocity and/or prolong refractoriness, facilitating interruption of reentrant circuits and restoration of sinus rhythm. DCC is generally more effective than drug therapy for conversion of AF to sinus rhythm. However, patients who undergo elective DCC must be sedated and/or anesthetized to avoid the discomfort associated with delivery of 120 to greater than or equal to 200 J of electricity to the chest. Therefore, it is important that patients scheduled to undergo elective DCC do not eat within approximately 8 to 12 hours of the procedure to avoid aspiration of stomach contents during the period of sedation/anesthesia. This often factors into the decision as to whether to use elective DCC or drug therapy for conversion of AF to sinus rhythm. If a patient presents with AF requiring nonemergent conversion to sinus rhythm, and the patient has eaten a meal that day, then pharmacologic

methods must be used for cardioversion on that day, or DCC must be postponed to the following day to allow for a period of fasting prior to the procedure.

A decision strategy for conversion of AF to sinus rhythm is presented in [Figure 9-7](#).²⁵ The cardioversion decision strategy depends greatly on the duration of AF. If the AF episode began within 48 hours, conversion to sinus rhythm is safe and may be attempted with elective DCC or specific drug therapy ([Fig. 9-7](#)). However, if the duration of the AF episode is longer than 48 hours or if there is uncertainty regarding the duration of the episode, two strategies for conversion may be considered. Data indicate that a thrombus may form in the left atrium during AF episodes of 48 hours or longer; if an atrial thrombus is present, the process of conversion to sinus rhythm, whether with DCC or drugs, can dislodge the atrial thrombus, leading to embolization and a stroke. Therefore, in patients experiencing an AF episode of 48 hours or longer, conversion to sinus rhythm should be deferred unless it is known that an atrial thrombus is not present. In the past, common practice in patients with AF of greater than 48 hours duration was to anticoagulate with warfarin, maintaining a therapeutic **international normalized ratio (INR)** for 3 weeks, after which cardioversion may be performed. Patients were subsequently anticoagulated for a minimum of 4 weeks following the restoration of sinus rhythm. Today, rather than send patients with ongoing AF home for 3 weeks of anticoagulation, it has become standard practice at many institutions to perform a **transesophageal echocardiogram (TEE)** to determine whether an atrial thrombus is present; if such a thrombus is not present, DCC or pharmacologic cardioversion may be performed within 24 hours. If this strategy is selected, hospitalized patients should undergo anticoagulation with IV unfractionated heparin, with the dose targeted to a partial thromboplastin time (PTT) of 60 seconds (range: 50 to 70 seconds), or warfarin therapy (target INR: 2.5; range: 2 to 3) during the hospitalization period prior to the TEE and cardioversion procedure. If a thrombus is not present during TEE and cardioversion is successful, patients should maintain anticoagulation with warfarin (target INR: 2.5; range: 2 to 3) for at least 4 weeks. If a thrombus is observed during TEE, then cardioversion should be postponed and anticoagulation should be continued indefinitely. Another TEE should be performed prior to a subsequent cardioversion attempt.²⁹

Conversion of AF to sinus rhythm is usually performed in patients with the first detected episode of AF or in patients with an episode of persistent AF. In patients with permanent AF, conversion to sinus rhythm is usually not attempted because cardioversion is unlikely to be successful, and in those rare patients in whom sinus rhythm is restored successfully, AF usually recurs shortly thereafter.

Maintenance of Sinus Rhythm/Reduction in the Frequency of Episodes of Paroxysmal AF In many patients, permanent maintenance of sinus rhythm following cardioversion is an unrealistic goal. Many, if not most, patients experience recurrence of AF after cardioversion. Similarly, in patients with paroxysmal AF, complete

Table 9-8

Drugs for Conversion of AF to Normal Sinus Rhythm

Treatment	Loading Dose	Maintenance Dose	Drug Interactions
Amiodarone	IV: 5–7 mg/kg over 30–60 minutes Oral (inpatient): 1.2–1.8 g per day in divided doses until 10 g total Oral (outpatient): 600–800 mg daily in divided doses until 10 g total	1.2–1.8 g via continuous IV infusion over 24 hours 200–400 mg once daily 200–400 mg once daily	Inhibits elimination of digoxin and warfarin
Dofetilide ^a		—	Cimetidine, hydrochlorothiazide, ketoconazole, medroxyprogesterone, promethazine, trimethoprim, verapamil (all inhibit dofetilide elimination)
Ibutilide	1 mg IV over 10 minutes, followed by a second 1 mg IV dose if necessary	—	—
Propafenone	600 mg single oral dose	—	—
Flecainide	200–300 mg single oral dose	—	—

AF, atrial fibrillation.

^aRecommended initial dofetilide doses are:

Calculated creatinine clearance (mL/min):	Dose
Greater than 60	500 mcg twice daily
40–60	250 mcg twice daily
20–40	125 mcg twice daily
Less than 20	Contraindicated

Patients must be hospitalized for 3 days during initiation of therapy.

Calculated creatinine clearance of greater than 60, 40–60, 20–40, and less than 20 mL/min corresponds to greater than 1, 0.67–1, 0.33–0.67, and less than 0.33 mL/s, respectively.

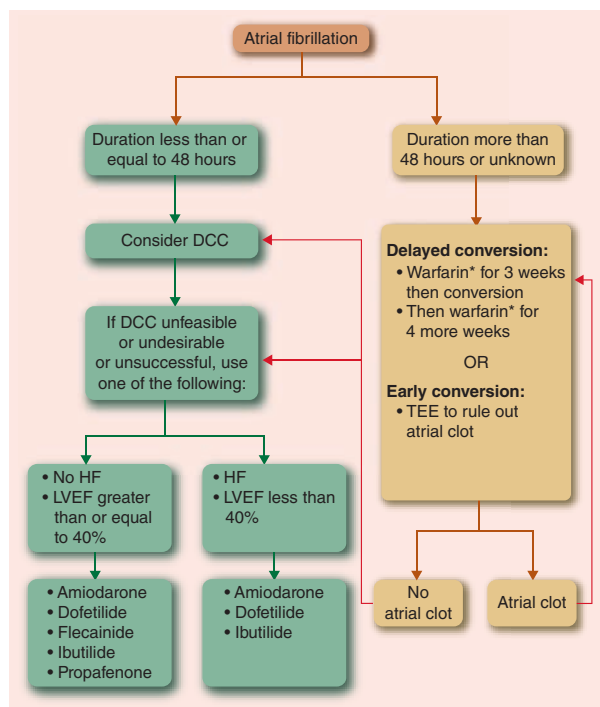

FIGURE 9-7. Decision algorithm for conversion of hemodynamically stable atrial fibrillation to normal sinus rhythm. (DCC, direct current cardioversion; HF, heart failure; LVEF, left ventricular ejection fraction; TEE, transesophageal echocardiogram; LVEF of 40% can also be expressed as 0.40.)
*International normalized ratio 2–3.

maintenance of sinus rhythm without recurrent episodes of AF is unrealistic. Therefore, a more realistic goal for many patients is not permanent maintenance of sinus rhythm, but rather reduction in the frequency of episodes of paroxysmal AF.

In recent years, numerous studies have been performed to determine whether drug therapy for maintenance of sinus rhythm is preferred to drug therapy for ventricular rate control.^{30–34} In these studies, patients have been assigned randomly to receive therapy either with drugs for rate control or with drugs for rhythm control (Table 9-9). These studies have found no significant differences in mortality in patients who received rhythm control therapy versus those who received rate control therapy.^{30–34} However, patients assigned to the rhythm control strategy were more likely to be hospitalized^{30,32–34} and were more likely to experience adverse effects associated with drug therapy.^{30,31}

4 Therefore, drug therapy for the purpose of maintaining sinus rhythm or reducing the frequency of episodes of AF should be initiated only in those patients with episodes of paroxysmal AF who continue to experience symptoms despite maximum tolerated doses of drugs for ventricular rate control. A decision strategy for maintenance therapy of sinus rhythm is presented in Figure 9-8.^{25,27} Drug therapy for maintenance of sinus rhythm and/or reduction in the frequency of episodes of paroxysmal AF should not be initiated in patients with underlying correctable causes of AF, such as hyperthyroidism; rather, the underlying cause of the arrhythmia should be corrected.

Table 9-9

Drugs for Maintenance of Sinus Rhythm/Reduction in the Frequency of Episodes of AF

Drug	Dose
Amiodarone	100–400 mg orally once daily
Dofetilide	As described in Table 9-8
Dronedaron	400 mg orally twice daily
Sotalol	80–160 mg orally twice daily
Propafenone	150–300 mg orally three times daily
Flecainide	100–150 mg orally three times daily

AF, atrial fibrillation.

Stroke Prevention All patients with paroxysmal, persistent, or permanent AF should receive therapy for stroke prevention unless compelling contraindications exist. A decision strategy for assigning patients to receive anticoagulation for stroke

prevention in AF is presented in Table 9-10.^{29,35} **5** In general, most patients require therapy with dabigatran or warfarin; in some patients with no risk factors for stroke, anticoagulation may not be necessary. For patients for whom oral anticoagulation is indicated (i.e., those with a CHADS₂ score of 1 or more), dabigatran 10 mg twice daily is suggested as preferable to warfarin titrated to an INR of 2.0–3.0.²⁹

The landscape of anticoagulation for stroke prevention in AF has changed with the availability of dabigatran, the FDA approval of rivaroxaban in November 2011, and the potential FDA approval of apixaban. Dabigatran is a direct thrombin inhibitor that was approved by the FDA in October 2010 for stroke prevention in patients with nonvalvular AF. Dabigatran is now preferred over warfarin for the prevention of stroke and systemic embolism in patients with AF and risk factors for stroke and systemic embolization who do not have a prosthetic heart valve or hemodynamically significant heart valve disease.^{29,36} Dabigatran should not be used in patients with severe kidney disease (creatinine clearance

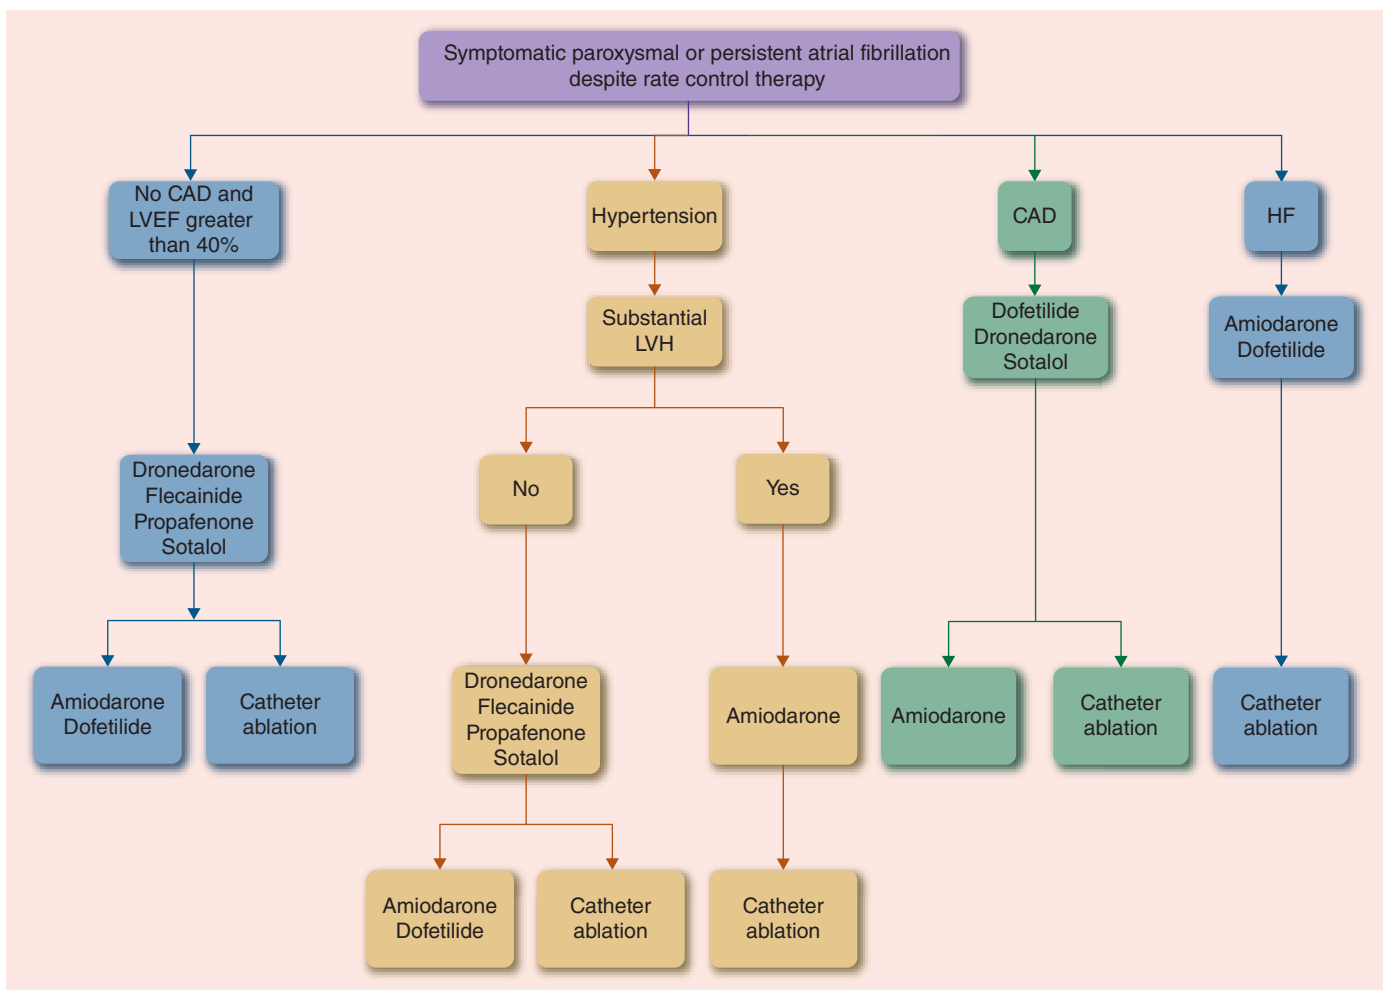

FIGURE 9-8. Decision algorithm for maintenance of sinus rhythm/reduction in the frequency of episodes of atrial fibrillation. (CAD, coronary artery disease; HF, heart failure; LVEF, left ventricular ejection fraction; LVH, left ventricular hypertrophy; LVEF of 40% can also be expressed as 0.40.)

Table 9–10

**American College of Chest Physicians
Recommendations for Stroke Prevention in AF^{29,35}**

CHADS ₂ Score	Degree of Risk	Recommended Stroke Prevention Strategy
0	Low	Antithrombotic therapy is not recommended. For patients who choose antithrombotic therapy: aspirin 75–325 mg daily
Greater than or equal to 1	Moderate-High	Oral anticoagulation recommended; dabigatran preferred over warfarin (INR: 2–3)

CHADS₂ score calculated as follows:

Congestive heart failure	1 point
Hypertension	1 point
Age greater than or equal to 75 years	1 point
Diabetes mellitus	1 point
Stroke or TIA history	2 points

AF, atrial fibrillation; INR, international normalized ratio; TIA, transient ischemic attack.

under 15 mL/min [0.25 mL/s]) or advanced liver disease (impaired baseline clotting function).³⁶ The recommended dabigatran dose is 150 mg twice daily, except for patients with severe kidney disease (creatinine clearance: 15 to 30 mL/min [0.25 to 0.50 mL/s]), for whom the recommended dose is 75 mg twice daily. Advantages of dabigatran include the fact that INR monitoring is not required, and the drug's onset of action is rapid, eliminating the need for bridging with unfractionated or low molecular weight heparins.³⁷ In addition, there is a lower likelihood of drug interactions with dabigatran than with warfarin. However, dabigatran is a p-glycoprotein substrate, and therefore concomitant administration with p-glycoprotein inhibitors such as ketoconazole, amiodarone, and verapamil may result in increases in plasma dabigatran concentrations.³⁷ Similarly, concomitant administration of dabigatran with p-glycoprotein inducers such as rifampin may reduce plasma dabigatran concentrations.³⁷ Disadvantages of dabigatran include the fact that, in cases of dabigatran-associated bleeding, there is no antidote to reverse dabigatran's effects.

For patients for whom warfarin is preferred over dabigatran (such as those with severe kidney disease), specific genetic tests to guide the initiation of therapy have been approved by the FDA. These tests assess single nucleotide polymorphisms on the gene that encodes cytochrome P-450 2C19, the primary hepatic enzyme responsible for warfarin metabolism, and the gene *VKORC1*, which encodes vitamin K epoxide reductase, the enzyme that is inhibited by warfarin as its mechanism of anticoagulation. Some advocate that all patients in whom warfarin therapy is being initiated should undergo genetic testing to guide the initiation of therapy; patients with specific

polymorphisms of one or both of these genes may require adjustment of the initial warfarin dose to achieve adequate anticoagulation or avoid overanticoagulation and toxicity.³⁸ Genetic testing to guide the initiation of warfarin therapy has not yet become standard practice, and many have questioned the efficacy and cost effectiveness of incorporation of routine genetic testing into warfarin therapy. The role of genetic testing in selecting initial warfarin doses is likely to continue to evolve but at the present time appears to be limited.

Algorithms for estimating the initial dose of warfarin have been developed incorporating clinical and pharmacogenetic information.^{39,40} One widely used algorithm, which provides warfarin dose computations with clinical data even if pharmacogenetic information is not obtainable, is available at <http://www.warfarindosing.org>.

Rivaroxaban, an oral factor Xa inhibitor, was approved by the FDA in November 2011 for stroke prevention in AF. Rivaroxaban was shown to be noninferior to warfarin for prevention of stroke or systemic embolism in patients with AF, and compared with warfarin, rivaroxaban was associated with a lower risk of intracranial and fatal bleeding.⁴¹ Apixaban, an investigational oral factor Xa inhibitor, was shown to be superior to warfarin for prevention of stroke or systemic embolism in patients with AF, with lower bleeding risk.⁴² At the time of the writing of this chapter, apixaban had not been approved by the FDA. The potential availability of these new anticoagulation options may markedly change the therapeutics of stroke prevention in AF in the future.

► Outcome Evaluation

- Monitor the patient to determine whether the goal of ventricular rate control is met: heart rate less than 110 bpm with relief of symptoms.
- Monitor ECG to assess continued presence of AF and to determine whether conversion to sinus rhythm has occurred.
- In patients receiving warfarin, monitor INR approximately monthly to make sure it is therapeutic (target: 2.5; range: 2 to 3).
- Monitor patients for adverse effects of specific drug therapy (Table 9–7). Monitor patients receiving warfarin or dabigatran for signs and symptoms of bruising or bleeding.

Patient Encounter Part 3: Creating a Care Plan

Based on the information presented, create a care plan for DT's acute AF episode and for long-term management of his AF.

Your plan should include (a) a statement of the drug-related needs and/or problems, (b) the goals of therapy, (c) a patient-specific detailed therapeutic plan, and (d) a plan for follow-up to determine whether the goals have been achieved and adverse effects avoided.

Paroxysmal Supraventricular Tachycardia

Paroxysmal supraventricular tachycardia (PSVT) is a term that refers to a number of arrhythmias that occur above the ventricles and require atrial or AV nodal tissue for initiation and maintenance.⁴³ The most common of these arrhythmias is known as AV reentrant tachycardia, in which the arrhythmia is caused by a reentrant circuit that involves the AV node or tissue adjacent to the AV node. Other types of PSVT include the relatively uncommon Wolff-Parkinson-White syndrome, which is caused by reentry through an accessory extra-AV nodal pathway. For the purposes of this section, the term PSVT refers to AV nodal reentrant tachycardia.

► Epidemiology and Etiology

Although PSVT can occur in patients experiencing myocardial ischemia or infarction, it often occurs in relatively young individuals with no history of cardiac disease. The overall incidence of PSVT is unknown.

► Pathophysiology

1 *Paroxysmal supraventricular tachycardia is caused by reentry that includes the AV node as a part of the reentrant circuit.* Typically, electrical impulses travel forward (antegrade) down the AV node and then travel back up the AV node (retrograde) in a repetitive circuit. In some patients, the retrograde conduction pathway of the reentrant circuit may exist in extra-AV nodal tissue adjacent to the AV node. One of these pathways usually conducts impulses rapidly while the other usually conducts impulses slowly. Most commonly, during PSVT the impulse conducts antegrade through the slow pathway and retrograde through the faster pathway; in approximately 10% of patients, the reentrant circuit is reversed.⁴³

► Treatment

• **Desired Outcomes** The desired outcomes for treatment are to terminate the arrhythmia, restore sinus rhythm, and

prevent recurrence. Drug therapy is used to terminate the arrhythmia and restore sinus rhythm; nonpharmacologic measures are used to prevent recurrence.

Termination of PSVT Hemodynamically unstable PSVT should be treated with immediate synchronized DCC, using an initial energy level of 50 to 100 J; if the initial DCC attempt is unsuccessful, the shock energy should be increased in a stepwise fashion.¹⁴

• The primary method of termination of hemodynamically stable PSVT is inhibition of impulse conduction and/or prolongation of the refractory period within the AV node. Because PSVT is propagated via a reentrant circuit involving the AV node, inhibition of conduction within the AV node interrupts and terminates the reentrant circuit.

Prior to initiation of drug therapy for termination of hemodynamically stable PSVT, some simple nonpharmacologic methods known as **vagal maneuvers** may be attempted.^{14,44} Vagal maneuvers stimulate the activity of the parasympathetic nervous system, which inhibits AV nodal conduction, facilitating termination of the arrhythmia. Vagal maneuvers alone may terminate PSVT in up to 25% of cases.¹⁴ Perhaps the simplest vagal maneuver is cough, which stimulates the vagus nerve. Instructing the patient to cough two or three times may successfully terminate the PSVT. Another vagal maneuver that may be attempted is carotid sinus massage; one of the carotid sinuses, located in the neck in the vicinity of the carotid arteries, may be gently massaged, stimulating vagal activity. Carotid sinus massage should not be performed in patients with a history of stroke or transient ischemic attack, or in those in whom carotid bruits may be heard on auscultation. The **Valsalva maneuver**, during which patients bear down against a closed glottis, may also be attempted.

If vagal maneuvers are unsuccessful, IV drug therapy should be initiated.^{14,43,44} Drugs that may be used for termination of hemodynamically stable PSVT are presented in **Table 9-11**. A decision strategy for pharmacologic termination of hemodynamically stable PSVT is presented in **Figure 9-9**.^{14,44}

Clinical Presentation and Diagnosis of PSVT

- May occur at any age, but most commonly during the fourth and fifth decades of life⁴⁴
- Occurs more commonly in females than in males; approximately two-thirds of patients that experience PSVT are women⁴³

Symptoms

- Symptoms typical of tachyarrhythmias such as PSVT include palpitations, dizziness, light-headedness, shortness of breath, chest pain (if underlying CAD is present), near-syncope, and syncope. Patients commonly complain of palpitations; often the complaint is "I can feel my heart beating fast" or "I can feel my heart fluttering" or "It feels like my heart is going to beat out of my chest"

- Other symptoms depend on the degree to which cardiac output is diminished, which in turn depends on the heart rate and the degree to which stroke volume is reduced by the rapidly beating heart

Diagnosis

- Because the symptoms of all tachyarrhythmias depend on heart rate and are therefore essentially the same, diagnosis depends on the presence of PSVT on the ECG, characterized by narrow QRS complexes (usually less than 0.12 seconds). P waves may or may not be visible, depending on the heart rate
- PSVT is a regular rhythm and occurs at rates ranging from 100 to 250 bpm

Table 9–11

Drugs for Termination of PSVT¹⁴

Drug	Mechanism	Dose	Drug Interactions
Adenosine	Direct AV nodal inhibition	6 mg IV rapid push followed by 20 mL saline flush. If no response in 1–2 minutes, 12 mg IV rapid push followed by 20-mL saline flush	Dipyridamole and carbamazepine accentuate response to adenosine
Diltiazem	Direct AV nodal inhibition	0.25 mg/kg IV over 2 minutes If insufficient response in 15 minutes, give second dose (0.35 mg/kg) IV over 2 minutes Maintenance infusion 5–15 mg/h	
Verapamil	Direct AV nodal inhibition	1. 2.5–5.0 mg IV over 2 minutes 2. May repeat as 5–10 mg IV every 15–30 minutes to total dose of 20–30 mg	
Digoxin	1. Vagal stimulation 2. Direct AV nodal inhibition	8–12 mcg/kg total loading dose, half of which should be administered over 5 minutes, with the remaining portion administered as 25% fractions at 4- to 8-hour intervals	Slow onset of action
β -Blockers	Direct AV nodal inhibition	Esmolol 500 mcg/kg IV over 1 minute then 50 mcg/kg/min continuous infusion. If inadequate response, give second loading dose of 500 mcg/kg and increase maintenance infusion to 100 mcg/kg/min. Increment dose increases in this manner as necessary to maximum infusion rate of 200 mcg/kg/min Propranolol 0.5–1.0 mg IV over 1 minute; repeat as necessary to a total dose of 0.1 mg/kg Metoprolol 5 mg IV over 1–2 minutes; repeat as necessary every 5 minutes to a total dose of 15 mg Atenolol 5 mg IV over 5 minutes; repeat 5 mg in 10 minutes if necessary	
Amiodarone	β -Blocker Calcium channel blocker	150 mg IV over 10 minutes; repeat if necessary. Follow with continuous infusion of 1 mg/min for 6 hours, followed by 0.5 mg/min. Total dose over 24 hours should not exceed 2.2 g	Inhibits elimination of digoxin and warfarin

AV, atrioventricular; PSVT, paroxysmal supraventricular tachycardia.

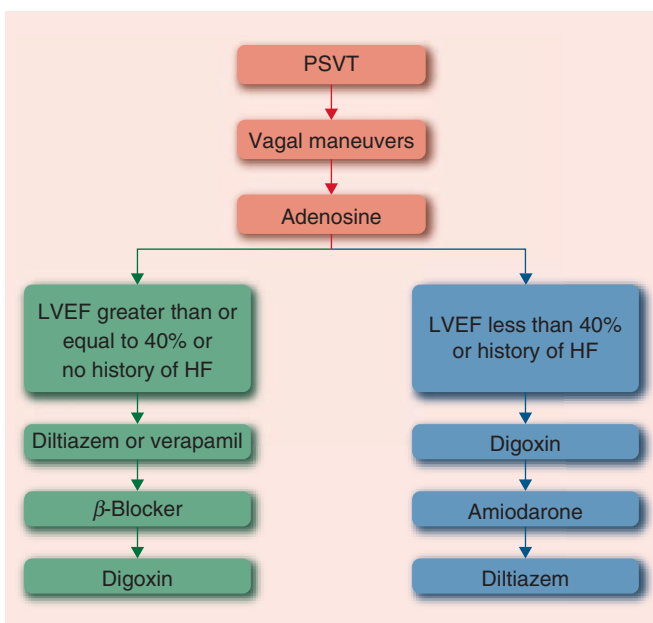

FIGURE 9–9. Decision algorithm for termination of PSVT. (HF, heart failure; LVEF, left ventricular ejection fraction; PSVT, paroxysmal supraventricular tachycardia; LVEF of 40% can also be expressed as 0.40.)

6 Adenosine is the drug of choice for pharmacologic termination of PSVT and is successful in 90% to 95% of patients. Adenosine inhibits conduction transiently and is associated with adverse effects (Table 9–7) including flushing, sinus bradycardia or AV nodal blockade, and bronchospasm in susceptible patients. In addition, adenosine may cause chest pain that mimics the discomfort of myocardial ischemia but is not actually associated with ischemia. The half-life of adenosine is approximately 10 seconds, due to deamination in the blood; therefore, in the vast majority of patients, adverse effects are of short duration.

If adenosine therapy is unsuccessful for termination of PSVT, subsequent choices of therapy depend on whether the patient has heart failure and/or a depressed left ventricular ejection fraction (LVEF).

Nonpharmacologic Therapy: Prevention of Recurrence

In the past, prevention of recurrence of PSVT was attempted using long-term oral therapy with drugs such as verapamil or digoxin. Unfortunately, oral therapy with these drugs was associated with relatively limited success. Currently, the treatment of choice for long-term prevention of recurrence of PSVT is **radiofrequency catheter ablation**. During this procedure, a catheter is introduced transvenously and directed

to the right atrium under fluoroscopic guidance. The catheter is advanced to the AV node, and radiofrequency energy is delivered to ablate, or destroy, one of the pathways of the reentrant circuit. This procedure usually achieves a complete cure of PSVT and is associated with a relatively low risk of complications, and it therefore obviates the need for long-term antiarrhythmic drug therapy in this population.

► Outcome Evaluation

- Monitor patients for termination of PSVT and restoration of normal sinus rhythm.
- Monitor patients for adverse effects of adenosine or any other antiarrhythmic agents administered (Table 9–7).

VENTRICULAR ARRHYTHMIAS

Ventricular Premature Depolarizations

VPDs are ectopic electrical impulses originating in ventricular tissue, resulting in wide, misshapen, abnormal QRS complexes. VPDs are also commonly known by other terms, including premature ventricular contractions (PVCs), ventricular premature beats (VPBs), and ventricular premature contractions (VPCs).

► Epidemiology, Etiology, and Pathophysiology

VPDs occur with variable frequency, depending on underlying comorbid conditions. The prevalence of complex or frequent VPDs is approximately 33% and 12% in men with and without CAD, respectively⁴⁵; in women, the prevalence of complex or frequent VPDs is 26% and 12% in those with and without CAD, respectively.⁴⁶ VPDs occur more commonly in patients with ischemic heart disease, a history of myocardial infarction, and heart failure due to LV dysfunction. They may also occur as a result of hypoxia, anemia, and following cardiac surgery.

- **1** VPDs occur as a result of abnormal ventricular automaticity due to enhanced activity of the sympathetic nervous system and altered electrophysiological characteristics of the heart during myocardial ischemia and following myocardial infarction.

In patients with underlying CAD or a history of myocardial infarction, the presence of complex or frequent VPDs is associated with an increased risk of mortality due to sudden cardiac death.⁴⁷

► Treatment

- **Desired Outcomes** The desired outcomes for treatment are to alleviate patient symptoms.

- **Pharmacologic Therapy** **7** *Asymptomatic VPDs should not be treated with antiarrhythmic drug therapy.* Based on the knowledge that complex or frequent VPDs increase the risk of sudden cardiac death in patients with a history of myocardial infarction, the Cardiac Arrhythmia Suppression Trials (CAST I and II)^{48,49} tested the hypothesis that suppression of asymptomatic VPDs with the drugs flecainide, encainide, or moricizine in patients with a relatively recent history of myocardial infarction would lead to a reduction in the incidence of sudden cardiac death. However, the results of the trial showed that not only did these antiarrhythmic agents not reduce the risk of sudden cardiac death, there was a significant *increase* in the risk of death in patients who received therapy with encainide or flecainide compared with those who received placebo.⁴⁸ During the continuation of the study with moricizine, a trend was found toward an increase in the incidence of death in the patients who received this antiarrhythmic drug as well.⁴⁹ A subsequent meta-analysis of studies of other Vaughan Williams class I agents, including quinidine, procainamide, and disopyramide, found that patients with complex VPDs who received these drugs following myocardial infarction were also at increased risk of death.⁵⁰ Therefore, all available evidence shows that patients with complex VPDs following myocardial infarction do not benefit from therapy with antiarrhythmic agents and that many of these drugs increase the risk of death. **7** *Therefore, asymptomatic VPDs should not be treated.*

Patients with symptomatic VPDs should be treated with β -blockers because the majority of patients with symptomatic VPDs have underlying CAD. β -Blockers have been shown to

Clinical Presentation and Diagnosis of VPDs

- VPDs are usually categorized as simple or complex: simple VPDs are those that occur as infrequent, isolated single abnormal beats; complex VPDs are those that occur more frequently and/or in specific patterns
- Two consecutive VPDs are referred to as a couplet.⁴⁷ The term *bigeminy* refers to VPDs occurring with every other beat; *trigeminy* means VPDs occurring with every third beat; *quadrigeminy* means VPDs occurring every fourth

beat.⁴⁷ VPDs occurring at a rate of more than 10 per hour or 6 or more per minute are defined as frequent⁴⁷

Symptoms

- Most patients who experience simple or complex VPDs are asymptomatic. Occasionally, patients with complex or frequent VPDs may experience symptoms of palpitations, light-headedness, fatigue, near-syncope, or syncope

reduce mortality in this population and have been shown to be effective for VPD suppression.⁵¹

► Outcome Evaluation

- Monitor patients for relief of symptoms.
- Monitor for adverse effects of β -blockers: reduced heart rate, decreased blood pressure, fatigue, masking of symptoms of hypoglycemia, glucose intolerance (in patients with diabetes), wheezing or shortness of breath (in patients with asthma or chronic obstructive pulmonary disease).

Ventricular Tachycardia

Ventricular tachycardia (VT) is a series of three or more consecutive VPDs at a rate greater than 100 bpm. VT is defined as nonsustained if it lasts less than 30 seconds and terminates spontaneously; sustained VT lasts greater than 30 seconds and does not terminate spontaneously but rather requires therapeutic intervention for termination.

► Epidemiology, Etiology, and Pathophysiology

Etiologies of VT are presented in [Table 9–12](#). The incidence of VT is variable, depending on underlying comorbidities. Up to 20% of patients who experience acute myocardial infarction experience ventricular arrhythmias.⁵² Approximately 2% to 4% of patients with myocardial infarction develop VT during the period of hospitalization.⁵¹ Nonsustained VT occurs in 34% to 79% of patients with heart failure.⁵³ Other etiologies of VT include electrolyte abnormalities such as hypokalemia, hypoxia, and some drugs ([Table 9–12](#)).

1 *Ventricular tachycardia is usually initiated by a precisely timed VPD, occurring during the relative refractory period, which provokes reentry within ventricular tissue.*

Sustained VT requires immediate intervention, because if untreated, the rhythm may cause sudden cardiac death via hemodynamic instability and the absence of a pulse (pulseless VT) or via degeneration of VT into VF.

Table 9–12

Etiologies of VT and VF

Coronary artery disease

Disopyramide	Trazodone
Flecainide	Venlafaxine
Ibutilide	
Procainamide	

VF, ventricular fibrillation; VT, ventricular tachycardia.

Clinical Presentation and Diagnosis of VT

Symptoms

- As with other tachyarrhythmias, symptoms associated with VT depend primarily on heart rate and include palpitations, dizziness, light-headedness, shortness of breath, chest pain (if underlying CAD is present), near-syncope, and syncope
- Patients with nonsustained VT may be asymptomatic if the duration of the arrhythmia is sufficiently short. However, if the rate is sufficiently rapid, patients with nonsustained VT may experience symptoms
- Patients with sustained VT are usually symptomatic, provided that the rate is fast enough to provoke symptoms. Patients with rapid sustained VT may be hemodynamically unstable
- In some patients, sustained VT results in the absence of a pulse or may deteriorate to ventricular fibrillation, resulting in the syndrome of sudden cardiac death

Diagnosis

- Diagnosis of VT requires ECG confirmation of the arrhythmia
- VT is characterized by wide, misshapen QRS complexes, with the rate varying from 140 to 280 bpm
- In most patients with VT, the shape and appearance of the QRS complexes are consistent and similar, referred to as monomorphic VT. However, some patients experience polymorphic VT, in which the shape and appearance of the QRS complexes vary

► Treatment

Desired Outcomes The desired outcomes for treatment are to terminate the arrhythmia and restore sinus rhythm, and to prevent sudden cardiac death.

- **Pharmacologic Therapy** Hemodynamically unstable VT should be terminated immediately using synchronized DCC beginning with 100 J (for monophasic shocks) and increasing subsequent shocks to 200, 300, and 360 J.¹⁴ In the event that VT is present but the patient does not have a palpable pulse (and therefore no blood pressure), asynchronous defibrillation should be performed, at 360 J for monophasic waveforms and starting at 120 to 200 J for biphasic waveforms.¹⁴

Drugs used for the termination of hemodynamically stable VT are presented in [Table 9–13](#). IV drug administration is required. A decision algorithm for management of hemodynamically stable VT is presented in [Figure 9–10](#). The initial choice of drug depends on whether the patient has normal left ventricular function or heart failure due to left ventricular systolic dysfunction. If the patient has normal left ventricular function with no history of heart failure, the drug of choice is procainamide, followed by amiodarone

Table 9-13

Drugs for Termination of VT

Drug	Loading Dose	Maintenance Dose
Procainamide	20–50 mg/min continuous IV infusion until arrhythmia suppressed, hypotension occurs, QRS duration increases greater than 50%, or maximum dose of 17 mg/kg is reached	1–4 mg/min continuous IV infusion
Amiodarone	150 mg IV over 10 minutes. Repeat as needed if VT recurs.	1 mg/min continuous infusion for 6 hours, 0.5 mg/min for 18 hours

VT, ventricular tachycardia.

FIGURE 9-10. Decision algorithm for termination of hemodynamically stable ventricular tachycardia. (HF, heart failure; LVEF, left ventricular ejection fraction; VT, ventricular tachycardia; LVEF of 40% can also be expressed as 0.40.)

in refractory cases.¹⁴ However, if the patient has heart failure associated with left ventricular systolic dysfunction, therapy with procainamide should be avoided due to the drug's negative inotropic effects and its propensity to cause hypotension and QT interval prolongation, for which patients with heart failure are at increased risk. Therefore, for patients with hemodynamically stable VT and concomitant heart failure due to left ventricular systolic dysfunction, treatment with IV amiodarone is recommended.¹⁴

Nonpharmacologic Therapy: Prevention of Sudden Cardiac Death **8** *In patients who have experienced VT and are at risk for sudden cardiac death, an **implantable cardioverter-defibrillator** (ICD) is the treatment of choice.*⁵⁴ An ICD is a device that provides internal electrical cardioversion of VT or defibrillation of VF; the ICD does not prevent the patient from developing the arrhythmia, but it reduces the risk that the patient will die of sudden cardiac death as a result of the arrhythmia. Whereas early versions of ICDs required a thoracotomy for implantation, these devices now may be implanted transvenously, similarly to pacemakers, markedly reducing the incidence of complications.

ICDs have been found to be significantly more effective than antiarrhythmic agents such as amiodarone or sotalol for reducing the risk of sudden cardiac death,^{55,56} and they are the preferred therapy.⁵⁴ However, many patients with ICDs receive concurrent antiarrhythmic drug therapy to reduce the frequency with which patients experience the discomfort of shocks and to prolong battery life of the devices. Combined pharmacotherapy with amiodarone and a β -blocker is more effective than monotherapy with sotalol or β -blockers for reduction in the frequency of ICD shocks.⁵⁷

► Outcome Evaluation

- Monitor patients for termination of VT and restoration of normal sinus rhythm.
- Monitor patients for adverse effects of antiarrhythmic drugs administered (Table 9-7).

Ventricular Fibrillation

VF is irregular, disorganized, chaotic electrical activity in the ventricles resulting in absence of ventricular depolarizations, and, consequently, lack of pulse, cardiac output, and blood pressure.

► Epidemiology and Etiology

Approximately 400,000 people die of sudden cardiac death annually in the United States. Although some of these deaths occur as a result of asystole, the majority occur as a result of primary VF or VT that degenerates into VF. Etiologies of VF are presented in Table 9-12 and are similar to those of VT.

► Treatment

- **Desired Outcomes** The desired outcomes for treatment are to (a) terminate VF, (b) achieve return of spontaneous circulation, and (c) achieve patient survival to hospital admission (in those with out-of-hospital cardiac arrest) and to hospital discharge.

Pharmacologic and Nonpharmacologic Therapy VF is by definition hemodynamically unstable, due to the absence of a pulse and blood pressure. Initial management includes provision of basic life support, including calling for help and initiation of cardiopulmonary resuscitation (CPR).¹⁴ Oxygen should be administered as soon as it is available. Most

Clinical Presentation and Diagnosis of VF

Symptoms

- VF results in immediate loss of pulse and blood pressure. Patients who are in the standing position at the onset of VF suddenly and immediately collapse to the ground

Diagnosis

- The absence of a pulse does not guarantee VF because the pulse may also be absent in patients with asystole, VT, or pulseless electrical activity
- Confirmation of the diagnosis with an ECG is necessary to determine appropriate treatment. ECG reveals no organized, recognizable QRS complexes. If treatment is not initiated within a few minutes, death will occur, or at best, resuscitation of the patient with permanent anoxic brain injury

importantly, defibrillation should be performed as soon as possible. It is critically important to understand that the only means of successfully terminating VF and restoring sinus rhythm is electrical defibrillation. Defibrillation should be attempted using 360 J for monophasic defibrillators, and 120 to 200 J for biphasic shocks, after which CPR should be resumed immediately while the defibrillator charges; if the first shock was unsuccessful, subsequent defibrillation attempts should be performed at equivalent or higher energy doses.¹⁴

If VF persists following two defibrillation shocks, drug therapy may be administered. 9 *The purpose of drug administration for treatment of VF is to facilitate successful defibrillation. Drug therapy alone will not result in termination of VF.* Drugs used for facilitation of defibrillation in patients with VF are listed in **Table 9-14**. Drug administration should occur during CPR, before or after delivery of a defibrillation shock. The vasopressor agents epinephrine or vasopressin are administered initially because it has been shown that a critical factor in successful defibrillation is maintenance of coronary perfusion pressure, which is achieved via the vasoconstricting effects of these drugs. A decision algorithm for the treatment of VF is presented in **Figure 9-11**. Epinephrine and vasopressin are equally effective for facilitation of defibrillation leading

Table 9-14

Drugs for Facilitation of Defibrillation in Patients with VF

Drug	Dose
Epinephrine	1 mg IV every 3–5 minutes
Vasopressin	40 units IV single dose
Amiodarone	300 mg IV diluted in 20–30 mL D ₅ W. One subsequent dose of 150 mg IV may be administered

D₅W, 5% dextrose in water; VF, ventricular fibrillation.

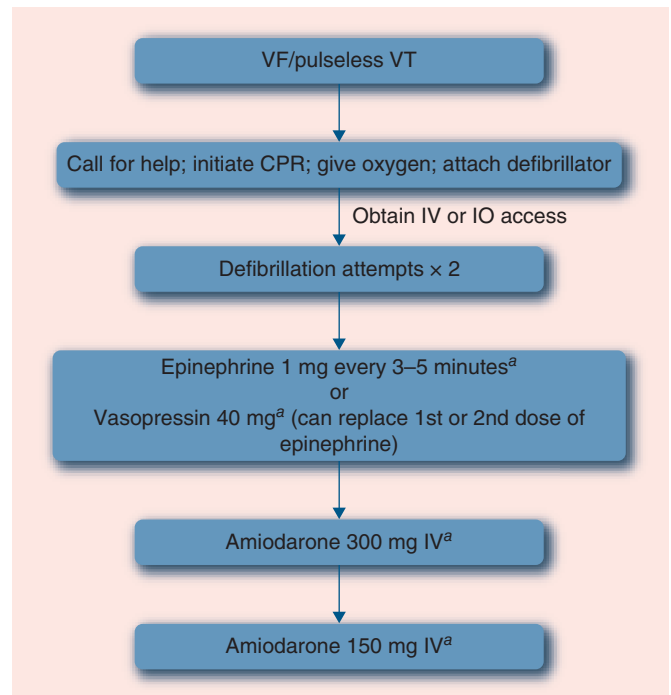

FIGURE 9-11. Decision algorithm for resuscitation of VF or pulseless VT. (CPR, cardiopulmonary resuscitation; IO, intraosseous; VF, ventricular fibrillation; VT, ventricular tachycardia). ^aDefibrillation attempt should be made after every dose of drug.

to survival to hospital admission in patients with out-of-hospital cardiac arrest due to VF. Amiodarone is effective for facilitation of defibrillation leading to survival to hospital admission in patients with VF.⁵⁸ Note that the amiodarone doses recommended for administration during a resuscitation attempt for VF (Table 9-14) are different than those recommended for administration for termination of VT (Table 9-13).

► Outcome Evaluation

- Monitor the patient for return of pulse and blood pressure, and for termination of VF and restoration of normal sinus rhythm.
- After successful resuscitation, monitor the patient for adverse effects of drugs administered (Table 9-7).

Torsades de Pointes

Torsades de pointes is a specific polymorphic VT associated with prolongation of the QT interval in the sinus beats that precede the arrhythmia.⁵⁹

► Epidemiology and Etiology

The incidence of torsades de pointes in the population at large is unknown. The incidence of torsades de pointes associated with specific drugs ranges from less than 1% to as high as 8% to 10%, depending on dose and plasma

Table 9-15

Drugs That Have Been Reported to Cause Torsades de Pointes⁵⁹

Amiodarone	Levofloxacin
Amitriptyline	Levomethadyl
Arsenic	Methadone
Bepidil	Metoclopramide
Chloroquine	Moxifloxacin
Chlorpromazine	Ondansetron
Ciprofloxacin	Pentamidine
Citalopram	Pimozide
Clarithromycin	Procainamide
Disopyramide	Propafenone
Dofetilide	Quetiapine
Doxepin	Quinidine
Droperidol	Risperidone
Erythromycin	Sertraline
Famotidine	Sotalol
Flecainide	Tacrolimus
Fluconazole	Thioridazine
Fluoxetine	Trazodone
Haloperidol	Trimethoprim-sulfamethoxazole
Ibutilide	Voriconazole
Indapamide	Ziprasidone
Ketoconazole	

concentration of the drug and the presence of other risk factors for the arrhythmia.

Torsades de pointes may be inherited or acquired. Patients with specific genetic mutations may have an inherited long QT syndrome, in which the QT interval is prolonged, and these patients are at risk for torsades de pointes. Acquired torsades de pointes may be caused by numerous drugs (Table 9-15); the list of drugs known to cause torsades de pointes continues to expand.

► Pathophysiology

Torsades de pointes is caused by circumstances, often drugs, that lead to prolongation in the repolarization phase of the ventricular action potential (Fig. 9-2) manifested on the ECG by prolongation of the QT interval. Prolongation of ventricular repolarization occurs via inhibition of efflux of potassium through potassium channels; therefore, drugs that inhibit conductance through potassium channels may cause QT interval prolongation and torsades de pointes.

1 Prolongation of ventricular repolarization likely promotes the development of early ventricular afterdepolarizations during the relative refractory period, which may provoke reentry leading to torsades de pointes.

10 Drug-induced torsades de pointes rarely occurs in patients without specific risk factors for the arrhythmia (Table 9-16). In most cases, administration of a drug known to cause torsades de pointes is unlikely to cause the arrhythmia; however, the likelihood of the arrhythmia increases markedly in patients with concomitant risk factors.

The onset of torsades de pointes associated with oral drug therapy is somewhat variable and in some cases may be

Table 9-16

Risk Factors for Drug-Induced Torsades de Pointes⁵⁹

QT _c interval greater than 500 ms
Increase in QT _c interval by more than 60 ms compared with the pretreatment value
Female sex
Age greater than 65 years
Heart failure
Electrolyte abnormalities: hypokalemia, hypomagnesemia, hypocalcemia
Bradycardia
Elevated plasma concentrations of QT interval-prolonging drugs due to drug interactions or absence of dose adjustment for organ dysfunction
Rapid IV infusion of torsades-inducing drugs
Concomitant administration of more than one agent known to cause QT interval prolongation/torsades de pointes
Genetic predisposition
Previous history of drug-induced torsades de pointes

QT_c, corrected QT interval.

delayed; often, a patient can be taking a drug known to cause torsades de pointes for months or longer without problem until another risk factor for the arrhythmia becomes present, which then may trigger the arrhythmia.

In some patients, torsades de pointes may be of short duration and may terminate spontaneously. However, torsades de pointes may not terminate on its own, and if left untreated, it may degenerate into VF and result in sudden cardiac death.⁵⁹ Several drugs, including terfenadine, astemizole, and cisapride, have been withdrawn from the U.S. market as a result of causing deaths due to torsades de pointes.

► Treatment

Desired Outcomes The desired outcomes for treatment include (a) prevention of torsades de pointes, (b) termination of torsades de pointes, (c) prevention of recurrence, and (d) prevention of sudden cardiac death.

Pharmacologic and Nonpharmacologic Therapy 10 In patients with risk factors for torsades de pointes, drugs with the potential to cause QT interval prolongation and torsades de pointes should be avoided or used with extreme caution, and diligent QT interval monitoring should be performed.

Management of drug-induced torsades de pointes includes discontinuation of the potentially causative agent. Patients with hemodynamically unstable torsades de pointes should undergo immediate synchronized DCC. In patients with hemodynamically stable torsades de pointes, electrolyte abnormalities such as hypokalemia, hypomagnesemia, or hypocalcemia should be corrected. Hemodynamically stable torsades de pointes is often treated with IV magnesium, irrespective of whether the patient is hypomagnesemic; magnesium has been shown to terminate torsades de pointes in normomagnesemic patients.¹⁴ Magnesium may be administered IV in doses of 1 to 2 g, diluted in 50 to

Clinical Presentation and Diagnosis of Torsades de Pointes

Symptoms

- As with other tachyarrhythmias, symptoms associated with torsades de pointes depend primarily on heart rate and arrhythmia duration, and they include palpitations, dizziness, light-headedness, shortness of breath, chest pain (if underlying CAD is present), near-syncope, and syncope
- Torsades de pointes may be hemodynamically unstable if the rate is sufficiently rapid
- Like sustained monomorphic VT, torsades de pointes may result in the absence of a pulse or may rapidly degenerate into VF, resulting in the syndrome of sudden cardiac death

Diagnosis

- Diagnosis of torsades de pointes requires examination of the arrhythmia on ECG
- Torsades de pointes, or “twisting of the points,” appears on ECG as apparent twisting of the wide QRS complexes around the isoelectric baseline
- The arrhythmia is associated with heart rates from 140 to 280 bpm
- Characteristic feature: a “long-short” initiating sequence that occurs as a result of a ventricular premature beat followed by a compensatory pause followed by the first beat of the torsades de pointes
- Episodes of torsades de pointes may self-terminate, with frequent recurrence

100 mL 5% dextrose in water (D₅W), administered over 5 to 10 minutes; doses may be repeated to a total of 12 g.

Alternatively, a continuous magnesium infusion may be initiated after the first bolus, at a rate of 0.5 to 1 g/h. Alternative treatments include transvenous insertion of a temporary pacemaker for overdrive pacing, which shortens the QT interval and may terminate torsades de pointes and reduce the risk of recurrence; or IV isoproterenol 2 to 10 mcg/min, to increase the heart rate and shorten the QT interval.

► Outcome Evaluation

- Monitor vital signs (heart rate and blood pressure).
- Monitor the ECG to determine the QT_c interval (maintain less than 470 ms in males and 480 ms in females)⁶⁰ and for the presence of torsades de pointes.
- Monitor serum potassium, magnesium, and calcium concentrations.
- Monitor for symptoms of tachycardia.

Patient Care and Monitoring

1. Perform a thorough medication history to determine whether the patient is receiving any prescription or nonprescription drugs that may cause or contribute to the development of an arrhythmia.
2. Evaluate the patient for the presence of drug-induced diseases, drug allergies, and drug interactions.
3. Determine and monitor the patient's serum electrolyte concentrations to determine the presence or absence of hypokalemia, hyperkalemia, hypomagnesemia, hypermagnesemia, or hypocalcemia.
4. Consider the patient's heart rate, blood pressure, and symptoms to determine whether he or she is hemodynamically stable or unstable.
5. Monitor the patient's 12-lead ECG or single rhythm strips to determine if an arrhythmia is present and to identify the specific arrhythmia, and evaluate and monitor the patient's symptoms.
6. Develop drug therapy treatment plans for management of the specific arrhythmia that the patient is experiencing: sinus bradycardia, AV nodal blockade, AF, PSVT, VPDs, VT (including torsades de pointes), or VF.
7. Develop specific drug therapy monitoring plans for the treatment plan implemented. Monitoring includes assessment of symptoms, ECG, adverse effects of drugs, and potential drug interactions.
8. In those receiving warfarin for AF, determine whether the patient's INR is therapeutic.
9. Provide information regarding safe and effective oral anticoagulation therapy:
 - Notify appropriate clinicians in the event of severe bruising, blood in urine or stool, or frequent nosebleeds.
 - Avoid radical changes in diet.
 - Avoid alcohol.
 - Do not take nonprescription medications or herbal/alternative/complementary medicines without notifying your physician, pharmacist, and/or healthcare team members.
10. Stress the importance of adherence to the therapeutic regimen.
11. Provide patient education regarding disease state and drug therapy.

Abbreviations Introduced in This Chapter

AF	Atrial fibrillation
ATPase	Adenosine triphosphatase
AV	Atrioventricular
bpm	Beats per minute
Ca	Calcium
CAD	Coronary artery disease
CAST	Cardiac Arrhythmia Suppression Trial
CCB	Calcium channel blocker
CPR	Cardiopulmonary resuscitation
DCC	Direct current cardioversion
D ₅ W	5% Dextrose in water
ECG	Electrocardiogram
ED	Emergency department
HF	Heart failure
ICD	Implantable cardioverter-defibrillator
INR	International normalized ratio
IO	Intraosseous
J	Joule
K	Potassium
LV	Left ventricular
LVEF	Left ventricular ejection fraction
LVH	Left ventricular hypertrophy
Na	Sodium
NYHA	New York Heart Association
PSVT	Paroxysmal supraventricular tachycardia
PTT	Partial thromboplastin time
PVC	Premature ventricular contraction
QT _c	Corrected QT interval
SA	Sinoatrial
TEE	Transesophageal echocardiogram
TIA	Transient ischemic attack
VPB	Ventricular premature beat
VPC	Ventricular premature contraction
VPD	Ventricular premature depolarization
VF	Ventricular fibrillation
VT	Ventricular tachycardia

10 Venous Thromboembolism

Edith A. Nutescu, Stuart T. Haines,
and Ann K. Wittkowsky

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Identify risk factors and signs and symptoms of deep vein thrombosis (DVT) and pulmonary embolism (PE).
2. Describe the processes of hemostasis and thrombosis, including the role of the vascular endothelium, platelets, coagulation cascade, and thrombolytic proteins.
3. Determine a patient's relative risk (low, moderate, or high) of developing venous thrombosis.
4. Formulate an appropriate prevention strategy for a patient at risk for DVT.
5. State at least two potential advantages of newer anticoagulants (i.e., low molecular weight heparins, fondaparinux, oral direct thrombin inhibitors, and oral direct factor Xa inhibitors) over traditional anticoagulants (i.e., unfractionated heparin and warfarin).
6. Select and interpret laboratory test(s) to monitor antithrombotic drugs.
7. Identify factors that place a patient at high risk of bleeding while receiving antithrombotic drugs.
8. Manage a patient with an elevated international normalized ratio (INR) with or without bleeding.
9. Identify warfarin drug–drug and drug–food interactions.
10. Formulate an appropriate treatment plan for a patient who develops a DVT or PE, and develop a comprehensive education plan for a patient who is receiving an antithrombotic drug.

KEY CONCEPTS

- 1 Antithrombotic therapies (thrombolytics and anticoagulants) require precise dosing and meticulous monitoring, as well as ongoing patient education. Well-organized anticoagulation management services improve the quality of patient care and reduce the overall cost.
- 2 The risk of venous thromboembolism (VTE) is related to several identifiable factors including age, prior history of VTE, major surgery (particularly orthopedic procedures of the lower extremities), trauma, malignancy, pregnancy, estrogen use, and hypercoagulable states. These risks are additive.
- 3 The symptoms of DVT or PE are nonspecific, and it is extremely difficult to distinguish VTE from other disorders on clinical signs alone. Therefore, objective tests are required to confirm or exclude the diagnosis.
- 4 At the time of hospital admission, all patients should be evaluated for their risk of VTE, and strategies to prevent VTE appropriate for each patient's level of risk should be routinely used. Prophylaxis should be continued throughout the period of risk.
- 5 In the absence of contraindications, the treatment of VTE should initially include a rapid-acting anticoagulant (e.g., unfractionated heparin [UFH], low molecular weight heparin [LMWH], or fondaparinux) overlapped with warfarin for at least 5 days and until the patient's international normalized ratio (INR) is greater than 2 and stable. Anticoagulation therapy should be continued for a minimum of 3 months. However, the duration of anticoagulation therapy should be based on the patient's risk of VTE recurrence and major bleeding.
- 6 Due to significant variability in interpatient response and changes in patient response over time, UFH requires close monitoring and periodic dose adjustment.
- 7 Bleeding is the most common adverse effect associated with antithrombotic drugs. A patient's risk of major hemorrhage is related to the intensity and stability of therapy, age, concurrent drug use, history of GI bleeding, risk of falls or trauma, and recent surgery.

- 8 Most patients with an uncomplicated deep vein thrombosis (DVT) can be managed safely at home.
- 9 Warfarin has been the primary oral anticoagulant used in the United States for the past 60 years. Warfarin is the anticoagulant of choice when long-term or extended anticoagulation is required.
- 10 Warfarin requires frequent laboratory monitoring to ensure optimal outcomes and minimize complications. Additionally, warfarin is prone to numerous clinically important drug–drug and drug–food interactions.

INTRODUCTION

Venous thromboembolism (VTE) is one of the most common cardiovascular disorders in the United States. VTE is manifested as **deep vein thrombosis** (DVT) and **pulmonary embolism** (PE) resulting from **thrombus** formation in the venous circulation (**Fig. 10–1**).¹ It is often provoked by prolonged immobility and vascular injury and most frequently seen in patients who have been hospitalized for a serious medical illness, trauma, or major surgery. VTE can also occur with little or no provocation in patients who have an underlying hypercoagulable disorder.

Although VTE may initially cause few or no symptoms, the first overt manifestation of the disease may be sudden death from PE, which can occur within minutes, before effective treatment can be given.² In addition to the symptoms produced by the acute event, there are long-term sequelae of VTE that can cause long-term pain and suffering. A history of VTE is a significant risk factor for recurrent thromboembolic events. The postthrombotic syndrome (PTS) is a complication of VTE that occurs due to damage to the vein caused by a blood clot and leads to development of symptomatic venous insufficiency such as chronic lower extremity swelling, pain, tenderness, skin discoloration, and ulceration.

The treatment of VTE is fraught with substantial risks.³ **1** *Antithrombotic therapies (thrombolytics and anticoagulants) require precise dosing and meticulous monitoring, as well as ongoing patient education.*^{4,5} *Well-organized anticoagulation management services improve the quality of patient care and reduce the overall cost.* A systematic approach to drug therapy management substantially reduces these risks, but bleeding remains a common and serious complication.⁵ Therefore, preventing VTE is paramount to improving outcomes. When VTE is suspected, a rapid and accurate diagnosis is critical to making appropriate treatment decisions. The optimal use of antithrombotic drugs requires not only an in-depth knowledge

FIGURE 10–1. Venous circulation. (From Witt DM, Nutescu EA, Haines S. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011:312.)

of their pharmacology and pharmacokinetic properties but also a comprehensive approach to patient management.⁶

EPIDEMIOLOGY AND ETIOLOGY

The true incidence of VTE in the general population is unknown because many patients, perhaps more than 50%, have no overt symptoms or go undiagnosed.⁷ An estimated 2 million people in the United States develop VTE each year, of whom 600,000 are hospitalized and 60,000 die. The estimated annual direct medical costs of managing the disease are well over \$1 billion. The incidence of VTE nearly doubles in each decade of life over the age of 50 and is slightly higher in men. As the population ages, the total number of cases of DVT and PE continues to rise.²

② *The risk of VTE is related to several factors including age, prior history of VTE, major surgery (particularly orthopedic procedures of the lower extremities), trauma, malignancy, pregnancy, estrogen use, and hypercoagulable states (Table 10–1).*² VTE risk factors can be categorized in one of the three elements of Virchow's triad: stasis in blood flow, vascular endothelial injury, and inherited or acquired changes in blood constituents resulting in hypercoagulation states. These risk factors are additive, and some can be easily identified in clinical practice. A prior history of venous **thrombosis** is perhaps the strongest risk factor for recurrent VTE, presumably because of damage to venous valves and obstruction of blood flow caused by the initial event. Rapid blood flow has an inhibitory effect on thrombus formation, but a slow rate of flow reduces the clearance of activated clotting factors in the zone of injury and slows the influx of regulatory substances. Stasis tips the delicate balance of procoagulation and anticoagulation in favor of **thrombogenesis**. The rate of blood flow in the venous circulation, particularly in the deep veins of the lower extremities, is relatively slow. Valves in the deep veins of the legs, as well as contraction of the calf and thigh muscles, facilitate the flow of blood back to the heart and lungs. Damage to the venous valves and periods of prolonged immobility result in venous stasis. Vessel obstruction, either from a thrombus or external compression, promotes clot propagation. Numerous medical conditions and surgical procedures are associated with reduced venous blood flow and increase the risk of VTE. Greater than normal blood viscosity, seen in myeloproliferative disorders like polycythemia vera for example, may also contribute to slowed blood flow and thrombus formation.

A growing list of hereditary deficiencies, gene mutations, and acquired diseases have been linked to hypercoagulability (Table 10–1).⁸ Activated protein C resistance is the most common genetic disorder leading to hypercoagulability, found in nearly 5% of individuals of northern European descent and in as many as 40% of those who experience an idiopathic DVT. Although these patients have normal plasma concentrations of protein C, they have a mutation on factor V that renders it resistant to degradation by

Table 10–1

Risk Factors for VTE

Risk Factor	Example
Age	Risk doubles with each decade after age 50
Prior history of VTE	Strongest known risk factor for DVT and PE
Venous stasis	Major medical illness (e.g., congestive heart failure) Major surgery (e.g., general anesthesia for greater than 30 minutes) Paralysis (e.g., due to stroke or spinal cord injury) Polycythemia vera Obesity Varicose veins Immobility (e.g., bedrest during hospital admission)
Vascular injury	Major orthopedic surgery (e.g., knee and hip replacement) Trauma (especially fractures of the pelvis, hip, or leg) Indwelling venous catheters
Hypercoagulable states	Malignancy, diagnosed or occult Activated protein C resistance/factor V Leiden Prothrombin (20210A) gene mutation Protein C deficiency Protein S deficiency AT deficiency Factor VIII excess (greater than 90th percentile) Factor XI excess (greater than 90th percentile) Antiphospholipid antibodies Dysfibrinogenemia PAI-I excess Pregnancy/postpartum
Drug therapy	Estrogen-containing oral contraceptive pills Estrogen replacement therapy SERMs HIT Chemotherapy

AT, antithrombin; DVT, deep vein thrombosis; HIT, heparin-induced thrombocytopenia; PAI-I, plasminogen activator inhibitor; PE, pulmonary embolism; SERMs, selective estrogen receptor modulators; VTE, venous thromboembolism.

activated protein C. This mutation is known as factor V Leiden, named after the city of Leiden, Holland, where the defect was initially reported. The prothrombin gene 20210A mutation is also a relatively common defect, occurring in as many as 3% of healthy individuals of southern European descent and 16% of those with an idiopathic DVT. Although less common, inherited deficiencies of the natural **anticoagulants** protein C, protein S, and antithrombin (AT) place patients at a high lifetime risk for VTE. Conversely, high concentrations of factors VIII, IX, and XI also increase the risk of VTE. Some patients have multiple genetic defects.

Acquired disorders of hypercoagulability include malignancy, antiphospholipid antibodies, estrogen use, and pregnancy.² The strong link between cancer and

thrombosis has been recognized since the late 1800s.⁹ Tumor cells secrete a number of procoagulant substances that activate the clotting cascade. Furthermore, patients with cancer often have suppressed levels of protein C, protein S, and AT. Antiphospholipid antibodies, commonly found in patients with autoimmune disorders such as systemic lupus erythematosus and inflammatory bowel disease, can cause venous and arterial thrombosis.⁸ The antiphospholipid antibody syndrome is associated with repeated pregnancy loss. The precise mechanism by which these antibodies provoke thrombosis is unclear, but they activate the coagulation cascade and platelets, as well as inhibit the anticoagulant activity of proteins C and S. Estrogen-containing contraceptives, estrogen replacement therapy, and many of the selective estrogen receptor modulators (SERMs) increase the risk of venous thrombosis.^{2,10,11} Although the mechanisms are not clearly understood, estrogens increase serum **clotting factor** concentrations and induce activated protein C resistance. Increased serum estrogen concentrations may explain, in part, the increased risk of VTE during pregnancy and the postpartum period.¹¹

PATHOPHYSIOLOGY

Hemostasis, the arrest of bleeding following vascular injury, is essential to life.¹² Within the vascular system, blood remains in a fluid state, transporting oxygen, nutrients, plasma proteins, and waste. When a vessel is injured, a dynamic interplay between thrombogenic (activating) and antithrombotic (inhibiting) forces result in the local formation of a hemostatic plug that seals the vessel wall and prevents further blood loss (Figs. 10–2, 10–3, and 10–4). A disruption of this delicate system of checks and balances may lead to inappropriate clot formation within the blood vessel that can obstruct blood flow or embolize to a distant vascular bed.

Under normal circumstances, the endothelial cells that line the inside of blood vessels maintain blood flow by producing a number of substances that inhibit platelet adherence, prevent the activation of the coagulation cascade, and facilitate **fibrinolysis**.¹² Vascular injury exposes the subendothelium (Fig. 10–3). Platelets readily adhere to the subendothelium, using glycoprotein (GP) Ib receptors found on their surfaces and facilitated by von Willebrand's factor (vWF). This causes platelets to become activated, releasing a number of procoagulant substances that stimulate circulating platelets to expose GP IIb and IIIa receptors and allow platelets to adhere to one another, resulting in platelet aggregation. The damaged vascular tissue releases tissue factor that activates the extrinsic pathway of the coagulation cascade (Fig. 10–4).

The **clotting cascade** is a stepwise series of enzymatic reactions that result in the formation of a fibrin mesh.¹² Clotting factors circulate in the blood in inactive forms. Once a precursor is activated by specific stimuli, it activates the next precursor in the sequence. The final steps in the cascade

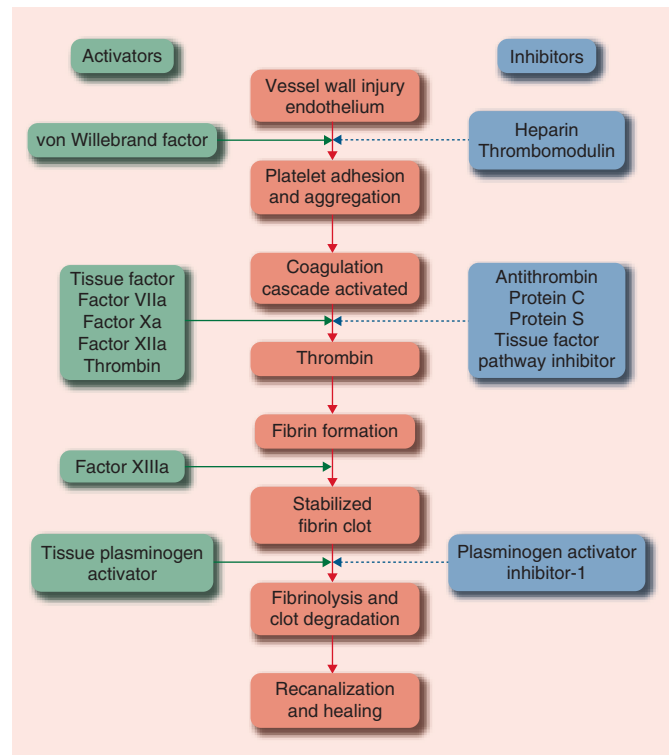

FIGURE 10-2. Hemostasis and thrombosis. (From Witt DM, Nutescu EA, Haines S. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011:314.)

are the conversion of **prothrombin** (factor II) to **thrombin** (factor IIa) and fibrinogen to **fibrin**. Thrombin plays a key role in the coagulation cascade; it is responsible not only for the production of fibrin, but also for the activation of factors V and VIII, creating a positive feedback loop that greatly accelerates the entire cascade. Thrombin also enhances platelet aggregation. Traditionally, the coagulation cascade has been divided into three distinct parts: the intrinsic, the extrinsic, and the common pathways (Fig. 10–4). This artificial division is misleading because there are numerous interactions between the three pathways.

A number of tempering mechanisms control coagulation (Fig. 10–2).¹² Without effective self-regulation, the coagulation cascade would proceed unabated until all the clotting factors and platelets are consumed. AT and heparin cofactor II (HCII) are circulating proteins that inhibit thrombin and factor Xa. The intact endothelium adjacent to the damaged tissue actively secretes several antithrombotic substances including heparan sulfate and thrombomodulin. Heparan sulfate exponentially accelerates AT and HCII activity. Protein C and its cofactor, protein S, are vitamin K-dependent anticoagulant proteins made in the liver. Activation of the clotting cascade activates protein C that, in turn, inhibits factor Va and VIIIa activity. Tissue factor pathway inhibitor (TFPI) inhibits the extrinsic coagulation pathway. When these self-regulatory mechanisms are

FIGURE 10-3. Vascular injury and thrombosis. (ADP, adenosine diphosphate; GP Ib, glycoprotein Ib; GP IIb/IIIa, glycoprotein IIb/IIIa; HK, high molecular weight kininogen; PAF, platelet activating factor-1; PAI-1, plasminogen activator inhibitor; PF-4, platelet factor-4; PGG₂/PGH, prostaglandins; PLA, phospholipase A; TS, thromboxane synthetase; TXA₂, thromboxane A₂; t-PA, tissue plasminogen activator; u-PA, urokinase plasminogen activator; vWF, von Willebrand's factor.) (From Witt DM, Nutescu EA, Haines S. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011:315.)

intact, the formation of the fibrin clot is limited to the zone of tissue injury. However, disruptions in the system often result in inappropriate localized or systemic clot formation.

The fibrinolytic protein plasmin degrades the fibrin mesh into soluble end products collectively known as fibrin split products or fibrin degradation products.¹³ The fibrinolytic system is also under the control of a series of stimulatory and inhibitory substances. Tissue plasminogen activator (t-PA) and urokinase plasminogen activator (u-PA) convert plasminogen to plasmin. Plasminogen activator inhibitor (PAI)-1 inhibits the plasminogen activators and α_2 -antiplasmin inhibits plasmin activity. Aberrations in the fibrinolytic system have also been linked to hypercoagulability.^{13,14}

CLINICAL PRESENTATION AND DIAGNOSIS

Although a thrombus can form in any part of the venous circulation, most begin in the lower extremities. Once formed, a venous thrombus may behave in a combination of

ways including (a) remain asymptomatic, (b) spontaneously lyse, (c) obstruct the venous circulation, (d) propagate into more proximal veins, (e) embolize, and/or (f) slowly incorporate into the endothelial layer of the vessel.¹⁴ Most patients with VTE never develop symptoms.² However, even those who initially experience no symptoms may suffer long-term consequences, such as PTS and recurrent VTE.

Given that VTE can be debilitating or fatal, it is important to treat it quickly and aggressively.¹⁵ However, because major bleeding induced by antithrombotic drugs can be equally harmful, it is important to avoid treatment when the diagnosis is not reasonably certain. Assessment of the patient's status should focus on the search for risk factors in the patient's medical history (Table 10-1).^{16,17} Venous thrombosis is uncommon in the absence of risk factors, and the effects of these risks are additive. Indeed, if a patient has multiple risk factors, VTE should be strongly suspected even when the symptoms are very subtle.

3 *The symptoms of DVT or PE are nonspecific, and it is extremely difficult to distinguish VTE from other disorders on clinical signs alone.¹⁶ Therefore, objective tests are required*

FIGURE 10-4. Summary of coagulation pathways. Specific coagulation factors (“a” indicates activated form) are responsible for the conversion of soluble plasma fibrinogen into insoluble fibrin. This process occurs via a series of linked reactions in which the enzymatically active product subsequently converts the downstream inactive protein into an active serine protease. In addition, the activation of thrombin leads to stimulation of platelets. (HK, high molecular weight kininogen; PK, prekallikrein; TF, tissue factor.) (From Freedman JE, Loscalzo J. Arterial and venous thrombosis. In: Longo DL, Fauci AS, Kasper DL, et al., eds. *Harrison’s Principles of Internal Medicine*, 18th ed. New York, NY: McGraw-Hill, 2012:985.)

to confirm or exclude the diagnosis. Patients with DVT frequently present with unilateral leg pain, swelling that can persist after a night’s sleep, and cyanosis of the skin in the affected leg. Similarly, PTS, a long-term complication of DVT caused by damage to the venous valves, produces chronic lower extremity swelling, pain, and tenderness that lead to skin discoloration and ulceration. To distinguish acute DVT from PTS and other possible diagnoses, a clinical prediction rule that incorporates signs, symptoms and risk factors can be used to categorize the patient as at a low, intermediate, or high probability of having acute DVT. This model, known as the Wells Criteria, is summarized in [Table 10-2](#).¹⁶ If the clinical probability of DVT is low, the D-dimer test can be used to confirm the patient does not have DVT. The D-dimer test is a quantitative measure of fibrin breakdown in the serum, and it is a marker of acute thrombotic activity. D-dimer assays are sensitive but not specific markers for VTE, so a negative D-dimer test can be used to rule out the diagnosis of DVT.

If the D-dimer test is positive in a low probability patient, or if the patient has a moderate or high probability of DVT, then an objective test is used to confirm the diagnosis of DVT. Contrast venography allows visualization of the entire venous system in the lower extremities. This radiographic contrast study is the most accurate and reliable method for the diagnosis of DVT and considered the gold standard in clinical trials.^{18,19} However, venography is an expensive invasive procedure that is technically difficult to

Table 10-2

Clinical Model/Wells Criteria for Evaluating the Pretest Probability of Deep Vein Thrombosis^a

Clinical Characteristic	Score
Active cancer (cancer treatment within previous 6 months or currently on palliative treatment)	+1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	+1
Recently bedridden for 3 days or more, or major surgery within the previous 12 weeks requiring general or regional anesthesia	+1
Localized tenderness along the distribution of the deep venous system	+1
Entire leg swollen	+1
Calf swelling at least 3 cm larger than that on the asymptomatic side (measured 10 cm below tibial tuberosity)	+1
Pitting edema confined to the symptomatic leg	+1
Collateral superficial veins (nonvaricose)	+1
Previously documented deep vein thrombosis	+1
Alternative diagnosis at least as likely as deep vein thrombosis	-2

^aClinical probability of deep vein thrombosis: low, less than 0; moderate, 1–2; high, greater than 3. In patients with symptoms in both legs, the more symptomatic leg is used.

Clinical Presentation and Diagnosis of DVT

General

- VTE most commonly develops in patients with identifiable risk factors (Table 10–1) during or following a hospitalization. Many, perhaps most, patients have asymptomatic disease. Patients may die suddenly of PE.

Symptoms

- The patient may complain of leg swelling, pain, warmth, and/or skin discoloration. Symptoms are nonspecific, and objective testing must be performed to establish the diagnosis.

Signs

- The patient's superficial veins may be dilated and a "palpable cord" may be felt in the affected leg.
- The patient may experience unilateral leg edema with measurable difference in leg circumference, erythema, increase in warmth, and tenderness with palpation of calf muscles.
- The patient may experience pain in back of the knee or calf in the affected leg when the examiner dorsiflexes the foot while the knee is slightly bent (Homan's sign).
- Note: The physical examination signs can be unreliable. Homan's sign (a positive test is pain in the calf or popliteal region with dorsiflexion of the foot) can also be unreliable.

Clinical Probability

- Apply the Wells Criteria to determine the probability the patient's signs, symptoms and risk factors are the result of DVT (Table 10–2).

Laboratory Tests

- The initial laboratory evaluation should include CBC with differential, coagulation studies (such as prothrombin time [PT]/**international normalized ratio** [INR], activated partial thromboplastin time [aPTT]), serum chemistries with renal and liver function, and urinalysis.
- Serum concentrations of D-dimer, a by-product of thrombin generation, will be elevated in an acute event. A negative D-dimer in a patient with low clinical probability of DVT can be used to rule out DVT.
- The patient may have an elevated erythrocyte sedimentation rate (ESR) and white blood cell (WBC) count.

Diagnostic Tests

- Duplex ultrasonography is the most commonly used test to diagnose DVT. It is a noninvasive test that can measure the rate and direction of blood flow and visualize clot formation in proximal veins of the legs. It cannot reliably detect small blood clots in distal veins. Coupled with a careful clinical assessment, it can rule in or out (include or exclude) the diagnosis in most cases.
- Venography (also known as phlebography) is the gold standard for the diagnosis of DVT. However, it is an invasive test that involves injection of radiopaque contrast dye into a foot vein. It is expensive and can cause anaphylaxis and nephrotoxicity.

perform and evaluate. Severely ill patients may be unable to tolerate the procedure, and many develop hypotension and cardiac arrhythmias. Furthermore, the contrast material is irritating to vessel walls and toxic to the kidneys. For these reasons, noninvasive testing is preferred in clinical practice for the evaluation of patients with suspected DVT. The preferred test is duplex ultrasonography. See the Clinical Presentation and Diagnosis of DVT textbox for further information.

Symptomatic PE usually produces shortness of breath, tachypnea, and tachycardia.¹⁶ **Hemoptysis** occurs in less than a third of patients. The most common subjective symptoms are dyspnea, pleuritic chest pain, apprehension (anxiety or a feeling of impending doom), and cough. The physical examination may reveal diminished breath sounds, crackles, wheezes, or a pleural friction rub during auscultation of the lungs. Cardiovascular collapse, characterized by cyanosis, shock, and oliguria, is an ominous sign.

Like DVT, the nonspecific nature of the signs and symptoms of PE requires further evaluation. **Table 10–3** describes a validated prediction model that can be used to stratify patients into high, moderate, and low probability of PE.¹⁶ In patients with a low clinical probability of PE,

the diagnosis of PE can be ruled out if D-dimer testing is negative. If D-dimer testing is positive, or if the patient has a moderate or high clinical probability of PE, diagnostic imaging studies should be performed. Pulmonary angiography allows the visualization of the pulmonary arteries. The diagnosis of VTE can be made if there is a persistent intraluminal filling defect observed on multiple x-ray films. However, as with DVT, a noninvasive test is preferred, such as computed tomography (CT) scans, magnetic resonance imaging (MRI), and ventilation/perfusion (V/Q) scans. See the Clinical Presentation and Diagnosis of PE textbox for further information.

PREVENTION

Given that VTE is often clinically silent and potentially fatal, prevention strategies have the greatest potential to improve patient outcomes.² To rely on the early diagnosis and treatment of VTE is unacceptable because many patients will die before treatment can be initiated. Furthermore, even clinically silent disease is associated with long-term morbidity from PTS and predisposes the patient to future thromboembolic events. Despite an immense body of literature that overwhelmingly

Clinical Presentation and Diagnosis of PE

General

- PE most commonly develops in patients with risk factors for VTE (Table 10–1) during or following a hospitalization. Although many patients will have symptoms of DVT prior to developing a PE, many do not. Patients may die suddenly before effective treatment can be initiated.

Symptoms

- The patient may complain of cough, chest pain, chest tightness, shortness of breath, wheezing, or palpitations.
- The patient may present with hemoptysis (spit or cough up blood).
- The patient may complain of dizziness or lightheadedness.
- Symptoms may be confused for a myocardial infarction or pneumonia, and objective testing must be performed to establish the diagnosis.

Signs

- The patient may have tachypnea (increased respiratory rate) and tachycardia (increased heart rate).
- The patient may appear diaphoretic (sweaty).
- The patient's neck veins may be distended reflecting increased jugular venous pressure.
- The examiner may hear diminished breath sounds, crackles, wheezes, or pleural friction rub, right ventricular S₃, or parasternal lift during auscultation of the lungs.
- In massive PE, the patient may appear cyanotic and hypotensive. In such cases, oxygen saturation by pulse oximetry or arterial blood gas will likely indicate the patient is hypoxic.

- In the worst cases, the patient may go into circulatory shock and die within minutes.

Clinical Probability

- Apply the Wells Criteria to determine the probability that the patient's signs, symptoms, and risk factors are the result of PE (Table 10–3).

Laboratory Tests

- Serum concentrations of D-dimer, a by-product of thrombin generation, will be elevated. A negative D-dimer in a patient with low clinical probability of PE can be used to rule out PE.
- The patient may have an elevated ESR and WBC count.
- The patient may have elevated serum LDH or AST (SGOT) with normal bilirubin.
- Serum troponin I and troponin T can be elevated in a large PE.

Diagnostic Tests

- A CT scan is the most commonly used test to diagnose PE, but some institutions still use a ventilation/perfusion (V/Q) scan. Spiral CT scans can detect emboli in the pulmonary arteries. A V/Q scan measures the distribution of blood and air flow in the lungs. When there is a large mismatch between blood and air flow in one area of the lung, there is a high probability the patient has a PE.
- Pulmonary angiography is the gold standard for diagnosis of PE. However, it is an invasive test that involves injection of radiopaque contrast dye into the pulmonary artery. The test is expensive and associated with a significant risk of mortality.

Table 10–3

Clinical Model/Wells Criteria for Evaluating the Pretest Probability of Pulmonary Embolism^a

Clinical Characteristic	Score

supports the widespread use of pharmacologic and non-pharmacologic strategies to prevent VTE, prophylaxis is underutilized in most hospitals. Even when prophylaxis is given, many patients receive prophylaxis that is less than optimal.

Educational programs and computerized clinical decision support systems have been shown to improve the appropriate use of VTE prevention methods.²

The goal of an effective VTE prophylaxis program is to identify all patients at risk, determine each patient's level of risk, and select and implement regimens that provide sufficient protection for the level of risk.²⁰ **4** *At the time of hospital admission, all patients should be evaluated for their risk of VTE, and strategies to prevent VTE appropriate for each patient's level of risk should be routinely used. Prophylaxis should be continued throughout the period of risk.*

- The risk classification criteria and recommended prophylaxis strategies published by the American College of Chest Physicians (ACCP) Conference on Antithrombotic Therapy are widely used in North America (Table 10–4).² Several pharmacologic and nonpharmacologic methods are effective for preventing VTE, and these can be used alone or in combination. Nonpharmacologic methods improve venous blood flow by mechanical means; drug therapy prevents thrombus formation by inhibiting the coagulation cascade.

Table 10-4

Risk Classification and Consensus Guidelines for VTE Prevention

Level of Risk	Risk of VTE	Prevention Strategies
Low Minor surgery, in mobile patients Medical patients who are fully mobile	Less than 10%	Early and aggressive ambulation
Moderate Major surgery, and no clinical risk factors Acutely ill medical patients (e.g., myocardial infarction, ischemic stroke, heart failure exacerbation) at bed rest	10–40%	UFH 5,000 units SC every 8–12 hours Dalteparin 2,500–5,000 units SC every 24 hours Enoxaparin 40 mg SC every 24 hours Fondaparinux 2.5 mg SC every 24 hours Tinzaparin 3,500 units SC every 24 hours IPC ^a ; GCS ^a
High Major lower extremity orthopedic surgery Hip fracture Major trauma	40–80%	Dalteparin 5,000 units SC every 24 hours Enoxaparin 30 mg SC every 12 hours or 40 mg SC every 24 hours Fondaparinux 2.5 mg SC every 24 hours Tinzaparin 75 units/kg SC every 24 hours Warfarin (target INR = 2–3) IPC ^a ; GCS ^a

GCS, graduated compression stockings; INR, International Normalized Ratio; IPC, intermittent pneumatic compression; SC, subcutaneous; UFH, unfractionated heparin; VTE, venous thromboembolism.

^aMechanical methods of prophylaxis are used in patients at high risk of bleeding complications

Nonpharmacologic Therapy

Ambulation as soon as possible following surgery lowers the incidence of VTE in low-risk patients.² Walking increases venous blood flow and promotes the flow of natural antithrombotic factors into the lower extremities. Although graduated compression stockings (GCS) can reduce the incidence of asymptomatic DVT in lower risk patients, they produce no significant reduction in mortality, symptomatic DVT, or PE.² Compared with anticoagulant drugs, GCS are relatively inexpensive and safe; however, in higher risk patients they are less effective than pharmacologic agents.² They are a good choice in low- to moderate-risk patients when pharmacologic interventions are contraindicated. When combined with pharmacologic interventions, GCS have an additive effect. However, some patients are unable to wear compression stockings because of the size or shape of their legs, and some patients may find them hot, confining, and uncomfortable.

Similar to GCS, intermittent pneumatic compression (IPC) devices increase the velocity of blood flow in the lower extremities.² These devices sequentially inflate a series of cuffs wrapped around the patient's legs from the ankles to the thighs and then deflate in 1- to 2-minute cycles. IPC has been shown to reduce the risk of VTE greater than 60% following general surgery, neurosurgery, and orthopedic surgery. Although IPC is safe to use in patients who have contraindications to pharmacologic therapies, it does have a few drawbacks: It is more expensive than GCS, it is a relatively

cumbersome technique, some patients may have difficulty sleeping while using it, and some patients find the devices hot, sticky, and uncomfortable. To be effective, IPC needs to be used throughout the day. In practice, this is difficult to achieve, and special efforts should be made to ensure the devices are worn and operational for most of the day.

Inferior vena cava (IVC) filters, also known as Greenfield filters, provide short-term protection against PE in very high-risk patients by preventing the **embolization** of a thrombus formed in the lower extremities into the pulmonary circulation.² Insertion of a filter into the IVC is a minimally invasive procedure. Despite the widespread use of IVC filters, there are very limited data regarding their effectiveness and long-term safety. The evidence suggests that IVC filters, particularly in the absence of effective antithrombotic therapy, are thrombogenic themselves and increase the long-term risk of recurrent DVT and of filter thrombosis. In the only randomized clinical trial examining the short- and long-term effectiveness of the filters in patients with a documented proximal DVT, treatment with IVC filters reduced the risk of PE by more than 75% during the first 12 days following insertion.²¹ However, this benefit was not sustained during 2 years of follow-up, and the long-term risk of recurrent DVT was nearly twofold higher in those who received a filter. Although IVC filters can reduce the short-term risk of PE in patients at highest risk, they should be reserved for patients in whom other prophylactic strategies cannot be used. To further reduce the long-term risk of VTE in association with IVC filters, pharmacologic prophylaxis is

necessary in patients with IVC filters in place, and warfarin therapy should begin as soon as the patient is able to tolerate it.² Retrievable filters are preferred, which can be removed once pharmacologic prophylaxis can be safely administered or once the patient is no longer at risk for VTE.

Pharmacologic Therapy

Numerous randomized clinical trials have extensively evaluated pharmacologic strategies for VTE prophylaxis.² Appropriately selected drug therapies can dramatically reduce the incidence of VTE following hip replacement, knee replacement, general surgery, myocardial infarction, and ischemic stroke (Table 10–4). The choice of medication and dose to use for VTE prevention must be based on the patient's level of risk for thrombosis and bleeding complications, as well as the cost and availability of an adequate drug therapy monitoring system.

The ACCP Conference on Antithrombotic Therapy recommends against the use of aspirin as the primary method of VTE prophylaxis.² Antiplatelet drugs clearly reduce the risk of coronary artery and cerebrovascular events in patients with arterial disease, but aspirin produces a very modest reduction in VTE following orthopedic surgeries of the lower extremities. The relative contribution of venous stasis in the pathogenesis of venous thrombosis compared with that of platelets in arterial thrombosis likely explains the reason for this difference.

The most extensively studied drugs for the prevention of VTE are unfractionated heparin (UFH), the low molecular weight heparins (LMWHs; dalteparin, enoxaparin, and tinzaparin), fondaparinux, and warfarin.² The LMWHs and fondaparinux provide superior protection against VTE when compared with low-dose UFH after hip and knee replacement surgery and in other high-risk populations. Even so, UFH remains an effective, cost-conscious choice for moderate-risk patient populations, provided it is given in the appropriate dose (Table 10–4). Low-dose UFH (5,000 Units every 12 or 8 hours) given subcutaneously (SC) has been shown to reduce the risk of VTE significantly in patients undergoing a wide range of general surgical procedures as well as following a myocardial infarction or stroke. For patients who are hospitalized with an acute medical illness, the available evidence supports the use of UFH (5,000 Units every 12 or 8 hours), enoxaparin 40 mg SC daily, dalteparin 5,000 Units SC daily, or fondaparinux 2.5 mg SC daily.

For the prevention of VTE following hip and knee replacement surgery, the effectiveness of low-dose UFH is considerably lower. Adjusted-dose UFH therapy provided SC, which requires dose adjustments to maintain the aPTT at the high end of the normal range, may be used in the highest risk patient populations. However, adjusted-dose UFH has been studied in only a few relatively small clinical trials and requires frequent laboratory monitoring. The LMWHs and fondaparinux appear to provide a high degree of protection against VTE in most high-risk populations. The appropriate prophylactic dose for each LMWH product is indication specific (Table 10–4). There is no evidence that one LMWH is superior to another for the prevention of VTE. Fondaparinux

was significantly more effective than enoxaparin in several clinical trials that enrolled patients undergoing high-risk orthopedic procedures, but it has not been shown to reduce the incidence of symptomatic PE or mortality and has heightened the risk of bleeding. To provide optimal protection, some experts believe the LMWHs should be initiated prior to surgery.²

Warfarin is another commonly used option for the prevention of VTE following orthopedic surgeries of the lower extremities.² Warfarin appears to be as effective as the LMWHs for the prevention of symptomatic VTE events in the highest risk populations. When used to prevent VTE, the dose of warfarin must be adjusted to maintain an INR between 2 and 3. Oral administration and low drug cost give warfarin some advantages over the LMWHs and fondaparinux. However, warfarin does not achieve its full antithrombotic effect for several days and requires frequent monitoring and periodic dosage adjustments, making therapy cumbersome. Warfarin should only be used when a systematic patient monitoring system is available.

Patient Encounter 1

AL is a 61-year-old obese woman with a history of diverticulosis admitted to the hospital after a 2-day period of severe abdominal pain, fever, nausea, and constipation. She is diagnosed with peritonitis and started on antibiotic therapy.

PMH: Diverticulosis × 10 years; depression × 5 years; chronic knee pain × 3 years; hypertension × 2 years

FH: Nonsignificant

SH: Occasional alcohol use. Employed in county government. Lives at home with spouse and pets.

Home Meds: Aspirin 81 mg by mouth once daily; hydrochlorothiazide 25 mg by mouth once daily; bupropion XL 300 mg by mouth once daily

Allergies: NKDA

VS: BP 135/70 mm Hg, HR 72 bpm, RR 16, T 38.7°C (101.6°F), wt 90 kg (198 lb)

Labs: WBC $22.4 \times 10^3/\text{mm}^3$ ($22.4 \times 10^9/\text{L}$); estimated glomerular filtration rate (eGFR) = 80 mL/min/1.73 m² (0.77 mL/s/m²)

Hospital treatment: bowel rest with nothing by mouth; metronidazole 500 mg IV every 8 hours; ceftriaxone 1 g IV every 24 hours

Which risk factor(s) predispose AL to VTE?

What is AL's estimated risk for developing VTE?

Given AL's presentation and history, create an appropriate VTE prophylaxis plan including the pharmacologic agent, dose, route, and frequency of administration, duration of therapy, and monitoring parameters.

Patient Encounter 2

FA is a 64-year-old woman with a new diagnosis of squamous cell cancer of the tongue who is admitted to the hospital for extensive surgical resection of her tongue, feeding tube placement, and Port-a-Cath placement for future chemotherapy.

PMH: Dyslipidemia × 8 years; history of hip fracture 3 years ago with subsequent lower left extremity DVT, treated with LMWH and warfarin for 3 months

FH: Nonsignificant

SH: Smoked half a pack per day for 25 years; occasional alcohol use. Lives alone and expects to be discharged to a rehabilitation facility postoperatively before returning home.

Home meds: Simvastatin 40 mg by mouth daily; oxycodone 5–10 mg by mouth every 5 hours as needed for pain; docusate 250 mg by mouth twice daily

Allergies: NKDA

VS: BP 110/60 mm Hg, HR 55 bpm, RR 18, T 37.0°C (98.6°F), wt 127 kg (280 lb), BMI 40 kg/m²

Labs: All within normal limits; eGFR = 96 mL/min/1.73 m² (0.92 mL/s/m²)

Which risk factor(s) predispose FA to VTE?

How should postoperative VTE be prevented in FA?

How long should FA receive VTE prophylaxis?

What education about VTE prophylaxis should FA receive?

A new option for VTE prevention following hip and knee replacement surgery is rivaroxaban, an oral factor Xa inhibitor that recently was approved for this indication in the United States. This agent is given at a fixed dose of 10 mg once daily, without the need for routine laboratory monitoring and dosing adjustments (as with warfarin) and without the inconvenience of administration by injection (as with LMWH and fondaparinux). Compared with enoxaparin 40 mg SC once daily for VTE prevention in hip replacement, and to both enoxaparin 40 mg SC once daily and 30 mg SC twice daily in knee replacement, rivaroxaban was more effective in preventing postoperative VTE, with a similar rate of bleeding complications.²² The role of this new agent has yet to be determined, but it may offer a convenient alternative to the agents that are currently recommended in evidence-based guidelines.²

The optimal duration for VTE prophylaxis is not well established.² Prophylaxis should be given throughout the period of risk. For general surgical procedures and medical conditions, once the patient is able to ambulate regularly and other risk factors are no longer present, prophylaxis can be discontinued. The risk of VTE in the first month following hospital discharge among patients who have undergone total knee replacement, total hip replacement, or hip fracture

repair is very high. Therefore, extended prophylaxis for 21 to 35 days following hospital discharge with an LMWH, fondaparinux, or warfarin is recommended.

TREATMENT

Desired Therapeutic Outcomes

The goal of VTE treatment is to prevent short- and long-term complications of the disease. In the short term (i.e., the first few days to 6 months), the aim of therapy is to prevent propagation or local extension of the clot, embolization, and death. In the long term (i.e., more than 6 months after the first event), the aim of therapy is to prevent complications, such as PTS, pulmonary hypertension, and recurrent VTE.^{15,23}

General Treatment Principles

Anticoagulant drugs are considered the mainstay of therapy for patients with VTE, and the therapeutic strategies for DVT and PE are essentially identical.^{15,23} **5** *In the absence of contraindications, the treatment of VTE should initially include a rapid-acting anticoagulant (e.g., UFH, LMWH, or fondaparinux) overlapped with warfarin for at least 5 days and until the patient's INR is greater than 2. Anticoagulation therapy should be continued for a minimum of 3 months. However, the duration of anticoagulation therapy should be based on the patient's risk of VTE recurrence and major bleeding.* The treatment of VTE can be divided into acute, subacute, and chronic phases (Fig. 10–5).^{23,24} The acute treatment phase of VTE is typically accomplished by administering a fast-acting parenteral anticoagulant (Table 10–5). The subacute and chronic phase treatments of VTE are usually accomplished using oral anticoagulant agents such as warfarin.^{15,23} In certain populations, such as patients with cancer and women who are pregnant, the LMWHs are the preferred agents during subacute and chronic treatment phases.¹⁵ In the last decade, several novel

Pharmacologic Options for the Initial Treatment of Acute VTE**UFH**

IV administration:^a use weight-based dosing nomogram (Table 10-7) or

SC administration: 17,500 units (250 units/kg) given every 12 hours (an initial 5,000 unit IV bolus dose is recommended to obtain rapid anticoagulation)

Adjust subsequent doses to attain a goal aPTT based on the institution-specific therapeutic range

or

SC administration: 333 units/kg followed by 250 units/kg given every 12 hours (fixed-dose unmonitored dosing regimen)

LMWHs

Dalteparin: 200 units/kg SC once daily or 100 units/kg SC twice daily^b

Enoxaparin: 1.5 mg/kg SC once daily or 1 mg/kg SC twice daily; if CrCl is less than 30 mL/min (0.50 mL/s): 1 mg/kg SC once daily

Tinzaparin: 175 units/kg SC once daily

Factor Xa Inhibitor

Fondaparinux:

For body weight less than 50 kg (110 lb), use 5 mg SC once daily

For body weight 50–100 kg (110–220 lb), use 7.5 mg SC once daily

For body weight greater than 100 kg (220 lb), use 10 mg SC once daily

aPTT, activated partial thromboplastin time; CrCl, creatinine clearance; LMWHs, low-molecular weight heparins; SC, subcutaneous; UFH, unfractionated heparin; VTE, venous thromboembolism.

^aIV administration preferred due to improved dosing precision.

^bNot FDA-approved for treatment of VTE in noncancer patients.

From Kearon C, Kahn SR, Agnelli G, et al. Antithrombotic therapy for venous thromboembolic disease: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines, 8th ed. Chest 2008;133:454S–545S.

anticoagulants, such as direct thrombin inhibitors (DTIs) and factor Xa inhibitors, have emerged as potential alternatives for the acute, subacute, and chronic phases of treatment. As data from clinical trials using these new agents in VTE treatment continue to emerge, their role in clinical practice will be better understood.^{15,23}

Treatment Options**► Pharmacologic Therapy**

Thrombolytics The role of **thrombolysis** in the treatment of VTE is controversial. **Thrombolytic** agents are proteolytic enzymes that have the ability to dissolve, or lyse, the fibrin clot (Table 10-6). Thrombolytics are administered systemically or directly into the thrombus using a catheter-directed infusion.¹⁵ Compared with anticoagulants, thrombolytics restore venous patency more quickly; however, the bleeding risk associated with their use is significantly higher.²⁵ In patients with DVT, thrombolytics decrease short-term pain and swelling and prevent destruction of the venous valves. It is not clear if thrombolytics decrease the incidence and

Table 10-6

Thrombolysis for the Treatment of VTE

- Thrombolytic therapy should be reserved for patients who present with shock, hypotension, right ventricular injury, or massive DVT with limb gangrene
- Diagnosis must be objectively confirmed before initiating thrombolytic therapy
- Thrombolytic therapy is most effective when administered as soon as possible after PE diagnosis, but benefit may extend up to 14 days after symptom onset
- **FDA-approved PE thrombolytic regimens:**
 - Streptokinase 250,000 units IV bolus over 30 minutes followed by 100,000 units/h for 12–24 hours^a
 - Urokinase 4,400 units/kg IV bolus over 10 minutes followed by 4,400 units/kg/h for 12–24 hours^a
 - Alteplase (t-PA) 100 mg IV over 2 hours
- **Non-FDA approved thrombolytic regimens:**
 - Reteplase two 10-unit IV boluses given 30 minutes apart
 - Tenecteplase weight-adjusted IV bolus over 5 seconds (30–50 mg with a 5-mg step every 10 kg from less than 60 to greater than 90 kg)
 - Factors that increase the risk of bleeding must be evaluated before thrombolytic therapy is initiated (i.e., recent surgery, trauma or internal bleeding, uncontrolled hypertension, recent stroke, or ICH)
 - Baseline labs should include CBC and blood typing in case transfusion is needed
 - UFH should not be used during thrombolytic therapy. Neither the aPTT nor any other anticoagulation parameter should be monitored during the thrombolytic infusion
 - aPTT should be measured following the completion of thrombolytic therapy:
 - If aPTT less than 2.5 times the control value, UFH infusion should be started and adjusted to maintain aPTT in therapeutic range
 - If aPTT greater than 2.5 times the control value, remeasure every 2–4 hours and start UFH infusion when aPTT is less than 2.5
 - Avoid phlebotomy, arterial puncture, and other invasive procedures during thrombolytic therapy to minimize the risk of bleeding

aPTT, activated partial thromboplastin time; CBC, complete blood count; DVT, deep vein thrombosis; ICH, intracranial hemorrhage; PE, pulmonary embolism; t-PA, tissue plasminogen activator; UFH, unfractionated heparin; VTE, venous thromboembolism.

^aTwo-hour infusions of streptokinase and urokinase are as effective and safe as alteplase.

severity of PTS. Clinical trials have failed to show any long-term benefits from the routine use of thrombolytics; therefore, their use in most patients is not recommended.^{15,25} In a select group of high-risk patients with massive iliofemoral DVT who are at risk of limb gangrene, thrombolysis may be considered.¹⁵

In patients with acute PE, the use of thrombolytics provides short-term benefits such as restoring pulmonary artery patency and hemodynamic stability.^{15,26} A meta-analysis of nine small randomized clinical trials showed a slightly lower risk of death or recurrent PE in patients treated with thrombolytics when compared with those treated with heparin alone. However, this small benefit was offset by a higher risk of major bleeding.²⁷ Streptokinase, urokinase, and t-PA are thrombolytics and have all been studied and

are FDA approved in the treatment of PE. All three agents have comparable thrombolytic capacity, but t-PA has the potential advantage of a shorter infusion time. Reteplase and tenecteplase are not currently FDA approved for the treatment of PE but have also been studied. Reteplase is administered as two 10-Unit IV boluses given 30 minutes apart, and tenecteplase is given as a weight-adjusted IV bolus over 5 seconds (the dose range is 30 to 50 mg, administered in 5-mg step increments for every 10 kg of body weight, i.e., dose for less than 60 kg is 30 mg, greater than or equal to 60 kg to less than 70 kg is 35 mg, greater than or equal to 70 kg to less than 80 kg is 40 mg, greater than or equal to 80 kg to less than 90 kg is 45 mg, and greater than or equal to 90 kg is 50 mg; the total dose should not exceed 50 mg).^{15,28} Given the relative lack of data to support their routine use, thrombolytics should be reserved for select high-risk circumstances (Table 10–6). Candidates for thrombolytic therapy are patients with acute massive **embolism** who are hemodynamically unstable (systolic blood pressure [SBP] less than 90 mm Hg) or with evidence of right ventricular injury (i.e., elevated troponins) and at low risk for bleeding.^{15,28}

Unfractionated Heparin UFH has traditionally been the drug of choice for indications requiring a rapid anticoagulation including the acute treatment of VTE. Commercially available

UFH preparations are derived from porcine intestinal mucosa or bovine lung. UFH is composed of a heterogeneous mixture of glycosaminoglycans with variable length, molecular weight, and pharmacologic properties. Unlike thrombolytics, UFH and other anticoagulants will not dissolve a formed clot but prevent its propagation and growth.^{4,29} Heparin exerts its anticoagulant effect by augmenting the natural anticoagulant, AT. A specific pentasaccharide sequence on the heparin molecule binds to AT and causes a conformational change that greatly accelerates its activity (Fig. 10–6). This complex inhibits thrombin (factor IIa), as well as factors Xa, IXa, XIa, and XIIa. Thrombin and factor Xa are most sensitive to this inhibition and are inactivated in an equal 1:1 ratio. To inactivate thrombin, the UFH molecule needs to form a ternary complex by binding to both AT and thrombin. Only UFH molecules that are at least 18 saccharide units long are able to form this bridge between AT and thrombin. In contrast, inhibition of factor Xa does not require the formation of a ternary complex. UFH molecules as short as five saccharide units can catalyze the inactivation of factor Xa. Due to its nonspecific binding to cellular proteins, UFH has several limitations, including poor bioavailability when given SC and significant intra- and interpatient variability in anticoagulant response.^{4,29}

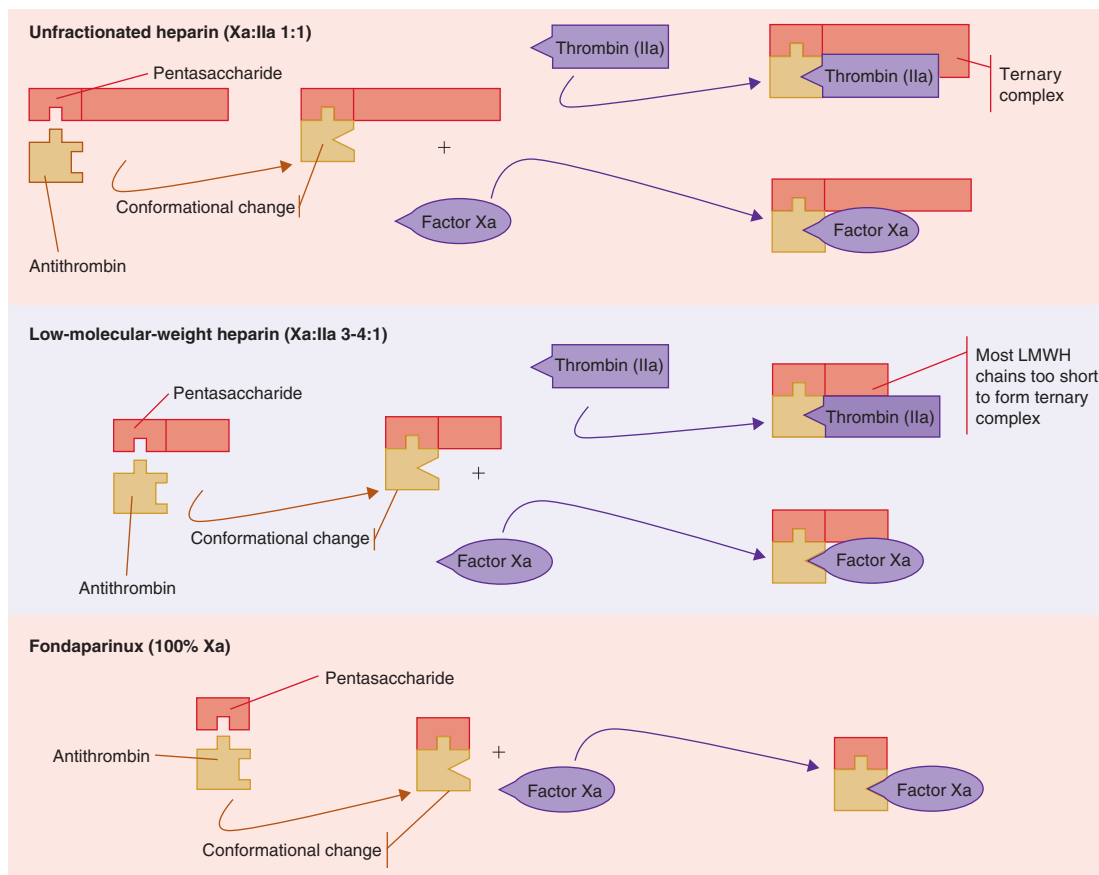

FIGURE 10–6. Mechanism of action of unfractionated heparin, low molecular weight heparin (LMWH), and fondaparinux. (From Witt DM, Nutescu EA, Haines S. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 8th ed. New York, NY: McGraw-Hill, 2011:318.)

UFH can be administered via the IV or SC route.⁴ When rapid anticoagulation is required, UFH should be administered IV and an initial bolus dose should be given. For the treatment of VTE, UFH is generally given as a continuous IV infusion. Intermittent IV bolus dosing is associated with a higher risk of bleeding and therefore not recommended. When given SC, the bioavailability of UFH ranges from 30% to 70%, depending on the dose given. Therefore, higher doses of UFH must be given if the SC route of administration is used. Onset of anticoagulation is delayed by 1 to 2 hours after the SC injection. Due to the risk of hematomas and erratic absorption, intramuscular (IM) administration is not recommended. The half-life of UFH is dose dependent and ranges from 30 to 90 minutes but may be significantly longer, up to 150 minutes, with high doses. UFH is eliminated by two mechanisms: (a) enzymatic degradation via a saturable zero-order process, and (b) renally via a first-order process. Lower UFH doses are primarily cleared via enzymatic processes, whereas higher doses are primarily renally eliminated. Clearance of UFH can be impaired in patients with renal and hepatic dysfunction. Patients with active thrombosis may require higher UFH doses due to a more rapid elimination or variations in the plasma concentrations of heparin-binding proteins. AT deficiency and elevated factor VIII levels are common in pregnant patients. AT deficiency has been linked to higher UFH dose requirements. The requirement of these higher UFH doses is termed *heparin resistance*. Factor VIII elevations can result in altered aPTT response to UFH, and monitoring with antifactor Xa levels is recommended.^{4,29}

The dose of UFH required to achieve a therapeutic anticoagulant response is correlated to the patient's weight.⁴ Weight-based dosing regimens should be used to exceed the therapeutic threshold in the first 24 hours after initiating treatment.^{4,30} Achieving a therapeutic aPTT in the first 24 hours after initiating UFH is critical because it has been shown to lower the risk of recurrent VTE.^{4,30} For nonobese patients, the actual body weight should be used to calculate the initial UFH dose (Table 10-7). For obese patients, using the actual body weight to calculate the initial dose is also generally recommended; however, data are more limited in morbidly obese patients, that is, weight greater than 150 kg (330 lb). Some experts recommend using an adjusted body weight (ABW) in these patients instead. The infusion rate is then adjusted based on laboratory monitoring of the patient's response. UFH can also be administered via the SC route; however, IV infusion is preferred by most clinicians because it can be dosed more precisely. If the SC route is selected, an initial 5,000-Unit IV bolus should be given followed by 17,500 units given SC every 12 hours. Subsequent doses of SC UFH need to be adjusted based on the patient's response.^{15,23,31} Alternatively, in patients with DVT, a fixed-dose, weight-based dose of unmonitored UFH regimen can also be used with an initial dose of 333 units/kg followed by 250 units/kg given SC every 12 hours.^{15,32}

6 Due to significant variability in interpatient response and changes in patient response over time, UFH requires close monitoring and periodic dose adjustment. The response to UFH can be monitored using a variety of laboratory tests including the aPTT, the whole blood clotting time,

Table 10-7

Weight-Based^a Dosing for UFH Administered by Continuous IV Infusion for VTE

Initial Loading Dose	Initial Infusion Rate
80 units/kg (maximum = 10,000 units)	18 units/kg/h (maximum = 2,300 units/h)
	Maintenance Infusion Rate
aPTT (seconds)	Dose Adjustment
Less than 37 (or less than 12 seconds below institution-specific therapeutic range)	80 units/kg bolus then increase infusion by 4 units/kg/h
37–47 (or 1–12 seconds below institution-specific therapeutic range)	40 units/kg bolus then increase infusion by 2 units/kg/h
48–71 (within institution-specific therapeutic range)	No change
72–93 (or 1–22 seconds above institution-specific therapeutic range)	Decrease infusion by 2 units/kg/h
Greater than 93 (or greater than 22 seconds above institution-specific therapeutic range)	Hold infusion for 1 hour then decrease by 3 units/kg/h

aPTT, activated partial thromboplastin time; IBW, ideal body weight; UFH, unfractionated heparin. VTE, venous thromboembolism.

^aUse actual body weight for all calculations. Adjusted body weight (ABW) may be used for morbidly obese patients (greater than 130% of IBW).

ABW = IBW + (Actual body weight – IBW) × 0.7.

activated clotting time (ACT), antifactor Xa activity, and the plasma heparin concentration.^{4,33} Although it has several limitations, the aPTT is the most widely used test in clinical practice to monitor UFH. Traditionally, therapeutic aPTT range is defined as 1.5 to 2.5 times the control aPTT value. However, due to variations in the reagents and instruments used to measure the aPTT in different laboratories, each institution should establish a therapeutic range for UFH. The institution-specific therapy range should correlate with a plasma heparin concentration of 0.2 to 0.4 units/mL by protamine titration or 0.3 to 0.7 units/mL by an amidolytic antifactor Xa assay.^{4,33} An aPTT should be obtained at baseline, 6 hours after initiating the heparin infusion, and 6 hours after each dose change because this is the time required to reach steady state. The UFH dose is then adjusted based on the aPTT measurement and the institutional-specific therapeutic range (Table 10-7). In patients with heparin resistance, antifactor Xa concentrations may be a more accurate method of monitoring the patient's response.^{4,33}

Side effects associated with UFH include bleeding, thrombocytopenia, hypersensitivity reactions, and, with prolonged use, alopecia, hyperkalemia, and osteoporosis.^{4,29}

7 Bleeding is the most common adverse effect associated with antithrombotic drugs including UFH therapy. A patient's risk of major hemorrhage is related to the intensity and stability of therapy, age, concurrent drug use, history of GI bleeding, risk of falls or trauma, and recent surgery. Several risk

Table 10–8

Risk Factors for Major Bleeding While Taking Anticoagulation Therapy

Anticoagulation intensity (e.g., INR greater than 5, aPTT greater than 120 seconds)
 Initiation of therapy (first few days and weeks)
 Unstable anticoagulation response
 Age older than 65 years
 Concurrent antiplatelet drug use
 Concurrent nonsteroidal anti-inflammatory drug or aspirin use
 History of GI bleeding
 Recent surgery or trauma
 High risk for fall/trauma
 Heavy alcohol use
 Renal failure
 Cerebrovascular disease
 Malinancy

aPTT, activated partial thromboplastin time; INR, international normalized ratio.

factors can increase the risk of UFH-induced bleeding (Table 10–8). The risk of bleeding is related to the intensity of anticoagulation. Higher aPTT values are associated with an increased risk of bleeding. The risk of major bleeding is 1% to 5% during the first few days of treatment.³ In addition to the aPTT, hemoglobin, hematocrit, and blood pressure should also be monitored. Concurrent use of UFH with other antithrombotic agents, such as thrombolytics and antiplatelet agents, also increases the risk of bleeding. Patients receiving UFH therapy should be closely monitored for signs and symptoms of bleeding, including epistaxis, hemoptysis, hematuria, **hematochezia**, **melen**a, severe headache, and joint pain. If major bleeding occurs, UFH should be stopped immediately and the source of bleeding treated.^{3,4} If necessary, use protamine sulfate to reverse the effects of UFH. The usual dose is 1 mg protamine sulfate per 100 units of UFH, up to a maximum of 50 mg, given as a slow IV infusion over 10 minutes. The effects of UFH are neutralized in 5 minutes, and the effects of protamine persist for 2 hours. If the bleeding is not controlled or the anticoagulant effect rebounds, repeated doses of protamine may be administered.⁴

Heparin-induced thrombocytopenia (HIT) is a very serious adverse effect associated with UFH use. Platelet counts should be monitored every 2 to 3 days during the course of UFH therapy.⁴ HIT should be suspected if the platelet count drops by more than 50% from baseline or to below $120 \times 10^3/\text{mm}^3$ ($120 \times 10^9/\text{L}$). HIT should also be suspected if thrombosis occurs despite UFH use. Immediate discontinuation of all heparin-containing products including the use of LMWHs is in order. Alternative anticoagulation should be initiated. In patients with contraindications to anticoagulation therapy, UFH should not be administered (Table 10–9).

UFH is an FDA pregnancy category C drug and may be used to treat VTE during pregnancy. UFH should be used with caution in the peripartum period due to the risk of maternal hemorrhage. UFH is not secreted into the breast

Table 10–9

Contraindications to Anticoagulation Therapy**General**

Active bleeding
 Hemophilia or other hemorrhagic tendencies
 Severe liver disease with elevated baseline PT
 Severe thrombocytopenia (platelet count less than $20 \times 10^3/\text{mm}^3$ [$20 \times 10^9/\text{L}$])
 Malignant hypertension
 Inability to meticulously supervise and monitor treatment

Product-Specific Contraindications

UFH

Hypersensitivity to UFH
 History of HIT

LMWHs

Hypersensitivity to LMWH, UFH, pork products, methylparaben, or propylparaben
 History of HIT or suspected HIT

Fondaparinux

Hypersensitivity to fondaparinux
 Severe renal insufficiency (CrCl less than 30 mL/min) [0.50 mL/s]

Body weight less than 50 kg (110 lb)

Bacterial endocarditis

Thrombocytopenia with a positive in vitro test for antiplatelet antibodies in the presence of fondaparinux

Lepirudin

Hypersensitivity to hirudins

Argatroban

Hypersensitivity to argatroban

Warfarin

Hypersensitivity to warfarin

Pregnancy

History of warfarin-induced skin necrosis

Inability to obtain follow-up PT/INR measurements

Inappropriate medication use or lifestyle behaviors

Dabigatran

Hypersensitivity to dabigatran

Severe renal insufficiency (CrCl less than 15 mL/min) [0.25 mL/s]

Rivaroxaban

Hypersensitivity to rivaroxaban

Severe renal insufficiency (CrCl less than 30 mL/min) [0.50 mL/s] when used for VTE prevention)

CrCl, creatinine clearance; HIT, heparin-induced thrombocytopenia; INR, international normalized ratio; LMWHs, low molecular weight heparins; PT, prothrombin time; UFH, unfractionated heparin; VTE, venous thromboembolism.

milk and is safe for use by women who wish to breast-feed.¹¹ For the treatment of VTE in children, the UFH dose is 50 units/kg bolus followed by an infusion of 20,000 units/m² per 24 hours. Alternatively, a loading dose of 75 units/kg followed by an infusion of 28 units/kg/h if younger than 12 months old and 20 units/kg/h if older than 1 year may be considered.³⁴

Low Molecular Weight Heparins The LMWHs are smaller heparin fragments obtained by chemical or enzymatic depolymerization of UFH. LMWHs are heterogeneous mixtures of glycosaminoglycans, and each product has slightly different molecular weight distributions and pharmacologic properties.⁴ Compared with UFH, LMWHs have improved

pharmacodynamic and pharmacokinetic properties. They exhibit less binding to plasma and cellular proteins, resulting in a more predictable anticoagulant response. Consequently, routine monitoring of anticoagulation activity and dose adjustments are not required in most patients. LMWHs have longer plasma half-lives, allowing once- or twice-daily administration, improved SC bioavailability, and dose-independent renal clearance. In addition, LMWHs have a more favorable side-effect profile than UFH. They are also associated with a lower incidence of HIT and osteopenia. Three LMWHs are currently available in the United States: dalteparin, enoxaparin, and tinzaparin.^{4,29}

Like UFH, LMWHs prevent the propagation and growth of formed thrombi. The anticoagulant effect is mediated through a specific pentasaccharide sequence that binds to AT. The primary difference in the pharmacologic activity of UFH and LMWH is their relative inhibition of thrombin (factor IIa) and factor Xa. Smaller heparin fragments cannot bind AT and thrombin simultaneously (Fig. 10–6). Due to their smaller chain length, LMWHs have relatively greater activity against factor Xa and inhibit thrombin to a lesser degree. The antifactor Xa-to-IIa activity ratio for the LMWHs ranges from 2:1 to 4:1. The SC bioavailability of the LMWHs is greater than 90%. The peak anticoagulant effect of the LMWHs is reached 3 to 5 hours after a SC dose. The elimination half-life is 3 to 6 hours and is agent specific. In patients with renal impairment, the half-life of LMWHs is prolonged.^{4,29}

The dose of LMWHs for the treatment of VTE is determined based on the patient's weight and is administered SC once or twice daily (Table 10–5). Once-daily dosing of enoxaparin appears to be as effective as twice-daily dosing; however, some data suggest that twice-daily dosing may be more effective in patients who are obese or have cancer.^{15,23,35} The dose of enoxaparin is expressed in milligrams, whereas the doses of dalteparin and tinzaparin are expressed in units of antifactor Xa activity. Due to their predictable anticoagulant effect, routine monitoring is not necessary in most patients.⁴ LMWHs have been evaluated in a large number of randomized trials and have been shown to be at least as safe and effective as UFH for the treatment of VTE.^{15,23} Indeed, the rate of mortality was lower in patients treated with a LMWH in clinical trials. This mortality benefit was primarily seen in patients with cancer.^{31,36}

Prior to initiating treatment with a LMWH, baseline laboratory tests should include **prothrombin time (PT)/INR**, aPTT, CBC, and serum creatinine. Monitor the CBC with platelet count every 3 to 5 days during the first 2 weeks of therapy, and every 2 to 4 weeks with extended use.⁴ Use LMWHs cautiously in patients with renal impairment due to the potential of drug accumulation and risk of bleeding. Specific dosing recommendations for patients with a creatinine clearance (CrCl) less than 30 mL/min (0.50 mL/s) are currently available for enoxaparin but are lacking for other agents of the class (Table 10–5). Higher mortality rate has been reported in elderly patients with renal dysfunction who were treated with the LMWH tinzaparin. Current guidelines recommend the use of UFH over LMWH in patients with severe renal dysfunction (CrCl less than 30 mL/min [0.50 mL/s]).^{15,37}

8 *Most patients with an uncomplicated DVT can be managed safely at home.* LMWHs can be easily administered in the outpatient setting, thus enabling the treatment of VTE at home. Several large clinical trials have demonstrated the efficacy and safety of LMWHs for outpatient treatment of DVT.^{15,20,31} Acceptance of this treatment approach has increased tremendously over the last several years among clinicians. Patients with DVT with normal vital signs, low bleeding risk, no other comorbid conditions requiring hospitalization, and who are stable may have anticoagulant initiated at home. Although the treatment of patients with PE in the outpatient setting is controversial, patients with submassive PE who are hemodynamically stable can be safely treated in the outpatient setting as well.^{15,26} Patients considered for outpatient therapy must be reliable or have adequate caregiver support and must be able to strictly adhere to the prescribed treatment regimen and recommended follow-up visits. Close patient follow-up is critical to the success of any outpatient DVT treatment program. Home DVT treatment results in cost savings and improved patient satisfaction and quality of life.^{20,37,38}

Laboratory methods of measuring a patient's response to LMWH may be warranted in certain situations.^{4,39} Although controversial, measurement of antifactor Xa activity has been the most widely used method in clinical practice and is recommended by the College of American Pathologists.³⁹

Monitoring of antifactor Xa activity may be considered in adult patients who are morbidly obese (weight greater than 150 kg [330 lb] or body mass index [BMI] greater than 50 kg/m²), weigh less than 50 kg (110 lb), or have significant renal impairment (CrCl less than 30 mL/min [0.50 mL/s]). Laboratory monitoring may also be useful in children and pregnant women. When monitoring antifactor Xa activity, the sample should be obtained approximately 4 hours after the SC dose is administered when peak concentration is anticipated. The therapeutic range for antifactor Xa activity has not been clearly defined, and there is a limited correlation between antifactor Xa activity and safety or efficacy.³⁹ For the treatment of VTE, an acceptable antifactor Xa activity range is 0.5 to 1 units/mL (0.5 to 1 kU/L) with twice-daily dosing. In patients treated with once-daily LMWH regimens, a target level between 1 and 2 units/mL (1 to 2 kU/L) is recommended by some experts.^{4,15,35,39}

Similar to UFH, bleeding is the major complication associated with LMWHs. The frequency of major bleeding appears to be numerically lower with LMWHs than with UFH.³¹ The incidence of major bleeding reported in clinical trials is less than 3%.¹⁵ Minor bleeding, especially bruising at the injection site, occurs frequently. Protamine sulfate will partially reverse the anticoagulant effects of the LMWHs and should be administered in the event of major bleeding. Due to its limited binding to LMWH chains, protamine only neutralizes 60% of their antithrombotic activity. If the LMWH was administered within the previous 8 hours, give 1 mg protamine sulfate per 1 mg of enoxaparin or 100 antifactor Xa units of dalteparin or tinzaparin. If the bleeding is not controlled, give 0.5 mg of protamine sulfate for every antifactor Xa 100 units of LMWH. Give smaller protamine doses if more than 8 hours have lapsed since the last LMWH dose.⁴

The incidence of HIT is lower with LMWHs than with UFH. However, LMWHs cross-react with heparin antibodies *in vitro* and should not be given as an alternative anticoagulant in patients with a diagnosis or history of HIT. Monitor platelet counts every few days during the first 2 weeks and periodically thereafter.⁴

In patients undergoing spinal and epidural anesthesia or spinal puncture, spinal and epidural hematomas have been linked to the use of LMWHs. In patients with in-dwelling epidural catheters, concurrent use of LMWHs and all other agents that impact hemostasis should be avoided. When inserting and removing the in-dwelling epidural catheters, the timing of LMWH administration around catheter manipulation should be carefully coordinated. Catheter manipulation should only occur at minimal or trough anticoagulant levels.⁴

LMWHs are an excellent alternative to UFH for the treatment of VTE in pregnant women.¹¹ The LMWHs do not cross the placenta, and they are FDA pregnancy category B. Because the pharmacokinetics of LMWHs may change during pregnancy, monitor antifactor Xa activity every 4 to 6 weeks to make dose adjustments.^{11,40} LMWHs have also been used to treat VTE in pediatric patients. Children younger than 1 year require higher doses (e.g., enoxaparin 1.5 mg/kg SC every 12 hours). Monitor antifactor Xa activity to guide dosing in children.³⁴

Factor Xa Inhibitors Fondaparinux, the first agent in this class, is an indirect inhibitor of factor Xa and exerts its anticoagulant activity by accelerating AT. Fondaparinux contains the specific five-saccharide sequence found in UFH that is responsible for its pharmacologic activity. Due to its small size, fondaparinux exerts inhibitory activity specifically against factor Xa and has no effect on thrombin (factor IIa; Fig. 10–6).^{29,41} Fondaparinux is currently the only agent of the class that is commercially available in the United States for the treatment of VTE. Idraparinux, rivaroxaban, and apixaban are antifactor Xa inhibitors that have completed or are currently undergoing phase 3 clinical trials for VTE treatment.⁴² Rivaroxaban was recently approved by the FDA for VTE prevention after major orthopedic surgery and stroke prevention in atrial fibrillation. The efficacy and safety of rivaroxaban for VTE treatment has been demonstrated in two recently published trials, and an indication for VTE treatment is expected in the near future. Fondaparinux and idraparinux are administered SC; rivaroxaban and apixaban are administered orally. After SC administration, fondaparinux is completely absorbed, and peak plasma concentrations are reached within 2 to 3 hours.^{41,42} After oral administration, rivaroxaban achieves peak plasma concentrations within 4 hours.⁴²

As synthetic drugs (unlike UFH and the LMWHs), factor Xa inhibitors cannot transmit animal pathogens, are consistent from batch to batch, and are available in an unlimited supply. Other favorable attributes of factor Xa inhibitors include a predictable and linear dose–response relationship, rapid onset of activity, and long half-life.^{29,41,42} Factor Xa inhibitors do not require routine coagulation monitoring or dose adjustments. Fondaparinux has a half-life of 17 to 21 hours, permitting

once-daily administration, but the anticoagulant effects of fondaparinux will persist for 2 to 4 days after stopping the drug. In patients with renal impairment, the anticoagulant effect persists even longer. Idraparinux has a significantly longer duration of activity and is being developed for once-weekly injection. The oral agents rivaroxaban and apixaban have half-lives ranging from 5 to 14 hours allowing once- or twice-daily administration.^{41,42} Rivaroxaban has a relative oral bioavailability of 80% and dual excretion via both the biliary (28%) and renal (66%) routes, and it is metabolized via multiple CYP450 pathways as well as non-CYP-mediated hydrolysis. Metabolism is primarily mediated through CYP3A4/3A5, and to a lesser extent CYP2J2, indicating a concern for drug interactions with other CYP3A4 or P-glycoprotein (P-gp) substrates. Rivaroxaban use is contraindicated in patients with hepatic disease, including Child-Pugh class B and C, because it has been associated with coagulopathy and clinically relevant bleeding. Approximately two-thirds of rivaroxaban is excreted renally, and use in patients with decreased renal function has led to increases in rivaroxaban exposure. Therefore, rivaroxaban should be used with caution in patients with moderate renal dysfunction (CrCl 30 to 49 mL/min [0.50 to 0.82 mL/s]) and contraindicated in patients with severe renal impairment when used for VTE prevention (CrCl less than 30 mL/min [0.50 mL/s]).⁴²

Neither fondaparinux nor idraparinux are metabolized in the liver and therefore have few drug interactions. However, concurrent use with other antithrombotic agents increases the risk of bleeding. Unlike the heparins, factor Xa inhibitors do not affect platelet function and do not react with the heparin platelet factor (PF)-4 antibodies seen in patients with HIT. Some centers use fondaparinux in patients with subacute HIT or a history of HIT who require anticoagulation therapy.^{4,29,41}

Fondaparinux is as safe and effective as IV UFH for the treatment of PE and SC LMWH for DVT treatment.^{43,44} The recommended dose for fondaparinux in the treatment of VTE is based on the patient's weight (Table 10–5). Fondaparinux is renally eliminated, and accumulation can occur in patients with renal dysfunction. Due to the lack of specific dosing guidelines, fondaparinux is contraindicated in patients with severe renal impairment (CrCl less than 30 mL/min [0.50 mL/s]). Baseline renal function should be measured and monitored closely during the course of therapy. Based on limited available data at this time, monitoring antifactor Xa activity to guide fondaparinux dosing is not recommended.^{4,15,29}

As with other anticoagulants, the major side effect associated with fondaparinux is bleeding. Fondaparinux should be used with caution in elderly patients because their risk of bleeding is higher. Patients receiving fondaparinux should be carefully monitored for signs and symptoms of bleeding. A CBC should be obtained at baseline and monitored periodically to detect the possibility of occult bleeding. In the event of major bleeding, fresh-frozen plasma and factor concentrates should be given. In the case of a life-threatening bleed, recombinant factor VIIa may be considered, but this is a very costly option and it can also increase the risk of thrombosis. Fondaparinux is not reversed by protamine.^{4,15,29,41}

Fondaparinux is pregnancy category B, but there are very limited data regarding its use during pregnancy. Use in pediatric patients has not been studied.^{4,29,41}

DTIs Given that thrombin is the central mediator of coagulation and amplifies its own production, it is a natural target for pharmacologic intervention. DTIs bind thrombin and prevent interactions with their substrates (Fig. 10-7). Several injectable DTIs are approved for use in the United States including lepirudin, bivalirudin, argatroban, and desirudin. One oral DTI (dabigatran) is available in the United States, with several other oral DTIs also in development. These agents differ in terms of their chemical structure, molecular weight, and binding to the thrombin molecule. Potential advantages of DTIs include a targeted specificity for thrombin, the ability to inactivate clot-bound thrombin, and an absence of platelet interactions that can lead to HIT. Unlike heparins, DTIs do not require AT as a cofactor and do not bind to plasma proteins. Therefore, they produce a more predictable anticoagulant effect. DTIs are considered the drugs of choice for the treatment of VTE in patients with a diagnosis or history of HIT.^{29,41,45}

The prototype of this class is hirudin, which was originally isolated from the salivary glands of the medicinal leech, *Hirudo medicinalis*. Hirudin itself is not commercially available, but recombinant technology has permitted production of hirudin derivatives, namely lepirudin and desirudin.^{29,41,45} Lepirudin has a short half-life of approximately 40 minutes after IV administration and 120 minutes when given SC. Elimination of lepirudin is primarily renal; therefore, doses must be adjusted based on the patient's renal function. The dose should be monitored and adjusted to achieve an aPTT

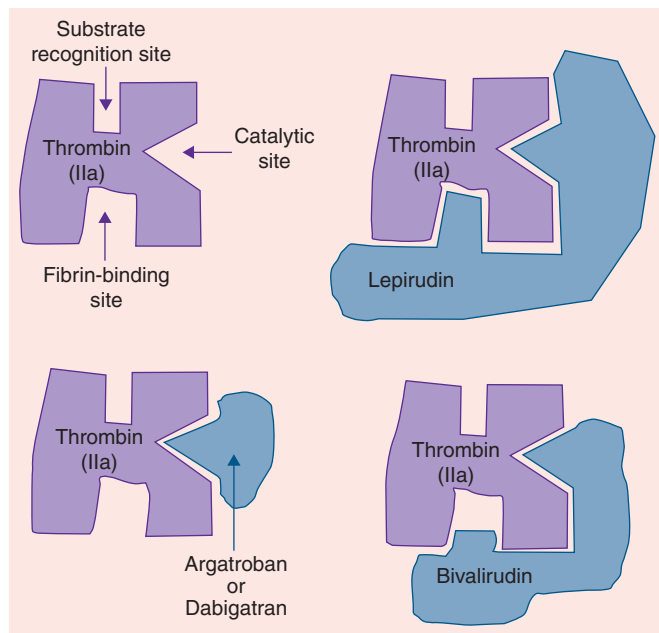

FIGURE 10-7. Mechanism of action of direct thrombin inhibitors. (From Witt DM, Nutescu EA, Haines S. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011:326.)

ratio of 1.5 to 2.5 times the baseline measurement. Lepirudin is currently approved for use in patients with HIT and related thrombosis. Up to 40% of patients treated with lepirudin develop antibodies to the drug.^{29,41,45}

Bivalirudin, a smaller molecular weight DTI, is given by IV infusion. Bivalirudin has a shorter elimination half-life (approximately 25 minutes) than lepirudin and is only partially eliminated renally. Unlike lepirudin, bivalirudin is a reversible inhibitor of thrombin and provides transient antithrombotic activity. Patients with moderate or severe renal impairment (CrCl less than 60 mL/min [1.0 mL/s]) may require dose adjustment because clearance of bivalirudin is reduced by approximately 20% in these patients. Bivalirudin is approved for use in patients with unstable angina undergoing percutaneous transluminal coronary angioplasty. The ACT is used to monitor the anticoagulant effect of bivalirudin during percutaneous coronary intervention (PCI).^{29,41,45}

Desirudin is a SC-administered DTI approved for VTE prevention after hip replacement surgery. Desirudin has an elimination half-life of 2 to 3 hours and typically dosed every 12 hours. It is primarily eliminated through the kidneys, so dose reduction is needed in patients with renal impairment. The aPTT should be used to measure desirudin's anticoagulant activity.^{29,41,45}

Argatroban is a small synthetic molecule that binds reversibly to the active site of thrombin (Fig. 10-7). Argatroban is IV administered and has a 40- to 50-minute elimination half-life. The aPTT must be monitored to assess its anticoagulant activity. Argatroban is hepatically metabolized; therefore, dose reductions and careful monitoring are recommended in patients with hepatic dysfunction. Renal impairment has no influence on the elimination half-life or dosing of argatroban. Argatroban is approved for prevention and treatment of thrombosis in patients with HIT and in patients with HIT undergoing PCI.^{29,41,45}

Small molecule DTIs have been structurally modified for oral administration. Several oral DTIs are in development, with one agent (dabigatran) currently approved in the United States for stroke prevention in patients with atrial fibrillation. Clinical trials have also been completed, and some are ongoing to investigate the efficacy and safety of dabigatran for the treatment of VTE. The potential advantages of oral DTIs include the ability to give them in fixed once- or twice-daily doses, without the need for routine coagulation monitoring, and a fast onset and offset of action, therefore offering more convenient anticoagulation options for patients and providers.^{41,45-46}

Dabigatran, is a direct reversible, competitive inhibitor of thrombin and an oral prodrug of dabigatran etexilate. Dabigatran is converted to dabigatran etexilate by serum esterases that are independent of CYP450 pathways. Dabigatran has a half-life of 12 to 17 hours in healthy subjects and onset of effect of 2 hours. Dabigatran has an oral bioavailability of approximately 3% to 7% and requires an acidic environment for absorption. The prodrug is contained in small pellets coated with an acid core. These pellets are enclosed in a capsule shell. This specific capsule formulation improves the dissolution and absorption of the prodrug, independent of gastric pH. Therefore the capsules should not be broken, chewed, or opened

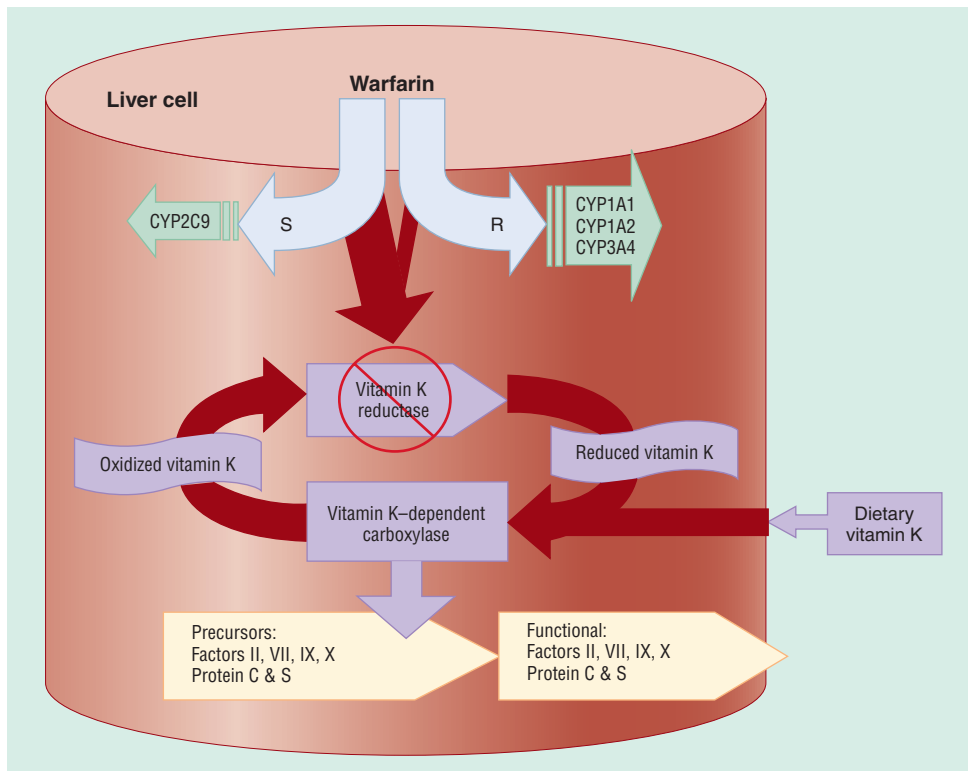

FIGURE 10–8. Pharmacologic activity and metabolism of warfarin. (CYP, cytochrome P-450 isoenzyme.) (From Witt DM, Nutescu EA, Haines S. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011:328.)

before administration. Dabigatran demonstrates 35% protein binding and is a substrate of the efflux transporter P-gp. Although the absence of CYP450 metabolism decreases potential for many drug interactions, coadministration with substrates, inhibitors, or inducers may affect the efficacy of dabigatran. Approximately 80% of dabigatran is eliminated in the urine, and a dose adjustment is recommended in patients with severe renal impairment (CrCl 15 to 30 mL/min [0.25 to 0.50 mL/s]). The use of dabigatran is contraindicated in patients with a CrCl less than 15 mL/min (0.25 mL/s).^{41,46}

Contraindications to the use of DTIs and risk factors for bleeding are similar to those of other antithrombotic agents (Tables 10–8 and 10–9). Bleeding is the most common side effect reported with the use of DTIs. Concurrent use of DTIs with thrombolytics significantly increases bleeding complications. Currently, there are no known antidotes to reverse the effects of the DTIs. Fresh-frozen plasma, factor concentrates, or recombinant factor VIIa should be given in the event of a major bleed. DTIs can increase the PT/INR and can interfere with the accuracy of monitoring and dosing of warfarin therapy. Data on the use of DTIs in pregnancy and pediatric patients are very limited.^{29,41,45}

Warfarin **9** Warfarin has been the primary oral anticoagulant used in the United States for the past 60 years. Warfarin is the anticoagulant of choice when long-term or extended anticoagulation is required. Warfarin is FDA approved for the prevention and treatment of VTE, as well as the prevention of thromboembolic complications in patients with myocardial infarction, atrial fibrillation, and heart valve replacement. Although very effective, warfarin has a narrow

therapeutic index, requiring frequent dose adjustments and careful patient monitoring.^{5,29}

Warfarin exerts its anticoagulant effect by inhibiting the production of the vitamin K–dependent coagulation factors II (prothrombin), VII, IX, and X, as well as the anticoagulant proteins C and S (Fig. 10–8). Warfarin has no effect on circulating coagulation factors that have been previously formed, and its full antithrombotic activity is delayed for 5 to 7 days, and potentially longer in slower metabolizers. This delay is related to half-lives of the clotting factors: 60 to 100 hours for factor II (prothrombin), 6 to 8 hours for factor VII, 20 to 30 hours for factor IX, and 24 to 40 hours for factor X. Proteins C and S, the natural anticoagulants, are inhibited more rapidly due to their shorter half-lives, 8 to 10 hours and 40 to 60 hours, respectively. Reductions in the concentration of natural anticoagulants before the clotting factors are depleted can lead to a paradoxical hypercoagulable state during the first few days of warfarin therapy. It is for this reason that patients with acute thrombosis should receive a fast-acting anticoagulant (heparin, LMWH, or fondaparinux) while transitioning to warfarin therapy.^{5,20,29}

Warfarin is a racemic mixture of two isomers, the S and the R forms. The S-isomer is two to five times more potent than the R-isomer. Both isomers are extensively bound to albumin. The two isomers are metabolized in the liver via several isoenzymes including cytochrome P-450 (CYP) 1A2, 2C9, 2C19, 2C18, and 3A4 (Fig. 10–8). Hepatic metabolism of warfarin varies greatly among patients, leading to very large interpatient differences in dose requirements and genetic variations in these isoenzymes; specifically, polymorphisms in the CYP2C9*2, CYP2C9*3 genotype result in significantly lower warfarin dose

requirement to achieve a therapeutic response, and VKORC1 haplotype mutations can result in hereditary warfarin resistance and increased warfarin requirements.⁵ Several algorithms that incorporate CYP2C9 genotype and the VKORC1 haplotype with other patient characteristics to predict warfarin maintenance dosing requirements have been developed and are being tested in large populations. Whether pharmacogenomic-based dosing will improve clinical outcomes has yet to be determined and is not widely recommended for practice incorporation at this time, but it does hold promise for a more personalized approach to warfarin dosing.^{5,47}

Warfarin does not follow linear kinetics. Small-dose adjustments can lead to large changes in anticoagulant response.

The dose of warfarin is determined by each patient's individual response to therapy and the desired intensity of anticoagulation. In addition to hepatic metabolism, warfarin dose requirements are influenced by diet, drug–drug interactions, and health status. Therefore, the dose of warfarin must be determined by frequent clinical and laboratory monitoring.^{5,20,29} Although there are conflicting data regarding the optimal warfarin induction regimen, most patients can start with 5 mg daily, and subsequent doses are determined based on INR response (Fig. 10–9). When initiating therapy, it is difficult to predict the precise warfarin maintenance dose that a patient will require. Patients who are younger (less than 55 years of age) and otherwise healthy can safely

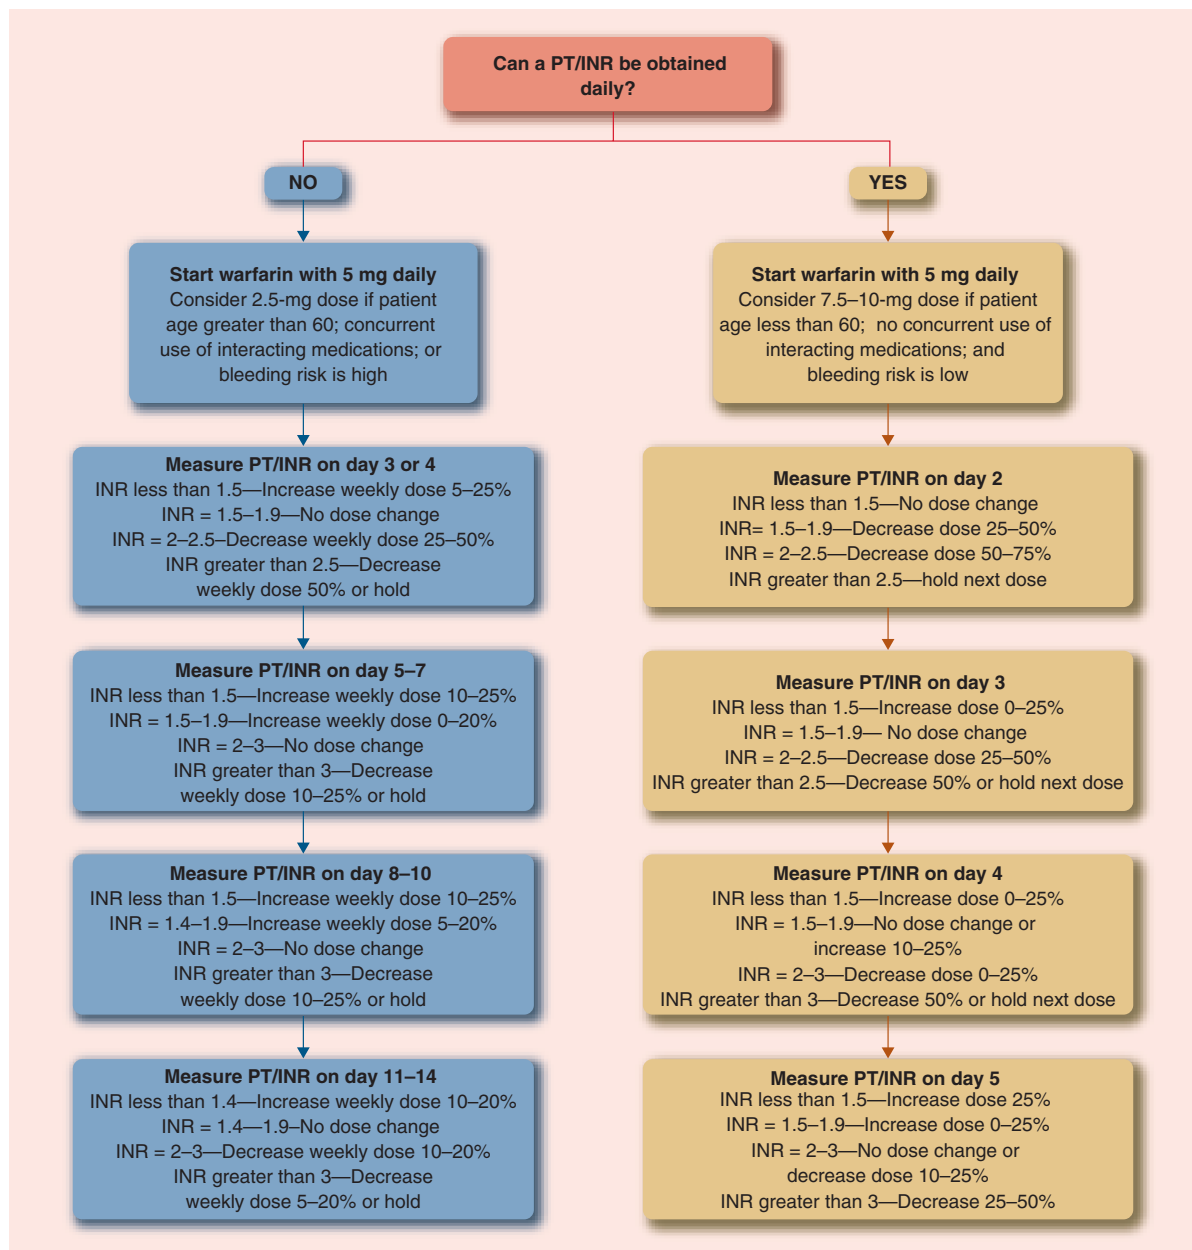

FIGURE 10–9. Initiation of warfarin therapy. (INR, international normalized ratio; PT, prothrombin time.) (From Witt DM, Nutescu EA, Haines S. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011:331.)

use higher warfarin “initiation” doses (e.g., 7.5 or 10 mg). A more conservative “initiation” dose (e.g., 5 mg or less) should be given to elderly patients (older than 75 years), patients with heart failure, liver disease, or poor nutritional status, and patients who are taking interacting medications or are at high risk of bleeding.^{5,23} Loading doses of warfarin (e.g., 15 to 20 mg) are not recommended. These large doses can lead to the false impression that a therapeutic INR has been achieved in 2 to 3 days and lead to potential future overdosing.⁵ Before initiating therapy, screen the patient for any contraindications to anticoagulation therapy and risk factors for major bleeding (Tables 10–8 and 10–9). In addition, conduct a thorough medication history including the use of prescription and nonprescription drugs, and any herbal supplements to detect interactions that may affect warfarin dosing requirements. In patients with acute VTE, a rapid-acting anticoagulant (UFH, LMWH, or fondaparinux) should be overlapped with warfarin for a minimum of 5 days and until the INR is greater than 2 and stable. This is important because the full antithrombotic effect will not be reached until 5 to 7 days or even longer after initiating warfarin therapy.^{5,15} The typical maintenance dose of warfarin for most patients will be between 25 and 55 mg per week, although some patients require higher or lower doses. Adjustments in the maintenance warfarin dose should be determined based on the total weekly dose and by reducing or increasing the weekly dose by increments of 5% to 25%. When adjusting the maintenance dose, wait at least 7 days to ensure that a steady state has been attained on the new dose before checking the INR again. Checking the INR too soon can lead to inappropriate dose adjustments and unstable anticoagulation status.⁵

10 *Warfarin requires frequent laboratory monitoring to ensure optimal outcomes and minimize complications.* The PT is the most frequently used test to monitor warfarin’s anticoagulant effect. The PT measures the biological activity of factors II, VII, and X. Due to wide variation in reagent sensitivity, different **thromboplastins** will result in different PT results, potentially leading to inappropriate dosing decisions.⁵ To standardize result reporting, the World Health Organization (WHO) developed a reference thromboplastin and recommended the INR to monitor warfarin therapy. The INR corrects for the differences in thromboplastin reagents and uses the following formula: $INR = (PT^{Patient}/PT^{Control})^{ISI}$. The International Sensitivity Index (ISI) is a measure of the thromboplastin’s responsiveness compared with the WHO reference.⁵ The goal or target INR for each patient is based on the indication for warfarin therapy. For the treatment and prevention of VTE, the INR target is 2.5 with an acceptable range of 2 to 3. In certain high-risk patients (e.g., certain mechanical heart valves), a higher target INR of 3 with a range of 2.5 to 3.5 is recommended.⁵ Before initiating warfarin therapy, a baseline PT/INR and CBC should be obtained. After initiating warfarin therapy, the INR should be monitored at least every 2 to 3 days during the first week of therapy. Once a stable response to therapy is achieved, INR monitoring is performed less frequently, weekly for the first 1 to 2 weeks, then every 2 weeks, and monthly thereafter.^{5,48} At each encounter, the patient should be carefully questioned regarding any

Patient Encounter 3, Part 1

CR is a 47-year-old woman who presents to the emergency department complaining of chest pain, shortness of breath, and lightheadedness. The patient states that her symptoms started with some mild left calf pain approximately 5 days ago. She started feeling short of breath and experiencing chest pain last evening. She could not sleep, and her shortness of breath has gotten progressively worse in the last several hours. CR was hospitalized because she was suspected to have a PE.

PMH: Obesity × 12 years; chronic obstructive pulmonary disease

FH: Mother died of a stroke; paternal grandmother had clots in her legs

SH: The patient is a bus driver.

Current meds: Albuterol (salbutamol) metered-dose inhaler as needed; ortho-Tri-Cyclen Lo by mouth daily; echinacea one to two tablets by mouth daily as needed; multivitamin one tablet by mouth daily

Allergies: Shellfish, NKDA

PE:

VS: BP 104/64 mm Hg, HR 102 bpm, RR 20, T 38°C (100.4°F), wt 96 kg (211 lb), ht 65 in. (165 cm)

Labs: Within normal limits; eGFR 101 mL/min/1.73 m² (0.97 mL/s/m²)

Procedures/Tests

ECG: Normal sinus rhythm

CXR: Slightly enlarged heart

V/Q scan: High probability of PE

What symptoms are consistent with the diagnosis of PE in CR’s case? What are the most likely etiologies for PE in this case?

What are appropriate initial and chronic treatment options for CR?

If UFH is chosen as the initial anticoagulation treatment option, what is the goal aPTT?

What is CR’s goal INR for warfarin therapy?

How long should CR remain on anticoagulation therapy?

Given the list of medications CR took prior to hospitalization, should any of these medications be discontinued or changed? If changed, what alternative therapy would you recommend?

factors that may influence the INR result. These factors include adherence to therapy, the use of interacting medications, consumption of vitamin K–rich foods, alcohol use, and general health status. Patients should also be questioned about symptoms related to bleeding and thromboembolic events. Warfarin dose adjustments should take into account not only the INR result but also patient-related factors that influence

the result. Structured anticoagulation therapy management services (anticoagulation clinics) have been demonstrated to improve the efficacy and safety of warfarin therapy when compared with “usual” medical care.^{5,48} Some patients engage in self-testing and self-management by using a point-of-care PT/INR device approved for home use. Highly motivated and well-trained patients are good candidates for self-testing or self-management.^{5,48}

7 Similar to other anticoagulants, warfarin’s primary side effect is bleeding. Warfarin can unmask an existing lesion. The incidence of warfarin-related bleeding appears to be highest during the first few weeks of therapy. The annual incidence of major bleeding ranges from 1% to 10% depending on the

quality of warfarin therapy management. Bleeding in the GI tract is most common. Intracranial hemorrhage (ICH) is one of the most serious complications because it often causes severe disability and death. The intensity of anticoagulation therapy is related to bleeding risk. Higher INRs result in higher bleeding risk, and the risk of ICH increases when the INR exceeds 4.^{3,5} Instability and wide fluctuations in the INR are also associated with higher bleeding risk. In cases of warfarin overdose or overanticoagulation, vitamin K may be used to reverse warfarin’s effect (Fig. 10-10).⁵ Vitamin K can be given by the IV or oral route; the SC route is not recommended. When given SC, vitamin K is erratically absorbed and frequently ineffective. The IV route

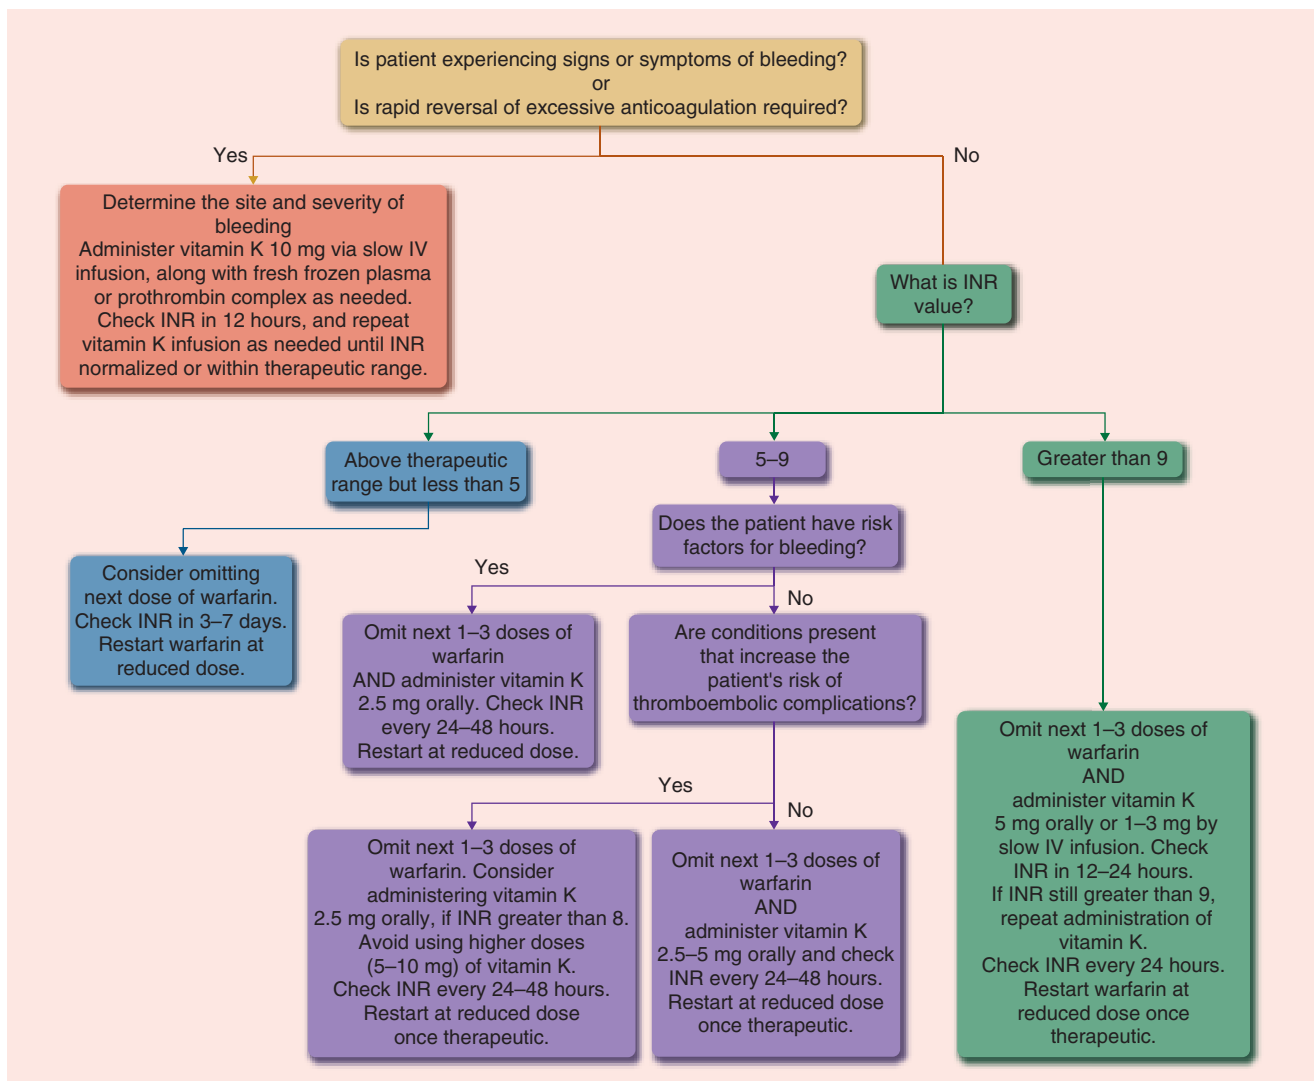

FIGURE 10-10. Management of an elevated INR in patients taking warfarin. Dose reductions should be made by determining the weekly warfarin dose and reducing the weekly dose by 10% to 25% based on the degree of INR elevation. Conditions that increase the risk of thromboembolic complications include history of hypercoagulability disorders (e.g., protein C or S deficiency, presence of antiphospholipid antibodies, antithrombin deficiency, or activated protein C resistance), arterial or venous thrombosis within the previous month, thromboembolism associated with malignancy, mechanical mitral valve in conjunction with atrial fibrillation, previous stroke, poor ventricular function, or coexisting mechanical aortic valve. (INR, international normalized ratio.) (From Witt DM, Nutescu EA, Haines S. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011:333.)

is reserved for cases of severe warfarin overdose (e.g., INR greater than 20) or major bleeding. Anaphylactoid reactions have been reported with rapid IV administration; therefore, slow infusion is recommended. An oral dose of vitamin K will reduce the INR within 24 hours. If the INR is still elevated after 24 hours, another dose of oral vitamin K can be given. The dose of vitamin K should be based on the INR elevation. A dose of 1 to 2.5 mg is sufficient when the INR is between 5 and 9, but 5 mg may be required for INRs greater than 9. Higher doses (e.g., 10 mg) can lead to prolonged warfarin resistance. In cases of life-threatening bleeding, fresh-frozen plasma or clotting factor concentrates should be administered, in addition to IV vitamin K. In patients in whom the INR is less than 9 and there is no active bleeding or imminent risk of bleeding, simply withholding warfarin until the INR decreases to within therapeutic range and reducing the weekly dose with more frequent monitoring is appropriate.⁵

Nonhemorrhagic side effects related to warfarin are rare but can be severe when they occur. Warfarin-induced skin necrosis presents as an eggplant-colored skin lesion or a maculopapular rash that can progress to necrotic gangrene. It usually manifests in fatty areas such as the abdomen, buttocks, and breasts. The incidence is less than 0.1%, and it generally appears during the first week of therapy. Patients with protein C or S deficiency or those who receive large loading doses of warfarin are at greatest risk.^{5,11} The mechanism is thought to be due to imbalances between procoagulant and anticoagulant proteins early in the course of warfarin therapy. Warfarin-induced purple toe syndrome is another rare side effect; patients present with a purplish discoloration of their toes. If these side effects are suspected, warfarin therapy should be discontinued immediately and an alternative anticoagulant given. There is a theoretical risk that warfarin may cause accelerated bone loss with long-term use, but to date there is no evidence to support this concern. Warfarin is teratogenic and is FDA pregnancy category X. It should be avoided during pregnancy, and women of childbearing potential should be instructed to use an effective form of contraception. UFH and LMWH are the agents of choice for the treatment of VTE during pregnancy.^{5,11}

10 Warfarin is prone to numerous clinically significant drug–drug and drug–food interactions (Tables 10–10, 10–11, and 10–12). Patients on warfarin should be questioned at every encounter to assess for any potential interactions with foods, drugs, herbal products, and nutritional supplements. When an interacting drug is initiated or discontinued, more frequent monitoring should be instituted. In addition, the dose of warfarin can be modified (increased or decreased) in anticipation of the expected impact on the INR.^{5,49} Warfarin-related drug interactions can generally be divided into two major categories: pharmacokinetic and pharmacodynamic. Pharmacokinetic interactions are most commonly due to changes in hepatic metabolism or binding to plasma proteins. Drugs that affect the CYP2C9, CYP3A4, and CYP1A2 have the greatest impact on warfarin metabolism. Interactions that impact the metabolism of the S-isomer result in greater changes in the INR than interactions

Table 10–10

Clinically Significant Warfarin Drug Interactions

Increase Anticoagulation Effect (↑ INR)	Decrease Anticoagulation Effect (↓ INR)	Increase Bleeding Risk
Acetaminophen	Amobarbital	Argatroban
Alcohol binge	Butabarbital	Aspirin
Allopurinol	Carbamazepine	Clopidogrel
Amiodarone	Cholestyramine	Danaparoid
Cephalosporins (with MTP side chain)	Dicloxacillin	Dipyridamole
Chloral hydrate	Griseofulvin	LMWHs
Chloramphenicol	Nafcillin	Nonsteroidal anti-inflammatory drugs
Cimetidine	Phenytoin	Ticlopidine
Ciprofloxacin	Primidone	UFH
Clofibrate	Rifampin

affecting the R-isomer. Pharmacodynamic drug interactions enhance or diminish the anticoagulant effect of warfarin, increasing the risk of bleeding or clotting, but may not alter the INR.^{5,49} There are increasing reports regarding dietary supplements, nutraceuticals, and vitamins that can interact with warfarin.⁵⁰ Patients on warfarin may experience changes in the INR due to fluctuating intake of dietary vitamin K. Patients should be instructed to maintain a consistent diet and avoid large fluctuations in vitamin K intake rather than strictly avoiding vitamin K–rich foods.⁵⁰

Table 10-11

Potential Warfarin Interactions With Herbal and Nutritional Products

Increased Anticoagulation Effect (Increase Bleeding Risk or ↑ INR)		Decreased Anticoagulation Effect (↓INR)
Amica flower	Ginkgo	Coenzyme Q ₁₀
Angelica root	Horse chestnut	Ginseng
Anise	Licorice root	Green tea
Asafoetida	Lovage root	St. John's wort

Patient Encounter 3, Part 2

CR is discharged home on warfarin therapy. She was referred to a local area antithrombosis center for monitoring of her oral anticoagulation therapy and has been maintained on warfarin 6 mg daily for the last 3 months. The patient presents today for a routine visit for anticoagulation monitoring and her INR is 10.3. She reports that 6 days ago she was started on ciprofloxacin 500 mg by mouth twice daily, which was prescribed by her primary care physician for a urinary tract infection. In addition, the primary care physician told the patient that her thyroid gland was enlarged and ordered some lab tests to determine if she has a thyroid problem. The patient has not received the results. She also reports that her intake of vitamin K-rich foods (spinach, broccoli, and cabbage) has increased significantly over the last month because she is trying to lose weight. CR has no other complaints today and denies any signs or symptoms of bleeding.

What is the most likely explanation for the elevated INR in CR's case?

Should CR be given vitamin K? If yes, discuss the dose, route of administration, and an appropriate patient monitoring plan.

How will you manage CR's warfarin therapy? Outline a plan including specific dose changes, timing of monitoring, and patient education.

► Nonpharmacologic Therapy

Thrombectomy Most cases of VTE can be successfully treated with anticoagulation. In some cases, removal of the occluding thrombus by surgical intervention may be warranted. Surgical or mechanical thrombectomy can be considered in patients with massive iliofemoral DVT when there is a risk of limb gangrene due to venous occlusion. The procedure can be complicated by recurrence of thrombus formation. In patients who present with massive PE, pulmonary embolectomy can be performed in emergency cases when conservative measures have failed. Patients who are hemodynamically unstable and have a contraindication to thrombolysis are candidates for pulmonary embolectomy. Administer heparin by IV infusion to achieve a therapeutic aPTT during the operation and postoperatively. Thereafter, give warfarin for the usual recommended duration.^{15,23,28}

Vena Cava Interruption Inferior vena cava (IVC) interruption is indicated in patients with PE who have a contraindication to anticoagulation therapy and in patients who have recurrent VTE while taking anticoagulation therapy.^{15,23,28} IVC interruption is accomplished by inserting a filter through the internal jugular vein or femoral vein and advancing it into the IVC using ultrasound or fluoroscopic guidance. IVC filters reduce the short-term risk of PE, but this

benefit is not sustained in the long term. The incidence of DVT at 1 year after IVC filter insertion is higher when compared with patients without filters. Survival after a PE is no different in patients with filters versus patients without filters.²¹ Therefore, anticoagulation therapy should be resumed as soon as possible after filter insertion and continued as long as the filter is in place due to the high risk of DVT.¹⁵ Temporary or removable filters are now increasingly used and are replacing the use of permanent filters.¹⁵

Compression Stockings PTS occurs in 20% to 50% of patients within 8 years after a DVT. Wearing GCS after a DVT reduces the risk of PTS by as much as 50%. Current guidelines recommend the use of GCS with an ankle pressure of 30 to 40 mm Hg for 2 years after a DVT. To be effective, GCS must fit properly. Traditionally, strict bed rest has been recommended after a DVT, but this approach has now been refuted, and patients should be encouraged to ambulate as tolerated.^{15,20}

APPROACH TO TREATING PATIENTS WITH VTE

Once the diagnosis of VTE has been confirmed with an objective test, promptly start anticoagulation therapy in full therapeutic doses. If there is high clinical suspicion of VTE, anticoagulation therapy may be initiated while waiting for the results of diagnostic tests.¹⁵ Initiate therapy with a rapid-acting anticoagulant such as UFH (given IV or SC), an LMWH (given SC), or fondaparinux (given SC) (Fig. 10–5 and Fig. 10–11). In patients with adequate renal function, the LMWHs and fondaparinux are preferred over UFH.¹⁵ Recent evidence also supports the use of dabigatran and rivaroxaban in the acute and long-term treatment of DVT,^{51,52} although neither agent is approved as of yet for this indication in the United States.

For the long-term treatment phase, an oral agent (i.e., warfarin), is the preferred approach. The novel oral agents (i.e., dabigatran, rivaroxaban) will provide more convenient alternatives to warfarin once approved and available for this indication. However, in patients with cancer, the LMWHs are recommended for the initial and subacute phase of treatment of VTE due to better efficacy in preventing recurrent thromboembolic events.¹⁵ The efficacy and safety of dabigatran and rivaroxaban for the treatment of VTE in patients with cancer have not been evaluated in prospective clinical trials. When warfarin is used for treatment of VTE, it is important to initiate warfarin on the first day of therapy after the first dose of rapid-acting anticoagulant is given and overlap the two therapies for a minimum of 5 days. Warfarin should be dosed to achieve a goal INR range of 2 to 3. Once the INR is stable and above 2, the rapid acting anticoagulant should be discontinued.

Anticoagulation therapy is continued for a minimum of 3 months but should be given longer depending on the underlying etiology of the VTE and the patient's risk factors (Table 10–13).¹⁵ Consider a thrombolytic only if the patient has a massive iliofemoral DVT and is at risk of limb gangrene. In patients with PE, consider a thrombolytic if the patient is

hemodynamically unstable (i.e., SBP less than 90 mm Hg) or has evidence of right ventricular injury (i.e., elevated troponins).²⁸ If there is a contraindication to anticoagulation therapy or the patient has a recurrent event while taking an anticoagulant, a vena cava filter should be inserted. Encourage early ambulation as tolerated by the patient during the initial treatment phase.¹⁵

► Outcome Evaluation

- Achieve optimal outcomes by (a) preventing the occurrence of VTE in patients who are at risk, (b) administering effective treatments in a timely manner to patients who develop VTE, (c) preventing treatment-related complications, and (d) reducing the likelihood of long-term complications including recurrent events.
- Given that VTE is often clinically silent and potentially fatal, strategies to increase the widespread use of prophylaxis have the greatest potential to improve patient outcomes. Thus relying on the early diagnosis and treatment of VTE is unacceptable because many patients will die before treatment can be initiated.
- Effective VTE prophylaxis programs screen all patients admitted to hospital for VTE risk factors, determine each patient's level of risk, and select and implement prevention strategies that provide sufficient protection for the level of risk.
- Periodically evaluate patients who are receiving VTE prophylaxis for signs and symptoms of DVT, such as swelling, pain, warmth, and redness of lower extremities, and for PE, such as chest pain, shortness of breath, palpitations, and hemoptysis.
- Providing effective treatment in a timely manner is the primary goal for patients who develop VTE. Treat DVT and PE quickly and aggressively with effective doses of anticoagulant drugs.
- The short-term aim of therapy is to prevent propagation or local extension of the clot, embolization, and death.
- Regularly monitor patients for the development of new symptoms or worsening of existing symptoms.
- Anticoagulant drugs require precise dosing and meticulous monitoring. Closely monitor patients receiving anticoagulant therapy for signs and symptoms of bleeding including epistaxis, hemoptysis, hematuria, bright red blood per rectum, tarry stools, severe headache, and joint pain. If major bleeding occurs, stop therapy immediately and treat the source of bleeding. In addition, closely monitor patients for potential drug–drug and drug–food interactions and adherence with the prescribed regimen.
- The long-term goals of therapy are to prevent complications such as the PTS, pulmonary hypertension, and recurrent VTE.
- Encourage all patients who have had DVT to wear GCS.
- Continue long-term therapy (i.e., warfarin) for an appropriate duration based on the etiology of the initial clot and the presence of ongoing risk factors.

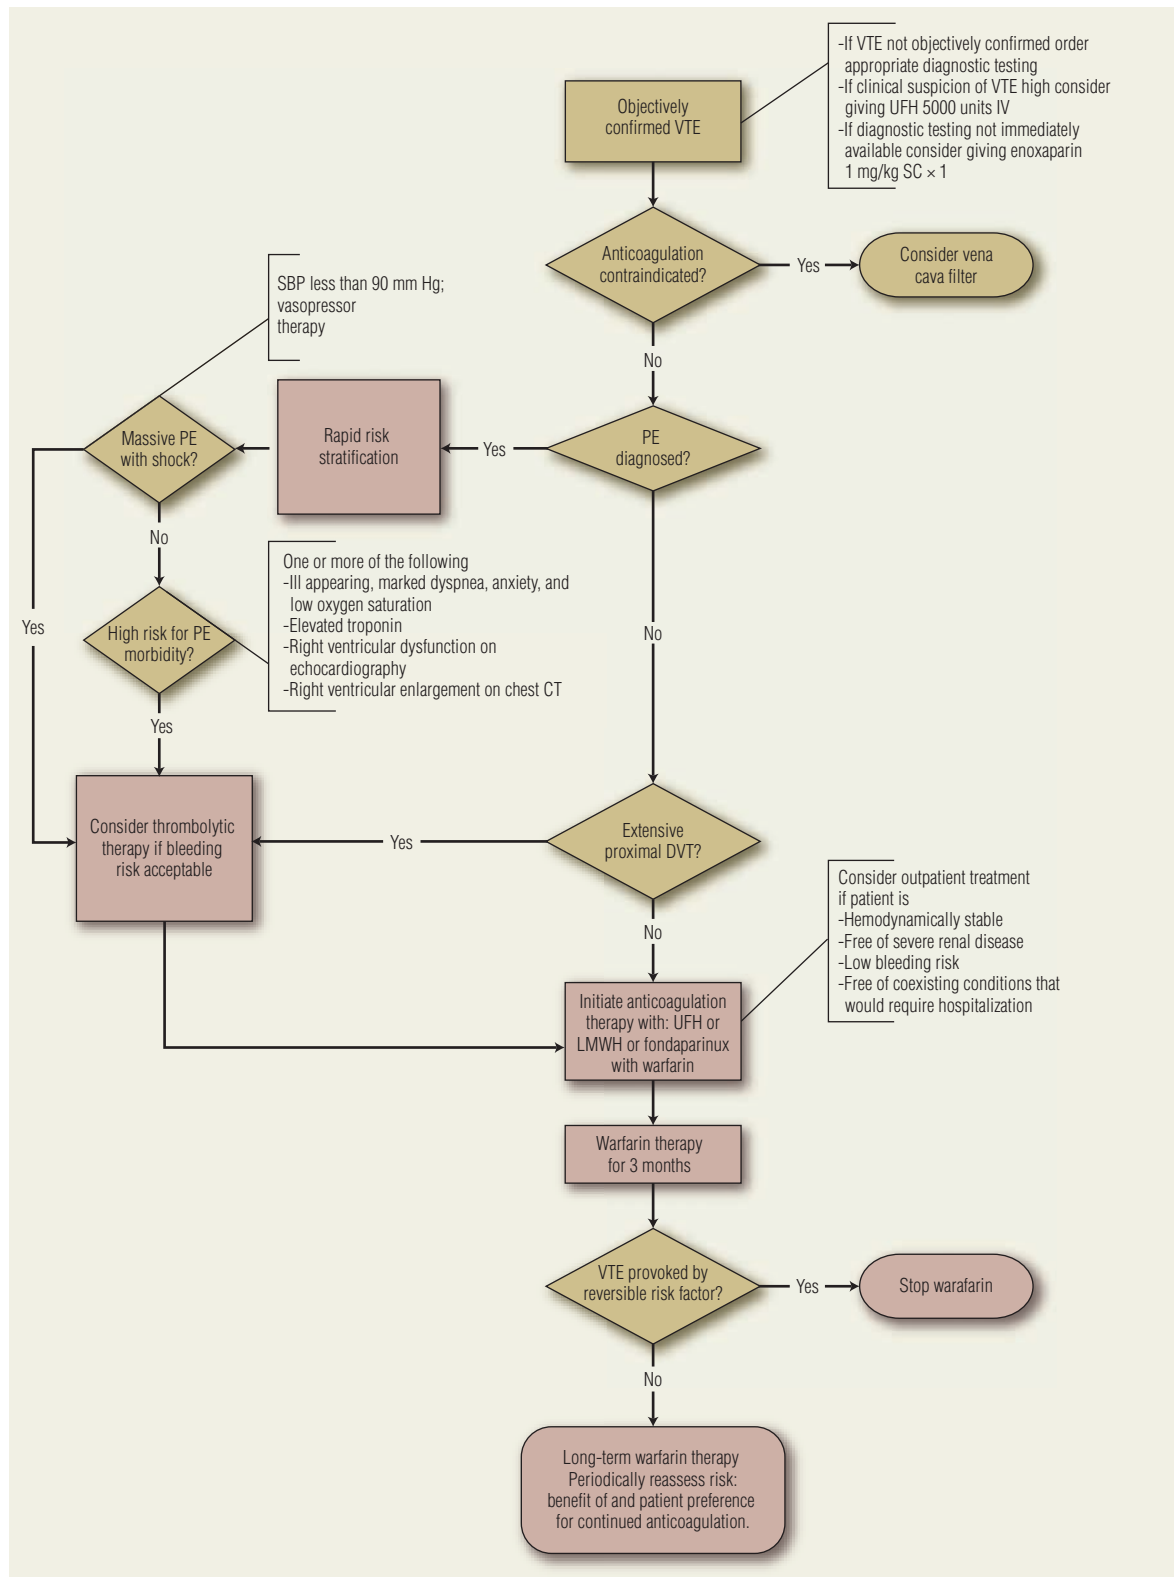

FIGURE 10-11. Treatment of VTE. (CT, computed tomography; DVT, deep vein thrombosis; LMWH, low molecular weight heparin; PE, pulmonary embolism; SBP, systolic blood pressure; SC, subcutaneous; UFH, unfractionated heparin; VTE, venous thromboembolism.) (From Witt DM, Nutescu EA, Haines S. Venous thromboembolism. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 8th ed. Table 10–13

Duration of Anticoagulation Therapy for the Treatment of VTE

Patient Characteristics	Drug	Duration of Therapy (Months)	Comments
First episode of VTE secondary to a transient (reversible) risk factor	Warfarin	3	Recommendation applies to both proximal and calf vein thrombosis
First episode, unprovoked VTE	Warfarin	At least 3	After 3 months of therapy, evaluate patient for risk–benefit of long-term therapy
First episode, unprovoked proximal DVT or unprovoked PE		Long term	If risk for bleeding is low and good adherence to therapy and monitoring requirements are maintained
First episode of VTE and cancer	LMWH	6	LMWH is recommended over warfarin for the initial 6 months Subsequent therapy (beyond the initial 6 months) until cancer is resolved is recommended with warfarin or LMWH
Second episode of unprovoked VTE	Warfarin	Long term	

DVT, deep vein thrombosis; LMWH, low molecular weight heparins; PE, pulmonary embolism; VTE, venous thromboembolism.

From Kearon C, Kahn SR, Agnelli G, et al. Antithrombotic therapy for venous thromboembolic disease: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines, 8th ed. Chest 2008;133:454S–545S.

Patient Encounter 4, Part 1

LN is a 77-year-old woman who developed a DVT in her left leg 5 weeks following elective right hip replacement surgery. The patient was hospitalized for the past 2 days for acute DVT treatment and was discharged this morning. The plan is to continue treatment at home and for the patient to follow up with her primary physician in 2 weeks. The patient was instructed to get as much rest as possible, limiting her physical activity and elevating her leg most of the day. The patient was instructed to get the following prescriptions filled at her neighborhood pharmacy as soon as possible:

Fondaparinux 7.5 mg SC daily #14 refill 0
Warfarin 10 mg PO daily #30 refill 2

PMH: Hypertension; dyslipidemia; major depressive disorder; gastroesophageal reflux disorder (GERD)

FH: Father died of “old age”; mother died of cancer; brother (age 72) has hypertension and had myocardial infarction (age 66)

SH: The patient is a retired college professor (music theory)

Current meds: Lisinopril 20 mg/HCTZ 12.5 mg PO daily; amlodipine 5 mg PO daily; simvastatin 20 mg PO daily;

fluoxetine 20 mg PO daily; omeprazole 20 mg PO daily; aspirin 81 mg PO daily for stroke prevention

Allergies: Sulfa: rash

PE:

VS: BP 144/60 mm Hg, HR 88 bpm, RR 12, wt 66 kg (145 lb), ht 62 in. (157 cm), BMI = 26.5 kg/m²

Labs: Within normal limits; except BUN = 21 mg/dL (7.5 mmol/L), SCr = 1.7 mg/dL (150 μmol/L), eGFR = 29 mL/min/1.73 m² (0.28 mL/s/m²), PT = 17.8 seconds, and INR = 1.8

Is the prescribed treatment appropriate for LN?

What changes in LN's treatment plan should be recommended at this time to the prescribing physician?

What follow-up laboratory tests should be obtained, and when should they be obtained?

How long should LN remain on anticoagulation therapy?

Given the current list of medications that LN is taking, should any of these medications be discontinued or changed? If changed, what alternative therapy would you recommend?

Develop a patient education plan for LN including appropriate techniques for self-administering injectable anticoagulants.

Patient Encounter 4, Part 2

LN has been taking warfarin for the past 3 months. Over the past 8 weeks, her INR has been in her goal range and no changes in her warfarin dose have been made. LN states that she is currently taking warfarin 5 mg every day except 2.5 mg on Wednesdays and Saturdays. LN states she has had two nosebleeds in the past month and notices that she bruises more easily, but she has had no major bleeding episodes. Her DVT symptoms essentially resolved within the first month after her diagnosis, but she's noticed some mild pain and swelling in her left leg the past 2 weeks. LN states that she has been taking naproxen sodium 220 mg twice daily for her leg pain. Given that LN has been tolerating the treatment well and is able to obtain the necessary laboratory tests in a timely manner, her primary care physician has recommended that she continue warfarin therapy for another 6 months. LN is not very pleased about this recommendation because she finds it difficult to moderate her vitamin K intake ("I love Brussels sprouts!") and the frequent blood tests are annoying.

PE:

VS: BP 136/62 mm Hg, HR 74 bpm, wt 65 kg (142 lb), BMI = 26.2 kg/m²

Labs: CBC within normal limits; PT = 21.8 seconds, and INR = 3.1 (drawn this morning)

How should LN's recurrent symptoms (i.e., pain and swelling in left leg) be evaluated and addressed?

Outline a patient education plan to prevent and manage nosebleeds.

Is the current treatment plan appropriate? Outline a plan including specific medication changes, nonpharmacologic treatment recommendations, and a follow-up plan.

Assume that anticoagulation therapy is appropriate. Is LN a good candidate for dabigatran therapy? Justify your answer.

Patient Care and Monitoring

Day 1

- It is critical to confirm the diagnosis of VTE
 - Clinical assessment: Look for risk factors for VTE
 - If DVT symptoms are present, obtain a venous ultrasound
 - If PE is suspected, obtain a V/Q or CT scan
 - D-dimer: This test may be a helpful adjunct to rule out VTE
- Obtain baseline laboratory tests. These tests must be obtained prior to initiating anticoagulation therapy:
 - PT and calculated INR
 - aPTT or antifactor Xa activity
 - Serum creatinine, serum albumin, and blood urea nitrogen (BUN)
 - Liver function tests
 - Complete blood count (CBC) with platelets
- Medications:
 - Screen the patient's medication profile including over-the-counter medications and herbal therapies used at home for potential drug–drug interactions with anticoagulation therapy
 - Initiate UFH, LMWH, or fondaparinux by injection (see Table 10–5 for dosing guidelines); [dabigatran and rivaroxaban will provide future therapeutic alternatives once approved by FDA for VTE treatment]
 - If warfarin will be used long term, start warfarin sodium orally every evening (see Fig. 10–9 for dosing guidelines)
 - Start pain medication if necessary (avoid nonsteroidal anti-inflammatory drugs)
- Patient education:
 - Educate the patient regarding the purpose of therapy and importance of proper monitoring of anticoagulant drugs. Assist the patient to determine an appropriate provider for long-term monitoring of anticoagulation therapy.
 - If LMWH, fondaparinux, or UFH is selected for home treatment, teach the patient how to self-administer (if the patient or a family member is unwilling or unable to self-administer, visiting nurse services should be arranged). Initial injection should be administered in the medical office or hospital.
 - If warfarin is selected, inform patient about the effects of vitamin K–rich foods on warfarin therapy. Moderate intake (less than 500–1,000 mcg) of vitamin K is acceptable. Provide patient with written material regarding vitamin K content of foods.
 - If warfarin is selected, inform the patient about the potential drug–drug interactions, including over-the-counter medications and dietary supplements (Tables 10–10, 10–11, and 10–12). Instruct the patient to call the healthcare practitioner responsible for monitoring warfarin therapy before starting any new medications or dietary supplements.
 - Instruct the patient regarding nonpharmacologic strategies including elevation of the affected extremity and antiembolic exercises such as flexion/extension of the ankle (for lower extremity VTE) or hand squeezing/relaxation (for upper extremity VTE).

(Continued)

Patient Care and Monitoring (Continued)

5. Follow-up steps:

- If LMWH, fondaparinux, or UFH is selected for home treatment, dispense to the patient a 5- to 7-day supply of prefilled LMWH or fondaparinux syringes in patient-specific dose.
- If the patient is to be treated with IV UFH, measure aPTT or antifactor Xa activity 6 hours after initiating the IV infusion. Adjust dose if necessary (Table 10–7) and measure aPTT or antifactor Xa activity every 6 hours after each dose change until therapeutic. Measure aPTT or antifactor Xa activity daily thereafter.
- Arrange for follow-up and long-term anticoagulation therapy management. Communicate with the patient's primary care physician and/or refer to a local antithrombosis service, if available. If the patient is to be treated primarily in the hospital, these arrangements can be made 1 to 2 days prior to hospital discharge.

6. Document all activities in medical record.

Day 2

1. If the patient is being treated with IV UFH, remeasure the aPTT or antifactor Xa activity, and adjust dose if necessary. If patient is being treated with LMWH, fondaparinux, or dabigatran, continue therapy.
2. Interview the patient to determine if there is worsening or new symptoms related to VTE. Ask the patient about overt bruising or bleeding, particularly at injection sites, as well as changes in stool or urine color.
3. Advise the patient to limit physical activity if pain persists and to elevate the extremity; increase activity as tolerated.
4. Document activities in medical record.

Days 3 to 5

1. If patient being treated with warfarin, measure PT/INR every 1 to 2 days.
2. Interview the patient to determine if there is worsening or new symptoms related to VTE. Inquire about and evaluate patient adherence to therapy. Ask the patient about overt bruising or bleeding, particularly at the injection site, as well as changes in stool or urine color. Advise the patient to limit physical activity if pain persists and to elevate the extremity; increase activity as tolerated.
3. If patient is being treated with warfarin, hold or adjust warfarin dose as necessary. If the patient is being treated with IV UFH, measure aPTT or antifactor Xa activity daily, and adjust dose if necessary. If the patient is being treated with an LMWH, fondaparinux, or dabigatran, continue therapy.
4. If patient is being treated with warfarin, reinforce previous patient education regarding potential drug–drug and drug–food interactions.

5. Document activities in medical record.

Days 6 to 8

1. Obtain CBC or platelet count. If patient is being treated with warfarin, measure PT/INR every 2 to 3 days.
2. Interview the patient to determine if there is worsening or new symptoms related to VTE. Inquire about and evaluate patient adherence to therapy. Ask the patient about overt bruising or bleeding, particularly at the injection site, as well as changes in stool or urine color. Advise the patient to limit physical activity if pain persists and to elevate the extremity; increase activity as tolerated.
3. If patient is being treated with warfarin, hold or adjust warfarin dose as necessary. Discontinue UFH, LMWH, or fondaparinux if INR is greater than 2 on two consecutive occasions.
4. If the patient is being treated with IV UFH and requires continued treatment, measure aPTT or antifactor Xa activity, and adjust dose if necessary.
5. If the patient is treated with UFH or LMWH and platelet count has dropped by greater than 50% from baseline or is less than $120 \times 10^3 \text{ mm}^3$ ($120 \times 10^9/\text{L}$), evaluate the patient for HIT.
6. Document activities in medical record.

Days 9 to 14

1. If patient is being treated with warfarin, measure PT/INR every 3 to 5 days.
2. Interview the patient to determine if there is worsening or new symptoms related to VTE. Inquire about and evaluate patient adherence to therapy. Ask the patient about overt bruising or bleeding, particularly at the injection site, as well as changes in stool or urine color. Advise the patient to elevate the extremity and increase activity as tolerated.
3. If patient is being treated with warfarin, hold or adjust warfarin dose as necessary. Discontinue UFH, LMWH, or fondaparinux if INR is greater than 2 on two consecutive occasions.
4. If the patient is being treated with IV UFH and requires continued treatment, measure aPTT or antifactor Xa activity, and adjust dose if necessary.
5. If the patient is being treated with UFH or LMWH, obtain CBC or platelet count. If the platelet count has dropped by more than 50% from baseline or is less than $120 \times 10^3/\text{mm}^3$ ($120 \times 10^9/\text{L}$), evaluate the patient for HIT.
6. If patient is being treated with warfarin, reinforce previous patient education regarding vitamin K intake and potential drug–drug interactions.
7. Document activities in medical record.

(Continued)

Patient Care and Monitoring (Continued)

Days 15 to 90

1. Interview the patient to determine if there is worsening or new symptoms related to VTE. Inquire about and evaluate patient adherence to therapy. Ask the patient about overt bruising or bleeding as well as changes in stool or urine color. Encourage the patient to increase activity as tolerated.
2. If the patient is being treated with warfarin, measure PT/INR every 1 to 4 weeks based on the stability of the INR and patient's health status. Adjust warfarin dose as needed to maintain INR between 2 and 3.
3. If the patient is being treated with warfarin, reinforce previous patient education regarding vitamin K intake and potential drug–drug interactions with warfarin.
4. If patient is being treated with warfarin, consider restarting LMWH or fondaparinux if INR drops below 1.5.
5. Document activities in medical record.

Three Months and Beyond

1. Interview the patient to determine if there is worsening or new symptoms related to VTE. Inquire about and evaluate patient adherence to therapy. Ask the patient about overt bruising or bleeding as well as changes in stool or urine color.
2. Reevaluate the risks and benefits of continuing warfarin therapy. If unproved VTE, consider continuing therapy (see Table 10–13).
3. If patient is being treated with warfarin, measure PT/INR every 1 to 4 weeks based on the stability of the INR and patient's health status. Adjust warfarin dose as needed to maintain INR between 2 and 3. Consider reducing goal INR to 1.5 to 2 if patient is unable to obtain blood tests every 4 weeks.
3. If patient is being treated with warfarin, reinforce previous patient education regarding vitamin K intake and potential drug–drug interactions with warfarin.
4. Document activities in medical record.

Abbreviations Introduced in This Chapter

ABW	Adjusted body weight
ACCP	American College of Chest Physicians
ACT	Activated clotting time
ADP	Adenosine diphosphate
aPTT	Activated partial thromboplastin time
AT	Antithrombin
BMI	Body mass index
BUN	Blood urea nitrogen
CBC	Complete blood count
CrCl	Creatinine clearance
CT	Computed tomography
CYP	Cytochrome P-450 isoenzyme
DTI	Direct thrombin inhibitor
DVT	Deep vein thrombosis
eGFR	Estimated glomerular filtration rate
ESR	Erythrocyte sedimentation rate
GCS	Graduated compression stockings
GERD	Gastroesophageal reflux disorder
GP	Glycoprotein
HCII	Heparin cofactor II
HIT	Heparin-induced thrombocytopenia
HK	High molecular weight kininogen
IBW	Ideal body weight
ICH	Intracranial hemorrhage
IM	Intramuscular
INR	International normalized ratio
IPC	Intermittent pneumatic compression (device)
ISI	International Sensitivity Index
IVC	Inferior vena cava
LMWH	Low molecular weight heparin

MRI	Magnetic resonance imaging
PAF	Platelet activating factor
PAI-1	Plasminogen activator inhibitor-1
PCI	Percutaneous coronary intervention
PE	Pulmonary embolism
PF	Platelet factor
PF-4	Platelet factor-4
PGG/PGH	Prostaglandins
P-gp	P-glycoprotein
PK	Prekallikrein
PLA	Phospholipase A
PT	Prothrombin time
PTS	Post-thrombotic syndrome
SBP	Systolic blood pressure
SC	Subcutaneous
SERM	Selective estrogen receptor modulator
TF	Tissue factor
TFPI	Tissue factor pathway inhibitor
t-PA	Tissue plasminogen activator
TS	Thromboxane synthetase
TXA	Thromboxane A
UFH	Unfractionated heparin
u-PA	Urokinase plasminogen activator
V/Q	Ventilation/perfusion (scan)
VTE	Venous thromboembolism
vWF	von Willebrand's factor
WBC	White blood cell
WHO	World Health Organization

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Stroke

Susan R. Winkler

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Differentiate the types of cerebrovascular disease including transient ischemic attack, ischemic stroke (cerebral infarction), and hemorrhagic stroke.
2. Identify modifiable and nonmodifiable risk factors associated with ischemic stroke and hemorrhagic stroke.
3. Explain the pathophysiology of ischemic stroke and hemorrhagic stroke.
4. Describe the clinical presentation of transient ischemic attack, ischemic stroke, and hemorrhagic stroke.
5. Evaluate the various treatment options for acute ischemic stroke.
6. Determine whether thrombolytic therapy is indicated in a patient with acute ischemic stroke.
7. Formulate strategies for primary and secondary prevention of acute ischemic stroke.
8. Evaluate treatment options for acute hemorrhagic stroke.

KEY CONCEPTS

- 1 Ischemic stroke, which may be thrombotic or embolic, is the abrupt development of a focal neurological deficit that occurs due to inadequate blood supply to an area of the brain.
- 2 Hemorrhagic stroke is a result of bleeding into the brain and other spaces within the CNS and includes subarachnoid hemorrhage (SAH), intracerebral hemorrhage (ICH), and subdural hematomas.
- 3 Transient ischemic attacks (TIAs) are a risk factor for acute ischemic stroke and precede acute ischemic stroke in approximately 15% of cases; therefore, preventive measures are the same for both TIA and ischemic stroke.
- 4 The long-term treatment goals for acute ischemic stroke include prevention of a recurrent stroke through reduction and modification of risk factors and by use of appropriate treatments.
- 5 All patients should have a brain computed tomography (CT) scan or magnetic resonance imaging (MRI) scan to differentiate an ischemic stroke from a hemorrhagic stroke because treatment differs and thrombolytic (fibrinolytic) therapy must be avoided until a hemorrhagic stroke is ruled out.
- 6 In carefully selected patients, alteplase should be given as soon as possible, preferably within 3 hours and not more than 4.5 hours after symptom onset.
- 7 Aspirin (ASA) therapy with an initial dose of 150 to 325 mg is recommended in most patients with acute ischemic stroke within 48 hours after stroke symptom onset.
- 8 Current stroke treatment guidelines recommend ASA, clopidogrel, or combination therapy with extended-release dipyridamole plus ASA as initial antiplatelet therapy for the secondary prevention of stroke.
- 9 Selection of the initial antiplatelet agent for secondary prevention of ischemic stroke should be individualized based on patient factors and cost. Clopidogrel and the combination of extended-release dipyridamole and ASA are preferred over ASA monotherapy.
- 10 There is no proven treatment for ICH. Management is based on neurointensive care treatment and prevention of complications.

EPIDEMIOLOGY

Cerebrovascular disease (CVD), or stroke, is the second most common cause of death worldwide and the fourth leading

cause of death in the United States, declining from the third most common cause of death as a result of decades of progress in the treatment and prevention of CVD.¹ Approximately 795,000 strokes occur in the United States each year. New strokes account for 610,000 of this total; recurrent strokes account for the remaining 185,000 strokes each year. Stroke is the leading cause of long-term disability in adults, with 90% of survivors having residual deficits. Moderate to severe disability is seen in 70% of survivors. An estimated 15% to 30% of stroke survivors are permanently disabled, and 20% require institutional care at 3 months after the stroke. The American Heart Association estimates there are over 7 million survivors of stroke in the United States. The societal impact and economic burden is great, with total costs of \$40.9 billion reported in the United States in 2007. Stroke mortality has declined due to improved recognition and treatment of risk factors; however, risk factor management is still inadequate. Stroke incidence increases with age, especially after age 55 years, resulting in an increased stroke incidence due to aging of the population.²

ETIOLOGY

Strokes can either be ischemic (88% of all strokes) or hemorrhagic (12% of all strokes). **Figure 11-1** provides a classification of stroke by mechanism. **1** *Ischemic stroke, which may be thrombotic or embolic, is the abrupt development of a focal neurological deficit that occurs due to inadequate blood supply to an area of the brain.* A thrombotic occlusion occurs when a **thrombus** forms inside an artery in the brain. An embolic stroke typically occurs when a piece of thrombus,

originating either inside or outside of the cerebral vessels, breaks loose and is carried to the site of occlusion in the cerebral vessels. An extracerebral source of emboli is often the heart, leading to cardioembolic stroke.

2 *Hemorrhagic stroke is a result of bleeding into the brain and other spaces within the CNS and includes subarachnoid hemorrhage (SAH), intracerebral hemorrhage (ICH), and subdural hematomas.* SAH results from sudden bleeding into the space between the inner layer and middle layer of the **meninges**, most often due to trauma or rupture of a cerebral aneurysm or arteriovenous malformation (AVM). ICH is bleeding directly into the brain parenchyma, often as a result of chronic uncontrolled hypertension. Subdural hematomas result from bleeding under the dura that covers the brain and most often occur as a result of head trauma.

CLASSIFICATION

Cerebral Ischemic Events

- There are two main classifications of cerebral ischemic events: **transient ischemic attack** (TIA) and ischemic stroke (cerebral infarction). A TIA is a transient episode of neurological dysfunction caused by focal brain, spinal cord, or retinal ischemia without acute infarction. TIAs have a rapid onset and short duration, typically lasting less than 1 hour and often less than 30 minutes. The symptoms vary depending on the area of the brain affected; however, no deficit remains after the attack. The classic definition of TIA was based on symptom duration of less than 24 hours; symptoms lasting 24 hours or greater were categorized

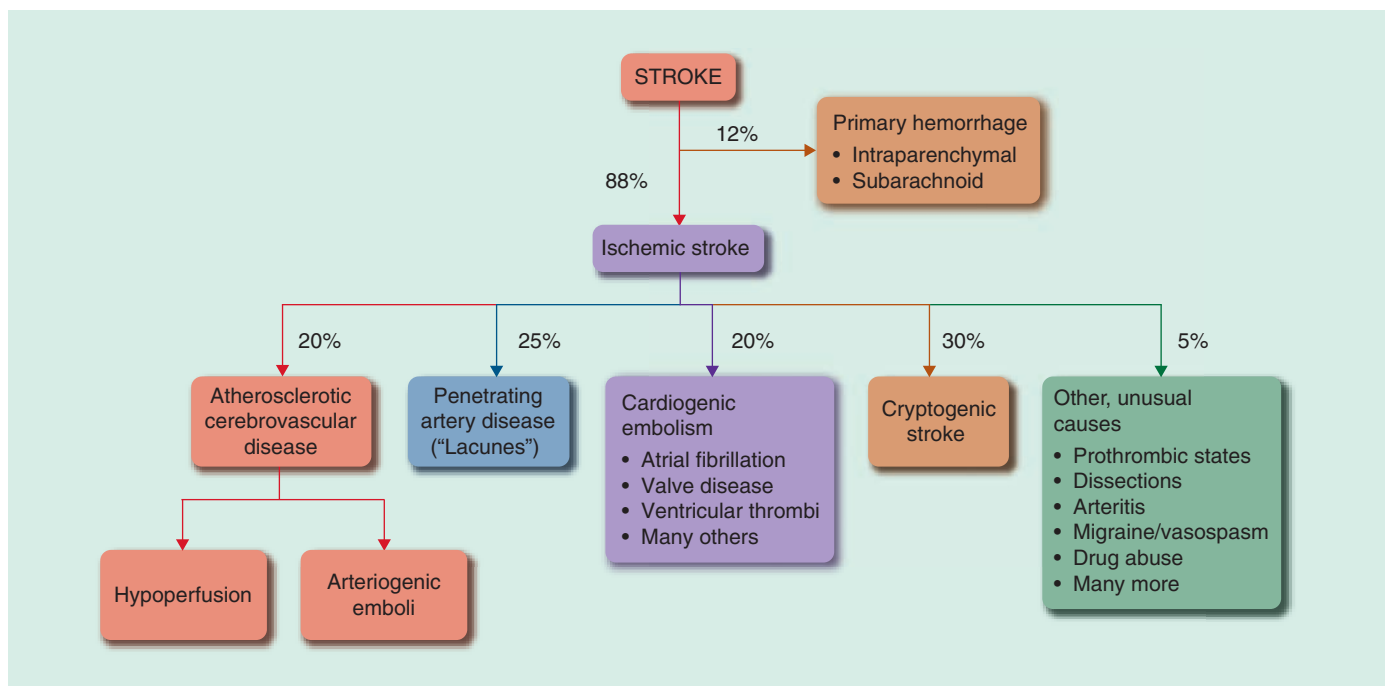

FIGURE 11-1. Classification of stroke. (From Fagan SC, Hess DC. Stroke. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 8th ed. New York, NY: McGraw-Hill, 2011:354, with permission.)

as ischemic stroke. Improved neuroimaging techniques have revealed that clinical symptoms lasting greater than 1 hour are often ischemic stroke based on evidence of tissue infarction. Using the classic definition of TIA would potentially miscategorize the event in up to one-third of cases. For this reason, the definition of TIA has been changed to eliminate the focus on time and encourage prompt diagnosis and classification of the event.³ **3** *TIA's are a risk factor for acute ischemic stroke and precede acute ischemic stroke in approximately 15% of cases; therefore, preventive measures are the same for both TIA and ischemic stroke.*⁴

Ischemic stroke is similar to a TIA; however, tissue injury and infarction are present, and in many patients, residual deficits remain after the event. A standardized tissue-based definition of cerebral infarction has been proposed as “cerebral infarction is defined as brain or retinal cell death due to prolonged ischemia.”⁵

Hemorrhagic Events

A sudden severe headache, nausea and vomiting, and **photophobia** may be the first signs and symptoms of hemorrhagic stroke. Neck pain and **nuchal rigidity** may also be experienced at the time of the hemorrhage. Patients may complain the headache is “the worst headache of my life,” especially if the cause is a SAH. It is important to note that a diagnosis of the type of stroke cannot be made solely on signs and symptoms because overlap occurs between the types of stroke.

Risk Factors

Assessment of risk factors for ischemic stroke as well as for hemorrhagic stroke is an important component of stroke prevention, diagnosis, and treatment of patients. A major goal in the long-term management of ischemic stroke involves primary prevention (prevention of the first stroke) and prevention of a recurrent stroke through the reduction and modification of risk factors. Risk factors for ischemic stroke can be divided into modifiable and nonmodifiable. **Table 11-1** provides a list of risk factors for ischemic stroke. Every patient should have risk factors assessed and treated, if possible, because management of risk factors can decrease the occurrence and/or recurrence of stroke.^{6,7}

Nonmodifiable risk factors for both types of stroke include age, gender, race/ethnicity, and genetic predisposition. Low birth weight is an additional risk factor for ischemic stroke. Ischemic stroke risk is increased in those older than 55 years of age, in men, and in African Americans, Hispanics, and Asian/Pacific Islanders. It is also increased in those with a family history of stroke. Modifiable risk factors include a number of treatable disease states and lifestyle factors that can greatly influence overall stroke risk. Hypertension is one of the major risk factors for both ischemic and hemorrhagic stroke. For ICH specifically, hypertension has been shown to increase risk by a factor of 3.68.^{7,8} Other risk factors for hemorrhagic stroke include trauma, cigarette smoking,

Table 11-1

Nonmodifiable and Modifiable Risk Factors for Ischemic Stroke

Nonmodifiable Factors

- Age (greater than 55 years)
- Gender (males greater than females)
- Race and ethnicity (African American, Hispanic, or Asian/Pacific Islander)
- Genetic predisposition
- Low birth weight

Modifiable Factors

- Hypertension (single most important risk factor)
- Cardiac disease
 - Atrial fibrillation (most important and treatable cardiac cause of stroke)
 - Mitral stenosis
 - Mitral annular calcification
 - Left atrial enlargement
 - Structural abnormalities such as atrial-septal aneurysm
 - Acute MI
- Transient ischemic attacks or prior stroke (major independent risk factor)
- Diabetes (independent risk factor)
- Dyslipidemia
- Lifestyle factors
 - Cigarette smoking
 - Excessive alcohol use
 - Physical inactivity
 - Obesity
 - Diet
 - Cocaine and IV drug use
 - Low socioeconomic status
- Increased hematocrit
- Sickle cell disease
- Hyperhomocysteinemia (less well documented)
- Migraine (risk not clear)
- Asymptomatic carotid stenosis
- Oral contraceptive use (with estrogen content greater than 50 mcg)

MI, myocardial infarction.

cocaine use, heavy alcohol use, anticoagulant use, and cerebral aneurysm and AVM rupture.

PATHOPHYSIOLOGY

Ischemic Stroke

In ischemic stroke, there is an interruption of the blood supply to an area of the brain either due to thrombus formation or an embolism. Loss of cerebral blood flow results in tissue hypoperfusion, tissue hypoxia, and cell death. Thrombus formation usually starts with lipid deposits in the vessel wall that cause turbulent blood flow. This leads to vessel injury and vessel collagen becoming exposed to blood. This vessel injury initiates the platelet aggregation process due to the exposed subendothelium. Platelets release adenosine diphosphate (ADP), which causes platelet aggregation and consolidation of the platelet plug. Thromboxane A₂ is released, contributing to platelet aggregation and vasoconstriction. The vessel injury also activates the coagulation cascade, which leads to thrombin production. Thrombin converts fibrinogen to

fibrin, leading to clot formation as fibrin molecules, platelets, and blood cells aggregate. Refer to Figures 7–3, 10–3, and 10–4 for a depiction of these processes.

After the initial event, secondary events occur at the cellular level that contribute to cell death. Regardless of the initiating event, the cellular processes that follow may be similar. Excitatory amino acids such as glutamate accumulate within the cells, causing intracellular calcium accumulation. Inflammation occurs and oxygen free radicals are formed resulting in the common pathway of cell death.

There is often a core of ischemia containing unsalvageable brain cells. Surrounding this core is an area termed the *ischemic penumbra*. In this area, cells are still salvageable; however, this is a time-sensitive endeavor. Without restoration of adequate perfusion, cell death continues throughout a larger area of the brain, ultimately leading to neurological deficits. No agents have been shown to be effective at providing neuroprotection at this time.

Hemorrhagic Stroke

The pathophysiology of hemorrhagic stroke is not as well studied as that of ischemic stroke; however, it is more complex than previously thought. Much of the process is related to the presence of blood in the brain tissue and/or surrounding spaces resulting in compression. The hematoma that forms may

Patient Encounter Part 1

TK is a 73-year-old (72 kg [158.4 lb], 64" [163 cm]) White woman who presents to the emergency department with weakness in her right arm and leg and difficulty speaking. Her symptoms began approximately 2 1/2 hours ago during breakfast, prompting her daughter to call the paramedics. Her past medical history is significant for hypertension, dyslipidemia, migraine, and a previous stroke 7 years ago. Social history is significant for moderate alcohol use and cigarette smoking 1/2 pack per day for the past 50 years. Current medications include perindopril 4 mg once daily, simvastatin 40 mg daily, multivitamin tablet once daily, and sumatriptan 25 mg at the onset of migraine.

What signs and symptoms does TK have that are suggestive of stroke?

What nonmodifiable and modifiable risk factors does TK have for acute ischemic stroke?

continue to grow and enlarge after the initial bleed, and early growth of the hematoma is associated with a poor outcome. Brain tissue swelling and injury is a result of inflammation caused by thrombin and other blood products. This can lead to increased intracranial pressure (ICP) and **herniation**.^{9,10}

Clinical Presentation and Diagnosis of Stroke

General

- The patient may not be able to reliably report the history owing to cognitive or language deficits. A reliable history may have to come from a family member or another witness.

Symptoms

- The patient may complain of weakness on one side of the body, inability to speak, loss of vision, **vertigo**, or falling. Stroke patients may complain of headache; however, with hemorrhagic stroke, the headache can be severe.

Signs

- Patients usually have multiple signs of neurologic dysfunction, and the specific deficits are determined by the area of the brain involved.
- Hemiparesis** or **monoparesis** occur commonly, as does a **hemisensory deficit**.
- Patients with vertigo and double vision are likely to have posterior circulation involvement.
- Aphasia** is seen commonly in patients with anterior circulation strokes.
- Patients may also suffer from **dysarthria**, visual field defects, and altered levels of consciousness.

Laboratory Tests

- There are no specific laboratory tests for stroke.

- Tests for hypercoagulable states, such as protein C deficiency and antiphospholipid antibody, should be done only when the cause of stroke cannot be determined based on the presence of well-known risk factors for stroke.

Other Diagnostic Tests

- A computed tomography (CT) scan of the head will reveal an area of hyperintensity (white) identifying that a hemorrhage has occurred. The CT scan will either be normal or hypointense (dark) in an area where an infarction has occurred. It may take 24 hours (and rarely longer) to reveal the area of infarction on a CT scan.
- Magnetic resonance imaging (MRI) of the head will reveal areas of ischemia earlier and with better resolution than a CT scan. Diffusion-weighted imaging can reveal an evolving infarct within minutes.
- Carotid Doppler studies will determine whether the patient has a high degree of stenosis in the carotid arteries supplying blood to the brain (extracranial disease).
- The electrocardiogram (ECG) will determine whether the patient has atrial fibrillation, which is a major risk factor for cardioembolic stroke.
- A transthoracic echocardiogram will identify whether there are heart valve abnormalities or problems with wall motion resulting in emboli to the brain.

DESIRED TREATMENT OUTCOMES

The short-term treatment goals for acute ischemic stroke include reducing secondary brain damage by reestablishing and maintaining adequate perfusion to marginally ischemic areas of the brain and protecting these areas from the effects of ischemia (i.e., neuroprotection).

4 The long-term treatment goals for acute ischemic stroke include prevention of a recurrent stroke through reduction and modification of risk factors and by use of appropriate treatments.

Short-term treatment goals for hemorrhagic stroke include rapid neurointensive care treatment to maintain adequate oxygenation, breathing, and circulation. Management of increased ICP and blood pressure (BP) are important in the acute setting. Long-term management includes prevention of complications and prevention of a recurrent bleed and delayed cerebral ischemia.

Prevention of long-term disability and death related to the stroke are important regardless of stroke type.

GENERAL APPROACH TO TREATMENT

5 All patients should have a brain computed tomography (CT) scan or magnetic resonance imaging (MRI) scan to differentiate an ischemic stroke from a hemorrhagic stroke because treatment differs and thrombolytic (fibrinolytic) therapy must be avoided until a hemorrhagic stroke is ruled out. A CT scan is the most important diagnostic test in patients with acute stroke. For those with an ischemic stroke, an evaluation should be done to determine the appropriateness of reperfusion therapy. In hemorrhagic stroke, a surgical evaluation should be completed to assess the need for surgical clipping of an aneurysm or other procedure to control the bleed and prevent rebleeding and other complications. Figure 11-2 provides an algorithm for the initial management of the acute stroke patient.

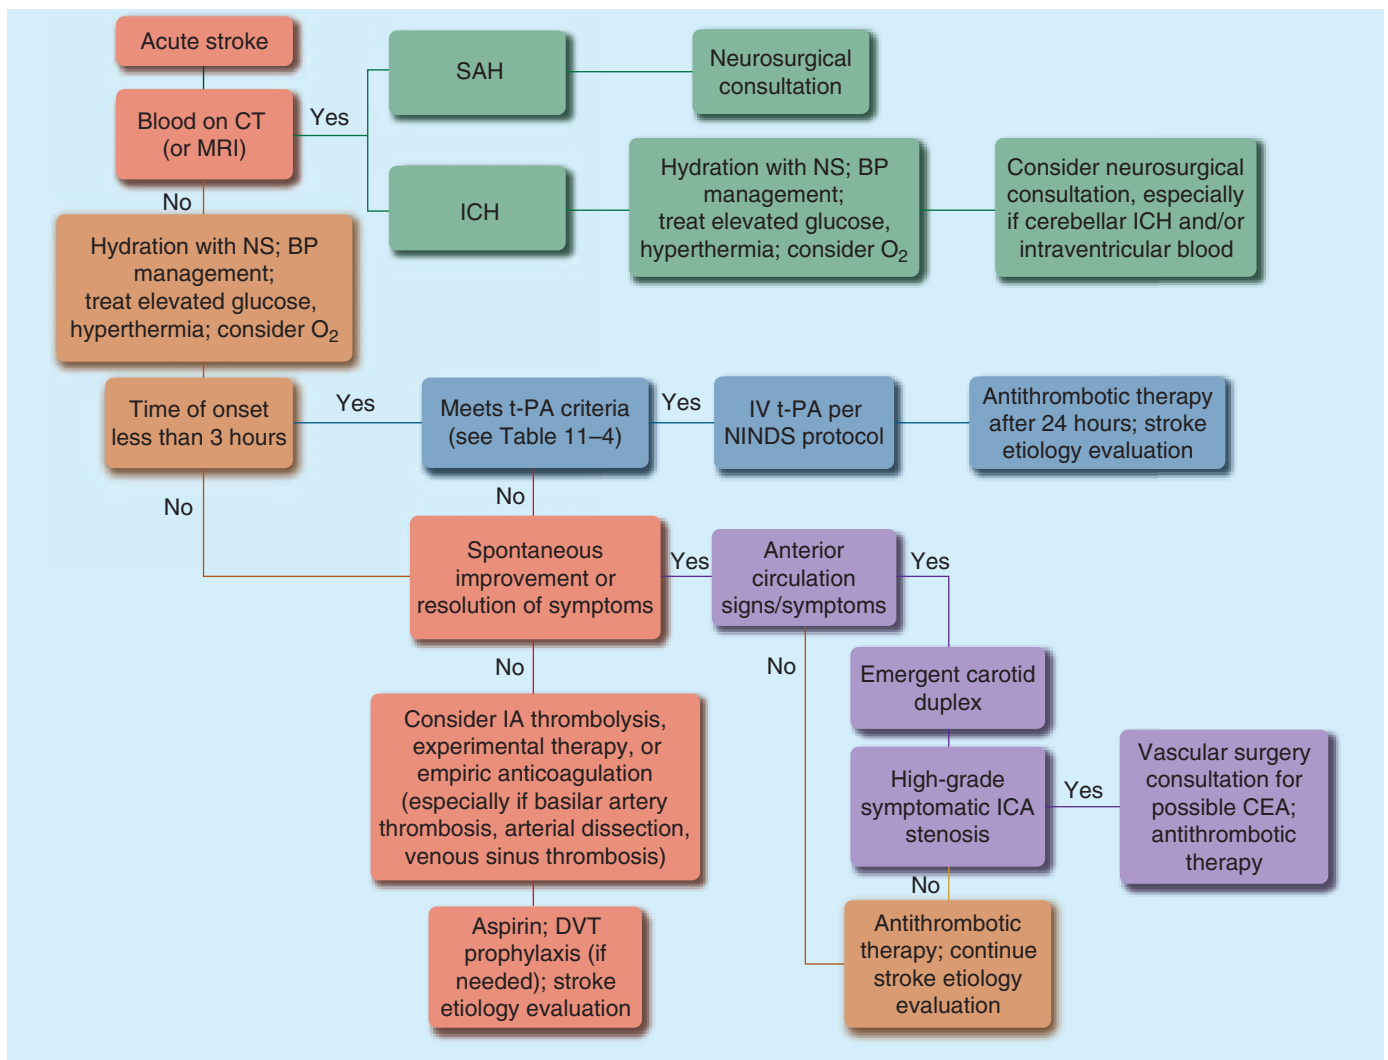

FIGURE 11-2. Acute stroke treatment algorithm. (BP, blood pressure; CEA, carotid endarterectomy; CT, computed tomography; DVT, deep vein thrombosis; IA, intraarterial; ICA, internal carotid artery; ICH, intracerebral hemorrhage; MRI, magnetic resonance imaging; NINDS, National Institute of Neurological Disorders and Stroke; NS, normal saline; SAH, subarachnoid hemorrhage; t-PA, tissue plasminogen activator.)

TREATMENT OF ACUTE ISCHEMIC STROKE

Acute ischemic stroke is a medical emergency. Identification of the time and manner of stroke onset is an important determinant in treatment. The time the patient was last without symptoms is used as the time of stroke onset. Because patients typically do not experience pain, determining the onset time can be difficult. It is also important to document risk factors and the previous functional status of the patient to assess current disability due to stroke.

Supportive Measures

Acute complications of ischemic stroke include cerebral edema, increased ICP, seizures, and **hemorrhagic conversion**. In the acute setting, supportive interventions and treatments to prevent acute complications should be initiated.

Tissue oxygenation should be maintained acutely. Measure the oxygen saturation using pulse oximetry and supplement the patient with oxygen if necessary. The oxygen saturation should be maintained at 92% (0.92) or greater.¹¹ Volume status and electrolytes should be corrected. If required, the blood glucose should be corrected because both hyperglycemia and hypoglycemia may worsen brain ischemia. When hypoglycemia is present, bolus with 50% dextrose immediately. A blood glucose that is severely elevated should be lowered to less than 200 mg/dL (11.1 mmol/L) using subcutaneous insulin. Recent guidelines suggest that treatment of hyperglycemia poststroke should be more aggressive than previously recommended. Treating glucose levels between 140 and 185 mg/dL (7.8 to 10.3 mmol/L) with subcutaneous insulin is a reasonable approach.^{12,13} If the patient is febrile, treat with acetaminophen because fever is associated with brain ischemia and increased morbidity and mortality after stroke. Alternatively, cooling devices can be used.^{12,14} Low-dose unfractionated heparin (UFH) or low-dose low molecular weight heparins (LMWHs) administered subcutaneously significantly decrease the risk of developing venous thromboembolism (VTE) poststroke. UFH 5,000 units subcutaneously every 8 to 12 hours or low-dose LMWHs should be given for VTE prophylaxis in patients who are not candidates for IV alteplase. In patients receiving IV alteplase, the administration of subcutaneous UFH or LMWHs should be delayed until 24 hours after the administration of alteplase to avoid bleeding complications.

In the setting of acute ischemic stroke, many patients have an elevated BP in the first 24 to 48 hours.¹⁵ BP should be optimized; however, hypertension should generally not be treated initially in acute ischemic stroke patients because it may cause decreased blood flow in ischemic areas, potentially increasing the infarction size. The cautious use of antihypertensive medications may be necessary in patients who are otherwise candidates for thrombolytic therapy, including those with severely elevated BP (systolic BP greater than 220 mm Hg or diastolic BP greater than 120 mm Hg), and those with other medical disorders requiring immediate lowering of BP. **Tables 11-2** and **11-3** provide recommendations on BP management in those eligible and not

Table 11-2

BP Recommendations for Ischemic Stroke (Not Eligible for Alteplase)

Systolic BP less than 220 mm Hg and diastolic BP less than 120 mm Hg	Observe unless other end-organ involvement
Systolic BP greater than 220 mm Hg or diastolic BP 121–140 mm Hg	Labetalol 10–20 mg IV over 1–2 minutes (may repeat every 10–20 minutes; maximum dose 300 mg) or nicardipine infusion 5 mg/h titrated to response
Diastolic BP greater than 140 mm Hg	Nitroprusside 0.25–0.3 mcg/kg/min titrated to response

BP, blood pressure.

Table 11-3

BP Recommendations for Ischemic Stroke (Eligible for Alteplase)

Before treatment: If systolic BP is greater than 185 mm Hg or diastolic BP is greater than 110 mm Hg	Labetalol 10–20 mg IV over 1–2 minutes (may repeat after 10 minutes) or nicardipine infusion 5 mg/h titrated to response or nitropaste 1–2 inches
During and after treatment: If systolic BP is 180–230 mm Hg or diastolic BP is 105–120 mm Hg	Labetalol 10 mg IV over 1–2 minutes (may repeat every 10–20 minutes; maximum dose 300 mg) or labetalol 10 mg IV followed by labetalol infusion 2–8 mg/min
If systolic BP is greater than 230 mm Hg or diastolic BP is 121–140 mm Hg	Labetalol 10 mg IV over 1–2 minutes (may repeat every 10–20 minutes; maximum dose 300 mg) or labetalol 10 mg IV followed by labetalol infusion 2–8 mg/min or nicardipine infusion 5 mg/h titrated to response
If diastolic BP is greater than 140 mm Hg	Nitroprusside 0.25–0.3 mcg/min titrated to response

BP, blood pressure.

eligible for alteplase. In those not eligible for alteplase, when BP is lowered, aim for a 10% to 15% reduction in systolic BP and diastolic BP in the first 24 hours after stroke onset. Avoid using sublingual calcium channel blockers because they may lower BP too rapidly. BP should be checked three times with each reading taken 5 minutes apart.

Nonpharmacologic Therapy

► Carotid Endarterectomy and Other Surgical Procedures

It is unknown whether carotid **endarterectomy** is of value when performed emergently after stroke, meaning within the first 24 hours after symptom onset.¹² Improvement

after surgery has been shown in some patients with mild to moderate neurological deficits. In patients with more severe neurological deficits, the utility of carotid endarterectomy is unclear. Emergency bypass procedures and middle cerebral artery **embolectomy** are controversial. Due to the lack of proven efficacy of these procedures when performed emergently in acute ischemic stroke, they are not routinely recommended.

Thrombolytic Therapy

► Alteplase

Alteplase (rt-PA; Activase) is an IV thrombolytic (fibrinolytic) that was approved for acute ischemic stroke treatment in 1996 based on the results of the National Institute of Neurological Disorders and Stroke (NINDS) rt-PA Stroke Trial.¹⁶ The American Stroke Association guidelines include alteplase as the only FDA-approved acute treatment for ischemic stroke and strongly encourage early diagnosis and treatment of appropriate patients.¹² **6** *In carefully selected patients, alteplase should be given as soon as possible, preferably within 3 hours and not more than 4.5 hours after symptom onset.* Based on several assessment scales, patients treated with alteplase were 30% more likely to have minimal or no disability at 3 months compared with patients given placebo. Alteplase treatment resulted in an 11% to 13% absolute increase in patients with excellent outcomes at 3 months, independent of patient age, stroke subtype, stroke severity, or prior use of aspirin (ASA).¹⁷ ICH within 36 hours after stroke onset occurred in 6.4% of those given alteplase versus 0.6% in those given placebo. There was no significant difference in mortality between the two groups at 3 months or 1 year. A dose of 0.9 mg/kg (maximum: 90 mg) is recommended; the first 10% is given as an IV bolus, and the remainder is infused over 1 hour. **Table 11–4** details the inclusion and exclusion criteria for the administration of alteplase in acute ischemic stroke.

Subsequent studies that followed the NINDS trial protocol have supported alteplase use in acute ischemic stroke and have shown similar rates for both response and ICH occurrence. When the clinical trials are pooled, study results show that the sooner alteplase is given after the onset of stroke symptoms, the greater the benefit seen in neurological outcome.¹⁸ Current guidelines recommend alteplase use within 3 hours after stroke onset in appropriate patients and further recommend that alteplase be started as soon as possible within this window of time.¹⁷ A treatment effect between 3.0 and 4.5 hours was evaluated in the European Cooperative Acute Stroke Study III (ECASS III) trial.¹⁹ In a second pooled analysis of the clinical trials that included the ECASS III trial, alteplase was shown to provide some benefit if administered within 4.5 hours of symptom onset.²⁰ A science advisory was published in 2009 updating the recommendations for alteplase use and extending the treatment window to 4.5 hours after stroke symptom onset.²¹ Research trials to evaluate combination treatments and new thrombolytic agents are underway in an effort to improve outcomes after ischemic stroke.²²

Antiplatelet agents, anticoagulants, and invasive procedures such as insertion of a central line or placement of a nasogastric tube should be avoided for 24 hours after the infusion of alteplase to prevent bleeding complications. Bladder catheterization should be avoided for 30 minutes postinfusion.

Efficacy is measured by the elimination of existing neurological deficits and the long-term improvement in neurological status and functioning based on neurological examinations and other outcome measures. Neurological examinations should be completed every 15 minutes during the infusion of alteplase, every 30 minutes for the first 6 hours after

Table 11–4

Inclusion and Exclusion Criteria for Alteplase Use in Acute Ischemic Stroke

Inclusion Criteria

- 18 years of age or older (more than 80 years old excluded from ECASS III trial)
- Clinical diagnosis of ischemic stroke causing a measurable neurological deficit
- Time of symptom onset well established to be less than 3 hours before treatment would begin; may extend timing to not more than 4.5 hours after symptom onset

Exclusion Criteria

- Evidence of intracranial hemorrhage on CT scan of the brain prior to treatment
- Minor or rapidly improving stroke symptoms
- Clinical presentation suggestive of SAH even with a normal head CT
- Active internal bleeding
- Known bleeding diathesis, including but not limited to (a) platelet count less than $100 \times 10^3/\text{mm}^3$ ($100 \times 10^9/\text{L}$); (b) heparin within 48 hours with an elevated aPTT; or (c) current oral anticoagulant use (e.g., warfarin) or recent use with an elevated PT (greater than 15 seconds) or INR (greater than 1.7)
- Intracranial surgery, serious head trauma, or previous stroke within 3 months
- Suspected aortic dissection associated with stroke
- Suspected subacute bacterial endocarditis or vasculitis
- History of GI or urinary tract hemorrhage within 21 days
- Major surgery or serious trauma within 14 days
- Recent arterial puncture at a noncompressible site
- Lumbar puncture within 7 days
- History of intracranial hemorrhage
- Known AVM or aneurysm
- Witnessed seizure at the same time as the onset of stroke symptoms occurred
- Recent acute MI
- SBP greater than 185 mm Hg or DBP greater than 110 mm Hg at the time of treatment, or patient requires aggressive treatment to reduce BP to within these limits
- Combination of previous stroke and diabetes mellitus (excluded from ECASS III trial)
- Oral anticoagulant use regardless of INR (excluded from ECASS III trial)

aPTT, activated partial thromboplastin time; AVM, arteriovenous malformation; CT, computed tomography; DBP, diastolic blood pressure; ECASS III, European Cooperative Acute Stroke Study III; INR, International Normalized Ratio; MI, myocardial infarction; PT, prothrombin time; SAH, subarachnoid hemorrhage; SBP, systolic blood pressure.

the infusion, and then every hour until 24 hours after alteplase administration. In the NINDS trial, neurological function was assessed 24 hours after the administration of alteplase using the National Institutes of Health Stroke Scale (NIHSS). This 42-point scale quantifies neurological deficits in patients who have had a stroke and is easily performed. At 3 months, the NIHSS and other neurological assessments were completed. Use of a standardized stroke scale such as the NIHSS is recommended at baseline and 24 hours after the administration of alteplase.

The major adverse effects of thrombolytic therapy are bleeding, including ICH and serious systemic bleeding. Mental status changes and a severe headache may indicate ICH. Signs of bleeding include easy bruising, hematemesis, guaiac-positive stools, black, tarry stools, hematoma formation, hematuria, bleeding gums, and nosebleeds. Angioedema is a potential side effect that may cause airway obstruction.

► Other Thrombolytics

- Streptokinase and other thrombolytics, except alteplase, are not indicated for use in acute ischemic stroke. Three large randomized controlled trials evaluating streptokinase were stopped early due to a high incidence of hemorrhage in the streptokinase-treated patients.^{23–25} Other thrombolytic agents, including tenecteplase, reteplase, desmoteplase, urokinase, and plasmin, are not recommended for treatment unless associated with a clinical trial. Although the results with these newer agents have been mixed, clinical trials are currently ongoing.^{12,22}

► Intraarterial Thrombolytics

Intraarterial (IA) thrombolytics may improve outcomes in selected patients with acute ischemic stroke due to large-vessel occlusion. Patients in two clinical trials received pro-urokinase (r-pro UK) plus heparin or heparin alone within 6 hours of symptom onset.^{26,27} Results from the first trial were not statistically significant but favored r-pro UK, whereas the results of the second trial showed a statistically significant benefit to r-pro UK. No difference in mortality was found, although the incidence of intracranial hemorrhage was greater in the r-pro UK plus heparin group versus heparin alone. Note that r-pro UK is not FDA-approved and not available for clinical use. A recent meta-analysis of five clinical trials evaluating IA thrombolytics found comparable results.²⁸ The treatment group was found to have a statistically significant benefit for either a good outcome or an excellent outcome. The incidence of intracranial hemorrhage was increased; however, no difference in mortality was observed. Interest in IA thrombolysis has continued as an option for patients who have contraindications to IV alteplase. It may be used in patients with middle cerebral artery occlusion within 6 hours of symptom onset. IA thrombolysis should be performed by qualified personnel and should not delay treatment with IV alteplase in eligible patients.¹²

Heparin

- Full-dose IV UFH has been commonly used in acute stroke therapy; however, no adequately designed trials have been conducted to establish its efficacy and safety. Current acute ischemic stroke treatment guidelines do not recommend routine urgent full-dose anticoagulation with UFH due to the lack of a proven benefit in improving neurological function and the risk of intracranial bleeding.^{12,17,29} Full-dose UFH may prevent early recurrent stroke in patients with large-vessel atherothrombosis or those thought to be at high risk of recurrent stroke (i.e., cardioembolic stroke); however, more study is required.

The major complications of heparin include conversion of the ischemic stroke into a hemorrhagic stroke, bleeding, and thrombocytopenia. The occurrence of severe headache and mental status changes may indicate ICH. Signs of bleeding mirror those listed for alteplase therapy. The hemoglobin, hematocrit, and platelet count should be obtained at least every 3 days to detect bleeding and thrombocytopenia.

LMWHs and Heparinoids

- Full-dose LMWHs and heparinoids are not recommended in the treatment of acute ischemic stroke.^{12,17,30} Studies with these agents have generally been negative, and no convincing evidence exists that these agents improve outcomes after ischemic stroke. An increased risk of bleeding complications and hemorrhagic transformation has been observed.

Antiplatelets

ASA in acute ischemic stroke was studied in two large randomized trials, the International Stroke Trial and the Chinese Acute Stroke Trial.^{31,32} Patients who received ASA within 24 to 48 hours of the onset of acute ischemic stroke symptoms were less likely to suffer early recurrent stroke, death, and disability. **7** *ASA therapy with an initial dose of 150 to 325 mg is recommended in most patients with acute ischemic stroke within 48 hours after stroke symptom onset.* The ASA dose may then be reduced to 50 to 100 mg daily to reduce bleeding complications.¹⁷

The administration of ASA should not replace other acute stroke treatments and should be delayed for 24 hours in those patients receiving alteplase. Clopidogrel either alone or in combination with ASA is not recommended in acute ischemic stroke. Glycoprotein IIb/IIIa receptor inhibitors are not recommended except in the setting of research.¹²

Ancrod

Ancrod is an investigational agent that acts to decrease plasma fibrinogen levels. Based on available clinical trials, ancrod appears to have a potential benefit when used within 3 hours of stroke symptom onset. A recent study using a 6-hour window after symptom onset found no difference in efficacy or mortality between the ancrod and placebo groups.

- Ancrod is not recommended for clinical use because efficacy and safety have not been definitively established.^{12,33}

PREVENTION OF ACUTE ISCHEMIC STROKE

Primary Prevention

► Aspirin

- The use of ASA in patients with no history of stroke or ischemic heart disease reduced the incidence of nonfatal myocardial infarction (MI) but not of stroke. The Women's Health Study evaluated over 39,000 women and found a benefit with ASA use in high-risk women 65 years and older.³⁴ Women with a history of hypertension, hyperlipidemia, diabetes, or a 10-year cardiovascular risk greater than or equal to 10% were found to have a reduced stroke risk. A recent meta-analysis found a higher risk of hemorrhagic stroke in men and a greater risk of major bleeding in both men and women.³⁵ Primary prevention guidelines recommend ASA for general cardiovascular prophylaxis (not specific to stroke) in men and women with a 10-year risk of cardiovascular events of 6% to 10% and in older women who are at high risk for stroke. The benefits must be weighed against the risk of major bleeding. Due to a lack of benefit observed in clinical trials, ASA is not recommended for primary prevention in patients with diabetes and asymptomatic peripheral arterial disease, or in those at low risk.⁶

► Diabetes

- Diabetes has been shown to be an independent risk factor for stroke. Intensive glycemic control has not been shown to reduce stroke risk in either type 1 or type 2 diabetes mellitus. Aggressive control of blood pressure according to the Joint National Committee on the Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) guidelines and management of dyslipidemia is recommended in individuals with diabetes.^{6,36} Hypertension therapy that includes an angiotensin-converting enzyme inhibitor (ACE-I) or angiotensin receptor blocker (ARB) and the use of a statin are recommended to reduce stroke risk.

Patient Encounter Part 2

TK arrives in the emergency department 3 hours after the onset of her symptoms. In the emergency department, an IV line is placed, a physical and neurological examination is completed, and TK is moved to the stroke unit. A head CT scan is negative for hemorrhagic stroke. Her blood pressure on admission to the stroke unit is 194/110 mm Hg. TK denies other exclusions to IV alteplase. The neurologist is evaluating TK for alteplase administration.

Identify your acute treatment goals for TK.

Is TK a candidate for IV alteplase at this time?

What acute management would be appropriate for TK in the stroke unit?

► Dyslipidemia

- Dyslipidemia has not previously been identified as an independent risk factor for stroke; however, recent studies have found a relationship between total cholesterol levels and stroke rate.⁶ Statin use may reduce the incidence of a first stroke in high-risk patients (e.g., hypertension, coronary heart disease, or diabetes) including patients with normal lipid levels. Stroke risk was decreased by 27% to 32% overall in large clinical trials.^{37,38} Patients with a history of MI, coronary artery disease (CAD), elevated lipid levels, diabetes, and other risk factors benefit from treatment with a lipid-lowering agent including patients with normal lipid levels.

► Hypertension

- Hypertension is the most important and well-documented risk factor for stroke. Lowering BP in patients who are hypertensive has been shown to reduce the relative risk of stroke, both ischemic and hemorrhagic, by 35% to 44%.³⁹ All patients should have their BP monitored and controlled appropriately based on current guidelines for BP management. The BP goal is less than 140/90 mm Hg in the general population and less than 130/80 mm Hg when renal disease or diabetes is present.³⁶ Many patients require two or more drug therapies to achieve BP control. For the primary prevention of stroke, reduction in BP is the main goal because one antihypertensive agent has not been clearly shown to be more beneficial than any other.

► Smoking Cessation

- The relationship between smoking and both ischemic and hemorrhagic stroke is clear. Smoking status should be assessed at every patient visit. Patients should be assisted and encouraged in smoking cessation as the stroke risk after cessation has been shown to decline over time. Effective treatment options are available including counseling, nicotine replacement products, and oral agents.

► Other Treatments

- A number of other disease states and lifestyle factors should be addressed as primary prevention of stroke. Atrial fibrillation is an important and well-documented risk for stroke. See [Chapter 9](#) for information on stroke prevention in atrial fibrillation. Asymptomatic carotid [stenosis](#), cardiac disease, sickle cell disease, obesity, and physical inactivity are other risks that should be assessed and managed appropriately.

Secondary Prevention

► Nonpharmacologic Therapy

- **Carotid Endarterectomy** The benefit of carotid endarterectomy for prevention of recurrent stroke has been studied in major clinical trials including a meta-analysis combining these clinical trials to evaluate 6,092 patients.⁴⁰ Carotid endarterectomy is recommended to prevent [ipsilateral](#) stroke in patients with symptomatic carotid artery stenosis of 70% or greater when the surgical risk is less than 6%.

In patients with symptomatic stenosis of 50% to 69%, a moderate reduction in risk is seen in clinical trials. In those patients with stenosis of 50% to 69% and a recent stroke, carotid endarterectomy is appropriate. In other patients, surgical risk factors and surgeon skill should be considered prior to surgery, and surgical risk should be less than 6%. Carotid endarterectomy is not beneficial for symptomatic carotid stenosis less than 50% and should not be considered in these patients.

Patients with asymptomatic carotid artery stenosis of 60% or more may benefit from carotid endarterectomy if surgical complication rates are low (less than 3%); however, this remains controversial. Recommendations suggest considering carotid endarterectomy in patients with carotid artery stenosis of 60% to 99% who are between 40 and 75 years of age if there is a 5-year life expectancy and the operative risks are low.⁴¹

Carotid Angioplasty Carotid angioplasty with **stenting** has evolved as a less invasive procedure with shorter recovery times for appropriate patients. Several trials have been completed comparing carotid angioplasty with stenting to carotid endarterectomy in symptomatic patients. A recent prospective randomized trial found no statistically significant difference in outcomes at 30 days and 4 years.⁴² Carotid angioplasty with stenting is an alternative to carotid endarterectomy in high-risk surgical candidates with greater than 50% stenosis by angiography and greater than 70% stenosis by noninvasive imaging when performed by skilled clinicians.⁴³

► Pharmacologic Therapy

Aspirin In a meta-analysis including 144,051 patients with previous MI, acute MI, previous TIA or stroke, or acute stroke, as well as others at high risk, ASA was found to decrease the risk of recurrent stroke by approximately 25%.⁴⁴ ASA decreases the risk of subsequent stroke by approximately 22% in both men and women with previous TIA or stroke.⁴⁴ Therefore, ASA is an option for initial therapy for secondary prevention of ischemic stroke. A wide range of doses have been used (30 to 1,500 mg/day); however, the FDA has approved doses of 50 to 325 mg for secondary ischemic stroke prevention. Current guidelines recommend varying ASA doses including ASA 50 to 100 mg daily and 50 to 325 mg daily.^{17,43} Lower ASA doses are currently recommended to decrease the risk of bleeding complications associated with higher doses of ASA. Adverse effects of ASA include GI intolerance, GI bleeding, and hypersensitivity reactions.

Ticlopidine Ticlopidine is slightly more beneficial in secondary stroke prevention than ASA in men and women.⁴³ The usual recommended dosage is 250 mg orally twice daily. Ticlopidine is costly, and side effects include bone marrow suppression, rash, diarrhea, and an increased cholesterol level. Neutropenia is seen in approximately 2% of patients. **Thrombotic thrombocytopenic purpura** (TTP) occurs in 1 of every 2,000 to 4,000 patients treated with ticlopidine. Monitoring of the complete blood count (CBC) is required

every 2 weeks for the first 3 months of therapy. Due to the costly laboratory monitoring required and the adverse effect profile, ticlopidine is typically avoided clinically.

Clopidogrel Clopidogrel is slightly more effective than ASA and similar in efficacy to the combination of extended-release (ER) dipyridamole plus aspirin.^{45,46} The usual dose is 75 mg orally taken once daily. Clopidogrel has a lower incidence of diarrhea and neutropenia than ticlopidine, and laboratory monitoring is not required. There have been 11 case reports of TTP occurring secondary to clopidogrel. Most occurred within the first 2 weeks of therapy; therefore, clinicians need to be aware of the potential for the development of TTP with clopidogrel. Proton pump inhibitors may decrease the effectiveness of clopidogrel. An H₂ blocker may be preferred in patients who require both acid suppression and clopidogrel.⁴⁷ Patients with a genetic variant of CYP2C19 classified as poor metabolizers may have a decrease in the active metabolite of clopidogrel.⁴⁸ Clopidogrel should be used as monotherapy for stroke prevention. It is an option for initial therapy for secondary prevention of ischemic stroke and considered first-line therapy in patients who also have peripheral arterial disease.

Extended-Release Dipyridamole Plus Aspirin Combination therapy with ER dipyridamole plus ASA was more effective than either treatment alone in the European Stroke Prevention Study 2 (ESPS 2).⁴⁹ Patients received either placebo, ASA 25 mg twice daily, ER dipyridamole 200 mg twice daily, or a combination of both agents. The risk reduction with ASA was 18.1% and 16.3% with ER dipyridamole, whereas the combination produced a 37% risk reduction. Headache and diarrhea were common adverse effects of dipyridamole; bleeding was more common in the treatment groups receiving ASA. This is the first study showing that combination antiplatelet therapy has additive effects over each agent alone. A trial comparing the combination of ER dipyridamole plus ASA to clopidogrel found no difference in outcomes; however, adverse events occurred more frequently in the combination of ER dipyridamole plus ASA group.⁴⁶ The currently available formulation is a combination product containing 25 mg ASA and 200 mg ER dipyridamole. This combination is an option for initial therapy, but is not appropriate for patients who are intolerant to ASA.

Current Clinical Trials Recent trials have been completed to evaluate other combinations of antiplatelet agents and to compare them against one another. In the Management of Atherothrombosis with Clopidogrel in High-risk Patients with Recent Transient Ischaemic Attack or Ischaemic Stroke (MATCH) trial, low-dose ASA plus clopidogrel combination therapy did not show a significant benefit in reducing recurrent stroke compared with clopidogrel alone.⁵⁰ This trial found that the addition of ASA to clopidogrel increased the risk of major bleeding. The Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA) trial compared the combination of clopidogrel plus low-dose ASA to low-dose ASA alone in patients with cardiovascular disease or

multiple risk factors.⁵¹ The combination did not show a benefit over monotherapy in the prevention of cardiovascular events. An increased bleeding risk was observed in the stroke subgroup. The combination of ASA and clopidogrel is not recommended due to these concerns. The European/Australasian Stroke Prevention in Reversible Ischaemia Trial (ESPRIT) compared the combination of ASA and dipyridamole with ASA alone.⁵² ASA was dosed between 30 and 325 mg daily and dipyridamole was dosed at 200 mg twice daily with 83% of patients using ER dipyridamole. This trial showed that the combination of ASA and dipyridamole was more effective at preventing recurrent stroke than ASA alone. In the Prevention Regimen for Effectively Avoiding Second Strokes (PRoFESS) trial, comparing the combination of ASA and ER dipyridamole to clopidogrel, neither agent was shown to be superior.⁴⁶

Antiplatelet Therapy Summary **8** *Current stroke treatment guidelines recommend ASA, clopidogrel, or combination therapy with ER dipyridamole plus ASA as initial antiplatelet therapy for the secondary prevention of stroke.^{17,43}*

9 *Initial choice of agent should be individualized based on patient factors and cost. Clopidogrel and the combination of ER dipyridamole and ASA are preferred over ASA monotherapy. Therapeutic failure in this patient population is challenging because no data are available to guide a treatment decision. When a patient is on therapeutic doses of ASA, yet experiences a recurrent TIA or stroke, switching to either clopidogrel or the combination of ASA and ER dipyridamole is a reasonable option. If failure occurs on either clopidogrel or the combination of ASA and ER dipyridamole, switching to the alternate drug may be appropriate.*

Warfarin Recent clinical trials have not found oral anticoagulation in those patients without atrial fibrillation or

carotid stenosis to be better than antiplatelet therapy. In patients without atrial fibrillation, antiplatelet therapy is recommended over warfarin. Patients with atrial fibrillation and a previous TIA or stroke have the highest risk of recurrent stroke. Long-term anticoagulation with warfarin is effective and therefore recommended in the primary and secondary prevention of cardioembolic stroke.^{17,43} The goal international normalized ratio (INR) for this indication is 2 to 3.

► Blood Pressure Management

Hypertension is an important risk factor for stroke; however, it had been unclear if lowering BP reduced the incidence of secondary ischemic stroke. In the Perindopril Protection Against Recurrent Stroke Study (PROGRESS), it was shown that BP reduction using the ACE-I perindopril alone resulted in a 28% reduction in recurrent stroke compared with placebo. With the addition of the diuretic indapamide to perindopril, a 43% reduction in stroke recurrence was seen.⁵³ This reduction in stroke incidence occurred even in patients who were not hypertensive. In patients with a previous history of TIA or stroke, the JNC 7 recommends a diuretic and an ACE-I.³⁶ **Table 11–5** provides drug and dosing recommendations for the treatment of ischemic stroke.

► Other Recommendations

Management of diabetes and lipids based on treatment guidelines, cessation of smoking, increased physical activity, and reducing alcohol use in heavy drinkers are additional recommendations for management of patients with previous stroke or TIA.⁴³ Statin therapy is recommended in patients with previous stroke or TIA, regardless of history of coronary heart disease.

Table 11–5

Recommendations for Pharmacotherapy of Ischemic Stroke

	Primary Agents	Alternatives
Acute treatment	Alteplase 0.9 mg/kg IV (maximum dose 90 mg); 10% as IV bolus, remainder infused over 1 hour in selected patients within 3 hours of onset ASA 150–325 mg started within 48 hours of onset (may reduce dose to 50–100 mg daily after 48 hours)	Alteplase 0.9 mg/kg IV (maximum dose 90 mg); 10% as IV bolus, remainder infused over 1 hour in selected patients between 3 and 4.5 hours of onset Alteplase (various doses) intraarterially up to 6 hours after onset in selected patients
Secondary prevention	ASA 50–325 mg daily Clopidogrel 75 mg daily ASA 25 mg + ER dipyridamole 200 mg twice daily	Ticlopidine 250 mg twice daily
Cardioembolic All patients	Warfarin (INR 2–3) ACE-I + diuretic or ARB; BP lowering: Perindopril 2–8 mg daily Indapamide 1.25–5 mg daily Statin therapy	

ACE-I, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; ASA, aspirin; BP, blood pressure; ER, extended-release; INR, International Normalized Ratio.

Patient Encounter Part 3

TK's blood pressure responds to the antihypertensive agent within 35 minutes and her current BP is 178/100 mm Hg. She is still experiencing weakness in the right arm and leg and difficulty speaking at times. The neurologist decides to administer IV alteplase because she is now 4 hours after the onset of symptoms and is being managed in the stroke unit.

What recommendations would you make regarding the administration of IV alteplase in TK?

What treatments would you recommend for TK at this time to reduce her risk of another stroke?

TREATMENT OF ACUTE HEMORRHAGIC STROKE

Supportive Measures

Acute hemorrhagic stroke is considered to be an acute medical emergency due to ICH, SAH, or subdural hematoma. Initially, patients experiencing a hemorrhagic stroke should be transported to a neurointensive care unit. ¹⁰ *There is no proven treatment for ICH. Management is based on neurointensive care treatment and prevention of complications.* Treatment should be provided to manage the needs of the critically ill patient including management of increased ICP, seizures, infections, and prevention of rebleeding and delayed cerebral ischemia. In those with severely depressed consciousness, rapid endotracheal intubation and mechanical ventilation may be necessary. BP is often elevated after hemorrhagic stroke; appropriate management is important to prevent rebleeding and expansion of the hematoma. Two trials in ICH patients have been completed evaluating early intensive BP management. Treatment guidelines have been updated to suggest that in patients with systolic BPs between 150 and 220 mm Hg, lowering the systolic BP to 140 mm Hg is a reasonable approach.⁵⁴ BP can be controlled with IV boluses of labetalol 10 to 80 mg every 10 minutes up to a maximum of 300 mg or with IV infusions of labetalol (0.5 to 2 mg/min) or nicardipine (5 to 15 mg/h). Deep vein thrombosis prophylaxis with intermittent compression stockings should be implemented early after admission. In those patients with SAH, once the aneurysm has been treated, heparin may be instituted. In ICH patients with lack of mobility after 1 to 4 days, heparin or LMWH may be started.^{9,54}

Nonpharmacologic Therapy

Patients with hemorrhagic stroke are evaluated for surgical treatment of SAH and ICH. In SAH, either clipping of the aneurysm or coil embolization is recommended within 72 hours after the initial event to prevent rebleeding. Coil embolization, also called coiling, is a minimally invasive procedure in which a platinum coil is threaded into the aneurysm. The flexible coil fills up the space to block blood flow into the aneurysm thereby preventing rebleeding. Surgical removal of the hematoma in patients with ICH is controversial because trials have not consistently shown improved outcomes. Minimally invasive

clot removal techniques with or without thrombolytic therapy aspiration have been evaluated; however, these procedures are considered investigational because outcomes are not certain. Current guidelines note that surgical treatment of ICH is uncertain and is not recommended except in specific patient situations.⁵⁴

Pharmacologic Therapy

► Calcium Antagonists

- Oral nimodipine is recommended in SAH to prevent delayed cerebral ischemia. It is recommended to begin oral nimodipine promptly after the initial event, but no later than 96 hours following SAH. Delayed cerebral ischemia occurs 4 to 14 days after the initial aneurysm rupture and is a common cause of neurological deficits and death. A meta-analysis of 12 studies was conducted and concluded that oral nimodipine 60 mg every 4 hours for 21 days following aneurysmal SAH reduced the risk of a poor outcome and delayed cerebral ischemia.⁵⁵

► Hemostatic Therapy

Recombinant factor VIIa has been shown to have a benefit in the treatment of ICH. The Recombinant Activated Factor VII Intracerebral Hemorrhage Trial compared doses of 40, 80, or 160 mcg/kg or placebo given as an IV infusion over 1 to 2 minutes within 4 hours after the onset of symptoms. Hematoma growth was decreased at 24 hours, mortality was decreased at 90 days, and overall functioning was increased at 90 days in the treatment group. An increased incidence of thromboembolic events was seen in the treatment group.⁵⁶ A recent phase 3 trial comparing 20 mcg/kg, 80 mcg/kg, and placebo showed that recombinant factor VIIa decreased growth of the hematoma, but did not improve survival or functional outcome. Intraventricular hemorrhage was more likely in the 80 mcg/kg group.⁵⁷ Current guidelines do not recommend treatment with recombinant factor VIIa due to an uncertain benefit and the increased risk of thromboembolic events. Further trials are warranted to determine specific patients that may benefit from therapy.⁵⁴

OUTCOME EVALUATION

- Stroke outcomes are measured based on the neurological status and functioning of the patient after the acute event. The NIHSS is a measure of daily functioning and used to assess patient status following a stroke.
- Early rehabilitation can reduce functional impairment after a stroke. Recent stroke rehabilitation guidelines have been endorsed by the American Heart Association and the American Stroke Association. These guidelines recommend that patients receive care in a multidisciplinary setting or stroke unit, receive early assessment using the NIHSS, and recommend that rehabilitation is started as soon as possible after the stroke. Other recommendations include screening for **dysphagia** and aggressive secondary stroke prevention treatments.⁵⁸
- **Table 11-6** provides monitoring guidelines for the acute stroke patient.

Table 11–6

Treatment	Parameter(s)	Monitoring Frequency	Comments
Ischemic stroke			
Alteplase	BP	Every 15 minutes × 2 hours, every 0.5 hour × 6 hours, every 1 hour × 16 hours; then every shift	
	Neurologic function	Neurological exam every 15 minutes × 1 hour, every 0.5 hour × 6 hours, every 1 hour × 17 hours; NIHSS 24 hours after alteplase infusion and at discharge	
	Bleeding	Clinical signs of bleeding every 2 hours × 24 hours	
ASA	Bleeding	Daily	
Clopidogrel	Hb/Hct, platelets ^a		
	Bleeding	Daily	
ASA/ER dipyridamole	Hb/Hct, platelets ^a		
Warfarin	Headache, bleeding	Daily	
	Hb/Hct, platelets ^a		
Warfarin	Bleeding, INR, Hb/Hct ^a	INR daily × 3 days; weekly until stable; then monthly	
Hemorrhagic stroke			
	BP, neurologic function, ICP	Every 2 hours in ICU	May require treatments to lower BP to less than 180 mm Hg systolic
Nimodipine for SAH	BP, neurologic function, fluid status	Every 2 hours in ICU	

ASA, aspirin; BP, blood pressure; ER, extended-release; Hb, hemoglobin; Hct, hematocrit; ICP, intracranial pressure; ICU, intensive care unit; INR, International Normalized Ratio; NIHSS, National Institutes of Health Stroke Scale; SAH, subarachnoid hemorrhage.

^aHb/Hct and platelets should be monitored at baseline and every 6 months for ASA, clopidogrel, ASA/ER dipyridamole, and warfarin treatment.

Patient Care and Monitoring

1. Assess the patient's signs and symptoms including the time of symptom onset and the time of arrival in the emergency department.
2. Perform thorough neurological and physical examinations evaluating for potential causes of the stroke.
3. Perform a CT scan to rule out a hemorrhagic stroke prior to administering any treatment.
4. Evaluate the inclusion and exclusion criteria for thrombolytic therapy to determine appropriateness for the patient.
5. Transfer the patient to a stroke center if available and develop a plan for the acute management of the patient.
6. Determine the patient's risk factors for stroke.
7. Develop a plan for the long-term management of risk factors in order to prevent a recurrent stroke.
8. Educate the patient on appropriate lifestyle modifications that will reduce stroke risk.
9. Educate the patient on their medication regimen stressing the importance of adherence.

Abbreviations Introduced in This Chapter

ACE-I	Angiotensin-converting enzyme inhibitor
ADP	Adenosine diphosphate
aPTT	Activated partial thromboplastin time
ARB	Angiotensin receptor blocker
ASA	Aspirin
AVM	Arteriovenous malformation
BPH	Benign prostatic hypertrophy
BP	Blood pressure
CAD	Coronary artery disease
CBC	Complete blood count
CEA	Carotid endarterectomy
CHARISMA	Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance
CT	Computed tomography
CVD	Cerebrovascular disease
DBP	Diastolic blood pressure
DVT	Deep vein thrombosis
ECASS III	European Cooperative Acute Stroke Study III
ECG	Electrocardiogram
ER	Extended release
ESPRIT	European/Australasian Stroke Prevention in Reversible Ischaemia Trial

ESPS 2	European Stroke Prevention Study 2
Hb	Hemoglobin
Hct	Hematocrit
IA	Intraarterial
ICA	Internal carotid artery
ICH	Intracerebral hemorrhage
ICP	Intracranial pressure
ICU	Intensive care unit
INR	International normalized ratio
JNC 7	Joint National Committee on the Prevention, Detection, Evaluation, and Treatment of High Blood Pressure
LMWH	Low molecular weight heparin
MATCH	Management of Atherothrombosis with Clopidogrel in High-risk Patients with Recent Transient Ischaemic Attack or Ischaemic Stroke
MI	Myocardial infarction
MRI	Magnetic resonance imaging
NIHSS	National Institutes of Health Stroke Scale
NINDS	National Institute of Neurological Disorders and Stroke
NS	Normal saline
PROFESS	Prevention Regimen for Effectively Avoiding Second Strokes
PROGRESS	Perindopril Protection Against Recurrent Stroke Study
PT	Prothrombin time
rt-PA	Alteplase
r-pro UK	Pro-urokinase
SAH	Subarachnoid hemorrhage
SBP	Systolic blood pressure
TIA	Transient ischemic attack
t-PA	Tissue plasminogen activator
TTP	Thrombotic thrombocytopenic purpura
UFH	Unfractionated heparin
VTE	Venous thromboembolism

12 Dyslipidemias

Matthew K. Ito

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Identify the major components within each lipoprotein and their role in lipoprotein metabolism and the development of atherosclerosis.
2. Identify the common types of lipid disorders.
3. Determine a patient's coronary heart disease risk and corresponding treatment goals according to the National Cholesterol Education Program Adult Treatment Panel III guidelines.
4. Recommend appropriate therapeutic lifestyle changes (TLC) and pharmacotherapy interventions for patients with dyslipidemia.
5. Identify the diagnostic criteria and treatment strategies for metabolic syndrome.
6. Describe the components of a monitoring plan to assess effectiveness and adverse effects of pharmacotherapy for dyslipidemias.
7. Educate patients about the disease state, appropriate TLC, and drug therapy required for effective treatment.

KEY CONCEPTS

- 1 The risk of atherosclerosis is directly related to increasing levels of serum cholesterol.
- 2 The National Cholesterol Education Program (NCEP) Adult Treatment Panel III guidelines have set the "optimal" level for low-density lipoprotein (LDL) cholesterol for all adults as less than 100 mg/dL (2.59 mmol/L).
- 3 The NCEP guidelines recommend that all adults older than 20 years should be screened at least every 5 years using a fasting blood sample to obtain a lipid profile.
- 4 The benefits of lowering LDL cholesterol to as low as 70 mg/dL (1.81 mmol/L) have been demonstrated in clinical trials; however, the lowest level at which to treat LDL cholesterol where there are no further benefits in coronary heart disease (CHD) risk has not yet been determined.
- 5 An adequate trial of therapeutic lifestyle changes (TLC) should be used in all patients, but pharmacotherapy should be instituted concurrently in higher-risk patients.
- 6 Typically, 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (or statins) are the medications of choice to treat high LDL cholesterol because of their: (1) ability to substantially reduce LDL cholesterol and reduce morbidity and mortality from atherosclerotic disease; (b) convenient once-daily dosing; and (c) low risk of side effects.
- 7 Patients with metabolic syndrome have an additional lipid parameter that needs to be assessed, namely non-high-density lipoprotein (non-HDL) cholesterol (total cholesterol minus HDL cholesterol). The target for non-HDL cholesterol is less than the patient's LDL cholesterol target plus 30 mg/dL (0.78 mmol/L).
- 8 After assessment and control of LDL cholesterol, patients with serum triglycerides of 200 to 499 mg/dL (2.26 to 5.64 mmol/L) should be assessed for atherogenic dyslipidemia (low HDL cholesterol and increased small-dense LDL particles) and metabolic syndrome.
- 9 Combination drug therapy is an effective means to achieve greater reductions in LDL cholesterol (statin plus ezetimibe or bile acid resin, bile acid resin plus ezetimibe, or three-drug combinations) as well as raising HDL cholesterol and lowering serum triglycerides (statin plus niacin or fibrate).
- 10 The evidence of reducing LDL cholesterol while substantially raising HDL cholesterol (statin plus niacin or fibrate) to reduce the risk of CHD-related events to a greater degree than statin monotherapy remains in question.

INTRODUCTION

1 The risk of **atherosclerosis** is directly related to increasing levels of serum cholesterol. Hypercholesterolemia (elevation in serum cholesterol) and other abnormalities in serum lipids play a major role in plaque formation leading to coronary heart disease (CHD) as well as other forms of atherosclerosis, such as **carotid** and **peripheral artery disease** (atherosclerosis of the peripheral arteries). This predictive relationship has been demonstrated from large epidemiological, animal, and genetic studies.¹ CHD is the leading cause of death in both men and women in the United States and most industrialized nations. It is also the chief cause of premature, permanent disability in the U.S. workforce. Annually, approximately 785,000 Americans experience a new heart attack and 470,000 will have a recurrent event. The average age of a first heart attack is 66.5 years for American men and 70.3 years for women. According to a 2011 report, the direct and indirect cost of CHD to the U.S. economy in 2007 was almost \$286.6 billion.² Clinical trials have consistently demonstrated that lowering serum cholesterol reduces atherosclerotic progression and mortality from CHD.

The development of CHD is a lifelong process. Except in rare cases of severely elevated serum cholesterol levels, years of poor dietary habits, sedentary lifestyle, and life-habit risk factors (e.g., smoking and obesity) contribute to the development of atherosclerosis.³ Unfortunately, many individuals at risk for CHD do not receive lipid-modifying therapy or are not optimally treated. This chapter helps identify individuals at risk, assesses treatment goals based on the level of CHD risk, and implements optimal treatment strategies and monitoring plans.

PATHOPHYSIOLOGY

Cholesterol and Lipoprotein Metabolism

Cholesterol is an essential substance manufactured by most cells in the body. Cholesterol is used to maintain cell wall integrity and for the biosynthesis of **bile acids** and steroid hormones. Other major lipids in our body are triglycerides and phospholipids. Because cholesterol is a relatively water-insoluble molecule, it is unable to circulate through the blood alone. Cholesterol along with triglycerides and phospholipids are packaged in a large carrier protein called a lipoprotein (Fig. 12-1). Lipoproteins are water soluble, which allows transportation of the major lipids in the blood. These lipoproteins are spherical and vary in size (approximately 1,000 to 6 nm) and density (less than 0.94 to 1.21 g/mL) (Table 12-1). The amount of cholesterol and triglycerides vary by lipoprotein size. The major lipoproteins in descending size and ascending density are chylomicrons, very low-density lipoprotein (VLDL), intermediate-density lipoprotein (IDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL). When clinical laboratories measure and report serum total cholesterol, what they are measuring and reporting are the total cholesterol molecules in all the major lipoproteins. The estimated value of LDL cholesterol is found using the

FIGURE 12-1. Lipoprotein structure. Lipoproteins are a diverse group of particles with varying size and density. They contain variable amounts of core cholesterol esters and triglycerides, and have varying numbers and types of surface apolipoproteins. The apolipoproteins function to direct the processing and removal of individual lipoprotein particles.

following equation (after fasting for 9 to 12 hours), which assumes the ratio of triglyceride to cholesterol molecules in VLDL is 5 to 1 molecules:

$$\text{LDL cholesterol (mg/dL)} = \text{total cholesterol} - (\text{HDL cholesterol} + \text{triglycerides}/5) \text{ using traditional units of mg/dL}$$

Where $\text{triglycerides}/5 = \text{VLDL cholesterol}$

(To convert total, LDL, and HDL cholesterol to SI units:
1 mg/dL = 0.02586 mmol/L)

For example, if an individual's triglycerides = 250 mg/dL, HDL = 35 mg/dL, and total cholesterol = 240 mg/dL, then $155 \text{ mg/dL} = 240 \text{ mg/dL} - (35 \text{ mg/dL} + 250 \text{ mg/dL}/5)$.

If serum triglycerides are greater than 400 mg/dL (4.52 mmol/L), the normal ratio of triglycerides to cholesterol of 5:1 in VLDL is disrupted, chylomicrons are present, or the patient has type III hyperlipoproteinemia, this formula becomes inaccurate and LDL cholesterol must be directly measured.³

Each lipoprotein has various proteins called apolipoproteins (Apos) embedded on the surface (Fig. 12-1). These Apos serve four main purposes; they (a) are required for assembly and secretion of lipoproteins (such as Apos B-48 and B-100); (b) serve as major structural components of lipoproteins; (c) act as ligands (Apo B-100 and Apo E) for binding to receptors on cell surfaces (LDL receptors); and (d) can be cofactors (such as Apo C-II) for activation of enzymes

Table 12-1

Physical Characteristics of Lipoproteins

Lipoprotein	Density Range (g/mL)	Size (nm)	Composition (%)		Apolipoprotein
			Cholesterol	Triglycerides	
Chylomicrons	Less than 0.95	100–1,000	3–7	85–95	A-I, A-II, A-IV, B-48, C-I, C-II, E
VLDL	Less than 1.006	40–50	20–30	50–65	B-100, C-I, C-II, C-III, E
IDL	1.006–1.019	25–30	40	20	B-100, E
LDL	1.019–1.063	20–25	51–58	4–8	B-100
HDL	1.063–1.21	6–10	18–25	2–7	A-I, A-II, C-I, C-II, C-III, E

HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very low-density lipoprotein.

(such as lipoprotein lipase [LPL]) involved in the breakdown of triglycerides from chylomicrons and VLDL.⁴ Apos A-I and A-II are major structural proteins on the surface of HDL. Apo A-I interacts with adenosine triphosphate (ATP) binding cassette A1 and G1 to traffic cholesterol from extrahepatic tissue (such as the arterial wall) to immature or **nascent** HDL.

Cholesterol from the diet as well as from bile enters the small intestine, where it is emulsified by bile salts into **micelles** (Fig. 12-2). These micelles interact with the **duodenal** and **jejunal enterocyte** surfaces, and cholesterol is transported from the micelles into these cells by the Niemann-Pick C1 Like 1 (NPC1L1) transporter.⁵ Some cholesterol and most

plant sterols, which are structurally similar to cholesterol, are exported back from the enterocyte into the intestinal lumen by the ATP-binding cassette (ABC) G5/G8 transporter. Cholesterol within enterocytes is esterified and packaged into chylomicrons along with triglycerides, phospholipids, and Apo B-48 as well as Apos C and E, which are then released into the **lymphatic** circulation. In the circulation, chylomicrons are converted to chylomicron remnants (through loss of triglycerides by the interaction of Apo C-II and LPL). During this process, chylomicrons also interact with HDL particles (Fig. 12-3) and exchange triglyceride and cholesterol content (facilitated by cholesterol ester transfer protein, or CETP), and

FIGURE 12-2. Intestinal cholesterol absorption and transport. Cholesterol from food and bile enter the gut lumen and are emulsified by bile acids into micelles. Micelles bind to the intestinal enterocytes, and cholesterol and other sterols are transported from the micelles into the enterocytes by a sterol transporter. Triglycerides synthesized by absorbed fatty acids, along with cholesterol and apolipoprotein B-48, are incorporated into chylomicrons. Chylomicrons are released into the lymphatic circulation and are converted to chylomicron remnants (through loss of triglyceride), and then taken up by the hepatic LDL receptor-related protein (LRP). (ABC G5/G8, ATP-binding cassette G5/G8; Apo, apolipoprotein; CE, cholesterol ester; FA, fatty acid; NPC1L1, Niemann-Pick C1 Like 1; TG, triglyceride.)

FIGURE 12-3. Reverse cholesterol transport. Cholesterol is transported from the arterial wall or other extrahepatic tissues back to the liver by HDL. Esterified cholesterol from HDL can be transferred to apolipoprotein B–containing particles in exchange for triglycerides. Cholesterol esters transferred from HDL to VLDL and LDL are taken up by hepatic LDL receptors or delivered back to extrahepatic tissue. (ABCA1, ATP-binding cassette A1; ABCG1, ATP-binding cassette G1; Apo, apolipoprotein; C, cholesterol; CE, cholesterol ester; CETP, cholesterol ester transfer protein; CM, chylomicrons; HDL, high-density lipoprotein; HL, hepatic lipase; LCAT, lecithin-cholesterol acyltransferase; LDL, low-density lipoprotein; SR-B1, scavenger receptors; TG, triglyceride; VLDL, very low-density lipoprotein.)

HDL particles acquire Apos A and C. Chylomicron remnant particles are then taken up by LDL-related protein (LRP).

In the liver, cholesterol and triglycerides are incorporated into VLDL along with phospholipids and Apo B-100 (Fig. 12-4). VLDL particles are released into the circulation where they acquire Apo E and Apo C-II from HDL. VLDL loses its triglyceride content through the interaction with LPL to form VLDL remnant and IDL. IDL can be cleared from the circulation by hepatic LDL receptors or further converted to LDL (by further depletion of triglycerides) through the action of hepatic lipases (HLs). Approximately 50% of IDL is converted to LDL. LDL particles are cleared from the circulation primarily by hepatic LDL receptors by interaction with Apo B-100. They can also be taken up by extrahepatic tissues or enter the arterial wall, contributing to atherogenesis.⁶

Cholesterol is transported from the arterial wall or other extrahepatic tissues back to the liver by HDL (Fig. 12-3). Apo A-I (derived from the intestine and liver) on nascent HDL interacts with ATP-binding cassette A1 (ABCA1) and G1 transporter on extrahepatic tissue. Cholesterol in nascent HDL is esterified by lecithin-cholesterol acyltransferase (LCAT) resulting in mature HDL. The esterified cholesterol can be transferred as noted previously to Apo B–containing particles in exchange for triglycerides. Triglyceride-rich HDL is hydrolyzed by HL, generating fatty acids and nascent HDL particles, or the mature HDL can bind to the scavenger receptors (SR-BI) on hepatocytes and transfer their cholesterol ester content for excretion in the bile.

A variety of genetic mutations occur in the steps just outlined during lipoprotein synthesis and metabolism that cause lipid disorders. The major genetic disorders and their effect on serum lipids are presented in Table 12-2. Disorders that increase serum cholesterol are generally those that affect the number or affinity of LDL receptors (also known as Apo B-E receptors) and are known as familial hypercholesterolemia (FH), or the ability of Apo B-100 to bind to the receptor known as familial defective Apo B-100. These patients commonly present with **corneal arcus** of the eye and **xanthomas** of extensor tendons of the hand and Achilles tendon, and premature CHD. Elevations in triglycerides are generally associated with overproduction of triglyceride-rich VLDL (greater than 5:1 ratio of triglyceride-to-cholesterol molecules in each particle), mutations in Apo E, or lack of LPL. Patients with extremely elevated serum triglycerides can develop **pancreatitis** and **tuberoeruptive xanthomas**. Most individuals have mild to moderate elevations in cholesterol caused by a polygenic disorder. Polygenic hypercholesterolemia is not as well understood as the single-gene disorders just discussed. Polygenic hypercholesterolemia is thought to be caused by various more subtle genetic defects as well as environmental factors such as diet and lack of physical activity.³

Pathophysiology of Clinical Atherosclerotic Disease

The most widely accepted theory of the process of atherosclerosis is that it is a low-grade inflammatory response

FIGURE 12-4. Endogenous lipoprotein metabolism. In liver cells, cholesterol and triglycerides are packaged into VLDL particles and exported into blood where VLDL is converted to IDL. Intermediate-density lipoprotein can be either cleared by hepatic LDL receptors or further metabolized to LDL. LDL can be cleared by hepatic LDL receptors or can enter the arterial wall, contributing to atherosclerosis. (Acetyl CoA, acetyl coenzyme A; Apo, apolipoprotein; CE, cholesterol ester; FA, fatty acid; HL, hepatic lipase; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LPL, lipoprotein lipase; VLDL, very low-density lipoprotein.)

Table 12-2

Selected Characteristics of Primary Dyslipidemias

Disorder	Estimated Frequency	Metabolic Defect	Main Lipid Parameter
Familial hypercholesterolemia homozygous	1/1 million	LDL-receptor negative	LDL-C greater than 500 mg/dL (12.93 mmol/L)
Heterozygous	1/300–1/500	Reduction in LDL receptors	LDL-C 250–500 mg/dL (6.47–12.93 mmol/L)
Familial defective Apo B-100	1/1,000	Single nucleotide mutation	LDL-C 250–500 mg/dL (6.47–12.93 mmol/L)
Polygenic hypercholesterolemia	Common	Metabolic and environmental	LDL-C 160–250 mg/dL (4.14–6.47 mmol/L)
Familial combined dyslipidemia	1/200–300	Overproduction of VLDL and/or LDL	LDL-C 250–350 mg/dL (6.47–9.05 mmol/L) TG 200–800 mg/dL (2.26–9.04 mmol/L)
Familial hyperapobetalipoproteinemia	5%	Increase Apo B production	Apo B greater than 125 mg/dL
Familial dysbetalipoproteinemia	0.5%	Apo E2/E2 phenotype	LDL-C 300–600 mg/dL (7.76–15.52 mmol/L) TG 400–800 mg/dL (4.52–9.04 mmol/L)
Familial hypertriglyceridemia			
Type IV	1/300	Unknown	TG 200–500 mg/dL (2.26–5.65 mmol/L)
Type V	1/205,000	Unknown	TG greater than 1000 mg/dL (11.3 mmol/L)
Hypoalphalipoproteinemia	3–5%	Defect in HDL catabolism	HDL-C less than 35 mg/dL (0.91 mmol/L)

Apo, apolipoprotein; C, cholesterol; HDL, high-density lipoprotein; LDL, low-density lipoprotein; TG, triglyceride; VLDL, very low-density lipoprotein.

FIGURE 12-5. The process of atherogenesis. Atherosclerosis is initiated by the migration and retention of LDL and remnant lipoprotein particles into the vessel wall. These particles undergo oxidation and are taken up by macrophages in an unregulated fashion. The oxidized particles participate to induce endothelial cell dysfunction leading to a reduced ability of the endothelium to dilate the artery and cause a prothrombotic state. The unregulated uptake of cholesterol by macrophages leads to foam cell formation and the development of a blood clot–favoring fatty lipid core. The enlarging lipid core eventually causes an encroachment of the vessel lumen. Early in the process, smooth muscle cells are activated and recruited from the media to the intima, helping to produce a collagen matrix that covers the growing clot protecting it from circulating blood. Later, macrophages produce and secrete matrix metalloproteinases that degrade the collagen matrix, leading to unstable plaque that may cause a myocardial infarction. (IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; MMP, matrix metalloproteinases; NO, nitric oxide; SR-BI, scavenger receptors.)

due to injury of the vascular endothelium induced by lipoprotein retention and oxidation in the arterial wall.⁶ The process begins when lipoproteins migrate between the **endothelial cells** into the arterial wall and bind to extracellular matrix molecules such as **proteoglycans** (Fig. 12-5). The initial lesion, known as a fatty streak, appears to form after accumulation of lipoproteins within the **intima**. After entering the intima, lipoproteins are then structurally modified by oxidation. Oxidized lipoproteins as well as other cytotoxic agents promote endothelial dysfunction by disturbing the production of vasoactive molecules such as **nitric oxide** that maintain vasomotor tone. Small, denser LDL particles migrate into the arterial wall more readily and are particularly susceptible to oxidation. The oxidized particles cause an increased expression of cell-adhesion molecules on vascular endothelial cells leading to recruitment of **monocytes** into the intima. The monocytes differentiate into **macrophages** and

express scavenger receptors, allowing enhanced uptake of these oxidized Apo B–containing lipoproteins. The macrophages continue to accumulate lipoproteins and ultimately develop into lipid-laden **foam cells**. Accumulation of foam cells leads to formation of a lipid-rich core, which marks the transition to a more complicated atherosclerotic plaque. Vascular wall remodeling leading to outward growth of the wall occurs to accommodate this lipid-rich core. Thus the vascular lumen is relatively well preserved, and generally the lesion would not be detected using traditional coronary angiographic techniques. Initially, smooth muscle cells migrate and proliferate from the **media** to the intima forming a protective fibrous cap that separates the potentially thrombogenic and necrotic lipid core from circulating blood. As the plaque matures, inflammatory cells secrete **matrix metalloproteinases** that degrade collagen and fibrin produced by smooth muscle cells that lead to a weakened fibrous cap. Ischemic events result when the fibrous

Clinical Presentation and Diagnosis

Lipid Panel

- Patients presenting with a total cholesterol level exceeding 200 mg/dL (5.17 mmol/L) or LDL cholesterol exceeding 100 mg/dL (2.59 mmol/L) should be evaluated for high cholesterol.
- Patients with serum triglycerides from 150 to 500 mg/dL (1.70 to 5.65 mmol/L) and serum HDL cholesterol less than 40 mg/dL (1.04 mmol/L) may have metabolic syndrome and need to be evaluated.

Physical Findings

- Patients with genetic disorders that cause a marked increase in serum LDL cholesterol (greater than 250 mg/dL [6.48 mmol/L]) may present with corneal arcus of the eye and xanthomas of extensor tendons of the hand and Achilles tendon.
- Patients with extremely elevated serum triglycerides (greater than 1,000 mg/dL [11.3 mmol/L]) can develop pancreatitis and tuberoeruptive xanthomas.

Indications for Lipid Panel

- All adults greater than 20 years of age should be screened at least every 5 years using a fasting blood

sample to obtain a lipid profile (total cholesterol, LDL cholesterol, HDL cholesterol, and triglycerides). A fasting lipid profile is preferred so an accurate assessment of LDL cholesterol can be performed, and fasting will allow the clearance of triglycerides carried by chylomicrons from the circulation, allowing VLDL cholesterol to be determined.

- Children between 2 and 20 years old should be screened for high cholesterol if their parents have premature CHD or if one of their parents has a total cholesterol greater than 240 mg/dL (6.21 mmol/L). Early screening will help to identify children at highest risk of developing CHD in whom early education and dietary intervention is warranted.

Indications for Other Tests

- Conditions that may produce lipid abnormalities (such as those listed in Table 12–3) should be screened for using appropriate tests. If present, these conditions should be properly addressed.

cap of these unstable plaques rupture and produce an occlusive **thrombus**. In contrast, repeated wound healing secondary to less significant plaque disruption that causes no symptoms might produce a more stable plaque as a consequence of smooth muscle cell, collagen, and fibrin accumulation and a resolution of the lipid core.⁶ These more stable plaques usually cause luminal encroachment (detected by traditional coronary angiographic techniques) and may produce **angina pectoris**. Unstable lesions usually outnumber the more stable plaques, thus accounting for most **acute coronary syndromes**. Evidence demonstrates that aggressive lipid lowering stabilizes these vulnerable lesions and restores endothelial function.^{3,6,7}

TREATMENT

In the United States, prevention and treatment of CHD are based primarily on guidelines issued in 2001 by the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III [ATP III]).³ The ATP IV guidelines are in development and will be available in 2012.⁸ LDL cholesterol is the primary diagnostic and therapeutic target. **2** *The NCEP ATP III guidelines have set the “optimal” level for LDL cholesterol for all adults as less than 100 mg/dL (2.59 mmol/L).* The NCEP panel issued an update in 2004 to the ATP III guidelines based on more recent clinical trial evidence.⁹ The update

outlines additional treatment options for certain patient populations, mainly those who are at very high risk of recurrent CHD events. These treatment options emphasize the benefits of diet, exercise, and weight control, and the use of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (or statins) as first-line drugs. If statins or other drugs used to treat hyperlipidemia are prescribed, doses that reduce LDL cholesterol by at least 30% to 40% should be recommended.⁹ In addition, an LDL cholesterol goal of less than 70 mg/dL as a “therapeutic option” was recommended in very high-risk individuals defined as those who experienced an acute coronary syndrome or patients with established CHD plus either multiple major risk factors (especially diabetes), severe and poorly controlled risk factors (especially continued cigarette smoking), or multiple risk factors of the metabolic syndrome.

The American Heart Association and American College of Cardiology issued guidelines for secondary prevention in patients with established CHD based on the results of two additional trials published after the 2004 NCEP update.¹⁰ These guidelines suggest it is reasonable to set an LDL cholesterol goal of less than 70 mg/dL (1.81 mmol/L) in all patients with CHD. If it is not possible to attain LDL cholesterol less than 70 mg/dL (1.81 mmol/L) due to a high baseline LDL cholesterol, it is generally possible to achieve an LDL cholesterol reduction of greater than 50% with more intensive LDL-lowering therapy, including combination

drug therapy. Most recently, the National Lipid Association Expert Panel on FH published their recommendations for the management of FH patients. This report goes beyond previously published guidelines by providing specific clinical guidance for the primary care clinician and lipid specialist with the goal of improving care of patients with FH and reducing their elevated risk for CHD.¹¹

Guidelines for Treatment

► Step 1: Patient Assessment

Determine lipoprotein profile after fasting for 9 to 12 hours.

3 The NCEP guidelines recommend that all adults older than 20 years should be screened at least every 5 years using a fasting blood sample to obtain a lipid profile (total cholesterol, LDL cholesterol, HDL cholesterol, and triglycerides). A fasting lipid profile is preferred so an accurate assessment of LDL cholesterol can be performed. Fasting permits the clearance of triglycerides carried by chylomicrons from the circulation, thus allowing VLDL cholesterol to be determined. Children between 2 and 20 years old should be screened for high cholesterol if their parents have premature CHD or if one of their parents has a total cholesterol greater than 240 mg/dL (6.21 mmol/L).³ Early screening will help identify children at highest risk of developing CHD, in whom early education and dietary intervention is warranted.

► Step 2: Rule Out Secondary Causes of Dyslipidemia

Certain drugs and diseases can cause abnormalities in serum lipids and should be evaluated (Table 12-3). Every effort should be made to correct or control underlying diseases such as hypothyroidism and diabetes. Concurrent medications known to induce lipid abnormalities should be evaluated for discontinuation prior to instituting long-term lipid-modifying therapy.³

► Step 3: Identify the Presence of Clinical Atherosclerotic Disease or Other Conditions That Confer High Risk for CHD Events

Individuals with established CHD, other clinical atherosclerotic disease (CAD), or diabetes have a greater than 20% risk over a 10-year period of developing CHD events.³ The ATP III guidelines set the target LDL cholesterol level at less than 100 mg/dL (2.59 mmol/L) for high-risk patients who have a history of one or more of the following:

- Myocardial infarction (MI)
- Unstable angina
- Chronic stable angina
- Coronary interventions (coronary bypass, percutaneous transluminal coronary angioplasty, or stents)
- Peripheral arterial disease (claudication or ankle-brachial index less than 0.9)

Table 12-3

LDL, low-density lipoprotein; HDL, high-density lipoprotein.

- Symptomatic carotid artery disease (stroke or transient ischemic attack)
- Diabetes (types 1 and 2)
- Multiple risk factors with a Framingham calculated risk (Fig. 12-6) greater than 20%

4 The benefits of lowering LDL cholesterol to as low as 70 mg/dL (1.81 mmol/L) have been demonstrated in clinical trials. Thus, in patients considered very high risk, an LDL cholesterol goal of less than 70 mg/dL (1.81 mmol/L) is a therapeutic option.^{9,10} These individuals have established CAD or present with acute coronary syndromes. 4 The lowest level at which to treat LDL cholesterol where there are no further benefits in CHD risk has not yet been determined.

► Step 4: Determine the Presence of Major Risk Factors According to ATP III

In individuals who do not have established CHD or CHD risk equivalent, the next step is to count major risk factors for CHD as presented in Table 12-4. These risk factors are considered independent predictors of CHD. HDL cholesterol

FIGURE 12-6. Framingham Point Scale for estimating 10-year CHD risk. The Framingham score is used to determine a patient’s CHD risk category when they are found to have two or more CHD risk factors (Table 12–4). This system assigns points to the following risk factors: age, total cholesterol level (in mg/dL), smoking status, HDL cholesterol level, and systolic blood pressure. The point total corresponds to the 10-year risk (%) of a CHD event (nonfatal myocardial infarction and coronary death), which serves as a basis for deciding how intensively to treat hypercholesterolemia and other risk factors. To calculate risk factor using the Framingham Point Scale, go to the following website: <http://www.nhlbi.nih.gov/guidelines/cholesterol/index.htm>. The Système International units for the corresponding conventional units in the Framingham Point Scale illustration include (a) total cholesterol (160 mg/dL = 4.14 mmol/L; 160–199 mg/dL = 4.14–5.15 mmol/L; 200–239 mg/dL = 5.17–6.18 mmol/L; 240–279 mg/dL = 6.21–7.21 mmol/L; 280 mg/dL = 7.24 mmol/L) and (b) HDL (60 mg/dL = 1.55 mmol/L; 50–59 mg/dL = 1.29–1.53 mmol/L; 40–49 mg/dL = 1.03–1.27 mmol/L; 40 mg/dL = 1.04 mmol/L). (BP, blood pressure; CHD, coronary heart disease; HDL, high-density lipoprotein.) (From <http://www.nhlbi.nih.gov/guidelines/cholesterol/index.htm>.)

Table 12-4

Risk Factors for Coronary Heart Disease According to ATP III

Risk Factor	Definition
Age (years)	Male greater than or equal to 45; female greater than or equal to 55
Family history of premature CHD events	Male first-degree relative at less than 55 years Female first-degree relative at less than 65 years
Hypertension	SBP greater than or equal to 140 mm Hg DBP greater than or equal to 90 mm Hg
HDL cholesterol	Less than 40 mg/dL (1.03 mmol/L)
Cigarette smoking	Within the past month

HDL cholesterol greater than or equal to 60 mg/dL (1.55 mmol/L) is considered a negative risk factor; thus subtract 1 risk factor from the total from above.

CHD, coronary heart disease; DBP, diastolic blood pressure; HDL, high-density lipoprotein; SBP, systolic blood pressure.

of greater than or equal to 60 mg/dL (1.55 mmol/L) is considered a negative risk factor and means one risk factor can be subtracted from the total count.³

► **Step 5: If Two or More Risk Factors Are Present Without CHD or CHD Risk Equivalent, Assess 10-Year CHD Risk**

- Listed in Table 12-5 are the risk groups that require risk calculations using the Framingham scoring system.³ Because individuals with two or more risk factors may carry a risk equivalent to individuals with established CHD, and therefore should be treated with the same intensity, a scoring system developed from the Framingham Coronary Heart Disease Study is used to estimate the 10-year risk of a

Table 12-5

CHD Risk Factors and Needed Risk Factors for Framingham Score Calculation

Risk Profile	10-Year Risk for CHD	Need for Framingham Calculation
Less than or equal to 1 risk factor	Less than 10%	No
Greater than or equal to 2 risk factors	0–10%	Yes
CAD or CAD risk equivalent	10–20%	Yes
Very high risk	Greater than 20%	No
	Much greater than 20%	No

CAD, clinical atherosclerotic disease; CHD, coronary heart disease.

nonfatal MI and CHD death (Fig. 12-6). This system assigns points to the following risk factors: age, total cholesterol level, smoking status, HDL cholesterol level, and systolic blood pressure. The score is used to determine a patient's risk category and the intensity of treatment to lower their LDL cholesterol. To calculate a Framingham score, visit the following website: <http://www.nhlbi.nih.gov/guidelines/cholesterol/index.htm>.

► **Step 6: Determine Treatment Goals and Therapy**

- Treatment goals for LDL cholesterol and thresholds for the institution of therapeutic lifestyle changes (TLC) and pharmacotherapy is the next step (Table 12-6).

► **Step 7: Initiate TLC If LDL Is Above Goal**

- TLC should be the first approach tried in all patients (Table 12-7).³ **5** *An adequate trial of TLC should be used in all patients, but pharmacotherapy should be instituted concurrently in higher-risk patients (Table 12-6).* This includes dietary restrictions of cholesterol and saturated fats as well as regular exercise and weight reduction. In addition, therapeutic options to enhance LDL cholesterol lowering such as consumption of plant stanols/sterols (which competitively inhibit incorporation of cholesterol into micelles) and dietary fiber should be encouraged. These therapeutic options collectively may reduce LDL cholesterol by 20% to 25%. For a more detailed overview of lifestyle modifications, refer to the ATP III guidelines³ and the American Heart Association's diet and lifestyle recommendations.¹²

► **Step 8: Consider Adding Drug Therapy If LDL Is Above Threshold Level**

Patients unable or unlikely to achieve their LDL cholesterol goals following a reasonable trial of TLC (typically 12 weeks for patients without CHD and sooner for those at high risk or with LDL cholesterol greater than 190 mg/dL [4.91 mmol/L] at baseline) are candidates for drug therapy (Table 12-6).

- 6** *Typically, statins are the medications of choice to treat high LDL cholesterol because of their (a) ability to substantially reduce LDL cholesterol and reduce morbidity and mortality from atherosclerotic disease, (b) convenient once-daily dosing, and (c) low risk of side effects.*

► **Step 9: Identify Patients with the Metabolic Syndrome**

- Diagnosis of the metabolic syndrome is made when three or more of the following risk factors are present:^{3,13}
 - Waist circumference greater than or equal to 40 inches (102 cm) in men (35 inches [89 cm] in Asian men), or 35 inches (89 cm) in women (31 inches [79 cm] in Asian women)
 - Triglycerides greater than or equal to 150 mg/dL (1.70 mmol/L) or on drug treatment for elevated triglycerides

Table 12-6

National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III [ATP III]) Treatment Goals for LDL Cholesterol and Thresholds for Starting Therapeutic Lifestyle Changes and Pharmacotherapy

Risk Category	LDL Cholesterol Goal	Initiate Therapeutic Lifestyle Changes (TLC)	Consider Drug Therapy
High Risk CHD or CHD risk equivalents (10-year risk greater than 20%)	Less than 100 mg/dL (2.59 mmol/L)	Greater than or equal to 100 mg/dL (2.59 mmol/L)	Greater than or equal to 100 mg/dL (2.59 mmol/L)
Very-High Risk	Optional goal of less than 70 mg/dL ^a (1.81 mmol/L)		
Moderately-High Risk Greater than or equal to 2 risk factors (10-year risk 10–20%)	Less than 130 mg/dL (3.36 mmol/L) (Optional goal of less than 100 mg/dL ^a [2.59 mmol/L])	Greater than or equal to 130 mg/dL (3.36 mmol/L)	Greater than or equal to 130 mg/dL (3.36 mmol/L) (consider drug options if LDL cholesterol 100–129 mg/dL [2.59–3.34 mmol/L])
Moderate Risk Greater than or equal to 2 risk factors (10-year risk less than 10%)	Less than 130 mg/dL (3.36 mmol/L)	Greater than or equal to 130 mg/dL (3.36 mmol/L)	Greater than 160 mg/dL (4.14 mmol/L)
Low Risk	Less than 160 mg/dL (4.14 mmol/L)	Greater than or equal to 160 mg/dL (4.14 mmol/L)	Greater than or equal to 190 mg/dL (4.91 mmol/L) (consider drug options if LDL cholesterol 160–189 mg/dL [4.14–4.89 mmol/L])

^aOptional goals indicated in the NCEP ATP III 2004 update of the guidelines.

CHD, coronary heart disease; LDL, low-density lipoprotein.

Table 12-7

Essential Components of Therapeutic Lifestyle Changes (TLC)

Component	Recommendation
LDL-raising nutrients Saturated fats Dietary cholesterol	Total fat range should be 25–35% for most cases Less than 7% of total calories and reduce intake of trans fatty acids Less than 200 mg/day
Therapeutic options for LDL-lowering plant stanols/sterols	2 g/day
Increased viscous (soluble) fiber	10–25 g/day
Total calories	Adjust caloric intake to maintain desirable body weight and prevent weight gain
Physical activity	Include enough moderate exercise to expend at least 200 kcal (837 kJ)/day

LDL, low-density lipoprotein.

- HDL cholesterol less than 40 mg/dL (1.03 mmol/L) in men or 50 mg/dL (1.29 mmol/L) in women or on drug treatment for reduced HDL cholesterol
- Blood pressure greater than or equal to 130/85 mm Hg or on drug treatment for hypertension
- Fasting blood glucose greater than or equal to 100 mg/dL (5.6 mmol/L) or on drug treatment for elevated glucose

Patients with the metabolic syndrome are twice as likely to develop type 2 diabetes and four times more likely to develop

CHD.^{3,14} These individuals are usually insulin resistant, obese, have hypertension, are in a **prothrombotic state**, and have atherogenic dyslipidemia characterized by low HDL cholesterol and elevated triglycerides, and an increased proportion of their LDL particles are small and dense.³

NCEP ATP III identified the metabolic syndrome as an important target for further reducing CHD risk. Treatment of the metabolic syndrome starts with increased physical activity, weight reduction (which also enhances LDL cholesterol lowering and insulin sensitivity), and

Patient Encounter 1, part 1

RH is a 44-year-old man with a history of hypertension who was recently diagnosed with CHD after complaining of increasing chest discomfort while exercising. A drug-eluting stent was placed in the left anterior descending artery after his coronary angiography revealed 85% luminal narrowing. He presents to the clinic to follow up after his hospitalization for evaluation of his cholesterol. He denies having chest pain since the first incident of discomfort that precipitated his hospitalization. He indicates no history of myocardial infarction, stroke, or peripheral artery disease. He has no siblings, both parents are alive, and his mother had an MI when she was 47 years old and has elevated cholesterol. He is married with two children. He does not smoke and exercises regularly. He has been fasting for approximately 11 hours.

Can RH be evaluated today for his cholesterol?

Does an assessment of his risk factors for CHD need to be conducted?

What additional information do you need to know for the evaluation of RH?

moderation of ethanol use and carbohydrate intake, which effectively reduce many of the associated risk factors. Each of the risk factors should be addressed independently as appropriate, including treatment of hypertension and use of aspirin in CHD patients to reduce the prothrombotic state.

7 Patients with metabolic syndrome have an additional lipid parameter that needs to be assessed, namely non-HDL cholesterol (total cholesterol minus HDL cholesterol).³ The target for non-HDL cholesterol is less than the patient's LDL cholesterol target plus 30 mg/dL (0.78 mmol/L). 8 After assessment and control of LDL cholesterol, patients with serum triglycerides between 200 and 499 mg/dL (2.26 and 5.64 mmol/L) should be assessed for atherogenic dyslipidemia (low HDL cholesterol, increased small-dense LDL particles) and metabolic syndrome. Non-HDL cholesterol estimates the cholesterol carried by all Apo B-containing lipoprotein particles. Thus non-HDL cholesterol represents the sum of LDL cholesterol, VLDL cholesterol, and other triglyceride-rich remnant particles. The non-HDL cholesterol goal is 30 mg/dL (0.78 mmol/L) higher than the LDL cholesterol goal. This is based on the premise that a VLDL cholesterol level less than or equal to 30 mg/dL (0.78 mmol/L) is normal. For example, the LDL cholesterol goal is less than 100 mg/dL (2.59 mmol/L) and the non-HDL cholesterol goal is less than 130 mg/dL (3.36 mmol/L) for a diabetic patient without a history of CHD. Two treatment approaches can be considered for achieving the non-HDL cholesterol goal: titrating existing LDL-lowering therapy or adding niacin or a fibrate to the LDL-lowering therapy.³ See the chapters on ischemic heart disease and diabetes mellitus for further information regarding metabolic syndrome.

► Step 10: Treatment of Elevated Triglycerides

Patients with serum triglycerides exceeding 500 mg/dL (5.65 mmol/L) are at increased risk of pancreatitis, especially when levels exceed 1,000 mg/dL (11.3 mmol/L).³ Reducing triglycerides in these individuals becomes the primary target for intervention. Reduction in fats, ethanol, and carbohydrates should be considered, and secondary causes (Table 12–3) should be assessed. Increase in exercise and weight loss if overweight should be encouraged. When pharmacotherapy is instituted, the goal is to reduce triglycerides to less than 150 mg/dL (1.70 mmol/L). Once triglycerides are less than 500 mg/dL (5.65 mmol/L) and the risk of pancreatitis is reduced, the primary focus of intervention should once again be on LDL cholesterol. As noted earlier, individuals with triglycerides between 200 and 499 mg/dL (2.26 and 5.64 mmol/L) have an increase in triglyceride-rich remnant lipoproteins and small-dense LDL particles. Non-HDL cholesterol should be a secondary target in these individuals. Niacin, fibrates, and ω -3 fatty acids are the most effective agents in patients with hypertriglyceridemia.³

Emerging and Life-Habit Risk Factors

In addition to the five major risks, the ATP III guidelines recognize other factors that contribute to CHD risk. These are classified as life-habit risk factors and emerging risk factors. Life-habit risk factors, consisting of obesity, physical inactivity, and an atherogenic diet, require direct intervention. For example, emerging risk factors are lipoprotein(a), prothrombotic/proinflammatory factors, lipoprotein-associated phospholipase A2 (Lp-PLA2), and C-reactive protein (CRP). CRP is a marker of low-level inflammation and appears to help predict CHD risk beyond LDL cholesterol and major CHD risk factors.¹⁴ In a recent trial, rosuvastatin significantly reduced the incidence of major cardiovascular events in apparently healthy persons without hyperlipidemia (LDL cholesterol less than 130 mg/dL [3.36 mmol/L]) but with elevated high-sensitivity CRP levels.¹⁵ These results will need to be considered by the ATP IV writing committee.⁸ In some patients, emerging risk factors may be used to guide the intensity of risk-reduction therapy. Deciding when to consider emerging risk factors requires the use of clinical judgment. The National Lipid Association recently reviewed a number of these emerging risk factors and has offered some clinical guidance on their use.¹⁶

Pharmacotherapy**► Statins (HMG-CoA Reductase Inhibitors)**

Statins are very effective LDL-lowering medications and are proven to reduce the risk of CHD, stroke, and death. Thus NCEP ATP III considers statins the preferred LDL-lowering medications. Data concerning the efficacy and safety of the statins now go back nearly 25 years. Statins are effective in reducing MIs, strokes, revascularization procedures,

Table 12–8

Effects of Lipid-Lowering Drugs on Serum Lipids at FDA-Approved Doses

Lipid-Lowering Drug	LDL Cholesterol	HDL Cholesterol	Triglycerides	Total Cholesterol
Statins				
Atorvastatin	–26% to –60%	+5% to +13%	–17% to –53%	–25% to –45%
Fluvastatin	–22% to –36%	+3% to +11%	–12% to –25%	–16% to –27%

^a% change relative to simvastatin 20 mg.

cardiovascular deaths, and, in some cases, total mortality. This effectiveness has been demonstrated in both genders, the elderly, patients with diabetes and hypertension, those with and without preexisting CHD, and following an acute coronary syndrome.^{15–27} Statins inhibit conversion of HMG-CoA to L-mevalonic acid and subsequently cholesterol. Statins lower LDL cholesterol levels by approximately 25% to 62% (Table 12–8). A substantial reduction in LDL cholesterol occurs at the usual starting dose, and each doubling of the daily dose only produces an additional 6% average reduction (known as the “rule of 6”). This is important when considering dose escalation versus adding on an additional LDL-lowering drug. Statins are moderately effective at reducing triglycerides and modestly raise HDL cholesterol (Table 12–8). By inhibiting the synthesis of L-mevalonic acid, statins in turn inhibit other important by-products in the cholesterol biosynthetic pathway that affect intracellular transport, membrane trafficking, and gene transcription.²⁸ This may explain some of the cholesterol-independent benefits (so-called pleiotropic effects) of statins such as reducing lipoprotein oxidation, enhancing endothelial

synthesis of nitric oxide, and inhibiting **thrombosis**. These pleiotropic effects are thought to contribute to the rapid/earlier benefits of statins on CHD risk while the decrease in serum lipids accounts for the slower late benefit.

Statins are well tolerated, with less than 4% of patients in clinical trials discontinuing therapy due to adverse side effects (Table 12–9). Elevations in liver function tests (LFTs) and **myopathy**, including **rhabdomyolysis**, are important adverse effects associated with the statins. Liver toxicity, defined as LFT elevations greater than three times the upper limit of normal, is reported in less than 2% of patients; however, the incidence is higher at higher doses, and the progression to liver failure is thought to be exceedingly rare. LFTs should be obtained at baseline and as clinically indicated thereafter. Annual monitoring of LFTs is usually sufficient. Myopathy, defined as muscle symptoms with creatine kinase (CK; or creatine phosphokinase [CPK]) 10 times the upper limit of normal, is reported to range from 0% to less than 0.5% for the currently marketed statins at FDA-approved doses. Rhabdomyolysis, defined as muscle symptoms with marked elevation in CK 10 times

Table 12-9

Formulation, Dosing, and Common Adverse Effects of Lipid-Lowering Drugs

Lipid-Lowering Drug	Dosage Forms	Usual Adult Maintenance Dose Range	Adverse Effects
Statins			
Atorvastatin	10-, 20-, 40-, 80-mg tablets	10–80 mg once daily (at any time of day). Dose adjustment in patients with renal dysfunction is not necessary	Most frequent side effects are constipation, abdominal pain, diarrhea, dyspepsia, and nausea. Statins should be discontinued promptly if serum transaminase levels (liver function tests) rise to three times upper limit of normal or if patient develops signs or symptoms of myopathy. Approximate equivalent doses of HMG-CoA reductase inhibitors are: atorvastatin 10 mg, fluvastatin 80 mg, lovastatin 40 mg, pitavastatin 2 mg, pravastatin 40 mg, simvastatin 20 mg, and rosuvastatin 5 mg
Fluvastatin	20-, 40- mg capsules; 80-mg extended-release tablets	20–40 mg/day as a single dose (evening) or 40 mg twice daily; 80 mg once daily (evening). Dose adjustments for mild to moderate renal impairment are not necessary	
Lovastatin	10-, 20-, 40-mg tablets	10 to 80 mg/day as a single dose (with evening meal) or divided twice daily with food. In patients with severe renal insufficiency (creatinine clearance less than 30 mL/min [0.5 mL/s]), dosage increases above 20 mg/day should be carefully considered and, if deemed necessary, implemented cautiously	
Lovastatin ER	20-, 30-, 60-mg tablets	20–60 mg/day as a single dose. In patients with severe renal insufficiency (creatinine clearance less than 30 mL/min [0.5 mL/s]), dosage increases above 20 mg/day should be carefully considered and, if deemed necessary, implemented cautiously	
Pravastatin	10-, 20-, 40-, 80-mg tablets	10 to 80 mg/day as a single dose at bedtime. In patients with a history of significant renal or hepatic dysfunction, a starting dose of 10 mg daily is recommended	
Pitavastatin	1-, 2-, 4-mg tablets	1–4 mg/day as a single dose can be taken with or without food, at any time of day. Moderate renal impairment (glomerular filtration rate 30–60 mL/min/1.73 m ² [0.29 to 0.58 mL/s/m ²]) and end-stage renal disease on hemodialysis: Starting dose of 1 mg once daily and maximum dose of 2 mg once daily	
Rosuvastatin	5-, 10-, 20-, 40 tablets	5–40 mg/day (at any time of day); 40 mg reserved for those who don't achieve LDL cholesterol goal on 20 mg. In patients with a history of significant renal or hepatic dysfunction, a starting dose of 10 mg daily is recommended	
Simvastatin	5-, 10-, 20-, 40-mg tablets	5 to 40 mg/day as a single dose in the evening, or divided. Recommended starting dose for patients at high risk of CHD is 40 mg/day. In patients with mild to moderate renal insufficiency dosage adjustment is not necessary. However, caution should be exercised in patients with severe renal insufficiency; such patients should be started at 5 mg/day and be closely monitored. Due to the increased risk of myopathy, including rhabdomyolysis, use of the 80-mg dose of simvastatin should be restricted to patients who have been taking simvastatin 80 mg chronically (e.g., for 12 months or more) without evidence of muscle toxicity. Because of an increased risk for myopathy in Chinese patients taking simvastatin 40 mg coadministered with lipid-modifying doses (greater than or equal to 1 g/day niacin) of niacin-containing products, caution should be used when treating Chinese patients with simvastatin doses exceeding 20 mg/day coadministered with lipid-modifying doses of niacin-containing products. Because the risk for myopathy is dose related, Chinese patients should not receive simvastatin 80 mg coadministered with lipid-modifying doses of niacin-containing products	

(Continued)

Table 12-9

Formulation, Dosing, and Common Adverse Effects of Lipid-Lowering Drugs (Continued)

Lipid-Lowering Drug	Dosage Forms	Usual Adult Maintenance Dose Range	Adverse Effects
Bile Acid Sequestrants			
Cholestyramine	4-g packets	4–24 g/day in two or more divided doses	Main side effects are nausea, constipation, bloating, and flatulence, although these may be less with colestevlam. Increasing fluid and dietary fiber intake may relieve constipation and bloating. Impair absorption of fat-soluble vitamins
Colesevelam	625-mg tablets	3,750–4,375 mg/day as a single dose or divided twice daily, with meals	
	3.75-g oral suspension packet	1 packet once a day with meals	
Colestipol	5-g packets 1-g tablets	5–30 g/day as a single dose or divided 2–16 g/day as a single dose or divided	
Cholesterol Absorption Inhibitors			
Ezetimibe	10-mg tablet	10 mg once daily. No dosage adjustment is necessary in patients with renal or mild hepatic insufficiency	The overall incidence of adverse events reported with ezetimibe alone was similar to that reported with placebo and generally similar between ezetimibe with a statin and statin alone. The frequency of increased transaminases was slightly higher in patients receiving ezetimibe plus a statin compared with those receiving statin monotherapy (1.3% vs. 0.4%).
Nicotinic Acid (Prescription products)			
Niacin ER (Niaspan)	500-, 750-, 1000-mg extended-release tablets	1000–2000 mg once daily at bedtime. Use with caution in patients with renal impairment	Side effects include flushing, itching, gastric distress, headache, hepatotoxicity, hyperglycemia, and hyperuricemia
Niacin IR (Niacor)	500-mg tablets	1–6 g/day in two to three divided doses. Do not exceed 6 g daily	
Fibric Acid Derivatives			
Fenofibrate	54-, 160-mg tablets ^a	54–160 mg/day; the dosage should be minimized in severe renal impairment	Most common side effects are nausea, diarrhea, abdominal pain, and rash. Increased risk of rhabdomyolysis when given with a statin. Fibric acids are associated with gallstones, myositis, and hepatitis
Gemfibrozil	600-mg tablets	1,200 mg/day in two doses, 30 minutes before meals; should be avoided in hepatic or severe renal impairment	
Combination Products			
Niacin ER and lovastatin	500 mg/20 mg, 750 mg/20 mg, 1000 mg/20 mg tablets	500 mg/20 mg to 2,000 mg/40 mg daily, at bedtime.	See previous entries for each drug (niacin ER and lovastatin)
Niacin ER and simvastatin	500 mg/20 mg, 500 mg/40 mg, 750 mg/20 mg, 1000 mg/20 mg, 1000 mg/40 mg	500 mg/20 mg to 2,000 mg/40 mg daily, at bedtime	See previous entries for each drug (niacin ER and simvastatin)

(Continued)

Table 12-9

Formulation, Dosing, and Common Adverse Effects of Lipid-Lowering Drugs (Continued)

Lipid-Lowering Drug	Dosage Forms	Usual Adult Maintenance Dose Range	Adverse Effects
Ezetimibe and simvastatin	10 mg/10 mg, 10 mg/20 mg, 10 mg/40 mg, 10 mg/80 mg	The dosage range is 10/10 mg/day through 10/40 mg/day. The recommended usual starting dose is 10/10 or 10/20 mg/day. Initiation of therapy with 10/10 mg/day may be considered for patients requiring less aggressive LDL cholesterol reductions. Due to the increased risk of myopathy, including rhabdomyolysis, use of the 10/80-mg dose of Vytorin should be restricted to patients who have been taking Vytorin 10/80 mg chronically (e.g., for 12 months or more) without evidence of muscle toxicity. Because of an increased risk for myopathy in Chinese patients taking simvastatin 40 mg coadministered with lipid-modifying doses (greater than or equal to 1 g/day niacin) of niacin-containing products, caution should be used when treating Chinese patients with Vytorin doses exceeding 10/20 mg/day coadministered with lipid-modifying doses (greater than or equal to 1 g/day niacin) of niacin-containing products. Because the risk for myopathy is dose-related, Chinese patients should not receive Vytorin 10/80 mg coadministered with lipid-modifying doses of niacin-containing products	See previous entries for each drug (ezetimibe and simvastatin)

CHD, coronary heart disease; ER, extended release; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; IR, immediate-release; LDL, low-density lipoprotein.

^aDose strengths vary depending on brand.

the upper limit of normal with creatinine elevation usually associated with **myoglobinuria** and brown urine, is very rare.²⁹ The concern of statin-associated myopathy has increased since the voluntary removal of cerivastatin from the world market in 2001 because the reported rate of fatal rhabdomyolysis was 16 to 80 times higher than the rate for any other statin, and many of these cases were reported in patients treated with concomitant gemfibrozil.³⁰ The American College of Cardiology/American Heart Association/National Heart, Lung and Blood Institute published a clinical advisory with a focus on myopathy.²⁹ Listed here are the risks associated with statin-induced myopathy published in this report:

- Small body frame and frailty
- Multisystem disease (e.g., chronic renal insufficiency, especially due to diabetes)
- Multiple medications (see below)
- Perioperative periods
- Specific concomitant medications or consumptions (check specific statin package insert for warnings): fibrates (especially gemfibrozil, but other fibrates too), nicotinic acid (rarely), cyclosporine, azole antifungals such as itraconazole and ketoconazole, macrolide antibiotics such as erythromycin and clarithromycin, protease inhibitors used to treat Acquired Immunodeficiency Syndrome (AIDS), nefazodone (antidepressant), verapamil, amiodarone, large quantities of grapefruit juice (usually more than 1 quart [about

950 mL] per day), and alcohol abuse (independently predisposes to myopathy).

- Baseline CK should be obtained in all patients prior to starting statin therapy. Follow-up CK should only be obtained in patients complaining of muscle pain, weakness, tenderness, or brown urine. Routine monitoring of CK is of little value in the absence of clinical signs or symptoms. Patient assessment for symptoms of myopathy should be done 6 to 12 weeks after starting therapy and at each visit. More frequent monitoring should be done in higher-risk individuals such as those just identified.

As mentioned earlier, statins inhibit production of other important by-products in the cholesterol biosynthesis pathway. Ubiquinone or coenzyme Q10 is an isoprenoid that plays a unique role in cellular electron transport and synthesizes energy. It is essential for the normal functioning of muscles. Statins have been shown to reduce blood levels of coenzyme Q10. The evidence of the value of supplementing coenzyme Q10 in patients experiencing statin-induced myopathy has been mainly anecdotal and is currently being evaluated in clinical trials.

Clinical trial data and several meta-analyses suggest that statins increase the risk of development of diabetes. The FDA recently added the warning of increased blood sugar and glycosylated hemoglobin (HbA1c) levels to the statin labels. The FDA continues to believe that the cardiovascular benefits of statins outweigh these small increased risks.

With the exception of pravastatin, which is mainly metabolized by isomerization in the gut to a relatively inactive

Patient Encounter 1, Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH: Hypertension for 9 years

FH: Father and mother both alive. Mother had MI at age 47.

SH: Works as a high school teacher and coaches the basketball team. He exercises regularly; drinks alcohol (2 to 3 beers) mainly on the weekends while watching sports on TV

Meds: Aspirin 325 mg once daily, clopidogrel 75 mg once daily, Verapamil SR 180 mg once daily

ROS: No chest pain, shortness of breath, or dizziness

PE:

VS: BP 142/86 mm Hg, pulse 71 beats per minute (bpm), respiratory rate 16 bpm, temperature 37°C (98.6°F), waist circumference 35 inches (89 cm)

CV: RRR, normal S₁, S₂; no murmurs, rubs, or gallops

Abd: Soft, nontender, nondistended; positive for bowel sounds, no hepatosplenomegaly or abdominal aortic aneurysm

Exts: Ankle-brachial index 1.1

Neck: No carotid and basilar bruits

EENT: Corneal arcus in both eyes

Labs: Total cholesterol 376 mg/dL (9.72 mmol/L), triglycerides 138 mg/dL (1.56 mmol/L), HDL cholesterol 42 mg/dL (1.09 mmol/L), LDL cholesterol 306 mg/dL (7.91 mmol/L), and glucose 98 mg/dL (5.4 mmol/L), all other labs within normal limits

Develop a care plan for RH.

metabolite, and pitavastatin, which primarily undergoes glucuronidation, the other statins undergo biotransformation by the cytochrome P-450 system. Therefore, drugs known to inhibit statin metabolism (e.g., cyclosporine A, erythromycin, gemfibrozil, protease inhibitors, ketoconazole, verapamil, rifampin, amiodarone) should be used cautiously or avoided. Medications such as cyclosporine A and gemfibrozil can inhibit drug transporters in the gut and liver, such as p-glycoprotein and organic anion-transporting polypeptide that can increase statin blood concentrations as well. The time until maximum effect on lipids for statins is generally 4 to 6 weeks.

► Cholesterol Absorption Inhibitors

Ezetimibe is the first drug in a new class of agents referred to as cholesterol absorption inhibitors. Ezetimibe blocks biliary and dietary cholesterol as well as phytosterol (plant sterol) absorption by interacting with the NPC1L1 transporter located in the brush border membrane of enterocytes (Fig. 12–2).⁵ Ezetimibe inhibits 54% of all intestinal cholesterol absorption on average. By reducing the cholesterol content within chylomicrons delivered to the liver, ezetimibe reduces liver cholesterol stores, inducing an upregulation of LDL receptors resulting in a decrease in serum cholesterol. As a result, ezetimibe also induces a compensatory increase in cholesterol biosynthesis. Because statins inhibit cholesterol biosynthesis, the compensatory increase in cholesterol biosynthesis by ezetimibe can be blocked by combining ezetimibe with a statin.

- Ezetimibe reduces LDL cholesterol by an average of 18% (Table 12–8). However, larger reductions can be seen in some individuals, presumably due to higher absorption of cholesterol. These individuals appear to have a blunted response to statin therapy. Ezetimibe lowers triglycerides by 7% to 9% and modestly increases HDL cholesterol.

Once absorbed, ezetimibe undergoes extensive glucuronidation in the intestinal wall to the active metabolite (ezetimibe glucuronide). Ezetimibe and the active metabolite are enterohepatically recirculated back to the site of action, which limits systemic exposure and may explain the low incidence of adverse effects (Table 12–9). Ezetimibe alone or with a statin is contraindicated in patients with active liver disease or unexplained persistent elevations in LFTs. Ezetimibe combined with simvastatin and simvastatin monotherapy were not associated with a reduction in **carotid intima-media thickness** in patients with heterozygous familial hypercholesterolemia.³¹ The patients studied in this trial were well managed (80% were receiving statins prior to enrollment) and had “near normal” measurements of carotid intima-media thickness at baseline, which may explain the study findings. However, ezetimibe combined with simvastatin was associated with a reduced incidence of ischemic cardiovascular events in low-risk patients with mild to moderate asymptomatic aortic stenosis compared with placebo,³² as well as reduced incidence of major atherosclerotic events in a wide range of patients with advanced chronic kidney disease.³³ Other clinical trials designed to determine ezetimibe's effects on CHD morbidity and mortality have not been completed. The time until maximum effect on lipids for ezetimibe is generally 2 weeks.

► Bile Acid Sequestrants

Cholestyramine, colestipol, and colesevelam are the bile acid-binding resins or sequestrants (BAS) currently available in the United States. Resins are highly charged molecules that bind to bile acids (which are produced from cholesterol) in the gut. The resin–bile acid complex is then excreted in the feces. The loss of bile causes a compensatory conversion of hepatic cholesterol to bile, reducing hepatocellular stores

of cholesterol and resulting in an upregulation of LDL receptors to replenish hepatocellular stores, which then result in a decrease in serum cholesterol. Resins have been shown to reduce CHD events in patients without CHD.³⁴

Resins are moderately effective in lowering LDL cholesterol but do not lower triglycerides (Table 12–8). Moreover, in patients with elevated triglycerides, the use of a resin may worsen the condition. This may be due to a compensatory increase in HMG-CoA reductase activity and results in an increase in assembly and secretion of VLDL. The increase in HMG-CoA reductase activity can be blocked with a statin, resulting in enhanced reductions in serum lipids (see section on combination therapy). Resins reduce LDL cholesterol from 15% to 30%, with a modest increase in HDL cholesterol (3% to 5%) (Table 12–8). Resins are most often used as adjuncts to statins in patients who require additional lowering of LDL cholesterol. Because these drugs are not absorbed, adverse effects are limited to the GI tract (Table 12–9). About 20% of patients taking cholestyramine or colestipol report constipation and symptoms such as flatulence and bloating. A large number of patients stop therapy because of this. Resins should be started at the lowest dose and escalated slowly over weeks to months as tolerated until the desired response is obtained. Patients should be instructed to prepare the powder formulations in 6 to 8 ounces (approximately 180 to 240 mL) of noncarbonated fluids, usually juice (enhances palatability) or water. Fluid intake should be increased to minimize constipation. Colesevelam is better tolerated with fewer GI side effects, although it is more expensive. All resins have the potential to prevent the absorption of other drugs such as digoxin, warfarin, thyroxine, thiazides, β -blockers, fat-soluble vitamins, and folic acid. Potential drug interactions can be avoided by taking a resin either 1 hour before or 4 hours after these other agents. Colesevelam appears less likely than the older agents to reduce drug absorption, but the manufacturer does recommend that colesevelam be dosed hours apart from other medications.³⁵ The time until maximum effect on lipids for resins is generally 2 to 4 weeks.

► Niacin

Niacin (vitamin B₃) has broad applications in the treatment of lipid disorders when used at higher doses than those used as a nutritional supplement. Niacin inhibits fatty acid release from adipose tissue and inhibits fatty acid and triglyceride production in liver cells. This results in an increased intracellular degradation of Apo B, and in turn, a reduction in the number of VLDL particles secreted (Fig. 12–4). The lower VLDL levels and the lower triglyceride content in these particles leads to an overall reduction in LDL cholesterol as well as a decrease in the number of small dense LDL particles. Niacin also reduces the uptake of HDL-Apo A1 particles and increases uptake of cholesterol esters by the liver, thus improving the efficiency of reverse cholesterol transport between HDL particles and vascular tissue (Fig. 12–4). Niacin is indicated for patients with elevated triglycerides, low HDL cholesterol, and elevated LDL cholesterol.³

Several different niacin formulations are available: niacin immediate-release (IR), niacin sustained-release (SR), and niacin extended-release (ER).^{36,37} These formulations differ in terms of dissolution and absorption rates, metabolism, efficacy, and side effects. Limitations of niacin IR and SR are flushing and **hepatotoxicity**, respectively. These differences appear related to the dissolution and absorption rates of niacin formulations and their subsequent metabolism. Niacin IR is available by prescription (Niacor) as well as a dietary supplement which is not regulated by the FDA.³⁶ Currently, there are no FDA-approved niacin SR products; thus all SR products are available only as dietary supplements.³⁸

Niacin IR is usually completely absorbed within 1 to 2 hours; thus it quickly saturates a high-affinity, low-capacity metabolic pathway, and most of the drug is metabolized by a second low-affinity, high-capacity system with metabolites associated with flushing.³⁸ Conversely, absorption of niacin SR may exceed 12 hours. Because niacin SR is absorbed over 12 or more hours, the high-affinity pathway metabolizes most of the drug, resulting in the production of metabolites associated with hepatotoxicity. Niacin ER was developed as a once-daily formulation to be taken at bedtime, with the goal of reducing the incidence of flushing without increasing the risk of hepatotoxicity. Niacin ER (Niaspan) is the only long-acting niacin product approved by the FDA for dyslipidemia. Niacin ER has an absorption rate of 8 to 12 hours, intermediate to niacin IR and SR, and therefore balances metabolism more evenly over the high-affinity, low-capacity pathway and the low-affinity, high-capacity pathway. Furthermore, taking niacin ER at bedtime can minimize the impact of flushing.

Niacin use is limited by cutaneous reactions such as flushing and pruritus of the face and body. The use of aspirin or a nonsteroidal anti-inflammatory drug (NSAID) 30 minutes prior to taking niacin can help alleviate these reactions because they are mediated by an increase in prostaglandin D₂.³ In addition, taking niacin with food and avoiding hot liquids or alcohol at the time niacin is taken is helpful in minimizing flushing and pruritus.

In general, niacin reduces LDL cholesterol from 5% to 25%, reduces triglycerides by 20% to 50%, and increases HDL cholesterol by 15% to 35% (Table 12–8). Niacin has been shown to reduce CHD events and total mortality,³⁹ as well as the progression of atherosclerosis when combined with a statin.⁴⁰ However, a recent trial that tested the effects of adding niacin ER to a statin (simvastatin) compared with statin alone in reducing long-term cardiovascular events in participants whose LDL cholesterol was controlled and who had a history of cardiovascular disease, low levels of HDL cholesterol, and high levels of triglycerides was stopped earlier than planned because no apparent benefits by adding niacin ER were found. Moreover, a small and unexplained increase in ischemic stroke in the niacin ER group was seen.⁴¹ Another larger trial with a similar study design is currently underway and will help to adjudicate niacin's role in combination drug therapy.⁴²

Niacin can raise uric acid levels, and in patients with diabetes can raise blood glucose levels. However, several

clinical trials have shown that niacin can be used safely and effectively in patients with diabetes.⁴³ Due to the high cardiovascular risk of patients with diabetes, the benefits of improving the lipid profile appear to outweigh any adjustment in diabetic medication(s) that is needed.⁴⁴

Niacin should be instituted at the lowest dose and gradually titrated to a maximum dose of 2 g daily for ER and SR products and no more than 6 g daily for IR products. FDA-approved niacin products are preferred because of product consistency. Moreover, niacin products labeled as “no flush” don’t contain nicotinic acid and therefore have no therapeutic role in the treatment of lipid disorders.³⁶ The time until maximum effect on lipids for niacins is generally 3 to 5 weeks.

► Fibrates

- The predominant effects of fibrates are a decrease in triglyceride levels by 20% to 50% and an increase in HDL cholesterol levels by 9% to 30% (Table 12–8). The effect on LDL cholesterol is less predictable. In patients with high triglycerides, however, LDL cholesterol may increase. Fibrates increase the size and reduce the density of LDL particles much like niacin. Fibrates are the most effective triglyceride-lowering drugs and are used primarily in patients with elevated triglycerides and low HDL cholesterol.

Fibrates work by reducing Apos B, C-III (an inhibitor of LPL), and E, and increasing Apos A-I and A-II through activation of peroxisome proliferator-activated receptor- α (PPAR- α), a nuclear receptor involved in cellular function. The changes in these Apos result in a reduction in triglyceride-rich lipoproteins (VLDL and IDL) and an increase in HDL.

Clinical trials of fibrate therapy in patients with elevated cholesterol and no history of CHD demonstrated a reduction in CHD incidence, although less than the reduction attained with statin therapy.⁴⁵ In addition, a large study of men with CHD, low HDL cholesterol, low LDL cholesterol, and elevated triglycerides demonstrated a 24% reduction in the risk of death from CHD, nonfatal MI, and stroke with gemfibrozil.⁴⁶ Fibrates may be appropriate in the prevention of CHD events for patients with established CHD, low HDL cholesterol, and triglycerides below 200 mg/dL (2.26 mmol/L). However, LDL-lowering therapy should be the primary target if LDL cholesterol is elevated. Evidence of a reduction in CHD risk among patients with established CHD has not been demonstrated with fenofibrate.

- The fibric acid derivatives are generally well tolerated. The most common adverse effects include dyspepsia, abdominal pain, diarrhea, flatulence, rash, muscle pain, and fatigue (Table 12–9). Myopathy and rhabdomyolysis can occur, and the risk appears to increase with renal insufficiency or concurrent statin therapy. If a fibrate is used with a statin, fenofibrate is preferred because it appears to inhibit the glucuronidation of the statin hydroxy and moiety less than gemfibrozil, allowing greater renal clearance of the statins.^{29,47} A CK level should be checked before therapy is started and if symptoms occur. Liver dysfunction has been reported, and LFTs should be monitored. Fibrates increase cholesterol in the bile and have caused gallbladder and bile

duct disorders, such as **cholelithiasis** and **cholecystitis**. Unlike niacin, these agents do not increase glucose or uric acid levels. Fibrates are contraindicated in patients with gallbladder disease, liver dysfunction, or severe kidney dysfunction. The risk of bleeding is increased in patients taking both a fibrate and warfarin. The time until maximum effect on lipids is generally 2 weeks for fenofibrate and 3 to 4 weeks for gemfibrozil.

► Omega-3 Fatty Acids

- Omega-3 fatty acids (eicosapentaenoic acid and docosahexaenoic acid), the predominant long-chain fatty acids in the oil of cold-water fish, lower triglycerides by as much as 45% when taken in large amounts (2 to 4 g). Omega-3 fatty acids may be useful for patients with high triglycerides despite diet and weight loss, alcohol restriction, and fibrate therapy. This effect may be modulated through PPAR- α and a reduction in Apo B-100 secretion. Omega-3 fatty acids reduce platelet aggregation and have antiarrhythmic properties, and therefore their use has been associated with a reduction in MI and sudden cardiac death, respectively.⁴⁸
- Prescription-grade omega-3 fatty acid ethyl esters are FDA approved at a dose of 4 g daily for the treatment of elevated triglycerides (greater than or equal to 500 mg/dL [greater than or equal to 5.65 mmol/L]). Use of high-quality ω -3 fatty acids free of contaminants such as mercury and organic pollutants should be encouraged when using these agents. Common side effects associated with ω -3 fatty acids are diarrhea and excess bleeding. Patients taking anticoagulant or antiplatelet agents should be monitored more closely when consuming these products because excessive amounts of ω -3 fatty acids (e.g., greater than 3 g daily) may lead to bleeding and may increase the risk of hemorrhagic stroke.

Combination Therapy

A large proportion of the U.S. population will not achieve their NCEP cholesterol targets for a variety of reasons.⁴⁹ These include inadequate patient adherence, adverse events, inadequate starting doses, lack of dose escalation, and lower treatment targets.^{3,50} Moreover, patients with concomitant elevations in triglycerides and/or low levels of HDL cholesterol may need combination drug therapy to normalize their lipid profile. **9** *Combination drug therapy is an effective means to achieve greater reductions in LDL cholesterol (statin plus ezetimibe or bile acid resin, bile acid resin plus ezetimibe, or three-drug combinations) as well as raising HDL cholesterol and lowering serum triglycerides (statin plus niacin or fibrate).*

► Combination Therapy for Elevated LDL Cholesterol

- For patients who do not achieve their LDL or non-HDL cholesterol goals with statin monotherapy and lifestyle modifications including those unable to tolerate high doses due to adverse effects, combination therapy may be appropriate. Resins or ezetimibe combine effectively with

statins to augment LDL cholesterol reduction. When added to a statin, ezetimibe can reduce LDL cholesterol levels by an additional 18% to 21% or up to 65% total reduction with maximum doses of the more potent statins. Ezetimibe and simvastatin are available as a combination tablet (Vytorin) and indicated as adjunctive therapy to diet for the reduction of elevated total cholesterol, LDL cholesterol, Apo B, triglycerides, and non-HDL cholesterol, and to increase HDL cholesterol. The usual starting dose is 10 mg/20 mg, and the maximum dose is 10 mg/40 mg (Table 12–9). Adverse events are similar to those of each product taken separately; however, the percentage of patients with LFT elevations greater than three times normal is slightly higher than with a statin alone, and there appears to be a slightly higher risk of myopathy and rhabdomyolysis when statins and ezetimibe are combined. The time until maximum effect on lipids for this combination is generally 2 to 6 weeks.

A statin combined with a resin results in similar reductions in LDL cholesterol as those seen with ezetimibe. However, the magnitude of triglyceride reduction is less with a resin compared with ezetimibe, and this should be considered in patients with higher baseline triglyceride levels. In addition, GI-adverse events and potential drug interactions limit the utility of this combination.

Ezetimibe and a resin can also be combined. A study that assessed the effects of adding ezetimibe to ongoing resin therapy showed an additional 19% reduction in LDL cholesterol and an additional 14% reduction in triglycerides. This combination was well tolerated.⁵¹

Some patients, in particular those with genetic forms of hypercholesterolemia such as FH (Table 12–2), require three or more drugs to manage their disorder. Regimens using a statin, resin, and niacin were found to reduce LDL cholesterol up to 75%.⁵² These early studies were conducted with lovastatin, so larger reductions would be expected with the more potent statins available today. It is recommended that patients with FH obtain a minimum of greater than or equal to 50% reduction in LDL cholesterol.¹⁶

► **Combination Therapy for Elevated Cholesterol and Triglyceridemia With or Without Low HDL Cholesterol**

Fibrates are the most effective triglyceride-lowering agents and also raise HDL cholesterol levels. Combination therapy with a fibrate, particularly gemfibrozil, and a statin has been found to increase the risk for myopathy. Of the 31 rhabdomyolysis deaths reported with cerivastatin use, 12 involved concomitant gemfibrozil.³⁰ Therefore, more frequent monitoring, thorough patient education, and consideration of factors that increase the risk as reviewed previously should be considered.

10 *The evidence of reducing LDL cholesterol while substantially raising HDL cholesterol (statin plus niacin or fibrate) to reduce the risk of CHD related events to a greater degree than statin monotherapy remains in question.* A recent trial randomized diabetes patients to simvastatin alone or simvastatin in combination with fenofibrate to determine if adding fenofibrate would further reduce CHD events. The

Patient Encounter 2

JR, a 58-year-old woman with a history of CHD, is obese (BMI: 32 kg/m²) and has been referred to you for a follow-up of her cholesterol. She is taking simvastatin 40 mg once daily in the evening for her cholesterol. Her blood glucose is 110 mg/dL (6.11 mmol/L). Her laboratory test results are within normal limits, except for her fasting lipid profile: total cholesterol 166 mg/dL (4.29 mmol/L), triglycerides 257 mg/dL (2.90 mmol/L), HDL cholesterol 46 mg/dL (1.19 mmol/L), LDL cholesterol 68 mg/dL (1.76 mmol/L), and non-HDL cholesterol 119 mg/dL (3.08 mmol/L).

What is your assessment of JR's cholesterol results?

What diagnostic parameters does JR have for metabolic syndrome?

Identify treatment goals for JR.

Assess JR's risk for statin-induced side effects.

Design a treatment plan for JR.

combination of fenofibrate and simvastatin did not reduce the overall rate of fatal cardiovascular events, nonfatal myocardial infarction, or nonfatal stroke, as compared with simvastatin alone. However in a prespecified subgroup analysis, incremental benefits of adding a fenofibrate to simvastatin therapy were noted in patients with triglycerides greater than or equal to 204 mg/dL (greater than or equal to 2.31 mmol/L) and HDL cholesterol less than or equal to 34 mg/dL (less than or equal to 0.88 mmol/L).⁵³ Combining niacin with a statin augments the LDL-cholesterol lowering potential of niacin while enhancing both the HDL cholesterol-raising effects and triglyceride-lowering effects of the statin. A statin combined with niacin appears to offer greater benefits for reducing atherosclerosis progression compared with a statin alone.³⁷ As mentioned earlier, however, the incremental benefits on reducing CHD events remains in question.⁴¹ Formulations combining ER niacin and lovastatin (Advicor) and ER niacin and simvastatin (Simcor) are available, and they are indicated for treatment of primary hypercholesterolemia and mixed dyslipidemia in patients treated with lovastatin or simvastatin who require further triglyceride lowering or HDL cholesterol raising and may benefit from having niacin added to their regimen. The combination is also indicated for patients treated with niacin who require further LDL-cholesterol lowering and may benefit from having lovastatin or simvastatin added to their regimen. The time until maximum effect on lipids for this combination is generally 3 to 6 weeks.

Niacin can be combined with a fibrate in patients with high elevations in serum triglycerides. The combination may increase the risk of myopathy compared with either agent alone.

Compared with monotherapy, combination therapy may reduce patient adherence through increased side effects and increased costs. When used appropriately and with proper precautions, however, they are effective in normalizing lipid

abnormalities, particularly in patients who cannot tolerate adequate doses of statin therapy for more severe forms of dyslipidemia.

► *Investigational Agents*

Numerous investigational drugs are in development for the treatment of lipid disorders and the prevention of atherosclerosis. Many of these will likely be used in combination with currently available lipid-modulating drugs. The most promising is an antisense drug that significantly reduced Apo B-100 and LDL cholesterol.⁵⁴ Other agents in development include newer statins; bile acid transport inhibitors; phytosterol analogs; acyl coenzyme A: cholesterol acyltransferase (ACAT) inhibitors; squalene

synthase inhibitors; CTEP inhibitors, proprotein convertase subtilisin/kexin type 9 (PCSK9), and newer PPAR- α , - γ , and - δ agonists, as well as dual PPAR- α/γ agonists.

These novel therapies will provide opportunities for developing different combination strategies to further reduce the risk of CHD even after adequate treatment with existing agents. Well-designed studies using noninvasive imaging technology and long-term follow-up periods are needed to ensure that there is a favorable risk-to-benefit ratio.

► *Outcome Evaluation*

- The successful outcome in cholesterol management is to reduce cholesterol and triglycerides below the NCEP ATP III goals in an effort to alter the natural course of atherosclerosis and decrease future cardiovascular events.

Patient Care and Monitoring

1. Assess the patient for the presence of CHD or other atherosclerosis disorders.
2. Assess major risk factors for CHD.
3. For patients without CHD or CHD risk equivalent, but two or more major CHD risk factors, perform the Framingham risk assessment.
4. Obtain fasting cholesterol profile and assess any abnormal lipid levels.
5. Obtain a thorough history of prescription, nonprescription, and natural drug product use. Determine what treatments for cholesterol the patient has used in the past (if any). Assess if the patient is taking any medications that may contribute to his or her abnormal lipid levels.
6. Assess concomitant diseases that may contribute to the patient's abnormal lipid levels.
7. Assess risk factors for metabolic syndrome.
8. Determine the treatment goal for LDL cholesterol based on the patient's CHD risk and non-HDL cholesterol goal if patient meets criteria for metabolic syndrome.
9. Educate all patients on therapeutic lifestyle changes (TLCs) and the importance of regular physical activity.
10. For patients exceeding their LDL cholesterol goal, initiate TLCs. Consider starting concurrent pharmacotherapy in patients in the high-risk or moderately high-risk categories. Pharmacotherapy should be initiated at a dose to reduce LDL cholesterol by 30% to 40% at a minimum. For patients with CHD who have an LDL cholesterol goal of less than 70 mg/dL, if it is not possible to attain this goal due to a high baseline LDL cholesterol, it is generally possible to achieve an LDL cholesterol reduction of greater than 50% with more intensive LDL-lowering therapy, including combination drug therapy.
11. For patients with familial hypercholesterolemia (FH), it is recommended that a greater than or equal to 50% reduction in LDL cholesterol be achieved.
12. Therapeutic lifestyle changes should be continued and intensified (consider adding plant sterols/stanols and increase fiber) after 6 weeks if not below LDL cholesterol target. For those patients above their LDL cholesterol target after adequate trial of TLC (12 to 18 weeks), pharmacotherapy should be strongly considered.
13. Institute appropriate pharmacotherapy based on lipid abnormality. Obtain appropriate baseline labs to monitor for adverse drug effects. Assess potential disease and drug interactions that may affect choice or intensity of pharmacotherapy.
14. Monitor response, safety, and adherence after a minimum of 4 to 6 weeks. Titrate therapy or add a second drug as needed.
15. Once the LDL cholesterol goal is achieved, assess non-HDL cholesterol in those with metabolic syndrome and intensify LDL-lowering therapy further or consider adding niacin or fibrate.
16. Provide patient education associated with CHD, hyperlipidemia, TLC, drug therapy, and therapy adherence.
17. Family screening is indicated if patient has FH.

- Use an adequate trial of TLC in all patients, but institute pharmacotherapy concurrently in higher-risk patients.
- When indicated, initiate drug therapy at a dose that will reduce LDL cholesterol in the range of 30% to 40%.
- Typically, statins are the medications of choice to treat high LDL cholesterol because of their ability to substantially reduce LDL cholesterol, ability to reduce morbidity and mortality from atherosclerotic disease, convenient once-daily dosing, and low risk of side effects.
- Use an individualized patient monitoring plan in an effort to minimize side effects, maintain treatment adherence, and achieve lipid goals.

Abbreviations Introduced in This Chapter

ABC	ATP-binding cassette
ABCA1	ATP-binding cassette A1
ABC G1	ATP-binding cassette G1
ABC G5/G8	ATP-binding cassette G5/G8
ACAT	Acyl coenzyme A: cholesterol acyltransferase
Acetyl CoA	Acetyl coenzyme A
AIDS	Acquired immunodeficiency syndrome
Apo	Apolipoprotein
ATP	Adenosine triphosphate
ATP III	Adult Treatment Panel III edition
BAS	Bile acid sequestrant
BP	Blood pressure
bpm	Beats per minute
C	Cholesterol
CAD	Clinical atherosclerotic disease
CE	Cholesterol ester
CETP	Cholesterol ester transfer protein
CHD	Coronary heart disease
CK	Creatine kinase
CM	Chylomicrons
CPK	Creatine phosphokinase
CRP	C-reactive protein
DBP	Diastolic blood pressure
ER	Extended-release
FA	Fatty acid
FH	Familial hypercholesterolemia
HbA1c	Glycosylated hemoglobin
HDL	High-density lipoprotein
HMG-CoA	3-hydroxy-3-methylglutaryl coenzyme A
HL	Hepatic lipase
IDL	Intermediate-density lipoprotein
IR	Immediate-release
LCAT	Lecithin-cholesterol acyltransferase
LDL	Low-density lipoprotein
LFT	Liver function test
LPL	Lipoprotein lipase
Lp-PLA2	Lipoprotein-associated phospholipase A2
LRP	LDL-related protein
MI	Myocardial infarction
MMP	Matrix metalloproteinase

NCEP	National Cholesterol Education Program
NO	Nitric oxide
NPC1L1	Niemann-Pick C1 Like 1
NSAID	Nonsteroidal anti-inflammatory drug
PPAR- α	Peroxisome proliferator-activated receptor- α
PCSK9	Proprotein convertase subtilisin/kexin 9
SBP	Systolic blood pressure
SR	Sustained-release
SR-BI	Scavenger receptors
TG	Triglyceride
TLC	Therapeutic lifestyle changes
VLDL	Very low-density lipoprotein

Hypovolemic Shock

Bradley A. Boucher and G. Christopher Wood

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. List the most common etiologies of decreased intravascular volume in hypovolemic shock patients.
2. Describe the major hemodynamic and metabolic abnormalities that occur in patients with hypovolemic shock.
3. Describe the clinical presentation including signs, symptoms, and laboratory test measurements for the typical hypovolemic shock patient.
4. Prepare a treatment plan with clearly defined outcome criteria for a hypovolemic shock patient that includes both fluid management and pharmacologic therapy.
5. Compare and contrast relative advantages and disadvantages of crystalloids, colloids, and blood products in the treatment of hypovolemic shock.
6. Formulate a stepwise monitoring strategy for a hypovolemic shock patient.

KEY CONCEPTS

- 1 Regardless of etiology, the most distinctive clinical manifestations of hypovolemic shock are arterial hypotension and metabolic acidosis. Metabolic acidosis is a consequence of an accumulation of lactic acid resulting from tissue hypoxia and anaerobic metabolism. If the decrease in arterial blood pressure (BP) is severe and protracted, such hypotension will inevitably lead to severe hypoperfusion and organ dysfunction.
- 2 Hypovolemic shock occurs as a consequence of inadequate intravascular volume to meet the oxygen and metabolic needs of the body.
- 3 Protracted tissue hypoxia sets in motion a downward spiral of events leading to organ dysfunction and eventual failure if untreated.
- 4 The overarching goals in treating hypovolemic shock are to restore effective circulating blood volume, as well as managing its underlying cause, thereby reversing organ dysfunction and returning to homeostasis.
- 5 Three major therapeutic options are available to clinicians for restoring circulating blood volume: crystalloids (electrolyte-based solutions), colloids (large molecular weight solutions), and blood products.
- 6 In the absence of ongoing blood loss, administration of 2,000 to 4,000 mL (approximately 4 to 8 pints) of

isotonic crystalloid normally reestablishes baseline vital signs in adult hypovolemic shock patients.

- 7 Colloid solutions administered are primarily confined to the intravascular space, in contrast to isotonic crystalloid solutions that distribute throughout the extracellular fluid space.
- 8 Blood products are indicated in adult hypovolemic shock patients who have sustained blood loss from hemorrhage exceeding 1,500 mL (approximately 3 pints).
- 9 Vasopressors may be warranted as a temporary measure in patients with profound hypotension or evidence of organ dysfunction in the early stages of shock.
- 10 Major treatment goals in hypovolemic shock following fluid resuscitation are as follows: arterial systolic blood pressure (SBP) greater than 90 mm Hg within 1 hour, organ dysfunction reversal, and normalization of laboratory measurements as rapidly as possible (less than 24 hours).

INTRODUCTION

The principal function of the circulatory system is to supply oxygen and vital metabolic compounds to cells throughout the body, as well as removal of metabolic waste products. **Circulatory shock** is a life-threatening condition whereby this principal function is compromised.¹ When circulatory

shock is caused by a severe loss of blood volume or body water, it is called **hypovolemic shock**, which is the focus of this chapter. **1** *Regardless of etiology, the most distinctive clinical manifestations of hypovolemic shock are arterial hypotension and metabolic acidosis. Metabolic acidosis is a consequence of an accumulation of lactic acid resulting from tissue hypoxia and anaerobic metabolism. If the decrease in arterial blood pressure (BP) is severe and protracted, such hypotension will inevitably lead to severe hypoperfusion and organ dysfunction. Rapid and effective restoration of circulatory homeostasis through the use of fluids, pharmacologic agents, and/or blood products is imperative to prevent complications of untreated shock and ultimately death.*

ETIOLOGY AND EPIDEMIOLOGY

Practitioners must have a good understanding of cardiovascular physiology to diagnose, treat, and monitor circulatory problems in critically ill patients. The interrelationships among the major hemodynamic variables are depicted in **Figure 13-1**.² These variables include arterial BP, cardiac output (CO), systemic vascular resistance (SVR), heart rate (HR), stroke volume (SV), left ventricular size, afterload,

myocardial contractility, and preload. Although an oversimplification, **Figure 13-1** is beneficial in conceptualizing where the major abnormalities occur in patients with circulatory shock as well as predicting the body's compensatory responses.

- Shock can be effectively categorized by etiology into four major types: hypovolemic, obstructive, cardiogenic, and distributive (**Table 13-1**).^{1,3,4} As noted, all patients with shock have profound decreases in arterial BP. Understanding the primary cause of the circulatory abnormality in these respective shock states is invaluable to their management.
- Hypovolemic shock is caused by a loss of intravascular volume either by hemorrhage or fluid loss (e.g., dehydration). Obstructive shock is caused by an obstruction that directly compromises inflow or outflow of blood from the heart. Cardiogenic shock is caused by diminished myocardial contractility that results in decreased CO with an increase in SVR. Lastly, distributive shock is caused by a major decrease in SVR with an increase in CO. Differentiating between the underlying abnormality and the associated compensatory response is also essential
- in terms of treatment and monitoring. Hypovolemic shock is considered to be essentially a profound deficit in preload, defined as the volume in the ventricles at the end of diastole.

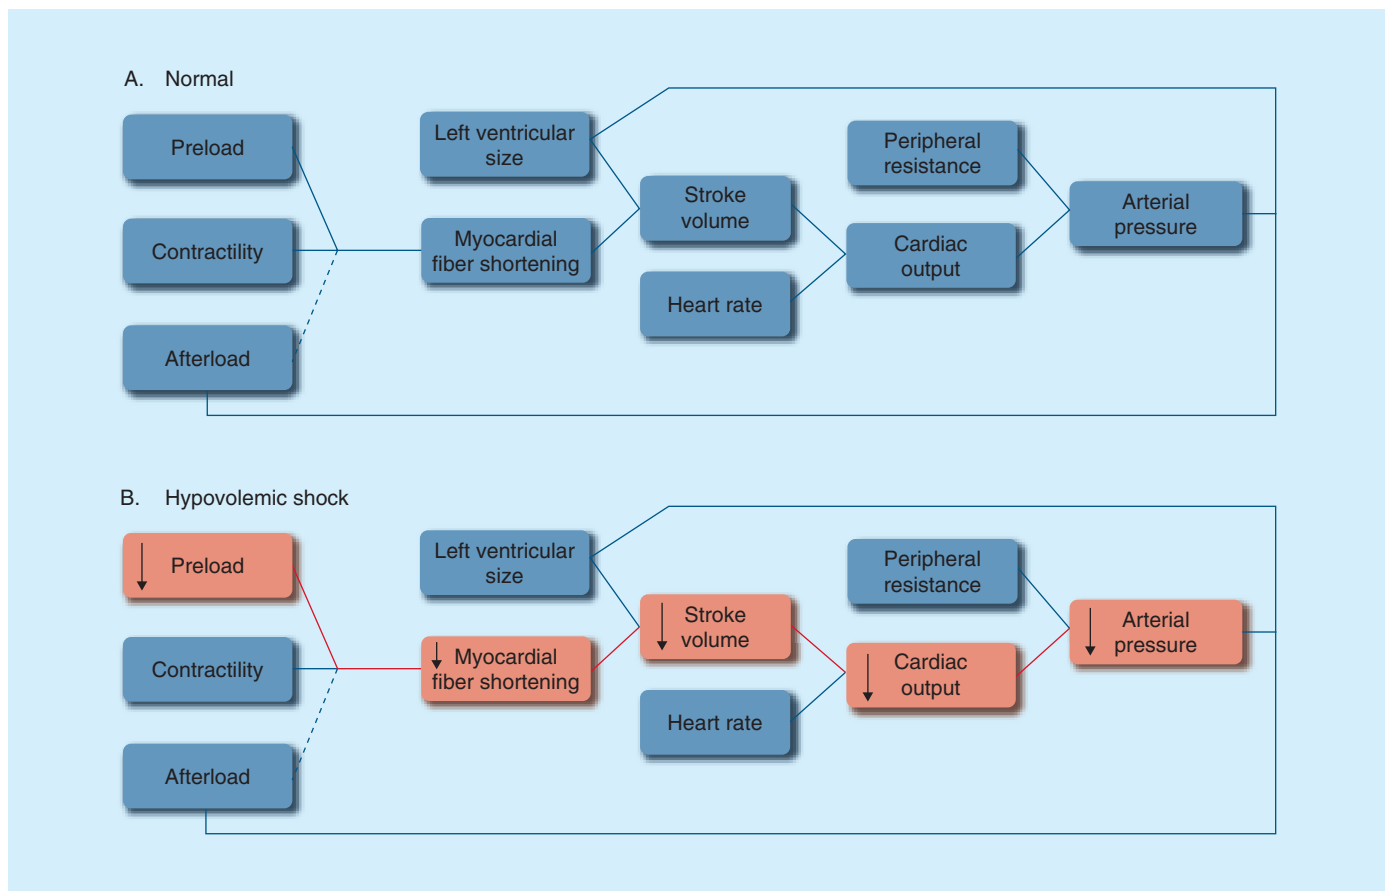

FIGURE 13-1. Hemodynamic relationships among key cardiovascular parameters (**A**). Solid lines represent a direct relationship; the broken line represents an inverse relationship. In **B**, the alterations typically observed in hypovolemic shock are highlighted with arrows depicting the likely direction of the alteration. (Panel A from Braunwald E. FIGURE 13-2. Distribution of body fluids showing the extracellular fluid volume, intracellular body fluid volume, and total body fluids in a 70-kg (154-lb) adult. Extracellular volume (ECV) comprises 14 L of total body fluid (42 L). Plasma volume makes up approximately 3 L of the 14 L of ECV. Intracellular volume accounts for the remaining 28 L of total body fluids with roughly 2 L located within the red blood cells. Blood volume (approximately 5 L) is also depicted and made up of primarily red blood cells and plasma. (From Guyton AC, Hall JE. Textbook of Medical Physiology, 8th ed. Philadelphia, PA: Saunders, 1991:275, with permission.)

Decreased preload results in subsequent decreases in SV, CO, and eventually, mean arterial pressure (MAP). As such, restoration of preload becomes an overriding goal in the management of hypovolemic shock.

The prognosis of shock patients depends on several variables including severity, duration, underlying etiology, preexisting organ dysfunction, and reversibility.⁵ Data are not readily available on the incidence of hypovolemic shock, although hypovolemia due to hemorrhage is a major factor in 40% to 50% of trauma deaths annually.⁶

PATHOPHYSIOLOGY

The total amount of water in a typical 70-kg (154-lb) adult is approximately 42 L (Fig. 13-2). About 28 of the 42 L are inside the cells of the body (intracellular fluid); the remaining 14 L are in the extracellular fluid space (fluid outside of cells, i.e., interstitial fluid and plasma). Circulating blood volume for a normal adult is roughly 5 L (70 mL/kg) and is composed of 2 L of red blood cell fluid (intracellular) and 3 L of plasma (extracellular). **2** By definition, hypovolemic shock occurs as a consequence of inadequate intravascular volume to meet the oxygen and metabolic needs of the body. Diminished intravascular volume can result from severe external or internal bleeding, profound fluid losses from GI sources such

as diarrhea or vomiting, or urinary losses such as diuretic use, diabetic ketoacidosis, or diabetes insipidus (Table 13-1).¹ Other sources of intravascular fluid loss can occur through damaged skin, as seen with burns, or via capillary leak into the interstitial space or peritoneal cavity, as seen with edema or ascites. This latter phenomenon is often referred to as third spacing because fluid accumulates in the interstitial space disproportionately to the intracellular and extracellular fluid spaces. Regional ischemia may also develop as blood flow is naturally shunted from organs such as the GI tract or the kidneys to more immediately vital organs such as the heart and brain.

Hypovolemic shock symptoms begin to occur with decreases in intravascular volume in excess of 750 to 1500 mL or 15% to 30% of the circulating blood volume (20 to 40 mL/kg in pediatric patients).⁷ As previously stated, decreases in preload or ventricular end-diastolic volumes result in decreases in SV. Initially, CO may be partially maintained by compensatory tachycardia. Similarly, reflex increases in SVR and myocardial contractility may diminish arterial hypotension. Regardless, rapid losses (e.g., minutes) undoubtedly have more profound effects than losses over a longer period (e.g., hours). This neurohumoral response to hypovolemia is mediated by the sympathetic nervous system in an attempt to preserve perfusion to vital organs such as the heart and brain. Two major end points of this response are to conserve

water to maximize intravascular volume and to improve tissue perfusion by increasing BP and CO (oxygen delivery). The body attempts to maximize its fluid status by decreasing water and sodium excretion through release of antidiuretic hormone (ADH), aldosterone, and cortisol. BP is maintained by peripheral vasoconstriction mediated by catecholamine release and the renin-angiotensin system.¹ CO is augmented by catecholamine release and fluid retention.^{1,4} Unfortunately, the increased sympathetic drive may become detrimental as tissue ischemia occurs with inconsistent microcirculatory flow.¹ Regardless, when intravascular volume losses exceed 1,500 mL (about 3 pints), the compensatory mechanisms are inadequate, typically resulting in a fall in CO and arterial BP; acute losses greater than 2,000 mL (about 4 pints) are life threatening (35 mL/kg in pediatric patients).⁸ The decrease in CO results in a diminished delivery of oxygen to tissues within the body and activation of an acute inflammatory response.^{1,6} Oxygen delivery can be further compromised by inadequate blood hemoglobin levels due to hemorrhage and/or diminished hemoglobin saturation due to impaired ventilation. Decreased delivery of oxygen and other vital nutrients results in diminished production of the energy substrate, adenosine triphosphate (ATP). Lactic acid is then produced as a by-product of anaerobic metabolism within tissues throughout the body.⁴ Hyperglycemia produced during the stress response from cortisol release is also a contributing factor in the development of lactic acidosis. Lactic acidosis indicates that inadequate tissue perfusion has occurred.⁴ **3** *Protracted tissue hypoxia sets in motion a downward spiral of events leading to organ dysfunction and eventual failure if untreated.* **Table 13–2** describes the effects of shock on the body's major organs. Relative failure of

more than one organ, regardless of etiology, is referred to as the multiple organ dysfunction syndrome (MODS). Involvement of the heart is particularly devastating considering the central role it plays in oxygen delivery and the potential for myocardial dysfunction to perpetuate the shock state. Preexisting

Clinical Presentation and Diagnosis of Hypovolemic Shock**General**

Patients will be in acute distress, although symptoms and signs will vary depending on the severity of the hypovolemia and whether the etiology is hemorrhagic versus nonhemorrhagic.

Symptoms

- Thirst
- Weakness
- Lightheadedness

Signs

- Hypotension, arterial systolic BP (SBP) less than 90 mm Hg or fall in SBP greater than 40 mm Hg
- Tachycardia
- Tachypnea
- Hypothermia
- **Oliguria**

- Dark, yellow-colored urine
- Skin color: pale to ashen; may be cyanotic in severe cases
- Skin temperature: cool to cold
- Mental status: confusion to coma
- **Pulmonary artery (PA) catheter** measurements: decreased CO, decreased SV, increased SVR, low **pulmonary artery occlusion pressure** (PAOP)

Laboratory Tests

- Hyponatremia
- Elevated serum creatinine (SCr)
- Elevated blood urea nitrogen
- Decreased hemoglobin/hematocrit (hemorrhagic hypovolemic shock)
- Hyperglycemia
- Increased serum lactate
- Decreased arterial pH

organ dysfunction and buildup of inflammatory mediators can also exacerbate the effects of hypovolemic shock to the point of irreversibility.⁶ For example, acute or chronic heart failure can lead to pulmonary edema, further aggravating gas exchange in the lungs and ultimately tissue hypoxia. Another example is multiple organ dysfunction, which is frequently observed in trauma patients. Specifically, MODS develops in approximately 20% of trauma patients who require fluid resuscitation. Only about one-third of early-onset MODS is quickly reversible (within 48 hours) with proper fluid resuscitation. Thus it is imperative that hypovolemic shock be treated quickly to avoid MODS.⁹

TREATMENT

Desired Outcomes

4 The overarching goals in treating hypovolemic shock are to restore effective circulating blood volume, as well as manage its underlying cause. In achieving this goal, the downward spiral of events that can perpetuate severe or protracted hypovolemic shock is interrupted. This is accomplished through the delivery of adequate oxygen and metabolic substrates such as glucose and electrolytes to the tissues throughout the body that will optimally bring about a restoration of organ function and return to homeostasis. Evidence of the latter is a return to the patient's baseline vital signs, relative normalization of laboratory test results, and alleviation of the other signs and symptoms of hypovolemic shock previously discussed. Concurrent supportive therapies are also warranted to avoid exacerbation of organ dysfunction associated with the hypovolemic shock event.

General Approach to Therapy

Securing an adequate airway and ventilation is imperative in hypovolemic shock patients consistent with the airway, breathing, and circulation (ABCs) of life support. Any compromise in ventilation only accentuates the tissue hypoxia occurring secondary to inadequate perfusion. Thus early sedation with tracheal intubation and mechanical ventilation typically occurs at this stage of resuscitation (Fig. 13-3). IV access is also essential for administration of fluids and medications, and it can be accomplished through the placement of peripheral IV lines or catheterization with central venous lines if rapid or large volumes of resuscitative fluids are indicated. Although primarily facilitating fluid administration, the IV lines provide access for blood samples for obtaining appropriate laboratory tests. Placement of an arterial catheter is advantageous to allow for accurate and continual monitoring of BP, as well as arterial blood gas (ABG) sampling. A bladder catheter should be inserted for ongoing monitoring of urine output. Baseline laboratory tests that should be done immediately include complete blood cell count with differential, serum chemistry profile, liver enzymes, prothrombin and partial thromboplastin times, and serum lactate. A urinalysis and an ABG should also be obtained, and ongoing electrocardiogram (ECG) monitoring should be performed.

In addition to restoring circulating blood volume, it is necessary to prevent further losses from the vascular space. This is especially true with hemorrhagic hypovolemic shock where identifying the bleeding site and achievement of hemostasis are critical in the successful resuscitation of the patient. This frequently involves surgical treatment of hemorrhages.

Upon stabilization, placement of a pulmonary artery (PA) catheter may be indicated based on the need for more extensive cardiovascular monitoring than is available from non-invasive measurements such as vital signs, cardiac rhythm, and urine output.^{10,11} Key measured parameters that can be obtained from a PA catheter are the pulmonary artery occlusion pressure (PAOP), which is a measure of left ventricular preload, and CO. From the CO values and simultaneous measurement of HR and BP, one can calculate the left ventricular SV and SVR.¹¹ Placement of a PA catheter should be reserved for patients at high risk of death due to the severity of shock or preexisting medical conditions such as heart failure.¹² Use of PA catheters in broad populations of critically ill patients is somewhat controversial because clinical trials have not shown consistent benefits with their use and may even be detrimental.^{1,13} However, critically ill patients with a high severity of illness may have improved outcomes from PA catheter placement. It is not clear why this was seen, but it could be that more severely ill patients have less physiological reserve and less “room for error” and benefit from the therapeutic decisions that come from detailed PA catheter data.¹⁴ An alternative to the PA catheter is placement of a central venous catheter that typically resides in the superior vena cava to monitor central venous pressure (CVP). Although central venous catheters are less expensive and more readily placed, they are not particularly accurate in monitoring effective fluid resuscitation.¹¹

Patient Encounter Part 1

RW is a 45-year-old man admitted to the emergency department (ED) with nausea and vomiting for the past 12 hours. The patient's wife was concerned because the emesis contained large amounts of bright red blood. The patient cannot reliably communicate with the healthcare team because he is confused. The initial diagnosis by the ED team is hypovolemic shock. A physical examination is being performed and blood samples are being sent to the laboratory.

What type of hypovolemic shock does RW have and what is the cause?

What signs and symptoms would you expect to see in this patient with hypovolemic shock?

What laboratory abnormalities might be expected in this patient?

Describe the first nonpharmacologic steps in treating RW.

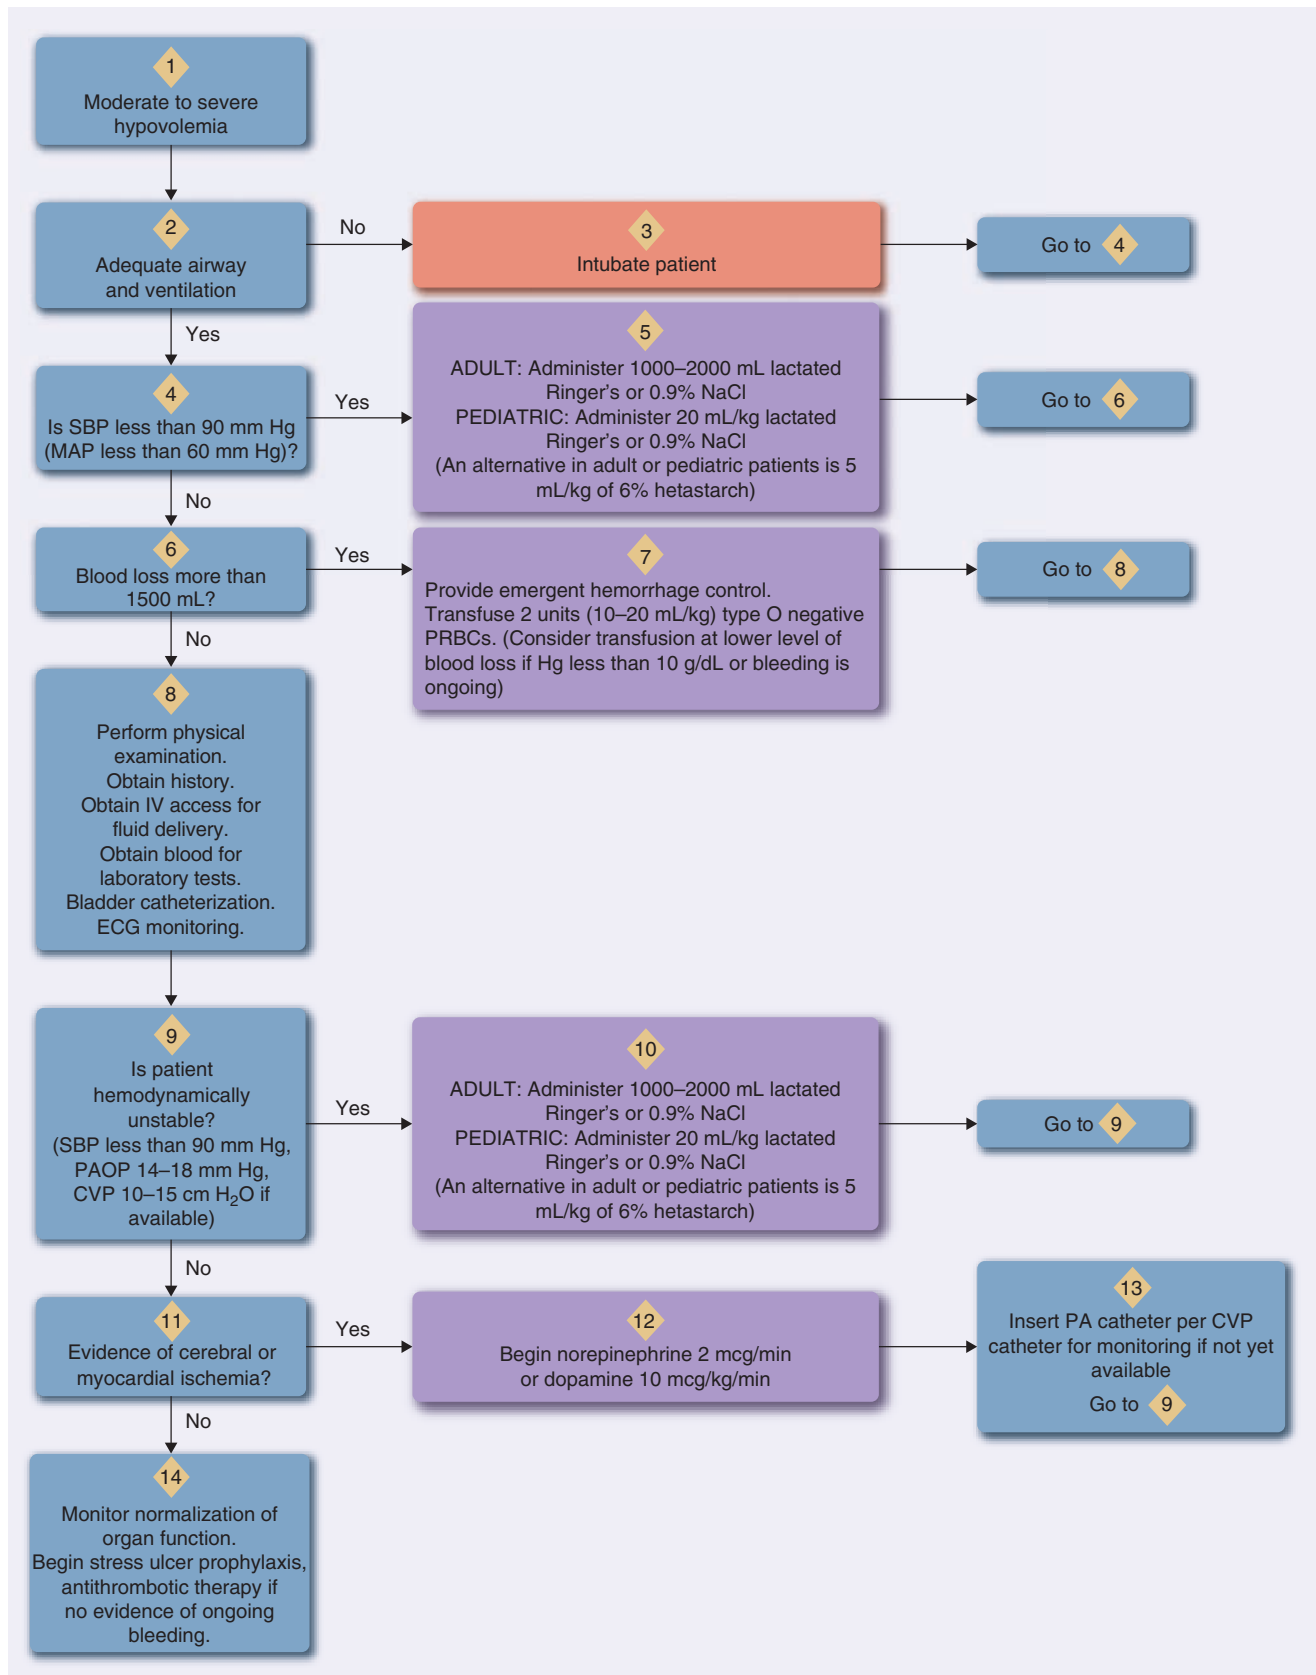

FIGURE 13-3. Treatment algorithm for the management of moderate to severe hypovolemia. (CVP, central venous pressure; ECG, electrocardiogram; MAP, mean arterial pressure; NaCl, sodium chloride or normal saline; PA, pulmonary artery; PAOP, pulmonary artery occlusion pressure; PRBCs, packed red blood cells; SBP, systolic blood pressure.) Hemoglobin concentration of 10 g/dL is equivalent to 100 g/L or 6.2 mmol/L.

► Fluid Therapy

The use of fluids is the cornerstone of managing all forms of shock including hypovolemic shock.¹ **5** *Three major therapeutic options are available to clinicians for restoring circulating blood volume: **crystalloids** (electrolyte-based solutions), **colloids** (large molecular weight solutions), and **blood products**.* Blood products are used only in instances involving hemorrhage (or severe preexisting anemia), thus leaving crystalloids and colloids as the mainstay of therapy in all types of hypovolemic shock, along with adjunctive **vasopressor** support. The aggressiveness of fluid resuscitation (rate and volume) is dictated by the severity of the hypovolemic shock and the underlying cause. Warming of all fluids to 37°C (98.6°F) prior to administration is an important consideration to prevent hypothermia, arrhythmias, and coagulopathy because they will have a negative impact on the success of the resuscitation effort.¹⁵

Crystalloids Conventional “balanced” crystalloids are fluids with (a) electrolyte composition that approximates plasma, such as lactated Ringer’s (LR), or (b) a total calculated osmolality similar to that of plasma (280 to 295 mOsm/kg

or mmol/kg), such as 0.9% sodium chloride (also known as normal saline [NS] or 0.9% NaCl) (Table 13–3).¹⁶ Thus conventional crystalloids distribute in normal proportions throughout the extracellular fluid space upon administration. In other words, expansion of the intravascular space only increases by roughly 200 to 250 mL for every liter of isotonic crystalloid fluid administered.⁶ Hypertonic crystalloid solutions such as 3% NaCl or 7.5% NaCl have osmolalities substantially higher than plasma. The effect observed with these fluids is a relatively larger volume expansion of the intravascular space. By comparison with conventional crystalloids, administration of 250 mL of 7.5% sodium chloride results in an intravascular space increase of 500 mL.⁶ This increase is a result of the fluid administered as well as osmotic drawing of intracellular fluid into the intravascular and interstitial spaces. This occurs because the hypertonic saline increases the osmolality of the intravascular and interstitial fluid compared with the intracellular fluid. Hypertonic saline also has the potential for decreasing the inflammatory response.¹ Despite these theoretical advantages, data are lacking demonstrating superiority of hypertonic crystalloid solutions compared with isotonic solutions.^{17,18}

Pentastarch	154	154					Pentastarch 10 g/dL (100 g/L)	5.0	326
5% Albumin	130–160	130–160					Albumin 5 g/dL (50 g/L)	6.9	
25% Albumin	130–160	130–160					Albumin 25 g/dL (250 g/L)	6.9	
5% PPF	130–160	130–160	0.25				Plasma proteins 5 g/dL (50 g/L) (88% albumin)	7.0	
Dextran 40	154	154					Dextran 10 g/dL (100 g/L) (avg. molecular weight 40 kDa)		
Dextran 70	154	154					Dextran 6 g/dL (60 g/L) (avg. molecular weight 70 kDa)	5.5	308
Dextran 75	154	154					Dextran 6 g/dL (60 g/L) (avg. molecular weight 75 kDa)	5.5	308

avg., average; Ca, calcium; Cl, chloride; K, potassium; kDa, kilodalton; Mg, magnesium; Na, sodium; NaCl, sodium chloride or normal saline; PPF, plasma protein fraction.

^aFor these values, mEq/L = mmol/L (e.g., 154 mEq/L Na = 154 mmol/L).

^bFor these values, mEq/L × 0.5 = mmol/L (e.g., 0.9 mEq/L Mg = 0.45 mmol/L Mg).

^cFor this value, mOsm/kg = mmol/kg (e.g., 308 mOsm/kg = 308 mmol/kg).

Crystalloids are generally advocated as the initial resuscitation fluid in hypovolemic shock because of their availability, low cost, and equivalent outcomes compared with colloids.¹⁰ A reasonable initial volume of an isotonic crystalloid (0.9% NaCl or LR) in adult patients is 1,000 to 2,000 mL (about 2 to 4 pints) administered over the first hour of therapy.⁷ Ongoing external or internal bleeding requires more aggressive fluid resuscitation. **6** *In the absence of ongoing blood loss, administration of 2,000 to 4,000 mL (about 4 to 8 pints) of isotonic crystalloid normally reestablishes baseline vital signs in adult hypovolemic shock patients.*¹⁹ Selected populations, such as burn patients, may require more aggressive fluid resuscitation, while other patient subsets such as those with cardiogenic shock or heart failure may warrant less aggressive fluid administration to avoid overresuscitation.²⁰ In hemorrhagic shock patients, approximately three to four times the shed blood volume of isotonic crystalloids is needed for effective resuscitation.²⁰

Side effects from crystalloids primarily involve fluid overload and electrolyte disturbances of sodium, potassium, and chloride.¹ Dilution of coagulation factors can also occur resulting in a dilutional coagulopathy.⁶ Two clinically significant differences between LR and NS is that LR contains potassium and has a lower sodium content (130 vs. 154 mEq/L or mmol/L). Thus LR has a greater potential than NS to cause hyponatremia and/or hyperkalemia. Alternatively, NS can cause hypernatremia, hyperchloremia, metabolic acidosis, and hypokalemia. Based on the more physiological composition and buffering capacity of LR, and their respective side-effect profiles, LR is deemed in theory to be the superior resuscitative fluid compared with NS by some authorities.²¹ However, improvements in outcome have not been documented.²²

Colloids Understanding the effects of colloid administration on circulating blood volume necessitates a review of those physiological forces that determine fluid movement between capillaries and the interstitial space throughout the circulation (Fig. 13-4).^{6,23} Relative hydrostatic pressure between the capillary lumen and the interstitial space is one of the major determinants of net fluid flow into or out of the circulation. The other major determinant is the relative colloid osmotic pressure between the two spaces. Administration of exogenous colloids results in an increase in the intravascular colloid osmotic pressure. The effects of colloids on intravascular volume are a consequence of their relatively large molecular size (greater than 30 kDa), limiting their passage across the capillary membrane in large amounts. Alternatively stated, colloids can be thought of as “sponges” drawing fluid into the intravascular space from the interstitial space. In the case of isosmotic colloids (5% albumin, 6% hetastarch, and dextran products), initial expansion of the intravascular space is essentially 65% to 75% of the volume of colloid administered, accounting for some “leakage” of the colloid from the intravascular space.⁶ **7** *Thus, in contrast to isotonic crystalloid solutions that distribute throughout the extracellular fluid space, the volume of iso-oncotic colloids administered remains relatively confined to the intravascular space.*

FIGURE 13-4. Operative forces at the capillary membrane tend to move fluid either outward or inward through the capillary membrane. In hypovolemic shock, one therapeutic strategy is the administration of colloids that can sustain and/or draw fluid from the interstitial space by increasing the plasma colloid osmotic pressure. (From Guyton AC, Hall JE. Textbook of Medical Physiology, 8th ed. Philadelphia, PA: Saunders, 1991:174, with permission.)

In the case of hyperoncotic solutions such as 25% albumin, fluid is pulled from the interstitial space into the vasculature, resulting in an increase in the intravascular volume that is much greater than the original volume of the 25% albumin that was administered. Although theoretically attractive, hyperoncotic solutions should not be used for hypovolemic shock because the expansion of the intravascular space is at the expense of depletion of the interstitial space. Exogenous colloids available in the United States include 5% albumin, 25% albumin, 5% plasma protein fraction (PPF), 6% hetastarch, 10% pentastarch, 10% dextran 40, 6% dextran 70, and 6% dextran 75 (Table 13-3). The first three products are derived from pooled human plasma. Hetastarch and pentastarch are semisynthetic hydroxyethyl starches derived from amylopectin. The dextran products are semisynthetic glucose polymers that vary in terms of the average molecular weight of the polymers. Superiority of one colloid solution over another has not been clearly established.²⁴

For years within the critical care literature, a controversy known as the “colloid versus crystalloid debate” raged over the relative merits of the two types (colloid and crystalloid) of resuscitation fluids. At the center of the debate was what the goal of fluid resuscitation in shock should be: immediate expansion of the intravascular space with colloids versus expansion of the entire extracellular fluid space with crystalloids. A randomized controlled study involving 6,997 critically ill patients (Saline versus Albumin Fluid Evaluation [SAFE] study) demonstrated no difference in mortality between patients receiving saline versus albumin.²⁵ Largely in response to the SAFE trial, the FDA issued a notice to healthcare providers in May 2005 declaring albumin safe for use in most critically ill patients.²⁶ Burn, traumatic brain injury, and septic shock patients were excluded from the SAFE trial; however, based on previous data, there does not appear to be a clear-cut overall advantage for either crystalloids or colloids in these patient groups.²⁶ Thus, although the debate is not fully resolved, most clinicians today prefer

using crystalloids based on their availability and inexpensive cost compared with colloids.^{20,27}

Generally, the major adverse effects associated with colloids are fluid overload, dilutional coagulopathy, and anaphylactoid/anaphylactic reactions.²⁸ Although derived from pooled human plasma, there is no risk of disease transmission from commercially available albumin or PPF products because they are heated and sterilized by ultrafiltration prior to distribution. Because of direct effects on the coagulation system with the hydroxyethyl starch and dextran products, they should be used cautiously in hemorrhagic shock patients. This is another reason why crystalloids may be preferred in hemorrhagic shock. Furthermore, hetastarch can result in an increase in amylase not associated with pancreatitis. As such, the adverse-effect profiles of the various fluid types should also be considered when selecting a resuscitation fluid.

Blood Products **8** *Blood products are indicated in hypovolemic shock patients who have sustained blood losses from hemorrhage exceeding 1,500 mL. This, in fact, is the only setting in which freshly procured whole blood is administered. In virtually all other settings, blood products are given as the individual components of whole blood units, such as packed red blood cells (PRBCs), fresh-frozen plasma (FFP), platelets, cryoprecipitate, and concentrated coagulation factors.²⁹ This includes ongoing resuscitation of hemorrhagic shock when PRBCs can be transfused to increase oxygen-carrying capacity in concert with crystalloid solutions to increase blood volume. In patients with documented coagulopathies, FFP for global replacement of lost or diluted clotting factors, or platelets for patients with severe thrombocytopenia (less than 20 to $50 \times 10^3/\text{mm}^3$ or 20 to $50 \times 10^9/\text{L}$) should be administered.^{30,31} Data suggests that increasing the ratio of FFP to PRBC units may be associated with improved mortality and a reduction in the number of PRBC transfusions in patients requiring multiple transfusions.^{32,33} Type O negative blood or “universal donor blood” is given in emergent cases of hemorrhagic shock. Thereafter, blood that has been typed and cross-matched with the recipient’s blood is given. The traditional threshold for PRBC transfusion in hypovolemic shock has been a serum hemoglobin of less than 10 g/dL (100 g/L or 6.2 mmol/L) and hematocrit less than 30% (0.30). However, for critically ill patients who have received appropriate fluid resuscitation and have no signs of ongoing bleeding, a*

more restrictive transfusion threshold of 7 g/dL (70 g/L or 4.34 mmol/L) appears to be safe.³⁴ Traditional risks from allogeneic blood product administration include hemolytic and nonhemolytic transfusion reactions and transmission of blood-borne infections in contaminated blood. However, recent large studies have also shown that transfusions are associated with higher mortality, possibly because of adverse immune and inflammatory effects.²⁹ Increased thromboembolic events and mortality have also been documented for patients receiving PRBCs stored longer than 28 days.³⁵ Thus administration of blood products should be restricted whenever possible and used as early as possible following donation. Due to blood shortages and associated risks with transfusions, there are ongoing research efforts concerning the development of red blood cell substitutes as a possible therapy alternative. Products that have reached clinical trials include perfluorocarbon emulsions and hemoglobin-based oxygen carriers (HBOCs).³⁶ These blood products have several advantages over PRBCs including greater availability (because donors are not needed), increased shelf life, absence of infectious risks, and no need for cross-matching. As such, red blood cell substitutes have the potential to serve as temporizing measures in hypovolemic shock patients until conventional red blood cell transfusions can be administered or in instances in which availability of donated PRBCs is extremely limited. Nonetheless, lack of adequate efficacy data and additional side effects associated with each of the respective red blood cell substitutes have precluded their approval in the United States at present.³⁶

► Pharmacologic Therapy

Vasopressor Therapy *Vasopressor is the term used to describe any pharmacologic agent that can induce arterial vasoconstriction through stimulation of the α_1 -adrenergic receptors. **9** Although replenishment of intravascular volume is undoubtedly the cornerstone of hypovolemic shock therapy, use of vasopressors may be warranted as a temporary measure in patients with profound hypotension or evidence of organ dysfunction in the early stages of shock.^{3,10} Vasopressors are typically used concurrently with fluid administration after the latter has not resulted in adequate restoration of blood pressure and/or tissue perfusion.³⁷ Table 13–4 lists those vasopressors used in the management of hypovolemic shock. Although vasopressor therapy may improve the hemodynamic*

Table 13–4

Vasopressor Drugs¹

Drug	Usual IV Dose	Adrenergic Effects			Potential to Cause Arrhythmias
		α	β_1	Dopaminergic	
Dopamine	10–30 mcg/kg/min ^a	+++	++	+++	+++
Norepinephrine	0.5–80 mcg/min	+++	++	0	++
Epinephrine	1–200 mcg/min	+	+++	0	+++
Phenylephrine	0.5–9 mcg/kg/min	+++	0	0	0

^aLower dosages of dopamine may not produce desired α_1 -adrenergic (vasopressor) effects.

profile in shock patients, data are lacking that they improve mortality.³⁸ Furthermore, a recent study found that early use of vasopressors (i.e., phenylephrine, norepinephrine, dopamine, vasopressin) in the resuscitation of patients with hemorrhagic shock may actually be associated with increased mortality.³⁹ Regardless, data suggest that if vasopressors are used, norepinephrine may be preferable to dopamine secondary to increased incidence of arrhythmias associated with the latter agent in the treatment of shock patients.^{40,41} Thus norepinephrine should be considered the first-line vasopressor therapy for these patients.³⁷ Epinephrine should be considered as a second-line vasopressor in patients with shock because of its association with tachyarrhythmias, impaired abdominal organ (splanchnic) circulation, and hypoglycemia.³⁷ Arginine vasopressin, although not a vasopressor per se, may be beneficial as an adjunctive therapy alone with vasopressors in refractory hemorrhage shock based on beneficial effects in other shock states.^{37,42,43} In cases involving concurrent heart failure, an inotropic agent such as dobutamine may be needed, in addition to the use of a vasopressor.

Vasopressors are almost exclusively administered as continuous infusions because of their very short duration of action and the need for close titration of their dose-related effects. Starting doses should be at the lower end of the dosing range followed by rapid titration upward if needed to maintain adequate BP. Monitoring of end-organ function such as adequate urine output should also be used to monitor therapy. Once BP is restored, vasopressors should be weaned and discontinued as soon as possible to avoid any untoward events. The most significant systemic adverse events associated with vasopressors are excessive vasoconstriction resulting in decreased organ perfusion and potential to induce arrhythmias (Table 13–4). Central venous catheters should be used to minimize the risk of local tissue necrosis that can occur with extravasation of peripheral IV catheters.

Hemostatic Agents

The off-label use of the procoagulant **recombinant activated factor VII** (rFVIIa) as an adjunctive agent to treat uncontrolled hemorrhage has gained popularity in recent years. However, a phase 3 randomized study of rFVIIa versus placebo in trauma patients with refractory hemorrhage demonstrated no differences in mortality despite a reduction in PRBC transfusions.⁴⁴ Furthermore, the off-label use of rFVIIa has been criticized based on an increased risk of arterial thromboembolic events in patients, especially patients older than 65 years.^{45,46} The optimal dose of rFVIIa in nonhemophilic patients is also unknown. In light of the uncertain efficacy, safety concerns, and its high acquisition costs, the use of rFVIIa cannot be advocated for patients with refractory hemorrhage. A promising alternative to rFVIIa in patients with hemorrhagic shock is tranexamic acid, an antifibrinolytic. A recent study of tranexamic acid in trauma patients with or at risk of significant bleeding demonstrated a decrease in mortality compared with placebo.⁴⁷ As such, the use of antifibrinolytics such as tranexamic acid or ϵ -aminocaproic acid

Patient Encounter Part 2

PMH: “Stomach ulcers” and “reflux” per the wife

Meds: Omeprazole 40 mg PO daily, enteric-coated aspirin 81 mg PO daily

SH: “A six-pack of beer” every day per the wife

FH: Noncontributory

PE: Ht 5’9” (175 cm), Wt 90 kg (198 lb)

VS: 80/40 mm Hg, P 130, RR 22, T 35.0°C (95.0°F), urine output: none since catheterization 10 minutes ago

Neuro: Confused upon entering the ED. Now with recent loss of consciousness

Cardiovascular: Heart sounds and ECG normal except for tachycardia

Pulmonary: Normal breath sounds but undergoing tracheal intubation for mechanical ventilation

Abd: WNL

Extremities: Noncontributory

Pertinent labs: pH 7.20, PaCO₂ 50 mm Hg (6.65 kPa), PaO₂ 70 mm Hg (9.31 kPa), Na 153 mEq/L (153 mmol/L), HCO₃⁻ 18 mEq/L (18 mmol/L), lactate 7.0 mg/dL (0.78 mmol/L), SCr 1.7 mg/dL (150 μ mol/L), Hct 28% (0.28)

Describe treatment goals for RW in the next hour.

Describe treatment goals for RW in the next 24 hours.

Develop a pharmacologic and fluid therapy plan for initial therapy. Defend your selections compared with alternative agents.

Discuss the role in therapy for blood products, sodium bicarbonate, and recombinant factor VIIa in RW at this time.

appear in guidelines as adjunctive agents to consider in the management of bleeding trauma patients.³¹

Supportive Care Measures

Lactic acidosis, which typically accompanies hypovolemic shock as a consequence of tissue hypoxia, is best treated by reversal of the underlying cause. Administration of alkalinizing agents such as sodium bicarbonate has not been demonstrated to have any beneficial effects and may actually worsen intracellular acidosis.⁴⁸ Because GI ischemia is a common complication of hypovolemic shock, prevention of stress-related mucosal disease should be instituted as soon as the patient is stabilized. The most common agents used for stress ulcer prophylaxis are the histamine₂-receptor antagonists and proton pump inhibitors. Prevention of thromboembolic events is another secondary consideration in hypovolemic shock patients. This can be accomplished with the use of external devices such as sequential compression devices and/or antithrombotic therapy such as the low molecular weight

Patient Encounter Part 3

One hour after the initial fluid bolus, RW's vital signs are BP 85/50 mm Hg, P 120, RR 20, urine output: 15 mL in the past hour. Pertinent new labs: lactate 4.8 mg/dL (0.53 mmol/L). RW has regained consciousness but is weak and confused.

Assessment RW's condition compared with 1 hour ago.

Develop a plan for additional therapy, if any, that you recommend at this time.

Describe how RW's past medical history affects your investigation of his GI bleed etiology and subsequent therapeutic plan.

Outline a plan for monitoring RW over the next 24 hours.

heparin products or unfractionated heparin. Patients with adrenal insufficiency due to preexisting disease, glucocorticoid use, or critical illness may have refractory hypotension despite resuscitation. Such patients should receive appropriate glucocorticoid replacement therapy (e.g., hydrocortisone).

► Outcome Evaluation

10 *Successful treatment of hypovolemic shock is measured by the restoration of BP to baseline values and reversal of associated organ dysfunction.* The likelihood of a successful fluid resuscitation is directly related to the expediency of treatment. Therapy goals include:

- Arterial SBP greater than 90 mm Hg (MAP greater than 60 mm Hg) within 1 hour
- Organ dysfunction reversal evident by increased urine output to greater than 0.5 mL/kg/h (1.0 mL/kg/h in pediatrics), return of mental status to baseline, and normalization of skin color and temperature over the first 24 hours
- HR should begin to decrease reciprocally to increases in the intravascular volume within minutes to hours
- Normalization of laboratory measurements expected within hours to days following fluid resuscitation. Specifically, normalization of base deficit and serum lactate is recommended within 24 hours to potentially decrease mortality⁴⁹
- Achievement of PAOP to a goal pressure of 14 to 18 mm Hg occurs (alternatively, CVP 8 to 15 mm Hg)

Patient Care and Monitoring

1. Does the patient have an adequate airway and ventilation (hemoglobin saturation greater than 92% [0.92])? If not, trained emergency personnel should consider performing tracheal intubation with initiation of mechanical ventilation.
2. Is there a detectable BP? If yes, obtain history, perform physical examination, obtain blood for baseline laboratory tests, and monitor ECG. If not, begin isotonic crystalloid fluid resuscitation immediately (see step 4).
3. Monitor the following serial laboratories for comparison to baseline values every 6 hours in the first 24 hours and daily thereafter until normalized: sodium, serum creatinine, blood urea nitrogen, serum lactate, glucose, bilirubin, hemoglobin, hematocrit, platelets, prothrombin time, partial thromboplastin time, ABGs, and pH.
4. Is the systolic BP less than 90 mm Hg (MAP less than 60 mm Hg)? If yes, start aggressive fluid therapy beginning with 1,000 to 2,000 mL lactated Ringer's over 1 hour in adults (20 mL/kg in pediatric patients). Monitor BP at least every 15 minutes (or continuously via an arterial catheter).
5. Is the patient bleeding? If yes, transfuse 5 to 10 mL/kg PRBCs. (Note: 1 unit PRBCs provides approximately 3% increase in hematocrit or 1 g/dL [10 g/L or 0.62 mmol/L] increase in hemoglobin.) Do not allow hemoglobin concentrations to fall below 7 g/dL (70 g/L or 4.34 mmol/L; hematocrit 20% [0.20]). Conventional acute goal hemoglobin concentration is 10 g/dL (100 g/L or 6.2 mmol/L; alternatively, hematocrit greater than or equal to 30% [0.30]). Provide emergent control of ongoing hemorrhaging.
6. Is there evidence of cerebral or myocardial ischemia? If yes, begin vasopressor therapy of dopamine 10 mcg/kg/min or norepinephrine 2 mcg/min. Titrate dosage every 5 minutes as needed. Wean and discontinue vasopressor as soon as the goal arterial BP has been achieved.
7. Has the goal arterial BP been achieved? If not, give additional fluid therapy hourly blending crystalloids and iso-oncotic colloids based on inadequate BP response.
8. Is the patient hemodynamically stable? If not, admit to the intensive care unit for ongoing treatment and monitoring. A PA catheter (or CVP catheter) should be inserted by trained medical personnel. Monitor PAOP to a goal pressure of 14 to 18 mm Hg and minimum cardiac index of 2.2 L/min/m² (alternatively CVP 8 to 15 cm H₂O).
9. Monitor normalization of organ function to baseline state including mental status, urine output to greater than 0.5 mL/kg/h (1 mL/kg/h in pediatric patients), normal skin color and temperature, and normalization of base deficit and/or lactate. Begin supportive care measures including stress ulcer prophylaxis and antithrombotic therapy if there is no evidence of ongoing bleeding.
10. Has the underlying cause of the hypovolemic shock been addressed to prevent its recurrence? If not, treat as necessary.
11. Is there any evidence of adverse events from the resuscitation therapies used such as fluid overload, electrolyte disturbances, transfusion reactions, and/or alterations in coagulation? If yes, manage the particular adverse event accordingly.

Abbreviations Introduced in This Chapter

ABCs	Airway, breathing, and circulation
ABG	Arterial blood gas
ADH	Antidiuretic hormone
ARDS	Acute respiratory distress syndrome
ATP	Adenosine triphosphate
BP	Blood pressure
Ca	Calcium
Cl	Chloride
CO	Cardiac output
CVP	Central venous pressure
ECG	Electrocardiogram
ECV	Extracellular volume
ED	Emergency department
FFP	Fresh-frozen plasma
HBOC	Hemoglobin-based oxygen carrier
Hct	Hematocrit
HR	Heart rate
K	Potassium
LR	Lactated Ringer's
MAP	Mean arterial pressure
Mg	Magnesium
MODS	Multiple organ dysfunction syndrome
Na	Sodium
NaCl	Sodium chloride, or normal saline
NS	Normal saline
PA	Pulmonary artery
PaO ₂	Partial pressure of arterial oxygen
PAOP	Pulmonary artery occlusion pressure
PaCO ₂	Partial pressure of arterial carbon dioxide
PPF	Plasma protein fraction
PRBCs	Packed red blood cells
rFVIIa	Recombinant activated factor VII
SAFE	Saline versus Albumin Fluid Evaluation
SBP	Systolic blood pressure
SCr	Serum creatinine
SV	Stroke volume
SVR	Systemic vascular resistance

14 Asthma

Lori Wilken and Michelle T. Martin

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Discuss the economic and health burden caused by asthma.
2. Explain the pathophysiology of asthma.
3. Describe the clinical presentation of acute and chronic asthma.
4. Identify factors that affect asthma severity.
5. Identify the goals of asthma management.
6. Classify asthma severity based on impairment due to asthma and future risk for negative outcomes due to asthma.
7. Recommend environmental control strategies for patients with identified allergies.
8. Educate patients on the use of inhaled drug delivery devices, peak flow meters, and asthma education plans.
9. Develop a therapeutic plan for patients with chronic asthma that maximizes patient response while minimizing adverse drug events and other drug-related problems.
10. Evaluate current asthma control and make therapeutic changes when necessary.
11. Develop a therapeutic plan for treating patients with acute asthma.

KEY CONCEPTS

- 1 Asthma is a complex disease that presents in a heterogeneous manner.
- 2 Asthma is the most prevalent chronic disease of childhood, and it causes significant morbidity and mortality in both adults and children.
- 3 Asthma is characterized by inflammation, airway hyperresponsiveness (AHR), and airway obstruction.
- 4 In chronic asthma, initial classification of asthma severity is based on current disease impairment and future risk.
- 5 Direct airway administration of asthma medications through inhalation is the most efficient route, and it minimizes systemic adverse effects.
- 6 Short-acting-inhaled β_2 -agonists are the most effective agents for reversing acute airway obstruction caused by bronchoconstriction and are the drugs of choice for treating acute asthma and symptoms of chronic asthma.
- 7 Inhaled corticosteroids (ICS) are the preferred therapy for all forms of persistent asthma in all age groups.

- 8 The intensity of pharmacotherapy for chronic asthma is based on disease severity for initial therapy and level of control for subsequent therapies.
- 9 In acute asthma, early and appropriate intensification of therapy is important to resolve the exacerbation and prevent relapse and future severe airflow obstruction.

INTRODUCTION

In 2011, the Global Strategy for Asthma Management and Prevention, Global Initiative for Asthma (GINA) defines asthma as “a chronic inflammatory disorder of the airways, involving airway hyperresponsiveness that leads to widespread and variable episodes of reversible airway obstruction.” This airway obstruction results in wheezing, breathlessness, chest tightness, and coughing, particularly at night or early in the morning.¹

1 Asthma is a complex disease that presents in a heterogeneous manner. Severity of chronic disease ranges from mild intermittent symptoms to a severe and disabling disease if left untreated. Despite variances in the underlying severity

of chronic asthma, all patients with asthma are at risk of acute severe disease. The National Heart, Lung, and Blood Institute (NHLBI) National Asthma Education and Prevention Program (NAEPP) Expert Panel Report-3 (EPR-3) *Guidelines for the Diagnosis and Management of Asthma*² and GINA emphasize the importance of treating underlying airway inflammation to control asthma and reduce asthma-associated risks.

EPIDEMIOLOGY AND ETIOLOGY

2 *Asthma is the most prevalent chronic disease of childhood, and it causes significant morbidity and mortality in both adults and children.*³ It is estimated that 235 million adults and children worldwide have asthma.⁴ The diagnosis of asthma increased from 2001 to 2009. In 2009, non-Hispanic blacks had the highest asthma rate of all racial groups, with 1 in 9 adults and 1 in 6 children having asthma. Puerto Ricans are twice as likely to be diagnosed with asthma and have the highest asthma rate among the Latino population.⁵ Nine deaths related to asthma occurred each day in the United States during 2007.³

Asthma is also a significant economic burden in the United States, with an estimated direct cost of \$14.8 billion in 2009. Prescription medications are the single largest direct medical expenditure and account for 71% of direct medical costs.⁶ Costs increase with disease severity, and it has been suggested that less than 20% of asthma patients account for more than 80% of direct medical expenditures.⁷

Asthma results from a complex interaction of genetic and environmental factors, but the underlying cause is not well understood. The onset of asthma occurs early in life for most patients. There appears to be an inherited component because the presence of asthma in a parent is a strong risk factor for development of asthma in a child. This risk increases when a family history of **atopy** is also present. The presence of atopy is a strong prognostic factor for continued asthma as an adult. Furthermore, the severity of early childhood asthma is a predictor of adult asthma severity.⁸

Environmental exposure also appears to be an important factor in the etiology of asthma. Patients with occupational asthma develop the disease late in life upon exposure to specific allergens in the workplace. Exposure to secondhand smoke after birth increases the risk of childhood asthma.⁹ Adult-onset asthma may be related to atopy, nasal polyps, aspirin sensitivity, occupational exposure, or a recurrence of childhood asthma.

PATHOPHYSIOLOGY

3 *Asthma is characterized by inflammation, airway hyper-responsiveness (AHR), and airway obstruction.* Inhaled antigens induce a type 2 T-helper CD4+ (T_H2) response. Antigens are taken up by antigen-presenting cells, and presentation of antigens to T-lymphocytes causes activation of the T_H2 type response. This leads to B-cell production of antigen-specific immunoglobulin E (IgE) as well as proinflammatory cytokines and chemokines that recruit and activate eosinophils, neutrophils, and alveolar macrophages.^{10,11}

Further exposure to the antigen results in cross-linking of cell-bound IgE in mast cells and basophils, causing the release of preformed inflammatory mediators such as histamine or generation of new inflammatory mediators such as leukotriene C_4 and prostaglandins.¹² Activation and degranulation of mast cells and basophils result in an early-phase response involving acute bronchoconstriction that lasts approximately 1 hour after allergen exposure.¹⁰

In the late-phase response, activated airway cells release inflammatory cytokines and chemokines, thereby recruiting more inflammatory cells into the lungs. The late-phase response occurs 4 to 6 hours after the initial allergen challenge and results in a less intense bronchoconstriction as well as increased AHR and airway inflammation.¹⁰

Airway Inflammation and Hyperresponsiveness

Although the symptoms of asthma are intermittent, airway inflammation is chronic.¹¹ Considerable variations in the pattern of inflammation may exist, resulting in phenotypic differences.^{1,2} T-lymphocytes release cytokines that coordinate eosinophilic infiltration and IgE production by B-lymphocytes.¹³ Mast cells, eosinophils, macrophages, neutrophils, fibroblasts, and airway smooth muscle cells are also activated in asthma. Mast cells infiltrate airway smooth muscle and bronchial epithelium and may cause mucous gland **hyperplasia**. Proinflammatory mediators generated during mast cell degranulation propagate the inflammatory response and contribute to AHR and airway remodeling.¹⁴

AHR is the exaggerated ability of the airways to narrow in response to a variety of stimuli. AHR is a characteristic feature of asthma and is related to airway inflammation and structural changes in the airways.^{1,2} Clinically, AHR manifests as increased variability of airway function. AHR is evaluated clinically using a methacholine or histamine bronchoprovocation test.¹⁵

Airway Obstruction

Symptoms of airway obstruction include chest tightness, cough, and **wheezing**. Airway obstruction can be caused by multiple factors including airway smooth muscle constriction, airway edema, mucus hypersecretion, and airway remodeling. Airway smooth muscle tone is maintained by an interaction between sympathetic, parasympathetic, and nonadrenergic mechanisms. Acute bronchoconstriction usually results from mediators such as histamine, cysteinyl leukotrienes, prostaglandins, and tryptase released or generated during degranulation of mast cells and basophils.^{1,2} Inflammatory mediators such as histamine, leukotrienes, and bradykinin increase microvascular permeability leading to mucosal edema, which causes the airways to become more rigid and limits airflow.¹⁶ These changes exaggerate the consequences of acute bronchoconstriction. In patients with asthma, there is an increased number and volume of mucous glands, with increased mucus secretion.¹⁷ Extensive mucus plugging may be a cause of persistent airway obstruction in acute severe attacks.

Although airway obstruction in asthma is generally reversible, some patients with asthma have an irreversible or fixed obstruction. *Airway remodeling* is the term used to describe the process that produces the structural airway changes leading to this fixed obstruction; it is characterized by airway epithelial damage, subepithelial **fibrosis**, airway smooth muscle **hypertrophy**, increased mucus production, and increased vascularity of the airways.^{2,16} These changes increase airflow obstruction and airway responsiveness and may decrease patient responsiveness to therapy.^{1,2}

CLINICAL PRESENTATION AND DIAGNOSIS

Please see the accompanying text box for the clinical presentation and diagnosis of asthma. The diagnosis of asthma is based on a detailed medical history, a physical examination

of the upper respiratory tract and skin, and spirometry. The clinician determines if episodic symptoms of airflow obstruction are present, whether airflow obstruction is at least partially reversible, and that alternative diagnoses are excluded.^{1,2} Spirometry is required for diagnosing asthma in patients older than 5 years because the medical history and physical examination are not reliable for characterizing the status of lung impairment or excluding other diagnoses.^{1,2}

► Chronic Asthma

- Chronic asthma is classified as either: (a) intermittent asthma or (b) persistent asthma that may be categorized as mild, moderate, or severe. Initial assessment of severity is made at the time of diagnosis, and initial therapy is based on this assessment. **Table 14–1** describes the categories of asthma severity in patients younger than 12 years. The assessment of severity is similar in older patients. However, in patients

Clinical Presentation and Diagnosis of Asthma

General

- Asthma severity ranges from normal pulmonary function with symptoms only during acute exacerbations to significantly decreased pulmonary function with continuous symptoms.
- Acute asthma can present rapidly (within 3 to 6 hours), but it is more common for deterioration to occur over a longer period, even days or weeks. Acute asthma can be a life-threatening event, and severity does not necessarily correspond to severity of the chronic disease.
- The patient's family history, social history, precipitating factors, history of exacerbations, development of symptoms, and treatments are important components of an asthma diagnosis.

Symptoms

- Patients usually complain of wheezing, shortness of breath, coughing (usually worse at night), and chest tightness.
- Patients may be anxious and agitated. In acute severe asthma, patients may be unable to communicate in complete sentences.
- Mental status changes may indicate impending respiratory failure.
- The presence of precipitating factors worsens symptoms.
- Symptoms usually have a pattern.

Signs

- Vital signs may reflect **tachypnea** and **tachycardia**.
- On inspection, there may be hyperexpansion of the thorax and use of accessory muscles.
- Auscultation of the lungs may detect end-expiratory wheezes in mild exacerbations or wheezing throughout inspiration and expiration in severe exacerbations.

- Bradycardia** and absence of wheezing may indicate impending respiratory failure.
- In acute asthma, patients may also present with **pulsus paradoxus**, **diaphoresis**, and **cyanosis**.

Laboratory tests

- Spirometry demonstrates reversible airway obstruction with an FEV_1/FVC less than 80% and either: (a) an increase in FEV_1 of 12% or 200 mL after receiving a bronchodilator, or (b) an increase of 10% in the predicted FEV_1 after receiving a bronchodilator.
- Spirometry may be normal if the patient is not symptomatic.
- Elevated immunoglobulin E (IgE) levels may be present.
- Some patients will have positive skin test or **radioallergosorbent test (RAST)** to allergens.

Other Diagnostic Tests

- Arterial blood gases (to evaluate P_{CO_2}) should be obtained for patients in severe distress, suspected hypoventilation, or when PEF or FEV_1 is 30% or less after initial treatment.
- A complete blood count with differential should be obtained in patients with fever or purulent sputum.
- Serum electrolytes should be obtained because frequent β_2 -agonist administration decreases serum potassium, magnesium, and phosphate.

Other Diagnostic Tests

- Pulmonary function tests
- Pulse oximetry
- Chest x-ray when pneumonia is suspected

Table 14-1

Classification of Asthma Severity in Patients 0 to 11 Years Old^a

	Components of Severity	Persistent			
		Intermittent	Mild	Moderate	Severe
Impairment	Symptoms	2 days/week or less	More than 2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings				
	Ages 0–4	0	1–2 times/month	3–4 times/month	More than 1 time/week
	Ages 5–11	2 times/month or less	3–4 times/month	More than 1 time/week but not nightly	Often 7 nights/week
	SABA use for symptoms (not prevention of EIB)	2 days/week or less	More than 2 days/week but not more than 1 time/day	Daily	Several times/day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Risk	Lung function ^b ages 5–11	FEV ₁ more than 80%, FEV ₁ /FVC more than 85%	FEV ₁ more than 80%, FEV ₁ /FVC more than 80%	FEV ₁ 60–80%, FEV ₁ /FVC 75–80%	FEV ₁ less than 60%, FEV ₁ /FVC less than 75%
	Exacerbations requiring systemic (oral) corticosteroids				
	Ages 0–4	0–1/year	2 or more exacerbations in 6 months, 4 or more wheezing episodes/year lasting for more than 1 day <i>and</i> risk factors for persistent asthma		
	Ages 5–11	0–1/year	2/year or more →		
	Recommended step for initiating treatment	Step 1	Step 2	Step 3, and consider short course of oral corticosteroids	

SABA, short-acting β_2 -agonist; EIB, exercise-induced bronchospasm.

^aFrom NHLBI National Asthma Education and Prevention Program, Expert Panel Report-3. Guidelines for the diagnosis and management of asthma. NIH Publication No. 07-4051. Bethesda, MD: U.S. Department of Health and Human Services, 2007, <http://www.nhlbi.nih.gov/guidelines/asthma>. See <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.pdf> for adults and children 12 years of age and older.

^bNormal FEV₁/FVC: ages 8–19 = 85%; ages 20–39 = 80%; ages 40–59 = 75%; ages 60–80 = 70%.

12 years of age and older, it is recommended to initiate treatment in severe persistent asthma at step 4 or 5 (instead of step 3 in children younger than 12 years).

4 In chronic asthma, initial classification of asthma severity is based on current disease impairment and future risk. The term *impairment* refers to the frequency and severity of symptoms, use of short-acting β_2 -agonists (SABA) for quick relief of symptoms, pulmonary function, and impact on normal activity and quality of life. *Risk* refers to the potential for future severe exacerbations and asthma-related death, progressive loss of lung function (adults) or reduced lung growth (children), and the occurrence of drug-related adverse effects.

► Acute Asthma

In acute asthma, the severity of an exacerbation does not depend on the classification of the patient's chronic asthma because even patients with intermittent asthma can have life-threatening acute exacerbations. Severity at the time of the evaluation can be estimated by signs and symptoms or presenting peak expiratory flow (PEF) or forced expiratory volume in 1 second (FEV₁). The exacerbation is considered *mild* if the patient is only having dyspnea with activity and the PEF is at least 70% of the personal best value, *moderate* if the dyspnea

limits activity and the PEF is 40% to 69% of the personal best, and *severe* with PEF less than 40% and dyspnea interferes with conversation or occurs at rest. When the patient is not able to speak and the personal best PEF is less than 25% of the personal best predicted value, it is a *life-threatening* exacerbation.

TREATMENT OF ASTHMA

Desired Outcomes

► Chronic Asthma

Therapy for chronic asthma is directed at maintaining long-term control of asthma using the least amount of medications and minimizing adverse effects.^{1,2} Treatment goals are to: (a) prevent chronic and troublesome symptoms, (b) require infrequent use (2 or fewer days/week) of SABA for quick relief of symptoms, (c) maintain normal or near-normal pulmonary function, (d) maintain normal activity levels, (e) meet patients' and families' expectations of satisfaction with asthma care, (f) prevent exacerbations of asthma and the need for emergency department visits or hospitalizations, (g) prevent progressive loss of lung function, and (h) provide optimal pharmacotherapy with minimal or no adverse effects.

Patient Encounter 1

JB is a 26-year-old woman with moderate persistent asthma. She has concerns about her asthma control. The temperature is getting colder outside, and cold weather has always been a trigger for her asthma. She also states that strong odors are a trigger. She is taking her asthma medications properly and without complaints. She recently saw the allergist, and her skin testing was positive for dust and molds. She uses an air purifier and a humidifier in her bedroom. She uses a cleaning service and leaves her home when it is being cleaned. She does not wear perfume and does wear a coat and hat in the wintertime.

What educational points may help with her asthma triggers?

What immunizations are recommended for her if she has not had any since childhood?

► Acute Asthma

Acute or worsening asthma can be a life-threatening situation and requires rapid assessment and appropriate intensification of therapy. Mortality associated with asthma exacerbations is usually related to inappropriate assessment of the severity of the exacerbation resulting in insufficient treatment or referral for medical care.¹⁸ The goals of therapy are to: (a) correct significant **hypoxemia**, (b) reverse airflow obstruction rapidly, and (c) reduce the likelihood of exacerbation relapse or recurrence of severe airflow obstruction in the future.^{1,2}

Nonpharmacologic Therapy

- Nonpharmacologic therapy is incorporated into each step of asthma care, and patient education occurs at all points where healthcare professionals interact with patients. Patient education begins at the time of diagnosis and is tailored to meet individual patient needs. Some components of asthma education involve asthma trigger avoidance, proper administration of inhaled medications, and asthma self-management.

► Factors Associated with Worsening Asthma Control

- Major triggers that may worsen asthma control include pollen, mold, dust mites, cockroaches, pet dander, air pollution, cold air, exercise, strong odors, emotions, tobacco smoke, certain medications, illicit drug use, sulfite-containing foods and beverages, and comorbid conditions (e.g., allergic rhinitis, sinusitis, upper respiratory infections, gastroesophageal reflux disease, obesity, obstructive sleep apnea, allergic bronchopulmonary aspergillosis, and hormonal changes).

► Trigger Avoidance

Education on identifying and controlling asthma triggers is critical to providing adequate asthma treatment.^{1,2} Environmental controls to reduce the allergen load in the patient's home may reduce asthma symptoms, school absences because of asthma, and unscheduled clinic and emergency visits for asthma.¹⁹ Various informational resources are available on controlling or avoiding asthma triggers.^{20,21}

Exercise is one of the most common precipitants of asthma symptoms. Shortness of breath, wheezing, or chest tightness usually occur during or shortly after vigorous exercise, peak 5 to 10 minutes after stopping the activity, and resolve within 20 to 30 minutes. Warming up prior to exercise and covering the mouth and nose with a scarf or mask during cold weather may prevent exercise-induced asthma. Pretreatment with a SABA 5 minutes prior to exercise is the treatment of choice and will protect against bronchospasm for 2 to 3 hours.² Regular treatment with an inhaled corticosteroid (ICS) also prevents bronchospasm associated with exercise.

- A yearly influenza vaccine is recommended for patients 6 months and older with asthma to decrease the risk of complications from influenza.²² The pneumococcal vaccine may decrease the risk of invasive pneumococcal disease in patients with asthma and is recommended as a one-time immunization before the age of 65 years and again after age 65.²³ In patients older than 11 years, providing a booster vaccine to protect against pertussis is becoming standard practice. The varicella vaccine is also highly recommended.²

Nonselective β -blockers, such as carvedilol, labetalol, nadolol, pindolol, propranolol, and timolol (including those in ophthalmic preparations) may worsen asthma control.

Patient Encounter 2

AJ is a 3-year-old girl seen today by the pediatrician. She has been diagnosed with intermittent asthma based on her symptoms. She is not symptomatic today, but a prescription for albuterol is provided to be used as needed for wheezing and worsening asthma symptoms.

What is the best way to deliver the medication for this patient's asthma?

What education is required for the method of medication delivery that you would recommend?

If AJ requires an inhaled corticosteroid in 6 weeks, what are the options for delivering it?

Describe the education that you would provide to AJ's parents about using an inhaled corticosteroid.

What is the best way to deliver asthma medication when AJ is 8 years old?

What education is required for the method of medication delivery you would recommend for an 8-year-old patient?

These agents are avoided in patients with asthma unless the benefits of therapy outweigh the risks.² In patients with asthma requiring β -blocker therapy, a β_1 -selective agent such as metoprolol or atenolol is the best option. Because selectivity is dose related, the lowest effective dose is used.

Patients with aspirin-sensitive asthma are usually adults and often present with the triad of rhinitis, nasal polyps, and asthma. In these patients, acute asthma may occur within minutes of receiving aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs). These patients are counseled against using NSAIDs.² Although acetaminophen is generally safe, doses larger than 1 g may cause acute asthmatic reactions in some patients.²⁴

Pharmacologic Therapy

Treatment of chronic asthma involves avoidance of triggers known to precipitate or worsen asthma and use of long-term control and quick-relief medications. Long-term control medications include ICS, inhaled long-acting β_2 -agonists (LABAs), oral theophylline, oral leukotriene receptor antagonists (LTRAs), and omalizumab. In patients with severe asthma, systemic corticosteroids may be used as a long-term control medication. Quick-relief medications include SABAs, anticholinergics, and short bursts of systemic corticosteroids.

► Drug Delivery Devices

5 *Direct airway administration of asthma medications through inhalation is the most efficient route and minimizes systemic adverse effects.* Inhaled asthma medications are available in metered-dose inhalers (MDIs), dry powder inhalers (DPIs), and nebulized solutions. Selection of the appropriate inhalation device depends on patient characteristics and medication availability (Table 14-2).

Poor inhaler technique results in increased oropharyngeal deposition of the drug, leading to decreased efficacy and increased adverse effects. Figure 14-1 describes the steps for appropriate use of MDIs. Because MDIs are challenging to use correctly, use of valved-holding chambers (VHCs) is recommended with MDIs to decrease the need for coordination of actuation with inhalation, decrease oropharyngeal deposition, and increase pulmonary drug delivery.^{25,26}

► β_2 -Adrenergic Agonists

β_2 -Agonists relax airway smooth muscle by directly stimulating β_2 -adrenergic receptors in the airway.²⁷ They also increase mucociliary clearance and stabilize mast cell membranes. The early-phase response to antigen in an asthma exacerbation is blocked by pretreatment with inhaled SABAs. Short-acting β_2 -agonists have significantly better

Table 14-2

Age Recommendations and Features of Inhalation Devices.²

Device Type	Recommended Age	Advantages	Disadvantages
Metered-dose inhaler (MDI)	5 years of age and older	<ul style="list-style-type: none"> Newer inhalers have a dose counter Delivery of medication in less than 2 min Portable, durable Lower medication dose needed vs. nebulization 	<ul style="list-style-type: none"> Older inhalers do not have a dose counter Technique/coordination may be difficult Propellant may taste bad or irritate the airways
MDI plus valved-holding chamber (VHC)	If less than 4 years old, use VHC with mask; If 4 years of age or older, use VHC	<ul style="list-style-type: none"> VHC enhances MDI technique VHC decreases topical side effects of ICS Albuterol MDI with VHC is as effective as nebulization for asthma exacerbation 	<ul style="list-style-type: none"> Bulky Lack of coverage by some insurance plans Limited testing of MDIs with various VHC, leading to unpredictable results Potential for increased systemic side effects with inhaled corticosteroids (ICS)
Jet nebulizer	Any age, preferably infants or elderly	<ul style="list-style-type: none"> No coordination required Oxygen may be delivered simultaneously with medications 	<ul style="list-style-type: none"> Requires 5–15 minutes to deliver medication Limited number of medications available for nebulization Not portable (most require electricity)
Ultrasonic nebulizer	Any age; preferably infants or elderly	<ul style="list-style-type: none"> Typically more portable than jet nebulizer Faster delivery of medications than jet nebulizer 	<ul style="list-style-type: none"> Heat generated from nebulizer breaks down suspensions for nebulization Do not use with budesonide suspension for nebulization
Dry powder inhaler (DPI)	Aerolizer 5 years of age and older; Diskus 4 years of age and older; Flexhaler 6 years of age and older; Twisthaler age 12 years and older	<ul style="list-style-type: none"> Easy to use; has dose counter Sweet taste Quick delivery of medication 	<ul style="list-style-type: none"> Limited product stability 30–45 days after opening Optimal delivery of medication in children less than 4 years old is not feasible because high inspiratory volume is needed Amount of lactose filler is insufficient to cause concern in lactose intolerance

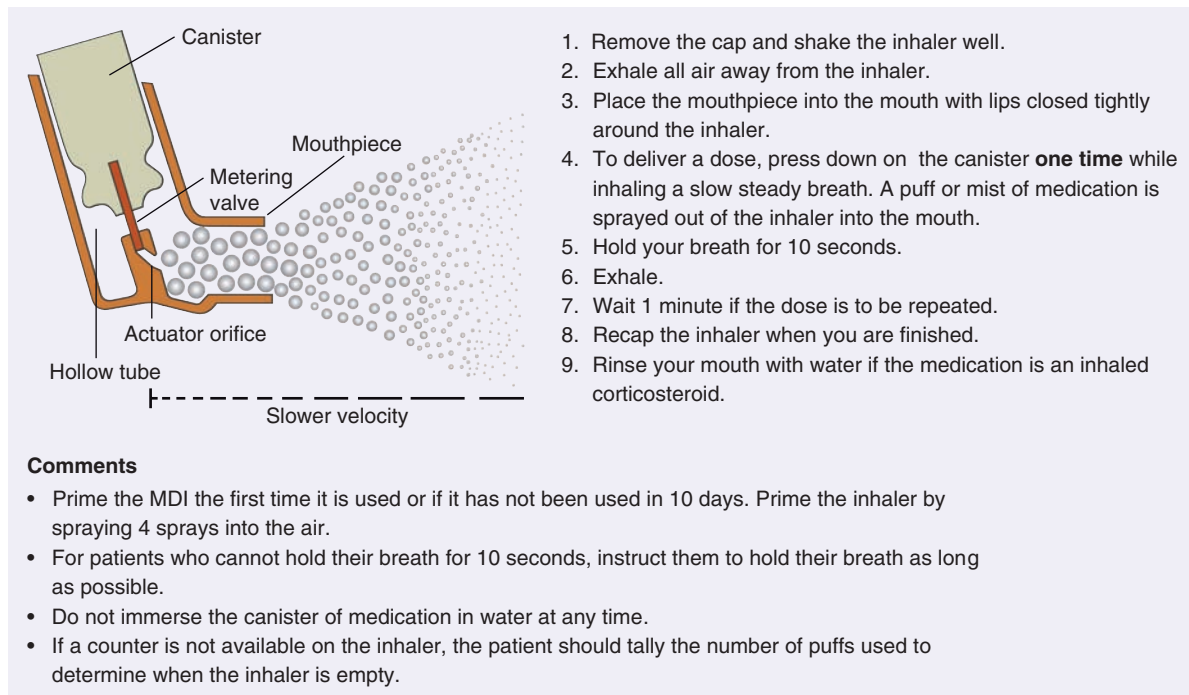

FIGURE 14-1. Proper Use of a Metered-Dose Inhaler (MDI). Inhaler image reprinted with permission from Kelly HW, Sorkness CA. Asthma. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach, 8th ed. New York: McGraw-Hill, 2011. Figure 33-4, 448

bronchodilating activity in acute asthma than theophylline or anticholinergic agents.

Adverse effects of β_2 -agonists include tachycardia, tremor, and hypokalemia, which are usually not troublesome with inhaled dosage forms. Oral β_2 -agonists have increased adverse effects and are not used in the treatment of asthma. Inhaled β_2 -agonists are classified as either short- or long-acting based on duration of action.

Short-Acting Inhaled β_2 -Agonists **6** *Inhaled SABAs are the most effective agents for reversing acute airway obstruction caused by bronchoconstriction and are the drugs of choice for treating acute asthma and symptoms of chronic asthma as well as preventing exercise-induced bronchospasm.¹ Inhaled SABAs have an onset of action of less than 5 minutes and a duration of action of 4 to 6 hours. Using an MDI with a spacer is quicker and at least as effective as administration by nebulization.*

Albuterol (known as salbutamol outside the United States), the most commonly used inhaled SABA, is available as an MDI and solution for nebulization. Levalbuterol, the pure R-enantiomer of albuterol (and referred to as R-salbutamol outside the United States), is available as an MDI and solution for nebulization. Levalbuterol has similar efficacy to albuterol and is purported to have fewer side effects; however, clinical trials have not demonstrated this benefit.²⁸

Doses for SABAs are provided in [Table 14-3](#). During an asthma exacerbation, the usual SABA doses are doubled and the regimen changes from as needed to scheduled use. Scheduled chronic daily dosing of SABAs is not recommended for two reasons. First, the need to use an inhaled SABA is one key indicator of uncontrolled asthma. Therefore, patients are educated to record SABA use. Second,

scheduled SABA use decreases the duration of bronchodilation provided by the SABA.

Long-Acting Inhaled β_2 -Agonists Salmeterol and formoterol are LABAs that provide up to 12 hours of bronchodilation after a single dose. Because of the long duration of bronchodilation, these agents are useful for patients experiencing nocturnal symptoms. Salmeterol is a partial agonist with an onset of action of approximately 30 minutes.

Formoterol is a full agonist that has an onset of action similar to that of albuterol, but it is not currently approved for the treatment of acute bronchospasm.

LABAs are indicated for chronic treatment of asthma as add-on therapy for patients not controlled on low to medium doses of ICS. Adding an LABA is at least as effective in improving symptoms and decreasing asthma exacerbations as doubling the dose of an ICS or adding an LTRA to ICS.²⁹ Adding an LABA to ICS therapy also reduces the amount of ICS necessary for asthma control.

Although both formoterol and salmeterol are effective as add-on therapy for moderate persistent asthma, neither agent should be used as monotherapy for chronic asthma. There may be an increased risk of severe asthma exacerbations and asthma-related deaths when LABAs are used alone.³⁰ The labeling for all drugs containing LABAs includes a black box warning against their use without an ICS. The risk of increased severe asthma exacerbations does not appear to be increased in adults receiving both an LABA and ICS.³¹

Salmeterol and formoterol are available in fixed-ratio combination products containing fluticasone, budesonide, or mometasone. Combination products may increase adherence because of the need for fewer inhalers and inhalations.

Table 14-3

Usual Dosages for Quick-Relief Medications for Asthma in Home Setting^{a,b}

Medications	Dosage Form	Children 0–11 years	Adults and Children 12 Years of Age and Older
Inhaled SABA			
Albuterol	HFA (MDI) 90 mcg/puff, 200 puffs/canister	1–2 puffs every 4–6 hours as needed	2 puffs every 4–6 hours as needed
Albuterol	Nebulizer solution 0.63 mg/3 mL, 1.25 mg/3 mL, 2.5 mg/3 mL, 5 mg/mL (0.5%)	0.63–5 mg in 3 mL saline every 4–6 hours as needed	1.25–5 mg in 3 mL saline every 4–8 hours as needed
Levalbuterol	HFA (MDI) 45 mcg/puff, 200 puffs/canister	2 puffs every 4–6 hours as needed for ages 5–11 years	2 puffs every 4–6 hours as needed
Levalbuterol	Nebulizer solution 0.31 mg/3 mL, 0.63 mg/3 mL, 1.25 mg/0.5 mL, 1.25 mg/3 mL	0.31–1.25 mg in 3 mL every 6–8 hours as needed	0.63–1.25 mg every 6–8 hours as needed
Systemic Corticosteroids			
Methylprednisolone	2, 4, 6, 8, 16, 32 mg oral tablets	40–60 mg/day by mouth as single or 2 divided doses for 3–10 days	40–60 mg/day by mouth as single or 2 divided doses for 3–10 days
Prednisolone	5 mg oral tablets; 5 mg/5 mL and 15 mg/5 mL oral liquid	1–2 mg/kg/day, (maximum 60 mg/day) for 3–10 days	40–60 mg/day by mouth as single or 2 divided doses for 3–10 days
Prednisone	1, 2.5, 5, 10, 20, 50 mg oral tablets; 5 mg/mL and 5 mg/5 mL oral liquid	1–2 mg/kg/day, (maximum 60 mg/day) for 3–10 days	40–60 mg/day by mouth as single or 2 divided doses for 3–10 days

HFA, hydrofluoroalkane; IM, intramuscular; MDI, metered-dose inhaler; N/A, safety and efficacy not established; SABA, short-acting β_2 -agonist.

^aDosages are provided for products that have been approved by the U.S. FDA or have sufficient clinical trial safety and efficacy data in the appropriate age ranges to support their use.

^bDoses are increased in the hospital/emergency department setting.

However, they offer less flexibility in dosage adjustment of individual ingredients if that is necessary. Doses used for long-term control of chronic asthma are provided in [Table 14-4](#).

► Corticosteroids

Corticosteroids are the most potent anti-inflammatory agents available for the treatment of asthma and are available in inhaled, oral, and injectable dosage forms. They decrease airway inflammation, attenuate AHR, and minimize mucus production and secretion. Corticosteroids also improve the response to β_2 -agonists.

Inhaled Corticosteroids 7 ICS are the preferred therapy for all forms of persistent asthma in all age groups.^{1,2} ICS are more effective than LTRA and theophylline in improving lung function and preventing emergency department visits and hospitalizations due to asthma exacerbations.^{1,2} The primary advantage of using ICS compared with systemic corticosteroids is the targeted drug delivery to the lungs, which decreases the risk of systemic adverse effects. Product selection is based on preference for dosage form, delivery device, and cost.

All ICS are equally effective if given in equipotent doses ([Table 14-5](#)).³² ICS have a flat dose–response curve; doubling the dose has a limited additional effect on asthma control.³³ The ICS are more effective when given twice daily rather than once daily.³² Cigarette smoking decreases the response to ICS, and smokers require higher doses of ICS than nonsmokers.³⁴ Although some beneficial effect is seen within 12 hours of administration of an ICS, 2 weeks of therapy is necessary

Patient Encounter 3

SR is a 25-year-old man with a past medical history of human immunodeficiency virus (HIV), asthma, and migraines. Until recently, his asthma was controlled with as-needed albuterol. Four weeks ago he was seen in clinic with worsening migraine headaches and was started on medication for migraine prophylaxis. He had an asthma exacerbation 2 weeks ago and was started on a medium-dose inhaled corticosteroid. Today he has complaints of weight gain and a “puffy face.” His medication regimen includes:

- Ritonavir 100 mg daily
- Darunavir 400 mg 2 tablets by mouth daily
- Raltegravir 400 mg by mouth twice daily
- Propranolol 20 mg by mouth twice daily
- Ibuprofen 200 mg 2 capsules by mouth every 8 hours as needed for headache
- Acetaminophen 325 mg 2 tablets by mouth every 4 hours as needed for headache
- Fluticasone 110 mcg 2 puffs twice daily
- Albuterol 90 mcg 2 puffs every 6 hours as needed for shortness of breath

Which of his medications is most likely worsening his asthma control?

Which of the medications are interacting and causing the weight gain and “puffy face”?

What would be an appropriate alternative asthma regimen?

Table 14-4

Usual Doses of Long-Term Control Medications in Asthma^a

Medication	Dosage Form	Ages 0–11 Years	Adult and Children Greater Than or Equal to 12 Years of Age
Inhaled Corticosteroids (see Table 14-5)			
Long-Acting β_2-Agonists			
Salmeterol	DPI 50 mcg/blister	Ages 0–4 years: N/A Ages 5–11 years: Contents of one blister every 12 hours	Contents of one blister every 12 hours
Formoterol	DPI 12 mcg/capsule	Ages 0–4 years: N/A Ages 5–11 years: Contents of one capsule every 12 hours	Contents of one capsule every 12 hours
Leukotriene Modifiers			
Montelukast	4 mg or 5 mg chewable tablets 4 mg granule packets 10 mg tablet	Ages 1–5 years: 4 mg at bedtime Ages 6–11 years: 5 mg at bedtime	Ages 12–14 years: 5 mg at bedtime Ages 15 and older: 10 mg at bedtime
Zafirlukast	10 or 20 mg tablets	Ages 0–6 years: N/A Ages 7–11 years: 10 mg twice daily	20 mg tablet twice daily
Zileuton	600 mg extended-release tablet 600 mg tablet	N/A N/A	1200 mg twice daily after meals 600 mg 4 times daily
Methylxanthines			
Theophylline	100, 200, 300, 400, 450, 600 mg extended-release tablets; 80 mg/15mL solution and elixir; liquids, sustained-release tablets and capsules	Ages less than 1 year: $[0.2 (\text{age in weeks}) + 5] \times \text{body weight in kg}$ (in divided doses/day) ^b Ages 1–11 years (less than 45 kg): Starting dose 12–14 mg/kg/day (max 300 mg/day) \times 3 days, increase to 16 mg/kg/day (max 400 mg/day) \times 3 days, then increase to 20 mg/kg/day (max 600 mg/day) Ages 1–11 years (45 kg or greater): Starting dose 300 mg/day (in divided doses) \times 3 days, titrate up 400 mg/day \times 3 days, then titrate up to usual maximum of 600 mg/day	Starting dose 300 mg/day (in divided doses or daily depending on product) \times 3 days, titrate up 400 mg/day \times 3 days, then titrate up to usual maximum of 600 mg/day; monitor serum levels
Immunomodulator			
Omalizumab	SC injection, 150 mg/1.2 mL after reconstitution with 1.4 mL sterile water for injection	N/A	150–375 mg SC every 2–4 weeks, depending on body weight and pretreatment serum IgE level. See dosing chart. ^c

DPI, dry powder inhaler; IgE, immunoglobulin E; N/A, safety and efficacy not established; SC, subcutaneously.

^aDosages are provided for products that have been approved by the U.S. FDA or have sufficient clinical trial safety and efficacy data in the appropriate age ranges to support their use.

^bSee guidelines for premature infants.

^c<http://www.gene.com/gene/products/information/pdf/xolair-prescribing.pdf>.

to see significant clinical effects. Longer treatment may be necessary to realize the full effects on airway inflammation.

For most delivery devices, the majority of the drug is deposited in the mouth and throat and swallowed.

Local adverse effects of ICS include oral candidiasis, cough, and **dysphonia**. The incidence of local adverse effects can be reduced by using a VHC and by having the patient rinse the mouth with water and expectorate after using the ICS. Decreasing the dose reduces the incidence of hoarseness.

Systemic absorption occurs via the pulmonary and oral routes. Systemic adverse effects are dose dependent and rare with low to medium doses. However, high-dose ICS

have been associated with adrenal suppression, decreased bone mineral density, skin thinning, cataracts, and easy bruising.² Nonprogressive growth suppression in children occurs primarily in the first month of treatment and is reported with low- and medium-dose ICS.^{35,36} A significant drug interaction causing Cushing's syndrome and adrenal insufficiency occurs when potent inhibitors of CYP3A4 (ritonavir, itraconazole, ketoconazole) are administered with high doses of ICS.³²

Considerable variability in response to ICS exists, with up to 40% of patients not responding to ICS. This lack of response may be related to a functional glucocorticoid-induced

^aN/A in children 0–4 years of age.

^bNot yet FDA approved in children 0–11 years of age.

^cDoses based on clinical trials. FDA approved in children ages 4–11 years at maximum dose of 110 mcg daily.

^dDoses based on clinical trials. A maximum of fluticasone/salmeterol 100/50 mcg, 1 inhalation twice daily is approved in children ages 4–11 years without specification of low, medium, or high dosage.

transcript 1 gene (*GLCCI1*) variant in some patients with asthma.³⁷ Future directions in pharmacogenomics will assist with individualized asthma treatment algorithms.

Systemic Corticosteroids Prednisone, prednisolone, and methylprednisolone are systemic corticosteroids used in asthma treatment. These medications are the cornerstone of treatment for acute asthma not responding to an SABA.^{1,2} Recommended doses for systemic corticosteroids are included in Table 14-3.

The onset of action for systemic corticosteroids is 4 to 12 hours. For this reason, systemic corticosteroids are started early in the course of acute exacerbations. The oral route is preferred in acute asthma; there is no evidence that IV corticosteroid administration is more effective. Therapy with systemic corticosteroids is continued until the PEF is 70% or more of the personal best measurement and asthma symptoms are resolved. The duration of therapy usually ranges from 3 to 10 days. Tapering the corticosteroid dose in patients receiving short bursts (up to 10 days) is usually not necessary because any adrenal suppression is transient and rapidly reversible.²

Because of serious potential adverse effects, systemic corticosteroids are avoided as long-term controller medication for asthma, if possible. Systemic corticosteroids are only used in patients who have failed other therapies, including immunomodulators. If systemic therapy is necessary, once-daily or every-other-day therapy is used with repeated attempts to decrease the dose or discontinue the drug.

► Anticholinergics

Two anticholinergic medications are available: ipratropium bromide and tiotropium bromide. Anticholinergic agents act by inhibiting the effects of acetylcholine on muscarinic

receptors in the airways and protecting against cholinergic-mediated bronchoconstriction.²⁷ The bronchodilating effects are not as effective as SABAs in asthma.

- Ipratropium bromide (Atrovent) is available as an MDI and solution for nebulization. Its onset of action is approximately 30 minutes, and the duration of action is 4 to 8 hours. The addition of ipratropium bromide to SABAs during a moderate to severe asthma exacerbation improves pulmonary function and decreases hospitalization rates in both adult and pediatric patients.³⁸ Combining an SABA with ipratropium is only indicated in the emergency department setting. There is no evidence to support continued use of ipratropium during hospitalization or for chronic asthma treatment.²

Tiotropium bromide (Spiriva) is a long-acting inhaled anticholinergic available in a DPI; it has an onset of action of approximately 30 minutes and duration of action longer than 24 hours. There is increasing evidence supporting its use as a long-term controller medication in patients with uncontrolled asthma already taking an ICS.^{39,40}

Anticholinergic drugs may cause bothersome adverse effects such as blurred vision, dry mouth, and urinary retention. Increased cardiovascular events have been reported for ipratropium but not tiotropium.^{41,42}

► Leukotriene Receptor Antagonists

The LTRAs are anti-inflammatory medications that either inhibit 5-lipoxygenase (zileuton) or competitively antagonize the effects of leukotriene D₄ (montelukast and zafirlukast).

- These agents improve FEV₁ and decrease asthma symptoms, SABA use, and asthma exacerbations. Although these agents offer the convenience of oral administration, they are significantly less effective than low ICS doses.^{2,43} Combining

an LTRA with an ICS or LABA is not as effective as an ICS plus an LABA.² LTRA are beneficial for asthma patients with allergic rhinitis or aspirin sensitivity. See Table 14–4 for dosing.

Montelukast (Singulair) is generally well tolerated with minimal need for monitoring and few drug interactions. Zileuton (Zyflo) and zafirlukast (Accolate) are not commonly used because of the risk of hepatotoxicity. Both zileuton and zafirlukast require liver function monitoring at baseline and every 3 months for the first year of use and then periodically thereafter. Zileuton and zafirlukast are metabolized through the CYP 2C9 hepatic pathway and have significant drug interactions. All three agents have reports of neuropsychiatric events, such as sleep disorders, aggressive behavior, and suicidal thoughts that need to be monitored.

► **Methylxanthines**

Theophylline has anti-inflammatory properties and causes bronchodilation by inhibiting phosphodiesterase and antagonizing adenosine.⁴⁴ Its use is limited because of inferior efficacy as a long-term controller medication compared with ICS, a narrow therapeutic index with potentially life-threatening toxicity, and multiple clinically important drug interactions.

Theophylline is primarily metabolized by CYP1A2 and CYP3A4 and is involved in a large number of disease and drug interactions. Theophylline exhibits nonlinear pharmacokinetics; therefore, serum concentration changes due to dosage adjustments, drug interactions, and hepatic function may not always be predictable.

Target serum theophylline concentrations are 5 to 15 mg/L (28 to 83 $\mu\text{mol/L}$); an increased risk of adverse effects outweighs the increased bronchodilation in most patients above 15 mg/L (83 $\mu\text{mol/L}$).⁴⁴ Headache, nausea, vomiting, and insomnia may occur at serum concentrations less than 20 mg/L (111 $\mu\text{mol/L}$) but are rare when the dose is started low and increased slowly. See Table 14–4 for dosing. More serious adverse effects can occur at higher concentrations (e.g., cardiac arrhythmias, seizures, and death).

► **Immunomodulators**

Omalizumab (Xolair) is a recombinant humanized monoclonal anti-IgE antibody that inhibits binding of IgE to receptors on mast cells and basophils, resulting in inhibition of inflammatory mediator release and attenuation of the early- and late-phase allergic response. Omalizumab is indicated for treatment of patients with moderate to severe persistent asthma whose asthma is not controlled by ICS and who have a positive skin test or in vitro reactivity to aeroallergens. Omalizumab significantly decreases ICS use, reduces the number and length of exacerbations, and increases asthma-related quality of life.⁴⁵

Omalizumab is given as a subcutaneous injection every 2 to 4 weeks in the office or clinic. The initial dose is based on the patient's weight and baseline total serum IgE concentration (see Table 14–4). Subsequent IgE levels are not monitored.

The most common adverse effects are injection site reactions and include bruising, redness, pain, stinging,

Patient Encounter 4

CE is a 52-year-old woman with severe persistent asthma since she was a child, allergic rhinitis, and gastroesophageal reflux disease (GERD). She is currently taking budesonide/formoterol 160/4.5 mcg, 2 puffs twice daily, montelukast 10 mg by mouth at bedtime, fluticasone 50 mcg/actuation 2 sprays in each nostril daily, omeprazole 20 mg by mouth daily, and prednisone 40 mg daily for 3 to 5 days every other month for asthma exacerbations. Her IgE level is 100 IU/mL (100 kIU/L) and her weight is 150 pounds (68 kg). She tested positive for allergies to pollens and dust mites.

The physician plans to start omalizumab. Do you agree with this plan?

What is the appropriate dose, route of administration, and frequency for this medication?

If omalizumab therapy is initiated, what information should be provided to the patient?

Outline a monitoring plan for omalizumab for an adult patient with asthma.

itching, and burning. Anaphylactic reactions are rare but may occur at any time after medication administration. Monitoring the patient for an anaphylactic reaction for 2 hours after medication administration is recommended for the first 3 months; thereafter, monitoring time can be reduced to 30 minutes.⁴⁶ It is also important to issue a prescription for and provide patient education on the use of subcutaneous epinephrine for an anaphylactic reaction from omalizumab.

Treatment of Chronic Asthma

8 *The intensity of pharmacotherapy for chronic asthma is based on disease severity for initial therapy and level of control for subsequent therapies. The least amount of medications necessary to meet the goals of asthma therapy is used.²*

The first step in asthma management is evaluating the patient's asthma severity and control (refer to Table 14–1 for descriptions of asthma severity). Pharmacologic treatment is initiated based on the recommendations for stepwise therapy (Fig. 14–2). The EPR-3 separates treatment recommendations into three categories based on patient age: (a) children younger than 5 years, (b) children between the ages of 5 and 11 years, and (c) individuals 12 years and older. Therapeutic plans must be individualized.

► **Intermittent Asthma**

Patients with intermittent asthma only need SABAs. This classification of asthma includes patients with exercise-induced bronchospasm (EIB), seasonal asthma, or asthma symptoms associated with infrequent trigger exposure. Patients pretreat with an SABA prior to exposure to a known trigger, such as exercise.

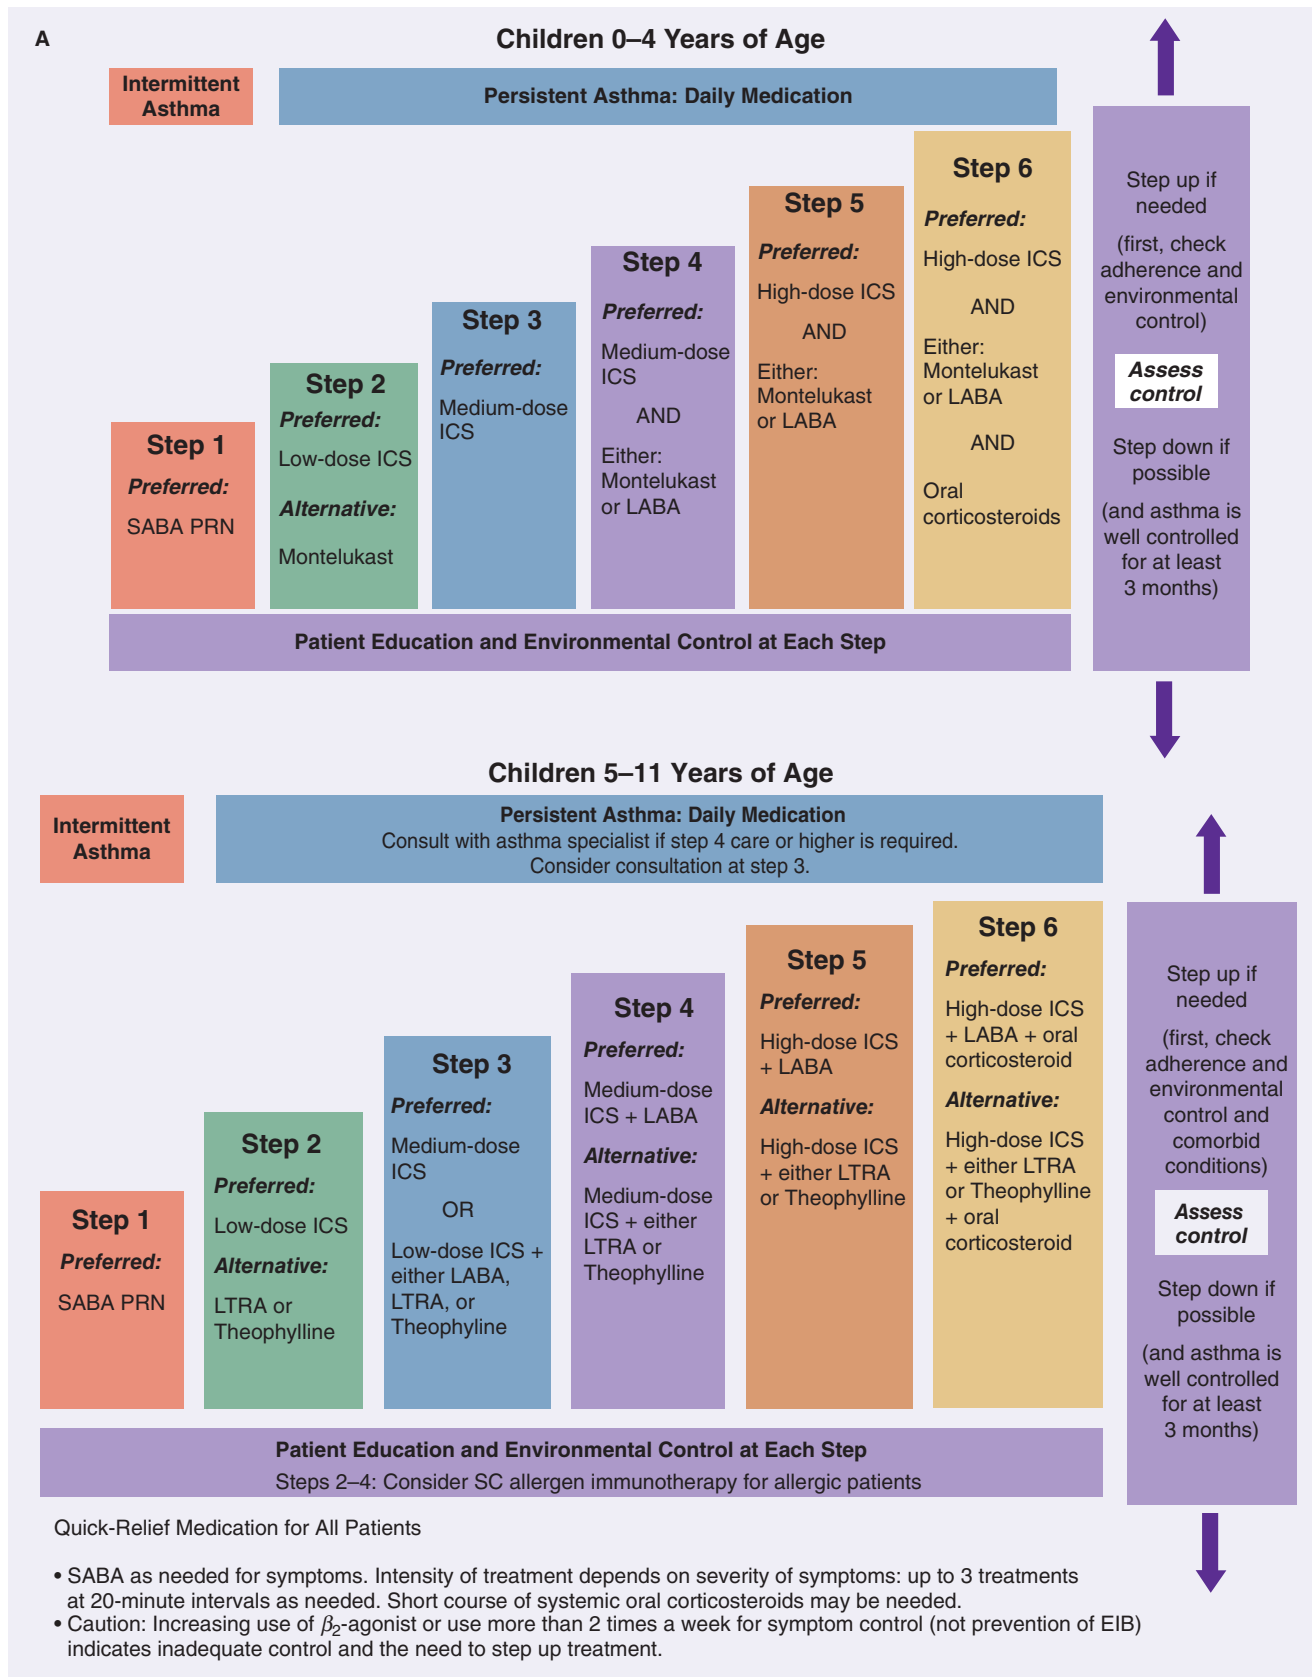

FIGURE 14-2. Stepwise approach for managing asthma in (A) children and (B) adults. (ICS, inhaled corticosteroid; LABA, long-acting β -agonist; LTRA, leukotriene receptor antagonist; PRN, as needed; SABA, short-acting β_2 -agonist; SC, subcutaneous.)

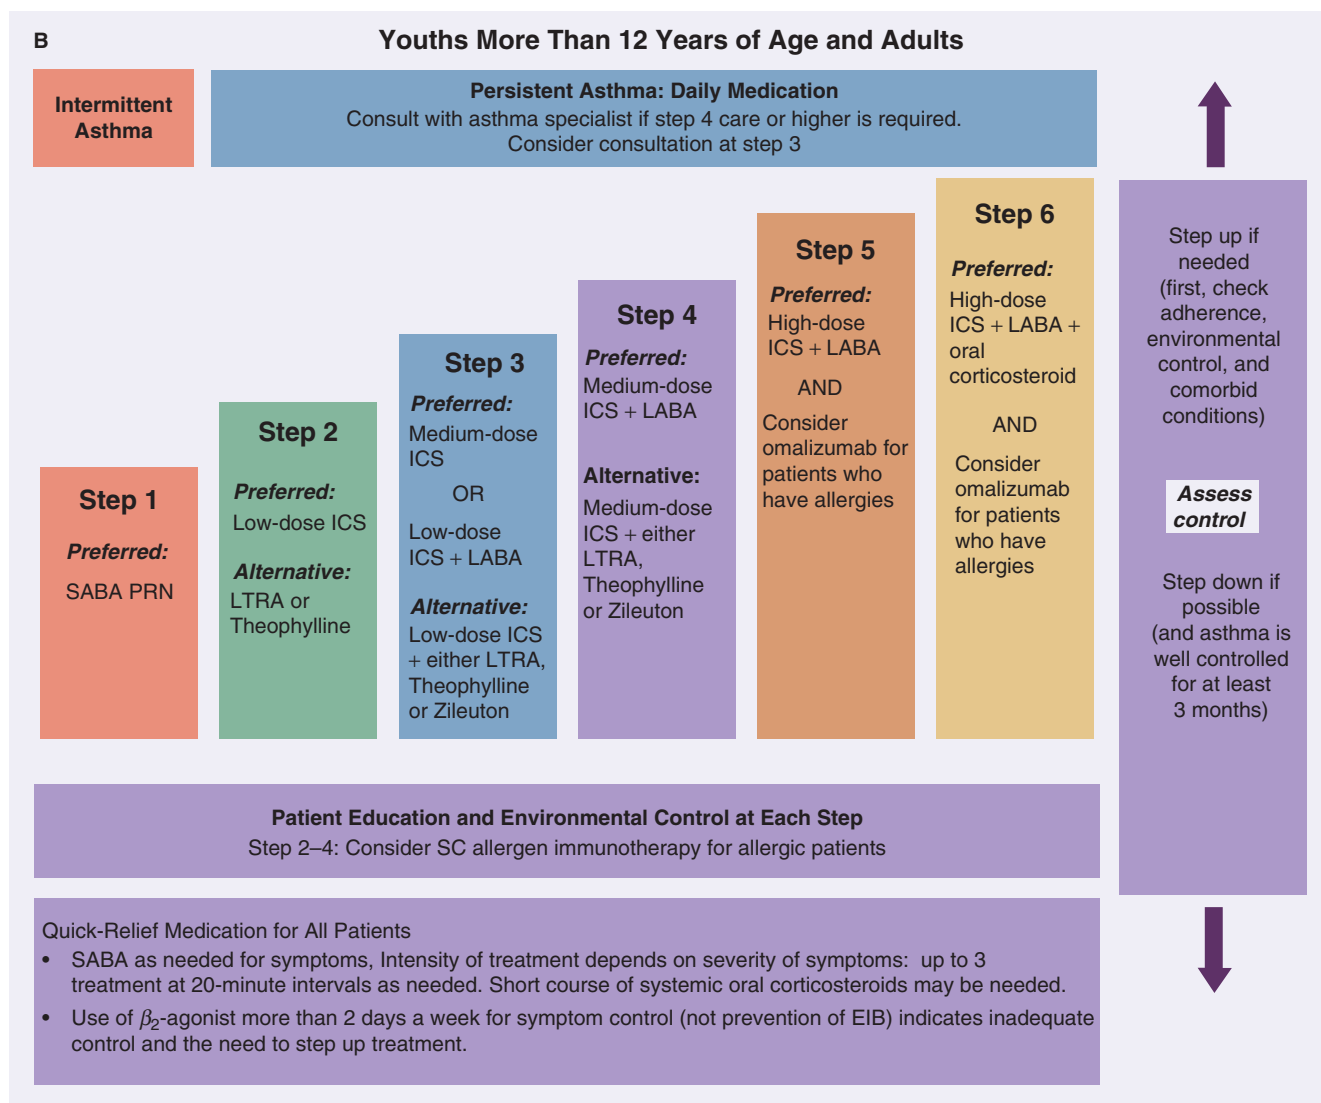

FIGURE 14-2. (Continued)

► Persistent Chronic Asthma

Patients with persistent chronic asthma require daily long-term control therapy. ICS are the long-term control medication of choice at all levels of severity (mild, moderate, and severe) and in all age groups.² SABAs are prescribed for all patients with chronic asthma for use on an as-needed basis.

After initiating therapy, patients are monitored within 2 to 6 weeks to ensure that asthma control has been achieved. Table 14-6 describes how to assess patients for asthma control. Before increasing therapy, the patient's inhaler technique and adherence to therapy is evaluated. Medication intensification is based on individualized response to therapy.²⁹

Patients with controlled asthma are monitored at 1- to 6-month intervals to ensure that control is maintained. A gradual stepdown in long-term controller therapy is attempted once control has been maintained for at least 3 months. Controversy exists about how to taper long-term controller medication. Current literature supports decreasing

the ICS dose before removing the LABA, despite FDA warnings to use LABA treatment for the shortest time period.⁴⁷

Treatment of Acute Asthma

9 In acute asthma, early and appropriate intensification of therapy is important to resolve the exacerbation and prevent relapse and future severe airflow obstruction. Early and aggressive treatment is necessary for quick resolution.⁴⁸

The optimal treatment of acute asthma depends on the severity of the exacerbation. The patient's condition usually deteriorates over several hours, days, or weeks. Figure 14-3 is an algorithm for home management of an asthma exacerbation.

Based on the initial response to SABA therapy, the severity of the exacerbation is assessed, and treatment is appropriately intensified. Patients deteriorating quickly or not responding to quick-relief medications should go to the emergency department for assessment and treatment of the asthma exacerbation. Figure 14-4 provides a treatment

Table 14-6

Assessing Asthma Control and Adjusting Therapy Based on Age¹

Components of Control	Well Controlled			Not Well Controlled			Very Poorly Controlled		
	Ages 0-4	Ages 5-11	12 Years or More	Ages 0-4	Ages 5-11	12 Years or More	Ages 0-4	Ages 5-11	12 Years or More
Symptoms	2 days/week or less but not more than once each day	2 days/week or less	2 days/week or less	More than 2 days/week or multiple times on 2 days/week or less	More than 2 days/week	More than 2 days/week	Throughout the day →		
Nighttime awakenings	1 time/month or less		2 times/month or less	More than 1 time/month	2 times/week or more	1-3 times/week	More than 1 time/week	2 times/week or more	4 times/week or more
SABA use for symptoms (not EIB prevention)	2 days/week or less			More than 2 days/week →			Several times per day →		
Interference with normal activity	None →			Some limitation →			Extremely limited →		
FEV ₁ or PEF _r	N/A	More than 80%	More than 80% predicted/personal best	N/A	60-80%	60-80% predicted/personal best	N/A	Less than 60%	Less than 60% predicted/personal best

Questionnaires: ATAQ ACQ ACT	N/A	N/A	0 0.75 or less ^a 20 or more	N/A	N/A	1-2 1.5 or more 16-19	N/A	N/A	3-4 N/A 15 or less
Exacerbations requiring oral systemic corticosteroids	0-1/year. Consider severity and interval since last exacerbation			2-3/year	2/year or more	2/year or more	More than 3/year	2/year or more	2/year or more
Reduction in lung growth or progressive loss of lung function	N/A	Requires long-term follow-up		N/A	Requires long-term follow-up		N/A	Requires long-term follow-up	
Treatment-related ADRs	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate with specific levels of control but should be considered in the overall assessment of risk.								
Recommended action for treatment. See Figure 14-4 for treatment steps.	Maintain current step. Follow-up every 1-6 months. Consider step down if well controlled at 3 months.			Step up 1 step. Reevaluate in 2-6 weeks. If ADRs, consider alternative treatment options.			Consider short course of systemic (oral) corticosteroids. Step up 1-2 steps. Reevaluate in 2 weeks. If ADRs, consider alternative treatment options.		

^aACQ values of 0.76-1.4 are indeterminate regarding well-controlled asthma.

ACT, Asthma Control Test; ACQ, Asthma Control Questionnaire; ATAQ, Asthma Therapy Assessment Questionnaire; ADR, adverse drug reaction; EIB, exercise-induced bronchospasm; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; N/A, safety and efficacy not established; PEF_r, peak expiratory flow rate; SABA, short-acting β_2 -agonist.

Patient Encounter 5

TM is a 6-year-old boy seen in the emergency department for an asthma exacerbation. He has not seen the doctor in over 1 year, and his parents ran out of refills for his asthma medications. He was previously prescribed budesonide 90 mcg, 1 inhalation twice daily and levalbuterol 2 puffs every 4 hours as needed for shortness of breath. His weight today is 50 pounds (23 kg). The physician makes the diagnosis of a moderate asthma exacerbation.

What medication regimen would you recommend for TM while in the emergency department?

The patient's asthma improves, and he is ready to be discharged home from the emergency department. His mother informs you that she is not able to afford the asthma medication. His insurance provider has albuterol, fluticasone, and mometasone on its formulary. Based on this information, what medication regimen would you recommend upon discharge from the emergency department?

Provide the patient and his mother with a written asthma action plan. The parent refuses to monitor peak flow readings.

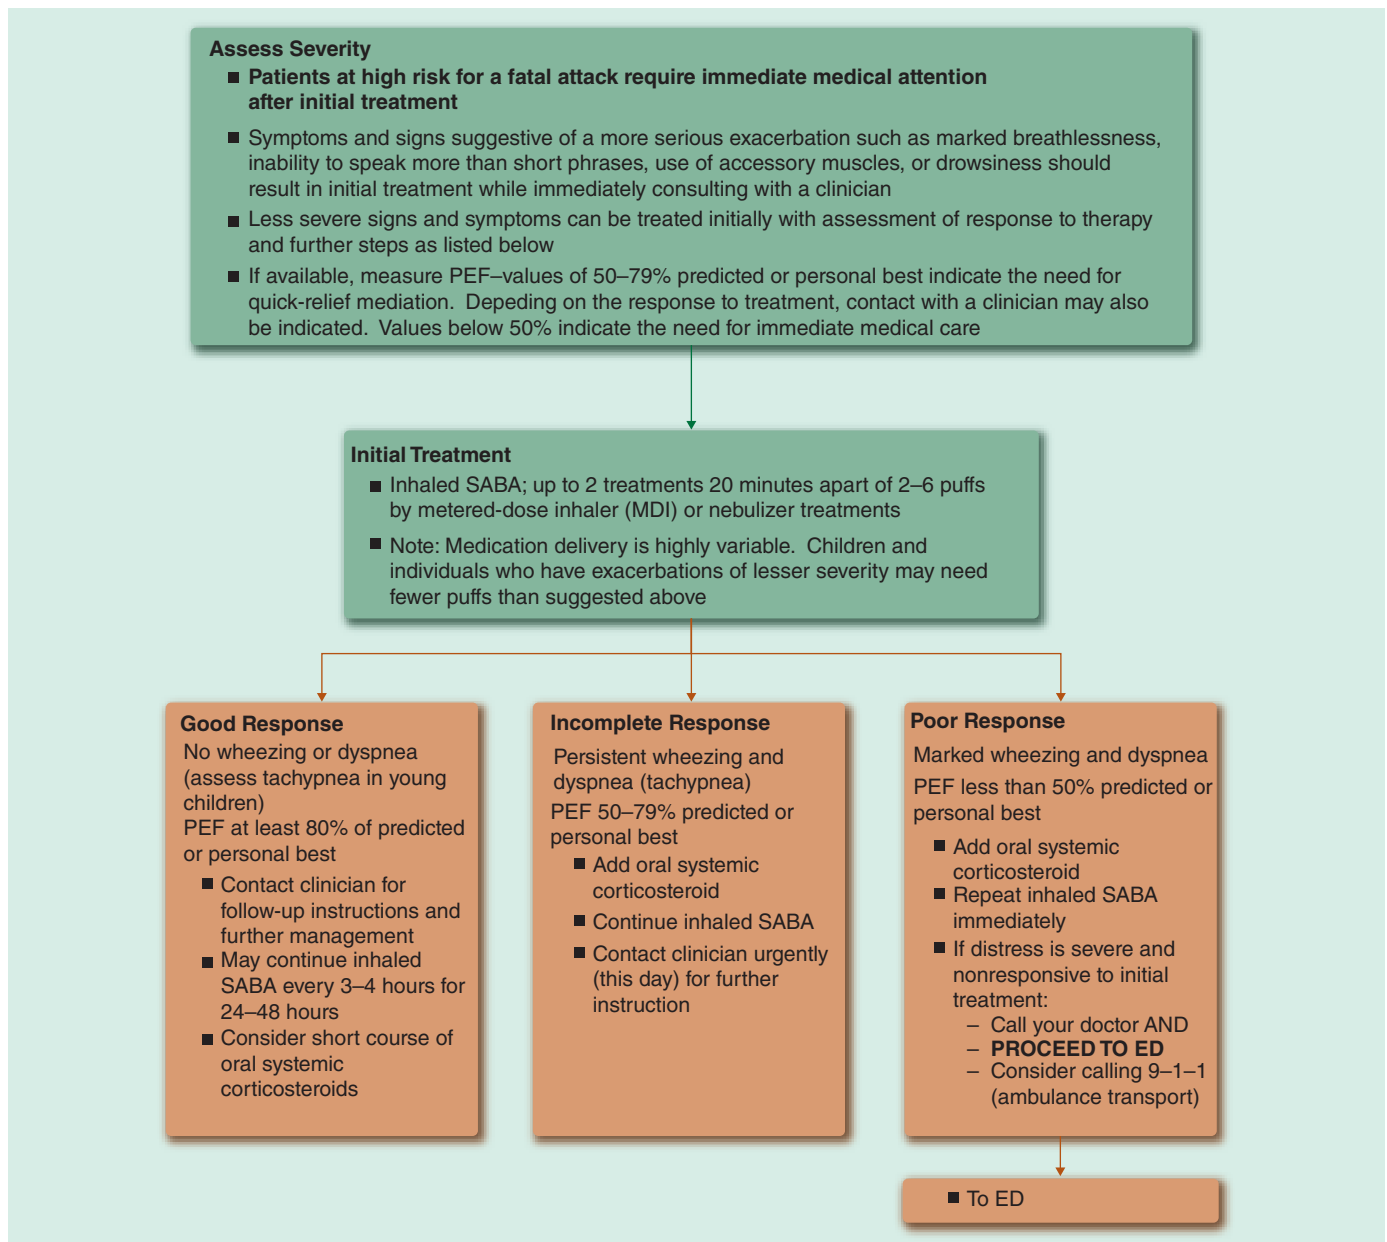

FIGURE 14-3. Management of asthma exacerbations: home treatment. (ED, emergency department; MDI, metered-dose inhaler; PEF, peak expiratory flow; SABA, short-acting β_2 -agonist; SC, subcutaneous.) (From NHLBI National Asthma Education and Prevention Program, Expert Panel Report-3. Guidelines for the diagnosis and management of asthma. NIH Publication No. 07-4051. Bethesda, MD: U.S. Department of Health and Human Services, 2007, <http://www.nhlbi.nih.gov/guidelines/asthma>.)

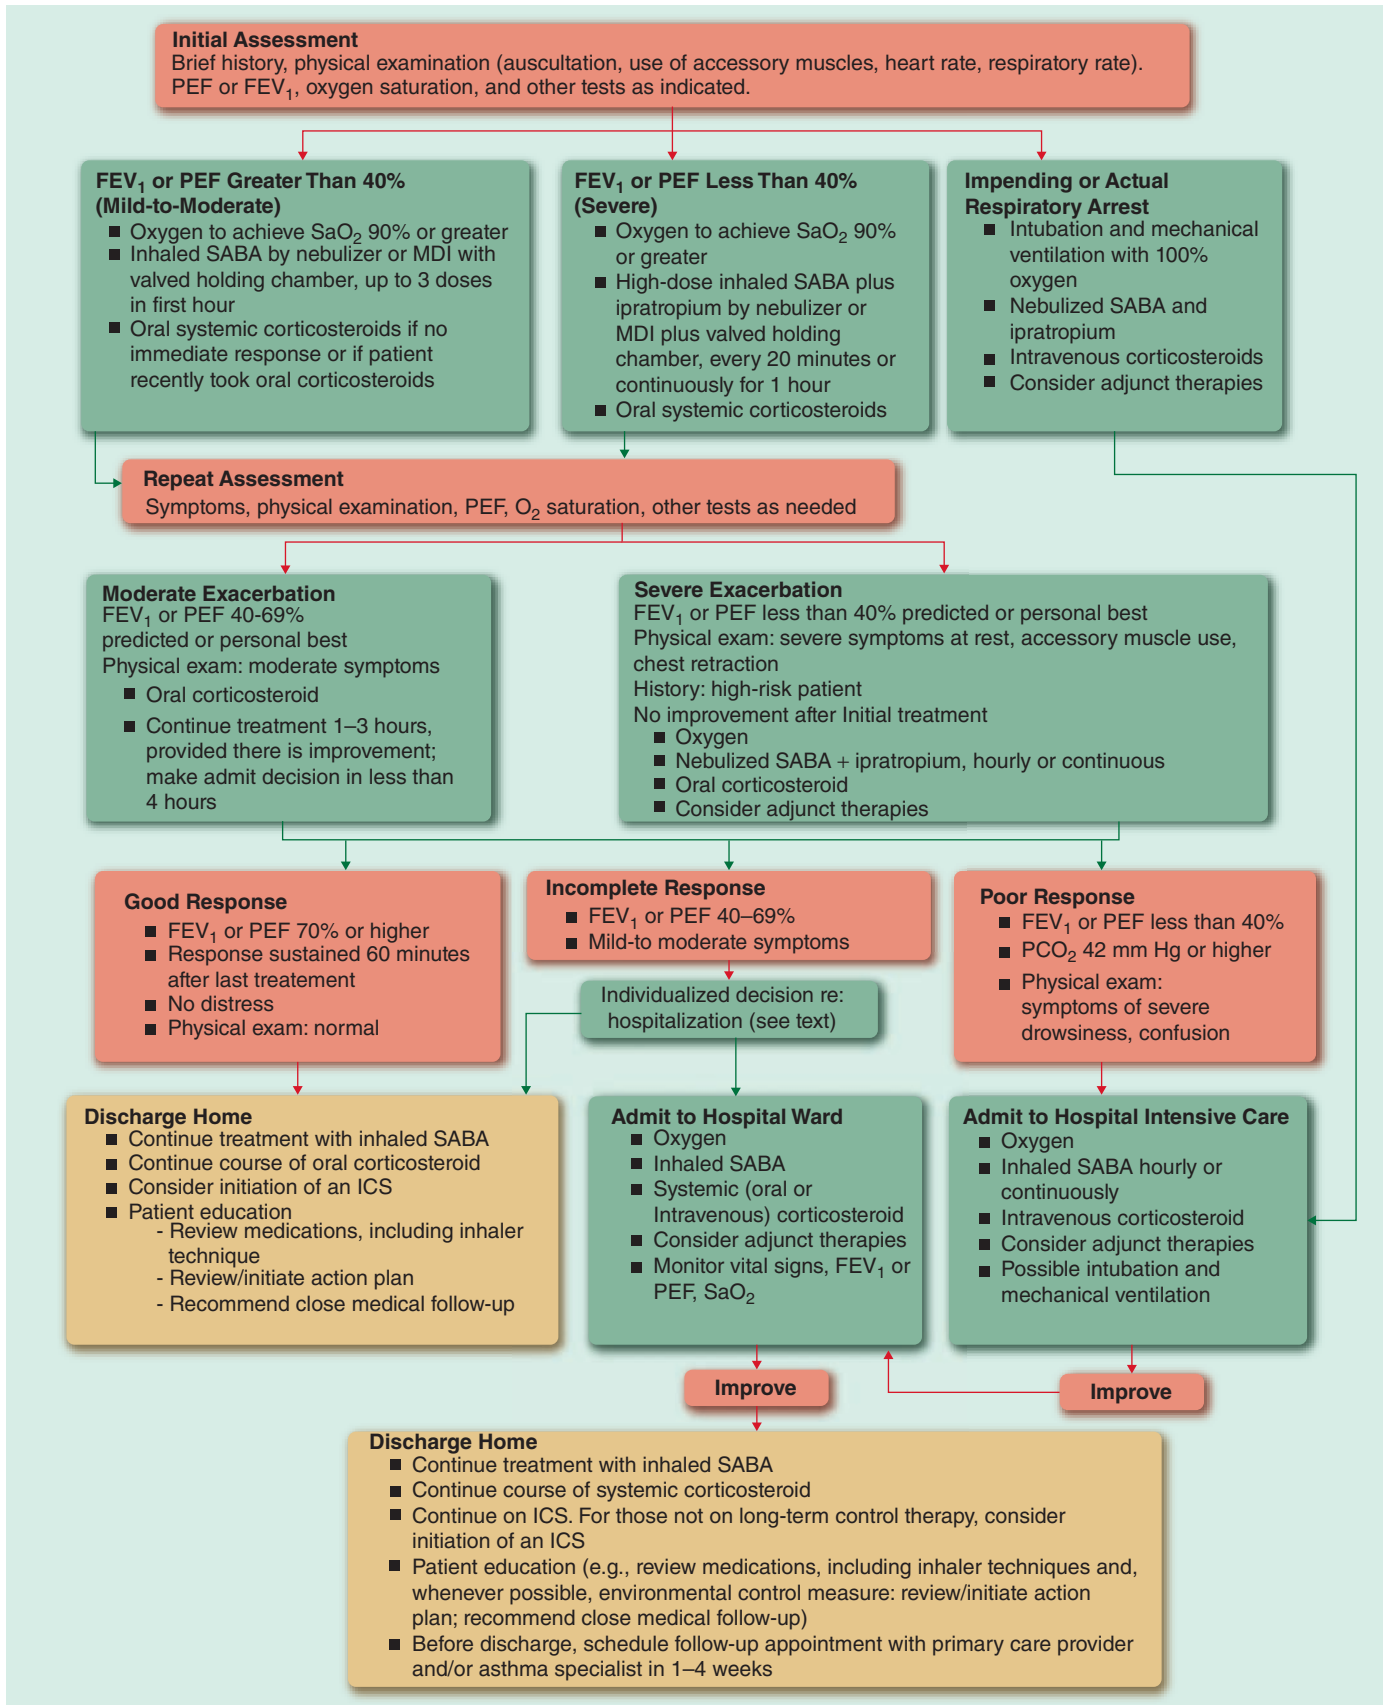

FIGURE 14-4. Management of asthma exacerbations: emergency department and hospital-based care. (FEV₁, forced expiratory volume in 1 second; ICS, inhaled corticosteroid; MDI, metered-dose inhaler; Pco₂, partial arterial pressure of carbon dioxide; PEF, peak expiratory flow; SABA, short-acting β_2 -agonist; Sao₂, oxygen saturation.) (From Ref. 2.)

algorithm for treating an asthma exacerbation in the emergency department. Patients responding to therapy in the emergency department with a sustained response to a SABA are discharged home. Patients are discharged with an SABA, a 3- to 10-day course of oral corticosteroid, an ICS, and perhaps other appropriate long-term controller medications.

Patients who do not respond adequately to intensive therapy in the emergency department within 3 to 4 hours are admitted to the hospital. During hospitalization, oxygen, continuous nebulization of SABA, systemic corticosteroids, and alternative treatments such as magnesium and heliox may be used to treat the exacerbation.

Patients with oxygen saturation less than 90% (less than 95% in children, pregnant women, and patients with coexisting heart disease) receive oxygen with the dose adjusted to keep oxygen saturation above these levels. Administration of low oxygen concentrations (less than 30% of the fraction of inspired air) by nasal cannula or facemask is usually sufficient to reverse hypoxemia in most patients.

Asthma Self-Management

Asthma self-management plans give patients the freedom to adjust therapy based on personal assessment of disease control using a predetermined plan. Written asthma action plans are part of standard care for asthma, although action plans alone do not improve asthma outcomes.⁴⁹

The plan includes instructions on daily management and how to recognize and handle worsening asthma.² Asthma control is assessed by evaluating symptoms of worsening asthma and/or monitoring PEF. Early signs of deterioration include increasing nocturnal symptoms, increasing use of inhaled SABAs, or symptoms that do not respond to increased use of inhaled SABAs. Providing patients with a prescription for oral corticosteroids to use on an as-needed basis for the initiation of an asthma exacerbation is part of asthma self-management.

Measurement of PEF is considered for patients with moderate to severe persistent asthma, a poor perception of worsening asthma or airflow obstruction, and those with an unexplained response to environmental or occupational exposures.² PEF is measured daily in the morning upon waking or when asthma symptoms worsen. For PEF-based asthma action plans, the patient's personal best PEF is established over a 2- to 3-week period when the patient is receiving optimal treatment.² Subsequent PEF measurements are evaluated in relation to their variability from the patient's best PEF measurement. PEF measurements in the range of 80% to 100% of personal best (green zone) indicate that current therapy is acceptable. A PEF in the range of 50% to 79% of personal best (yellow zone) indicates an impending exacerbation, and therapy is intensified with SABA therapy, possibly oral corticosteroids, and a call to the physician. A PEF less than 50% (red zone) signals a medical alert; patients use their SABA immediately, take oral corticosteroids, and go to the emergency department.

Special Populations

► Pregnancy

Approximately 4% to 8% of pregnant women are affected by asthma with about a third experiencing worsening asthma during pregnancy.⁵⁰ Because uncontrolled asthma is a greater risk to the fetus than asthma medication use, it is safer for pregnant women to have asthma treated with medications than to experience worsening asthma. Consequently, asthma exacerbations should be managed aggressively with pharmacotherapy. The stepwise approach to asthma therapy in pregnancy is similar to that for the general population.

Budesonide has the most safety data in humans and is the preferred ICS; it is the only ICS classified as pregnancy category B. However, there are no data indicating that other ICS contribute to increased risk to the mother or fetus.

- Albuterol is the drug of choice for the treatment of asthma symptoms and exacerbations in pregnancy.

► Young Children

Although asthma is the most common disease in children, diagnosing and monitoring it in this population is challenging. Treatment in children 0 to 4 years of age is extrapolated from studies completed in adults and older children. Albuterol and ICS are the treatments of choice in this group. However, use of montelukast is common because of the drug formulation. Route of delivery is an important issue. Nebulization treatment is commonly used, and MDI with VHC is becoming more popular due to its decreased time of administration compared with nebulization. Budesonide is the only corticosteroid available in nebulization form and is approved for use in this age group.⁵¹

OUTCOME EVALUATION

Chronic Asthma

- Assess symptoms such as wheezing, shortness of breath, chest tightness, cough, nocturnal awakenings, and activity level. Use validated questionnaires (such as the Asthma Control Test) to objectively document control.
- Monitor the use of SABAs. Using an SABA more than twice a week in intermittent asthma may indicate the need to initiate long-term control therapy. Use of more than one canister per month indicates the need to step up long-term control therapy.
- Determine the frequency of patient exacerbations. Frequent exacerbations, unscheduled clinic visits, emergency department visits, and hospitalizations due to asthma may indicate the need to reassess the patient's asthma regimen and environment.
- Measure the patient's lung function using office spirometry at each clinic visit for patients older than 5 years.
- Identify environmental factors triggering asthma exacerbations and provide trigger avoidance recommendations.

Patient Care and Monitoring

Chronic Asthma

1. Ask about patient (or caregiver) goals and satisfaction with asthma control.
2. Assess asthma control with a validated questionnaire (Asthma Control Test, Asthma Therapy Assessment Questionnaire, or Asthma Control Questionnaire).
3. Evaluate the number of asthma exacerbations since the last clinic visit, including emergency department visits and/or oral corticosteroid use.
4. Measure spirometry at each clinical visit in patients older than 5 years.
5. Evaluate medication issues, including side effects, adherence, cost, and any patient concerns.
6. Review proper use of inhalers, including indication, technique, and determining when to get a refill.
7. Provide an updated asthma action plan with medication changes at least yearly.
8. Review environmental asthma triggers and avoidance plans.
9. Update immunizations.
10. Check spirometry yearly.
11. Schedule follow-up physician visits depending on asthma control (2 weeks to 6 months).

Acute Asthma

1. Assess for wheezing, chest tightness, and shortness of breath.
2. Obtain and evaluate peak flow measurement.
3. Assess severity of dyspnea (i.e., it occurs only with activity, it limits activity, it occurs at rest and interferes with conversation, or the patient is too dyspneic to speak).
4. Evaluate response to SABA.
5. Check respiratory rate.
6. Obtain oxygenation saturation.
7. Assess use of accessory muscles in infants.
8. Perform other tests as appropriate: arterial blood gases, serum electrolytes, chest radiography, and electrocardiogram.
9. Review previous need for emergency department and hospital management for asthma exacerbations.
10. Plan for patient and family response to asthma exacerbations.
11. Provide education about proper inhaler technique, indication and proper use of medications, and self-titration of medications with worsening asthma.
12. Educate about environmental triggers.
13. Provide a follow-up appointment with the primary care physician within 1 to 4 weeks.

- Perform medication reconciliation to identify discrepancies in medications prescribed and used by the patient and to determine drug and disease state interactions.
- Assess the patient's inhaler technique at every visit and always ensure proper technique before stepping up therapy.
- Determine adherence to long-term controller medications. Assess the patient's understanding of the indication for long-term controller medication and identify adverse events, cost issues, and need for refills.
- Review and update the patient's asthma action plan and provide the patient with a written copy of the plan.
- Update the patient's immunization status and provide an annual influenza vaccination.

- Measure oxygenation using pulse oximetry and provide oxygen via nasal cannula if needed. The goal oxygen saturation is greater than 90% in adults and greater than 95% in children, pregnant women, and patients with coexisting cardiovascular disease.
- Obtain a P_{CO_2} measurement via arterial blood gases in patients with severe asthma exacerbations. An increased P_{CO_2} indicates the potential for respiratory failure.
- Monitor serum potassium for hypokalemia upon admission and periodically throughout the admission in patients receiving high-dose or continuous nebulization of SABA.

Acute Asthma

In addition to the outcomes measured for chronic asthma, acute asthma monitoring also includes the following:

- Measure PEF and assess asthma symptoms. The goal PEF measurement is 70% of the patient's personal best peak flow after the first three doses of an inhaled SABA and improved asthma symptoms. Spirometry is not usually conducted in the emergency department.

Abbreviations Introduced in This Chapter

AHR	Airway hyperresponsiveness
CFC	Chlorofluorocarbon
CYP	Cytochrome P-450 isoenzyme
DPI	Dry powder inhaler
EPR-3	Expert Panel Report-3
FEV ₁	Forced expiratory volume in 1 second
FVC	Forced vital capacity
HFA	Hydrofluoroalkane

ICS	Inhaled corticosteroid
IgE	Immunoglobulin E
LABA	Long-acting β_2 -agonist
MDI	Metered-dose inhaler
NAEPP	National Asthma Education and Prevention Program
NHLBI	National Heart, Lung, and Blood Institute
NSAID	Nonsteroidal anti-inflammatory drug
Pao ₂	Partial arterial pressure of oxygen
Pco ₂	Partial arterial pressure of carbon dioxide
PEF	Peak expiratory flow
SABA	Short-acting β_2 -agonist
T _H 2	Type 2 T-helper CD4+ cell

15 Chronic Obstructive Pulmonary Disease

Tara R. Whetsel and Nicole D. Verkleeren

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of chronic obstructive pulmonary disease (COPD).
2. Identify signs and symptoms of COPD.
3. List the treatment goals for a patient with COPD.
4. Design an appropriate COPD treatment regimen based on patient-specific data.
5. Develop a monitoring plan to assess effectiveness and adverse effects of pharmacotherapy for COPD.
6. Formulate an appropriate education plan for a patient with COPD.

KEY CONCEPTS

- 1 Inflammation plays a key role in the pathophysiology of chronic obstructive pulmonary disease (COPD), but it differs from that seen in asthma; therefore, the use of and response to anti-inflammatory medications are different.
- 2 An integrated approach of health maintenance (e.g., smoking cessation), drug therapy, and supplemental therapy (e.g., oxygen and pulmonary rehabilitation) should be used in a stepwise manner. Symptom severity and risk of COPD exacerbations can be used to guide therapy decisions.
- 3 Smoking cessation slows the rate of decline in pulmonary function in patients with COPD.
- 4 Bronchodilators are the mainstay of treatment for symptomatic COPD. They reduce symptoms and improve exercise tolerance and quality of life.
- 5 Inhaled corticosteroids are recommended for patients with severe and very severe COPD and frequent exacerbations that are not adequately controlled by long-acting bronchodilators.
- 6 Antibiotics should be used in patients with COPD exacerbations who: (a) have all three cardinal symptoms (increased dyspnea, increased sputum volume, and increased purulence); (b) have increased sputum purulence and one other cardinal symptom; or (c) experience a severe exacerbation requiring mechanical ventilation.

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is a progressive disease characterized by airflow limitation that is not fully reversible. It is caused by exposure to noxious particles or gases, most commonly cigarette smoke. It is a major cause of morbidity and mortality and a leading cause of disability in the United States.

Previous definitions of COPD included chronic bronchitis and emphysema. Chronic bronchitis is defined clinically as a chronic productive cough for at least 3 months in each of two consecutive years in a patient in whom other causes have been excluded.¹ Chronic bronchitis can exist in patients with normal spirometry and may precede the development of COPD. Emphysema is defined pathologically as destruction of alveoli.¹ The major risk factor for both conditions is cigarette smoking, and many patients share characteristics of each condition. Therefore, guidelines have moved away from using these subsets and instead focus on chronic airflow limitation.

The Global Initiative for Chronic Obstructive Lung Disease (GOLD) is an expert panel of health professionals who have developed a consensus document with recommendations for the diagnosis and care of patients with COPD.¹ The online document is updated annually and is commonly referred to as the GOLD guidelines. Major revisions were released in January 2012. The American College of Physicians (ACP), American College of Chest Physicians (ACCP), American Thoracic Society (ATS), and European Respiratory Society (ERS) have jointly published guidelines for the diagnosis

and management of stable COPD.² The GOLD guidelines are more comprehensive and include recommendations for managing exacerbations and comorbidities, whereas the ACP guidelines provide a more thorough review of major clinical trials impacting recommendations.

EPIDEMIOLOGY AND ETIOLOGY

In 2008, 13.1 million U.S. adults 18 years of age and older were estimated to have COPD.³ The true prevalence is larger; COPD is underdiagnosed because many patients have few or no symptoms in the early stages.

COPD is the third leading cause of death in the United States; in 2007, 124,477 adults died from the disease.³ In 2010, COPD was estimated to cost the United States \$49.9 billion, with direct medical costs accounting for \$29.5 billion of the total.³ Morbidity, mortality, and costs are all expected to increase; by 2030, it is expected to be the fourth leading cause of death worldwide.¹

Exposures and host factors play a role in the development of COPD. Cigarette smoking is the leading cause of COPD and accounts for 80% to 90% of cases in developed countries.⁴ Environmental tobacco smoke (i.e., secondhand smoke) may increase the risk of COPD.¹ Occupational exposure to dusts and chemicals (vapors, irritants, and fumes) also plays a role. Environmental air pollution has been implicated as an etiologic factor, but its exact role is unclear. Not all smokers develop clinically significant COPD, which suggests that genetic susceptibility plays a role. The best documented genetic factor is a rare hereditary deficiency of α_1 -antitrypsin (AAT). Severe deficiency of this enzyme results in premature and accelerated development of emphysema. Asthma and airway hyperresponsiveness have been identified as risk factors, but how they influence the development of COPD is unknown. Failure to reach maximal lung function, due to recurrent infections or exposure to tobacco smoke during childhood, may also increase the risk of COPD.

PATHOPHYSIOLOGY

COPD is characterized by pathologic changes in the central airways, peripheral airways, lung **parenchyma**, and pulmonary vasculature. Chronic inflammation in the lung from repeated exposure to noxious particles and gases is primarily responsible for these changes.¹ An imbalance between **proteinases** and **antiproteinases** in the lung and oxidative stress are also thought to be important in the pathogenesis of COPD. These processes may be a result of ongoing inflammation or may arise from environmental (e.g., oxidants in cigarette smoke) or genetic (e.g., AAT deficiency) factors (**Fig. 15-1**).¹ In addition to these destructive processes, chronic inflammation and exposure to noxious particles and gases disrupts or impairs the normal protective and repair mechanisms.

Inflammation is present in the lungs of all smokers. It is unclear why only 15% to 20% of smokers develop

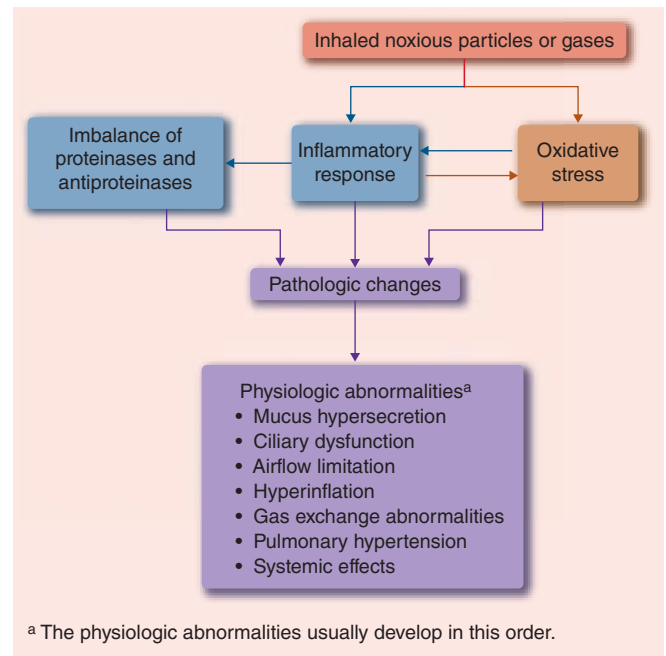

FIGURE 15-1. Pathophysiology of COPD.

COPD, but susceptible individuals appear to have an exaggerated inflammatory response.⁵ ① *The inflammation of COPD differs from that seen in asthma, so the use of and response to anti-inflammatory medications are different.* The inflammation of asthma is mainly mediated through eosinophils and mast cells. In COPD, the primary inflammatory cells include neutrophils, macrophages, and CD8⁺ T lymphocytes.⁶ Eosinophils may be increased in some patients, particularly during exacerbations. Activated inflammatory cells release a variety of mediators, most notably leukotriene B₄, interleukin-8, and tumor necrosis factor- α (TNF- α). Various proteinases, such as elastase, cathepsin G, and proteinase-3, are secreted by activated neutrophils. These mediators and proteinases are capable of sustaining inflammation and damaging lung structures.

Proteinases and antiproteinases are part of the normal protective and repair mechanisms in the lungs. The imbalance of proteinase–antiproteinase activity in COPD is a result of either increased production or activity of destructive proteinases or inactivation or reduced production of protective antiproteinases. AAT (an antiproteinase) inhibits trypsin, elastase, and several other proteolytic enzymes. Deficiency of AAT results in unopposed proteinase activity, which promotes destruction of alveolar walls and lung parenchyma, leading to emphysema.

Markers of oxidative stress (e.g., hydrogen peroxide, nitric oxide, and 8-isoprostane) have been found in the epithelial fluid, breath, and urine of cigarette smokers and patients with COPD.¹ Increased oxidative stress contributes to COPD in a variety of ways. Oxidants (e.g., reactive oxygen species, superoxide, and nitric oxide) can react with and damage a variety of molecules leading to cell

dysfunction and damage to the lung extracellular matrix. Oxidative stress promotes inflammation and contributes to the proteinase–antiproteinase imbalance by reducing antiproteinase activity. In addition, oxidants constrict airway smooth muscle, contributing to reversible airway narrowing.

In the central airways (the trachea, bronchi, and bronchioles greater than 2 to 4 mm in internal diameter), inflammatory cells and mediators stimulate mucus-secreting gland **hyperplasia** and mucus hypersecretion. Mucus hypersecretion and ciliary dysfunction lead to chronic cough and sputum production. The major site of airflow obstruction is the peripheral airways (small bronchi and bronchioles with an internal diameter less than 2 mm). Three mechanisms are postulated to be involved in the narrowing of these small airways.⁵ First, airways may be blocked by inflammatory exudates and mucus hypersecretion. Second, loss of elasticity and destruction of alveolar attachments leads to loss of support and closure of small airways during expiration. Third, infiltration of inflammatory cells, increased smooth muscle tissue, and fibrosis cause thickening of airway walls. Of these three mechanisms, the structural changes in the airway walls are the most important cause of fixed airflow obstruction.

As airflow obstruction worsens, the rate of lung emptying is slowed and the interval between inspirations does not allow expiration to the relaxation volume of the lungs. This leads to pulmonary hyperinflation, which initially only occurs during exercise but later is also seen at rest. Hyperinflation contributes to the discomfort associated with airflow obstruction by flattening the diaphragm and placing it at a mechanical disadvantage.

In advanced COPD, airflow obstruction, damaged bronchioles and alveoli, and pulmonary vascular abnormalities lead to impaired gas exchange. This results in **hypoxemia** and eventually **hypercapnia**. Hypoxemia is initially present only during exercise but occurs at rest as the disease progresses. Inequality in the **ventilation-to-perfusion ratio** (V_A/Q) is the major mechanism behind hypoxemia in COPD. As hypoxemia worsens, the body may compensate by increasing the production of erythrocytes in an attempt to increase oxygen delivery to tissues.

Pulmonary hypertension develops late in the course of COPD, usually after the development of severe hypoxemia. It is the most common cardiovascular complication of COPD and can result in **cor pulmonale**, or right-sided heart failure. Hypoxemia plays the primary role in the development of pulmonary hypertension by causing vasoconstriction of the pulmonary arteries and promoting vessel wall remodeling. Destruction of the pulmonary capillary bed by emphysema further contributes by increasing the pressure required to perfuse the pulmonary vascular bed. Cor pulmonale is associated with venous stasis and thrombosis that may result in pulmonary embolism. Another important systemic effect is the progressive loss of skeletal muscle mass, which contributes to exercise limitations and declining health status. These extrapulmonary effects may contribute to disease severity and should not be overlooked.

CLINICAL PRESENTATION AND DIAGNOSIS

See text box on the next page for the clinical presentation of COPD.

Diagnosis

A suspected diagnosis of COPD should be based on the patient's symptoms and history of exposure to risk factors. **Spirometry** is required to confirm the diagnosis, using the ratio of forced expiratory volume in 1 second (FEV_1) to forced vital capacity (FVC). A postbronchodilator FEV_1/FVC ratio less than 70% confirms airflow limitation that is not fully reversible.^{1,2} Spirometry results can further be used to classify severity of airflow limitation (**Table 15-1**). Full pulmonary function tests (PFTs) with lung volumes and diffusion capacity and arterial blood gases (ABGs) are not necessary to establish the diagnosis or severity of COPD.

Table 15-1

GOLD Classification of Severity of Airflow Limitation in Patients with FEV_1/FVC Less Than 70%

Classification	Postbronchodilator FEV_1
GOLD 1: Mild	80% predicted or greater
GOLD 2: Moderate	50–79% predicted
GOLD 3: Severe	30–49% predicted
GOLD 4: Very severe	Less than 30% predicted

FEV_1 , forced expiratory volume in 1 second; FVC, forced vital capacity; GOLD, Global Initiative for Chronic Obstructive Lung Disease.

Patient Encounter, Part 1

MB, a 58-year-old woman with a medical history of osteoarthritis, presents to the clinic complaining of shortness of breath and cough that began 3 or 4 years ago. Her symptoms have gradually worsened over the past year. She is only able to walk one flight of stairs without getting short of breath. In the morning she has a cough associated with yellowish phlegm production. She is a current smoker of about one and a half packs of cigarettes a day and has done so for the last 38 years. She drinks on average one beer a day. She denies any recreational drug use. She does not have any significant occupational exposures to dust, gases, or fumes.

What information is suggestive of COPD?

What risk factors does she have for COPD?

What additional information do you need to create a treatment plan for this patient?

Clinical Presentation of COPD

General

- Patients with COPD are asymptomatic initially. The disease is usually not diagnosed until declining lung function leads to significant symptoms and prompts patients to seek medical care.

Symptoms

- The onset of symptoms is variable and does not correlate well with severity of airflow limitation measured by FEV₁.¹
- Initial symptoms include chronic cough (for more than 3 months) that may be intermittent at first, chronic sputum production, and dyspnea on exertion.
- As COPD progresses, dyspnea at rest develops and the ability to perform activities of daily living declines.

Signs

- Observation of the patient may reveal use of accessory muscles of respiration (manifested as paradoxical movements of the chest and abdomen, in a seesaw-type motion), pursed-lips breathing, and hyperinflation of the chest with increased anterior–posterior diameter (“barrel chest”).
- On lung auscultation, patients may have distant breath sounds, wheezing, a prolonged expiratory phase, and **rhonchi**.

- In advanced COPD, signs of hypoxemia may include **cyanosis** and tachycardia.
- Signs of cor pulmonale include increased pulmonic component of the second heart sound, jugular venous distention (JVD), lower extremity edema, and hepatomegaly.

Laboratory Tests

- Hematocrit may be elevated and may exceed 55% (0.55) (**polycythemia**).
- Pulse oximetry should be obtained in patients with an FEV₁ less than 35% predicted or signs or symptoms suggestive of cor pulmonale or respiratory failure.¹ If oxygen saturation is less than 92%, ABGs should be assessed. COPD patients characteristically exhibit normal or increased arterial carbon dioxide tension (Paco₂) and decreased arterial oxygen tension (Pao₂).
- An AAT level should be obtained in younger patients (less than 45 years old) presenting with COPD signs and symptoms, especially if there is a strong family history of emphysema.

It is important to distinguish COPD from asthma because treatment and prognosis differ. Differentiating factors include age of onset, smoking history, triggers, occupational history, and degree of reversibility measured by pre- and postbronchodilator spirometry. In some patients, a clear distinction between asthma and COPD is not possible. Management of these patients should be similar to that of asthma. Bronchiectasis, cystic fibrosis, obliterative bronchiolitis, congestive heart failure, and tuberculosis are other possible differential diagnoses that are usually easier to distinguish from COPD. Chest radiography or high-resolution computed tomography (CT) along with patient presentation help rule out these other lung diseases.

TREATMENT

Desired Outcomes

- The goals of COPD management include: (a) smoking cessation, (b) reducing symptoms, (c) improving exercise tolerance, (d) minimizing the rate of decline in lung function, (e) maintaining or improving the quality of life, (f) preventing and treating exacerbations, and (g) limiting complications.

General Approach to Treatment

- 2 An integrated approach of health maintenance (e.g., smoking cessation), drug therapy, and supplemental therapy (e.g., oxygen and pulmonary rehabilitation) should be used in a stepwise manner. Symptom severity and risk of COPD exacerbations can be used to guide therapy decisions (Table 15–2). Figure 15–2 provides an overview of the management of stable COPD.

Nonpharmacologic Therapy

► Smoking Cessation

- 3 Smoking cessation slows the rate of decline in pulmonary function in patients with COPD.^{7,8} Stopping smoking can also reduce cough and sputum production and decrease airway reactivity. Therefore, it is a critical part of any treatment plan for patients with COPD. Unfortunately, achieving and maintaining cessation is a major challenge. A clinical practice guideline from the U.S. Public Health Service recommends a specific action plan depending on the current smoking status and desire to quit (Fig. 15–3).⁹ Brief interventions are effective and can increase cessation rates significantly. The five As and the five Rs can be used to guide brief interventions (Table 15–3).

Table 15-2

Assessment of Symptoms and Future Risk of Exacerbations

Patient Category ^a	Characteristics	Spirometric Classification	Exacerbations Per Year	mMRC Grade	CAT Score
A	Low risk, fewer symptoms	GOLD 1 or 2	0–1	0–1	Less than 10
B	Low risk, more symptoms	GOLD 1 or 2	0–1	2 or more	10 or more
C	High risk, fewer symptoms	GOLD 3 or 4	2 or more	0–1	Less than 10
D	High risk, more symptoms	GOLD 3 or 4	2 or more	2 or more	10 or more

mMRC, modified Medical Research Council Questionnaire; CAT, COPD Assessment Test; GOLD, Global Initiative for Chronic Obstructive Lung Disease.

^aWhen assessing risk, choose the highest risk according to spirometric classification or exacerbations per year. For symptom assessment, use mMRC or CAT; CAT is preferred because it provides a more comprehensive assessment. It is unnecessary to use both mMRC and CAT.

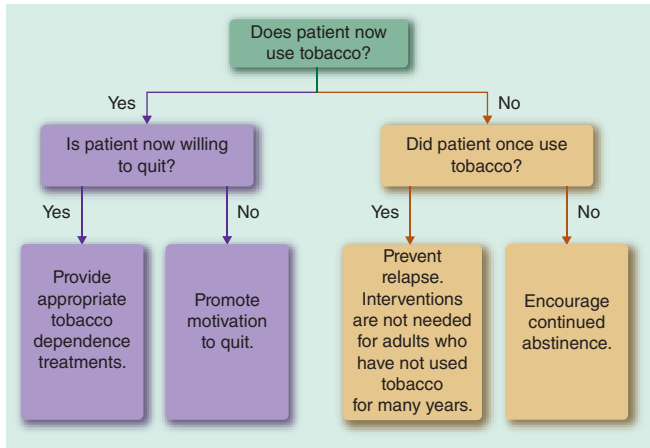

FIGURE 15-3. Algorithm for routine assessment of tobacco use status. (From Fiore MC, Jaén CR, Baker TB, et al. Treating tobacco use and dependence. Clinical Practice Guideline. U.S. Department of Health and Human Services, 2008, www.surgeongeneral.gov/tobacco/treating_tobacco_use08.pdf)

Table 15-3

Components of Brief Interventions for Tobacco Users

The 5 As for Brief Intervention

- Ask:** Identify and document tobacco-use status for every patient at every visit
- Advise:** Urge every tobacco user to quit
- Assess:** Is the tobacco user willing to make a quit attempt at this time?
- Assist:** Use counseling and pharmacotherapy to help patients willing to make a quit attempt
- Arrange:** Schedule follow-up contact, preferably within the first week after the quit date

The 5 Rs to Motivate Smokers Unwilling to Quit at Present

- Relevance:** Tailor advice and discussion to each smoker
- Risks:** Help the patient identify potential negative consequences of tobacco use
- Rewards:** Help the patient identify the potential benefits of quitting
- Roadblocks:** Help the patient identify barriers to quitting
- Repetition:** Repeat the motivational message at every visit

All tobacco users should be assessed for their readiness to quit and appropriate strategies implemented. Those who are ready to quit should be treated with a combination of counseling on behavioral and cognitive strategies and pharmacotherapy (nicotine replacement therapy, sustained-release bupropion, or varenicline; refer to Smoking Cessation in Chap. 36). In COPD patients, the likelihood of sustained abstinence is higher with nicotine replacement therapy than that with sustained-release bupropion.¹⁰

► Pulmonary Rehabilitation

Pulmonary rehabilitation results in significant and clinically meaningful improvements in dyspnea, exercise capacity,

health status, and healthcare utilization.¹¹ It should be prescribed for symptomatic patients with an FEV₁ less than 50% predicted.² Clinicians may consider pulmonary rehabilitation for symptomatic patients with an FEV₁ above 50% predicted, but evidence of benefit is less clear. A comprehensive pulmonary rehabilitation program should include exercise training, smoking cessation, nutrition counseling, and education.

Rehabilitation programs may be conducted in the inpatient, outpatient (most common), or home setting. The minimum length of an effective program is 6 weeks; the longer the program, the more sustained the results.^{1,11} It is important for patients to continue with a home exercise program to maintain the benefits gained from the pulmonary rehabilitation program.

► Long-Term Oxygen Therapy

Long-term administration of oxygen (more than 15 hours/day) to patients with chronic respiratory failure has been shown to reduce mortality and improve quality of life.^{1,2}

Oxygen therapy should be initiated in stable patients with COPD who have severe resting hypoxemia as determined by Pao₂ at or below 55 mm Hg (7.32 kPa) or oxygen saturation (Sao₂) at or below 88%^{1,2}; or Pao₂ between 55 and 60 mm Hg (7.32 to 7.98 kPa) or Sao₂ of 89% and evidence of pulmonary hypertension, peripheral edema suggesting congestive heart failure, or polycythemia.¹

The dual-prong nasal cannula is the standard means of delivering continuous flow of oxygen. The goal of therapy is to increase the baseline oxygen saturation to at least 90% and/or Pao₂ to at least 60 mm Hg (7.98 kPa), allowing adequate oxygenation of vital organs. The flow rate, expressed as liters per minute, must be increased during exercise and sleep and can be adjusted based on pulse oximetry. Hypoxemia also worsens during air travel; patients requiring oxygen should generally increase their flow rate by 3 L/min during flight.¹

Oxygen therapy should be continued indefinitely if it was initiated while the patient was in a stable state (rather than during an acute episode). Withdrawal of oxygen because of improved Pao₂ in such a patient may be detrimental.

► Surgery

Bulectomy, lung volume reduction surgery, and lung transplantation are surgical options for very severe COPD. These procedures may result in improved spirometry, lung volumes, exercise capacity, dyspnea, health-related quality of life, and possibly survival. Patient selection is critical because not all patients benefit. Refer to the ATS/ERS COPD standards for a detailed discussion of appropriate selection of surgical candidates.¹²

Pharmacologic Therapy of Stable COPD

The medications available for COPD are effective for reducing or relieving symptoms, improving exercise tolerance, reducing the number and severity of exacerbations, and improving quality of life. Evidence showing that medications slow the rate of decline in lung function is inconclusive.^{1,2}

► Bronchodilators

- 4 *Bronchodilators are the mainstay of treatment for symptomatic COPD. They reduce symptoms and improve exercise tolerance and quality of life.*¹ They can be used as needed for symptoms or on a scheduled basis to prevent or reduce symptoms. Bronchodilator drugs commonly used in COPD include β_2 -agonists, anticholinergics, and theophylline. The choice depends on availability, individual response, side-effect profile, and preferences. The inhaled route is preferred, but attention must be paid to proper inhaler technique training. Long-acting bronchodilators are more expensive than short-acting bronchodilators but are superior on important clinical outcomes, including frequency of exacerbations, degree of dyspnea, and health-related quality of life.^{1,13} Monotherapy with long-acting bronchodilators is preferred; combination therapy may be appropriate in symptomatic patients with an FEV₁ less than 60% predicted, although it is unclear when combination therapy provides added benefit.²

β_2 -Agonists β_2 -Agonists cause airway smooth muscle relaxation by stimulating adenylyl cyclase to increase the formation of cyclic adenosine monophosphate (cAMP). They may also improve mucociliary transport. β_2 -Agonists are available in inhalation, oral, and parenteral dosage forms; the inhalation route is preferred because of fewer adverse effects.

- These drugs are also available in short-acting and long-acting formulations (Table 15-4). The short-acting β_2 -agonists include albuterol (known as salbutamol outside the United States), levalbuterol (known as R-salbutamol outside the United States), and terbutaline. They are used as “rescue” therapy for acute symptom relief. Most COPD patients need continuous bronchodilator therapy on a scheduled basis every day. For these patients, short-acting β_2 -agonists are inconvenient because of the need for frequent dosing. In addition, short-acting β_2 -agonists have been associated with a slight, but statistically significant, loss of effectiveness when used regularly longer than 3 months (tachyphylaxis).¹⁴

Long-acting β_2 -agonists include salmeterol, formoterol, arformoterol, and indacaterol. Salmeterol is a partial agonist with a slower onset of action than short-acting β_2 -agonists. Formoterol is a more complete agonist and has an onset of action similar to that of albuterol. Arformoterol is the (R,R)-isomer of formoterol; both are available for nebulization, providing an alternative for patients with poor inhaler technique. Indacaterol is a partial agonist with a fast onset of action similar to that of albuterol. Full agonists (formoterol and arformoterol) produce greater response at full receptor capacity than partial agonists (salmeterol and indacaterol). Bronchodilator effects of long-acting β_2 -agonists last at least 12 hours except for indacaterol, which has a 24-hour duration of action. The U.S. FDA approved indacaterol at a lower dose (75 mcg) than that used in other countries. The effect of this lower dose on the rate of exacerbations is unknown. Formoterol and salmeterol decrease COPD exacerbations and improve exercise tolerance, dyspnea,

- and quality of life.¹³ Patients treated with long-acting β_2 -agonists should also have a short-acting β_2 -agonist such as albuterol available for as-needed use (“rescue” medication).

Adverse effects of both long- and short-acting β_2 -agonists are dose related and include palpitations, tachycardia, hypokalemia, and tremor. Sleep disturbance may also occur and appears to be worse with higher doses of inhaled long-acting β_2 -agonists. Increasing doses beyond those clinically recommended is without benefit and could be associated with increased adverse effects. Patients should be advised to avoid excessive use of short-acting β_2 -agonists while being treated with long-acting β_2 -agonists.

Anticholinergics Ipratropium and tiotropium are inhaled anticholinergic medications commonly used for COPD. They produce bronchodilation by competitively blocking muscarinic receptors in bronchial smooth muscle. They may also decrease mucus secretion, although this effect is variable. Tiotropium dissociates from receptors extremely slowly, resulting in a half-life longer than 36 hours, allowing for once-daily dosing. Ipratropium has an elimination half-life of about 2 hours, necessitating dosing every 6 to 8 hours.

- Tiotropium significantly decreases exacerbations and related hospitalizations, reduces symptoms, and improves quality of life compared with placebo or ipratropium.¹⁵ When added to other respiratory medications for COPD, tiotropium reduces the rate of exacerbations, increases the time to first exacerbation, improves dyspnea, and reduces the incidence of respiratory failure compared with placebo.¹⁶ Tiotropium may be more effective than salmeterol for reducing exacerbations in patients with moderate to very severe COPD.¹⁷ Other comparative studies and meta-analyses have found little to no differences among long-acting bronchodilators.^{1,2} Patients using tiotropium as maintenance therapy should be prescribed albuterol as their rescue therapy. The combination of ipratropium and tiotropium is not recommended because of the risks of excessive anticholinergic effects.

Inhaled anticholinergics are well tolerated with the most common adverse effect being dry mouth. Occasional metallic taste has also been reported with ipratropium. Other anticholinergic adverse effects include constipation, tachycardia, blurred vision, and precipitation of narrow-angle glaucoma symptoms. Urinary retention could be a problem, especially for those with concurrent bladder outlet obstruction. Earlier studies suggested that inhaled anticholinergics may increase the risk of myocardial infarction and cardiovascular death in patients with COPD.^{18,19} More recent large trials of tiotropium have found no increased cardiovascular risk.^{16,17}

- Methylxanthines** Theophylline is a nonspecific phosphodiesterase inhibitor that increases intracellular cAMP within airway smooth muscle resulting in bronchodilation. It has a modest bronchodilator effect in patients with COPD, and its use is limited due to a narrow therapeutic index, multiple drug interactions, and adverse effects. Theophylline should be reserved for patients who cannot use inhaled medications or who remain symptomatic despite appropriate use of inhaled bronchodilators.

Table 15-4

Maintenance Medications for COPD

	Medication	Onset	Peak	Duration	Usual Dose	
Short-Acting β_2-Agonists	Albuterol^a Nebulization	5–15 minutes	0.5–2 hours	2–6 hours	2.5 mg every 6–8 hours (max: 30 mg/day)	
		Inhalation	5–15 minutes	0.5–2 hours	2–6 hours	MDI (90 mcg/puff) 1–2 puffs every 4–6 hours (max: 1,080 mcg/day)
		Oral	7–30 minutes	2–3 hours	4–6 hours ER: 8–12 hours	2–4 mg 3–4 times a day ER: 4–8 mg every 12 hours (max: 32 mg/day)
	Levalbuterol Nebulization	10–20 minutes	1.5 hours	5–8 hours	0.63–1.25 mg 3 times/day, 6–8 hours apart (max: 3.75 mg/day)	
		Inhalation	5–10 minutes	1–1.5 hours	3–6 hours	MDI (45 mcg/puff) 1–2 puffs every 4–6 hours (max: 540 mcg/day)
	Terbutaline Oral	0.5–2 hours	1–3 hours	6–8 hours	2.5–5 mg 3 times/day, 6 hours apart ⁹ (max: 15 mg/day)	
Long-Acting β_2-Agonists	Formoterol Inhalation	1–3 minutes	1–3 hours	12 hours	Powder (12 mcg/inhalation) 1 inhalation every 12 hours (max: 24 mcg/day)	
		Nebulization	1–3 minutes	1–3 hours	12 hours	20 mcg every 12 hours (max: 40 mcg/day)
	Salmeterol Inhalation	10 minutes to 2 hours	2–5 hours	12 hours	Powder (50 mcg/inhalation) 1 inhalation every 12 hours (max: 100 mcg/day)	
		Indacaterol Inhalation	5 minutes	1–4 hours	24 hours	Powder (75 mcg/inhalation) 1 inhalation every 24 hours (max: 75 mcg/day)
	Arformoterol Nebulization		7–20 minutes	1–3 hours	12 hours	15 mcg every 12 hours (max: 30 mcg/day)
	Short-Acting Anticholinergic	Ipratropium Nebulization	1–30 minutes	1.5–2 hours	4–6 hours	500 mcg every 6–8 hours (max: 2,000 mcg/day)
Inhalation			1–30 minutes	1.5–2 hours	4–6 hours	MDI (18 mcg/puff) 2 puffs 4 times/day (max: 216 mcg/day)
Long-Acting Anticholinergic	Tiotropium Inhalation	30 minutes	1–4 hours	24 hours	Powder (18 mcg/inhalation) 1 inhalation every 24 hours (max: 18 mcg/day) ^c	
Methylxanthine	Theophylline Oral	0.5–2 hours	Up to 24 hours, depending on formulation	6–24 hours	400–600 mg/day divided every 6–24 hours based on formulation (max: 800 mg/day) Adjust dose to serum concentrations of 5–15 mcg/mL (5–15 mg/L; 28–83 μ mol/L)	
Phosphodiesterase-4 Inhibitor	Roflumilast Oral	4 weeks	—	—	500 mcg daily ^d	
Inhaled Corticosteroids	Beclomethasone	1–7 days	1–4 weeks		MDI (40, 80 mcg/puff) 40–160 mcg twice a day (max: 640 mcg/day)	
		1–7 days	1–2 weeks		Powder (90, 180 mcg/inhalation) 180–360 mcg twice a day (max: 1,440 mcg/day)	
	Ciclesonide	1–7 days	1–4 weeks		MDI (80, 160 mcg/puff) 80–320 mcg 1 or 2 times/day (max: 640 mcg/day)	

(Continued)

Table 15-4

Maintenance Medications for COPD (Continued)

Medication	Onset	Peak	Duration	Usual Dose
Fluticasone	1–7 days	1–2 weeks		MDI (44, 110, 220 mcg/puff) 88–440 mcg twice a day (max: 1,760 mcg/day) Powder (50, 100, 250 mcg/inhalation) 100–1000 mcg twice a day (max: 2,000 mcg/day)
Mometasone	1–7 days	1–2 weeks		Powder (110, 220 mcg/inhalation) 220–440 mcg 1 or 2 times/day (max: 880 mcg/day)

In elderly patients, start with the lowest recommended dose and increase as necessary.

ER, extended-release; MDI, metered-dose inhaler.

^aAlbuterol is known as salbutamol outside the United States.

^bNot recommended if creatinine clearance (CrCl) less than or equal to 10 mL/min (0.17 mL/s); for CrCl 11–50 mL/min (0.18–0.83 mL/s), reduce dose by 50%.

^cPatients with reduced activity in the CYP2D6 pathway (poor metabolizers [PMs]) have higher plasma concentrations than those with normal activity (extensive metabolizers [EMs]); PMs may require lower doses and should be monitored closely for adverse effects.

^dNot recommended in patients with moderate or severe hepatic impairment.

Theophylline's bronchodilatory effects depend on achieving adequate serum concentrations, and therapeutic drug monitoring is needed to optimize therapy because of wide interpatient variability. If theophylline is used, serum concentrations in the range of 5 to 15 mcg/mL (5 to 15 mg/L; 28 to 83 μ mol/L) provide adequate clinical response with a greater margin of safety than the traditionally recommended range of 10 to 20 mcg/mL (10 to 20 mg/L; 55 to 111 μ mol/L). The most common adverse effects include heartburn, restlessness, insomnia, irritability, tachycardia, and tremor. Dose-related adverse effects include nausea and vomiting, seizures, and arrhythmias.

Tobacco smoke contains chemicals that induce the cytochrome P-450 isoenzymes 1A1, 1A2, and 2E1. Theophylline is metabolized by 1A2 and 2E1, and therefore smoking leads to increased clearance and subsequently decreased plasma levels of the drug.²⁰ Because most patients with COPD are current or past smokers, it is important to assess current tobacco use and adjust the theophylline dose as required based on altered plasma theophylline levels if tobacco use changes.

► Corticosteroids

Inhaled corticosteroids improve symptoms, lung function, quality of life, and exacerbation rates in patients with an FEV₁ less than 60%.^{1,2} They do not appear to modify the rate of decline in pulmonary function or improve mortality.^{1,21}

5 *Inhaled corticosteroids are recommended for patients with severe and very severe COPD and frequent exacerbations that are not adequately controlled by long-acting bronchodilators.*¹ Monotherapy with inhaled corticosteroids is less effective than when combined with a long-acting β_2 -agonist and is therefore not recommended.¹ Combination inhaler devices

(Advair [fluticasone/salmeterol], Symbicort [budesonide/formoterol], and Dulera [mometasone/formoterol]) are convenient and ensure patients receive both medications.

The most common adverse effects from inhaled corticosteroids include oropharyngeal candidiasis and hoarse voice. These can be minimized by rinsing the mouth after use and by using a spacer device with metered-dose inhalers (MDIs). Increased bruising, decreased bone density, and increased incidence of pneumonia have also been reported; the clinical importance of these effects remains uncertain.^{1,2,21} Upon discontinuation of inhaled corticosteroids, some patients may experience deterioration in lung function and an increase in dyspnea and mild exacerbations.²²

Long-term use of oral corticosteroids should be avoided due to an unfavorable risk-to-benefit ratio. The steroid myopathy that can result from long-term use of oral corticosteroids weakens muscles, further decreasing the respiratory drive in patients with advanced disease.

► Phosphodiesterase-4 Inhibitors

Phosphodiesterase (PDE)-4 inhibitors are believed to reduce inflammation by inhibiting the breakdown of cAMP. They do not cause direct bronchodilation. Roflumilast is an oral PDE-4 inhibitor approved for prevention of COPD exacerbations in patients with severe COPD associated with chronic bronchitis and a history of exacerbations.

Roflumilast has more frequent adverse events than inhaled treatment options and only a modest benefit in lung function and exacerbation rate.^{1,23} Common adverse effects include diarrhea, weight loss, nausea, headache, insomnia, decreased appetite, and abdominal pain; neuropsychiatric effects such as anxiety and depression have also been reported.

Roflumilast is an option in select patients who are not adequately controlled by long-acting bronchodilators.¹

► Combination Therapy

- For patients who remain symptomatic on monotherapy, a combination of bronchodilators can be used.^{1,2} Combining albuterol plus ipratropium, a long-acting β_2 -agonist plus theophylline, or a long-acting β_2 -agonist plus tiotropium, produces a greater change in spirometry than either drug alone.^{1,24,25} Administering a long-acting β_2 -agonist plus ipratropium leads to fewer exacerbations than either drug alone.²⁶ Some studies have found an increase in adverse events without added benefit when combinations of bronchodilators are used.

Triple therapy with inhaled corticosteroid, long-acting β_2 -agonist, and tiotropium is commonly used. Triple therapy appears to improve lung function and quality of life but may not further reduce exacerbations or dyspnea.²⁷⁻²⁹ Further studies are needed to determine if the benefits of triple therapy outweigh the increased risk of adverse effects and added cost.

Potential benefits and risks of any combination therapy should be considered on a case-by-case basis. Patients should be monitored closely and therapy should be changed if the combination is not more effective.

► Immunizations

- Serious illness and death in COPD patients can be reduced by about 50% with annual influenza vaccination. The optimal time for vaccination is usually from early October through mid-November. A onetime pneumococcal polysaccharide vaccine should be administered to all adults with COPD. Patients older than 65 years should be revaccinated if it has been more than 5 years since initial vaccination and they were younger than 65 years at the time.

► α_1 -Antitrypsin Augmentation Therapy

The ATS and the ERS have published standards for the diagnosis and management of individuals with AAT deficiency.³⁰ They recommend IV augmentation therapy for individuals with AAT deficiency and moderate airflow obstruction (FEV_1 35% to 60% predicted). In these patients, augmentation therapy appears to reduce overall mortality and slow the decline in FEV_1 , although large randomized controlled trials have not been conducted.

Augmentation therapy consists of weekly transfusions of pooled human AAT with the goal of maintaining adequate plasma levels of the enzyme. The benefits of augmentation therapy are unclear in patients with severe (FEV_1 less than 35% predicted) or mild (FEV_1 greater than 60% predicted) airflow obstruction. Augmentation therapy is not recommended for individuals with AAT deficiency who do not have lung disease.

► Other Pharmacologic Therapies

Leukotriene modifiers (e.g., zafirlukast and montelukast) have not been adequately evaluated in COPD patients and are

not recommended for routine use. Small short-term studies showed improvement in pulmonary function, dyspnea, and quality of life when leukotriene modifiers were added to inhaled bronchodilator therapy.³¹ Additional long-term studies are needed to clarify their role.

N-acetylcysteine has antioxidant and mucolytic activity, which makes it a promising agent for COPD treatment, but clinical trials have produced conflicting results. One of the largest trials found *N*-acetylcysteine to be ineffective in reducing the decline in lung function and preventing exacerbations.³² Routine use cannot be recommended at this time.

A recent trial found that prophylactic treatment with daily azithromycin significantly reduced the incidence of acute exacerbations in select subgroups of COPD patients; however, the risks of microbial resistance associated with long-term antibiotic use should be further studied before continuous prophylactic use of antibiotics can be recommended.³³

Antitussives are contraindicated because cough has an important protective role. Opioids may be effective for dyspnea in advanced disease but may have serious adverse effects; they may be used to manage symptoms in terminal patients.

Traditionally, β -blockers have been used sparingly, if at all, in patients with COPD due to concerns of worsening dyspnea. An observational study in 2010 suggested that β -blockers may improve outcomes in patients with COPD.³⁴ More studies are needed before β -blockers can be recommended for COPD, but they appear to be safe and thus can be used to treat comorbidities when needed.³⁵ Selective β_1 -blockers should be used, and patients should be monitored for worsening symptoms.

Therapy of COPD Exacerbations

An exacerbation is acute worsening of the patient's symptoms from his or her usual stable state that is beyond normal day-to-day variations; an exacerbation warrants a change in medications. Common symptoms are worsening of dyspnea, increased sputum production, and change in sputum color. The most common causes of an exacerbation are respiratory infection and air pollution, but the cause cannot be identified in about one-third of severe exacerbations.¹

- Treatment depends on the symptoms and severity of the exacerbation. Mild exacerbations can often be treated at home with short-acting inhaled bronchodilators with or without oral corticosteroids. Antibiotics are indicated when there are specific signs of airway infection (e.g., change in color of sputum and/or increased sputum production or dyspnea) or when mechanical ventilation is needed. Moderate to severe exacerbations require management in the emergency department or hospital. Management should consist of controlled oxygen therapy, bronchodilators, oral or IV corticosteroids, antibiotics if indicated, and consideration of mechanical ventilation (noninvasive or invasive).

► Bronchodilators

- Albuterol is the preferred bronchodilator for treatment of acute exacerbations because of its rapid onset of action. Ipratropium can be added to allow for lower doses of albuterol,

Patient Encounter, Part 2: The Medical History, Physical Examination, and Diagnostic Tests

PMH: Osteoarthritis for 6 years

SH: Unemployed; married with three children

FH: Diabetes and colon cancer in mother; COPD and heart disease in sister; schizophrenia in brother

Meds: Aspirin 81 mg daily, calcium carbonate 500 mg plus vitamin D 400 IU 1 tablet twice daily, albuterol MDI 1 to 2 puffs every 4 to 6 hours as needed; naproxen 500 mg 1 tablet twice daily

ROS: (–) fever, chills, or night sweats; (–) skin rash; (–) nasal congestion, drainage; (–) chest pain, paroxysmal nocturnal dyspnea, orthopnea; (+) shortness of breath, cough with yellowish phlegm; (–) wheezing; (–) hemoptysis; (–) heartburn, reflux symptoms, N/V/D, change in appetite, change in bowel habits; (+) joint pain in knee; (–) pedal edema

PE:

VS: BP 128/78 mm Hg, P 76 bpm, RR 20/min, T 35.8°C (96.4°F), Wt 60 kg (132 lb), Ht 64 in. (163 cm), BMI 22.7 kg/m²

HEENT: EOMI; mucosal membranes are moist; no evidence of JVD; no palpably enlarged cervical lymph nodes

Lungs: Clear breath sounds; expiratory phase is very diminished; no wheezes, rhonchi, or crackles

CV: RRR, normal S₁, S₂; no murmur, gallop, or rub

Abd: Soft, nontender, audible bowel sounds, no hepatosplenomegaly

Ext: No cyanosis, edema, or finger clubbing

Pulmonary Function Tests

	Prebronchodilator		Postbronchodilator	
	Actual	% Predicted	Actual	% Predicted
FVC (L)	2.76	85%	2.83	87%
FEV ₁ (L)	1.21	48%	1.11	44%
FEV ₁ /FVC (%)			39%	

CXR: Upper lobe bullous emphysema with hyperexpansion bilaterally

COPD Assessment Test score: 19

Given this additional information, what is your assessment of the patient's condition?

What nonpharmacologic and pharmacologic alternatives are feasible for this patient?

Develop a treatment plan for this patient.

thus reducing dose-dependent adverse effects such as tachycardia and tremor. Delivery can be accomplished through MDI and spacer or nebulizer. The nebulizer route is preferred in patients with severe dyspnea and/or cough that would limit delivery of medication through an MDI with spacer. If response is inadequate, theophylline can be considered; however, clinical evidence supporting its use is lacking.

► Oral Corticosteroids

- Systemic corticosteroids shorten the recovery time, help to restore lung function more quickly, and reduce the risk of early relapse.³⁶ The GOLD guidelines recommend oral prednisolone 30 to 40 mg/day for 10 to 14 days. Shorter courses (7 days or fewer) may be as effective, but further studies are needed.³⁷ Prolonged treatment and/or higher doses do not result in greater efficacy and increase the risk of adverse effects. If inhaled corticosteroids are part of the patient's usual treatment regimen, they should be continued during systemic therapy.

► Antibiotics

The role of antibiotics in treating COPD exacerbation is evolving, and evidence suggests that subsets of patients may benefit from antibiotic treatment. **6** *Antibiotics should be used in patients with COPD exacerbations who: (a) have all three cardinal symptoms (increased dyspnea, increased sputum*

*volume, and increased purulence); (b) have increased sputum purulence and one other cardinal symptom; or (c) experience a severe exacerbation requiring mechanical ventilation.*¹

The predominant bacterial organisms in patients with mild exacerbations are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. In patients with more severe underlying COPD, other bacteria such as enteric gram-negative bacilli (*Escherichia coli*, *Klebsiella pneumoniae*, and *Enterobacter cloacae*) and *Pseudomonas aeruginosa* may be more common. Selection of empirical antibiotic therapy should be based on the most likely organism(s) thought to be responsible for the infection and on local resistance patterns. A risk stratification approach has been advocated to help guide antibiotic selection.^{1,12,38} This approach is based on risk factors found to be predictive of treatment failure or early relapse. Patients at risk for poor outcome are candidates for more aggressive initial antibiotic treatment. **Table 15-5** provides recommended antibiotic treatment based on this risk stratification approach.^{1,12,38}

- Antibiotic treatment for most patients should be maintained for 5 to 10 days. Exacerbations due to certain infecting organisms (*P. aeruginosa*, *E. cloacae*, and methicillin-resistant *Staphylococcus aureus*), although not common, require more lengthy courses of therapy (21 to 42 days).

If there is worsening clinical status or inadequate clinical response in 48 to 72 hours, reevaluate the patient, consider sputum Gram stain and culture if not already obtained, and

Table 15-5

Recommended Antibiotic Therapy in Acute Exacerbations of COPD

Patient Characteristics	Likely Pathogens	Recommended Antibiotics ^{a,b}
Mild Exacerbation Without Risk Factors for Poor Outcome		
Not requiring hospitalization Less than three exacerbations per year No comorbid illness FEV ₁ greater than 50% predicted No recent antibiotic therapy	<i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i> <i>Moraxella catarrhalis</i> <i>Chlamydia pneumoniae</i> Viruses	<i>Oral First-Line Therapy:</i> β-Lactam (high-dose amoxicillin) ^c β-Lactam/β-lactamase inhibitor (amoxicillin-clavulanate) Tetracycline Trimethoprim/sulfamethoxazole <i>Alternative Oral Therapy:</i> Macrolides (azithromycin, clarithromycin) Second- or third-generation cephalosporins (cefuroxime, cefpodoxime, cefdinir, cefprozil) <i>IV Therapy:</i> Not recommended
Moderate Exacerbation With Risk Factors for Poor Outcome		
FEV ₁ less than 50% predicted Comorbid diseases Three or more exacerbations per year Antibiotic therapy in the previous 3 months	Above organisms plus: Resistant pneumococci (β-lactamase producing, penicillin-resistant), <i>Escherichia coli</i> , <i>Proteus</i> spp, <i>Enterobacter</i> spp, <i>Klebsiella pneumoniae</i>	<i>Oral First-Line Therapy:</i> β-Lactam/β-lactamase inhibitor (amoxicillin-clavulanate) <i>Alternative Oral Therapy:</i> Fluoroquinolone with enhanced pneumococcal activity (levofloxacin, gemifloxacin, moxifloxacin) <i>IV Therapy:</i> β-lactam/β-lactamase inhibitor (ampicillin-sulbactam) Second- or third-generation cephalosporin (cefuroxime, ceftriaxone) Fluoroquinolone with enhanced pneumococcal activity (levofloxacin, moxifloxacin)
Severe Exacerbation With Risk Factors for <i>Pseudomonas aeruginosa</i>		
Recent hospitalization Four or more courses of antibiotics in the last year Very severe COPD (GOLD 4) Previous isolation of <i>P. aeruginosa</i>	Above organisms plus: <i>P. aeruginosa</i>	<i>Oral First-Line Therapy:</i> Antipseudomonal fluoroquinolone (ciprofloxacin, high-dose levofloxacin) <i>IV Therapy:</i> Antipseudomonal β-lactamase-resistant penicillin (piperacillin-tazobactam) Third- or fourth-generation cephalosporin with antipseudomonal activity (ceftazidime, ceftipime) Antipseudomonal fluoroquinolone (ciprofloxacin, high-dose levofloxacin)

COPD, chronic obstructive pulmonary disease; FEV₁, forced expiratory volume in 1 second.

^aAntibiotics are indicated for patients with COPD exacerbations who: (a) have all three cardinal symptoms (increased dyspnea, increased sputum volume, and increased purulence); (b) have increased sputum purulence and one other cardinal symptom; or (c) experience a severe exacerbation requiring mechanical ventilation.

^bAntibiotic choices should take into consideration local resistance patterns.

^cHigh-dose amoxicillin is recommended due to the prevalence of penicillin-resistant *S. pneumoniae*.

adjust antimicrobial therapy. If Gram stain and culture results are available, narrow the antibiotic therapy according to cultured organism(s) and sensitivities. If no cultures have been obtained, or cultures remain negative, consider additional antibiotics and/or change to antibiotics with a broader spectrum of activity.

► Oxygen

The goal of oxygen therapy is to maintain Pao₂ above 60 mm Hg (7.98 kPa) or Sao₂ above 90% to prevent tissue hypoxia and preserve cellular oxygenation.¹² The GOLD guidelines recommend a target Sao₂ of 88% to 92%.¹ Increasing the Pao₂ much further confers little added benefit and may increase

the risk of CO₂ retention, which may lead to respiratory acidosis. ABGs should be obtained after 30 to 60 minutes to assess for hypercapnia and acidosis.

In advanced COPD, caution should be used because overly aggressive administration of oxygen to patients with chronic hypercapnia may result in respiratory depression and respiratory failure. In these patients, mild hypoxemia, rather than CO₂ accumulation, triggers their drive to breathe.

► Assisted Ventilation

Mechanical ventilation can be administered as invasive (through an endotracheal tube) or noninvasive (by nasal

or facial mask). Noninvasive mechanical ventilation (NIV) is preferred whenever possible. It improves signs and symptoms, decreases the length of hospital stay, and most importantly, reduces mortality.¹ Appropriate patients to consider for NIV include those with at least one of the following characteristics: (a) severe dyspnea with clinical signs suggestive of respiratory muscle fatigue such as use of accessory muscles and paradoxical abdominal motion; (b) respiratory acidosis (arterial pH at or below 7.35 and/or Paco_2 at or above 45 mm Hg [5.99 kPa]).¹ Invasive mechanical ventilation should be used in patients with more severe symptoms and in those failing NIV.

OUTCOME EVALUATION

- Monitor the patient for improvement in symptoms (dyspnea, cough, sputum production, exercise tolerance, sleep disturbance, and fatigue).
- Changes in FEV_1 should not be the main outcome assessed. FEV_1 changes are weakly related to symptoms, exacerbations, and health-related quality of life (outcomes that are important to patients). There is no evidence to support routine periodic spirometry after initiation of therapy.² The GOLD guidelines recommend annual spirometry to assess decline in lung function.¹

Patient Care and Monitoring

1. Assess the patient's symptoms and history of exposure to risk factors. For new patients, obtain a detailed medical history including:
 - Medical conditions, especially history of respiratory disorders
 - Immunization status (pneumococcal and influenza)
 - Family history of COPD or other chronic respiratory disease
 - History of exacerbations or previous hospitalizations for respiratory disorders
 - Impact of disease on the patient's life, including limitation of activity, missed work, and feelings of depression or anxiety
2. Obtain spirometry measurements to assess airflow limitation and aid in severity classification and treatment decisions. Measure oxygen saturation in patients with an FEV_1 less than 35% predicted or signs or symptoms suggestive of cor pulmonale or respiratory failure. If oxygen saturation is less than 92%, ABGs should be assessed.
3. Obtain a thorough history of prescription, nonprescription, and dietary supplement use. Assess inhaler technique and adherence to the medication regimen. Ask the patient about effectiveness of medications at controlling symptoms and adverse effects.
4. Ask current tobacco users about daily quantity, past quit attempts, and current readiness to quit.
5. Design a therapeutic plan including lifestyle modifications (e.g., smoking cessation) and optimal drug therapy. Consider need for pulmonary rehabilitation, oxygen therapy, and/or surgery.
6. Provide patient education about the disease state and therapeutic plan:
 - What COPD is, and what its natural course is like
 - Smoking cessation counseling
 - Role of regular exercise and healthy eating
 - How and when to take medications; importance of adherence to the medication plan; adverse effects and how to minimize them
 - Signs and symptoms of an exacerbation and what to do if one occurs
 - Advanced directives and end-of-life issues for patients with more severe disease
7. Determine the follow-up period based on patient status and needs (typically 3 to 6 months).
8. Follow-up visits should include:
 - Assessment of tobacco use and/or quit attempts
 - Assessment of change in symptoms. Suggested questions for assessing whether a patient has had a symptomatic response to treatment include¹:
 - ✓ Have you noticed a difference since starting this treatment?
 - ✓ If you are better: Are you less breathless? Can you do more? Can you sleep better? Describe what difference it has made to you.
 - ✓ Is that change worthwhile to you?
 - Review of drug therapy (dosages, adherence, inhaler technique, effectiveness, adverse effects, and drug interactions)
 - Evaluation of exacerbation frequency, severity, and likely causes
9. Perform spirometry at least annually to assess disease progression.
10. Provide annual influenza vaccination.
11. Assess inhaler technique at every visit. Have the patient demonstrate proper use of each device using a placebo inhaler or personal inhaler. Proper use of these devices is critical for therapeutic success.

Table 15-6

Medical Research Council Dyspnea Scale

Grade	Modified Grade	Statement About Perceived Breathlessness ^a
1	0	"I only get breathless with strenuous activity"
2	1	"I get short of breath when hurrying on the level or up a slight hill"
3	2	"I walk slower than people of the same age on the level because of breathlessness or I have to stop for breath after a mile or so on the level at my own pace"
4	3	"I stop for breath after walking 100 yards (91 m) or after a few minutes on the level"
5	4	"I am too breathless to leave the house or I get breathless while dressing"

^aThe last statement to which the patient answers "yes" is his or her grade.

- The Medical Research Council dyspnea scale can be used to monitor physical limitation due to breathlessness (Table 15-6). The scale is simple to administer and correlates well with scores of health status.³⁹
- The COPD Assessment Test (CAT) is an eight-item questionnaire that can be used every 2 to 3 months to assess for trends and changes in symptoms and disease impact on daily life.¹ It can be accessed at www.catestonline.org.
- Assess quality of life using the St. George's Respiratory Questionnaire, which has been validated and is specific for COPD patients.⁴⁰
- Monitor theophylline levels with goal serum concentrations in the range of 5 to 15 mcg/mL (5 to 15 mg/L; 28 to 83 μmol/L). Trough levels should be obtained 1 to 2 weeks after initiation of treatment and after any dosage adjustment. Routine levels are not necessary unless toxicity is suspected or disease has worsened.

Abbreviations Introduced in This Chapter

AAT	α ₁ -Antitrypsin
ABG	Arterial blood gas
ATS	American Thoracic Society
cAMP	Cyclic adenosine monophosphate
COPD	Chronic obstructive pulmonary disease
ERS	European Respiratory Society
FEV ₁	Forced expiratory volume in 1 second
FVC	Forced vital capacity
GOLD	Global Initiative for Chronic Obstructive Lung Disease
MDI	Metered-dose inhaler
MMRC	Modified Medical Research Council
NIV	Noninvasive mechanical ventilation

Paco ₂	Partial pressure of arterial carbon dioxide
Pao ₂	Partial pressure of arterial oxygen
PDE-4	Phosphodiesterase-4
PFTs	Pulmonary function tests
Sao ₂	Arterial oxygen saturation
TNF-α	Tumor necrosis factor-α
V _A /Q	Ventilation-to-perfusion ratio

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Cystic Fibrosis

Kimberly J. Novak

LEARNING OBJECTIVES

● **Upon completion of the chapter, the reader will be able to:**

1. Explain the pathophysiology of cystic fibrosis (CF) and its multiorgan system involvement.
2. Describe the common clinical presentation and diagnosis of CF.
3. Consider long-term treatment goals with respect to clinical course and prognosis of CF.
4. Identify nonpharmacologic therapies for CF management.
5. Recommend appropriate pharmacologic therapies for chronic CF management.
6. Design appropriate antibiotic regimens for acute pulmonary exacerbations of CF.
7. Use pharmacokinetic principles when calculating drug doses in CF patients.
8. Formulate monitoring plans for acute and chronic CF pharmacotherapy.

KEY CONCEPTS

- 1 In cystic fibrosis (CF), the CF transmembrane regulator (CFTR) chloride channel is dysfunctional and usually results in decreased chloride secretion and increased sodium absorption, leading to altered viscosity of fluid excreted by the exocrine glands and mucosal obstruction.
- 2 Pulmonary disease is characterized by thick mucus secretions, impaired mucus clearance, chronic airway infection and colonization, obstruction, and an exaggerated neutrophil-dominated inflammatory response.
- 3 Maximizing nutritional status through pancreatic enzyme replacement and vitamin and nutritional supplements is necessary for normal growth and development and for maintaining long-term lung function.
- 4 Airway clearance therapy is a necessary routine for all CF patients to clear secretions and control infection.
- 5 Antibiotic therapy is indicated in three distinct situations over the course of CF: (a) early eradication and delay of colonization, (b) suppression of bacterial growth once colonization occurs, and (c) reduction of bacterial load in acute overgrowth.
- 6 Antibiotic selection is based on periodic culture and sensitivity data, typically covering all organisms identified during the preceding year. If no culture data

are available, empirical antibiotics should cover the most likely organisms for the patient's age group.

- 7 Antibiotic regimens in severe CF exacerbations usually include an IV antipseudomonal β -lactam plus an aminoglycoside.
- 8 CF patients have larger volumes of distribution for many antibiotics due to an increased ratio of lean body mass to total body mass and lower fat stores. CF patients also have an enhanced total body clearance, although the exact mechanism has not been determined.
- 9 Titration of pancreatic enzyme doses is based on control of steatorrhea, stool output, and abdominal symptoms.
- 10 Because CF-related diabetes results from insulin insufficiency, exogenous insulin replacement is usually required.

INTRODUCTION

Cystic fibrosis (CF) is an inherited multiorgan system disorder affecting children and, increasingly, adults. It is the most common life-shortening genetic disease among whites and the major cause of severe chronic lung disease and pancreatic insufficiency in children. Disease generally manifests as mucosal obstruction of exocrine glands caused by defective ion transport within epithelial cells. Due to the array of affected organ systems and complicated medical therapies, appropriate CF treatment necessitates multidisciplinary team collaboration.

EPIDEMIOLOGY AND ETIOLOGY

In the United States, CF most commonly occurs in whites, ranging from 1 in 1,900 to 3,700 individuals. CF is less common in Hispanics (1 in 9,000), African Americans (1 in 15,000), and Asian Americans (1 in 32,000).¹ CF is inherited as an autosomal recessive trait, and approximately 1 in 25 whites are **heterozygous** carriers. Offspring of a carrier couple (each parent being heterozygous) have a 1 in 4 chance of having the disease (**homozygous**), a 1 in 2 chance of being a carrier (heterozygous), and a 1 in 4 chance of receiving no trait. The gene mutation is found on the long arm of chromosome 7 and encodes for the CF transmembrane regulator (CFTR) protein, which functions as a chloride channel to transport water and electrolytes. Over 1,800 mutations have been described in the CF gene; however, the $\Delta F508$ mutation is the most common and is present in 70% to 90% of CF patients in the United States.²⁻⁴

PATHOPHYSIOLOGY

CF is a disease of exocrine gland epithelial cells where CFTR expression is prevalent. Normally, these cells transport chloride through CFTR chloride channels with sodium and water accompanying this flux across the cell membrane (Fig. 16-1). CFTR is regulated by protein kinases in response to varying levels of the intracellular second messenger cyclic-3',5'-adenosine monophosphate (cAMP). CFTR also downregulates the epithelial sodium channel and regulates calcium-activated chloride and potassium channels, and it may function in exocytosis and formation of plasma membrane molecular complexes and proteins important in inflammatory responses.³ ① *In CF, the CFTR chloride channel is dysfunctional and usually results in decreased chloride secretion and increased sodium absorption, leading to altered viscosity of fluid excreted by the exocrine glands and mucosal obstruction.*

FIGURE 16-1. Electrolyte transport in the airway epithelial cell. (Ca, calcium; cAMP, cyclic-3', 5'-adenosine monophosphate; Cl, chloride; Na, sodium; K potassium.) (From Milavetz G, Smith JJ. Cystic fibrosis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 7th ed. New York, NY: McGraw-Hill, 2008:536.)

Pulmonary System

Chronic lung disease is a hallmark of CF, leading to death in 90% of patients. ② *Pulmonary disease is characterized by thick mucus secretions, impaired mucus clearance, chronic airway infection and colonization, obstruction, and an exaggerated neutrophil-dominated inflammatory response.*⁵ This process leads to air trapping, **atelectasis**, mucus plugging, **bronchiectasis**, cystic lesions, pulmonary hypertension, and eventual respiratory failure. In the U.S. CF population, pulmonary function declines approximately 2% per year, as measured by forced expiratory volume in 1 second (FEV₁). An individual's rate of decline varies depending on severity of CFTR dysfunction and comorbidities.¹ Sinusitis and nasal polyps are also common, and microbial colonization is similar to that of the lungs.

Bacterial pathogens are often acquired in age-dependent sequence, and prevalence is tracked in the Cystic Fibrosis Foundation Patient Registry. Early infection is most often caused by *Staphylococcus aureus* and nontypeable *Haemophilus influenzae*. *Pseudomonas aeruginosa* infection is the most significant CF pathogen among all age groups. *P. aeruginosa* expresses extracellular toxins that perpetuate lung inflammation. Mucoid strains of *P. aeruginosa* produce an alginate biofilm layer that interferes with antibiotic penetration. Other organisms identified later in the disease course include *Stenotrophomonas maltophilia*, *Achromobacter (Alcaligenes) xylosoxidans*, *Burkholderia cepacia*, fungi including *Candida* and *Aspergillus* species, and nontuberculous mycobacteria among others.¹ Cultured organisms may represent initial infection, chronic colonization, or microbial overgrowth in an acute exacerbation.

Gastrointestinal System

GI involvement often presents as meconium ileus, small bowel obstruction shortly after birth due to abnormally thick **meconium**. Older CF patients may similarly develop distal intestinal obstruction syndrome (DIOS) due to fecal impaction in the terminal ileum and cecum.

Maldigestion due to pancreatic enzyme insufficiency is present in 85% to 90% of CF patients.^{6,7} Thick pancreatic secretions and cellular debris obstruct pancreatic ducts and lead to fibrosis. Volume and concentration of pancreatic enzymes and bicarbonate are reduced, leading to maldigestion of fat and protein and subsequent malabsorption of fat-soluble vitamins (A, D, E, and K). Symptoms include abdominal distention, **steatorrhea**, flatulence, and malnourishment despite voracious intake. Maldigestion is progressive and may develop later in a previously pancreatic-sufficient patient. Other complications may include GI reflux, dysmotility, salivary dysfunction, **intussusception**, **volvulus**, **atresia**, **rectal prolapse**, and complications related to corrective surgery for meconium ileus.⁷

Hepatobiliary disease occurs due to bile duct obstruction from abnormal bile composition and flow. Hepatomegaly, splenomegaly, and cholecystitis may be present. Hepatic **steatosis** may be present due to effects of malnutrition.

Progression from cholestasis (impaired bile flow) to portal fibrosis and to focal and multilobar cirrhosis, esophageal varices, and portal hypertension takes several years. Many patients are compensated and asymptomatic but may be susceptible to acute decompensation in the event of extrinsic hepatic insult from viruses, medications, or other factors.⁸

Endocrine System

CF-related diabetes (CFRD) occurs in approximately 20% of adolescents and 40% to 50% of adults, disproportionately affecting women. Although it shares characteristics of both type 1 and type 2 diabetes mellitus, CFRD is categorized separately. Reduced functional pancreatic islet cells and increased islet **amyloid** deposition results in insulin insufficiency, the primary cause of CFRD. Insulin secretion is delayed in response to glucose challenge, and absolute insulin secretion over time is reduced. Some insulin resistance may also be present in CFRD and may fluctuate in relation to infection and inflammation.⁹

Postprandial hyperglycemia is common, but because some basal insulin secretion is maintained, fasting hyperglycemia is less severe and ketosis is rare.⁶ Diet, acute and chronic infection, and corticosteroid use lead to fluctuations in glucose tolerance over time.⁹ CFRD is associated with greater nutritional failure, increased pulmonary disease, and earlier mortality. Pulmonary function decline and nutritional consequences associated with progressive CFRD may overshadow risks of long-term macrovascular and microvascular disease.

Reproductive System

CF patients often experience delayed puberty. In females, menarche occurs 18 months later than average; menstrual irregularity is common, and fertility is reduced due to increased cervical mucus viscosity. Due to increasing life expectancy, pregnancy is becoming more common; however, outcomes depend on prepartum nutritional and pulmonary status. Almost all males with CF are **azoospermic** due to congenital absence of the vas deferens with resultant obstruction; however, conception still occurs occasionally. Conception can also occur through application of assisted reproductive technologies.¹⁰

Musculoskeletal System

Several factors contribute to development of bone disease in CF: (a) malabsorption of vitamins D and K and calcium, (b) poor nutrition and decreased body mass, (c) physical inactivity, (d) corticosteroid therapy, and (e) delayed puberty. Chronic pulmonary infection, through release of inflammatory cytokines, can increase bone resorption and decrease formation. Osteopenia, osteoporosis, pathological fractures, and **kyphosis** can occur.¹¹ Episodic or chronic arthritis and hypertrophic pulmonary osteoarthropathy may occur due to immune complex formation in response to chronic inflammation.¹² Digital **clubbing** is commonly observed and is a marker for hypoxia.

Hematological System

Anemia may be present due to impaired erythropoietin regulation, nutritional factors (vitamin E and iron malabsorption), or chronic inflammation. Increased cytokine production can lead to shortened red blood cell survival, reduced erythropoietin response, and impaired mobilization of iron stores. Additionally, with chronic hypoxia, normal hemoglobin and hematocrit values may represent relative anemia.¹³ Increased red blood cell production is a physiological response to hypoxia; however, this response may be blunted in CF and may result in symptoms of anemia despite normal lab values.

Abnormal bleeding or clotting may also be observed as a result of vitamin K malabsorption, antibiotic-associated depletion of GI flora and vitamin K synthesis, reduced coagulation factor synthesis due to liver disease, and/or a procoagulant state due to inflammation.

Integumentary System

Sweat contains abnormally high concentrations of sodium and chloride due to impaired reabsorption within the sweat duct from loss of CFTR channels. Patients are usually asymptomatic (other than a characteristic salty taste to the skin).³ In rare instances such as hot weather or excessive sweating during physical activity, patients may become dehydrated and experience symptoms of hyponatremia (nausea, headache, lethargy, and confusion).

CLINICAL PRESENTATION AND DIAGNOSIS

See the text box on the next page for the clinical presentation of CF.

Diagnosis

- Diagnosis of CF is based on two separate elevated sweat chloride concentrations of 60 mEq/L (60 mmol/L) or greater obtained through pilocarpine **iontophoresis** (the “sweat test”). Genetic testing (CFTR mutation analysis) may be performed to confirm the diagnosis, screen in utero, or detect carrier status. More than 70% of diagnoses are made by 12 months of age, and almost all are made by age 12. CF is a component of required newborn screening panels in all U.S. states in an effort to identify patients prior to symptom development, initiate early intervention with CF therapies, and improve long-term outcomes.¹⁴ A positive newborn screen for CF is not diagnostic (due to false-positive results among CF carriers), nor does a negative screen universally exclude the diagnosis. All “positive screens” are referred to a CF care center for sweat chloride test and genetic evaluation.

Clinical Course and Prognosis

Life expectancy has greatly increased from a predicted survival of 16 years of age in 1970 to more than 40 years for

Clinical Presentation of CF

General

- CF is usually diagnosed in neonates (meconium ileus at birth or newborn screening) or during early childhood. Some patients may present later in life due to less severe symptoms or misdiagnosis.

Symptoms

- Pulmonary: Chronic cough, sputum production, decreased exercise tolerance, and recurrent respiratory tract infections (pneumonia and sinusitis). Acute infection may be marked by increased cough, changes in sputum (darker and thicker), **hemoptysis**, dyspnea, and fever.
- GI: Numerous large, foul-smelling loose stools (steatorrhea), flatulence, and abdominal pain. Intestinal obstruction may present as abdominal pain and distention and/or decreased bowel movements.
- Nutritional: Poor weight gain, voracious appetite, and hunger. Dry skin, skin rash, and visual disturbances may be noted in vitamin deficiency.
- CFRD: Weight loss, increased thirst, and more frequent urination.

Signs

- Obstructive airway disease: tachypnea, dyspnea, cyanosis, wheezes, crackles, sternal retractions, digital clubbing, and barrel chest.
- Failure to thrive: Despite apparent adequate caloric intake, children may be below age-based normal in both height and weight, and adults may be near/below ideal body weight or have a low BMI.
- Salty taste to the skin.
- Hepatobiliary disease: Asymptomatic or evidenced by hepatomegaly, splenomegaly, or prolonged bleeding.
- Recurrent pancreatitis (usually in pancreatic-sufficient patients): Episodic epigastric abdominal pain, persistent vomiting, and fever.

Laboratory Tests

- WBC with an associated increase in polymorphonuclear (PMN) leukocytes and bands may occur in acute pulmonary infection; however, infection may occur without these laboratory abnormalities.
- Maldigestion: Decreased serum levels of fat-soluble vitamins (A, D, E, and K). Decreased vitamin K levels may result in elevated prothrombin time (PT) and international normalized ratio (INR).
- Glucose intolerance: Blood glucose between 140 and 199 mg/dL (7.8 to 11.0 mmol/L) 2 hours after an oral glucose-tolerance test.
- CFRD: Blood glucose 200 mg/dL (11.1 mmol/L) or higher 2 hours after an oral glucose-tolerance test or fasting hyperglycemia (fasting blood glucose 126 mg/dL (7.0 mmol/L) or more regardless of the postglucose challenge level).
- Hepatobiliary disease: Serum aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, γ -glutamyltransferase, and bilirubin may be elevated.

Other Tests

- Microbial cultures (sputum, throat, **bronchoalveolar lavage**, or sinus): Isolation of *P. aeruginosa*, *S. aureus*, *S. maltophilia*, and other CF-related organisms.
- PFTs: Decreased FEV₁, decreased forced vital capacity (FVC), and increased residual volume. Values are typically lower during acute pulmonary exacerbations.
- Chest x-ray or chest CT scan: Infiltrates, atelectasis, bronchiectasis, and mucus plugging.
- Abdominal x-ray or CT scan: If present, intestinal obstruction may be manifested as meconium ileus, DIOS, or intussusception. Rectal prolapse may be noted on physical examination.
- Maldigestion: Elevated fecal fat content, reduced fecal pancreatic elastase-1 (less than or equal to 200 mcg/g of feces).

patients born in the 1990s.⁶ The average age of patients in the Cystic Fibrosis Foundation Registry is now more than 16 years, and 47% of CF patients in the 2010 Registry annual report are over 18 years old with the oldest age 78.¹⁴

Clinical course varies among patients because of multiple genetic mutations and heterogeneous profile of the $\Delta F508$ mutation. Some patients develop severe lung disease early in childhood and reach end-stage disease by adolescence, whereas others maintain near-normal lung function into adulthood. Newly diagnosed adults tend to present with chronic respiratory symptoms but usually have milder lung disease, less frequent *Pseudomonas* infection, and less severe pancreatic insufficiency.⁶

TREATMENT

Desired Outcomes

- Therapeutic outcomes in CF care relate to chronic and acute treatment goals. With chronic management, the primary goals are to delay disease progression and optimize quality of life. **3** *Maximizing nutritional status through pancreatic enzyme replacement and vitamin and nutritional supplements is necessary for normal growth and development and for maintaining long-term lung function.* Reduction of airway inflammation and infection and aggressive preventive therapies minimize acute pulmonary exacerbations and delay pulmonary decline. In pulmonary exacerbations, therapy is

Patient Encounter, Part 1

TJ is a 2-month-old male infant being seen at the cystic fibrosis center due to an abnormal newborn screen. Sweat chloride testing is performed on bilateral thighs with results reported as follows:

Sample 1: Sweat chloride 120 mEq/L (120 mmol/L)

Sample 2: Sweat chloride 138 mEq/L (138 mmol/L)

Upon parental interview, TJ is a voracious eater and has six to eight loose stools per day. He is entirely breastfed and has just regained his birth weight of 3.1 kg. Parents also report that he passed his meconium in the newborn nursery on his second day of life and that he arches and cries after most feeds. TJ has been otherwise healthy.

What information is consistent with a diagnosis of cystic fibrosis (CF)?

What are the next steps in the CF diagnostic process for TJ?

TJ's parents are overwhelmed with his diagnosis of CF and are very worried about his life expectancy. How would you explain his prognosis?

directed toward reducing acute airway inflammation and obstruction through more aggressive airway clearance and antibiotic therapy with a goal of returning lung function to pre-exacerbation levels or greater.

Nonpharmacologic Therapy

► Airway Clearance Therapy

4 Airway clearance therapy is a necessary routine for all CF patients to clear secretions and control infection, even at diagnosis prior to becoming symptomatic. Waiting until development of a first pneumonia or daily symptoms delays benefits and may facilitate a faster pulmonary decline. The traditional form of chest physiotherapy (CPT) is known as percussion and postural drainage. Areas of the patient's chest, sides, and back are rapidly "clapped" by hand in different patient positions, followed by cough or forced expiration to mobilize secretions. Patients may also be taught autogenic drainage, which consists of deep breathing exercises followed by forced cough.

Several airway clearance devices are also available. Flutter valve devices use oscillating positive expiratory pressure (OPEP) to cause vibratory airflow obstruction and an internal percussive effect to mobilize secretions. Intrapulmonary percussive ventilation (IPV) provides continuous oscillating pressures during inhalation and exhalation. High-frequency chest compression (HFCC) with an inflatable vest that provides external oscillation is most commonly used. Vest therapy is often preferred because patients can perform therapy independently from an early age.^{6,15}

If performed appropriately, airway clearance techniques provide similar efficacy, so choice should be based on patient preference and adherence. Effective cough and expectoration of mucus are essential for good clearance technique. Airway clearance therapy is typically performed once or twice daily for maintenance care and is increased to three or four times per day for acute exacerbations.

► Nutrition

Most CF patients have increased caloric needs due to increased energy expenditure through increased work of breathing, increased basal metabolism, and maldigestion.

- Prevention of malnutrition requires early patient-specific nutritional intervention. Caloric requirements to promote age-appropriate weight gain or maintenance are typically 110% to 200% of the recommended daily allowance (RDA) for age, gender, and size and increase as disease progresses.¹⁶

Nutrition in malnourished patients consists of baseline required calories plus additional calories for weight gain. Even with aggressive diet and oral supplements, the caloric requirement may not be achieved, and placement of a **gastrostomy** or **jejunostomy** tube to support nighttime supplemental feeds may be necessary.⁶ Patients with refractory malabsorption, CFRD, and/or tube feedings have unique caloric needs. Collaboration with dietitians specially trained in CF nutrition is essential.

Pharmacologic Therapy

► Pulmonary System

Airway clearance therapy is usually accompanied by bronchodilator treatment (albuterol [known as salbutamol outside the United States] by nebulizer or metered-dose inhaler) to stimulate mucociliary clearance and prevent bronchospasm associated with therapy (**Table 16-1**).

- A mucolytic agent is administered subsequently to reduce sputum viscosity and enhance clearance. Dornase alfa (Pulmozyme) is a recombinant human (rh) DNase that selectively cleaves extracellular DNA released during neutrophil degradation in viscous CF sputum. Nebulization of dornase alfa 2.5 mg once or twice daily improves daily pulmonary symptoms and function, reduces pulmonary exacerbations, and improves quality of life.¹⁷

Hypertonic saline for inhalation (Hyper-Sal) 7% or 3.5% is often used as an add-on mucolytic agent via osmotic effects or for sputum induction. It must be preceded by a bronchodilator due to a greater incidence of bronchospasm and may not be tolerated by some patients.¹⁸ N-acetylcysteine is another mucolytic agent, but its unpleasant odor and taste limit patient acceptance.⁶

Many patients with CF also have reactive airways or concurrent asthma and benefit from long-acting β_2 -agonists.⁶ Patients with recurrent wheezing or dyspnea who have demonstrated improvement with albuterol (salbutamol) should be considered for maintenance asthma therapy, as should patients with bronchodilator-responsive pulmonary

Table 16-1

Common Pulmonary Medications in CF

Medication	Pediatric Dose	Adult Dose
Albuterol (salbutamol)	2.5 mg nebulized with chest physiotherapy 2 to 4 times daily; alternatively, two puffs via metered-dose inhaler may be substituted	2.5 mg nebulized with chest physiotherapy 2 to 4 times daily; alternatively, two puffs via metered-dose inhaler may be substituted
Dornase alfa	2.5 mg nebulized once or twice daily	2.5 mg nebulized once or twice daily
Hypertonic saline 7%, 3.5%, or 3%	4 mL nebulized 1–4 times/day	4 mL nebulized 1–4 times/day
Azithromycin	Body weight 25–39 kg: 250 mg on Mondays, Wednesdays, and Fridays	Body weight 40 kg or more: 500 mg on Mondays, Wednesdays, and Fridays
Ibuprofen ^a	20–30 mg/kg/dose given twice daily	20–30 mg/kg/dose given twice daily
Ivacaftor ^b	150 mg every 12 hours	150 mg every 12 hours

^aAdjusted to achieve peak plasma concentrations of 50 to 100 mcg/mL (243 to 485 μ mol/L). Maintain chronic dosing with same dosage form and manufacturer. Note that therapy is not always continued into adulthood.

^bDose may require adjustment in patients with moderate or severe hepatic impairment and/or when coadministered with moderate or strong CYP3A inhibitors.

function tests (PFTs). Inhaled corticosteroids may attenuate reactive airways and reduce airway inflammation in some patients; however, clear benefit in CF has not been established.^{1,19} Drug delivery to the site of inflammation is limited by mucus plugging, which may limit efficacy. Patients on asthma therapies should administer these medications after airway clearance to optimize drug delivery. Montelukast, antihistamines, and/or intranasal steroids are sometimes used for CF patients with allergic or rhinosinusitis symptoms.

Long-term systemic corticosteroids reduce airway inflammation and improve lung function. However, beneficial effects diminish upon discontinuation, and concern for long-term adverse effects limits use as maintenance therapy.¹⁹ In clinical practice, systemic corticosteroids may be used short term in acute exacerbations or for treatment of allergic response to *Aspergillus* colonization (allergic bronchopulmonary aspergillosis, or ABPA); however, dose and duration of therapy should be minimized.^{1,20}

High-dose ibuprofen targeting peak concentrations of 50 to 100 mcg/mL (243 to 485 μ mol/L) has been shown to slow progression of disease, particularly in children 5 to 13 years of age with mild lung disease (FEV1 greater than 60% [0.60]). At high doses, ibuprofen inhibits the lipoxygenase pathway, reducing neutrophil migration and function as well as release of lysosomal enzymes. At lower concentrations achieved with analgesic dosing, neutrophil migration increases, potentially increasing inflammation.^{21,22} A dose of 20 to 30 mg/kg given twice daily is usually needed to attain target levels, but interpatient variability necessitates serum concentration monitoring.²¹ Due to monitoring requirements and concerns regarding long-term safety and tolerability, only a few CF centers prescribe high-dose ibuprofen.^{1,19}

Azithromycin is a macrolide antibiotic commonly used in CF as an anti-inflammatory agent to improve overall lung function, although long-term clinical safety and efficacy data are lacking. Proposed mechanisms include interference with

Pseudomonas alginate biofilm production, bactericidal activity during stationary *Pseudomonas* growth, neutrophil inhibition, interleukin-8 reduction, and reduction in sputum viscosity.^{23,24} Due to its long tissue half-life, azithromycin is typically dosed 3 days per week (Monday, Wednesday, and Friday) at 500 mg for patients weighing at least 40 kg and 250 mg for patients weighing 25 to 39 kg. Alternatively, patients may take 500 or 250 mg either daily or only Monday through Friday, based on the same weight parameters. Patients should have a screening acid-fast bacillus sputum culture prior to initiation and then every 6 months due to risk for selection of macrolide-resistant nontuberculous mycobacteria (a contraindication to chronic azithromycin therapy).¹⁹

Antibiotic Therapy

5 Antibiotic therapy is used in three distinct clinical settings within the course of CF: (a) eradication and delay of colonization in early lung disease, (b) suppression of bacterial growth once colonization is present, and (c) reduction of bacterial load in acute exacerbations in an attempt to return lung function to pre-exacerbation levels or greater.¹

6 Antibiotic selection is based on periodic culture and sensitivity data, typically covering all organisms identified during the preceding year. If no culture data are available, empirical antibiotics should cover the most likely organisms for the patient's age group. Due to altered pharmacokinetics and microorganism resistance, dose optimization is key (Table 16-2).

Severity of pulmonary symptoms also guides antibiotic selection. For recent-onset or mild symptoms, patients may be treated with outpatient oral and inhaled antibiotics for 14 to 21 days. Oral fluoroquinolones are a mainstay for *P. aeruginosa* treatment in CF, even in children. Despite concerns regarding cartilage and tendon toxicity in young animals, clinical practice has not shown an increased risk in human children.²⁵ To prevent development of resistance and promote synergy,

Table 16-2
Selected Antibiotic Dosing in CF^a

Antibiotic	Pediatric Dose (mg/kg/day)	Adult Maximum Daily Dose	Interval (hours)
Intravenous			
Tobramycin, gentamicin ^b	10	None	8–24
Amikacin ^b	30	None	8–24
Ceftazidime	150–200	6–8 g	6–8
Cefepime	150	6 g	8
Piperacillin–tazobactam ^c	400	16 g	6
Ticarcillin–clavulanate ^c	400–600	12–18 g	4–6
Meropenem	120	6 g	8
Imipenem–cilastatin ^c	100	2 g	6
Aztreonam	200	8 g	6
Ciprofloxacin	30	1.2 g	8–12
Levofloxacin	10–20	750 mg	12–24
Nafcillin	200	12 g	4–6
Vancomycin ^b	60	None	6–12
Linezolid	30	1.2 g	8–12
Colistin	5–8	480 mg	8
Chloramphenicol ^b	60–80	4 g	6
Oral			
Amoxicillin ± clavulanic acid ^c	45–90	4 g	12
Dicloxacillin	100	2 g	6
Cephalexin	50–100	4 g	6–8
Trimethoprim–sulfamethoxazole ^d	10–20	1,280 mg	6–12
Clindamycin	30	1.8 g	6–8
Ciprofloxacin	40	2 g	12
Levofloxacin	10–20	750 mg	12–24
Minocycline ^e	4	200 mg	12
Linezolid	30	1.2 g	8–12
Inhaled			
Tobramycin	160–600 mg/day	600 mg	12
Aztreonam lysine	225 mg/day	225 mg	8
Colistin	75–150 mg/day	300 mg	12

^aAll doses assume normal renal and hepatic function. Consult a specialized drug reference for dosage adjustment if function is impaired. Dose and/or interval may require adjustment.

^bEmpirical starting doses only. Adjust dose per therapeutic drug monitoring.

^cDose based on β -lactam component.

^dDose based on trimethoprim component.

^eChildren older than 8 years.

inhaled tobramycin, aztreonam, or colistin is usually added for double coverage.^{1,26} Methicillin-sensitive *S. aureus* (MSSA) may be treated with oral amoxicillin–clavulanic acid, dicloxacillin, first- or second-generation cephalosporins, trimethoprim–sulfamethoxazole, clindamycin, doxycycline, or minocycline, depending on sensitivity. Likewise, methicillin-resistant *S. aureus* (MRSA) may be treated with oral trimethoprim–sulfamethoxazole, clindamycin, doxycycline, minocycline, or linezolid. *H. influenzae* often produces β -lactamases but can usually be treated with amoxicillin–clavulanic acid, a cephalosporin, or trimethoprim–sulfamethoxazole.

Oral trimethoprim–sulfamethoxazole or minocycline may be used to treat *S. maltophilia*.

For severe infections or patients failing outpatient therapy, IV antibiotic therapy is prescribed for 2 to 3 weeks as inpatient therapy. Depending on the availability of home health services, some patients may be discharged to finish their course or even receive their entire course at home. **7** *Typical regimens for severe infections include an antipseudomonal β -lactam plus an aminoglycoside for added synergy and delay of resistance development.*^{1,26,27} Cephalosporins tend to be better tolerated and offer the benefit of less frequent administration. Extended-spectrum penicillins have been associated with a higher incidence of allergy. Aztreonam offers the added benefit of little cross-reactivity in penicillin- or cephalosporin-allergic patients; however, it has no gram-positive coverage. Meropenem should be reserved for organisms resistant to all other antibiotics to minimize development of resistance in the carbapenem drug class.

Tobramycin IV is generally the first-line aminoglycoside. Isolates are usually resistant to gentamicin, and amikacin is reserved for tobramycin-resistant strains. Pharmacokinetic goals are listed in **Table 16-3**. Higher peak serum concentrations are targeted to maximize efficacy, whereas lower serum trough levels are targeted to reduce risk of toxicity. Some centers use once-daily dosing (tobramycin 10 to 15 mg/kg/day or amikacin 35 mg/kg/day) targeting higher peaks and lower troughs. Because aminoglycosides exhibit concentration-dependent killing, once-daily dosing may optimize this effect. However, time below the minimum inhibitory concentration (MIC) is prolonged with once-daily administration in children, possibly leading to loss of synergy for a substantial portion of the dosing interval. Due to a shorter half-life, once-daily dosing is not always optimal for younger children. However, it may be a reasonable option for some children, adolescents, and adults in whom the time below the MIC can be minimized. Long-term studies are needed to examine the efficacy and resistance patterns associated with once-daily aminoglycosides in the CF population.^{1,26,27}

Most other serious gram-negative infections are also treated with combination therapy. *S. maltophilia* is highly resistant and most often treated with trimethoprim–sulfamethoxazole or ticarcillin–clavulanate. *A. xylosoxidans* and *B. cepacia* may have minimal therapeutic options. A fluoroquinolone may be substituted for an aminoglycoside based on sensitivity data or presence of renal dysfunction and/or ototoxicity. Due to excellent bioavailability, fluoroquinolones, trimethoprim–sulfamethoxazole, doxycycline, minocycline, and linezolid should be used orally for most patients. Due to toxicity risk, colistin IV and chloramphenicol IV are reserved for life-threatening highly resistant infections.

Inpatient treatment of MRSA can consist of IV vancomycin or oral agents as previously described, depending on the severity of infection and concomitant organisms. Vancomycin IV may also be converted to oral stepdown therapy upon discharge.

Table 16–3

Pharmacokinetic Goals in Cystic Fibrosis

Antibiotic	Traditional Units of Measurement		SI Units of Measurement	
	Goal Peak ^a (mcg/mL)	Goal Trough ^b (mcg/mL)	Goal Peak ^a (μmol/L)	Goal Trough ^b (μmol/L)
Tobramycin, gentamicin	10–12 ^c 20–30 ^d	Less than 1.5 ^c Less than 1 ^d	21–26 ^c 42–63 ^d	Less than 3.2 ^c Less than 2.1 ^d
Amikacin	30–40 ^c 60–90 ^d	Less than 5 ^c Less than 3 ^d	51–68 ^c 103–154 ^d	Less than 8.6 ^c Less than 5.1 ^d
Vancomycin	– ^e	15–20	– ^e	10–14

Note: Values reported in mcg/mL are numerically equivalent to mg/L.

^aPeaks calculated 30 minutes after end of infusion for aminoglycosides.

^bTroughs calculated immediately prior to the time the dose is due.

^cGoals refer to traditional dosing (every 8 or 12 hours). Higher peaks may be targeted with corresponding lower trough concentrations for aminoglycosides based on center practice.

^dGoals refer to once-daily (high-dose extended interval) dosing.

^eNot routinely measured.

Chronic or rotating inhaled antibiotic maintenance therapy may be used to suppress *P. aeruginosa* colonization; however, long-term systemic antibiotics are not recommended due to emergence of resistance.¹ Inhaled tobramycin (TOBI) is typically administered to patients 6 years of age and older in alternating 28-day cycles of 300 mg nebulized twice daily, followed by a 28-day washout period to minimize development of resistance. Long-term cyclical administration improves pulmonary function, decreases microbial burden, and reduces hospitalization for IV therapy.^{28,29} Due to minimal systemic absorption, pharmacokinetic monitoring is not necessary with normal renal function. Lower doses of nebulized tobramycin solution for injection have been used in younger children, and *Pseudomonas* eradication studies used 300 mg twice daily in children as young as 6 months.³⁰

Aztreonam lysine for inhalation (Cayston) is approved for *P. aeruginosa* suppression in 28-day on/off cycles for CF patients 6 years of age and older. A dose of 75 mg three times daily is given via the Altera nebulizer system, a novel high-efficiency drug delivery device.^{31,32} Both aztreonam lysine and its drug-specific nebulizer system are currently only available through a specialty mail-order pharmacy access program.

Nebulized colistin using the IV formulation may be an option in patients with tobramycin-resistant strains or intolerance to inhaled tobramycin or aztreonam lysine. Pretreatment with albuterol is necessary due to increased risk of bronchoconstriction.^{1,6}

Selection of inhaled antibiotics is based on culture data and patient preference. Alternating inhaled antibiotic regimens are sometimes used in patients with more advanced lung disease. Inhaled antibiotics are typically stopped during acute exacerbations requiring IV therapy because drug delivery is reduced with increased sputum

production, and concomitant use of IV aminoglycosides may increase risk of toxicity.²⁶

Pharmacokinetic Considerations

8 *CF patients have larger volumes of distribution for many antibiotics due to an increased ratio of lean body mass to total body mass and lower fat stores. CF patients also have enhanced total body clearance, although the exact mechanism has not been determined. Increased renal clearance, increased glomerular filtration rate, decreased protein binding, increased tubular secretion, decreased tubular reabsorption, extrarenal elimination, and increased metabolism have all been proposed.*

Because of these pharmacokinetic changes, higher doses of aminoglycosides are needed to achieve target serum levels and promote adequate tissue penetration. Higher doses of β-lactam antibiotics are also needed to achieve and sustain levels above the MIC. Trimethoprim–sulfamethoxazole displays enhanced renal clearance and hepatic metabolism in the CF population. Fluoroquinolones and vancomycin have fewer pharmacokinetic deviations; however, higher doses are typically needed to attain inhibitory serum and tissue concentrations against CF pathogens.³³

Although most CF patients have shorter drug half-lives and larger volumes of distribution than non-CF patients, some patients exhibit decreased renal clearance. Concomitant use of nephrotoxic medications, presence of diabetic nephropathy, history of transplantation (immunosuppressant use and/or procedural hypoxic injury), age-related decline in renal function in adult patients, and cumulative lifetime exposure to aminoglycosides decrease clearance. Evaluation of previous pharmacokinetic parameters and trends, along with incorporation of new health information, is key to appropriate dosing.

Gastrointestinal System

- Pancreatic enzyme replacement is the mainstay of GI therapy. Enzyme products available in the United States (Table 16-4) are formulated as capsules containing enteric-coated microspheres or microtablets that escape inactivation of enzymes by gastric acid and promote dissolution in the more alkaline duodenum. Capsules may be opened and the microbeads swallowed with food (for infants and young children), as long as they are not chewed or mixed with alkaline or hot foods (which denature enzymes). Although different products may contain similar enzyme ratios, they are not bioequivalent and cannot be interchanged.^{6,34} Due to an ongoing mandated FDA approval process, product availability has been evolving in recent years.
- Pancreatic enzymes are initiated at 500 to 1,000 units/kg/meal of lipase component (because fats are the most difficult components to digest) with half-doses given for snacks. Enzymes should be taken at the beginning or divided throughout the meal and must be given with any fat-containing snack. Infants are typically started at 1,500 to 2,500 units of lipase per 120 mL of formula or breast milk and may require division of capsule contents via visual estimation to obtain appropriate doses. Pancreatic enzymes cannot be placed in formula bottles due to inability to pass consistently through the nipple slit. Instead, enzyme microbeads are placed on a small dot of infant applesauce (or moistened infant rice cereal) and administered via infant spoon with subsequent nursing or bottle-feeding to facilitate swallowing. The oral mucosa must be examined afterward to ensure that all enzymes are swallowed, because remnant microbeads can cause oral erosions (ulcers).
 - 9 Titration of pancreatic enzyme doses is based on control of steatorrhea, stool output, and abdominal symptoms. Infants should have no more than three to four stools per day,

whereas older patients should have no more than two to three (children) or one to two (adolescents/adults) well-formed stools per day. Doses are titrated at 2- to 3-week intervals in increments of 150 to 250 units of lipase/kg/meal (or the next easily administered capsule or half-capsule) up to 2,500 units/kg/meal. Higher doses should be used cautiously due to risk of fibrosing colonopathy.^{6,7,34} Patients responding poorly to maximal doses of one product may benefit from changing to another product⁶ and/or addition of a histamine H₂-receptor antagonist or proton pump inhibitor. Acid suppression may boost the effective enzyme dose, if duodenal pH is not alkaline enough to neutralize residual gastric acid and dissolve enteric coating. Acid suppression also treats concomitant gastroesophageal reflux disease.^{6,7,34}

- Fat-soluble vitamin supplementation is usually required in pancreatic insufficiency. Specially formulated products for CF patients (AquADEKs, SourceCF, and Vitamax) are usually sufficient to attain normal serum vitamin levels at a dose of 1 mL daily for infants, one tablet daily for younger children, and one tablet/capsule twice daily for teenagers and adults. Additional supplementation may be needed in uncontrolled malabsorption or for replacement of severe vitamin deficiency.^{6,34} Appetite stimulants such as cyproheptadine may be an option for promoting nutrition and weight gain, but efficacy has not been established.

Ursodiol at 20 mg/kg/day in two divided doses may slow progression of liver disease. It improves bile flow and may displace toxic bile acids that accumulate in a cholestatic liver, stimulate bicarbonate secretion into the bile, offer a cytoprotective effect, and reduce elevated liver enzymes.^{6,8}

Treatment of DIOS consists of enteral administration of polyethylene glycol (PEG) electrolyte solutions. Enemas may also be used to facilitate stool clearance, and severe presentations may require surgical resection. IV fluids are often required to correct dehydration due to vomiting or decreased oral intake. Reevaluation of enzyme adherence and dosing is essential to prevent recurrence, and some patients may require daily PEG administration (MiraLAX).⁶

Table 16-4

Common Pancreatic Enzyme Replacement Products

Trade Name ^a	Lipase (Units)	Amylase (Units)	Protease (Units)
Creon 3,000	3,000	15,000	9,500
Creon 6,000	6,000	30,000	19,000
Creon 12,000	12,000	60,000	38,000
Creon 24,000	24,000	120,000	76,000
Pancreaze MT 4	4,200	17,500	10,000
Pancreaze MT 10	10,500	43,750	25,000
Pancreaze MT 16	16,800	70,000	40,000

Zenpep 5,000	5,000	27,000	17,000
Zenpep 10,000	10,000	55,000	34,000
Zenpep 15,000	15,000	82,000	51,000
Zenpep 20,000	20,000	109,000	68,000
Zenpep 25,000	25,000	136,000	85,500

^aThe number after a trade name refers to the number of thousands of units of lipase contained per dosage form.

Patient Encounter, Part 2

TJ's parents have received CF disease state education and have met the multidisciplinary CF team. Additional laboratory testing has been sent to confirm the CF genotype. The team would like to initiate first-line CF therapies at this time because TJ displays symptoms of pancreatic insufficiency as outlined in Part 1. TJ weighs 3.1 kg and is 52 cm long.

Given this information, what is your assessment of TJ's nutritional status?

What are the treatment goals for this patient?

What nonpharmacologic therapy should be initiated?

What pharmacologic therapy should be initiated?

► Endocrine System

Patients with mild CFRD may be managed with carbohydrate modification if nutritional status is optimal. However, most patients present with poor nutrition and weight loss and require more aggressive treatment. **10** *Because CFRD results from insulin insufficiency, exogenous insulin replacement is usually required.* Many patients can be successfully managed by meal coverage with short- or rapid-acting insulin (regular, lispro, or aspart) dosed per carbohydrate counting. Patients with fasting hyperglycemia or patients receiving nighttime tube feedings typically also require longer-acting basal insulin. Regular home glucose monitoring is essential to appropriate therapy. Oral antidiabetic agents have not been studied adequately in CFRD, and routine use is not recommended.^{6,9}

► Musculoskeletal System

CF patients with low bone mineral density and low serum vitamin D levels may improve bone health through supplemental vitamin D analogs beyond those found in standard CF vitamins. For ergocalciferol (or cholecalciferol), a minimum of 400 IU and 800 IU should be taken daily by infants and patients older than 1 year of age, respectively.^{11,34} Total weekly or biweekly doses of 12,000 IU for children younger than 5 years of age and 50,000 IU for patients 5 years of age and older may be required to achieve target vitamin D concentrations. Supplemental calcium should be provided if 1,300 to 1,500 mg of elemental calcium intake cannot be achieved through diet.^{11,34}

Antiresorptive agents (oral or IV bisphosphonates) may be used to treat adult CF patients with osteoporosis. Remaining upright daily for 30 minutes after dosing may be difficult for patients needing to perform airway clearance therapy, so products offering less frequent dosing should be considered. Gastroesophageal reflux or cirrhosis-associated esophageal varices may complicate therapy and increase the risk of erosive esophagitis. Pamidronate 30 mg IV every 3 months has increased bone mineral density in adult CF patients, and studies using IV bisphosphonates in children with CF are underway.¹¹ Androgen replacement in male CF patients with documented hypogonadism may benefit bone health in some patients.¹¹

Short courses of nonsteroidal anti-inflammatory drugs (NSAIDs) can be used to treat CF-related arthritis and hypertrophic pulmonary osteoarthropathy.⁶ The impact on neutrophil recruitment in the lung with long-term NSAID therapy at lower analgesic doses is unknown.

► Innovative Therapeutic Directions

Development of new therapies has extended the CF lifespan over the past several decades. Since the discovery of the CF gene and the CFTR protein defect, research has focused on gene therapy to restore normal CFTR function through DNA transfer. Newer research efforts focus on gene mutation-specific pharmacologic approaches

Patient Encounter, Part 3

TJ is now 9 months old (weight: 8.5 kg) and presents to a routine CF clinic appointment. His parents report that TJ has had a cough productive of yellow sputum for the past week and an intermittent low-grade fever of 101.1°F (38.4°C). Also, TJ is not eating as well as he usually does and has been sleeping more. The following vital signs are noted by clinic staff: RR 45/min, T 101.3°F (38.5°C), oxygen saturation 94% (0.94). Review of TJ's throat cultures since diagnosis reveals the following organisms: *H. influenzae* (β -lactamase positive), *P. aeruginosa* (sensitive to ceftazidime, cefepime, piperacillin/tazobactam, ticarcillin-clavulanate, aztreonam, meropenem, ciprofloxacin, levofloxacin, and tobramycin; resistant to amikacin and gentamicin), and *S. maltophilia* (sensitive to trimethoprim-sulfamethoxazole, minocycline, and ticarcillin-clavulanate; resistant to ceftazidime, meropenem, and levofloxacin). TJ has no known drug allergies.

Based on the information available, design an antibiotic regimen for outpatient therapy of TJ's first pulmonary exacerbation.

What antibiotic(s) and dose(s) would you recommend for inpatient therapy?

Develop a monitoring plan to assess antibiotic response.

to correct or modulate dysfunctional CFTR protein on a gene-specific basis (VX-770, VX-809, ataluren).¹⁴ Additional research is being conducted with inhaled antibiotics (tobramycin powder for inhalation, liposomal amikacin), anti-inflammatory therapies, antipseudomonal vaccines, and exogenous cationic antimicrobial peptides to mimic those found naturally in the lung.¹

In January 2012, the FDA approved ivacaftor (Kalydeco, formerly VX-770) as the first CFTR potentiator for treatment of CF patients 6 years and older who have at least one G551D CFTR gene mutation (present in approximately 4% of the CF population in the United States). Ivacaftor treatment (added to standard CF care) is associated with improved lung function (approximately 10% increase in FEV₁), decreased pulmonary exacerbations, weight gain, and increased quality of life.³⁵ Ivacaftor tablets are dosed at 150 mg orally every 12 hours with fat-containing food. Therapy is generally well tolerated, although elevated liver enzymes have been reported and should be monitored quarterly in the first year of therapy. Additional CFTR potentiators targeting other CFTR gene mutations are currently under investigation.

OUTCOME EVALUATION

Pulmonary System

- Monitor for changes in pulmonary symptoms (cough, sputum production, respiratory rate, and oxygen saturation). Symptoms should improve with antibiotics

Patient Care and Monitoring

1. Perform a thorough history of prescription, nonprescription, and alternative medications. Assess adherence, including timing of inhaled medications with respect to airway clearance therapies and timing of enzymes and insulin with regard to meals. Is the patient taking medications not prescribed by the CF center team?
2. Is the patient on all appropriate maintenance medications? Are medications at the appropriate doses for weight and/or age? If the patient is admitted, are maintenance medications ordered?
3. Evaluate the medication regimen for drug interactions, adverse reactions, and allergies.
4. Assess pulmonary symptoms. Review the incidence and quality of cough, dyspnea, respiratory rate, sputum production, and fever. Are the patient's PFTs decreased? Is there an oxygen requirement?
5. Review culture and sensitivity history over the last 1 to 2 years. What antibiotics were used in the past, and did the patient appear to respond better to a particular regimen? Is the patient currently on antibiotics, and if so, are the symptoms improving? Recommend an appropriate antibiotic regimen based on culture and sensitivity data.
6. Review the pharmacokinetic history. Are there likely changes in clearance since the last antibiotic course? Will the patient be discharged home on IV antibiotics? Can the IV regimen be simplified or made more convenient for home administration? Recommend appropriate doses based on the patient's clearance and an appropriate but convenient schedule.
7. Perform pharmacokinetic adjustments as necessary. Recommend a monitoring plan for the antibiotic course. Are any other laboratory tests necessary? Are signs of toxicity present?
8. Assess nutritional status. Is the patient gaining or maintaining weight according to age? Are any oral supplements or tube feedings being used?
9. Assess GI symptoms. What is the quantity and quality of bowel movements? Does the patient have bloating, flatulence, or abdominal pain?
10. Assess quality-of-life measures such as physical, psychological, and social well-being.
11. Understand that CF therapy is complicated, and recommend regimens that ease care burden.
12. Educate the patient and family, stressing importance of adherence to the regimen.

and aggressive airway clearance therapy. PFTs should be markedly increased after 1 week and trend back to pre-exacerbation levels after 2 weeks of therapy. If improvement lags, 3 weeks of therapy may be needed.

- For IV antimicrobial therapy, obtain serum drug levels for aminoglycosides and/or vancomycin and perform pharmacokinetic analysis. Adjust the dose, if needed, according to the parameters in Table 16–3. Obtain follow-up trough levels and serum creatinine at weekly intervals or sooner if renal function is unstable. Hearing tests may be scheduled yearly or per patient preference.

Gastrointestinal System

- Monitor short- and long-term nutritional status through evaluation of height, weight, and body mass index (BMI). Ideally, parameters should be near the normals (50th percentile) for non-CF patients.
- Evaluate the patient's stool patterns. Steatorrhea indicates suboptimal enzyme replacement or noncompliance. Infants should have two to three well-formed stools daily, whereas older children and adults may have one or two stools daily.
- Monitor efficacy of vitamin supplementation through yearly serum vitamin levels. Obtain levels more frequently if treating a deficiency.

Endocrine System

- Monitor blood glucose several times daily in patients with CFRD or those taking systemic corticosteroids. Follow A1C levels on an outpatient basis to assess long-term glucose control. Levels may be falsely low in CF due to a shorter red blood cell half-life.

Abbreviations Introduced in This Chapter

ABPA	Allergic bronchopulmonary aspergillosis
BMI	Body mass index
cAMP	Cyclic 3',5'-adenosine monophosphate
CF	Cystic fibrosis
CFRD	Cystic fibrosis-related diabetes
CFTR	Cystic fibrosis transmembrane regulator
CPT	Chest physiotherapy
DIOS	Distal intestinal obstruction syndrome
ESBL	Extended-spectrum β -lactamase
FEV1	Forced expiratory volume in 1 second
FVC	Forced vital capacity
HFCC	High-frequency chest compression
INR	International normalized ratio
IPV	Intrapulmonary percussive ventilation
MIC	Minimum inhibitory concentration
MRSA	Methicillin-resistant <i>Staphylococcus aureus</i>
MSSA	Methicillin-sensitive <i>S. aureus</i>
NSAID	Nonsteroidal anti-inflammatory drug
OPEP	Oscillating positive expiratory pressure

PEG	Polyethylene glycol
PFT	Pulmonary function test
PMN	Polymorphonuclear
PT	Prothrombin time
RDA	Recommended daily allowance

Gastroesophageal Reflux Disease

Dianne Williams May and Marie A. Chisholm-Burns

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Explain the underlying causes of gastroesophageal reflux disease (GERD).
2. Differentiate among typical, atypical, and complicated symptoms of GERD.
3. Determine which diagnostic tests should be recommended based on the patient's clinical presentation.
4. Identify the desired therapeutic outcomes for patients with GERD.
5. Recommend appropriate lifestyle modifications and pharmacotherapy interventions for patients with GERD.
6. Discuss other nonpharmacologic interventions that may be appropriate for patients with GERD.
7. Formulate a monitoring plan to assess the effectiveness and safety of pharmacotherapy for GERD.
8. Educate patients on appropriate lifestyle modifications and drug therapy issues including compliance, adverse effects, and drug interactions.

KEY CONCEPTS

- 1 Esophageal gastroesophageal reflux disease (GERD) syndromes can be divided into two distinct categories: (a) symptomatic esophageal syndromes and (b) syndromes associated with esophageal tissue injury.
- 2 Patients with GERD may display symptoms described as: (a) typical, (b) atypical, or (c) complicated.
- 3 Patients presenting with uncomplicated typical symptoms of reflux (heartburn and regurgitation) do not usually require invasive esophageal evaluation.
- 4 The goals of treatment of GERD are to alleviate symptoms, decrease the frequency of recurrent disease, promote healing of mucosal injury, and prevent complications.
- 5 Treatment for GERD involves one or more of the following modalities: (a) patient-specific lifestyle changes and patient-directed therapy, (b) pharmacologic intervention primarily with acid-suppressing agents, (c) antireflux surgery, or (d) endoscopic therapies.
- 6 Acid-suppressing therapy is the mainstay of GERD treatment and should be considered for anyone not responding to lifestyle changes and patient-directed therapy after 2 weeks.

- 7 Antireflux surgery or endoscopic therapies offer an alternative treatment for refractory GERD or when pharmacologic management is undesirable.
- 8 Many patients with GERD experience relapse if medication is withdrawn, and long-term maintenance treatment may be required in these patients.
- 9 Patient medication profiles should be reviewed for drugs that may aggravate GERD.

INTRODUCTION

Gastroesophageal reflux disease (GERD) is defined as troublesome symptoms and/or complications caused by refluxing the stomach contents into the esophagus.^{1,2} The key is that these troublesome symptoms adversely affect the well-being of the patient.² 1 *Esophageal GERD syndromes can be divided into two distinct categories: (a) symptomatic esophageal syndromes and (b) syndromes associated with esophageal tissue injury.*² Symptomatic (or symptom-based) esophageal syndrome is associated with severe reflux symptoms with normal endoscopic findings. Syndromes associated with esophageal tissue injury include erosive esophagitis, strictures, Barrett's esophagus, and esophageal adenocarcinoma. Erosive esophagitis occurs when the esophagus is repeatedly exposed to refluxed

material for prolonged periods. The inflammation that occurs progresses to erosions of the squamous epithelium.

Barrett's esophagus is a complication of GERD, characterized by replacement of the normal squamous epithelial lining of the esophagus by specialized columnar-type epithelium. Barrett's esophagus is more likely to occur in patients with a long history (years) of reflux and may be a risk factor for developing adenocarcinoma of the esophagus because of this change in the epithelial lining. The risk of progression to high-grade dysplasia or adenocarcinoma remains controversial but can be a source of psychological stress for those with Barrett's esophagus.

Certain extraesophageal syndromes have an association with GERD and manifest as symptoms occurring outside the esophagus. Chronic cough, laryngitis, and asthma have the strongest association with GERD. Reflux chest pain syndrome may also occur with chest pain often being indistinguishable from cardiac chest pain. With all of these extraesophageal or "atypical" manifestations, other causes must be ruled out before considering a diagnosis of GERD.

EPIDEMIOLOGY AND ETIOLOGY

GERD is prevalent in patients of all ages and appears to be increasing in both adults and children. It is estimated that 14% to 20% of adults in the United States are affected.³ Although mortality associated with GERD is rare, symptoms can significantly decrease quality of life. The true prevalence and incidence of GERD are unknown because: (a) many patients do not seek medical treatment, (b) symptoms do not always correlate well with disease severity, and (c) there is no standard method for diagnosing the disease. There does not appear to be a major gender difference in incidence except for its association with pregnancy. Gender is an important factor in the development of Barrett's esophagus, which occurs more frequently in males.

PATHOPHYSIOLOGY

The retrograde movement of acid or other noxious substances from the stomach into the esophagus is a major factor in the development of GERD.⁴ Commonly, gastroesophageal reflux is associated with defective lower esophageal sphincter (LES) pressure or function. Problems with other normal mucosal defense mechanisms such as anatomic factors, esophageal clearance, mucosal resistance, gastric emptying, epidermal growth factor, and salivary buffering may also contribute to the development of GERD. Other factors that may promote esophageal damage upon reflux into the esophagus include gastric acid, pepsin, bile acids, and pancreatic enzymes. Therapeutic regimens for GERD are designed to maximize normal mucosal defense mechanisms and attenuate these other factors that contribute to the disease.

Lower Esophageal Sphincter Pressure

The LES is a manometrically defined zone of the distal esophagus with an elevated basal resting pressure. The sphincter is

normally in a tonic, contracted state, preventing the reflux of gastric material from the stomach. It relaxes on swallowing to permit the free passage of food into the stomach.

Mechanisms by which defective LES pressure may cause gastroesophageal reflux are threefold. First, and probably most important, reflux may occur after spontaneous transient LES relaxations that are not associated with swallowing.⁵ Esophageal distention, vomiting, belching, and retching can cause relaxation of the LES. Transient decreases in sphincter pressure are responsible for approximately 40% of the reflux episodes in patients with GERD.⁵

Second, reflux may occur after transient increases in intra-abdominal pressure (stress reflux).⁴ An increase in intra-abdominal pressure such as that occurring during straining, bending over, or a Valsalva maneuver may overcome a weak LES, and thus may lead to reflux.

Third, the LES may be atonic, thus permitting free reflux. Although transient relaxations are more likely to occur when there is normal LES pressure, the latter two mechanisms are more likely when the LES pressure is decreased by such factors as fatty foods, gastric distention, or smoking. Certain foods and medications may worsen esophageal reflux by decreasing LES pressure or by irritating the esophageal mucosa (Table 17-1).^{6,7}

Table 17-1

Foods and Medications That May Worsen GERD Symptoms

Decreased LES Pressure

Foods

Fatty meal/fried foods	Coffee, caffeinated drinks
Carminatives (e.g., peppermint)	Garlic
Chocolate	Onions
	Chili peppers

Medications

Anticholinergics	Ethanol
Barbiturates	Isoproterenol
Benzodiazepines	Narcotics (e.g., morphine)
Caffeine	Nicotine
Dihydropyridine calcium channel blockers	Nitrates
Dopamine	Phentolamine
Estrogen	Progesterone
	Theophylline

Direct Irritants to the Esophageal Mucosa

Foods

Spicy foods	Tomatoes
Citrus fruits, orange juice	Coffee, carbonated beverages

Medications

Bisphosphonates	NSAIDs
Aspirin	Quinidine
Iron	Potassium chloride

GERD, gastroesophageal reflux disease; LES, lower esophageal sphincter; NSAIDs, nonsteroidal anti-inflammatory drugs.

Anatomic Factors

Disruption of the normal anatomic barriers by a hiatal hernia was once thought to be a primary etiology of gastroesophageal reflux and esophagitis. Currently, the presence of a hiatal hernia is generally considered to be a separate entity that may or may not be associated with reflux.

Esophageal Clearance

Many patients with GERD produce normal amounts of acid, but the acid produced spends too much time in contact with the esophageal mucosa. The contact time depends on the rate at which the esophagus clears the noxious material, as well as the frequency of reflux. The esophagus is cleared by primary peristalsis in response to swallowing or by secondary peristalsis in response to esophageal distention and gravitational effects.

Swallowing contributes to esophageal clearance by increasing salivary flow. Saliva contains bicarbonate that buffers the residual gastric material on the surface of the esophagus. The production of saliva decreases with increasing age, making it more difficult to maintain a neutral intraesophageal pH. Therefore, esophageal damage due to reflux occurs more often in the elderly and patients with **Sjögren's syndrome** or **xerostomia**. Swallowing is also decreased during sleep, which contributes to nocturnal GERD in some patients.

Mucosal Resistance

The esophageal mucosa and submucosa consist of mucus-secreting glands that contain bicarbonate. Bicarbonate moving from the blood to the lumen can neutralize acidic refluxate in the esophagus. A decrease in this normal defense mechanism can potentially lead to erosions in the esophagus. When the mucosa is repeatedly exposed to the refluxate in GERD, or if there is a defect in the normal mucosal defenses, hydrogen ions diffuse into the mucosa, leading to the cellular acidification and necrosis that ultimately cause esophagitis.

Gastric Emptying and Increased Abdominal Pressure

Gastric volume is related to the amount of material ingested, rate of gastric secretion, rate of gastric emptying, and amount and frequency of duodenal reflux into the stomach. Delayed gastric emptying can lead to increased gastric volume and can contribute to reflux by increasing intragastric pressure. Factors that increase gastric volume and/or decrease gastric emptying, such as smoking and high-fat meals, are often associated with gastroesophageal reflux. This partially explains the prevalence of postprandial gastroesophageal reflux. Obesity has been linked to GERD because of increased abdominal pressure. Morbidly obese patients may also have more transient LES relaxations, incompetent LES, and impaired esophageal motility.⁵

Composition of Refluxate

The composition, pH, and volume of the refluxate are other factors associated with gastroesophageal reflux. Duodenogastric reflux esophagitis, or "alkaline esophagitis," refers to esophagitis induced by the reflux of bilious and pancreatic fluid. Although bile acids have both a direct irritant effect on the esophageal mucosa and an indirect effect of increasing hydrogen ion permeability of the mucosa, symptoms are more often related to acid reflux than to bile reflux. The percentage of time that esophageal pH is below 4 is greater for patients with severe disease.

The pathophysiology of GERD is a complex process. It is difficult to determine which occurs first: gastroesophageal reflux leading to defective peristalsis with delayed clearing or an incompetent LES pressure leading to gastroesophageal reflux. Understanding factors associated with the development of GERD is essential to providing effective treatment (**Fig. 17-1**).

CLINICAL PRESENTATION AND DIAGNOSIS

- 2 Patients with GERD may display symptoms described as: (a) typical, (b) atypical, or (c) complicated (see Clinical Presentation box on next page).

Diagnosis of GERD

The most useful tool in the diagnosis of GERD is the clinical history, including both the presenting symptoms and associated risk factors. 3 Patients presenting with

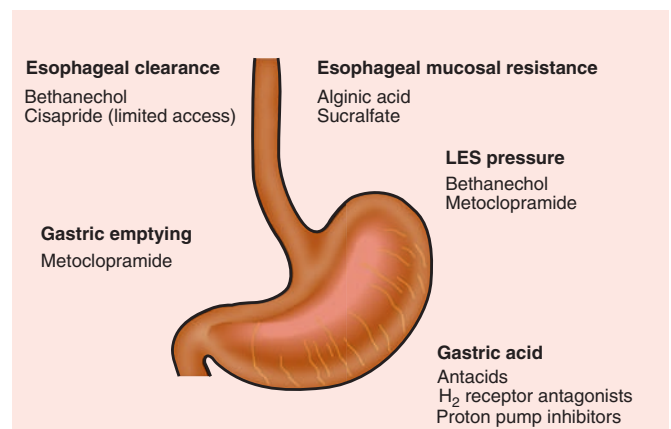

FIGURE 17-1. Therapeutic interventions in the management of gastroesophageal reflux disease. Pharmacologic interventions are targeted at improving defense mechanisms or decreasing aggressive factors. (LES, lower esophageal sphincter.) (Adapted with permission from Williams DB, Schade RR. Gastroesophageal reflux disease. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach, 8th ed. New York, NY: McGraw-Hill, 2008:553.)

Clinical Presentation of GERD

Typical Symptoms

- Heartburn is the hallmark symptom and is described as a substernal sensation of warmth or burning rising up from the abdomen that may radiate to the neck. It may be waxing and waning in character.
- Regurgitation.
- Symptoms may be worse after a fatty meal, when bending over, or when lying in a recumbent position.¹
- Hypersalivation and belching.

Atypical Symptoms

- Asthma, chronic cough, hoarseness, pharyngitis, chest pain, and dental erosions.
- It is important to distinguish GERD symptoms from those of other diseases.

Complicated Symptoms

- Continual pain, dysphagia (difficulty swallowing), odynophagia (painful swallowing), bleeding, unexplained weight loss, unexplained anemia, and choking.
- These symptoms may be indicative of complications of GERD such as Barrett's esophagus, esophageal strictures, or esophageal cancer.

Patient Encounter, Part 1

JM is a 58-year-old African American woman who comes to your clinic with a 1-year history "severe burning" in her throat and regurgitation. She wakes up at least once a night with heartburn. She has been self-medicating with over-the-counter ranitidine 75 mg at bedtime for the last 6 months with no improvement. Her past medical history is significant for anxiety, hypothyroidism, hypertension, and diabetes. Her weight is 86 kg and her height is 5' 4" (163 cm). She smokes 2 packs of cigarettes per day. Drug allergies include lisinopril (angioedema).

What symptoms does the patient have that are consistent with GERD?

Would you classify this patient as having a symptom-based esophageal GERD syndrome, a tissue-injury based esophageal GERD syndrome, or extraesophageal syndrome? Explain.

Which risk factors does she have that may worsen her GERD symptoms?

uncomplicated, typical symptoms of reflux (heartburn and regurgitation) do not usually require invasive esophageal evaluation. These patients generally benefit from a trial of patient-specific lifestyle modifications and empiric acid-suppressing therapy.² A clinical diagnosis of GERD is assumed in

those responding to appropriate therapy. Further diagnostic testing is indicated to: (a) avert misdiagnosis, (b) identify complications, and (c) evaluate empiric treatment failures.

• **Endoscopy** with biopsy is the preferred diagnostic test for assessing the mucosa for esophagitis, Barrett's esophagus, and esophageal adenocarcinoma. It should also be performed in patients with troublesome dysphagia, unexplained weight loss, epigastric mass, or patients with esophageal GERD syndrome who have not responded to an empiric trial of twice-daily proton pump inhibitor (PPI) therapy.² Previous data suggested that long-standing symptomatic GERD is a possible risk factor for developing Barrett's esophagus, and consequently, esophageal adenocarcinoma.⁸ Unfortunately, the presence of Barrett's esophagus may not correlate well with reflux symptoms. This may explain why endoscopic screening for esophageal adenocarcinoma in patients with severe long-standing symptoms has not been as successful as expected.⁹

• Patients with esophageal GERD syndromes who have failed twice-daily PPI therapy and have normal findings on endoscopy may benefit from manometry. Manometry helps to localize the LES for ambulatory pH monitoring, evaluates peristaltic function in patients considering surgery, and identifies possible motor disorders.²

• In patients with normal endoscopic and manometry findings who are still symptomatic despite appropriate treatment, esophageal pH monitoring may be useful. There are various methods that may be used including ambulatory impedance pH, catheter pH, or wireless pH monitoring. These tests can objectively prove that symptoms are reflux related.² **Impedance pH monitoring** allows reflux episodes to be characterized as acid or nonacid.¹⁰ This method may be useful in patients with refractory symptoms. Wireless pH monitoring can record data for up to 48 hours and therefore may be more sensitive than catheter studies for detecting esophageal acid exposure.² For best results, PPI therapy should be withheld for 7 days prior to ambulatory impedance pH, catheter pH, or wireless pH monitoring.²

TREATMENT

Desired Outcomes

- **4** *The goals of treatment of GERD are to alleviate symptoms, decrease the frequency of recurrent disease, promote healing of mucosal injury, and prevent complications. Inadequate treatment and consequent long-term acid exposure may lead to complications such as Barrett's esophagus and possibly esophageal adenocarcinoma.²*

General Approach to Treatment

- **5** *Treatment for GERD involves one or more of the following modalities: (a) lifestyle changes and patient-directed therapy, (b) pharmacologic intervention primarily with acid-suppressing agents, (c) antireflux surgery, or (d) endoscopic therapies. The first therapeutic option used depends on the patient's condition (i.e., frequency of symptoms, degree of esophagitis, and presence of complications; [Table 17-2](#)).*

Table 17-2

Therapeutic Approach to GERD in Adults

Patient Presentation	Recommended Treatment Regimen	Comments

Given this additional information, are there any other factors that could be contributing to her GERD symptoms?

Should patient-directed therapy with over-the-counter ranitidine 75 mg at bedtime be continued? Explain.

What nonpharmacologic and pharmacologic changes would you recommend for her GERD therapy?

JM returns to your clinic after her second 8-week course of lansoprazole 30 mg once daily because her symptoms still have not improved. What would you recommend next for this patient?

When would further diagnostic testing be indicated?

adequate acid suppression is rare. In these cases, the diagnosis should be confirmed through further diagnostic tests before long-term, high-dose therapy or antireflux surgery or endoscopic therapies are considered.

Nonpharmacologic Therapy

Nonpharmacologic treatment of GERD includes patient-specific lifestyle modifications, antireflux surgery, or endoscopic therapies.

► Lifestyle Modifications

- Although most patients do not respond to lifestyle changes alone, the importance of maintaining these changes throughout the course of GERD therapy should be discussed. The most beneficial lifestyle changes include: (a) losing weight if overweight or obese, and (b) elevating the head of the bed if symptoms are worse when recumbent. Elevating the head

of the bed about 6 to 10 in. (15 to 25 cm) with a foam wedge (not just elevating the head with pillows) decreases nocturnal esophageal acid contact time and should be recommended.

Other lifestyle modifications should be considered based on the circumstances of the individual patient. These include: (a) eating smaller meals and avoiding meals 3 hours before sleeping, (b) avoiding foods or medications that exacerbate GERD, (c) smoking cessation, and (d) avoiding alcohol.

Patient medications and food histories should be evaluated to identify potential factors that may exacerbate GERD symptoms (see Table 17–1). Patients should be monitored closely for symptoms when medications known to worsen GERD are started.

► Antireflux Surgery and Endoscopic Therapies

- 7 *Antireflux surgery or endoscopic therapies offer alternative treatments for refractory GERD or when pharmacologic management is undesirable.* Surgical intervention is a viable alternative for selected patients with well-documented GERD.² The goal of surgery is to reestablish the antireflux barrier, to position the LES within the abdomen where it is under positive (intra-abdominal) pressure, and to close any associated hiatal defect. It should be considered in patients who: (a) fail to respond to or are intolerant to pharmacologic treatment, (b) opt for surgery despite successful treatment because of lifestyle considerations, (c) have complications of GERD, or (d) have extraesophageal manifestations.^{2,11}

Three main endoscopic approaches for the management of GERD are available: (a) application of radiofrequency energy to the LES area, (b) endoscopic suturing to produce a plication, and (c) endoscopic injection of bulking agents, or implantation of a bioprosthesis into the lower esophageal sphincter zone.¹² These cannot currently be recommended for routine use in patients with esophageal GERD syndromes.²

Pharmacologic Therapy

► Antacids and Antacid–Alginic Acid Products

- Antacids are an appropriate component of treating mild GERD because they are effective for immediate, symptomatic relief. They are often used concurrently with other acid-suppressing therapies. Common antacids include magnesium hydroxide/aluminum hydroxide combination products (e.g., Mylanta, Maalox) and those containing calcium carbonate, such as Tums.

An antacid product combined with alginic acid (Gaviscon) is not a potent neutralizing agent but forms a highly viscous solution that floats on the surface of the gastric contents. This viscous solution serves as a protective barrier for the esophagus against reflux of gastric contents.

Dosage recommendations for antacids vary and range from hourly dosing to administration on an as-needed basis. In general, antacids have a short duration of action, which requires frequent administration throughout the day to provide continuous acid neutralization.

Antacids also have clinically significant drug interactions with ferrous sulfate, isoniazid, sulfonyleureas, and quinolone

antibiotics. Antacid–drug interactions are influenced by antacid composition, dose, dosage schedule, and formulation.

► **Histamine₂-Receptor Antagonists**

The histamine₂-receptor antagonists (H₂RAs)—cimetidine, famotidine, nizatidine, and ranitidine—decrease acid secretion by inhibiting the histamine₂-receptors in gastric parietal cells. When given in divided doses, they are effective for patients with mild to moderate GERD.¹ Standard doses provide symptomatic improvement in about 60% of patients after 12 weeks of therapy.¹ Healing rates per endoscopy tend to be lower (50%).¹ Response to the H₂RAs depends on the severity of disease, the dosage regimen used, and the duration of therapy.

For symptomatic relief of mild GERD, low-dose, nonprescription H₂RAs may be beneficial. For patients not responding to patient-directed therapy with over-the-counter (OTC) agents after 2 weeks, standard-dose acid-suppressing therapy is warranted. Although higher doses of H₂RAs may provide greater symptomatic and endoscopic healing rates, limited information exists regarding their safety, and they can be less effective and more costly than once-daily PPIs.

Because all H₂RAs have similar efficacy, selection should be based on differences in dosage regimen, safety profile, and cost. In general, H₂RAs are well tolerated. Patients should be monitored for adverse effects and potential drug interactions. Cimetidine has the most drug interactions.

► **Proton Pump Inhibitors**

The PPIs—esomeprazole, lansoprazole, omeprazole, pantoprazole, rabeprazole, and dexlansoprazole—block gastric acid secretion by inhibiting gastric H⁺/K⁺-adenosine triphosphatase in gastric parietal cells. This produces a profound, long-lasting antisecretory effect capable of maintaining the gastric pH above 4, even during acid surges seen postprandially.

The PPIs are superior to H₂RAs in patients with moderate to severe GERD. This includes not only patients with erosive esophagitis or complicated symptoms (Barrett's esophagus or strictures) but also those with symptomatic esophageal syndromes. Symptomatic relief is seen in approximately 83% of patients, and healing rates at 8 weeks as judged by endoscopy are 78%.¹

A PPI should be given empirically to patients with troublesome symptoms of GERD. If the standard once-daily course of therapy is not effective in eliminating symptoms, then empiric therapy with twice-daily dosing should be given. Patients not responding to twice-daily PPI therapy should be considered treatment failures, and further diagnostic evaluation should be performed.² Evidence does not support using higher than normal doses of PPIs in patients with Barrett's esophagus with the sole intent of reducing the risk of progression to dysplasia or cancer.¹³ The risks and benefits of long-term PPI therapy in patients with Barrett's esophagus should be considered.

Comparable daily doses of PPIs are omeprazole 20 mg = esomeprazole 20 mg = lansoprazole 30 mg = dexlansoprazole

30 mg = rabeprazole 20 mg = pantoprazole 40 mg. The PPIs degrade in acidic environments and are therefore formulated in delayed-release capsules or tablets.¹⁴ Lansoprazole, esomeprazole, and omeprazole contain enteric-coated (pH-sensitive) granules in a capsule form. For patients unable to swallow the capsule, pediatric patients, or those with a nasogastric tube, the contents of the capsule can be mixed in applesauce or placed in orange juice.¹⁵ The acidic juices help maintain the integrity of the enteric-coated pellets until they reach the small intestine.¹⁵ Esomeprazole pellets can be mixed with water prior to delivery through a nasogastric tube.¹⁵ Lansoprazole is also available in a delayed-release orally disintegrating tablet. Esomeprazole and omeprazole are available in a delayed-release oral suspension powder packet.

Omeprazole is also available in an immediate-release formulation combined with sodium bicarbonate (Zegerid). The proposed benefit of this combination product is fast onset of action and increase in pH by the sodium bicarbonate, which helps prevent degradation of omeprazole in the stomach. Sodium bicarbonate may also stimulate gastrin production, which may activate the proton pumps and optimize the effectiveness of omeprazole.

Patients taking pantoprazole or rabeprazole should be instructed not to crush, chew, or split the delayed-release tablets. Pantoprazole and esomeprazole are available in IV formulations that offer an alternative route for patients unable to take oral medications. The IV product is not more effective than the oral forms and is significantly more expensive.

Patients should be instructed to take their PPI in the morning, 30 to 60 minutes before breakfast to maximize efficacy, because these agents inhibit only actively secreting proton pumps. Although usually given prior to breakfast, patients with nighttime symptoms may benefit from taking their PPI prior to the evening meal.¹ If a second dose is needed, it should be administered before the evening meal and not at bedtime.¹ Regardless of the time of day, PPIs should be given prior to a meal to gain the most benefit. The exception to this is the immediate-release omeprazole–sodium bicarbonate combination product, which can be given at bedtime.

All PPIs can decrease the absorption of drugs (e.g., ketoconazole) that require an acidic environment to be absorbed. All PPIs are metabolized by the cytochrome P-450 system to some extent. Omeprazole and lansoprazole are metabolized by CYP2C19 enzymes. Concerns have been raised about PPIs used concurrently with clopidogrel, a prodrug that must be converted to its active form by CYP2C19. Inhibition of CYP2C19 by PPIs has been suggested to decrease the effectiveness of clopidogrel and increase the risk of cardiac events. A recent consensus report found little evidence to suggest cardiovascular harm when PPIs were used concurrently with clopidogrel.¹⁶ Omeprazole is the most likely PPI to cause problems in patients on clopidogrel, and the FDA has identified this agent as the only one of concern. Patients who are slow metabolizers or the slow biotransformer phenotype for clopidogrel require further study. The consensus report recommended PPIs due to superior efficacy in patients with a history of upper GI

bleeding or with multiple risk factors for GI bleeding who require antiplatelet therapy.¹⁶ Risk factors for GI bleeding include a history of bleeding or other complication of peptic ulcer disease; advanced age; use of anticoagulants, corticosteroids, or nonsteroidal anti-inflammatory drugs (NSAIDs); and presence of *Helicobacter pylori*.¹⁶ Consider an H₂RA for patients at lower risk of GI bleeding.

No interactions with lansoprazole, pantoprazole, or rabeprazole have been seen with CYP2C19 substrates such as diazepam, warfarin, or phenytoin.¹⁷ Esomeprazole does not appear to interact with warfarin or phenytoin. Pantoprazole is metabolized by a cytosolic sulfotransferase and therefore less likely to have significant drug interactions than other PPIs. Although generally not of major concern, omeprazole may inhibit the metabolism of warfarin, diazepam, and phenytoin. Drug interactions with omeprazole are of particular concern in patients who are considered “slow metabolizers,” approximately 3% of the white population. Unfortunately, it is unclear which patients have the polymorphic gene variation that makes them slow metabolizers. Alternatively, patients who are considered rapid metabolizers, which is most common in the Asian population (12% to 20%), may not respond as well as those who are considered slow metabolizers.¹⁸ This genetic variation among patients may alter the effect of PPIs due to the ability of their enzyme system to metabolize the drug.¹⁸ Esomeprazole is metabolized more by CYP3A4 enzymes and may be affected less by the patient’s genotype.¹⁹

The PPIs are generally well tolerated. The most common side effects are headache, diarrhea, constipation, and abdominal pain. Potential concerns about long-term use of PPIs include development of hypergastrinemia, enteric infections, vitamin B₁₂ deficiency, or hypomagnesemia. Prolonged hypergastrinemia associated with PPI use causing enterochromaffin-like cell hyperplasia or carcinoid tumors has not been convincingly proven.²⁰ Enteric infections, including *Clostridium difficile*, may be caused by numerous factors (e.g., age, antibiotic use, contact with infected healthcare worker, crowding, and immunosuppression). Therefore, the role PPIs may play in the development of these infections is speculative. PPIs may inhibit the secretion of intrinsic factor by the parietal cells, which may lead to decreased absorption of vitamin B₁₂ with subsequent deficiency. There is little evidence to support clinical relevance to this finding. Although hypomagnesemia is a rare side effect of PPI therapy, it can potentially be life threatening. Higher doses and long-term use (more than 1 year) are most likely to be associated with hypomagnesemia.

Conflicting data are available regarding the risk of fractures in patients taking concomitant PPI therapy.²¹ A recent FDA advisory warned of the potential risk for osteoporosis and fractures in patients taking long-term PPI therapy (more than 1 year) or high-dose PPI therapy.²¹ The advisory was revised 10 months later to remove the fracture risk warning on the OTC PPIs because fractures with short-term low-dose PPI are unlikely.²² Another study showed that fracture risk with PPI use was only significant in those who also had other risk factors for fracture or

osteoporosis.²³ Because the data are conflicting, patients with clear indications should receive PPI therapy. Routine bone density studies or calcium supplementation are not warranted based on PPI use alone.²

Because all PPIs have similar efficacy, selection of the specific agent should be based on factors such as differences in dosage regimen, safety profile, and cost.

► Prokinetic Agents

The prokinetic agents include metoclopramide and bethanechol. The inferior efficacy and adverse effect profiles of metoclopramide and bethanechol limit their use in the treatment of GERD, and they are not recommended.

► Mucosal Protectants

Sucralfate, a nonabsorbable aluminum salt of sucrose octasulfate, has very limited value in the treatment of GERD and is not recommended.

Combination Therapy

Two agents of different therapeutic classes should not be used routinely. Only modest improvements have been shown when a prokinetic agent is combined with a standard dose of an H₂RA. Therefore, patients not responding to standard H₂RA doses should be switched to a PPI instead of adding a prokinetic agent. Monotherapy with a PPI is not only more effective, but it also improves compliance with once-daily dosing and is ultimately more cost effective.

The addition of an H₂RA at bedtime to PPI therapy has been suggested to decrease nocturnal acid breakthrough. Although there may be an immediate effect to control symptoms and keep the pH greater than 4, tachyphylaxis may quickly develop. If H₂RAs are used at night, it may be preferable to only use them as needed to provide a “drug holiday” that may lessen the occurrence of tachyphylaxis.²⁴ There is no evidence supporting the addition of a nocturnal dose of an H₂RA to twice-daily PPI therapy.² Immediate-release omeprazole–sodium bicarbonate has been shown to decrease nocturnal acid exposure compared with pantoprazole administered daily with the evening meal and lansoprazole administered at bedtime. Although more studies are needed, immediate-release omeprazole may offer an effective option for controlling nocturnal acid exposure and symptoms over the addition of an H₂RA.

Maintenance Therapy

8 Many patients with GERD experience relapse if medication is withdrawn, and long-term maintenance treatment may be required in these patients.¹ Candidates for maintenance therapy include patients whose symptoms return once therapy is discontinued or decreased, patients with a history of esophagitis healed by PPIs, patients with complications such as Barrett’s esophagus or strictures, and perhaps patients with atypical symptoms. In some patients, the dose of acid-suppressing therapy may be titrated to the lowest dose that controls symptoms.²

The goal of maintenance therapy is to improve quality of life by controlling symptoms and preventing complications. Acid suppressing therapy should be reduced to the lowest dose that controls symptoms and routinely evaluated to determine if long-term therapy is indicated. This is especially true in light of more recent safety concerns with long-term PPI use.

The H₂RAs may be effective maintenance therapy for patients with mild disease. The PPIs are first choice for maintenance treatment of moderate to severe GERD. A short course of “on-demand” therapy may be appropriate in patients with symptomatic esophageal syndromes without esophagitis when symptom control is the primary outcome of interest.² Antacids have the fastest onset and may be used in combination with an H₂RA or PPI for on-demand symptom relief.

Although patients with a history of esophagitis and/or complications generally require long-term maintenance therapy with a PPI, the dose should be titrated down to the lowest effective dose to provide adequate symptom control.² Long-term use of higher PPI doses is not indicated unless the patient has complicated symptoms, has erosive esophagitis per endoscopy, or has had further diagnostic evaluation to determine degree and frequency of acid exposure. Antireflux surgery and endoscopic therapies may be viable alternatives to long-term drug use for maintenance therapy in selected patients.

Special Population Considerations

► *Patients with Extraesophageal GERD*

GERD therapy has not been shown to be beneficial in treating extraesophageal symptoms in patients without concomitant typical GERD symptoms.² Other causes should be ruled out before attributing the symptoms to GERD. Chronic cough, laryngitis, and asthma have established associations with GERD.² In patients presenting with extraesophageal GERD syndromes such as laryngitis or asthma, treatment with twice-daily PPI therapy for 2 months is probably warranted when there is a concomitant esophageal GERD syndrome.² Patients with suspected reflux chest pain syndrome should receive twice-daily PPI therapy for 4 weeks after cardiac causes have been excluded. Manometry and pH or impedance pH monitoring should be considered in patients who do not respond to PPI therapy.²

Maintenance therapy is generally indicated in patients with extraesophageal GERD syndromes and concomitant esophageal GERD syndromes but not with reflux chest pain syndrome alone.²

► *Pediatric Patients with GERD*

Generally, gastroesophageal reflux (GER) is a normal physiologic process occurring several times per day with no clinical consequence. As with adults, GERD is present when symptoms become troublesome or if complications are present.²⁵

Regurgitation is common in pediatric patients and usually described as the effortless and nonprojectile passage of

refluxed gastric contents into the pharynx or mouth. This is also known as spitting-up or the “happy spitter,” which may occur daily in as many as 50% of infants younger than 3 months.²⁵ Reflux episodes are common during transient LES relaxations not related to swallowing.²⁵ This is due to developmental immaturity of the LES. Other causes include impaired luminal clearance of gastric acid and type of infant formula. Patients with neurologic impairment, obesity, repaired esophageal atresia, congenital esophageal disease, cystic fibrosis, hiatal hernia, repaired achalasia, lung transplant, or family history are at a higher risk for developing GERD.²⁵

Uncomplicated GERD usually resolves by 12 to 18 months of life and responds to supportive therapy, including dietary adjustments such as smaller meals, more frequent feedings, or thickened infant formula. Postural management (e.g., positioning the infant in an upright position, especially after meals) may also be helpful. If lifestyle modifications are not effective, medical therapy may be indicated. Acid suppression with either an H₂RA or PPI is the mainstay of pharmacologic therapy.²⁵ Monotherapy with an H₂RA is commonly used; ranitidine 2 to 4 mg/kg/day IV (or 4 to 8 mg/kg/day orally) is effective in neonates and pediatric patients. However, chronic use may lead to tachyphylaxis.

The use of PPIs in pediatric patients has increased significantly. Safety and effectiveness of lansoprazole has been shown for pediatric patients 1 to 17 years old for short-term treatment of symptomatic GERD and erosive esophagitis.²⁶ Studies in adolescents (12 to 17 years old) demonstrated pharmacokinetics similar to those seen in adults.²⁶ The recommended dose is 15 mg once daily for children weighing 30 kg or less and 30 mg once daily for those weighing more than 30 kg. The approved GERD dose of omeprazole in children 12 to 17 years old is 20 mg to 40 mg and 10 mg to 20 mg in patients 1 to 11 years old. Although not approved in pediatric patients younger than 1 year, omeprazole 1 mg/kg/day (given once or twice daily) has been used for esophagitis. The long-term safety of prolonged use in children is unknown, and therefore clinicians must carefully weigh risk versus benefit.²⁵

► *Elderly Patients with GERD*

Older individuals have decreased host defense mechanisms such as slowed gastric emptying and decreased saliva production. These patients often do not seek medical attention because they believe their symptoms are part of the normal aging process. PPIs are the most useful option in this population because they have superior efficacy and are dosed once daily. In addition, there are fewer drug–drug and drug–disease state interactions compared with H₂RAs and metoclopramide. Elderly patients may be sensitive to the CNS effects of metoclopramide and H₂RAs.

► *Patients with Refractory GERD*

Refractory GERD may be present in patients not responding to 4 to 8 weeks of twice-daily PPI therapy. Compliance and timing of medication should always be assessed prior

to deciding that a patient is refractory to acid-suppressing therapy. Endoscopy is indicated to determine if underlying pathology exists. In addition, patients with esophagitis may have a genotype that renders the PPIs less effective.¹⁷ Patients with normal endoscopy should undergo further testing with ambulatory pH monitoring or impedance monitoring to identify acid and nonacid reflux episodes, respectively.¹⁷ Patients not responding to PPI therapy may in fact have nonacid reflux approximately 20% to 30% of the time.¹⁰ Consideration may be made to switch to an alternative PPI, due to variability of patient responses, before increasing to twice-daily PPI in patients not responding to once-daily PPI therapy. Up to 20% of patients on twice-daily PPI therapy with continued symptoms have nonacid reflux.^{27,28} Non-reflux-related esophageal causes may include dysmotility syndromes such as achalasia or scleroderma, or eosinophilic esophagitis.²⁹

OUTCOME EVALUATION

- Monitor for symptom relief and the presence of complicated symptoms.
- Record the frequency and severity of symptoms by interviewing the patient after 4 to 8 weeks of acid-suppressing therapy. Continued symptoms may indicate the need for long-term maintenance therapy.
- Monitor for adverse drug reactions, drug–drug interactions, and adherence.
- Educate patients about symptoms that suggest the presence of complications requiring immediate medical attention, such as dysphagia or odynophagia.
- Refer patients who present with atypical symptoms to their physician for further diagnostic evaluation.
- Reassess the need for chronic PPI therapy.
- **9** Review patient profiles for drugs that may aggravate GERD.

Patient Encounter, Part 3: Monitoring for Safety and Efficacy

JM returns to your clinic for her annual follow-up appointment. Her GERD symptoms are now well controlled, and she is receiving maintenance therapy with lansoprazole 30 mg every morning. She is worried that she may develop a bone fracture if she continues her proton pump inhibitor, but her symptoms return when she tries to stop it. She wants to know if she should start a calcium supplement to prevent fractures.

What would you tell this patient about taking calcium supplements as a prophylactic measure to prevent fractures due to PPI use?

Based on the information presented, how should you monitor the patient for safety and efficacy outcomes?

Patient Care and Monitoring

1. Assess symptoms to determine if further diagnostic evaluation is necessary. Does the patient have complications?
2. Perform a thorough medication history by evaluating nonprescription, prescription, and dietary supplement products.
3. Determine what treatments have been helpful in the past.
4. Instruct patient to avoid foods that aggravate GERD symptoms.
5. Educate patient on lifestyle modifications.
6. Review the results of diagnostic tests.
7. Recommend appropriate therapy and develop a plan to assess effectiveness. Patients should receive 4 to 8 weeks of empiric acid-suppressing therapy. Patients who fail to respond should be assessed for compliance and proper medication administration. Twice-daily PPI therapy should be considered in patients not responding to once-daily therapy.
8. Evaluate for adverse drug reactions, drug allergies, and drug interactions.
9. Stress the importance of adherence.
10. Determine if long-term maintenance treatment is necessary.
11. Assess improvement in quality-of-life measures.
12. Provide patient education on disease, lifestyle modifications, and drug therapy:
 - What causes GERD and what are things to avoid?
 - What are possible complications?
 - When should medications be taken?
 - What potential adverse effects may occur?
 - Which drugs may interact with their therapy?
 - What warning signs should be reported to the physician?

Abbreviations Introduced in This Chapter

GER	Gastroesophageal reflux
GERD	Gastroesophageal reflux disease
H ₂ RA	Histamine ₂ -receptor antagonist
LES	Lower esophageal sphincter
NSAID	Nonsteroidal anti-inflammatory drug
PPI	Proton pump inhibitor

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Peptic Ulcer Disease

Catherine A. Bourg, Erika L. Grigg,
and Dianne Williams May

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Recognize differences between ulcers induced by *Helicobacter pylori*, nonsteroidal anti-inflammatory drugs (NSAIDs), and stress-related mucosal damage (SRMD) in terms of risk factors, pathogenesis, signs and symptoms, clinical course, and prognosis.
2. Identify desired therapeutic outcomes for patients with *H. pylori*-associated ulcers and NSAID-induced ulcers.
3. Identify factors that guide selection of an *H. pylori* eradication regimen and improve adherence with these regimens.
4. Determine the appropriate management for a patient taking a nonselective NSAID who is at high risk for ulcer-related GI complications (e.g., GI bleed) or who develops an ulcer.
5. Devise an algorithm for the evaluation and treatment of a patient with signs and symptoms suggestive of an *H. pylori*-associated or NSAID-induced ulcer.
6. Given patient-specific information and the prescribed drug treatment regimen, formulate a monitoring plan for a patient who is receiving drug therapy either to eradicate *H. pylori* or to treat an active NSAID-induced ulcer or GI complication.

KEY CONCEPTS

- 1 Patients with peptic ulcer disease (PUD) should avoid exposure to factors known to worsen the disease, exacerbate symptoms, or lead to ulcer recurrence (e.g., NSAID use, alcohol consumption, or cigarette smoking).
- 2 Reliance on conventional antiulcer drug therapy as an alternative to *Helicobacter pylori* eradication is inappropriate because it is associated with a higher incidence of ulcer recurrence and ulcer-related complications.
- 3 Eradication therapy with a proton pump inhibitor (PPI)-based three-drug regimen should be considered for all patients who test positive for *H. pylori* and have an active ulcer or a documented history of either an ulcer or ulcer-related complication. Different antibiotics should be used if a second course of *H. pylori* eradication therapy is required.
- 4 In patients at risk for NSAID-induced ulcers, PPIs at standard doses reduce the risk of both gastric and duodenal ulcers as effectively as misoprostol and more effectively than histamine₂-receptor antagonists (H₂RAs).
- 5 Selective cyclooxygenase (COX)-2 inhibitors are no more effective than the combination of a PPI and

a nonselective NSAID in reducing the incidence of ulcers and are associated with a greater incidence of cardiovascular (CV) events (e.g., ischemic stroke).

- 6 Indications for stress ulcer prophylaxis include major trauma or surgery, severe head trauma, multiple organ failure, burns covering more than 25% to 30% of body, severe sepsis, shock, mechanical ventilation, coagulopathy, and high-dose corticosteroid use.
- 7 Low-dose maintenance therapy with a PPI or H₂RA is only indicated in patients with severe complications secondary to PUD such as gastric outlet obstruction or patients who need to be on long-term NSAIDs or high-dose corticosteroids and are at high risk for bleeding.

INTRODUCTION

Peptic ulcer disease (PUD) refers to a defect in the gastric or duodenal mucosal wall that extends through the **muscularis mucosa** into the deeper layers of the submucosa.¹ PUD is a significant cause of morbidity and is associated with substantial healthcare costs. Over the past several decades, the prevalence of PUD has declined due to the discovery of *Helicobacter pylori* and effective acid-suppressing medications. Although there are many etiologies of PUD (**Table 18-1**), the three most common causes are (a) *H. pylori* infection, (b) use of NSAIDs,

Table 18-1

Etiologies of Peptic Ulcer Disease

<i>Helicobacter Pylori</i> -Positive Infection	NSAID-Induced PUD
Viral infections (e.g., CMV or HSV, especially in immunocompromised patients)	Tumors (cancer, lymphoma, primary, or metastatic)
Stress related mucosal damage	Cameron ulcer (ulcer within a hiatal hernia where the hernia passes the diaphragmatic hiatus)
Acid hypersecretory state (e.g., ZES)	Radiation damage
Anastomotic site ulcer	Idiopathic
Chemotherapy	Vascular insufficiency

CMV, cytomegalovirus; HSV, herpes simplex virus; NSAID, nonsteroidal anti-inflammatory drug; PUD, peptic ulcer disease; ZES, Zollinger–Ellison syndrome.

or, less commonly, (c) stress-related mucosal damage (SRMD).

Complications of PUD include GI bleeding, perforation, and obstruction. Complications of untreated or undiagnosed *H. pylori* infection include gastric cancer and PUD. This chapter focuses mainly on strategies to optimize pharmacotherapy for patients with PUD related to *H. pylori* or NSAID therapy. Stress ulcer prophylaxis (SUP) is an issue seen in hospitalized patients and is also discussed briefly.

EPIDEMIOLOGY AND ETIOLOGY

The prevalence of *H. pylori* has decreased over the past few decades, probably due to improved sanitary conditions; however, *H. pylori* infection remains a public health issue in developing countries.^{2,3} The prevalence of *H. pylori* in the United States and Canada is about 30%, whereas the global prevalence is greater than 50%. Factors that influence the incidence and prevalence of *H. pylori* include age, ethnicity, sex, geography, and socioeconomic status. Unfortunately, there is no vaccine available for *H. pylori* because the exact source of the infection is not yet known.³

In the United States, PUD affects approximately 4.5 million people annually with lifetime prevalence estimated to be 11% to 14% in men and 8% to 11% in women. PUD costs an estimated \$5.65 billion per year including hospitalizations, outpatient care, and work loss expenditures, not including medication costs.⁴ Despite the widespread use of conventional and effective antiulcer therapy, ulcers frequently recur.² *H. pylori* infection and NSAID use account for most cases of PUD. Although hospitalizations related to PUD have decreased over the past 2 decades, the incidence of PUD-related complications such as bleeding and perforation remains unchanged.²

In general, ulcers related to *H. pylori* infection more commonly affect the duodenum, whereas ulcers related to NSAIDs more frequently affect the stomach (Fig. 18-1). However, ulcers may be found in either location from either cause. Gastric ulcers (GUs) may occur anywhere in the stomach; duodenal ulcers (DUs) tend to occur most often in the duodenal bulb. The epigastric pain associated with a DU typically occurs during the fasting state or at night and

is often relieved by food, whereas pain from a GU is usually aggravated by food intake.⁵ Malignancy is more commonly found with GU than DU.¹

Helicobacter Pylori

- Helicobacter pylori* causes **gastritis** in all infected patients. However, only a small proportion (less than 10%) of patients actually develops symptomatic PUD. In 2005, Warren and Marshall received the Nobel Prize for recognizing *H. pylori* eradication as a cure for PUD.⁶

H. pylori is usually contracted in the first few years of life and tends to persist indefinitely unless treated. The infection normally resides in the stomach and is transmitted via the fecal–oral route or through ingestion of fecal-contaminated water or food. Prevalence varies greatly throughout the world, increasing with older age and with lower socioeconomic

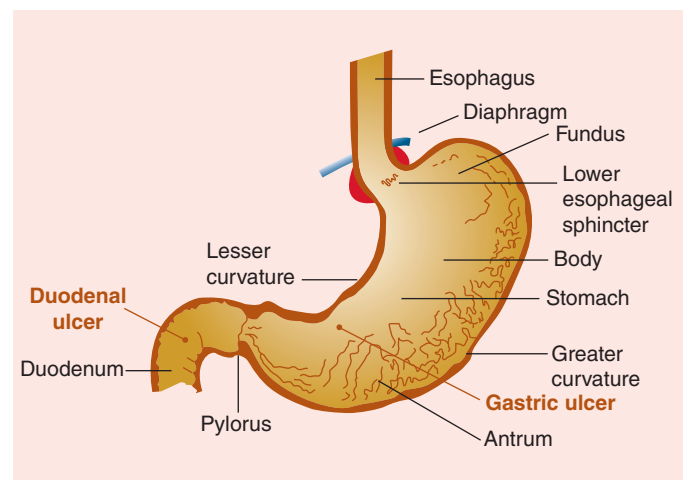

FIGURE 18-1. Anatomic structure of the stomach and duodenum and most common locations of gastric and duodenal ulcers (From Berardi R, Fugit R. Peptic ulcer disease. In: DiPiro JT; Talbert RA; Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 8th ed. New York, NY: McGraw-Hill, 2011:563–585.)

status during childhood.⁷ Infection with *H. pylori* is more common in developing countries because of the presence of contaminated food and water.

Nonsteroidal Anti-inflammatory Drugs

NSAIDs are one of the most widely used classes of medications in the United States, particularly in the elderly. The odds of GI bleeding are increased by five- to sixfold in patients taking NSAIDs. Up to 4% of NSAID users have a serious ulcer-related complication, accounting for up to 100,000 hospitalizations and more than 20,000 deaths in the United States per year.² Chronic NSAID ingestion leads to symptoms of nausea and dyspepsia in nearly half of patients. Peptic ulceration occurs in up to 30% of patients who use NSAIDs (including aspirin) chronically, with GI bleeding or perforation occurring in 1.5% of patients who develop an ulcer.²

Risk factors for NSAID-induced peptic ulcers and complications are presented in **Table 18–2**. Important principles to consider when estimating the risk for developing PUD in a patient taking an NSAID include the following: (a) risk factors are generally additive, (b) some risk factors (e.g., corticosteroid therapy) are not independent risk factors for ulceration but increase PUD risk substantially when combined with NSAID therapy, and (c) many of the risk factors postulated to increase PUD risk in a patient taking an NSAID (e.g., rheumatoid arthritis, tobacco smoking, and alcohol consumption) remain unproven and thus should not generally be considered independent risk factors for NSAID-induced ulceration.⁸ Whether *H. pylori* infection is a risk factor for NSAID-induced ulcers remains controversial; however, *H. pylori* and NSAIDs act independently to increase ulcer risk and ulcer-related bleeding and also appear to have synergistic effects.⁹

Stress-Related Mucosal Damage

SRMD occurs most frequently in critically ill patients and is due to compromised mesenteric perfusion resulting in

mucosal defects.⁵ Although the etiology of stress ulceration is multifactorial, there are two necessary conditions: gastric mucosal ischemia and intraluminal acid.¹⁰ SRMD usually develops within the first few hours after a major trauma or serious illness. The ulcers are usually superficial; however SRMD may also penetrate into the submucosa and result in significant GI bleeding.¹⁰

Physiologically stressful situations that lead to SRMD include sepsis, organ failure, prolonged mechanical ventilation, thermal injury, trauma, and surgery. The utility of stress ulcer prophylaxis (SUP) has been well described in a certain subset of critically ill patients, and guidelines have been published (**Table 18–3**).¹¹ Proton pump inhibitors (PPIs) and H₂RAs are the drugs of choice for SUP.

Zollinger–Ellison Syndrome

Zollinger–Ellison syndrome (ZES) is caused by a gastrin-producing tumor called a gastrinoma. This results in a state of gastric acid hypersecretion in which patients develop diarrhea and malabsorption. Ulcers tend to be numerous and have a high risk of perforation and bleeding.⁵ Radiographic and endoscopic procedures are used to localize and stage the tumor. High-dose oral PPI therapy is the treatment of choice for ZES and may be used long term in patients when the tumor cannot be identified or fully resected.⁵ Patients without hepatic metastases should undergo surgical resection of tumor.

Other Causative Factors

Cigarette smoking is associated with a higher prevalence of ulcers in patients infected with *H. pylori*; however, it does

Table 18–2

Established Risk Factors for Ulcers and GI Complications Related to NSAID Use

- Age over 60 years
- Concomitant anticoagulant use
- Preexisting coagulopathy (elevated INR or thrombocytopenia)
- Concomitant corticosteroid or selective serotonin reuptake inhibitor therapy
- Previous PUD or PUD complications (bleeding/perforation)
- CV disease and other comorbid conditions
- Multiple NSAID use (e.g., low-dose aspirin in conjunction with another NSAID)
- Duration of NSAID use (greater than 1 month)
- High-dose NSAID use
- NSAID-related dyspepsia
- Cigarette smokers

CV, cardiovascular; INR, international normalized ratio; NSAID, nonsteroidal anti-inflammatory drug; PUD, peptic ulcer disease.

Table 18–3

ASHP Guidelines on Appropriate Indications for SUP in ICU patients (1999)

- Mechanical ventilation for longer than 48 hours
- Coagulopathy or hepatic failure (platelet count less than 50 10³/mm³ (50 10⁹/L), INR greater than 1.5, or aPTT less than two times control)
- History of GI ulceration or bleeding within 1 year of admission
- Head trauma or Glasgow Coma Score of 10 or less (or inability to obey simple commands)
- Thermal injuries to more than 35% of body surface area
- Multiple traumas (injury severity score of 16 or greater)
- Partial hepatectomy
- Transplant patients in the ICU perioperatively
- Spinal cord injuries
- Two of the following risk factors: sepsis, ICU stay for more than 1 week, occult bleeding lasting 6 or more days, and use of high-dose corticosteroids (more than 250 mg/day of hydrocortisone or equivalent)

ASHP, American Society of Health-System Pharmacists; SUP, stress ulcer prophylaxis; ICU, intensive care unit; INR, international normalized ratio; aPTT, activated partial thromboplastin time.

not seem to increase the risk of recurrence once *H. pylori* has been eradicated.² The exact mechanisms for the detrimental effects of smoking on the gastric mucosa are unclear but may involve increased pepsin secretion, duodenogastric reflux of bile salts, elevated levels of free radicals, and reduced bicarbonate and **prostaglandin** (PG) production.¹² It is unknown whether nicotine or one of the other ingredients found in cigarettes is responsible for these deleterious effects.

Until the discovery of *H. pylori*, psychological stress was considered one of the primary causes of PUD. Although psychosocial factors such as life stress, baseline personality patterns, and depression may influence PUD prevalence, a clear causal relationship has not been demonstrated.²

Dietary factors such as coffee, tea, cola, alcohol, and a spicy diet may cause dyspepsia but have not been shown independently to increase PUD risk. Although caffeine increases gastric acid secretion and alcohol ingestion causes acute gastritis, there is no conclusive evidence that either of these substances is an independent risk factor for PUD.²

PATHOPHYSIOLOGY

Ulcer formation is the net result of a lack of homeostasis between factors within the GI tract responsible for the breakdown of food (e.g., gastric acid and pepsin) and factors that promote mucosal defense and repair (e.g., bicarbonate, mucus secretion, and PGs).

Gastric Acid and Pepsin

Hydrochloric acid and pepsin are the primary substances that cause gastric mucosal damage in PUD. Three different stimuli (e.g., histamine, acetylcholine, and gastrin) are responsible for acid secretion through their interactions with the histaminic, cholinergic, and gastrin receptors on the surface of parietal cells. Gastric acid output occurs in two stages: (a) basal acid output, which reflects the baseline output of acid during the fasting state, and (b) maximal acid output, which occurs in response to meals. Basal acid secretion follows a circadian cycle and is modulated by the effects of acetylcholine and histamine acting on the parietal cell.¹³

Food can cause gastric acid secretion in two ways. In the **cephalic** phase of acid secretion, the vagus nerve stimulates acid secretion in response to the sight, smell, or taste of food. In both the gastric and intestinal phases of acid secretion, the physical distention caused by food induces gastrin secretion resulting in acid production. After stimulation by histamine, acetylcholine, and gastrin, acid is secreted by the H⁺-K⁺-ATPase (proton) pump, located on the luminal side of parietal cells. Acid secretion in PUD is usually normal or slightly elevated. NSAID ingestion usually does not affect acid secretion, whereas *H. pylori* infection usually leads to a slight increase in acid output. This is in contrast to ZES, in which acid secretion is substantially elevated.¹³

Pepsinogen released from chief cells in the body of the stomach is converted to pepsin in the presence of an acidic environment and plays a key role in the initiation of protein digestion, proteolysis of collagen, and as a signal for the

release of other digestive enzymes such as gastrin and cholecystokinin.¹⁴ The proteolytic activity of pepsin appears to influence ulcer formation.

Mucosal Defense and Repair

Several defense and repair mechanisms are responsible for preventing mucosal damage and subsequent ulcer formation. The mucus/phospholipid and bicarbonate barrier, through its buffering action, is the primary source of defense for the gastric epithelial surface against gastric acid.² It allows an acidic environment to be maintained in the lumen but a near neutral pH to be maintained on the epithelial lining. This lining has a number of protective mechanisms responsible for the repair of damaged cells, production of defense mechanisms, and the promotion of epithelial growth.

PGs inhibit gastric acid secretion and have numerous mucosal protective effects, including stimulation of mucus, bicarbonate, and phospholipid production. They also increase mucosal blood flow and stimulate epithelial cell regeneration.² Damage to the mucosal defense system is the primary method by which *H. pylori* or NSAIDs cause peptic ulcers.

► *Helicobacter Pylori*

H. pylori, a gram-negative microaerophilic S-shaped rod, is found on the surface of the gastric epithelium and has a number of adaptive functions to allow it to live within the acidic environment of the stomach. *H. pylori* colonization does not necessarily reflect an active infection because the organism can attach itself to the gastric epithelium without invading cells. The motility provided by the flagella allows the organism to penetrate the mucous gel barrier and cause an acute infection in the epithelial cells.⁷ The organism is able to survive in the acidic environment of the stomach via production of urease, an enzyme that hydrolyzes urea (found in gastric juice) into carbon dioxide and ammonia.⁷ Cellular invasion by *H. pylori* is necessary for an active infection. In addition to PUD, *H. pylori* infection may also result in gastric cancer (0.1% to 3%) and gastric mucosa-associated lymphoid-tissue (MALT) lymphoma (less than 0.01%).⁷

A number of host and pathogenic factors contribute to the ability of *H. pylori* to cause gastroduodenal mucosal injury including (a) direct mucosal damage, (b) alterations to host inflammatory responses, and (c) hypergastrinemia leading to a state of elevated acid secretion. *H. pylori* isolated from patients with PUD carry a high virulence that include a strong adhesive property and increased production of potentially toxic enzymes.⁵ The complex interplay between bacterial virulence factors and an enhanced inflammatory response results in a chronic *H. pylori* infection that increases acid production and reduces various host protective factors.

Nonsteroidal Anti-inflammatory Drugs

Nonselective NSAIDs (those that inhibit both COX-1 and COX-2) cause gastric mucosal damage by two primary mechanisms: direct or topical irritation of the gastric epithelium and systemic inhibition of endogenous mucosal PG synthesis. COX-2 NSAIDs

have been shown to reduce, but not eliminate the risk of PUD and its complications.⁵

Direct irritation of the mucosal lining by NSAIDs occurs because NSAIDs are weak acids. Less acidic agents, such as nonacetylated salicylates, may confer decreased GI toxicity.¹⁵ Although the direct irritant effects of NSAIDs play a contributory role in the development of NSAID-induced gastritis, this mechanism generally plays a minor role in the evolution of NSAID-induced PUD.

The systemic effects of NSAIDs are the primary cause of PUD. COX is the rate-limiting enzyme in the PG synthesis pathway (Fig. 18-2). Inhibition of PG production is the primary therapeutic effect of NSAIDs. COX is responsible for the conversion of arachidonic acid to PGs such as PGG₂ and PGH₂. COX-1 is routinely found in body tissues that produce PGs for normal physiological maintenance. In contrast, COX-2 is an inducible enzyme that is expressed during states in which cytokines and inflammatory mediators are elevated (e.g., fever and pain). Inhibition of the COX-1 isoenzyme decreases production of endogenous PGs, particularly PGE₁, PGE₂, and PGI₂. Administration of NSAIDs parenterally (e.g., ketorolac) and rectally (e.g., indomethacin) is associated with an incidence of PUD similar to that with oral NSAIDs. Topical NSAIDs (e.g., diclofenac) would be unlikely to cause PUD given the very low serum concentrations that are achieved with this route of administration compared with that observed with oral therapy.

PGs are important factors in gastric healing and protection. Inhibition of PG production by NSAIDs compromises these important protective mechanisms. Finally, the antiplatelet effects of NSAIDs may worsen bleeding complications associated with PUD.

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical Presentation

See text box on next page for the clinical presentation of PUD. Dyspepsia refers to upper abdominal discomfort and

is found in 10% to 40% of the general population. PUD is found in 5% to 15% of patients with dyspepsia. Patients with new onset dyspepsia who are older than 50 years and patients of any age with alarming features should undergo an upper endoscopy to evaluate for PUD.^{1,16,17}

Patients with dyspepsia who are younger than 50 to 55 years and do not have alarming features should be tested for *H. pylori* and treated if positive.^{1,16,18} NSAIDs should also be stopped if possible. Patients who test negative for *H. pylori* should be offered a trial (4 to 8 weeks) of acid suppression or they can proceed with endoscopy evaluation. Upper endoscopy should be performed in any patient who has persistent dyspepsia symptoms despite a trial of acid suppressive therapy.¹

PUD can be classified as uncomplicated or complicated. Complicated disease implies GI bleeding, obstruction, or perforation. Hemorrhage is the most common complication of PUD and may occur when an ulcer erodes the wall of a gastric or duodenal artery. GI bleeding may be occult or may present as **melena** or **hematemesis**. Bleeding occurs in approximately 15% of PUD patients and is more common in patients older than 60 years, particularly those who ingest NSAIDs.¹⁹ Up to 20% of patients who develop a PUD-related hemorrhage do not have prior symptoms. Mortality associated with PUD remains 5% to 10% despite advances in medical and endoscopic therapies.¹⁹ Endoscopic therapy achieves successful hemostasis in 90% of patients; however, rebleeding may occur in 10% to 30% of high-risk patients even after successful initial treatment.²⁰

Perforation, another complication of PUD, requires emergent surgical intervention. These patients should not undergo endoscopy.

Gastric outlet obstruction occurs in approximately 2% of PUD patients and is usually caused by ulcer-related inflammation or scar formation. Patients typically present with early satiety after meals, nausea, vomiting, abdominal pain, and weight loss. Ulcer healing with conventional acid suppressive therapy, cessation of NSAID use, and treatment of *H. pylori* infection

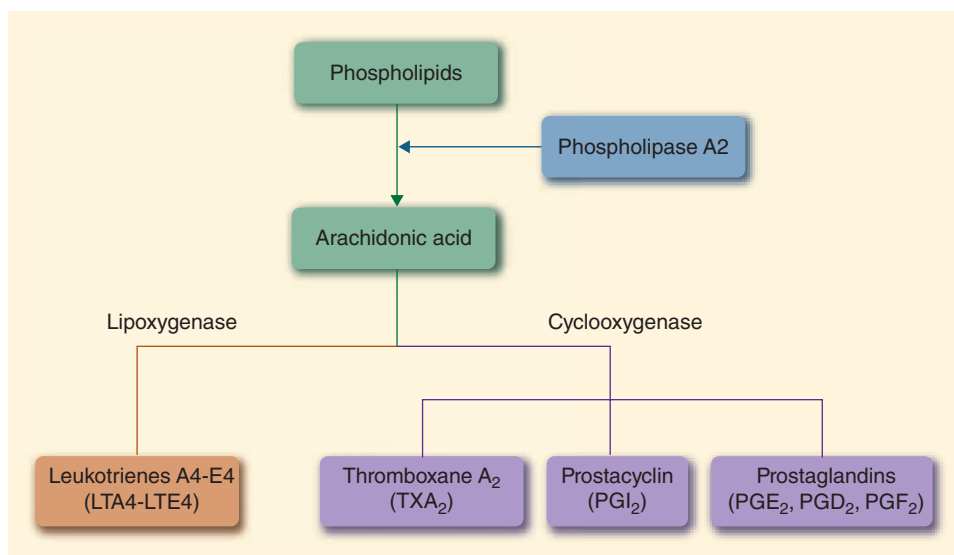

FIGURE 18-2. The arachidonic acid pathway.

Clinical Presentation of PUD

Symptoms

- Mild epigastric pain that may be described as burning, gnawing, or aching in character.
- Abdominal pain may be described as burning or a feeling of discomfort.
- Some patients report nocturnal pain.
- The severity of pain often fluctuates.
- The intensity of pain can vary widely (e.g., from dull to sharp).
- DU pain occurs 1 to 3 hours after meals and may be relieved by food ingestion.
- GU pain occurs immediately after meals and is often aggravated by food.
- Patients may also complain of heartburn, belching, bloating, nausea, or vomiting.

Signs

- Weight loss may be associated with nausea and vomiting.
- Complications such as bleeding, perforation, or obstruction may occur.
- Alarm signs and symptoms include family history of upper GI malignancy, unintentional weight loss, overt GI bleeding, iron deficiency anemia, progressive dysphagia or odynophagia, early satiety, persistent vomiting, prior history of esophagogastric malignancy, palpable mass, or lymphadenopathy.

if indicated is the primary treatment, but if unsuccessful, endoscopic therapy with balloon dilation is required.¹

Diagnosis

Diagnostic tests for the presence of *H. pylori* can be either endoscopic or nonendoscopic.^{7,18} Endoscopic diagnosis requires the extraction of gastric tissue samples that are subsequently tested for *H. pylori*.¹⁸ Recent antibiotic use can lead to a false-negative biopsy result. The choice of testing depends on availability, cost, clinical situation, pretest probability of infection, population prevalence of infection, and recent use of antisecretory treatment and antibiotics.³ Testing for *H. pylori* infection is indicated in patients with active PUD, past history of documented PUD, or gastric MALT lymphoma.¹⁸

Nonendoscopic testing methods include serologic testing, urea breath test, and stool antigen assay.^{7,18} These tests are less invasive and less expensive than endoscopic procedures. The urea breath test is usually the first-line test to detect active *H. pylori* infection because it has a sensitivity and specificity greater than 95% and a short turnaround time.⁷ Concomitant acid-suppressive or antibiotic therapy may give false-negative results.⁷ The urea breath test can also be used to confirm eradication of *H. pylori* infection.⁷

Office-based serologic testing provides a quick assessment (within 15 minutes) of an exposure to *H. pylori*, but this method is not able to determine active versus previously treated *H. pylori* infection because patients can remain **seropositive** for years after eradication. In addition, it is less sensitive and specific than the urea breath test.⁷ Serologic testing is recommended and considered diagnostic in patients with a bleeding ulcer, gastric atrophy, MALT lymphoma, and recent or current antibiotic or acid-suppressing therapy.²¹

Stool antigen assays can be useful for the initial diagnosis or to confirm *H. pylori* eradication, and they are affected less by concomitant medication use.⁷ The sensitivity and specificity of the stool antigen assay is greater than 95%.⁷ The use of antimicrobial agents within 4 weeks, PPIs within 2 weeks, and H₂RAs within 24 hours of testing can suppress the infection, reduce the sensitivity of testing, and should be avoided.⁷

Endoscopic testing is an invasive and expensive way to test for *H. pylori*, but it is indicated in patients older than 50 years with new symptoms of dyspepsia or any patient with alarming features.^{1,16,18} *H. pylori* is difficult to culture because the organism grows slowly and requires specialized culture media and a controlled microaerophilic environment.²² Rapid urease testing is inexpensive, but its sensitivity is reduced in the posttreatment setting.¹⁸

Radiologic and/or endoscopic procedures are usually required to document the presence of ulcers. However, the cost and complexity of testing has led to the promotion of early empiric treatment strategy for patients at low risk for PUD-related sequelae (e.g., malignancy). An empiric treatment strategy is appropriate for symptomatic patients younger than 50 to 55 years without alarming features or evidence of PUD complications.^{7,16,18}

TREATMENT

The treatment selected for PUD depends on the etiology of the ulcer, whether the ulcer is new or recurrent, and whether complications have occurred. **Figure 18-3** shows an algorithm for the evaluation and treatment of a patient with signs and symptoms suggestive of an *H. pylori*-associated or NSAID-induced ulcer.

Desired Outcomes

- The goals of PUD therapy are to resolve symptoms, reduce acid secretion, promote epithelial healing, prevent ulcer-related complications, and prevent ulcer recurrence. For *H. pylori*-related PUD, eradication of *H. pylori* is an additional outcome. *H. pylori* eradication does not cause or worsen gastroesophageal reflux disease.³

Nonpharmacologic Therapy

► Risk Factor Avoidance

- 1 Patients with PUD should avoid exposure to factors known to worsen the disease, exacerbate symptoms, or lead to ulcer recurrence. Patients should be advised to reduce psychological

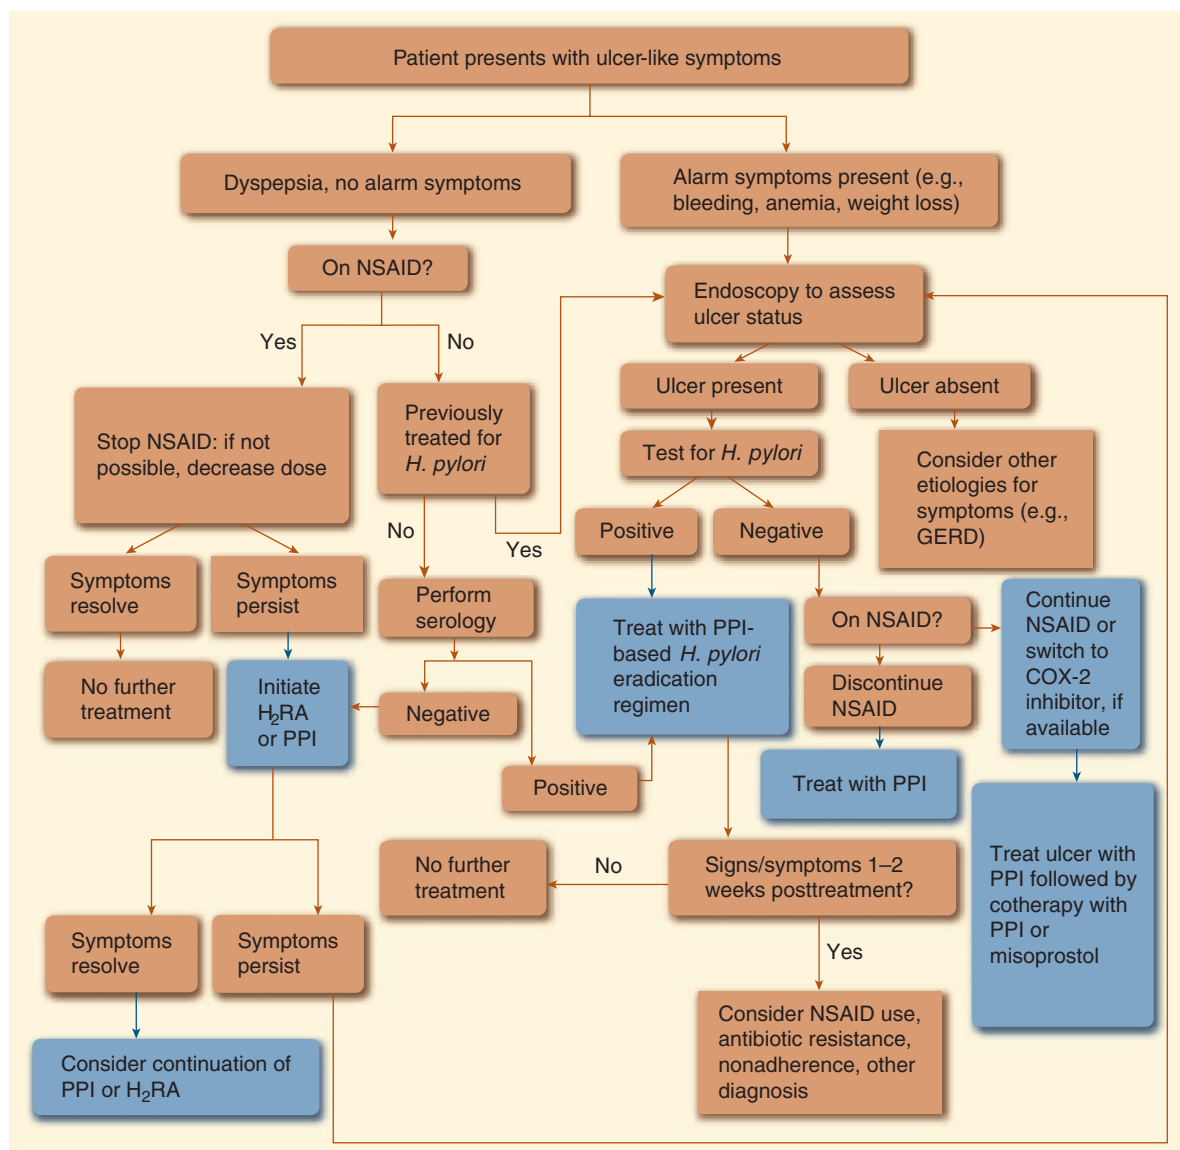

FIGURE 18-3. Approach to the patient presenting with ulcer-like symptoms. (GERD, gastroesophageal reflux disease. (HP, *Helicobacter pylori*; H₂RA, histamine₂-receptor antagonist; NSAID, nonsteroidal anti-inflammatory drug; PPI, proton pump inhibitor.) (From Berardi R, Fugit R. Peptic ulcer disease. In: DiPiro JT; Talbert RA; Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011:563–585.)

stress and avoid cigarette smoking, alcohol consumption, and NSAID or aspirin use. Patients who require chronic NSAID therapy (e.g., for rheumatoid arthritis) may be given prophylaxis with misoprostol or a PPI (see section on prevention of NSAID-induced ulcers).

► Surgery

The high success rates of medical therapies have reduced the number of surgical procedures performed. Elective surgeries performed for PUD have decreased by more than 70% since the 1980s mainly due to *H. pylori* eradication.²³ For this reason, surgical interventions are generally reserved for complicated or refractory PUD.⁹ Definitive surgical procedures to treat PUD usually involve some type of **vagotomy** (to block further acid secretion) with or without partial **gastrectomy**.⁹

Complications are rare but can include dumping syndrome, bile reflux, diarrhea, malabsorption, and gastric atony.⁹

For patients with acute GI bleeding, endoscopic hemostasis can be achieved using contact thermal therapy, mechanical therapy using clips, or epinephrine injection followed by either thermal or mechanical therapy.¹⁹ **Angiography** with embolization of bleeding lesions can be used if the bleeding cannot be stopped endoscopically and the patient is either high risk for surgery or not a surgical candidate.²⁴

Pharmacologic Therapy

► Treatment of *H. pylori*-Associated Ulcers

- The primary goal of *H. pylori* therapy is to completely eradicate the organism using an effective antibiotic-containing regimen.

2 *Reliance on conventional acid-suppressive drug therapy alone as an alternative to *H. pylori* eradication is inappropriate because it is associated with a higher incidence of ulcer recurrence and ulcer-related complications.* Reinfection rates are generally low after the initial course of therapy as long as the patient was adherent. The *H. pylori* regimen that is chosen should have a per-protocol cure rate of 90% or more or a cure rate based on intention-to-treat analysis of 80% or more.¹⁸ In addition to proven efficacy, the optimal treatment regimen should cause minimal adverse events, have low risk for the development of bacterial resistance, and be cost effective.^{7,18}

H. pylori treatment regimens are presented in **Table 18–4**.

3 *Eradication therapy with a PPI-based three-drug regimen should be considered for all patients who test positive for *H. pylori* and have an active ulcer or a documented history of either an ulcer or ulcer-related complication. Different antibiotics should be used if a second course of *H. pylori* eradication therapy is required.* The cure rates of *H. pylori* with H₂RAs in combination with antibiotics are lower than with PPIs.

The first-line regimen should consist of triple drug therapy with a PPI plus clarithromycin and either amoxicillin or metronidazole.^{7,25} Amoxicillin should not be used in penicillin-allergic patients, and metronidazole should be

avoided if alcohol is going to be consumed. A single daily dose of a PPI may be less effective than twice-daily dosing when used as part of a triple-drug regimen. Substitution of one PPI for another is acceptable and does not affect eradication rates. Monotherapy with a single antibiotic or antiulcer agent is not recommended due to high failure rates. In the United States, two-drug regimens consisting of a PPI and a single antibiotic are also not recommended.²²

The duration of therapy for *H. pylori* eradication is controversial. U.S. guidelines recommend 10 or 14 days of therapy. Compared with 7 days of triple therapy, a 10-day duration increases eradication rates by 4% and 14 days by 5% to 12%.^{21,25} Longer courses of therapy may decrease adherence and increase drug costs; ultimately, the most effective eradication regimens still fail in 10% to 20% of patients.⁵

Bismuth-based four-drug regimens have clinical cure rates similar to three-drug PPI-based regimens. Bismuth-based regimens usually include tetracycline, metronidazole, and an acid suppressing agent (e.g., PPI or H₂RA). Bismuth salts promote ulcer healing through antibacterial and mucosal protective effects. Drawbacks of bismuth-based regimens include frequency of administration (four times a day), risk for salicylate toxicity in patients with renal impairment, and propensity for bothersome side effects (e.g., stool and tongue discoloration, constipation, nausea, and vomiting).⁵ Therefore, bismuth-based quadruple therapy is usually considered second-line therapy.

The combination product Pylera (bismuth subcitrate potassium 140 mg, metronidazole 125 mg, and tetracycline 125 mg) when used in combination with omeprazole 20 mg twice daily is as effective as omeprazole–amoxicillin–clarithromycin in eradicating *H. pylori* in patients with DU.²² The usual dose is three capsules four times daily after meals and at bedtime with 8 oz. (237 mL) water for 10 days.

Helidac is a package of 14 blister cards with each card containing a single-day supply of bismuth subsalicylate (two 262.4-mg chewable tablets four times daily), metronidazole (250-mg tablet four times daily), and tetracycline (500-mg capsule four times daily). Unlike Pylera, Helidac is not a combination product; all three medications must be taken four times daily for 14 days in combination with an H₂RA rather than a PPI. However, cure rates are less with H₂RA than with PPI and therefore not preferred.⁷ A 10-day course of Pylera or a 14-day course of Helidac are substantially more expensive than the costs of their individual generic and nonprescription components.

Patients may remain infected with *H. pylori* after the initial course of therapy because of reinfection, nonadherence, or antimicrobial resistance. Factors associated with decreased adherence include polypharmacy, need for frequent drug administration or long treatment duration, and use of drugs that may cause intolerable side effects. Potential adverse drug effects include taste disturbances (clarithromycin and metronidazole), nausea, vomiting, abdominal pain, and diarrhea. Superinfections with oral thrush or vaginal candidiasis can occur. Alcohol should be avoided during treatment with metronidazole or tinidazole due to the potential for a disulfiram-like reaction with alcohol use.²²

Patient Encounter 1

A 62-year-old man presents with abdominal pain and heartburn that occur two to three times per week. He also reports a 10-pound (4.5-kg) weight loss in the last 6 weeks, despite not dieting or increasing physical activity.

PMH: Hypertension × 5 years

FH: Mother alive at 84 with hypertension, type 2 diabetes; father deceased at 68 following MI

SH: Smokes 1/2 pack per day; 2 alcoholic beverages 3 times per week; no illicit drug use

Allergies: NKDA

Meds: Lisinopril/hydrochlorothiazide 20/25 mg daily, acetaminophen 500 mg as needed for headache

Based on this patient's clinical presentation, what is the most appropriate course of action to establish a diagnosis?

*The patient receives a diagnosis of *H. pylori* infection based on the diagnostic method recommended. What eradication therapy would you recommend?*

*The patient completes a course of eradication therapy, and 3 months later he presents with similar dyspeptic symptoms. *H. pylori* recurrence is confirmed with a urea breath test. Discuss possible reasons for treatment failure in this patient.*

What regimen would you recommend for salvage eradication therapy?

Table 18-4

Drug Regimens to Eradicate *Helicobacter Pylori*^{a,b}

Treatment Regimen	Cure Rates ^b
Three Drugs	
Clarithromycin 500 mg + metronidazole 500 mg (or tinidazole 500mg) + omeprazole 20 mg, each given two times a day	Good to excellent
Clarithromycin 500 mg + amoxicillin 1 g + lansoprazole 30 mg, each given two times a day	Good to excellent
Four Drugs	
Helidac (bismuth subsalicylate 525 mg + metronidazole 250 mg + tetracycline 500 mg, each given four times a day) + H ₂ RA (conventional healing dose) ^c	Good
Bismuth subsalicylate 525 mg four times a day + metronidazole 250 mg four times a day + amoxicillin 1 g twice daily + PPI twice daily ^d	Good
Pylera (bismuth subcitrate potassium 140 mg + metronidazole 125 mg + tetracycline 125 mg) 3 capsules two times a day + omeprazole 20 mg two times a day × 10 days	Good to excellent
Rescue Therapy	
Bismuth subsalicylate 525 mg + metronidazole 500 mg + tetracycline 500 mg, each given four times a day + omeprazole 20 mg two times a day ^d	Good to excellent
Amoxicillin 1 g + rifabutin 150 mg + pantoprazole 40 mg, each given two times a day ^e	Good to excellent
Amoxicillin 1 g + levofloxacin 250 mg + pantoprazole 40 mg, each given two times a day ^e	Good to excellent
Sequential Therapy	
Days 1-5: Amoxicillin 1 g + PPI, each given twice daily	Good to excellent
Days 6-10: Clarithromycin 500 mg + metronidazole 500 mg (or tinidazole 500 mg) + PPI, each given twice daily	

^aRegimens are based on efficacy for a 14-day treatment duration unless otherwise noted.

^bBased on cure rates of 80% to 90% = good; and greater than 90% = excellent.

^cAlthough commercially available, regimens containing H₂RAs are not preferred.

^dDuration of therapy is 7 to 10 days.

^eGiven for 10 to 14 days.

H₂RA, histamine-2 receptor antagonist; PPI, proton pump inhibitor.

Preexisting antimicrobial resistance accounts for up to 70% of all treatment failures and is most often related to metronidazole or clarithromycin. Metronidazole-resistant strains are more prevalent in Asia (85%) than North America (40%).²² Clarithromycin resistance rates are approximately 10% in the United States. Primary resistance to amoxicillin and tetracycline remains low in both the United States and Europe.²² Culture and sensitivity studies are not routinely performed with *H. pylori* infection unless a patient has already failed two different treatment regimens.^{7,18,21}

Initiation of a second *H. pylori* treatment regimen after failure of initial treatment is usually associated with a lower success rate. Reasons for failure are often the same as those reported with failure of the initial regimen. In these situations, quadruple therapy for 14 days is generally required, and metronidazole or clarithromycin should be replaced by another antibiotic if either one of these agents was used in the initial regimen.²² If both clarithromycin and metronidazole were used as initial therapy, a regimen consisting of amoxicillin 1 g twice daily, levofloxacin 250 mg twice daily, and a PPI twice daily may be used for 10 to 14 days.²⁶ Another salvage therapy consisting of a PPI twice daily, amoxicillin 1 g twice daily, and rifabutin 300 mg once daily for 10 to 14 days resulted in eradication rates greater than 80%.^{5,27,28}

There is no standard third-line therapy for *H. pylori* treatment. If the patient was adherent with initial treatment, then culture and sensitivity testing should be completed in order to select an antimicrobial regimen with adequate sensitivities.^{5,21} Sequential therapy is a possible alternative 10-day regimen that may also be used to treat *H. pylori* infection and consists of using different combinations of antibiotics for 5 days each in addition to a PPI twice daily. Eradication rates are reported between 84% and 93%.²⁹

Confirmation of *H. pylori* infection eradication is recommended in patients with a history of *H. pylori*-associated ulcer, MALT lymphoma, those who have undergone resection for early gastric cancer, and patients whose symptoms persist after *H. pylori* treatment for dyspepsia.⁷ Eradication may be confirmed by either a urea breath test or stool antigen testing. Eradication may also be confirmed on endoscopy; however, this should only be done when endoscopy is required because this method is more expensive and invasive.⁷

► Treatment of NSAID-Induced Ulcers

- Treatment recommendations to heal NSAID-induced ulcers or provide maintenance therapy in patients receiving NSAIDs are shown in [Table 18-5](#). Choice of regimen depends on whether NSAID use is to be continued. NSAIDs should

Table 18-5

Oral Drug Regimens to Heal Peptic Ulcers or Maintain Ulcer Healing in the Absence of Antibiotic Therapy

Drug	DU or GU Healing (mg/day)	Maintenance of DU or GU Healing (mg/day)
Mucosal Protectant		
Sucralfate	1 g four times a day	1 g four times a day
	2 g two times a day	1–2 g two times a day
H₂-Receptor Antagonists		
Cimetidine	300 mg four times a day	400–800 mg daily
	400 mg two times a day	
	800 mg at bedtime	
Famotidine	20 mg two times a day	20–40 mg daily
	40 mg at bedtime	
Nizatidine	150 mg two times a day	150–300 mg daily
	300 mg at bedtime	
Ranitidine	150 mg two times a day	150–300 mg daily
	300 mg at bedtime	
Proton Pump Inhibitors		
Dexlansoprazole	30–60 mg daily	30–60 mg daily
Esomeprazole	20–40 mg daily	20–40 mg daily
Lansoprazole	15–30 mg daily	15–30 mg daily
Omeprazole	20–40 mg daily	20–40 mg daily
Pantoprazole	40 mg daily	40 mg daily
Rabeprazole	20 mg daily	20 mg daily

DU, duodenal ulcer; GU, gastric ulcer.

Patient Encounter 2

A 68-year-old woman presents with reports of dark, tarry stools for 3 days. She denies coffee-ground emesis or recent weight loss but reports occasional abdominal pain.

PMH: Hypertension × 10 years, type 2 diabetes × 5 years, dyslipidemia × 5 years, osteoarthritis × 3 years

FH: Parents deceased; mother with stroke at age 82, father with MI at age 74; one sister alive at 74 with hypertension, type 2 diabetes, and dyslipidemia

SH: Denies tobacco or illicit drug use; two glasses of red wine at card club on Saturdays

Allergies: NKDA

Meds: Lisinopril 40 mg daily, amlodipine 5 mg daily, metformin 1,000 mg twice daily, glipizide 10 mg twice daily, simvastatin 40 mg daily, diclofenac 75 mg twice daily, aspirin 81 mg daily, Tums Extra Strength as needed for dyspeptic symptoms

Other: An endoscopy is performed and reveals a duodenal ulcer that is negative for *H. pylori*.

What risk factors does this patient have for GI complications related to NSAID use?

Make a recommendation for treatment of this patient's ulcer.

Discuss the use of prophylactic therapy in this patient after the treatment course is completed.

be discontinued if possible and replaced with alternatives (e.g., acetaminophen), when possible. For patients who cannot discontinue NSAID therapy, PPIs, H₂RAs, or sucralfate are effective for ulcer healing and to prevent further recurrences.⁵ PPIs are usually preferred because they provide more rapid relief of symptoms, have the strongest acid suppression, and heal ulcers more quickly than H₂RAs or sucralfate.⁵ Standard doses of H₂RAs effectively heal DUs but are minimally effective in GUs. In ulcers larger than 5 mm, the rate of ulcer healing may be as low as 25% after 8 weeks of therapy with an H₂RA.⁹ A PPI provides equivalent efficacy with treatment duration of only 4 weeks. PPI therapy should only be continued for longer than 4 weeks if an ulcer is confirmed to still be present or if the patient develops severe complications from PUD.

► Prevention of NSAID-Induced Ulcers

Prophylactic regimens against PUD are often required in patients on long-term NSAID or aspirin therapy for osteoarthritis (OA), rheumatoid arthritis (RA), or cardioprotection.³⁰ Misoprostol, H₂RAs, PPIs, and COX-2 selective inhibitors have been evaluated in controlled trials to reduce the risk of NSAID-induced PUD. **4** *In patients at risk for NSAID-induced ulcers, PPIs at standard doses reduce the risk of both gastric and DU as effectively as misoprostol and more effectively than H₂RAs.* In addition, PPIs are generally better tolerated than misoprostol.

Although acute GI bleeding is the most serious adverse outcome of NSAID therapy, few studies have compared PUD

prophylaxis strategies using this outcome measure due to the low frequency with which bleeding occurs in NSAID users, the small size of most prophylaxis studies, and their short duration.³⁰

Misoprostol Misoprostol is a synthetic PGE1 analog that exogenously replaces PG stores. It is indicated for reducing the risk of NSAID-induced GUs in patients at high risk of complications from GUs (e.g., the elderly and patients with concomitant debilitating disease), as well as patients at high risk of developing gastric ulceration, such as patients with a history of ulcers. Misoprostol at 200 mcg four times a day reduces ulcer complications by inhibiting acid secretion and promoting mucosal defense.⁹ Misoprostol use is limited by a high frequency of bothersome GI effects such as abdominal pain, flatulence, and diarrhea, and it is contraindicated in pregnancy due to potential abortifacient effects. Arthrotec is a combination product that contains diclofenac (either 50 or 75 mg) and misoprostol 200 mcg in a single tablet. Misoprostol is indicated for patients at high risk for NSAID-induced ulceration, and it has been found to be superior to H₂RAs for the prevention of NSAID-induced ulcers.

H₂-Receptor Antagonists The efficacy of H₂RAs (e.g., famotidine 40 mg daily) in preventing NSAID-related ulcers varies.³¹ DUs appear to respond better than GUs (the most frequent type of ulcer-associated with NSAIDs). Higher doses of H₂RAs (e.g., famotidine 40 mg twice daily) may reduce the risk of NSAID-induced GUs and DUs, but results from clinical trials are variable.

Duexis, a prescription combination product containing ibuprofen 800 mg and famotidine 26.6 mg, is indicated for the relief of signs and symptoms of RA and OA and to decrease the risk of developing upper GI ulcers. The recommended dosage is one tablet by mouth three times daily. Clinical trials evaluating this agent are 6 months or less in duration and primarily evaluated patients younger than 65 years with no ulcer history.³²

Proton Pump Inhibitors PPI therapy is more effective than H₂RAs in reducing the risk of nonselective NSAID-related GUs and DUs. PPIs are as effective as misoprostol but better tolerated. All PPIs are effective when used in standard doses. In patients who experience a PUD-related bleeding event while taking aspirin but who require continued aspirin therapy, the addition of a PPI reduces the incidence of recurrent GI bleeding.⁵ Prevacid NapraPAC provides naproxen (either 250, 375, or 500 mg) and lansoprazole 15 mg in individual blister packages.

COX-2 Selective Inhibitors With the availability of NSAIDs with COX-2 selectivity, clinicians postulated that these agents would avoid the need to add an additional prophylactic agent in patients with PUD risk factors. **5** *However, selective COX-2 inhibitors are no more effective than the combination of a PPI and a nonselective NSAID in reducing the incidence of ulcers and are associated with a greater incidence of CV events (e.g., ischemic stroke).*⁵ Celecoxib is the only agent in this class that remains on the market; its postulated improved GI safety when compared with nonselective NSAIDs has not

been established.³³ Controlled studies also demonstrate that celecoxib is no better than the combination of diclofenac and omeprazole.³⁴

Longer term studies evaluating the CV risks associated with use of COX-2 inhibitors found a higher incidence of CV mortality compared with traditional NSAIDs.^{35,36} This prompted the withdrawal of both rofecoxib and valdecoxib from the market and the inclusion of a black box warning in the celecoxib package insert.³⁷ Given the CV risk of the COX-2 inhibitors, a nonselective NSAID and a PPI is recommended instead of celecoxib in patients at high risk for NSAID-related PUD.^{5,38}

Sucralfate This drug is a negatively charged, nonabsorbable agent that forms a complex by binding with positively charged proteins in exudates, forming a viscous, paste-like adhesive substance that protects the ulcerated area of the gastric mucosa against gastric acid, pepsin, and bile salts.^{9,15} Limitations of sucralfate include the need for multiple daily dosing, large tablet size, and interaction with a number of other medications (e.g., digoxin and fluoroquinolones).

Adverse effects of sucralfate include constipation, nausea, metallic taste, and the possibility for aluminum toxicity in patients with renal failure. Sucralfate is effective in the treatment of NSAID-related ulcers when the NSAID will be stopped, but it is not recommended for NSAID-related ulcer prophylaxis.

► Prevention of Stress-Related Mucosal Damage

Prevention of stress ulcers involves maintaining hemodynamic stability to maximize mesenteric perfusion and pharmacologic suppression of gastric acid production. SUP is only indicated in intensive care unit (ICU) patients with certain risk factors.¹¹ **6** *Indications for stress ulcer prophylaxis include major trauma, major surgery, severe head trauma, multiple organ failure, burns covering more than 25% to 30% of body, severe sepsis, shock, mechanical ventilation, coagulopathy, and high-dose steroid use.*³⁹ The clinician must weigh the risks and benefits of using acid suppression, especially PPIs, in low-risk patients. PPIs and H₂RAs are the drugs of choice for SUP; however, antacids and sucralfate may be acceptable options in some patients.

► Long-Term Maintenance of Ulcer Healing

7 *Low-dose maintenance therapy with a PPI or H₂RA is only indicated in patients with severe complications secondary to PUD such as gastric outlet obstruction or patients who need to be on long-term NSAIDs or high-dose corticosteroids and are at high risk for bleeding.* Drug regimens and doses for PUD treatment and maintenance are presented in Table 18-5.

► Treatment of GI Bleeding

The immediate priorities in treating patients with a bleeding peptic ulcer are to achieve IV access, correct fluid losses, and restore hemodynamic stability. Insertion of a nasogastric tube is helpful in initial patient assessment, but the absence of bloody or coffee-ground material does not definitively

Patient Encounter 3

A 45-year-old man is brought to the surgical ICU after emergency surgery for a ruptured appendix. The physician would like him to remain NPO (nothing by mouth, except for medications) for at least a couple of days until he improves clinically and can sit up in bed.

PMH: Hypertension × 10 years, type 2 diabetes × 5 years

FH: Father with type 2 diabetes

SH: Smokes 1 pack per day; no alcohol use; no illicit drug use

Allergies: NKDA

Meds: Lisinopril/hydrochlorothiazide 20/25 mg daily, metformin 500 mg twice daily, ibuprofen 800 mg alternating with oxycodone 5 mg /acetaminophen 325 mg 2 tablets every 8 hours for surgical site pain

Based on this patient's clinical presentation, is he a candidate for stress ulcer prophylaxis?

What pharmacologic therapy would you recommend for this patient?

Two days later, the patient is transferred to a general medicine floor and begins a regular diet that is well tolerated. Ibuprofen has been discontinued, and he is alternating between oxycodone/acetaminophen and acetaminophen alone to relieve incision site pain. He is sitting up in bed and feeling much better. Is this patient still a candidate for stress ulcer prophylaxis?

rule out ongoing or recurrent bleeding; about 15% of patients without bloody nasogastric tube output have a high-risk lesion at endoscopy.¹⁹

Patients should be started on IV PPI therapy because optimal platelet aggregation, partially inhibited fibrinolysis, and better clot stabilization on the ulcer are achieved when the gastric pH is greater than 6.²⁰ IV PPI therapy should be continued for 72 hours because most rebleeding occurs during this time followed by oral PPI. Three-day PPI infusion therapy has been shown to be as effective as twice-daily IV PPI therapy.²⁰

► Treatment of Refractory Ulcers

Refractory ulcers are defined as ulcers that fail to heal despite 8 to 12 weeks of acid suppressive therapy.¹ The presence of refractory ulcers requires a thorough assessment, including evaluation of medication adherence, extensive counseling and questioning regarding recent over-the-counter and prescription medication use, and testing for *H. pylori* using a different method than previously done if testing was negative. Changing from H₂RA therapy to a PPI should be considered.¹⁵ Other considerations include esophagogastroduodenoscopy (EGD) with biopsy of the ulcer to exclude malignancy, *H. pylori* testing (if not done initially), serum gastrin measurement to exclude ZES, and gastric acid

Patient Encounter 4

A 64-year-old man presents to the emergency department complaining of vomiting blood and having black, tarry stools for the past 24 hours. He has never had a prior similar episode, and he denies any abdominal pain or unintentional weight loss.

PMH: Hypertension × 5 years, gout × 2 years

Allergies: NKDA

SH: Smokes 1 pack per day; drinks 6 to 12 beers per day; no illicit drug use

FH: Father died at 75 from heart disease (MI); mother died at 82 from a stroke

Meds: Metoprolol 50 mg twice daily, allopurinol 100 mg daily, NSAIDs (ibuprofen, naproxen) for gout flares as needed

PE:

VS: BP 72/46, P 132, RR 22, T 37.3°C (99.2°F)

Gen: Slightly confused, obese male

CV: Tachycardic, regular, no murmurs

Resp: Tachypneic, clear bilaterally

Abd: Soft, obese, nontender, nondistended, hypoactive bowel sounds

Rect: Melena, no pain, normal sphincter tone

What are the most important initial steps in the management of this patient?

After the patient is stabilized, what should be done next?

An EGD shows a 2-cm duodenal ulcer with an adherent clot in the duodenal bulb. The clot is removed and shows a visible vessel. The lesion is injected with epinephrine, and three clips are placed successfully to control the bleeding. What additional management steps should be taken for this patient? How would you identify the etiology of his ulcer?

studies. Increasing the starting dose of PPI therapy may heal up to 90% of refractory ulcers after 8 weeks of therapy.¹⁵

OUTCOME EVALUATION¹⁵

- Obtain a baseline complete blood count (CBC). Recheck the CBC if the patient exhibits alarm signs or symptoms.
- Obtain a baseline serum creatinine measurement. Calculate the estimated creatinine clearance and adjust the dose of H₂RAs and sucralfate if needed.
- Obtain a history of symptoms from the patient. Monitor for improvements in pain symptoms (e.g., epigastric or abdominal pain) daily.
- Monitor the patient for the development of any alarm signs and symptoms.

Patient Care and Monitoring

General Recommendations: *H. pylori*-Associated and NSAID-Induced Ulcers

1. Assess the severity of signs and symptoms. Identify the presence of any alarm signs and symptoms.
2. Educate the patient on monitoring for alarm signs and symptoms.
3. Obtain a history of prescription medication, over-the-counter medication, and dietary supplement use.
4. Encourage lifestyle modifications such as reducing tobacco use and ethanol ingestion and decreasing psychological stress.
5. Determine the appropriate duration for acid-suppressive therapy.
6. Define the current impact of PUD on the patient's quality of life and the improvement in these outcomes sought with drug therapy.
7. Evaluate current drug therapy for potential adverse drug reactions and drug interactions.

H. pylori-Associated Ulcers

1. Recommend an appropriate drug regimen that will eradicate the organism.
2. Identify the patient's drug allergies and avoid drug classes a patient is allergic to.

3. Educate patients on specific adverse drug effects, particularly with metronidazole (avoidance of alcohol), bismuth (change in stool color), and clarithromycin (taste disturbance).
4. Assess the potential for drug interactions, particularly in patients taking regimens containing metronidazole, clarithromycin, and/or cimetidine.
5. Recommend different antibiotics if this treatment regimen is a result of failure of a prior *H. pylori* regimen.
6. Educate the patient on the importance of adherence to eradication therapy.

NSAID-Associated Ulcers

1. Assess for risk factors for NSAID ulcers and recommend an appropriate strategy to reduce ulcer risk.
2. Monitor for signs and symptoms of complications associated with NSAID-related ulceration.
3. Recommend an appropriate treatment regimen to heal the ulcer.
4. Assess and counsel patients on potential adverse drug events and drug interactions.
5. Inform patients who are receiving prophylactic therapy on the importance of its use, potential adverse drug events, and the possible alarm symptoms associated with PUD.

- Recommend a follow-up visit if signs and symptoms worsen at any time or do not improve within the defined treatment period.
- Assess for potential drug interactions whenever there is a change in the patient's medications.
- Educate the patient on the importance of adhering to the *H. pylori* eradication regimen.
- Monitor the patient for complications related to antibiotic therapy (e.g., diarrhea or oral thrush) during and after completion of *H. pylori* eradication therapy.
- Recommend follow-up care if the patient's signs and symptoms do not improve after completion of *H. pylori* eradication therapy.

INR	International normalized ratio
MALT	Mucosa-associated lymphoid tissue
NSAID	Nonsteroidal anti-inflammatory drug
PG	Prostaglandin
PPI	Proton pump inhibitor
PUD	Peptic ulcer disease
SRMD	Stress-related mucosal damage
SUP	Stress ulcer prophylaxis
ZES	Zollinger–Ellison syndrome

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Abbreviations Introduced in This Chapter

COX	Cyclooxygenase
CV	Cardiovascular
DU	Duodenal ulcer
EGD	Esophagogastroduodenoscopy
GU	Gastric ulcer
H ₂ RA	Histamine-2 receptor antagonist

19 Inflammatory Bowel Disease

Brian A. Hemstreet

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Characterize the pathophysiologic mechanisms underlying inflammatory bowel disease (IBD).
2. Recognize the signs and symptoms of IBD, including major differences between ulcerative colitis (UC) and Crohn's disease (CD).
3. Identify appropriate therapeutic outcomes for patients with IBD.
4. Describe pharmacologic treatment options for patients with acute or chronic symptoms of UC and CD.
5. Create a patient-specific drug treatment plan based on symptoms, severity, and location of UC or CD.
6. Recommend appropriate monitoring parameters and patient education for drug treatments for IBD.

KEY CONCEPTS

- 1 Inflammatory bowel disease (IBD) includes both ulcerative colitis (UC) and Crohn's disease (CD) and is associated with chronic inflammation of various areas of the GI tract.
- 2 Differentiation of UC and CD is based on signs and symptoms as well as characteristic endoscopic findings including the extent, pattern, and depth of inflammation.
- 3 Patients may manifest extraintestinal symptoms of IBD, such as arthritis, primary sclerosing cholangitis, erythema nodosum, and pyoderma gangrenosum, among others.
- 4 Major treatment goals for patients with IBD include alleviation of signs and symptoms, induction of remission, suppression of inflammation during acute episodes, and maintenance of remission thereafter.
- 5 When designing a drug regimen for treatment of IBD, several factors should be considered, including the patient's symptoms, medical history, current medication use, drug allergies, and location and severity of disease.
- 6 Antidiarrheal medications that reduce GI motility, such as loperamide, diphenoxylate/atropine, and codeine, should be avoided in patients with active IBD due to the risk of precipitating acute colonic dilation (toxic megacolon).
- 7 Treatment of acute episodes of UC is dictated by the severity and extent of disease, and first-line therapy of mild to moderate disease involves oral or topical aminosalicylate derivatives.
- 8 Maintenance of remission of UC may be achieved with oral or topical aminosalicylates. Immunosuppressants such as azathioprine, 6-mercaptopurine (6-MP), or infliximab can be used for unresponsive patients or those who develop corticosteroid dependency.
- 9 Treatment of active mild to moderate CD involves use of oral budesonide or oral or topical aminosalicylate derivatives, whereas moderate to severe disease may require systemic corticosteroid or anti-tumor necrosis factor (anti-TNF) antibody therapy.
- 10 Maintenance of remission of CD may be achieved with immunosuppressants (azathioprine, 6-MP, or methotrexate), biologic agents (infliximab, adalimumab, certolizumab pegol, or natalizumab), and less frequently with oral or topical aminosalicylate derivatives.

INTRODUCTION

1 *Inflammatory bowel disease (IBD) encompasses both Crohn's disease (CD) and ulcerative colitis (UC). Both disorders are associated with chronic inflammation of various regions within the GI tract. Differences exist between UC and CD with regard to the regions of the GI tract that may be affected as well as in the distribution and depth of inflammation. Some patients with IBD may also have inflammation involving organs other than the GI tract, known as extraintestinal manifestations. Symptoms of IBD are associated with significant morbidity,*

reduction in quality of life, and substantial costs to the healthcare system. For purposes of this chapter, references made to IBD include both UC and CD. Significant differences between UC and CD are discussed separately when applicable.

EPIDEMIOLOGY

IBD is most common in Western countries such as the United States and Northern Europe. The age of initial presentation of IBD is bimodal, with patients typically diagnosed between the ages of 20 to 40 or 60 to 80 years. The incidence and prevalence of UC in the United States are reported as 9 to 12 cases per 100,000 and 205 to 240 cases per 100,000.¹⁻⁶ The incidence and prevalence of CD is reported as 6 to 8 cases per 100,000 and 100 to 200 cases per 100,000.⁶ Peak incidence of UC occurs between the ages of 15 and 30 years.⁶

Men and women are approximately equally affected by IBD in Western countries.⁶ In general, whites are affected more often than blacks, and persons of Jewish descent also have higher reported incidences of IBD. One of the greatest risk factors for development of IBD is a positive family history of the disease. The incidence of IBD is 10 to 40 times greater in patients with a first-degree relative who has IBD compared with the general population.^{4,5,7} A positive family history may be more of a contributing factor for development of CD than UC.⁷⁻⁹

ETIOLOGY

The exact cause of IBD is not fully understood. Processes thought to be involved in its development include genetic predisposition, dysregulation of the inflammatory response within the GI tract, or perhaps environmental or antigenic factors.^{3,4} The fact that a positive family history is a strong predictor of IBD supports the theory that genetic predisposition may be responsible in many cases. Many potential candidate genes have been identified. An example is a gene found on chromosome 16 that encodes for nucleotide oligomerization domain 2 (NOD2).⁶ NOD2 is a cytoplasmic protein expressed in macrophages, monocytes, and gut epithelial cells thought to be involved in recognition and degradation of bacterial products by the gut wall. Less is known about genetic alterations that may predispose patients to UC, but UC may share common genetic features with CD.

An alteration in the inflammatory response regulated by intestinal epithelial cells may also contribute to development of IBD. This may involve inappropriate processing of antigens presented to the GI epithelial cells.^{3,4,10,11} The inflammatory response in IBD may actually be directed at bacteria that normally colonize the GI tract. Products derived from these bacteria may translocate across the mucosal layer of the GI tract and interact with various cells involved in immunologic recognition. The result is T-cell stimulation, excess production of proinflammatory cytokines, and persistent inflammation within the GI tract.

The intestinal mucosa of patients with CD has a preponderance of CD4+ type 1 helper T cells (Th1), whereas patients with UC have more CD4+ lymphocytes with atypical type 2

helper T cells (Th2).¹⁰ Likewise, drugs such as nonsteroidal anti-inflammatory drugs (NSAIDs) that disrupt the integrity of the GI mucosa may facilitate mucosal entry of intestinal antigens and lead to disease flares in patients with IBD.¹²

The role of antigens derived from dietary intake in the development of IBD is less well defined. There is some speculation that ingestion of large quantities of refined carbohydrates or margarine leads to higher rates of CD. Use of oral contraceptives has been associated with increased development of IBD in some cohort studies, but a strong causal relationship has not been proven.^{6,8} Isotretinoin use has also been associated with the development of IBD.

Lastly, positive smoking status has been shown to have protective effects in UC, leading to reductions in disease severity.⁶ The opposite is true in CD because smoking may lead to increases in symptoms or worsening of the disease.^{6,10}

PATHOPHYSIOLOGY

Ulcerative Colitis

- The inflammatory response in UC is propagated by atypical type 2 helper T cells that produce proinflammatory cytokines such as interleukin (IL)-1, IL-6, and tumor necrosis factor- α (TNF- α).⁸ As discussed previously, a genetic predisposition to UC may partially explain the development of excessive colonic and rectal inflammation. The finding of positive perinuclear antineutrophil cytoplasmic antibodies (pANCA) in association with the human leukocyte antigen (HLA)-DR2 allele in a large percentage of patients with UC supports this theory.¹³

The potential role of environmental factors in development of UC implies that the immune response is directed against an unknown antigen. The findings that development and severity of UC are reduced in patients who smoke, or in those with appendectomies, may support the theory that these factors may somehow modify either the genetic component or phenotypic response to immunologic stimuli.^{3,12}

The inflammatory process within the GI tract is limited to the colon and rectum in patients with UC (**Fig. 19-1**). Most patients with UC have involvement of the rectum (*proctitis*) or both the rectum and the sigmoid colon (proctosigmoiditis). Inflammation involving the entire colon is referred to as *pancolitis* or extensive disease. Left-sided (distal) disease, defined as inflammation extending from the rectum to the splenic flexure, occurs in 30% to 40% of patients.¹² A small number of cases of UC involve mild inflammation of the terminal ileum, referred to as “backwash ileitis.”

The pattern of inflammation in UC is continuous and confluent throughout the affected areas of the GI tract. The inflammation is also superficial and does not typically extend below the submucosal layer of the GI tract (**Fig. 19-2**). Ulceration or erosion of the GI mucosa may be present and varies with disease severity. The formation of *crypt abscesses* within the mucosal layers of the GI tract is characteristic of UC and may help to distinguish it from CD. Severe inflammation may also result in areas of hypertrophied GI mucosa, which may manifest as *pseudopolyps* within the

FIGURE 19-1. Major GI landmarks and disease distribution in inflammatory bowel disease.

colon.¹³ The inflammatory response may progress in severity, leading to mucosal friability and significant GI bleeding.

Crohn's Disease

As with UC, the immune activation seen in CD involves the release of many proinflammatory cytokines. Cytokines thought to play major roles in CD are derived from T-helper type 1 cells and include interferon- γ , TNF- α , and IL-1, IL-6, IL-8, and IL-12. TNF- α is a major contributor to the inflammatory process seen in CD. Its physiologic effects include activation of macrophages, procoagulant effects in the vascular endothelium, and increases in production of matrix metalloproteinases in mucosal cells.¹³⁻¹⁵ Excessive production of both interferon- γ and TNF- α may account for the excessive clinical evidence of granulomatous disease in patients with CD.¹¹ TNF- α is also thought to induce production of nuclear factor $\kappa\beta$, which stimulates further production of TNF- α and other proinflammatory cytokines.^{3,15}

The role of an immune response directed against endogenous bacteria as the initiating factor is more evident in CD, as evidenced by the apparent strong T-helper 1 activation against bacteria seen in animal models of this disease. The role of dietary antigens in the development of CD compared with UC is also another potential initiating factor. Excess ingestion of refined sugars or margarine may be higher in patients who develop CD.⁸

The distribution of inflammation in CD differs from that seen in UC because any part of the entire GI tract may be affected in CD. The small intestine is the site most commonly involved. Within the small intestine, the terminal ileum and cecum are almost always affected. Approximately 20% of patients have isolated colonic involvement, whereas inflammation proximal

FIGURE 19-2. Depth of disease penetration in ulcerative colitis and Crohn's disease.

to the small intestine is almost never seen without the presence of small or large intestinal disease.¹³

In contrast to UC, the pattern of inflammation in CD is described as discontinuous. Areas of inflammation are intermixed with areas of normal GI mucosa, resulting in characteristic "skip lesions." Superficial **aphthous ulcers** may also develop in the GI mucosa. These ulcers may coalesce into larger linear ulcers, resulting in fissure formation as they increase in depth, giving rise to the characteristic "cobblestone" pattern observed upon examination of the mucosa.

Furthermore, the inflammation may be **transmural**, penetrating to the muscularis or serosal layers of the GI tract (Fig. 19-2). The propensity for transmural involvement may lead to serious complications of CD such as **strictures**, **fistulae**, abscesses, and perforation.¹³ Although rectal inflammation is typically less common in CD than UC, several types of perianal lesions may be observed in patients with CD. These include skin tags, hemorrhoids, fissures, anal ulcers, abscesses, and fistulae.¹⁴

CLINICAL PRESENTATION AND DIAGNOSIS

2 Differentiation between UC and CD is based on signs and symptoms as well as characteristic endoscopic findings, including the extent, pattern, and depth of inflammation (see Clinical Presentation box).

Extraintestinal Manifestations and Complications of IBD

3 Patients may manifest signs and symptoms of disease in areas outside the GI tract. These extraintestinal manifestations may occur in various body regions.^{5,13} Painful joint complications

Clinical Presentation of IBD

General

- Patients with CD or UC may present with similar symptoms.
- The onset may be insidious and subacute.
- Some patients present with extraintestinal manifestations before GI symptoms occur.
- In approximately 10% of cases it may not be possible to distinguish between UC and CD. These patients are described as having “indeterminate colitis.”

Symptoms

- *Ulcerative colitis*: Diarrhea (bloody, watery, or mucopurulent), rectal bleeding, abdominal pain/cramping, weight loss and malnutrition, tenesmus, constipation (with proctitis)
- *Crohn's disease*: Diarrhea (less bloody than UC), rectal bleeding (less than UC), abdominal pain/cramping, weight loss and malnutrition (more common than UC), fatigue/malaise

Signs

- *Ulcerative colitis*: Fever, tachycardia (with severe disease), dehydration, arthritis, hemorrhoids, anal fissures, perirectal abscesses
- *Crohn's disease*: Fever, tachycardia (with severe disease), dehydration, arthritis, abdominal mass and tenderness, perianal fissure or fistula

Laboratory Tests

- *Ulcerative colitis*: Leukocytosis, decreased hematocrit/hemoglobin, elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP), positive test for fecal occult blood, (+) perinuclear antineutrophil cytoplasmic antibodies (pANCA; up to 70% of patients)
- *Crohn's disease*: Leukocytosis, decreased hematocrit/hemoglobin, elevated ESR or CRP, positive test for fecal occult blood, (+) anti-*Saccharomyces cerevisiae* antibodies (up to 50% of patients), hypoalbuminemia with severe disease

associated with IBD include sacroiliitis and ankylosing spondylitis. Ocular involvement with episcleritis, uveitis, or iritis may manifest as blurred vision, eye pain, and photophobia. Associated skin findings include pyoderma gangrenosum (involving papules and vesicles that develop into painful ulcerations) and erythema nodosum (red nodules of varying size typically found on the lower extremities). Nephrolithiasis may also develop at a higher rate in patients with IBD. Oxalate stones are more common in CD, and uric acid-containing stones are more common in UC.¹³

Liver and biliary manifestations of IBD include an increased incidence of gallstone formation in patients with CD and development of sclerosing cholangitis or cholangiocarcinoma in patients with UC. Patients with UC are also at increased risk for development of colorectal cancer and should undergo periodic cancer screening. Ongoing inflammation due to active IBD may induce a hypercoagulable state, resulting in higher rates of both arterial and venous thromboembolism. Likewise, inflammation and recurrent blood loss may result in the development of chronic anemia. Patients with IBD also have higher rates of osteopenia, osteoporosis, and fractures, which are most strongly associated with use of corticosteroids.¹⁶ Patients with IBD are also at risk for developing thromboembolic disease, such as deep vein thrombosis and pulmonary embolism.

A serious complication of UC is toxic megacolon, defined as dilation of the transverse colon of greater than 6 cm (2.4 in.). Patients with toxic megacolon typically manifest systemic signs of severe inflammation such as fever, tachycardia, and abdominal distention.^{3,13} Surgical intervention, including colonic resection, may be necessary to acutely manage toxic megacolon.

Formation of strictures, abscesses, fistulae, and obstructions in patients with CD is possible. Patients with CD may develop significant weight loss or nutritional deficiencies secondary to malabsorption of nutrients in the small intestine, or as a consequence of multiple small- or large-bowel resections. Common nutritional deficiencies encountered in IBD include vitamin B₁₂, fat-soluble vitamins, zinc, folate, and iron. Malabsorption in children with CD may contribute to significant reductions in growth and development.

Diagnosis

Because patients often present with nonspecific GI symptoms, initial diagnostic evaluation includes methods to characterize the disease and rule out other potential etiologies. This may include stool cultures to examine for infectious causes of diarrhea.

Endoscopic approaches are typically used and may include colonoscopy, proctosigmoidoscopy, or possibly upper GI endoscopy in patients with suspected CD. Endoscopy is useful for determining the disease distribution, pattern and depth of inflammation, and to obtain mucosal biopsy specimens. Supplemental information from imaging procedures, such as computed tomography, abdominal x-ray, abdominal ultrasound, or intestinal barium studies may provide evidence of complications such as obstruction, abscess, perforation, or colonic dilation.³

After the diagnosis is made, the information derived from diagnostic testing and the patient's medical history and symptoms are used to gauge disease severity. The severity of

Patient Encounter 1, Part 1

A 32-year-old white man presents to the emergency department with complaints of crampy abdominal pain and 6 to 7 loose stools per day. He describes intermittent blood in the stool and states that these symptoms have been present for 3 days. He also reports malaise, fatigue, fever, and excessive thirst. He denies any sick contacts. He denies vomiting and has been using nonprescription loperamide for the last 36 hours to treat diarrhea. He consumes alcohol socially and does not use tobacco. He is admitted to the general medicine floor for management of his symptoms.

What other pertinent pieces of history would be beneficial to obtain from this patient regarding potential contributing factors or causes?

How would you classify the severity of this patient's IBD based on the information presented?

What additional information would you obtain prior to recommending drug therapy?

active UC is generally classified as mild, moderate, severe, or fulminant.¹ Mild UC typically involves up to four bloody or watery stools per day without systemic signs of toxicity or elevation of erythrocyte sedimentation rate (ESR). Moderate disease is classified as more than four stools per day with evidence of systemic toxicity. Severe disease is considered more than six stools per day and evidence of anemia, tachycardia, or an elevated ESR or C-reactive protein (CRP). Lastly, fulminant UC may present as more than 10 stools per day with continuous bleeding, signs of systemic toxicity, abdominal distention or tenderness, colonic dilation, or a requirement for blood transfusion.

A similar classification scheme is used to gauge the severity of active CD.² Patients with mild to moderate CD are typically ambulatory and have no evidence of dehydration; systemic toxicity; loss of body weight; or abdominal tenderness, mass, or obstruction. Moderate to severe disease is considered in patients who fail to respond to treatment for mild to moderate disease or those with fever, weight loss, abdominal pain or tenderness, vomiting, intestinal obstruction, or significant anemia. Severe to fulminant CD is classified as the presence of persistent symptoms or evidence of systemic toxicity despite outpatient corticosteroid treatment, or the presence of cachexia, rebound tenderness, intestinal obstruction, or abscess.

TREATMENT

Desired Outcomes

Pharmacologic interventions for IBD are designed to target the underlying inflammatory response. Treatment goals involve both management of active disease and prevention of disease relapse. **4** *Major treatment goals include alleviation of signs and symptoms and suppression of inflammation during acute*

episodes and maintenance of remission thereafter. Addressing active IBD in a timely and appropriate manner may prevent major complications such as perforation and may reduce the need for hospitalization or surgical intervention.

Once control of active disease is obtained, treatment regimens are designed to achieve the following long-term goals: (a) maintenance of remission and prevention of disease relapse, (b) improvement in the patient's quality of life, (c) prevention of surgical intervention or hospitalization, (d) management of extraintestinal manifestations, (e) prevention of malnutrition, and (f) prevention of treatment-associated adverse effects.

General Approach to Treatment

5 *When designing a drug regimen for treatment of IBD, several factors should be considered, including the patient's symptoms; medical history; current medication use; drug allergies; and extent, location, and severity of disease.* A thorough patient history may also help to identify a family history of IBD or potential exacerbating factors, such as tobacco or NSAID use.

Nonpharmacologic Therapy

No specific dietary restrictions are recommended for patients with IBD, but avoidance of high-residue foods in patients with strictures may help to prevent obstruction. Avoidance of excess fat in the diet may be preferred as well. Nutritional strategies in patients with long-standing IBD may include use of vitamin and mineral supplementation. Administration of vitamin B₁₂, folic acid, fat-soluble vitamins, and iron may be needed to prevent or treat deficiencies. In severe cases, enteral or parenteral nutrition may be needed to achieve adequate caloric intake.

Patients with IBD, particularly those with CD, are also at risk for bone loss. This may be a function of malabsorption or an effect of repeated courses of corticosteroids.¹⁶ Risk factors for osteoporosis should be determined, and baseline bone density measurement may be considered.¹⁶ Vitamin D and calcium supplementation should be used in all patients receiving long-term corticosteroids. Oral bisphosphonate therapy may also be considered in patients receiving prolonged courses of corticosteroids or in those with osteopenia or osteoporosis.

Surgical intervention is a potential treatment option in patients with complications such as fistulae or abscesses, or in patients with medically refractory disease. UC is curable with performance of a total colectomy. Patients with UC may opt to have a colectomy to reduce the chance of developing colorectal cancer. Patients with CD may have affected areas of intestine resected. Unfortunately, CD may recur following surgical resection. Repeated surgeries may lead to significant malabsorption of nutrients and drugs consistent with development of short-bowel syndrome.

Pharmacologic Therapy

Several pharmacologic classes are available for the acute treatment and maintenance therapy of IBD. Because there may be differences in the underlying disease process, distribution,

and severity between CD and UC, response rates to drugs in the same pharmacologic class may differ between these two diseases. Therefore, initial selection of an appropriate agent for patients with active IBD should be designed to deliver maximum efficacy while minimizing toxicity. Response rates to individual classes of medications for both UC and CD are discussed within the specific treatment section for each disease.

► Symptomatic Interventions

Patients with active IBD often have severe abdominal pain and diarrhea. Medications used to manage these types of symptoms may have adverse consequences in patients with active IBD. 6 **Antidiarrheal medications that reduce GI motility such as loperamide, diphenoxylate/atropine, and codeine should be avoided in patients with active IBD due to the risk of precipitating acute colonic dilation (toxic megacolon).**¹³ Drugs with anticholinergic properties, such as hyoscyamine and dicyclomine, are often used to treat intestinal spasm and pain, but these drugs may also reduce GI motility and should generally be avoided in active IBD.

Patients who have had multiple intestinal resections due to CD may have diarrhea related to the inability to reabsorb bile salts. Cholestyramine has been demonstrated to improve diarrheal symptoms in this population.¹⁴ NSAIDs should be avoided for pain management due to their ability to worsen IBD symptoms. Opioid analgesics should be used with caution because they may significantly reduce GI motility.

► Aminosalicylates

The aminosalicylates are among the most commonly used drugs for inducing and maintaining remission in patients with IBD (Table 19-1). These drugs are designed to

deliver 5-aminosalicylate (5-ASA, mesalamine) to areas of inflammation within the GI tract. Although the mechanism of mesalamine is not fully understood, it appears to have favorable anti-inflammatory effects. The delivery of mesalamine to the affected sites is accomplished by either linking mesalamine to a carrier molecule or altering the formulation to release drug in response to changes in intestinal pH. Topical suppositories and enemas are designed to deliver mesalamine directly to the distal colon and rectum.^{7,17-20}

The prototypical aminosalicylate is sulfasalazine, which is composed of mesalamine linked by a diazo bond to the carrier molecule sulfapyridine. This linkage prevents premature absorption of mesalamine in the small intestine. Once sulfasalazine is delivered to the colon, bacterial degradation of the diazo bond frees mesalamine from sulfapyridine. Sulfapyridine is then absorbed and excreted renally while mesalamine acts locally within the GI tract.

Newer mesalamine products utilize nonsulfapyridine methods for drug delivery. Olsalazine uses two mesalamine molecules linked together, whereas balsalazide uses the inert carrier molecule 4-aminobenzoyl- β -alanine. Both drugs use a diazo bond similar to sulfasalazine. Other mesalamine formulations are pH-dependent formulations that release mesalamine at various points throughout the GI tract. The newest mesalamine products include Lialda, a multimatrix (MMX) formulation with a pH-sensitive coat that releases in the terminal ileum, allowing for once-daily dosing.¹⁷ Enteric-coated mesalamine granules that also use a polymer matrix for extended release (Apriso) are also able to be given in a once-daily fashion.

Sulfasalazine is associated with various adverse effects, most of which are thought to be due to the sulfapyridine component. Common adverse effects that may be dose related

Table 19-1

Aminosalicylates for Treatment of IBD

Drug	Trade Names	Formulation	Strengths	Daily Dosage Range (g)	Site of Action
Sulfasalazine	Azulfidine	Immediate-release or enteric-coated tablets	500 mg	2-6	Colon
	Azulfidine Entabs				
	Sulfazine	Suspension	250 mg/5mL		
	Sulfazine EC				
Mesalamine	Rowasa	Enema	4 g/60 mL	4	Distal left colon and rectum
	Asacol	Delayed-release resin tablet	400 mg,	1.6-4.8	Distal ileum and colon
	Asacol-HD		800 mg		
	Canasa	Rectal suppository	1,000 mg	1	Rectum
	Pentasa	Microgranule controlled-release capsule	250 mg	2-4	Small bowel
			500 mg	2-4	Colon
	Lialda	MMX formulated pH-dependent polymer film coated tablet	1.2 g	1.2-4.8	Terminal ileum and colon
Apriso	Enteric-coated granules in polymer matrix	375 mg	1.5	Colon	
Olsalazine	Dipentum	Delayed-release capsule	250 mg	1-3	Colon
Balsalazide	Colazal	Delayed-release capsule	750 mg	2-6.75	Colon

MMX, multimatrix.

include headache, dyspepsia, nausea, vomiting, and fatigue.^{20–22} Idiosyncratic effects include bone marrow suppression, reduction in sperm counts in males, hepatitis, and pulmonitis. Hypersensitivity reactions may occur in patients allergic to sulfonamide-containing medications. Patients who are genetically slow acetylators may be more prone to adverse effects.

The use of nonsulfapyridine-based aminosalicylates has led to greater tolerability. Although the adverse effects are similar to those of sulfasalazine, they occur at a much lower rate. Olsalazine, in particular, is associated with a higher incidence of secretory diarrhea. These agents can also be used safely in patients with a reported sulfonamide allergy. They are more expensive than sulfasalazine products that are available generically.

► Corticosteroids

Corticosteroids have potent anti-inflammatory properties and are used in active IBD to suppress inflammation rapidly. They may be administered systemically or delivered locally to the site of action by altering the drug formulation (Table 19–2). Because these drugs usually improve symptoms and disease severity rapidly, they should be restricted to short-term management of active disease. Long-term use of systemic corticosteroids is associated with significant adverse effects, including cataracts, skin atrophy, hypertension, hyperglycemia, adrenal suppression, osteoporosis, increased risk of infection, and delayed growth in children, among others.^{20–22}

Budesonide is a high-potency glucocorticoid used in CD that has low systemic bioavailability when administered orally.²³ The formulation releases budesonide in the terminal ileum for treatment of disease involving the ileum or ascending colon. Due to its reduced bioavailability, budesonide may prevent some long-term adverse effects in patients who have steroid-dependent IBD.^{22,23}

Table 19–2

Corticosteroids for Treatment of IBD

Drug	Trade Names	Daily Dose
Prednisone	Generic	20–60 mg orally
Prednisolone	Generic	20–60 mg orally
Budesonide	Entocort EC	Induction: 9 mg orally Maintenance: 6 mg orally
Methylprednisolone	Medrol (orally) Solu-Medrol (IV)	15–60 mg orally or IV
Hydrocortisone	Solu-Cortef	300 mg IV in three divided doses
	Cortenema	100 mg rectally at bedtime
	Cortifoam	90 mg rectally once or twice daily
	Anucort-HC 25 mg	25–50 mg rectally twice daily
	Proctocort 30 mg	25–50 mg rectally twice daily

► Immunosuppressants

Agents targeting the excessive immune response or cytokines involved in IBD are potential treatment options (Table 19–3). Azathioprine and its active metabolite 6-mercaptopurine (6-MP) are inhibitors of purine biosynthesis and reduce IBD-associated GI inflammation. They are most useful for maintaining remission of IBD or reducing the need for long-term use of corticosteroids.^{22,24} Use in active disease is limited by their slow onset of action, which may be as long as 3 to 12 months. Adverse effects associated with azathioprine and 6-MP include hypersensitivity reactions resulting in pancreatitis, fever, rash, hepatitis, and leukopenia.^{21,22,24} Patients should be tested for activity of thiopurine methyltransferase (TPMT), the major enzyme responsible for metabolism of azathioprine prior to use. Deficiency or reduced activity of TPMT may result in toxicity from azathioprine and 6-MP.

Methotrexate is a folate antagonist used primarily for maintaining remission of CD. It may be administered orally, subcutaneously, or IV and may result in a steroid-sparing effect in patients with steroid-dependent disease.^{6,22}

Table 19–3

Immunosuppressant and Biologic Agents for Treatment of IBD

Drug	Trade Name(s)	Dose
Azathioprine	Imuran, Azasan	1.5–2.5 mg/kg/day orally
6-Mercaptopurine	Purinethol	1.5–2.5 mg/kg/day orally
Methotrexate	Trexall	15–25 mg weekly (IM/SC/orally)
Cyclosporine	Sandimmune	4 mg/kg/day IV continuous infusion
Infliximab	Remicade	Induction: 5 mg/kg IV at 0, 2, and 6 weeks; 10 mg/kg per dose IV for nonresponders Maintenance: 5 mg/kg IV every 8 weeks
Adalimumab	Humira	Induction: 160 mg SC day 1 (given as four 40-mg injections in 1 day or as two 40-mg injections per day for 2 consecutive days), then 80 mg SC 2 weeks later (day 15) Maintenance: 40 mg SC every other week, starting on day 29 of therapy
Certolizumab	Cimzia	Induction: 400 mg SC initially, then 400 mg SC at 2 and 4 weeks Maintenance: 400 mg SC every 4 weeks if initial response
Natalizumab	Tysabri	Induction/maintenance: 300 mg IV every 4 weeks

IM, intramuscular; PEG, polyethylene glycol.

Long-term methotrexate use may result in serious adverse effects, including hepatotoxicity, pulmonary fibrosis, and bone marrow suppression.

Cyclosporine is a cyclic polypeptide immunosuppressant typically used to prevent organ rejection in transplant patients. Its use is restricted to patients with fulminant or refractory symptoms in patients with active IBD. Significant toxicities associated with cyclosporine are nephrotoxicity, risk of infection, seizures, hypertension, and liver function test abnormalities.^{1,22}

► Biologic Agents

Several biologic agents targeting TNF- α are used for the treatment of IBD (Table 19-3). Reduction in TNF- α activity is associated with improvement in the underlying inflammatory process. Infliximab is the prototypical agent and is used in both UC and CD, whereas the other agents are approved for use only in CD. Due to its chimeric structure (i.e., 75% human, 25% mouse), antibodies to infliximab may develop, resulting in loss of efficacy over time. Newer biologic agents are humanized and have a lower propensity for antibody development.²⁵

Disadvantages of anti-TNF biologic therapy include the need for parenteral administration, significant drug cost, and the potential for serious adverse effects. Adverse effects

may include infusion-related reactions such as fever, chest pain, hypotension, and dyspnea. Antibodies may develop to infliximab over time that may reduce its efficacy and predispose patients to development of infusion-related adverse effects. All of the TNF- α inhibitors have also been associated with reactivation of serious infections, particularly intracellular pathogens such as tuberculosis, as well as hepatitis B.^{15,21} These agents should not be used in patients with current infections, and patients should be screened for latent tuberculosis and viral hepatitis prior to initiating therapy. Exacerbation of heart failure is also a potential adverse effect, and biologic agents should be avoided in patients with advanced or decompensated heart failure.^{15,20,21} The anti-TNF- α biologics also carry a risk of developing lymphoma, including a rare form known as hepatosplenic T-cell lymphoma. The risk appears to be highest in younger male patients and those using concomitant azathioprine or 6-MP. Therefore, this potential risk should be considered in patients who meet these criteria.

Natalizumab is a humanized monoclonal antibody that antagonizes integrin heterodimers, prevents α_4 -mediated leukocyte adhesion to adhesion molecules, and prevents migration across the endothelium.²⁶ It has been associated with development of progressive multifocal leukoencephalopathy, and its use is restricted to patients with CD who have failed other

Patient Encounter 1, Part 2: Medical History and Physical Examination

PMH: Type 1 diabetes, appendectomy at age 25, seasonal allergies

FH: Both parents alive; father has history of MI and type 2 DM. Mother has a history of hypothyroidism; brother with type 1 DM

SH: Works as an electrical engineer; social alcohol use and no tobacco use

Allergies: Penicillin (rash)

Meds: Loperamide orally as needed, insulin glargine 25 units at bedtime; insulin aspart with meals based on correction factor, fluticasone nasal spray once daily, cetirizine 10 mg as needed

ROS: (+) Diarrhea, abdominal pain, fatigue, fever, thirst

PE:

VS: BP 120/75 mm Hg, P 110 bpm, RR 17/min, T 38.3°C (100.9°F)

CV: Tachycardia with normal rhythm. No murmurs, rubs, or gallops

HEENT: Dry mucous membranes

Skin: Dry with evidence of tenting

Abd: Soft, nondistended, moderate diffuse tenderness, (+) bowel sounds, (–) hepatosplenomegaly, (–) masses, heme (+) stool

MS: 5/5 strength in upper and lower extremities; normal ROM

Labs: Sodium 132 mEq/L (132 mmol/L), potassium 2.8 mEq/L (2.8 mmol/L), chloride 99 mEq/L (99 mmol/L), bicarbonate 28 mEq/L (28 mmol/L), BUN 27 mg/dL (9.6 mmol/L), serum creatinine 1.4 mg/dL (124 μ mol/L), serum glucose 180 mg/dL (10.0 mmol/L) albumin 4.2 g/dL (42 g/L), ALT 25 IU/L (0.42 μ kat/L), AST 23 IU/L (0.38 μ kat/L), ESR 110 mm/h, CRP 0.9 mg/dL (9 mg/L), A1C 7.8% (0.078; 62 mmol/mol hemoglobin), hemoglobin 10 g/dL (100 g/L or 6.2 mmol/L), hematocrit 31%, (0.31), WBC count $17.0 \times 10^3/\text{mm}^3$ ($17.0 \times 10^9/\text{L}$), platelets $420 \times 10^3/\text{mm}^3$ ($420 \times 10^9/\text{L}$), Urinalysis: 2+ protein; (–) ketones; SG = 1.025, (–) bacteria; (–) WBCs

Abdominal x-ray: (–) obstruction, free-air, or colonic dilation

Colonoscopy: Diffuse superficial inflammation extending to the hepatic flexure with evidence of recent bleeding, (–) polyps or strictures, biopsy taken

Path: Evidence of crypt abscesses and PMN infiltration

How is this additional information helpful in determining disease type and severity?

What factors should you consider in choosing appropriate therapy for this patient?

What treatment options would you consider at this time?

therapies. Natalizumab should not be used concomitantly with immunosuppressants or TNF- α inhibitors, and use requires enrollment in the manufacturer's prescribing program.

► Other Agents

Antibiotics have been studied based on the rationale that they may interrupt the inflammatory response directed against endogenous bacterial flora. Metronidazole and ciprofloxacin have been the two most widely studied agents.^{1,2,27} Metronidazole may benefit some patients with pouchitis (inflammation of surgically created intestinal pouches) and patients with CD who have had ileal resection or have perianal fistulas. Ciprofloxacin has shown some efficacy in refractory active CD. Both drugs may cause diarrhea, and long-term use of metronidazole is associated with the development of peripheral neuropathy.

Because smoking is associated with reduced symptoms of UC, nicotine has been studied as a potential treatment option. However, results have been mixed; transdermal nicotine may result in some improvement in mild to moderate UC symptoms and may be more effective in patients who are

ex-smokers.^{1,28} Daily doses between 15 and 25 mg appear to be most effective.

Probiotics such as *Lactobacillus acidophilus* or *Bifidobacterium* have been used with the rationale that modification of the host flora may alter the inflammatory response. There are minimal data to support use of probiotics in CD.² In patients with UC, the probiotic preparation VSL#3 demonstrated efficacy in reducing recurrence of pouchitis in patients with ileal pouch anal anastomosis and may prevent relapse in mild to moderate disease.^{1,29}

Treatment of UC

Drug and dosing guidelines based on disease severity and location are presented in [Table 19-4](#).

► Mild to Moderate Active UC

7 *Treatment of acute episodes of UC is dictated by the severity and extent of disease, and first-line therapy of mild to moderate disease involves oral or topical aminosalicylate*

Table 19-4

Treatment Recommendations for UC

Disease Severity and Location	Active Disease	Maintenance of Remission
Mild Disease		
Proctitis	Mesalamine suppository 1 g rectally daily	May reduce suppository frequency to 1 g 3 times/week
Left-sided disease	Mesalamine enema 1 g rectally daily, or Mesalamine 2.4–4.8 g/day or sulfasalazine 4–6 g/day orally	May reduce enema frequency to 1 g every other day, or taper to mesalamine 1.6–2.4 g/day or sulfasalazine 2–4 g/day orally
Extensive disease	Mesalamine 2.4–4.8 g/day or sulfasalazine 4–6 g/day orally	Taper to mesalamine 1.6–2.4 g/day or sulfasalazine 2–4 g/day orally
Moderate Disease		
Proctitis	Mesalamine suppository 1 g rectally daily; If no response to mesalamine: • Prednisone 40–60 mg/day orally	May reduce suppository frequency to 1 g 3 times/week; taper prednisone as soon as possible; Consider adding azathioprine or 6-MP 1.5–2.5 mg/kg/day orally
Left-sided disease	Mesalamine enema 1 g rectally at bedtime daily, or mesalamine 2.4–4.8 g/day or sulfasalazine 4–6 g/day orally May combine enema and oral therapies	May reduce enema frequency to 1 g 3 times/week if symptoms permit May reduce dose of oral agents if symptoms permit; consider adding azathioprine or 6-MP 1.5–2.5 mg/kg/day orally
Extensive disease	Mesalamine 2.4–4.8 g/day or sulfasalazine 4–6 g/day orally; If no response to mesalamine or sulfasalazine: • Prednisone 40–60 mg/day orally; or • Infliximab 5 mg/kg IV at weeks 0, 2, and 6	Taper mesalamine to 1.6–2.4 g/day or sulfasalazine 2–4 g/day orally; If prednisone or infliximab were required: • Taper prednisone as soon as possible; • Give infliximab 5 mg/kg IV every 8 weeks Consider adding azathioprine or 6-MP 1.5–2.5 mg/kg/day orally
Severe or Fulminant Disease		
	Hydrocortisone 300 mg IV daily (or equivalent) × 7 days, or Infliximab 5 mg/kg IV at weeks 0, 2, and 6 If no response to IV corticosteroids or infliximab: • Cyclosporine 4 mg/kg/day IV	Change to oral corticosteroid and taper as soon as possible Restart oral mesalamine or sulfasalazine May continue infliximab at maintenance doses of 5 mg/kg every 8 weeks

6-MP, 6-mercaptopurine.

derivatives. Topical suppositories and retention enemas are preferred for active distal UC (left-sided disease and proctitis) because they deliver mesalamine directly to the site of inflammation. Topical mesalamine is superior to both topical corticosteroids and oral aminosalicylates for inducing remission in active mild to moderate UC.^{1,30–33} Enemas are appropriate for patients with left-sided disease because the medication will reach the splenic flexure. Suppositories deliver mesalamine up to approximately 20 cm and are most appropriate for treating proctitis.^{6,7,30}

Topical mesalamine products provide a more rapid response than oral preparations. Improvement in symptoms may be seen in as little as 2 days, but up to 4 weeks of treatment may be necessary for maximal response. Oral and topical mesalamine preparations may be used together to provide maximal effect. Oral mesalamine may also be used for patients who are unwilling or unable to use topical preparations.^{30–32}

Topical corticosteroids are typically reserved for patients who do not respond to topical mesalamine.^{1,22} Patients should be properly educated regarding appropriate use of topical products. This includes proper administration and adequate retention of topical mesalamine products in order to maximize efficacy.

For patients with more extensive disease extending proximal to the splenic flexure, oral sulfasalazine or any of the newer oral mesalamine products is considered first-line therapy.^{1,6} Doses should provide 4 to 6 g of sulfasalazine or 2.4 g of mesalamine or equivalent.⁶ Although little differences in efficacy exist between mesalamine products, sulfasalazine and olsalazine have a higher incidence of adverse effects.¹⁷ Use of the once-daily formulations of mesalamine may improve patient adherence.¹⁷ Induction of remission may require 4 to 8 weeks of therapy at appropriate treatment doses.

Oral corticosteroids may be used for patients who are unresponsive to sulfasalazine or mesalamine. Prednisone doses of 40 to 60 mg/day (or equivalent) are recommended.^{1,22} Azathioprine or 6-MP is used for patients unresponsive to corticosteroids or those who become steroid dependent. Infliximab 5 mg/kg may also be used for patients who are unresponsive to conventional oral therapies and may reduce the need for colectomy after 3 months of treatment. Infliximab may also be used in patients who are refractory to or dependent on corticosteroids.³³

► Severe or Fulminant UC

Patients with severe UC symptoms require hospitalization for management of their disease. If the patient is unresponsive to oral or topical mesalamine and oral corticosteroids, a course of IV corticosteroids should be initiated.¹ Hydrocortisone 300 mg/day given in three divided doses or methylprednisolone 60 mg daily for 7 to 10 days are the preferred therapies.^{1,22}

Infliximab 5 mg/kg is also an option for severe UC. Cyclosporine 2 to 4 mg/kg/day given as a continuous IV infusion should be reserved for patients unresponsive to 7 to 10 days of IV corticosteroid therapy.

Patients with fulminant disease are treated similarly, although infliximab is not indicated for this population.

Patients with fulminant UC should be assessed for signs of significant systemic toxicity or colonic dilation, which may require earlier surgical intervention.

► Maintenance of Remission in UC

Unfortunately, up to 50% of patients receiving oral therapies and up to 70% of untreated patients relapse within 1 year after achieving remission.³⁴ For this reason, patients may require maintenance drug therapy indefinitely to preserve remission.

8 *Maintenance of remission of UC may be achieved with*

oral or topical aminosalicylates. In patients with proctitis, mesalamine suppositories 1 g daily may prevent relapse in up to 90% of patients.^{1,7,30} Mesalamine enemas are appropriate for left-sided disease and may often be dosed two to three times weekly. Oral mesalamine at lower doses (e.g., 1.2 to 1.6 g/day) may be combined with topical therapies to maintain remission. Topical or oral corticosteroids are not effective for maintaining remission of distal UC and should be avoided.

Oral sulfasalazine or mesalamine is effective in maintaining remission in patients with more extensive disease.^{1,6} Lower daily doses (e.g., 2 to 4 g sulfasalazine or 2 to 2.4 g mesalamine) may be used for disease maintenance. As with distal UC, oral corticosteroids are not effective for maintaining remission and should be avoided due to the high incidence of adverse effects.

8 *Immunosuppressants such as azathioprine, 6-MP, or*

infliximab can be used for unresponsive patients or those who develop corticosteroid dependency. Remission may be maintained in up to 58% of patients after 5 years of treatment.^{1,6,24} Intermittent infliximab dosing (5 mg/kg IV every 8 weeks) may be used to maintain disease remission and reduce the need for corticosteroids in patients with

Patient Encounter 2

A 47-year-old African American woman presents to the clinic for follow-up management of CD. She has disease in the jejunum, ileum, and ascending colon that was diagnosed 12 months ago. She takes Pentasa 1,000 mg four times per day. She reports 2–3 loose stools/day on 5–6 days per week with intermittent blood and abdominal pain. This is interfering with her daily activities and ability to work and socialize. Her medical history is also significant for GERD and dyslipidemia, for which she takes omeprazole and atorvastatin. She reports an allergy to shellfish (hives).

How would you assess this patient's disease control and current drug therapy?

What treatment options are available?

How would you educate this patient on her drug therapy for IBD, including any changes you would consider making to her current therapy?

Table 19-5

Treatment Recommendations for CD

Disease Location and Severity	Active Disease	Maintenance of Remission
Mild Disease		
Ileal or ileocolonic	Mesalamine 3.2–4.8 g/day or sulfasalazine 4–6 g/day orally	Taper mesalamine 1.6–2.4 g/day or sulfasalazine 2–4 g/day orally
Ileal ± ascending colon	Budesonide 9 mg daily orally for up to 8 weeks	Taper budesonide to 6 mg daily for up to 3 months
Perianal	Mesalamine 2.4–4.8 g/day or sulfasalazine 4–6 g/day orally May add metronidazole 10–20 mg/kg/day or ciprofloxacin 1 g daily	Taper mesalamine to 1.6–2.4 g/day or sulfasalazine 2–4 g/day orally
Moderate Disease	Same treatment as for mild disease but may consider: <ul style="list-style-type: none"> • Infliximab or adalimumab or certolizumab (see Table 19-3 for dosage regimens) or • Prednisone 40–60 mg/day orally, or • Budesonide 9 mg/day orally for up to 8 weeks • Consider natalizumab if no response to prior therapies <p>If fistulizing disease, consider:</p> <ul style="list-style-type: none"> • Infliximab, adalimumab, or certolizumab pegol 	Continue aminosalicylate at maintenance dose; If loss of response to infliximab, consider adalimumab Taper prednisone as soon as possible; Taper budesonide to 6 mg daily for 3 months Consider adding azathioprine or 6-MP 1.5–2.5 mg/kg/day orally or methotrexate 12.5–25 mg orally or IM/SC once weekly Consider natalizumab if no response to previous therapies Taper corticosteroid as soon as possible
Severe or Fulminant Disease	Hydrocortisone 300 mg IV daily (or equivalent) × 7 days, or Infliximab (severe or fistulizing disease) 5 mg/kg IV at 0, 2, and 6 weeks <ul style="list-style-type: none"> • Adalimumab or certolizumab or • Consider natalizumab if no response to prior therapies <p>Consider cyclosporine 4 mg/kg/day for refractory disease</p>	May continue infliximab, adalimumab, certolizumab, or natalizumab (see Table 19-3 for dosage regimens) Consider adding azathioprine or 6-MP 1.5–2.5 mg/kg/day orally or methotrexate 12.5–25 mg orally or IM/SC weekly

6-MP, 6-mercaptopurine; IM, intramuscular; SC, subcutaneous.

moderate to severe UC. Colectomy is an option for patients with progressive disease who cannot be maintained on drug therapy alone.

► Treatment of CD

Drug and dosing guidelines based on disease severity and location are presented in [Table 19-5](#).

► Mild to Moderate Active CD

9 Induction of remission of mild to moderate active CD may be accomplished with oral budesonide or possibly aminosalicylates. Budesonide 9 mg orally once daily for up to 8 weeks may be used for mild to moderate active CD in patients with involvement of the terminal ileum or ascending colon, with success expected in 50% to 69% of patients.^{6,22,23,35} Because the formulation releases budesonide in the terminal ileum, it is not effective in reaching sites distal to the ascending colon.^{24,36} Conventional oral corticosteroids such as prednisone and methylprednisolone may also be used and may be slightly more effective than budesonide for inducing remission, but they carry a higher risk of adverse effects.⁶

Mesalamine products have demonstrated minimal efficacy but may be tried in patients with ileal, ileocolonic, or colonic CD.^{2,6,36} These drugs are typically better tolerated

than sulfasalazine at full treatment doses. Induction of remission may require up to 16 weeks of treatment at full doses.³⁵ Sulfasalazine 4 to 6 g/day is most effective for patients with active colonic or ileocolonic involvement, with response rates of approximately 50%.^{2,5,35}

Metronidazole or ciprofloxacin can be used in patients who do not respond to budesonide or oral aminosalicylates. Response rates of up to 50% are reported, but data are conflicting, and these agents should generally not be considered first-line therapy.^{2,6,27}

► Moderate to Severe Active CD

9 Patients with moderate to severe active CD may be treated with oral corticosteroids (e.g., prednisone 40 to 60 mg daily) or budesonide (moderate activity), or anti-TNF antibody therapies (infliximab, adalimumab, or certolizumab pegol) (moderate to severe activity).^{2,6} Budesonide 9 mg orally once daily may be used for moderately active CD involving the terminal ileum or ascending colon. All anti-TNF- α therapies are effective in inducing closure and cessation of drainage in patients with fistulae.⁶

Infliximab is an effective alternative to corticosteroid therapy for patients with moderate to severe CD including patients with fistulizing or perianal disease.^{14,23,35} The recommended

regimen for induction of remission is infliximab 5 mg/kg at weeks 0, 2, and 6; it is effective in inducing remission in approximately 80% of patients at 8 weeks. Complete closure of existing enterocutaneous fistulae occurs in approximately 50% of patients.^{14,23,35}

Adalimumab is effective in moderate to severe active CD and used preferably in patients with diminished response to infliximab. The approved adult dose of 160 mg on day 1, 80 mg at 2 weeks, and 40 mg at day 29 resulted in a remission rate of 36% at 4 weeks.^{6,16}

Certolizumab is also effective, with a dose of 400 mg subcutaneously initially, and then at 2 and 4 weeks resulting in a clinical response rate of 37% at 6 weeks.^{15,22} Natalizumab 300 mg IV every 4 weeks has been reported to induce remission in up to 37% of patients at 10 weeks, which was similar to placebo.^{6,16,32}

For patients with simple perianal fistulae, antibiotics (metronidazole or ciprofloxacin), infliximab, adalimumab, and certolizumab pegol are appropriate treatment options. Complex perianal fistulae are those associated with multiple openings, abscess, stricture, or penetration into the vaginal wall. These types of perianal fistulae may require surgical intervention but may also be amenable to treatment with antibiotics, infliximab, azathioprine, or 6-MP.^{2,6,16,15,22}

► Severe to Fulminant Active CD

Most patients with severe to fulminant CD require hospitalization for appropriate treatment. Patients should be assessed for possible surgical intervention if abdominal distention, masses, abscess, or obstruction are present. Daily IV doses of corticosteroids equivalent to prednisone 40 to 60 mg are recommended as initial therapy to rapidly suppress severe inflammation.

If there are no contraindications, infliximab 5 mg/kg followed by 5 mg/kg at weeks 2 and 6 may be used for severe active CD. There is no evidence that infliximab is either safe or effective for fulminant disease. Adalimumab or certolizumab are also options for patients with severe CD, particularly those who have lost response to infliximab or those who are nonresponsive to traditional therapies. Natalizumab can be used for severe CD but is reserved for patients failing other available therapies, including TNF- α inhibitors.

Adjunctive therapy with fluid and electrolyte replacement should be initiated. Nutritional support with enteral or parenteral nutrition may be indicated for patients unable to eat for more than 5 to 7 days.² Some evidence suggests that enteral nutrition provides anti-inflammatory effects in patients with active CD.^{36,37}

Limited evidence indicates that cyclosporine, or possibly tacrolimus, may be effective as salvage therapy for patients who fail IV corticosteroid therapy.^{2,6,22} Surgical intervention may ultimately be necessary for medically refractory disease.

► Maintenance of Remission in CD

Patients with CD are at high risk for disease relapse after induction of remission. Within 2 years, up to 80% of patients experience a relapse; therefore, most patients should be evaluated for indefinite maintenance therapy.

10 Maintenance of remission of CD may be achieved with immunosuppressants (azathioprine, 6-MP, or methotrexate), biologic agents (infliximab, adalimumab, certolizumab pegol, or natalizumab), and less frequently with oral or topical aminosalicilate derivatives.

In contrast to their use in UC, sulfasalazine and the newer aminosalicylates are marginally effective in preventing CD relapse in patients with medically induced remission, with success rates of only 10% to 20% at 1 year.^{6,34} Despite not being recommended as first-line therapy, aminosalicylates are routinely used to maintain remission of CD. Some evidence suggests that aminosalicylates may prevent or delay disease recurrence in patients with surgically induced remission.^{2,34}

Several other treatment options exist for maintaining remission that may also reduce the need for corticosteroids. Infliximab has been shown to maintain remission in 46% of patients compared with 23% of those treated with placebo over a 54-week period.^{15,22,32} Adalimumab 40 mg subcutaneously given every other week has been shown to maintain remission in up to 36% of patients at 56 weeks of treatment.^{15,38} Certolizumab 400 mg IV every 4 weeks has also been effective in maintaining remission in up to 61% of patients at 26 weeks.^{15,32} Patients with a baseline CRP of greater than 1 mg/dL (10 mg/L) may have a more favorable response. Natalizumab may also be used for maintenance in patients unresponsive to anti-TNF- α agents. Up to 40% of patients may maintain remission at 15 months.^{15,32}

Azathioprine and 6-MP in oral doses up to 2.5 mg/kg/day have been shown to maintain remission in 45% of patients for up to 5 years.^{2,6,22,24,29} These drugs may be used to prevent disease recurrence after surgically induced remission. Methotrexate in doses ranging from 12.5 to 25 mg once weekly given orally, intramuscularly, or subcutaneously has resulted in remission rates of up to 52% at 3 years.^{6,29,34} Corticosteroids, although effective for inducing remission rapidly, are not effective for maintenance therapy and are associated with significant adverse effects with long-term use. Therefore, systemic or topical corticosteroids should not be used for maintaining remission in patients with IBD. Unfortunately up to 50% of patients treated acutely with corticosteroids become dependent on them to prevent symptoms.²

In place of conventional corticosteroids, budesonide 6 mg orally once daily may be used for up to 3 months after remission induction for mild to moderate CD or in patients dependent on corticosteroids, although budesonide's efficacy is questionable when extended to this duration.⁶

Treatment of IBD in Special Populations (Table 19–6)

► Elderly Patients

Approximately 8% to 20% of patients with UC and 7% to 26% of patients with CD are elderly at initial diagnosis.³⁸ In general, IBD presents similarly in elderly patients compared with younger individuals. Elderly patients may have more comorbid diseases, some of which may make the diagnosis of IBD more difficult. Such conditions include ischemic colitis,

Table 19-6

Dosing Considerations of IBD Therapies in Special Populations

Therapy	Pediatric Patients	Elderly Patients	Pregnancy ⁴⁴⁻⁴⁶
Sulfasalazine	Age more than 2 years: 40–60 mg/kg/day in 3–6 divided doses; 30 mg/kg/day in 3–6 divided doses for maintenance	No specific changes	Category B Administer folic acid 2 mg daily during prenatal period and pregnancy
Mesalamine	No specific changes; Balsalazide indicated for age more than 5 years	No specific changes	Category B (Olsalazine Category C) Generally considered safe and effective
Corticosteroids	No specific changes	No specific changes Elderly patients at high risk for osteoporosis	Older agents not rated Budesonide category C Generally considered safe and effective
TNF- α inhibitors	Infliximab indicated for pediatric patients: 5 mg/kg at 0, 2, and 6 weeks, then every 8 weeks Adalimumab has been used at doses of 80 mg SC day 0, then 40 mg SC every other week	Avoid in patients with heart failure Elderly patients at higher risk for infections	Category B Pregnancy registry for adalimumab via manufacturer
Natalizumab	Dose of 3 mg/kg IV at 0, 4, and 8 weeks reported; data are lacking in children	No specific changes	Category C Report pregnancy to manufacturer's pregnancy registry
Azathioprine 6-Mercaptopurine	1.5–2 mg/kg/day to start	No specific changes	Category D Accepted as safe Avoid initiating during pregnancy, but continue if patient is already receiving when pregnant
Methotrexate	17 mg/m ² orally/SC/IM	No specific changes	Category X Contraindicated
Cyclosporine	No specific changes	No specific changes	Category C Use only in refractory patients
Metronidazole	30–50 mg/kg/day divided every 6 hours	No specific changes	Category B Use short courses if possible
Ciprofloxacin	Avoid use	Adjust dose for CrCl less than 50 mL/min (0.83 mL/s)	Category C Consider other alternatives

CrCl, creatinine clearance; IM, intramuscular; SC, subcutaneously.

diverticular disease, and microscopic colitis. Increased age is also associated with a higher incidence of adenomatous polyps, but the onset of IBD at an advanced age does not appear to increase the risk of developing colorectal cancer. Elderly patients may also use more medications, particularly NSAIDs, which may induce or exacerbate colitis.

Treatment of elderly patients with IBD is similar to that for younger patients, but special consideration should be given to some of the medications used. Corticosteroids may worsen diabetes, hypertension, heart failure, or osteoporosis. The TNF- α inhibitors should be used cautiously in patients with heart failure and should be avoided in New York Heart Association class III or IV disease. Lastly, elderly patients requiring major surgical interventions may be at higher risk for surgical complications or may not meet eligibility criteria for surgery because of comorbid conditions, age-related organ dysfunction, or reduced functional status.

► Children and Adolescents

CD occurs in approximately 4.56 per 100,000 pediatric patients, and UC occurs in about 2.14 cases per 100,000.³⁹

A major issue in children with IBD is the risk of growth failure secondary to inadequate nutritional intake and corticosteroid therapy. Failure to thrive may be an initial presentation of IBD in this population. Aggressive nutritional interventions may be required to facilitate adequate caloric intake. Chronic corticosteroid therapy may also be associated with reductions in growth and bone demineralization. Exploration of using lower doses in patients who are corticosteroid dependent may result in fewer problems with altered height velocity.⁴⁰ Guidelines for management of acute severe UC in children have recently been published and favor use of methylprednisolone as first-line therapy, with calcineurin inhibitors or infliximab used for unresponsive patients.⁴¹

The aminosalicylates, azathioprine, 6-MP, and infliximab are all viable options for treatment and maintenance of IBD in pediatric patients. Infliximab is approved for use in the United States for patients 6 to 17 years of age with moderate to severe active CD. Use of immunosuppressive therapy or infliximab may help reduce overall corticosteroid exposure. Adalimumab is approved for use in patients 4 years of age or older with juvenile rheumatoid arthritis. Limited recent information suggests that adalimumab may

be effective in pediatric patients with CD.^{42,43} Certolizumab and natalizumab are only FDA approved for use in adult patients with IBD; data in children are limited.⁴⁴

► Pregnant Women

Inducing and maintaining remission of IBD prior to conception is the optimal approach in women planning to become pregnant. Active IBD may result in prematurity and low birth weight. Thus pregnant women with IBD should be monitored closely, particularly during the third trimester.^{45–47}

Patients do not need to discontinue drug therapy for IBD once they become pregnant, but certain adjustments may be required.^{45–47} The aminosalicylates are considered safe to use in pregnancy, but sulfasalazine is associated with folate malabsorption. Because pregnancy results in a higher folate requirement, pregnant patients treated with sulfasalazine should be supplemented with folic acid 1 mg orally twice daily.⁴⁵

As with nonpregnant patients, corticosteroids may be used for treatment of active disease but not for maintenance of

remission. Generally, corticosteroids confer no additional risk on the mother or fetus and are generally well tolerated. Both azathioprine and 6-MP have been used successfully in pregnant patients and appear to carry minimal risk, despite carrying an FDA pregnancy category D rating.⁴⁶ Infliximab, adalimumab, and certolizumab are all FDA category B drugs and appear to carry minimal risk in pregnant patients.⁴⁷ Little is known about excretion of these drugs in breast milk, so benefit versus risk should be considered if they are used during nursing. Natalizumab is a pregnancy category C drug and should be used only when other therapies have been exhausted.

Methotrexate is a known abortifacient and carries an FDA category X pregnancy rating. Thus, it is contraindicated during pregnancy. Metronidazole carries a theoretical risk of mutagenicity in humans, but short courses are safe during pregnancy. Prolonged use of metronidazole should be avoided in pregnant patients due to lack of safety data supporting its use.⁴⁵ Ciprofloxacin should be avoided in pregnant women. First-trimester use of the antidiarrheal diphenoxylate has been associated with fetal malformations and should be avoided.

Patient Care and Monitoring

1. Evaluate the patient's symptoms to determine if they are consistent with UC or CD. Determine whether the patient has evidence of extraintestinal manifestations or GI complications related to IBD. Identify any psychosocial problems related to the presence of IBD.
2. If the patient is presenting with an exacerbation of preexisting IBD, determine if the symptoms are similar in type and severity to the patient's previous episodes.
3. Assess the patient's medical history for pertinent drug allergies, tobacco use, and current prescription and nonprescription drug therapies. Determine if any of the medications could exacerbate IBD. If applicable, inquire about adherence or recent changes to the patient's current IBD drug regimen.
4. Use available diagnostic laboratory, endoscopic, and imaging data to gauge the extent and severity of the patient's disease.
5. Construct a drug treatment plan based on the disease severity and location. Identify potential contraindications or financial barriers to drug therapy. Inquire if the patient has an aversion to or inability to properly use certain drug formulations that you may wish to recommend, such as topical (rectal) products.
6. Assess whether the patient will require maintenance therapy after remission induction. If so, identify the treatment duration. Decide when the patient should receive follow-up care.
7. Outline parameters to evaluate the efficacy and toxicity of the drug regimen you are recommending.
8. Determine whether the patient will need preventive drug therapy or diagnostic testing to prevent or screen for potential drug-related toxicities.
8. Educate the patient on proper use of drug therapy, including when to expect symptom improvement after initiation of treatment and which signs or symptoms to report that might be related to adverse drug effects.
9. Provide patient education on the proper use of aminosalicylate medications and assess regularly for adherence. Include the following:
 - Proper use of suppositories and enemas
 - The appropriate number of tablets or capsules to take per day. Reinforce that tablets and capsules are delayed release and should not be crushed, opened, or chewed.
 - Appropriate dose titration, particularly with oral sulfasalazine
 - The time frame the patient can expect improvement based on drug dose and disease severity
 - Signs or symptoms of potential adverse effects
10. Once remission is achieved, evaluate the patient's drug regimen to determine if dose reductions or changes in frequency of administration are required. Reinforce the need for adherence to drug therapy in order to maximize effectiveness.
11. Educate patients about their disease state. Refer patients to available support groups or IBD organizational resources if they are having difficulty in coping with their disease.

OUTCOME EVALUATION

- Monitor for improvement of symptoms in patients with active IBD, such as reduction in the number of daily stools, abdominal pain, fever, and heart rate.
- For patients in remission, assure that proper maintenance doses of medications are used and educate the patient to seek medical attention if symptoms recur or worsen.
- Evaluate patients receiving systemic corticosteroid therapy for improvement in symptoms and opportunities to taper or discontinue corticosteroid therapy. For patients using more than 5 mg daily of prednisone for more than 2 months or for steroid-dependent patients consider the following:
 - Central bone mineral density testing to evaluate the need for preventive or therapeutic bisphosphonate therapy;
 - Periodic monitoring of blood glucose, lipids, and blood pressure;
 - Evaluation for evidence of cushingoid features or signs or symptoms of infection.
- When considering treatment with azathioprine or 6-MP, obtain baseline complete blood count (CBC), liver function tests, and TPMT activity. These tests, except TPMT, should be monitored closely (every 2 to 4 weeks) at the start of therapy and then approximately every 3 months during maintenance therapy.
- With azathioprine and 6-MP, monitor for hypersensitivity reactions including severe skin rashes and pancreatitis. Educate the patient regarding signs and symptoms of pancreatitis (nausea, vomiting, and abdominal pain).
- Prior to initiating methotrexate therapy, obtain CBC, serum creatinine, liver function tests, chest x-ray, and pregnancy test (if female). Monitor blood counts weekly for 1 month, then monthly thereafter.
- Prior to initiating infliximab, adalimumab, or certolizumab, obtain a tuberculin skin test to rule out latent tuberculosis, monitor for signs and symptoms of tuberculosis, and measure viral hepatitis serologies. Also monitor patients with a prior history of hepatitis B virus infection for signs of liver disease, such as jaundice. Assure that patients do not have a clinically significant systemic infection or New York Heart Association class III or IV heart failure.
- In patients receiving infliximab, monitor for infusion-related reactions such as hypotension, dyspnea, fever, chills, or chest pain when administering IV doses.
- In patients with fistulae, monitor at every infliximab, adalimumab, or certolizumab dosing interval for evidence of fistula closure and overall reduction in the number of fistulae.
- Obtain a magnetic resonance imaging procedure prior to initiation of natalizumab therapy. Monitor patients for signs of progressive multifocal leukoencephalopathy such as mental status changes, signs of liver disease (e.g., jaundice), and hypersensitivity reactions following administration.

Abbreviations Introduced in This Chapter

5-ASA	5-Aminosalicylate
6-MP	6-Mercaptopurine
CD	Crohn's disease
CRP	C-reactive protein
ESR	Erythrocyte sedimentation rate
HLA	Human leukocyte antigen
IBD	Inflammatory bowel disease
IL	Interleukin
NOD2	Nucleotide oligomerization domain 2
NSAID	Nonsteroidal anti-inflammatory drug
pANCA	Perinuclear antineutrophil cytoplasmic antibodies
PPAR- γ	Peroxisome proliferator activated receptor- γ
PR	Per rectum
TNF- α	Tumor necrosis factor- α
TPMT	Thiopurine methyltransferase
UC	Ulcerative colitis

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Nausea and Vomiting

Sheila Wilhelm and Melissa Lipari

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Identify several causes of nausea and vomiting.
2. Describe the pathophysiologic mechanisms of nausea and vomiting.
3. Identify the three stages of nausea and vomiting.
4. Distinguish between simple and complex nausea and vomiting.
5. Create goals for treating nausea and vomiting.
6. Recommend a treatment regimen for a patient with nausea and vomiting associated with cancer chemotherapy, surgery, pregnancy, or motion sickness.
7. Outline a monitoring plan to evaluate the treatment outcomes for nausea and vomiting.

KEY CONCEPTS

- 1 Nausea and vomiting are symptoms that can be due to a number of different causes.
- 2 To treat nausea and vomiting most effectively, it is important to first identify the underlying cause of the symptoms.
- 3 Nonpharmacologic approaches to treating nausea and vomiting include dietary, physical, and psychological changes.
- 4 For prevention of acute chemotherapy-induced nausea and vomiting (CINV) for patients receiving moderately or highly emetogenic chemotherapy, a combination of antiemetics with different mechanisms of action is recommended.
- 5 Droperidol or a 5-hydroxytryptamine (serotonin) type 3 (5-HT₃) receptor antagonist should be administered at the end of surgery to patients at high risk for developing postoperative nausea and vomiting (PONV).
- 6 Nausea and vomiting affect the majority of pregnant women; the teratogenic potential of the therapy is the primary consideration in drug selection.
- 7 Because the vestibular system is replete with muscarinic type cholinergic and histaminic (H₁) receptors, anticholinergics and antihistamines are the most commonly used pharmacologic agents to prevent and treat motion sickness.

INTRODUCTION

Nausea and vomiting are due to complex interactions of the gastrointestinal (GI) system, the vestibular system, and various portions of the brain. Nausea and vomiting have a variety of causes that can be simple or complex. Preventing and treating nausea and vomiting require pharmacologic and nonpharmacologic measures tailored to individual patients and situations.

ETIOLOGY AND EPIDEMIOLOGY

- 1 Nausea and vomiting are symptoms that can be due to a number of different causes. Various disorders of the GI, cardiac, neurologic, and endocrine systems can lead to nausea and vomiting (Table 20-1).¹⁻³ Cancer chemotherapy agents are rated according to their emetogenic potential, and antiemetic therapy is prescribed based on these ratings. Due to potentially severe nausea and vomiting, some patients are unable to complete their chemotherapy treatment regimen. Radiation therapy can induce nausea and vomiting, especially when it is used to treat abdominal malignancies.⁴

Oral contraceptives, hormone therapy, oral hypoglycemic agents, anticonvulsants, and opioids are other common therapies that can cause nausea and vomiting.^{1,5} Some medications, such as digoxin and theophylline, cause nausea and vomiting in a dose-related fashion. Nausea and vomiting may indicate higher than desired drug concentrations. Ethanol and other toxins also cause nausea and vomiting.

Table 20-1

Causes of Nausea and Vomiting

GI or Intraoperative	Cardiac	Neurologic	Other Causes	Therapy Induced	Endocrine/Metabolic
Obstructing disorders	Cardiomyopathy	Motion sickness	Bulimia and	Cancer	Pregnancy (morning
Pyloric obstruction	Myocardial	Labyrinthitis	anorexia	chemotherapy	sickness and
Small bowel obstruction	infarction	Head trauma	nervosa	Antibiotics	hyperemesis
Colonic obstruction	Congestive heart	Migraine headache	Cyclic vomiting	Cardiac	gravidarum)
Achalasia	failure	Increased intracranial	syndrome	antiarrhythmics	Renal disease (uremia)
Superior mesenteric artery		pressure		Digoxin	Diabetes (ketoacidosis)
syndrome		Intracranial		Oral hypoglycemics	Thyroid and
Enteric infections		hemorrhage		Oral contraceptives	parathyroid disease
Inflammatory bowel		Meningitis		Theophylline	Adrenal insufficiency
diseases		Hydrocephalus		Opioids	Electrolyte abnormalities
Pancreatitis		Psychogenic		Anticonvulsants	(hyponatremia,
Appendicitis		Depression		Radiation therapy	hypercalcemia)
Cholecystitis		Self-induced		Ethanol	
Biliary colic		Anticipatory		Toxins	
Gastroparesis		Rumination		Operative	
Postvagotomy syndrome				procedures	
Intestinal pseudo-					
obstruction					
Functional dyspepsia					
Gastroesophageal reflux					
Peptic ulcer disease					
Hepatitis					
Peritonitis					
Gastric malignancy					
Liver failure					

Postoperative nausea and vomiting (PONV) occurs in 30% of surgical patients overall and in up to 70% of high-risk patients.^{6,7} This can be due to severing or disturbing the vagus nerve leading to gastric motility abnormalities. Additional risk factors for PONV include female gender, history of motion sickness or PONV, nonsmoking status, and use of opioids in the postoperative period.⁷⁻⁹ The choice of anesthetic agents and the duration of surgery may also contribute to PONV.^{6,7,9}

Pregnancy-associated nausea and vomiting is common, affecting 70% to 85% of pregnant women, especially early in pregnancy.¹⁰ Approximately one-half of pregnant women experience nausea and vomiting of pregnancy (NVP), one-quarter experience nausea alone, and one-quarter are not affected.¹⁰ In 0.5% to 2% of pregnancies, this can lead to **hyperemesis gravidarum**, a potentially life-threatening condition of prolonged nausea, vomiting, and consequently, malnutrition.¹⁰

PATHOPHYSIOLOGY

Nausea and vomiting consist of three stages: **nausea**, **retching**, and **vomiting**. Nausea is the subjective feeling of a need to vomit.^{1,5} It is often accompanied by autonomic symptoms such as pallor, tachycardia, diaphoresis, and salivation. Retching, which follows nausea, consists of diaphragm, abdominal wall, and chest wall contractions and spasmodic breathing against a closed glottis.¹ Retching can occur without vomiting, but this stage produces the pressure gradient needed for vomiting, although no gastric contents

are expelled. Vomiting, or **emesis**, is a reflexive, rapid, and forceful oral expulsion of upper GI contents due to powerful and sustained contractions in the abdominal and thoracic musculature.¹ Vomiting, like nausea, can be accompanied by autonomic symptoms.

Regurgitation, unlike vomiting, is a passive process without involvement of the abdominal wall and diaphragm wherein gastric or esophageal contents move into the mouth.¹ In patients with gastroesophageal reflux disease (GERD), one hallmark symptom is acid regurgitation.

Various areas in the brain and the GI tract are stimulated when the body is exposed to noxious stimuli (e.g., toxins), GI irritants (e.g., infectious agents), or chemotherapy. These areas include the **chemoreceptor trigger zone (CTZ)** in the area postrema of the fourth ventricle of the brain, the vestibular system, visceral afferents from the GI tract, and the cerebral cortex.^{2,3,5} These in turn stimulate regions of the reticular areas of the medulla within the brainstem. This area is the central vomiting center, the area of the brainstem that coordinates the impulses sent to the salivation center, respiratory center, and the pharyngeal, GI, and abdominal muscles that lead to vomiting (**Fig. 20-1**).¹¹

The CTZ, located outside the blood-brain barrier, is exposed to cerebrospinal fluid and blood.^{2,3} Therefore, it is easily stimulated by uremia, acidosis, and the circulation of toxins such as chemotherapeutic agents. The CTZ has many 5-hydroxytryptamine (serotonin) type 3 (5-HT₃), neurokinin-1 (NK₁), and dopamine (D₂) receptors.^{2,12} Visceral vagal nerve fibers are rich in 5-HT₃ receptors. They respond to GI distention, mucosal irritation, and infection.

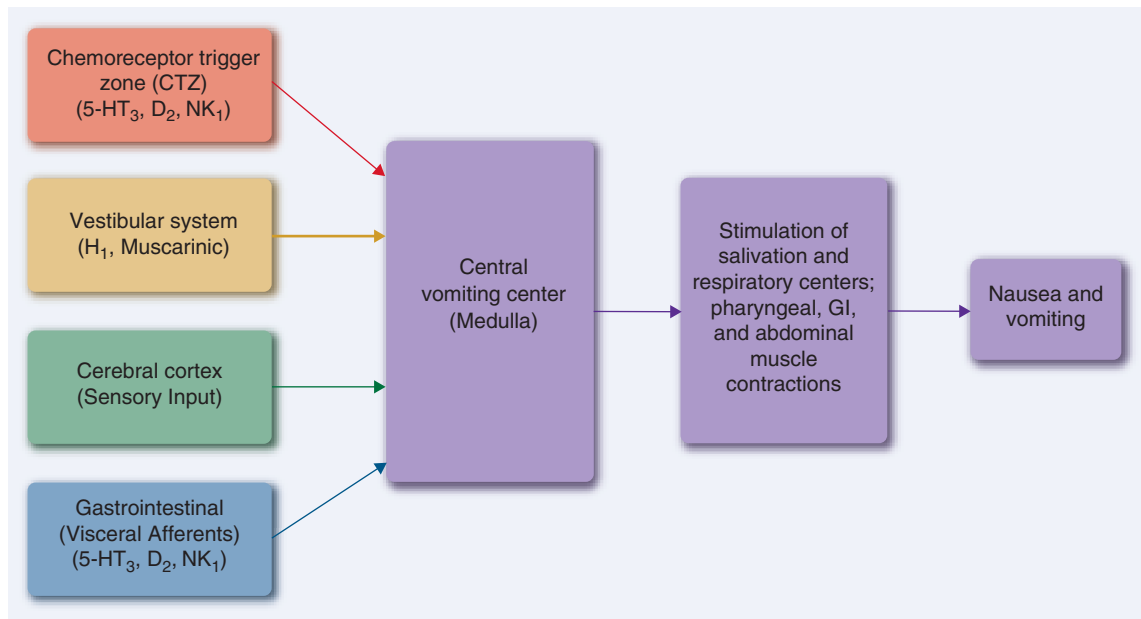

FIGURE 20-1. Physiologic pathways that result in nausea and vomiting. (5-HT₃, serotonin type 3 receptor; D₂, dopamine type 2 receptor; H₁, histamine type 1 receptor, NK₁, neurokinin-1.) (From ASHP Therapeutic Guidelines on the Pharmacologic Management of Nausea and Vomiting in Adult and Pediatric Patients Receiving Chemotherapy or Radiation Therapy or Undergoing Surgery. *Am J Health Syst Pharm* 1999;56:729–764.)

Motion sickness is caused by stimulation of the vestibular system.¹³ This area contains many histaminic (H₁) and muscarinic cholinergic receptors. The higher brain (i.e., cerebral cortex) is affected by sensory input such as sights, smells, or emotions that can lead to vomiting. This area is involved in anticipatory nausea and vomiting associated with chemotherapy.

Nausea and vomiting can be classified as either simple or complex.¹⁴ Simple nausea and vomiting occurs occasionally and is either self-limiting or relieved by minimal therapy. It does not have detrimental effects on hydration status, electrolyte balance, or weight because it is short lived.

Alternatively, complex nausea and vomiting requires more aggressive therapy because electrolyte imbalances, dehydration, and weight loss may occur. Unlike simple nausea and vomiting, complex nausea and vomiting can be caused by exposure to noxious agents.

CLINICAL PRESENTATION AND DIAGNOSIS

Refer to the box below for the clinical presentation and diagnosis of nausea and vomiting.

Clinical Presentation and Diagnosis of Nausea and Vomiting

Symptoms

- Patients with nausea often complain of autonomic symptoms such as diaphoresis, general disinterest in surroundings, pallor, faintness, and salivation.

Signs

- With complex and prolonged nausea and vomiting, patients may show signs of malnourishment, weight loss, and dehydration (dry mucous membranes, skin tenting, tachycardia, and lack of axillary moisture).

Laboratory Tests

- Dehydration, electrolyte imbalances, and acid–base disturbances may be evident in complex and prolonged nausea and vomiting.

- Dehydration is suggested by elevated blood urea nitrogen (BUN) and serum creatinine (SCr) concentrations, especially with a BUN-to-SCr ratio of 20:1 or greater (for results reported in mg/dL).
- Calculated fractional excretion of sodium (FeNa) less than 1% in patients with compromised baseline renal function and less than 0.2% in patients with normal baseline renal function indicates dehydration and reduced renal perfusion.
- Low serum chloride and elevated serum bicarbonate levels indicate metabolic alkalosis.
- Arterial blood gases with a normal or elevated pH indicates metabolic alkalosis that may or may not be compensated.
- Hypokalemia may occur from GI potassium losses and intracellular potassium shifts to compensate for alkalosis.

TREATMENT

Desired Outcomes

- The primary goal of treatment is to relieve the symptoms of nausea and vomiting, which should increase the patient's quality of life. Drug therapy for nausea and vomiting should be safe, effective, and economical.

General Approach to Treatment

2 To treat nausea and vomiting most effectively, it is important to first identify the underlying cause of the symptoms. Treating the cause (if possible) will in turn eliminate the nausea and vomiting.

Profuse or prolonged vomiting can lead to complications of dehydration and metabolic abnormalities. Patients must have adequate hydration and electrolyte replacement orally (if tolerated) or IV to prevent and correct these problems. Some pharmacologic treatments work locally in the GI tract (e.g., antacids and prokinetic agents), whereas others work in the central nervous system (CNS) (e.g., antihistamines and anticholinergics).¹

Nonpharmacologic Therapy

A variety of effective pharmacologic treatments exist for nausea and vomiting, but they all have unwanted adverse treatment effects. For this reason, nonpharmacologic treatment options may be considered in selected patients.

Nonpharmacologic options are desirable for treating NVP due to concern for teratogenic effects with drug therapies. When treating PONV, the nonpharmacologic approach is appealing to minimize additive CNS depression with antiemetics and anesthetic agents. 3 Nonpharmacologic approaches to treating nausea and vomiting include dietary, physical, and psychological changes.

Dietary approaches are the cornerstone of treatment for NVP.¹⁵ They are included in treatment guidelines even though there is little evidence to support their effectiveness.¹⁰ Recommendations include eating frequent small meals; avoiding spicy or fatty foods; eating high-protein snacks; and eating bland or dry foods the first thing in the morning.^{10,15} Women who have higher protein portions in their diet may experience less severe NVP.¹⁶ The use of ginger was effective in NVP in some studies.¹⁷ In addition to dietary changes, women taking a multivitamin at the time of conception may be less likely to seek medical attention for NVP.¹⁰

Acupressure and electro-acupoint stimulation of the P6 (Neiguan) point on the inside of the wrist seem safe and cost effective; however, efficacy data in the treatment of NVP, PONV, and motion sickness are conflicting.^{10,18,19} Hypnosis and psychotherapy are also safe during pregnancy and in situations where adverse drug effects and interactions are a concern.

Pharmacologic Therapy

Table 20–2 contains the names, usual dosages, and common adverse effects of the pharmacologic treatments for nausea and vomiting.^{1,4,7,14}

► Anticholinergics (Scopolamine)

Scopolamine blocks muscarinic receptors in the vestibular system, thereby halting signaling to the CNS. It is effective for preventing and treating motion sickness and has some efficacy in preventing PONV.^{20,21} Scopolamine is available as an adhesive transdermal patch (Transderm Scop) that is effective for up to 72 hours after application. This may be beneficial for patients unable to tolerate oral medications or those requiring continuous prevention of motion sickness (e.g., passengers on cruise ships). Scopolamine is associated with adverse anticholinergic effects such as sedation, visual disturbances, dry mouth, and dizziness.

► Antihistamines

Antihistamines are commonly used to prevent and treat nausea and vomiting due to motion sickness, vertigo, or migraine headache.^{1,13,22} Their efficacy is presumably due to the high concentration of H₁ and muscarinic cholinergic receptors within the vestibular system. Similarly to scopolamine, antihistamines such as diphenhydramine and meclizine cause undesired effects including drowsiness and blurred vision. Cetirizine and fexofenadine, two second-generation antihistamines without CNS depressant properties, were found to be ineffective for treating motion sickness, perhaps because they lack CNS effects.²²

Some antihistamines such as diphenhydramine, dimenhydrinate, and meclizine are available without a prescription, making self-treatment convenient for patients. Antihistamines are available in a variety of dosage forms, including oral capsules, tablets, and liquids. Liquid formulations are convenient for children or adults who are unable to swallow solid dosage forms.

► Dopamine Antagonists

Stimulation of D₂ receptors in the CTZ leads to nausea and vomiting (Fig. 20–1). Phenothiazine antiemetics act primarily via a central antidopaminergic mechanism in the CTZ.¹ Phenothiazines commonly used to treat nausea and vomiting include promethazine, prochlorperazine, chlorpromazine, and thiethylperazine. They are available as oral solids and liquids, rectal suppositories, and parenteral formulations. This permits effective use of phenothiazines in a variety of settings including treatment of severe motion sickness or vertigo, gastritis or gastroenteritis, NVP, PONV, or chemotherapy-induced nausea and vomiting (CINV).^{4,6,7,10,23–25}

Phenothiazines may cause sedation, orthostatic hypotension, and **extrapyramidal symptoms (EPS)** such as dystonia (involuntary muscle contractions), tardive dyskinesia (irreversible and permanent involuntary movements), and akathisia (motor restlessness or anxiety).^{1,26} Chronic phenothiazine use has been associated with EPS, but single doses have also caused these effects.²⁷

Droperidol, a butyrophenone, is another centrally acting antidopaminergic agent effective for preventing PONV and treating opioid-induced nausea and vomiting.^{1,6} It may also be used for treating CINV for patients who are intolerant

Table 20-2

Antiemetic Agents: Doses for Adults and Children and Adverse Effects

Drug	Adult Dosing	Pediatric Dosing	Adverse Effects ^a
Anticholinergics			
Scopolamine (Transderm Scop)	TD: 1.5-mg patch applied every 72 hours as needed	N/A	Most common: Dry mouth, drowsiness, impaired eye accommodation Rare: Disorientation, memory disturbances, dizziness, hallucinations
Antihistamines			
Cyclizine (Marezine)	Orally: 50 mg every 4–6 hours as needed	Orally, 6–11 years: 25 mg every 6–8 hours as needed (maximum: 3 tablets/day)	Most common: Sedation, dry mouth, constipation
Dimenhydrinate (Dramamine)	Orally: 50–100 mg every 4–6 hours as needed	Orally, 2–6 years: 12.5–25 mg every 6–8 hours Orally, 6–12 years: 25–50 mg every 6–8 hours	Less common: Confusion, blurred vision, urinary retention
Diphenhydramine (Benadryl)	Orally: 25–50 mg every 4–6 hours IV/IM: 10–50 mg every 2–4 hours as needed	Orally/IV/IM: 2–6 years: 6.25 mg every 4–6 hours, max 37.5 mg/day; 6–12 years: 12.5–25 mg every 4–6 hours, max 150 mg/day	
Hydroxyzine (Atarax, Vistaril)	Orally/IV/IM: 25–100 mg every 4–6 hours as needed	Orally: 0.6 mg/kg IM: 0.5–1 mg/kg	
Meclizine (Bonine, Antivert)	Orally: 12.5–25 mg every 12–24 hours as needed	Orally: 12 years or older: Use adult dose	
Phenothiazines			
Chlorpromazine (Thorazine)	Orally: 10–25 mg every 4–6 hours as needed IV/IM: 25–50 mg every 4–6 hours as needed	Orally, 6 months and older: 0.5 mg/kg every 4–6 hours as needed IV/IM: 6 months and older: 0.5–1 mg/kg every 6–8 hours; max dose less than 5 years: 40 mg/day; max for 5–12 years: 75 mg/day	Most common: Sedation, lethargy, skin sensitization Less common: Cardiovascular effects, extrapyramidal effects, cholestatic jaundice, hyperprolactinemia
Prochlorperazine (Compazine)	Orally: 5–10 mg 3–4 times a day as needed Supp: 25 mg twice daily as needed IV/IM 2.5–10 mg every 3–4 hours as needed	Orally: over 2 years and more than 9 kg: 0.4 mg/kg/day or 10 mg/m ² daily in 2–3 divided doses; Max daily dose: 9–13 kg, 7.5 mg; 13.1–17 kg, 10 mg; 17.1–37 kg, 15 mg Supp: See PO dosing IM: over 2 years and more than 9 kg: 0.13 mg/kg	
Promethazine (Phenergan)	Orally/IM/IV/Supp: 12.5–25 mg every 4–6 hours as needed	Orally/IM/IV/Supp: 2 years and older: 0.25–0.5 mg/kg or 7.5–15 mg/m ² 4–6 times daily; maximum 25 mg/dose	
Butyrophenones			
Droperidol (Inapsine) ^b	IM/IV: 0.625–2.5 mg every 4–6 hours as needed	IM/IV: 2–12 years: 0.05–0.1 mg/kg (max 2.5 mg) every 4–6 hours as needed	Most common: Sedation, hypotension, tachycardia Less common: Extrapyramidal effects, dizziness, increase in blood pressure, chills, hallucinations
Haloperidol (Haldol)	Orally, IM/IV: 0.5–5 mg every 12 hours as needed	N/A	
Benzamides			
Domperidone (Motilium) ^c	Orally: 10–20 mg every 4–8 hours as needed Supp: 30–60 mg every 4–8 hours as needed	Orally: 0.2–0.4 mg/kg every 4–8 hours as needed for CINV prophylaxis Supp: Max daily dose based on weight: 10–15 kg, 30 mg; 15.5–25 kg, 60 mg; 25.5–35 kg, 90 mg; 35.5–45 kg, 120 mg	Most common: Sedation, restlessness, diarrhea (metoclopramide), agitation, CNS depression
Metoclopramide (Reglan) ^d	PONV: 10–20 mg PO/IV/IM 10 minutes prior to anesthesia CINV Prophylaxis: 1–2 mg/kg PO/IV every 2–4 hours	N/A	Less common: Extrapyramidal effects (more frequent with higher doses), hypotension, neuroleptic syndrome, supraventricular tachycardia (with IV administration)

(Continued)

Table 20-2

Antiemetic Agents: Doses for Adults and Children and Adverse Effects (Continued)

Drug	Adult Dosing	Pediatric Dosing	Adverse Effects ^a
Trimethobenzamide (Tigan)	Orally: 300 mg 3–4 times a day as needed IM: 200 mg 2–4 times a day as needed	Orally: 15–20 mg/kg/day divided into 3–4 doses Not recommended	
Corticosteroids			
Dexamethasone (Decadron)	C/IV: 12–20 mg orally/IV day 1, then 8–12 mg PO/IV daily PONV: 4–5 mg orally/IV at induction of anesthesia	C/IV: 10 mg/m ² prior to chemotherapy then 5 mg/m ²	Most common: GI upset, anxiety, insomnia
Methylprednisolone (Solu-Medrol)	125–500 mg orally/IV every 6 hours for total of 4 doses	N/A	Less common: Hyperglycemia, facial flushing, euphoria, perineal itching or burning (with dexamethasone, probably secondary to vehicle and rate of injection)
Cannabinoids			
Dronabinol (Marinol)	Orally: 5–15 mg/m ² every 2–4 hours as needed	Use adult dose, use with caution and adjust dose based on response	Most common: Drowsiness, euphoria, somnolence, vasodilation, vision difficulties, abnormal thinking, dysphoria
Nabilone (Cesamet)	Orally: 1–2 mg 2–3 times a day as needed	N/A	Less common: Diarrhea, flushing, tremor, myalgia
Benzodiazepines			
Lorazepam (Ativan)	Orally/IV: 0.5–2 mg prior to chemotherapy	Orally/IV: 2–15 years old: 0.05 mg/kg (up to 2 mg) prior to chemotherapy	Most common: Sedation, amnesia
Alprazolam (Xanax)	Orally: 0.5–2 mg 3 times a day prior to chemotherapy	N/A	Rare: Respiratory depression, ataxia, blurred vision, hallucinations, paradoxical reactions (weeping, emotional reactions)
Serotonin Antagonists			
Dolasetron (Anzemet)	C/IV: 1.8 mg/kg or 100 mg IV/po before chemotherapy; PONV: 12.5 mg IV 15 minutes before end of anesthesia or at onset of N/V or 100 mg PO within 2 hours before surgery	C/IV, 2–16 years: 1.8 mg/kg IV/po (maximum 100 mg) PONV: 0.35 mg/kg IV (maximum 12.5 mg) OR 1.2 mg/kg PO (maximum 100 mg) within 2 hours before surgery	Most common: Headache, asymptomatic prolongation of electrocardiographic interval
Granisetron (Kytril)	C/IV: 10 mcg/kg IV prior to chemotherapy; or 1 mg orally 1 hour before chemotherapy and 1 mg 12 hours after the first dose, or 2 mg 1 hour before chemotherapy PONV: 1 mg IV before induction of anesthesia OR immediately before reversal of anesthesia, OR at onset of N/V	C/IV: 2–16 years: Use adult dosing IV or PO regimen PONV: Not recommended for pediatric patients	Less common: Constipation, asthenia, somnolence, diarrhea, fever, tremor or twitching, ataxia, lightheadedness, dizziness, nervousness, thirst, muscle pain, warm or flushing sensation on IV administration
Granisetron (Sancuso)	C/IV: 1 patch 24–48 hours before chemotherapy; may be worn for up to 7 days (delivers 3.1 mg granisetron per 24 hours)	N/A	Rare: Transient elevations in hepatic transaminases
Ondansetron (Zofran) ^e	C/IV: orally: 24 mg prior to chemotherapy as a single dose, or 8 mg prior to chemotherapy; repeat every 12 hours.	C/IV: orally: 4–11 years: 4 mg 30 minutes prior to chemotherapy, repeat at 4 and 8 hours and every 8 hours for 1–2 days after chemotherapy completion	Granisetron may be degraded by direct sunlight or exposure to sunlamps. Patients should be advised to cover the patch application site (e.g., with clothing) if there is a risk of exposure to sunlight or sunlamps during use and for 10 days after removal

(Continued)

Table 20-2

Antiemetic Agents: Doses for Adults and Children and Adverse Effects (Continued)

Drug	Adult Dosing	Pediatric Dosing	Adverse Effects ^a
Palonosetron (Aloxi)	IV: 8–12 mg IV 30 minutes prior to chemotherapy, or 0.15 mg/kg 3 times a day beginning prior to chemotherapy	IV: over 6 months: 0.15 mg/kg 3 times a day beginning prior to chemotherapy	
	PONV: 4 mg IV/IM before anesthesia induction or at onset of N/V; 16 mg orally once given 1 hour before anesthesia induction CINV: 0.25 mg IV 30 minutes before chemotherapy; 0.5 mg orally 1 hour before chemotherapy PONV: 0.075 mg IV before anesthesia induction	PONV: 1 month–12 years: 4 mg IV/IM before anesthesia induction for over 40 kg and 0.1 mg/kg IV for under 40 kg Oral recommendations not available N/A	
Neurokinin-1 Antagonist Aprepitant (Emend)	CINV: 150 mg IV (fosaprepitant) 30 minutes before chemotherapy on first day of chemotherapy only; or 125 mg orally on day 1, 1 hour prior to chemotherapy followed by 80 mg on days 2 and 3 PONV: 40 mg orally 3 hours prior to anesthesia induction	N/A	Most common: Fatigue, hiccups Less common: Dizziness, headache, insomnia Rare: Transient elevations in hepatic transaminases

CINV, chemotherapy-induced nausea and vomiting; IM, intramuscularly; Inj, injectable dosage form for IV or IM use; N/A, not available; PONV, postoperative nausea and vomiting; TD, transdermal; Supp, rectal suppository.

^aMost common, greater than 10%; less common, 1% to 10%; rare, less than 1%. On the basis of U.S. FDA-approved labeling and generalized to drug class.

^bSee text for warnings.

^cNot available in the United States.

^dReduce dose by half if creatinine clearance is less than 40 mL/min (0.67 mL/s).

^eDaily dose not to exceed 8 mg in severe hepatic impairment (Child-Pugh score 10 or more).

to serotonin receptor antagonists and corticosteroids.⁴ Its adverse effects include sedation, agitation, and restlessness. In addition, droperidol carries a U.S. FDA black box warning regarding the potential for QT interval prolongation and cardiac arrhythmias that may result in torsades de pointes and sudden cardiac death.²⁸ Droperidol should not be used in patients with a prolonged QT interval or in those who are at risk for developing a prolonged QT interval (e.g., heart failure, electrolyte abnormalities, or concurrently taking other medications that may prolong the QT interval).²⁸ A 12-lead ECG is recommended prior to treatment with droperidol.

Haloperidol is another butyrophenone with some antiemetic effects at low doses (0.5 to 2 mg).⁷ It has been explored as an alternative to droperidol.²⁹

Both metoclopramide and domperidone (not available in the United States) act as D₂ receptor antagonists centrally in the CTZ and peripherally in the GI tract.^{1,30} They also

display cholinergic activity, which increases lower esophageal sphincter tone and promotes gastric motility. Because metoclopramide and domperidone have both antiemetic and prokinetic effects, both are used for a variety of disorders including PONV, CINV, NVP, gastroparesis, GERD, and migraine headaches.^{1,4,6,10,31,32} Metoclopramide is available in injectable, oral solid, and oral liquid dosage forms, allowing for its use in both hospitalized and ambulatory patients. Other substituted benzamides include trimethobenzamide and benzquinamide.

Metoclopramide crosses the blood–brain barrier and has centrally mediated adverse effects. Young children and the elderly are especially susceptible to these effects, which include somnolence, reduced mental acuity, anxiety, depression, and EPS (akathisia, dystonia, and tardive dyskinesia).³³ The overall incidence of adverse effects is estimated to be 10% to 20%.¹

Domperidone minimally crosses the blood–brain barrier and is less likely to cause the centrally mediated adverse

effects seen with metoclopramide.^{1,33} It should not be used for patients with underlying long QT interval or for those on other medications that prolong the QT interval. Both metoclopramide and domperidone can cause hyperprolactinemia, galactorrhea, and gynecomastia.

► Corticosteroids

Corticosteroids, especially dexamethasone and methylprednisolone, are used alone or in combination with other antiemetics for preventing and treating PONV, CINV, or radiation-induced nausea and vomiting.^{4,7,12,34} They are administered either orally or IV. Their efficacy is thought to be due to the release of 5-HT, reduction in the permeability of the blood–brain barrier, and reduction of inflammation.³⁵ Common adverse effects with short-term use include GI upset, anxiety, insomnia, and hyperglycemia.⁴ Because their use is generally of short duration, long-term adverse effects (e.g., reduction in bone mineral density, corticosteroid-related diabetes, and cataracts) are not usually seen.

► Cannabinoids

Cannabinoids have antiemetic activity when used alone or in combination with other antiemetics.³⁶ Dronabinol and nabilone are commercially available oral formulations used for preventing and treating refractory CINV.^{4,36} Cannabinoids are thought to exert their antiemetic effect centrally, although the exact mechanism of action is unknown.³⁶ Sedation, euphoria, hypotension, ataxia, dizziness, and vision difficulties can occur with cannabinoids.

► Benzodiazepines

Benzodiazepines, especially lorazepam, are used to prevent and treat CINV.^{4,12,34} Lorazepam is thought to prevent input from the cerebral cortex and limbic system from reaching the central vomiting center in the brainstem.¹¹ Sedation and amnesia are common side effects. Respiratory depression can occur with high doses or when other central depressants such as alcohol are combined with benzodiazepines.

► Serotonin Antagonists

Serotonin is a monoamine neurotransmitter synthesized in neurons in the CNS and in enterochromaffin cells of the GI tract. Chemotherapeutic agents release 5-HT, which is a predominant mediator in nausea and vomiting.³⁷ This increase in 5-HT concentrations stimulates the visceral vagal nerve fibers and CTZ, thereby triggering nausea and vomiting.² Selective 5-HT₃ receptor antagonists (ondansetron, granisetron, dolasetron, and palonosetron) are available to prevent and treat nausea and vomiting due to stimulation of these receptors, especially for prevention and treatment of CINV and PONV.^{4,6,7,9,12,34,37} These agents are well tolerated; the most common adverse effects are headache, somnolence, diarrhea, and constipation.⁴

Palonosetron is the first 5-HT₃ antagonist to be approved for prevention of both acute and delayed CINV.⁴ Compared with

the other 5-HT₃ antagonists, palonosetron has a longer serum half-life (40 hours compared with 4 to 9 hours) and a higher receptor-binding affinity, which may contribute to its efficacy in preventing delayed CINV.³⁸ Palonosetron combined with dexamethasone is the 5-HT₃ antagonist of choice for prevention of CINV due to moderately emetogenic chemotherapy.⁴

► Neurokinin-1 Receptor Antagonists

Neurokinin-1 (NK-1) receptors are found on vagal afferents in the GI tract, as well as in the brain.³⁹ Substance P is a neurokinin neurotransmitter that binds to NK-1 receptors and is believed to mediate both acute and delayed nausea and vomiting. Aprepitant is the first NK-1 receptor antagonist antiemetic drug.⁴⁰ Aprepitant is effective for preventing acute and delayed CINV when used with a 5-HT₃ antagonist and a corticosteroid.^{4,40,41} It is also effective for the prevention of PONV.^{7,42} Aprepitant has numerous drug interactions because it is an inhibitor and substrate of the CYP 3A4 metabolic pathway, which is involved in the metabolism of many drugs.⁴³

Chemotherapy-Induced Nausea and Vomiting

CINV is classified as: (a) acute (occurring within 24 hours after receiving chemotherapy), (b) delayed (occurring more than 24 hours after receiving chemotherapy), or (c) anticipatory (occurring prior to chemotherapy in patients who experienced acute or delayed nausea and vomiting with previous courses).^{4,34} Risk factors for CINV include poor emetic control with prior chemotherapy, female gender, low chronic alcohol intake, and younger age.³⁴ Chemotherapeutic agents are classified according to their emetogenic potential (Table 20–3), which aids in predicting CINV.^{4,12,44} Risk factors that are useful in predicting anticipatory nausea and vomiting include poor prior control of CINV and a history of motion sickness or NVP.⁴

4 For prevention of acute CINV for patients receiving moderately or highly emetogenic chemotherapy, a combination of antiemetics with different mechanisms of action is recommended (Table 20–4).^{4,12,34} Patients receiving chemotherapeutic agents with low emetogenic potential should receive a corticosteroid as CINV prophylaxis, and those receiving chemotherapy with minimal emetogenic risk do not require prophylaxis.

Delayed nausea and vomiting is more difficult to prevent and treat. It occurs most often with cisplatin- and cyclophosphamide-based regimens, especially if delayed nausea and vomiting occurred with previous courses of chemotherapy.^{4,34} Patients at greatest risk are those who previously had poorly controlled acute CINV.⁴

Antiemetics can be administered either IV or orally for CINV, depending on patient characteristics such as ability to take oral medications, dosage form availability, and cost.⁴ The IV and oral routes are equally effective.

Patients undergoing chemotherapy should have antiemetics available to treat breakthrough nausea and vomiting even if prophylactic antiemetics were given.^{4,34} A variety of antiemetics may be used, including lorazepam, dexamethasone, methylprednisolone, prochlorperazine,

Table 20-3

Emetogenicity of Chemotherapeutic Agents

Minimal Emetogenic Potential (Less Than 10% Risk) ^a	Moderate Emetogenic Potential (30%–90% Risk)
Bevacizumab	Azacitidine
Bleomycin	Alemtuzumab
Busulfan	Bendamustine
Cetuximab	Carboplatin
Chlorambucil	Clofarabine
2-Chlorodeoxyadenosine	Cyclophosphamide
Erlotinib	less than 1,500 mg/m ²
Fludarabine	Cytarabine greater than
Hydroxyurea	1,000 mg/m ²
Pralatrexate	Daunorubicin ^b
Rituximab	Doxorubicin ^b
Vinblastine	Epirubicin ^b
Vincristine	Idarubicin ^b
Vinorelbine	Ifosfamide
	Irinotecan
	Oxaliplatin
Low Emetogenic Potential (10%–30% Risk)	High Emetogenic Potential (Greater Than 90% Risk)
Bortezomib	Carmustine
Cabazitaxel	Cisplatin
Catumaxomab	Cyclophosphamide
Cytarabine 1 g/m ² or less	1,500 mg/m ² or more
Docetaxel	Dactinomycin
Doxorubicin liposome injection	Dacarbazine
Etoposide	Lomustine
Fluorouracil	Mechlorethamine
Gemcitabine	Pentostatin
Methotrexate	Streptozotocin
Mitomycin	
Mitoxantrone	
Paclitaxel	
Panitumumab	
Pemetrexed	
Temsirolimus	
Topotecan	
Trastuzumab	

^a% risk^a is the incidence of emesis without the administration of antiemetics.

^bAnthracyclines when combined with cyclophosphamide are considered high emetic risk.

From Refs. 4, 12, 34.

promethazine, metoclopramide, 5-HT₃ antagonists, and dronabinol. If breakthrough CINV occurs, it may be best treated with an antiemetic with a mechanism of action that differs from the medications already administered.

The best strategy for preventing anticipatory nausea and vomiting is to prevent acute and delayed CINV by using the most effective antiemetic regimens recommended based on the emetogenic potential of the chemotherapy and patient factors. CINV should be aggressively prevented with the first cycle of therapy rather than waiting to assess patient response to less effective regimens. If anticipatory nausea and vomiting occurs, benzodiazepines and behavioral therapy such as relaxation techniques are the recommended approaches.^{4,12}

Patient Encounter 1

A 45-year-old woman with a diagnosis of refractory non-Hodgkin's lymphoma has received chemotherapy in the past and is about to undergo her first round of chemotherapy with cytarabine 1 g/m². She is concerned about experiencing nausea and vomiting after treatment because this has been an issue with previous treatments. She often experienced nausea and vomiting both before receiving chemotherapeutic agents and afterward on the day of therapy.

Past medical history: Hypertension, dyslipidemia × 2 years

Social history: Does not smoke; occasional alcohol use

Family history: Hypertension, diabetes mellitus type 2

Current medications: Lisinopril 20 mg daily, simvastatin 20 mg daily

Vital signs: Blood pressure 132/82, Heart rate 80 bpm, Temperature 98.6°F (37.0°C)

Labs: Serum creatinine 0.9 mg/dL (80 μmol/L), total cholesterol 161 mg/dL (4.16 mmol/L), LDL 96 mg/dL (2.48 mmol/L), HDL 47 mg/dL (1.22 mmol/L), triglycerides 89 mg/dL (1.01 mmol/L)

What types of CINV does this patient experience?

What is the emetogenic potential of this patient's new chemotherapy regimen?

What nonpharmacologic and pharmacologic options are available for this woman?

Postoperative Nausea and Vomiting

PONV is a common complication of surgery and can lead to delayed discharge and unanticipated hospitalization.⁶ The overall incidence of PONV for all surgeries and patient populations is 25% to 30%, but PONV can occur in 70% to 80% of high-risk patients.^{6,7,9} Risk factors for PONV include patient factors (female sex, nonsmoking status, and history of PONV or motion sickness), anesthetic factors (use of volatile anesthetics, nitrous oxide, or intraoperative or postoperative opioids), and surgical factors (duration and type of surgery).⁶⁻⁹

The first step in preventing PONV is reducing baseline risk factors when appropriate.^{6,7} For example, the incidence of PONV may be less with regional anesthesia than general anesthesia, and nonsteroidal anti-inflammatory drugs may cause less PONV than opioid analgesics.

5 Droperidol or a 5-HT₃ receptor antagonist should be administered at the end of surgery to patients at high risk for developing PONV.^{1,6,9} Dexamethasone is also effective when given as a single dose prior to induction of anesthesia.⁶ Anticholinergics and antihistamines are also effective for preventing PONV.⁶

Aprepitant, an NK-1 receptor antagonist, prevents PONV; however, it does not appear to be more effective than other

Table 20–4

Recommended Drug Regimens for Prevention of CINV Based on Emetogenic Risk

Emetogenic Risk	Acute CINV (Day 1)	Delayed CINV (Days 2–4)
Minimal	None	None
Low	Dexamethasone	None
Moderate	Palonosetron ^a + dexamethasone Alternative regimen: Any 5-HT ₃ antagonist + aprepitant ^b + dexamethasone	Dexamethasone (days 2 and 3) Aprepitant (days 2 and 3)
High (includes AC regimens)	Any 5-HT ₃ antagonist + dexamethasone + aprepitant ^b	Aprepitant (days 2 and 3) + dexamethasone (days 2–3 or days 2–4)

AC, anthracycline (daunorubicin, doxorubicin, epirubicin, or idarubicin) plus cyclophosphamide; CINV, chemotherapy-induced nausea and vomiting.

^aIf palonosetron is not available, may substitute a first generation 5-HT₃ antagonist, preferably granisetron or ondansetron.

^bIf fosaprepitant 150 mg IV is substituted for oral aprepitant on day 1, subsequent aprepitant doses on days 2 and 3 are not required.

From Refs. 4, 12, 34.

agents and is costly.⁷ Conversely, metoclopramide, ginger, and cannabinoids have been shown to be of limited utility for PONV and are not recommended.⁷

Combinations of antiemetics are recommended to prevent PONV for high-risk patients.⁷ Droperidol plus a 5-HT₃ antagonist or dexamethasone plus a 5-HT₃ antagonist are effective combinations.⁷

If PONV occurs despite appropriate prophylaxis, it should be treated with an antiemetic from a pharmacologic class not already administered.^{7,9} If no prophylaxis was used, a low-dose 5-HT₃ antagonist should be used.^{7,9}

Nausea and Vomiting of Pregnancy

6 Nausea and vomiting affects most pregnant women; the **teratogenic potential** of the therapy is the primary consideration in drug selection.¹⁰ Risks and benefits of any therapy must be weighed by the healthcare professional and the patient.

Nonpharmacologic therapy such as dietary, physical, and behavioral approaches should be considered first.^{10,15} Pyridoxine (vitamin B₆) 10 to 25 mg three to four times daily alone or in combination with an antihistamine such as doxylamine is often used for NVP.^{10,15–17} This combination was previously marketed as Bendectin or Debendox but was withdrawn due to concerns over possible teratogenic effects, although the literature did not support this claim.⁴⁵ Pyridoxine is well tolerated, but doxylamine and other antihistamines commonly cause drowsiness.

For more severe NVP, promethazine, metoclopramide, and trimethobenzamide may be effective and have not been associated with teratogenic effects.^{10,15} Ondansetron, which is pregnancy category B, has been used to treat severe NVP. Animal data do not indicate a safety concern in pregnancy, but safety and efficacy data in humans for NVP are sparse.

In rare instances (0.5–2% of pregnancies), NVP progresses to hyperemesis gravidarum.¹⁰ Treatment may require the use of enteral or parenteral nutrition if weight loss is

present. A corticosteroid such as methylprednisolone may be considered. Methylprednisolone is associated with oral clefts in the fetus when used during the first trimester. Therefore, corticosteroids should be reserved as a last resort and should be avoided during the first 10 weeks of gestation.^{10,15,45}

Motion Sickness and Vestibular Disturbances

Nausea and vomiting can be caused by disturbances of the vestibular system in the inner ear.^{13,46} Vestibular disturbances can result from infection, traumatic injury, neoplasm, and motion. Patients may experience dizziness and vertigo in addition to nausea and vomiting. If a patient is susceptible to motion sickness, some general preventive measures include minimizing exposure to movement, restricting visual activity, ensuring adequate ventilation, reducing the magnitude of movement, and taking part in distracting activities.¹³

7 Because the vestibular system is replete with muscarinic-type cholinergic and histaminic (H₁) receptors, anticholinergics

Patient Encounter 2

A 27-year-old healthy woman seeks your advice. She is 10 weeks pregnant and complains of constant nausea, frequent vomiting, and weight loss. She does not smoke or drink alcohol. She was not taking prenatal vitamins prior to her pregnancy.

What type of nausea and vomiting is this patient experiencing?

What are some nonpharmacologic and pharmacologic treatment options that may help prevent and treat this patient's nausea and vomiting?

Should this patient seek additional medical attention for her current symptoms?

Patient Encounter 3

A 54-year-old man who presents to your practice is planning a road trip for a family vacation. His past medical history includes benign prostatic hypertrophy and hypertension treated with dutasteride and lisinopril, respectively. He has experienced nausea and vomiting during long car rides in the past and is seeking your advice.

What recommendations for nonpharmacologic interventions would you give this patient to help prevent motion sickness?

What are the pharmacologic options for this patient to prevent or treat nausea and vomiting?

What potential adverse effects would you counsel this patient about?

and antihistamines are the most commonly used pharmacologic agents to prevent and treat motion sickness. Oral medications should be taken prior to motion exposure to allow time for adequate absorption. Once nausea and vomiting due to motion sickness occur, oral medication absorption may be unreliable, making the therapies ineffective. Scopolamine, the anticholinergic medication used for motion sickness, is available as a transdermal patch, which may be helpful for patients who cannot tolerate oral medications or who require treatment for a prolonged period.²⁰ Drowsiness and reduced mental acuity are the most bothersome side effects of antihistamines and anticholinergics. Visual disturbances, dry mouth, and urinary retention can also occur.

OUTCOME EVALUATION

- The symptoms of simple nausea and vomiting are self-limited or can be relieved with minimal treatment. Monitor patients for adequate oral intake and alleviation of nausea and vomiting.
- Patients with complex nausea and vomiting may have malnourishment, dehydration, and electrolyte abnormalities.
- Monitor patients for adequate oral intake. If the patient has weight loss, assess whether enteral or parenteral nutrition is needed.
- Assess for dry mucous membranes, skin tenting, tachycardia, and lack of axillary moisture to determine if dehydration is present.
- Obtain blood urea nitrogen (BUN), serum creatinine (SCr), calculated fractional excretion of sodium (FeNa), serum electrolytes, and arterial blood gases.
- Ask patients to rate the severity of nausea.
- Monitor the number and volume of vomiting episodes.
- Ask patients about adverse effects to the antiemetics used. Use this information to assess efficacy and tailor the patient's antiemetic regimen.

Patient Care and Monitoring

1. Identify the underlying cause of the nausea and vomiting and eliminate it if possible. Counsel the patient to avoid known triggers.
2. Assess the patient to determine whether the nausea and vomiting is simple or complex and whether patient-directed therapy is appropriate.
3. Obtain a thorough patient history including the prescription, nonprescription, and herbal medications being used. Identify any substances that may be causing or worsening nausea and vomiting. Determine which treatments for nausea and vomiting have been used in the past and their degree of efficacy.
4. Develop a treatment plan with the patient and other healthcare professionals if appropriate. Choose therapeutic options based on the underlying cause of nausea and vomiting, duration and severity of symptoms, comorbid conditions, medication allergies, presence of contraindications, risk of drug–drug interactions, and treatment adverse-effect profiles.
5. Use the oral route of administration if the patient has mild nausea with minimal or no vomiting. Seek an alternative route (e.g., transdermal, rectal suppository, or parenteral) if the patient is unable to retain oral medications due to vomiting.
6. Educate the patient about nonpharmacologic measures such as stimulus avoidance, dietary changes, acupressure or acupuncture, and psychotherapy.
7. To assess efficacy, ask the patient whether he or she is still experiencing nausea or vomiting while using the therapy. Assess whether treatment failure is due to inappropriate medication use or the need for additional or different treatments and proceed accordingly.
8. Assess adverse effects by asking the patient what he or she has experienced. Patient observation or examination is also useful for diagnosing adverse effects such as EPS.
9. Provide patient education regarding causes of nausea and vomiting, avoidance of triggers, potential complications, therapeutic options, medication adverse effects, and when to seek medical attention.

Abbreviations Introduced in This Chapter

ASCO	American Society of Clinical Oncology
BUN	Blood urea nitrogen
CINV	Chemotherapy-induced nausea and vomiting
CNS	Central nervous system
CTZ	Chemoreceptor trigger zone
D ₂	Dopamine type 2 receptor
EPS	Extrapyramidal symptoms

FeNa	Fractional excretion of sodium
GERD	Gastroesophageal reflux disease
GI	Gastrointestinal
H ₁	Histamine type 1 receptor
5-HT ₃	5-Hydroxytryptamine (serotonin) type 3 receptors
NK ₁	Neurokinin type 1 receptors
NVP	Nausea and vomiting of pregnancy
PONV	Postoperative nausea and vomiting
SCr	Serum creatinine

Self-assessment questions and answers are available at <http://www.mhpharmacotherapy.com/pp.html>.

Constipation, Diarrhea, and Irritable Bowel Syndrome

Beverly C. Mims and Clarence E. Curry Jr.

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Identify the causes of constipation.
2. Compare the features of functional constipation with those of irritable bowel syndrome (IBS) with constipation (IBS-C).
3. Recommend general and dietary modifications and therapeutic interventions for the treatment of functional constipation.
4. Distinguish between acute and chronic diarrhea.
5. Compare and contrast diarrhea caused by different infectious agents.
6. Explain how medication use can lead to diarrhea.
7. Discuss nonpharmacologic strategies for treating diarrhea.
8. Identify the signs and symptoms of IBS.
9. Contrast IBS with diarrhea (IBS-D) and IBS with constipation (IBS-C).
10. Discuss the goals of IBS treatment.
11. Evaluate the effectiveness of principal pharmaceutical therapies for IBS.

KEY CONCEPTS

- 1 Constipation is defined in many ways, and it is important to know what is meant when the term is used.
- 2 Functional constipation exists when criteria are fulfilled for at least 3 months with symptom onset at least 6 months before diagnosis.
- 3 General and dietary modifications should be employed prior to the use of laxatives in most instances of constipation.
- 4 Oral laxatives comprise the primary pharmacologic intervention for relief of constipation.
- 5 When diarrhea is severe and oral intake is limited, dehydration can occur, particularly in the elderly and infants.
- 6 The primary treatment of acute diarrhea includes fluid and electrolyte replacement, dietary modifications, and drug therapy.
- 7 Irritable bowel syndrome (IBS) is generally described as a functional disorder rather than a distinct disease entity.
- 8 IBS symptoms typically cluster around two main types: IBS with diarrhea and IBS with constipation.

- 9 Diagnosis of IBS is made by symptom-based criteria and the exclusion of organic disease.
- 10 The principal goal of IBS treatment is to reduce or control symptoms.

CONSTIPATION

1 *Constipation is defined in many ways, and it is important to know what is meant when the term is used.* Constipation, when not associated with symptoms of irritable bowel syndrome (IBS), can be defined as a heterogeneous disorder characterized by disorganized passage of feces resulting in infrequent stools, difficult passage of stools, or both.¹ It may be described as difficulty in passing stool with too much effort, unproductive urges, too small amount of stool, too hard consistency of stool, painful elimination of stool, or a feeling of incomplete evacuation. The existence of some or all of these symptoms suggests the presence of constipation when the frequency of elimination of feces is limited to less than two times weekly or when more than 3 days have passed without elimination of stool.¹ 2 *Functional constipation exists when symptoms last for at least 3 months with onset at least 6 months prior to diagnosis.*²

EPIDEMIOLOGY AND ETIOLOGY

Constipation is a common complaint of patients seeking medical attention, and about one-third of patients with constipation seek medical treatment. Constipation occurs in approximately 20% of the population.³ Approximately 2.5 million physician visits and 90,000 hospitalizations per year in the United States are due to constipation.^{4,5} Many medications and some disease states are associated with constipation. Constipation is associated with high socioeconomic costs and has considerable quality-of-life ramifications.⁶

Elderly patients, nonwhites, women, and those of lower educational and socioeconomic levels are more likely to report being constipated. Constipation in children can occur because of a change in the usual diet or fluid intake, a deviation from usual toileting routines such as during vacations, avoidance of bowel movements because of pain associated with having a stool, or due to the use of medications. Children who are diagnosed with severe constipation at a young age are likely to continue to suffer through puberty.

PATHOPHYSIOLOGY

Constipation can be due to primary and secondary causes (Table 21-1). Primary or idiopathic constipation is categorized as normal-transit constipation, slow-transit constipation, and **dyssynergic defecation**. In the normal-transit type, colonic motility is unchanged and patients tend to experience hard stools despite normal movements. In the slow-transit type, motility is decreased leading to infrequent, harder, drier stools. In dyssynergic defecation (also known as pelvic floor dysfunction), patients have lost the ability to relax the anal sphincter while coordinating muscle contractions of the pelvic floor. Some causes of secondary constipation are listed in Table 21-1.

Table 21-1

Causes of Constipation

Primary Causes

Normal-transit constipation (includes idiopathic or functional disorders)
 Slow-transit constipation (includes motility disorders)
 Defecatory or rectal evacuation disorders (e.g., Hirschsprung's disease, pelvic floor dyssynergia)

Secondary Causes (Selected)

Endocrine/metabolic conditions (diabetes mellitus, hypothyroidism, hypercalcemia)
 GI conditions (IBS, diverticulitis, hemorrhoids)
 Neurogenic conditions (brain trauma, spinal cord injury, cerebrovascular accident, Parkinson's disease)
 Psychogenic (postponing the urge to defecate, psychiatric conditions)
 Medications (analgesics, anticholinergics, calcium channel blockers, clonidine, diuretics, phenothiazines, tricyclic antidepressants, iron supplements, calcium- and aluminum-containing antacids)
 Miscellaneous (immobility, poor diet, laxative abuse, hormonal disturbances)

Constipation affects about 50% of pregnant women. Progesterone levels may be responsible in part for slowing digestion. Reabsorption mechanisms may affect colon water during pregnancy leading to harder stools and more difficult bowel movements. Intake of iron supplements may also contribute to constipation during pregnancy.

CLINICAL PRESENTATION AND DIAGNOSIS

Refer to the box below for the clinical presentation of constipation.

Diagnosis

- A complete history should be obtained so that the patient's symptoms can be evaluated and the diagnosis of functional constipation confirmed. The diagnosis of **functional**

Clinical Presentation of Constipation

Symptoms

- Functional constipation (constipation occurring in the absence of a demonstrated pathologic condition) involves the presence of at least two of the following symptoms: straining, lumpy or hard stools, sensation of incomplete evacuation, sensation of anorectal obstruction or blockage, need for manual maneuvers to facilitate defecation, and/or infrequent bowel movements (fewer than three per week).
- Other complaints may include painful or difficult defecation, bloating, and absence of loose stools.
- Alarm (or red flag) symptoms include worsening of constipation, blood in the stools, weight loss, fever, anorexia, nausea, and vomiting.
- The patient should seek medical attention when symptoms are severe, last longer than 3 weeks, are disabling, when alarm symptoms occur, or whenever a significant change in usual bowel habits occurs.

Laboratory Tests (to Identify Secondary Causes)

- Thyroid function tests; abnormal thyroid hormone levels may suggest hypothyroidism, which may be associated with constipation.
- Serum calcium; either increased or decreased serum calcium levels may be associated with constipation.
- Glucose; increased blood glucose may indicate diabetes mellitus, which may be associated with constipation.
- Serum electrolytes; dehydration may be associated with constipation.
- Urinalysis may also indicate dehydration, if present.
- Complete blood count (CBC); anemia may be due to cancer or another systemic disorder accompanied by constipation.

constipation is suggested by the presence of two or more of the following criteria: (a) straining, (b) hard or lumpy stools, (c) sensation of incomplete evacuation, (d) sensation of anorectal blockage/obstruction, (e) need for manual maneuvers, or (f) fewer than three defecations per week for at least 25% of defecations. The symptoms must have been present for the last 3 months with onset at least 6 months prior to diagnosis. In addition, the criteria for meeting the diagnosis of IBS are not met.²

Dietary habits should be evaluated; patients should be encouraged to maintain adequate fiber intake and hydration. Evaluation of psychosocial status is recommended. Constipation may occur in patients who are depressed or in psychosocial distress. A complete family history should be obtained, particularly as it relates to inflammatory bowel disease and colon cancer. A full record of prescription and over-the-counter medications is mandatory to identify drug-related causes of constipation.

In most cases, there is no underlying cause of constipation, and the physical examination and rectal examination are normal. **Endoscopic evaluation** is required in patients who have weight loss, rectal bleeding, or anemia with constipation. These examinations can be used to exclude the presence of cancer or strictures, especially in patients older than 50 years. Endoscopic evaluation is appropriate in patients without alarm symptoms and those younger than 50 years. However, all adults older than 50 years who present with new-onset constipation should undergo endoscopic evaluation to rule out malignancy.⁷

TREATMENT

Desired Outcomes

In patients with constipation, the principal goals are to: (a) identify and treat secondary causes, (b) relieve symptoms, and (c) restore normal bowel function.

Nonpharmacologic Therapy

3 *General and dietary modifications should be employed prior to the use of laxatives in most instances of constipation.* Treatment of constipation depends on the characteristics and severity of symptoms. Intake of dietary fiber increases fecal bulk by promoting movement of water into the feces and bacterial proliferation. Increasing fiber intake to 20 to 35 g/day may help improve symptoms. Foods high in fiber include beans, whole grains, bran cereals, fresh fruits, and vegetables such as asparagus, brussels sprouts, cabbage, and carrots. Persons with constipation should avoid excessively processed low-fiber foods such as luncheon meats, hot dogs, certain cheeses, and ice cream.

Adequate fluid intake is also important; patients should be encouraged to drink when thirsty. The thirst mechanism changes with age; maintenance of a daily intake diary may assist patients who need to be reminded to drink fluids.

Walking and other aerobic exercises help to tone the muscles of the lower abdominal area, which promotes

propulsion in the bowel. Constipation is a frequent complaint of sedentary persons.

Each day most persons experience a strong peristaltic wave known as the gastrocolic reflex. A bowel movement usually follows. When the urge to have a bowel movement occurs, it should not be ignored. Some people put off having a stool for various reasons, which may lead to more difficulty in passing stool. Time should be planned daily to attempt having a stool. A busy lifestyle should not be allowed to interfere with normal bowel function.

In patients with pelvic floor dysfunction, biofeedback electromyography provides retraining for sensation and control of the rectal floor.⁸ Laxatives are employed to extend the treatment of constipation. The recommended route of administration depends on individual patient needs.

Pharmacologic Therapy

4 *Oral laxatives are the primary pharmacologic intervention for relief of constipation (Table 21-2).* There are several different drug classes, as described next.

► Bulk Producers

These agents are either naturally derived (psyllium), semisynthetic (polycarbophil), or synthetic (methylcellulose). They act by swelling in intestinal fluid, forming a gel that aids in fecal elimination and promoting peristalsis. They may cause flatulence (which is less common with methylcellulose) and abdominal cramping. Bulk-forming laxatives must be taken with sufficient water (8 oz or 240 mL/dose) to avoid becoming lodged in the esophagus and producing obstruction or worsening constipation. Hypersensitivity reactions may occur and rarely may be manifested as an anaphylactic reaction.

► Hyperosmotics

These products cause water to enter the lumen of the colon. Lactulose, sorbitol, and glycerin are osmolar sugars. Polyethylene glycol 3350 with electrolytes is most useful for acute complete bowel evacuation prior to GI examination. Polyethylene glycol 3350 without electrolytes is useful in patients who are experiencing acute constipation or who have had inadequate response to other agents.⁹ Lactulose causes acidification of the contents of the colon, increases water content of the gut, and softens the stool. Glycerin causes local irritation and possesses hyperosmotic action. Osmotic agents may cause flatulence, abdominal cramping, and bloating.

Sorbitol and glycerin may be administered rectally for treatment of constipation. Rectal discomfort and irritation may occur when administered rectally. Glucose levels should be monitored in diabetic patients who ingest oral sorbitol.

► Lubricants

Lubricant laxatives work by coating the stool, which allows it to be expelled more easily. The oily film covering the stool also keeps the stool from losing its water to intestinal

Table 21-2

Dosage Recommendations for Laxatives and Cathartics

Agent	Adults and Children Ages 12 and Over	Children Ages 6–11 Years
Agents That Cause Softening of Feces in 1–3 Days		
Bulk-forming agents/osmotic laxatives		
Methylcellulose	4–6 g/day	0.45–1.5 g po per dose up to 3 g/day
Polycarbophil	4–6 g po daily	On advice of practitioner
Psyllium	Varies with product	On advice of practitioner
Emollients		
Docusate sodium	50–360 mg po daily	50–100 mg po daily
Docusate calcium	50–360 mg po daily	On advice of practitioner
Docusate potassium	100–300 mg po daily	100 mg po daily
Lactulose	15–30 mL po daily	7.5 mL (5 g) po daily
Sorbitol	30–50 g/day po daily	2 mL/kg (as 70% solution) po daily
Mineral oil	15–30 mL po daily	5–15 mL po daily
Agents That Result in Soft or Semifluid Stool in 6–12 Hours		
Bisacodyl (oral)	5–15 mg po	5–10 mg (0.3 mg/kg) po
Senna	Dose varies with formulation	6–25 mg po once or twice daily
Agents That Cause Watery Evacuation in 1–6 Hours		
Magnesium citrate ^a	120–300 mL po	100–150 mL po
Magnesium hydroxide ^a	30–60 mL po (15–30 mL of concentrate po)	2.5–5 mL po up to 4 times
Magnesium sulfate ^a	10–30 g po	5–10 g po
Bisacodyl (suppository)	10 mg rectally	5 mg rectally (1/2 suppository)
Polyethylene glycol–electrolyte preparations	Up to 4 L po	Safety and efficacy not established

po, orally.

^aMagnesium can accumulate in renal dysfunction.

Adapted from Powell PH, Fleming VH. Diarrhea, constipation and irritable bowel syndrome. In: DiPiro JT, Talbert RL, Yee GC, et al., eds., *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011:621–638, with permission.

reabsorption processes. Mineral oil (liquid petrolatum) is a nonprescription heavy oil that should be used with caution, if at all, because it can be aspirated into the lungs and cause lipid pneumonia when ingested orally. This is of particular concern in the young or the elderly. It may also interfere with the absorption of fat-soluble vitamins.

► Stimulant Laxatives

Diphenylmethane derivatives (e.g., bisacodyl) and anthraquinones (e.g., senna) have a selective action on the nerve

plexus of intestinal smooth muscle leading to enhanced motility. Enteric-coated bisacodyl tablets should be swallowed whole to avoid gastric irritation and vomiting. Ingestion should be avoided within 1 to 2 hours of antacids, H₂-receptor antagonists, proton pump inhibitors, and milk. Bisacodyl rectal suppository and enema products are available. The onset of effect is rapid but the effects can be harsh (cramping), depending on the dose taken. Castor oil is another member of this class that is used less frequently. Castor oil is classified as pregnancy category X. It is associated with uterine contractions and rupture. The use of castor oil in breastfeeding is considered as “possibly unsafe.”

► Emollients

Also known as surfactants and stool softeners, emollients (e.g., salts of docusate) act by increasing the surface-wetting action on the stool leading to a softening effect. They reduce friction and make the stool easier to pass. These agents are not recommended for treating constipation of long duration.

► Saline Agents

Salts of sodium, magnesium, and phosphate pull water into the lumen of the intestines resulting in increased enteral pressure. Magnesium and phosphate may accumulate in patients with renal dysfunction. Principal concerns with sodium phosphate derivative use include dehydration, hypernatremia, hyperphosphatemia, acidosis, hypocalcemia, and worsening renal function. Patients with congestive heart failure and renal dysfunction should be advised to avoid these agents. Nonprescription oral sodium phosphate solutions were voluntarily recalled by the manufacturer because of the risk of acute phosphate nephropathy. Prescription oral phosphate products contain a black box warning about use in high-risk patients.

► Lubiprostone

Lubiprostone (Amitiza), a bicyclic acid oral agent, is approved for treatment of chronic idiopathic constipation in adults. It has not been studied in children. Lubiprostone acts locally on intestinal chloride channels and increases intestinal fluid secretion, resulting in increased intestinal motility and thereby increasing the passage of stool.⁹

Lubiprostone is contraindicated in patients with a history of mechanical GI obstruction and should not be used in patients suspected of having GI obstruction. Safety has not been established in pregnant women; animal studies indicated the potential to cause fetal loss. Women who could become pregnant should have a negative pregnancy test result prior to beginning therapy with lubiprostone. Patients receiving lubiprostone who become pregnant should be advised of the potential harm to the fetus (pregnancy category C).

Patients who experience adverse effects of dyspnea, nausea, and diarrhea should report them to their prescribers. Other adverse effects include abdominal distention, abdominal pain, flatulence, vomiting, and loose stools. Nausea is a prominent

adverse effect and may be minimized by taking lubiprostone with food.

The recommended dose of lubiprostone is 24 mcg orally twice daily with food and water. The capsule should be swallowed whole; it should not be chewed or broken apart. Studies evaluated lubiprostone use for no longer than 4 weeks. Patients should be assessed periodically for the need to continue therapy. Lubiprostone has not been studied in children or patients with renal or hepatic dysfunction.¹⁰

► **Methylnaltrexone Bromide**

Methylnaltrexone bromide (Relistor) is indicated for opioid-induced constipation in patients with advanced illness, receiving palliative care, and who have experienced insufficient response to laxative therapy. It is a selective antagonist of opioid binding at the mu-receptor. It has limited ability to cross the blood–brain barrier and causes laxation in patients with opioid-induced constipation without reducing the analgesic effects of opioids or inducing opioid withdrawal.

Methylnaltrexone bromide is administered subcutaneously no more than once daily or every other day dosages based on body weight. Patients weighing 38 to 62 kg should receive 8 mg, patients weighing 62 to 114 kg should receive 12 mg, and patients who weigh more than 114 kg should receive 0.15 mg/kg (rounded up to the nearest 0.1 mL of volume). In patients with renal impairment (creatinine clearance less than 30 mL/min [0.5 mL/s]), the dose should be reduced by 50%. Dosing in dialysis-dependent patients has not been studied. No dosage adjustment is necessary in patients with mild to moderate hepatic impairment (Child-Pugh class A and B). Dosage in patients with severe hepatic impairment has not been studied.

Pregnancy adverse effects of methylnaltrexone were not observed in animal experiments. No well-controlled and adequate studies exist in pregnant women (pregnancy category B).

The most common side effects are abdominal pain and cramping, flatulence, nausea, dizziness, hyperhidrosis, and diarrhea. Additional adverse effects are body temperature increase, muscle spasm, and syncope. Methylnaltrexone is contraindicated in patients with known or suspected GI obstruction.

► **Alvimopan**

Alvimopan (Entereg) is an opioid receptor antagonist that blocks opioid binding at the mu-receptor. It selectively binds to mu-receptors in the GI tract and antagonizes the peripheral effects of opioids on GI secretion and motility. Early experience suggests that it does not affect opioid analgesic effects or induce opioid withdrawal syndromes.

Alvimopan may be administered only by hospitals that are enrolled in the ENTEREG Access Support and Education (E.A.S.E.) Program. Alvimopan is limited to the short-term inpatient use (no more than 15 doses). Hospital staff education programs must be conducted. Hospitals may contact the E.A.S.E. program at 1-866-423-6567.

E.A.S.E. program trained hospital staff may administer the initial dose of alvimopan 15 mg orally 30 minutes to 5 hours prior to surgery with or without food. The maintenance dose is 12 mg by mouth twice daily beginning the day after surgery for a maximum of 7 days or until the patient is discharged. The maximum total therapy must not exceed 15 doses. Alvimopan is not dispensed to patients who have been discharged from the hospital.

Alvimopan is contraindicated in patients who have taken treatment doses of opioids for more than 7 consecutive days immediately prior to alvimopan administration because these patients may be more sensitive to GI side effects. The effects of alvimopan were reportedly affected by the use of opioid analgesics.

Adverse effects associated with alvimopan include hypokalemia, dyspepsia, urinary retention, anemia, and back pain. An increased incidence of myocardial infarction was observed in one 12-month alvimopan study.

► **Treatment Recommendations**

Slow-transit constipation can be treated with chronic administration of hyperosmotic laxatives. Senna, bisacodyl, and other stimulants should be used only when the others fail to deliver the desired effect.

Laxatives may provide appropriate relief when constipation occurs during the postpartum period, when not breastfeeding, and in immobile patients. Patients who are not constipated but who need to avoid straining (e.g., patients with hemorrhoids, hernia, or myocardial infarction) may benefit from stool softeners or mild laxatives such as polyethylene glycol 3350.

Laxatives should not be given to children younger than 6 years unless prescribed by a physician. Because children may not be able to describe their symptoms well, they should be evaluated by a healthcare provider before being given a laxative. Treating secondary causes may resolve the constipation without the use of laxatives. As in adults, children benefit from a healthy balanced diet, adequate fluid, and regular exercise.

Because many elderly persons experience constipation, laxative use is sometimes viewed as a normal part of daily life. However, oral ingestion of mineral oil can be a special hazard in bedridden elderly persons because it can lead to pneumonia through inhalation of oil droplets into the lungs. Lactulose may be a better choice in this situation. Regular use of any laxative that affects fluid and electrolytes may result in significant unwanted adverse effects.

Bulk producers are commonly used during pregnancy. Stool softeners (pregnancy category C) are probably safe to use at any time during a pregnancy because they are poorly absorbed. Lactulose and magnesium products are classified as pregnancy category B. No human studies are available concerning use of lactulose in pregnant women. Magnesium-based antacids are not classified according to pregnancy categories and are associated with low-risk and minimal absorption in pregnant women. Long-term use of magnesium citrate should be avoided (pregnancy category B).

Patient Encounter 1

EO is a 45-year-old man who requests a recommendation for treatment of constipation. Review of his medication profile reveals the following medications: sertraline 100 mg daily, multivitamin with minerals daily, ibuprofen 200 mg as needed for joint pain, calcium carbonate 650 mg as needed for dyspepsia, hydrochlorothiazide 25 mg daily, and amlodipine 10 mg daily.

What general approach to this patient should be employed?

What are the possible contributing causes of his constipation?

What nonpharmacologic and pharmacologic therapies would be appropriate for his condition?

To avoid constipation, pregnant women should be advised to eat regular meals that are balanced among fruits, vegetables, and whole grains; maintain adequate water intake; and get appropriate exercise.

Patients with the following conditions should use laxatives only under the supervision of a healthcare provider: (a) colostomy; (b) diabetes mellitus (some laxatives contain large amounts of sugars such as dextrose, galactose, and/or sucrose); (c) heart disease (some products contain sodium); (d) kidney disease; and (e) swallowing difficulty (bulk-formers may produce esophageal obstruction).

OUTCOME EVALUATION

- Ask the patient about the absence or improvement in symptoms to determine whether laxative therapy is effective. Patients should have an increase in stool frequency to three or more well-formed stools per week. Patients should report the absence of prolonged defecation time or the absence of the need for excessive straining.
- When acute overuse or chronic misuse of saline or stimulant laxatives is suspected, it may be necessary to check for electrolyte disturbances (e.g., hypokalemia, hypernatremia, hyperphosphatemia, or hypocalcemia).
- Some laxatives (e.g., bulk producers) contain significant amounts of sodium or sugar and may be unsuitable for salt-restricted or diabetic patients. Monitoring of fluid retention (edema) and blood pressure changes are indicated in patients on sodium-restricted diets. Glucose monitoring may be required in diabetic patients as needed with chronic use. Use of low-sodium or sugar-free products may be indicated.
- Saline laxatives containing magnesium, potassium, or phosphates should be used cautiously in persons with reduced kidney function. Monitor appropriate serum electrolyte concentrations in patients with unstable renal function evidenced by changing serum creatinine or creatinine clearance.

Patient Care and Monitoring for Constipation

1. Assess the patient's symptoms to determine if patient-directed therapy is appropriate or whether the patient should be evaluated by a physician. Determine type, frequency, and duration of symptoms; presence or absence of abdominal pain; and exclude the presence of alarm symptoms.
2. Review available information to determine the most likely cause or type of constipation. List associated factors and what seems to make it better or worse. Assess dietary habits, fluid intake, and level of physical activity.
3. Obtain a thorough history of prescription, nonprescription, and dietary supplement use. Determine what treatments have been helpful in the past, whether the patient is taking any medications that may contribute to constipation, usual diet, and fluid intake (consider fluid intake in relationship to fiber intake). Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions. Medications implicated in causing constipation include nonsteroidal anti-inflammatory drugs, analgesics, antidepressants, diuretics, some antihypertensives, calcium- and aluminum-containing products, and iron products.
4. Remember that no single therapy has proven effective for all patients who present with constipation.
5. Develop a plan to assess the effectiveness of laxative use in cases of functional constipation.
6. Provide patient education about constipation, dietary modifications, and drug therapy. Consider asking, "Do you take the time to have a bowel movement?"
7. Advise the patient about when to expect onset of relief and that if symptoms continue or worsen to seek further medical attention.

- All laxatives are contraindicated in patients with abdominal pain, nausea, vomiting, symptoms of appendicitis, or undiagnosed abdominal pain. Patients should consult their physicians if sudden changes in bowel habits persist for more than 14 days or if use of a laxative for 7 days results in no effect.

DIARRHEA

Diarrhea is a symptom of an underlying problem, not a disease. It is characterized by increased stool frequency (usually more than three times daily), stool weight, liquidity, and decreased consistency of stools compared with a patient's usual pattern. Acute diarrhea is defined as diarrhea lasting for 14 days or less. Diarrhea lasting more than 30 days is called chronic diarrhea. Illness of 15 to 30 days is referred to as persistent diarrhea.¹¹

EPIDEMIOLOGY AND ETIOLOGY

Most cases of diarrhea in adults are mild and resolve quickly. Infants and children (especially younger than 3 years) are highly susceptible to the dehydrating effect of diarrhea, and its occurrence in this age group should be taken seriously.

Acute Diarrhea

Acute diarrhea has many possible causes, but infection is the most common. Infectious diarrhea occurs because of food and water contamination via the fecal–oral route. Viruses are the cause in a large proportion of cases. Likely viral suspects include Rotavirus, Norwalk, and adenovirus. Patients usually exhibit sudden low-grade fever, vomiting, and watery stools. Some practitioners use the terms *acute diarrhea* and *acute gastroenteritis* interchangeably. However, they are not synonymous because diarrheal events do not invariably produce enteritis or involve the stomach.

Bacterial precipitants in many other cases include *Escherichia coli*, *Salmonella* species, *Shigella* species, *Vibrio cholerae*, and *Clostridium difficile*. The term *dysentery* describes some of these bacterial infections when associated with serious occurrences of bloody diarrhea. Additionally, acute diarrheal conditions can be prompted by parasites and protozoa such as *Entamoeba histolytica*, *Microsporidium*, *Giardia lamblia*, and *Cryptosporidium parvum*. Most of these infectious agents can cause **traveler's diarrhea**, a common malady afflicting travelers worldwide. It usually occurs during or just after travel following the ingestion of fecally contaminated food or water. It has an abrupt onset but usually subsides within 2 to 3 days.

Noninfectious causes of acute diarrhea include drugs and toxins (Table 21–3), laxative abuse, food intolerance, IBS, inflammatory bowel disease, ischemic bowel disease, lactase deficiency, Whipple's disease, pernicious anemia, diabetes mellitus, malabsorption, fecal impaction, diverticulosis, and celiac sprue.

Lactose intolerance is responsible for many cases of acute diarrhea, especially in patients of African descent, Asians, and Native Americans. Possible food-related causes include

fat substitutes, dairy products, and products containing nonabsorbable carbohydrates.

The diarrhea of IBS is sudden and perhaps watery but likely loose, usually accompanied by urgency, bloating, and abdominal pain occurring upon arising in the morning or immediately following a meal. Inflammatory bowel disease is typically associated with the sudden onset of bloody diarrhea accompanied by urgency, crampy abdominal pain, and fever. Patients who experience bowel ischemia may develop bloody diarrhea, particularly if they progress to shock.

Chronic Diarrhea

Chronic diarrhea lasts 4 weeks or more. Most cases result from functional or inflammatory bowel disorders, endocrine disorders, malabsorption syndromes, and drugs (including laxative abuse). In chronic diarrhea, daily watery stools may not occur. Diarrhea may be either intermittent or persistent.

PATHOPHYSIOLOGY

During normal processes, approximately 9 L (about 2.4 gallons) of fluid traverse the GI tract daily. Of this amount, 2 L represent gastric juice, 1 L is saliva, 1 L is bile, 2 L are pancreatic juice, 1 L is intestinal secretions, and 2 L are ingested. Of these 9 L of fluid presented to the intestine, only about 150 to 200 mL remain in the stool after reabsorptive processes occur.

Any event that leads to a significant increase in the amount of fluid retained in the stool may result in diarrhea. Large-stool diarrhea often signifies small intestinal involvement, whereas small-stool diarrhea usually originates in the colon. Diarrhea may be classified according to pathophysiologic mechanisms that include osmotic, secretory, inflammatory, and altered motility.

Osmotic diarrhea results from the intake of unabsorbable but water-soluble solutes in the intestinal lumen leading to water retention. Common causes include lactose intolerance and ingestion of magnesium-containing antacids.

Secretory diarrhea results in an increase in the net movement (secretion) of ions into the intestinal lumen leading to an increase in intraluminal fluid. Medications, hormones, and toxins may be responsible for secretory activity.

Inflammatory (or exudative) diarrhea results from changes to the intestinal mucosa that damage absorption processes and lead to an increase in proteins and other products in the intestinal lumen with fluid retention. The presence of blood or fecal leukocytes in the stool is indicative of an inflammatory process. The diarrhea of inflammatory bowel disease (e.g., ulcerative colitis) is inflammatory in nature.

Increased motility results in decreased contact between ingested food and drink and the intestinal mucosa, leading to reduced reabsorption and increased fluid in the stool. Diarrhea resulting from altered motility is often established after other mechanisms have been excluded. IBS-related diarrhea is due to altered motility.

Although diarrhea can often be attributed to a specific mechanism, some patients develop diarrhea due to overlapping mechanisms. For example, malabsorption syndromes

Table 21–3

Selected Drugs and Substances That May Cause Acute Diarrhea

Drugs

Antibiotics	Hydralazine	Metformin	Sorbitol
Colchicine	Laxatives	Misoprostol	Theophylline
Digitalis	Mannitol	Quinidine	Thyroid products

Dietary Supplements

St. John's wort	Echinacea	Ginseng	Aloe vera
-----------------	-----------	---------	-----------

Poisons

Arsenic	Cadmium	Mercury	Monosodium glutamate
---------	---------	---------	----------------------

and traveler's diarrhea are associated with both secretory and osmotic diarrhea.

Drug-induced diarrhea can occur by several mechanisms. First, water can be drawn into the intestinal lumen osmotically. Second, the intestinal bacterial ecosystem can be upset leading to the emergence of invasive pathologic organisms triggering secretory and inflammatory processes. Saline laxatives are an example of the first mechanism, and many antibiotics act by the second. A third way is through altered motility as may occur with tegaserod maleate. Other drugs such as procainamide or colchicine produce diarrhea through undetermined mechanisms. Discontinuation of the offending drug may be the only measure needed to ameliorate the diarrhea.

CLINICAL PRESENTATION AND DIAGNOSIS

Refer to the box below for the clinical presentation of diarrhea.

Diagnosis

Patients with diarrhea should be questioned about the onset of symptoms, recent travel, diet, source of water,

and medication use. Other important considerations include duration and severity of the diarrhea along with an accounting of the presence of associated abdominal pain or vomiting, blood in the stool, stool consistency, stool appearance, stool frequency, and weight loss. Although most cases of diarrhea are self-limited, infants, children, elderly persons, and immunocompromised patients are at risk for increased morbidity.

Findings on physical examination can assist in determining hydration status and disease severity. The presence of blood in the stool suggests an invasive organism, an inflammatory process, or perhaps a neoplasm. Large-volume stools suggest a small-intestinal disorder, whereas small-volume stools suggest a colon or rectal disorder. Patients with prolonged or severe symptoms may require colonoscopic evaluation to identify the underlying cause.

Treatment

Most healthy adults with diarrhea do not develop significant dehydration or other complications and can be treated symptomatically by self-medication. **5** *When diarrhea is severe and oral intake is limited, dehydration can occur, particularly in the elderly and infants.* Other complications

Clinical Presentation of Diarrhea

Signs and Symptoms of Acute Diarrhea

- Patients with acute diarrhea have the abrupt onset of loose, watery, or semiformal stools.
- Abdominal cramps and tenderness, rectal urgency, nausea, bloating, and fever may be present.
- The disorder is generally self-limited, lasting 3 to 4 days even without treatment.
- Patients with acute infectious diarrhea from invasive organisms also have bloody stools and severe abdominal pain.

Laboratory Tests in Acute Diarrhea

- Stool cultures can help identify infectious causes. Cultures are subject to time delay. New methodology using real-time polymerase chain reaction shortens the reporting time.
- Stool may also be analyzed for mucus, fat, osmolality, fecal leukocytes, and pH. The presence of mucus suggests colonic involvement. Fat in the stool may be due to a malabsorption disorder. Fecal leukocytes can be found in inflammatory diarrheas including infections and caused by invasive bacteria (e.g., *E. coli*, and *Shigella* and *Campylobacter* species). Stool pH (normally greater than 6) is decreased by bacterial fermentation processes.
- Stool volume and electrolytes can be assessed in large-volume watery stools to determine whether the diarrhea is osmotic or secretory.

- CBC and blood chemistries may be helpful in patients whose symptoms persist. The presence of anemia, leukocytosis, or neutropenia may provide further clues to the underlying cause.

Signs and Symptoms of Chronic Diarrhea

- In patients with chronic diarrhea, symptoms may be severe or mild. Weight loss can be demonstrated, and weakness may be present.
- Dehydration may be manifested by decreased urination, dark-colored urine, dry mucous membranes, increased thirst, and tachycardia.

Laboratory Tests in Chronic Diarrhea

- All of the tests described for acute diarrhea would be used to establish a diagnosis of chronic diarrhea because the differential diagnosis is more complicated. The data obtained can help categorize the diarrhea as watery, inflammatory, or fatty, narrowing the focus on a primary disorder.
- Colonoscopy allows visualization and biopsy of the colon and is preferred if blood has been found in the stool or if the patient has acquired immune deficiency syndrome.

of diarrhea resulting from fluid loss include electrolyte disturbances, metabolic acidosis, and cardiovascular collapse.

Children are more susceptible to dehydration (particularly when vomiting occurs) and may require medical attention early in their course, especially if younger than 3 years. Physician intervention is also necessary for elderly patients who are sensitive to fluid loss and electrolyte changes due to concurrent chronic illness.

Patients should undergo medical evaluation in the following circumstances: (a) moderate to severe abdominal tenderness, distention, or cramping; (b) bloody stools; (c) evidence of dehydration (e.g., thirst, dry mouth, fatigue, dark-colored urine, infrequent urination, reduced urine, dry skin, lack of skin elasticity, rapid pulse, rapid breathing, muscle cramps, muscle weakness, sunken eyes, or lightheadedness); (d) high fever (greater than or equal to 38.3°C or 101°F); (e) evidence of weight loss greater than 5% of total body weight; and (f) diarrhea that lasts longer than 48 hours.

Desired Outcomes

The goals of treatment for diarrhea are to relieve symptoms, maintain hydration, treat the underlying cause(s), and maintain nutrition. 6 *The primary treatment of acute diarrhea includes fluid and electrolyte replacement, dietary modifications, and drug therapy.*

Nonpharmacologic Therapy

► Fluid and Electrolytes

Fluid replacement is not a treatment to relieve diarrhea but rather an attempt to restore fluid balance. In many parts of the world where diarrheal states are frequent and severe, fluid replacement is accomplished using **oral rehydration solution** (ORS), a measured mixture of water, salts, and glucose. The solution recognized by the World Health Organization consists of 75 mEq/L (75 mmol/L) sodium, 75 mmol/L glucose, 65 mEq/L (65 mmol/L) chloride, 20 mEq/L (20 mmol/L) potassium, and 10 mEq/L (3.3 mmol/L) citrate, having a total osmolarity of 245 mOsm/L. A simple solution can be prepared from 1 L water mixed with eight teaspoonfuls of sugar and one teaspoonful of table salt. Some commercial products include Pedialyte, Rehydralyte, and CeraLyte.

Consistent intake of water (perhaps by slowly sipping), along with eating as tolerated, should restore lost fluids and salt for typical diarrhea sufferers. Patients may also replace lost fluid by drinking flat soft drinks such as ginger ale, tea, fruit juice, broth, or soup. Although sports drinks may be used to treat dehydration, caution should be exercised so they are not viewed as a casual panacea. Severe diarrhea may require use of parenteral solutions, and parenteral products should be used if patients are vomiting or unconscious.¹²

► Dietary Modifications

Once an acute diarrheal situation ensues, patients typically eat less as they become focused on the diarrhea. Both

children and adults should attempt to maintain nutrition. Food provides nutrients and fluid volume that help replace what is lost. However, food-related fluid may not be enough to compensate for diarrheal losses. Some foods may be inappropriate if they irritate the GI tract or if they are implicated as the cause of the diarrhea. Patients with chronic diarrhea may find that increasing bulk in the diet may help (e.g., rice, bananas, whole wheat, and bran).

Pharmacologic Therapy

The goal of drug therapy is to control symptoms, enabling the patient to continue with as normal a routine as possible while avoiding complications (Table 21-4). Most infectious diarrheas are self limited or curable with anti-infective agents.

Table 21-4

Pharmacotherapy for Diarrhea

Drug	Usual Oral Dose	Type of Diarrhea
Attapulgite	Adults: 1,200–1,500 mg after each loose stool. Maximum: 9,000 mg in 24 hours Children 6–12 years: 750 mg after each loose stool. Maximum: 4,500 mg in 24 hours	Acute and chronic
Calcium polycarbophil	Adults: 1,000 mg 4 times daily or after each loose stool, not to exceed 12 tablets/day Children 6–12 years: 500 mg 3 times daily Children 3–6 years: 500 mg twice daily	Chronic
Loperamide	Adults: 4 mg initially, then 2 mg after each subsequent loose stool. Maximum: 16 mg in 24 hours Children maximum doses: Age 2–5: 3 mg Age 6–8: 4 mg Age 8–12: 6 mg	Acute and chronic
Diphenoxylate/atropine	Adults: Two tablets (5 mg) initially, then one tablet every 3–4 hours, not to exceed 20 mg in 24 hours Children 2–12 years: Oral solution (avoid tablets) 0.3–0.4 mg/kg/day in divided doses. Do not administer to children younger than 2 years	Acute and chronic
Bismuth subsalicylate	Adults: 30 mL (regular strength) or 2 tablets, repeated every 30–60 minutes as needed. Maximum: 8 doses daily Children: Consumers should speak with a physician before giving to children under 12 years of age	Traveler's and nonspecific acute diarrhea

► Adsorbents and Bulk Agents

Attapulgite adsorbs excess fluid in the stool with few adverse effects. Formulations of attapulgite are available in Canada but not generally within the United States. Calcium polycarbophil is a hydrophilic polyacrylic resin (widely available in the United States) that also works as an adsorbent, binding about 60 times its weight in water and leading to the formation of a gel that enhances stool formation. Neither attapulgite nor polycarbophil is systemically absorbed. Calcium polycarbophil is effective in reducing fluid in the stool. However, caution must be exercised because it can also adsorb nutrients and other medications, thereby reducing their benefits. Its administration should be separated from other oral medications by 2 to 3 hours. Psyllium and methylcellulose products may also be used to reduce fluid in the stool and relieve chronic diarrhea.

► Antiperistaltic (Antimotility) Agents

Antiperistaltic drugs prolong intestinal transit time, thereby reducing the amount of fluid lost in the stool. The two drugs in this category are loperamide HCl (available over-the-counter as Imodium A-D and generically) and diphenoxylate HCl with atropine sulfate (available by prescription as Lomotil and generically). The atropine is included only as an abuse deterrent; when taken in large doses, the unpleasant anticholinergic effects of atropine negate the euphoric effect of diphenoxylate. Both loperamide and diphenoxylate are effective in relieving symptoms of acute noninfectious diarrhea and are safe for most patients experiencing chronic diarrhea. These products should be discontinued in patients whose diarrhea worsens despite therapy.

► Antisecretory Agents

Bismuth subsalicylate (BSS) is thought to have antisecretory and antimicrobial effects and is used to treat acute diarrhea. Although it passes largely unchanged through the GI tract, the salicylate portion is absorbed in the stomach and small intestine. For this reason, BSS should not be given to people who are allergic to salicylates, including aspirin. Caution should be exercised with regard to the total dose given to patients taking salicylates for other reasons to avoid **salicylism**. Patients taking BSS should be informed that their stool will turn black.

Octreotide is an antisecretory agent that has been used for severe secretory diarrhea associated with cancer chemotherapy, human immunodeficiency virus, diabetes, gastric resection, and GI tumors. It is administered as a subcutaneous or IV bolus injection in an initial dose of 50 mcg three times daily to assess the patient's tolerance to GI adverse effects. Biweekly serum levels of insulinlike growth factor (IGF)-1 or somatomedin C can be used as a guide to dose titration. Possible adverse effects include nausea, bloating, pain at the injection site, and gallstones (with prolonged therapy).

► Probiotics

Probiotics are dietary supplements containing bacteria that may promote health by enhancing the normal microflora of the GI tract while resisting colonization by potential pathogens. Probiotics can stimulate the immune response and suppress the inflammatory response. Yogurt can provide relief from diarrhea due to lactose intolerance. It supports digestion of lactose because the bacteria used to make yogurt produce lactase and digest the lactose before it reaches the colon. The *Lactobacillus acidophilus* in yogurt, cottage cheese, and acidophilus milk improve digestion of lactose and may prevent or relieve diarrhea related to lactose deficiency and milk intake. Although lactase is not a probiotic, lactase tablets may also be used to prevent diarrhea in susceptible patients.

► Antiinfectives

Empiric antibiotic therapy is an appropriate approach to traveler's diarrhea. Eradication of the causal microbe depends on the etiologic agent and its antibiotic sensitivity. Most cases of traveler's diarrhea and other community-acquired infections result from enterotoxigenic (ETEC) or enteropathogenic *Escherichia coli* (EPEC). Routine stool cultures do not identify these strains; primary empiric antibiotic choices include fluoroquinolones such as ciprofloxacin or levofloxacin. Azithromycin may be a feasible option when fluoroquinolone resistance is encountered. Rifaximin is another agent that can effectively treat traveler's diarrhea (see additional discussion of rifaximin in the irritable bowel syndrome section).

Patient Encounter 2

DT, a 48-year-old woman, lives in a rural community and works as an elementary school bus driver. She presents to the clinic complaining of fatigue, nausea, vomiting, episodes of mild abdominal pain, and frequent watery stools for the past 2 days. Her lips appear chapped, and she also states that she has been thirstier than usual and her saliva has been thick and sticky. She also states that her heart was racing after her evening walk the night before, which was atypical for her. She had been feeling tired over the past few days when workmen repairing her home's septic system occupied much of her time. Her husband took her temperature before bringing her to the clinic and said the reading was 100°F (37.8°C). She is otherwise healthy and reports no known allergies or medical conditions; she takes a multivitamin daily.

Assess the likelihood that DT's diarrhea is due to an invasive microorganism.

Identify which of her symptoms suggest the presence of dehydration.

Discuss potential treatment measures for this woman.

Although most cases of infectious diarrhea resolve with therapy, routine antibiotic use may contribute to antimicrobial resistance. Empiric treatment should be considered for other acute infectious diarrhea including those caused by nonhospital-acquired invasive organisms such as *Campylobacter*, *Salmonella*, and *Shigella* organisms producing moderate to severe fever, **tenesmus**, and bloody stools. Shiga toxin-producing *Escherichia coli* (STEC) O157 should not be treated with quinolones, trimethoprim-sulfamethoxazole, or antimotility agents.¹³

OUTCOME EVALUATION

- Monitor the patient with diarrhea from the point of first contact until symptoms resolve, keeping in mind that most episodes are self-limiting.
- Question the patient to determine whether symptom resolution occurs within 48 to 72 hours in acute diarrhea.
- Monitor for the maintenance of hydration, particularly when symptoms continue for more than 48 hours.

Patient Care and Monitoring for Diarrhea

1. Assess the patient's symptoms to determine if patient-directed therapy is appropriate or whether the patient should be evaluated by a physician. Determine the type of symptoms, severity, frequency, and exacerbating factors. Remember to inquire about recent foreign travel.
2. Determine if the patient is dehydrated.
3. Determine whether the patient has a history of disease that might be associated with diarrhea.
4. Obtain a thorough current history of prescription, nonprescription, and dietary supplement use. Remember to review the current therapy as a potential cause of diarrhea.
5. Determine if any diarrhea treatments have been attempted, including home remedies.
6. Medical referral is advised if the patient is pregnant, breast-feeding, younger than 3 or older than 70 years, or has multiple medical conditions.
7. If home care is recommended, provide clear instructions about how to proceed if symptoms do not improve or new symptoms emerge.
8. Discuss the importance of maintaining nutrition by modifying the diet.
9. Educate the patient about: (a) the causes of acute and chronic diarrhea, (b) the possible complications of diarrhea, (c) the goals of treatment for diarrhea, (d) the antidiarrheal medication used to manage acute or chronic diarrhea, and (e) if appropriate, the circumstances when antibiotics are used to treat diarrhea.

Look for increasing thirst, decreased urination, dark-colored urine, dry mucous membranes, and rapid heartbeat as suggestive of dehydration, especially when nausea and vomiting have been present.

- Monitor for symptom control in patients with chronic diarrhea.
- When antibiotics are used, monitor for completion of the course of therapy.

IRRITABLE BOWEL SYNDROME

IBS is a disorder of the GI tract that interferes with the normal functions of the colon. At various points in the past, IBS has been referred to as **mucous colitis**, **spastic colon**, irritable colon, or nervous stomach. **7** *IBS is generally described as a functional disorder rather than a disease per se. A functional disorder involves symptoms that cannot be attributed to a specific injury, infection, or other physical problem. A functional disorder occurs because of altered physiologic processes rather than structural or biochemical defects and may be subject to nervous system influence.*

IBS is associated with frequent fluctuation in symptoms, loss of productivity, and decreased quality of life. Although IBS has been referred to as **functional bowel disease**, true functional bowel disease may be more indicative of widespread GI involvement including (but not limited to) the colon.

EPIDEMIOLOGY AND ETIOLOGY

IBS is one of the most common disorders seen in primary care and the most common reason for referral to gastroenterologists. Although between 15% and 20% of Americans suffer from IBS, only about one-quarter of those affected seek medical attention. The associated costs to society are estimated to be billions of dollars,¹⁴ and the recurrent nature of IBS contributes to these costs through missed workdays, inattention on the job, and high consumption of health services.

In the United States, IBS affects women about twice as often as men. However, this may reflect a woman's tendency to seek medical care more often than a man. IBS can occur at any age but is most common between 20 and 50 years; onset beyond age 60 is rare. However, prevalence for older adults is the same as for young persons. Prevalence is similar in whites and African Americans but may be lower in people of Hispanic origin. A genetic link is unproven, but IBS seems more common in certain families.

There is a strong association between emotional distress and IBS. Psychosocial trauma (e.g., a history of abuse, recent death of a close relative or friend, or divorce) is more likely to be found in patients presenting with IBS than in the general population. An increased prevalence of psychiatric disorders such as anxiety, depression, personality disorders, and somatization (psychological distress expressed as physical

symptoms) occurs among adult patients with IBS. Alcohol consumption and smoking have not been shown to be risk factors for developing IBS.¹⁵ However, alcohol use can worsen symptoms in affected persons.

Some people show first evidence of IBS after contracting gastroenteritis (sometimes referred to as postinfectious IBS). This has led to speculation about whether infection heightens GI tract susceptibility. Women with IBS may have symptoms triggered by menstrual periods.

PATHOPHYSIOLOGY

Enteric nerves control intestinal smooth muscle action and are connected to the brain by the autonomic nervous system. IBS is thought to result from dysregulation of this “brain–gut axis.” The enteric nervous system is composed of two ganglionated plexuses that control gut innervation: the submucous plexus (Meissner’s plexus) and the myenteric plexus (Auerbach’s plexus). The enteric nervous system and the CNS are interconnected and interdependent. A number of neurochemicals mediate their function, including serotonin (5-hydroxytryptamine or 5-HT), acetylcholine, substance P, and nitric oxide, among others.

Serotonin is of great importance because the GI tract contains the largest amounts in the body. Two 5-HT receptor subtypes, 5-HT₃ and 5-HT₄, are involved in gut motility, visceral sensitivity, and gut secretion. The 5-HT₃ receptors slow colonic transit and increase fluid absorption, whereas 5-HT₄ receptor stimulation results in accelerated colonic transit.

Although no single pathologic defect has been found to account for the pattern of exacerbations and remissions seen in IBS, CNS abnormalities, dysmotility, visceral hypersensitivity, and a number of other factors have been implicated.¹⁶

The passage of fluids into and out of the colon is regulated by epithelial cells. In IBS, the colonic lining (epithelium) appears to work properly. However, increased movement of the contents in the colon can overwhelm its absorptive capacity. Disturbed intestinal motility appears to be a central feature of IBS, which leads to altered stool consistency. Studies suggest that the colon of IBS sufferers is abnormally sensitive to normal stimuli.¹⁷ This enhanced visceral sensitivity manifests as pain, especially related to gut distention.

IBS activity may be affected by the immune system. Some IBS patients have been found to have antibodies that may indicate food hypersensitivity that might be involved in symptom production.¹⁸ Specifically, sensitivity has been demonstrated to common foods such as wheat, beef, pork, soy, and eggs. Recent evidence suggest that an immune component may be involved in IBS patients who experience bloating and dysmotility-like dyspepsia and that gender specificity exists.¹⁹

CLINICAL PRESENTATION AND DIAGNOSIS

Refer to the box on the next page for the clinical presentation of IBS.

Diagnosis

9 *The diagnosis of IBS is made by symptom-based criteria and the exclusion of organic disease.* IBS is diagnosed by obtaining a careful and thorough history to identify symptoms characteristic of the disorder. It is equally important to distinguish among IBS and conditions having similar symptoms. Patients should be questioned about the character of their stools. This should include questions about frequency, consistency, color, and size. Moreover, because of the functional nature of IBS, a patient may present with symptoms of upper GI problems such as gastroesophageal reflux disease or with excessive flatulence. Patients should also be questioned about diet to determine whether symptoms seem to occur in relationship to meals or specifically after consumption of certain dietary products.

Barium enema, sigmoidoscopy, or colonoscopy may be indicated in the presence of red flag symptoms (fever, weight loss, bleeding, and anemia, possibly accompanied by persistent severe pain), which often point to a potentially serious non-IBS problem. A barium enema may identify polyps, diverticulosis, tumors, or other abnormalities that might be responsible for the symptoms. In addition, exaggerated haustral contractions may be noted with barium enema. Such contractions impede stool movement and contribute to constipation. Flexible sigmoidoscopy can be performed to identify obstruction in the rectum and lower colon, whereas colonoscopy can evaluate the entire colon for organic disease.

IBS diagnosis has long been symptom based. Manning defined the first widely used practical criteria: (a) abdominal pain relieved by defecation with either (i) looser stools with pain onset, or (ii) frequent stools with pain onset; (b) abdominal distention; (c) mucus in the stool; and (d) sensation of incomplete evacuation.^{14,20}

The Rome III criteria are the most current diagnostic criteria and can also be applied clinically.² They presume the absence of a structural or biochemical explanation for the symptoms. The Rome III criteria define IBS as occurring when symptoms of recurrent abdominal pain or discomfort exist for at least 3 days/month in the last 3 months associated with two or more of the following: (a) improvement with defecation, (b) onset associated with a change in the frequency of stool, and/or (c) onset associated with a change in the form (appearance) of stool. These criteria should be fulfilled for the previous 3 months with symptom onset at least 6 months prior to diagnosis. IBS is unlikely if symptom onset occurs in old age, the disorder has a steady but aggressive course, or the patient experiences frequent awakening because of symptoms.

TREATMENT

General Approach to Treatment

10 *The principal goal of IBS treatment is to reduce or control symptoms.* The treatment strategy is based on: (a) the prevailing symptoms and their severity, (b) the degree of functional impairment, and (c) the presence of psychological

Clinical Presentation of IBS

Symptoms

- Patients report a history of abdominal pain or discomfort that is relieved with defecation. Symptom onset is associated with change in frequency or appearance of stool. Some persons experience hard, dry stools, whereas others experience loose or watery stools. Some stools may be small and pellet-like in appearance; others may be narrow and pencil-like.
- **8** *Symptoms can typically be categorized as either IBS with diarrhea (IBS-D) or IBS with constipation (IBS-C). Patients with IBS-D usually report more than three loose or watery stools daily. Those with IBS-C usually have fewer than three bowel movements per week; stools are typically hard and lumpy and accompanied by straining. However, stool frequency may be normal in many cases. The Rome III diagnostic criteria (see [Diagnosis](#)) place more emphasis on stool form unlike Rome II, which emphasized frequency.*
- Although many patients fit into one of these subtypes, some patients report alternating episodes of diarrhea and constipation (irritable bowel syndrome with constipation and diarrhea [IBS-M], where M represents mixed).
- Other common symptoms include: (a) feelings of incomplete evacuation, (b) abdominal fullness, (c) bloating, (d) flatulence, (e) passage of clear or white mucus with a stool, and (f) occasional fecal incontinence.
- Periods of normal stools and bowel function are punctuated by episodes of sudden symptoms.
- Symptoms are often exacerbated by stress.
- Left lower quadrant abdominal pain is often brought on or made worse by eating. Passage of stool or flatus may provide some relief.
- IBS-C can often be distinguished from functional constipation primarily by the presence of abdominal pain and discomfort. Although pain and discomfort may be present in some patients with functional constipation, it is an expected feature of IBS.
- Patients with IBS may experience comorbidities outside the GI tract such as fibromyalgia, sleep disturbances, headaches, dyspareunia, and temporomandibular joint syndrome.

Signs

- The physical examination is often normal in IBS.
- The patient may appear to be anxious.
- Palpation of the abdomen may reveal left lower quadrant tenderness, which may indicate a tender sigmoid colon.
- Abdominal distention may be present in some cases.
- The following “red flag” or alarm features are *not* associated with IBS and may indicate inflammatory bowel disease, cancer, or other disorders: fever, weight loss, bleeding, and anemia, which may be accompanied by persistent severe pain.

Laboratory Tests

- In most cases, laboratory testing reveals no abnormalities in IBS, but certain tests can be used to identify other causes for the patient’s symptoms.
- CBC may identify anemia, which may suggest blood loss and an organic source for GI symptoms.
- Serum electrolytes and chemistries may indicate metabolic causes of symptoms.
- Thyroid-stimulating hormone (TSH) should be ordered when thyroid dysfunction is suspected. Hypothyroidism may be responsible for constipation and related symptoms.
- Stool testing for ova and parasites may identify *C. difficile* and amoebae as possible causes of diarrhea rather than IBS.
- Fecal leukocytes can be found in inflammatory diarrhea, especially when due to invasive microorganisms.
- A positive stool guaiac test indicating blood in the GI tract does not support a diagnosis of IBS.
- An elevated erythrocyte sedimentation rate is consistent with a systemic inflammatory process such as inflammatory bowel disease rather than IBS.
- Testing for lactase deficiency can confirm the presence of lactose intolerance, which may explain the symptoms.

components. A standard treatment regimen is not possible because of the heterogeneous nature of the IBS patient population. Patients suffering from IBS can benefit from clinician support and reassurance, because specific pathology is unlikely to be found.

Nonpharmacologic Therapy

► Diet and Other General Modifications

Dietary modification is a standard therapeutic modality. Food hypersensitivities and adverse effects are thought to occur

widely in IBS patients, especially those with IBS with diarrhea subtype. Elimination diets are the most commonly used strategy, usually focusing on milk and dairy products, fructose and sorbitol, wheat, and beef. Flatulence may be controlled by reducing gas-causing foods such as beans, celery, onions, prunes, bananas, carrots, and raisins. Response to elimination diets varies widely, but they may be useful in individual patients. Care must be taken to avoid creating nutritional deficits while attempting to eliminate an offending food.

Probiotics may also be an option for some patients with IBS. *Bifidobacterium infantis* is one product used for its effect in

Patient Encounter 3, Part 1

A recently divorced 33-year-old African American woman presents to the clinic complaining of headaches, sleep disturbances, cramping abdominal pain, bloating, excessive flatulence, and loose watery stools. When asked to show where her abdomen hurts, she specifically points to both her lower left and lower right abdomen. She indicates that the pain seems to lessen after a bowel movement. Further, she states the symptoms have become worse over the last month, alternating between episodes of watery stools and hard, dry stools that make it difficult to defecate. During some weeks, her diarrheal episodes cause her to call in sick to work. During other weeks, she can go a couple of days without a single bowel movement. She recently canceled a trip to California with friends because she was worried about her body "acting up." She was diagnosed with fibromyalgia 7 months ago and reports that her deceased mother (7 years ago) had irritable bowel syndrome. Her doctor started nortriptyline to treat fibromyalgia. She states that the nortriptyline has helped but not eliminated her joint and muscle pain.

Identify symptoms characteristic of IBS in this patient.

Discuss how this patient fits within the typical epidemiologic profile of patients with IBS.

constipation, diarrhea, gaseousness, bloating, and abdominal discomfort. Reportedly, it is not associated with significant untoward effects.²¹ The usual dose is one 4-mg capsule daily.

► Psychological Treatments

Psychotherapy focused on reducing the influence of the CNS on the gut has been studied. Cognitive behavioral therapy (CBT), dynamic psychotherapy, relaxation therapy, and hypnotherapy have been reported to be effective in some patients. However, psychological approaches are not considered replacements for usual care.²²

Pharmacologic Therapy

► Botanicals

Peppermint oil is widely advocated; it acts as an antispasmodic agent due to its ability to relax GI smooth muscle. However, it also relaxes the lower esophageal sphincter, which could allow reflux of gastric contents into the esophagus. The usual dose is 1 to 2 enteric-coated capsules containing 0.2 mL of peppermint oil two to three times daily.

Matricaria recutita, known as German chamomile, is also purported to have antispasmodic properties. It is taken most often as a tea up to four times a day. Benzodiazepine, alcohol, and warfarin users should be cautioned against taking this product because it can cause drowsiness, and it contains

Patient Encounter 3, Part 2

Upon further questioning, the patient recalls experiencing similar symptoms 7 years ago when her mother lost her battle to lung cancer. She never sought medical attention because her symptoms slowly subsided within a few weeks after her mother's funeral. She is a full-time pharmacy technician and recently started studying for the PCAT, which she plans to take in a couple of months. Her diet consists mostly of frozen dinners and fast food to fit her busy lifestyle.

PMH: Insomnia, headaches, fibromyalgia

FH: Mother had IBS (unspecified type)

SH: Smokes occasionally (during times of stress) and has a glass of wine with dinner.

Meds:

Nortriptyline 25 mg by mouth three times daily for fibromyalgia

Edluar 10 mg one sublingually at bedtime as needed for insomnia

Ibuprofen 600 mg by mouth every 6 hours as needed for headache

Loperamide 2 mg by mouth as needed for diarrhea

Docusate sodium 100 mg by mouth as needed for constipation

Allergies: Penicillin (rash, hives, and difficulty breathing after taking amoxicillin at the age of 9).

PE:

General: Well nourished; somewhat anxious and nervous when speaking.

VS: BP 129/82 mmHg; Pulse 85 bpm; RR 18 breaths/min; Temperature 97.4°F (36.3°C); Height 5'4" (163 cm); Weight 104 lbs (47.3 kg)

Integ: Nails are chewed up; skin appears dry and scaly

HEENT: PERRLA, EOMI

Ext: Normal, no swelling

Chest: Clear to A and P bilaterally

CV: RRR

Abd: (+) BS, tender LLQ and LRQ

Rectal: No abnormalities, negative stool guaiac test.

Which of this patient's findings are indicative of IBS?

Propose a comprehensive treatment approach to IBS in this patient. Where appropriate, consider the presence and influence of comorbidities.

coumarin derivatives.²³ Primrose oil is used by some patients, but evidence of effectiveness is lacking.

► Antispasmodics

Antispasmodic agents such as dicyclomine or hyoscyamine have been among the most frequently used medications for

treating abdominal pain in patients with IBS (Table 21-5). Side effects include blurred vision, constipation, urinary retention, and (rarely) psychosis. Although their effectiveness remains unconfirmed, these drugs may deserve a trial in patients with intermittent postprandial pain.^{14,20}

► Antidepressants

Tricyclic antidepressants (TCAs) such as amitriptyline and doxepin have been used with some success in the treatment of IBS-related pain (Table 21-5). They modulate pain principally through their effect on neurotransmitter reuptake, especially norepinephrine and serotonin. Their helpfulness in functional GI disorders seems independent of mood-altering effects normally associated with these agents. Low-dose TCAs (e.g., amitriptyline, desipramine, or doxepin 10 to 25 mg daily) may help patients with IBS who predominantly experience diarrhea or pain.

Table 21-5 Common Pharmacologic Treatments for IBS	
Generic (Brand) Name	Dose
Antispasmodics	
Dicyclomine (Bentyl)	10–20 mg po every 4–6 hours as needed
Hyoscyamine (Levsin)	0.125–0.25 po mg or sublingually every 4 hours as needed
Propantheline bromide (Pro-Banthine)	15 mg po 3 times a day (before meals) and 30 mg at bedtime
Clidinium bromide plus chlordiazepoxide HCl (Librax)	5–10 mg po 3–4 times a day
Hyoscyamine, scopolamine, atropine, phenobarbital (Donnatal)	1–2 tablets po 3–4 times daily
Tricyclic Antidepressants (TCAs) In IBS with Diarrhea:	
Amitriptyline	50–150 mg po daily
Doxepin	10–150 mg po daily
Selective Serotonin-Reuptake Inhibitors In IBS with Constipation:	
Paroxetine (others can be used)	10–40 mg po daily
Bulk-Forming Laxatives	
Psyllium (Metamucil)	2.5–4 g po daily
Methylcellulose (Citrucel)	4–6 g po daily
Antimotility Agents	
Loperamide (Imodium A/D)	4 mg po; then 2 mg po after each loose stool; daily maximum: 16 mg
5-HT₃ Receptor Antagonist	
Alosetron (Lotronex) ^a	1 mg po daily
5-HT₄ Receptor Agonist	
Tegaserod maleate (Zelnorm) ^b	6 mg po twice daily

^aWithdrawn from general use; available only under special circumstances.

^bWithdrawn from general use; available only as emergency treatment.

The selective serotonin-reuptake inhibitors (SSRIs) paroxetine, fluoxetine, and sertraline are potentially useful due to the significant effect of serotonin in the gut. SSRIs principally act on 5-HT₁ or 5-HT₂ receptors, but they can also have some effect on gut-predominant 5-HT₃ and 5-HT₄ receptors, perhaps reducing visceral hypersensitivity. They may be beneficial for patients with IBS-C or when the patient presents with IBS complicated by a mood disorder.²⁴ Serotonin–norepinephrine reuptake inhibitors may offer some benefit in IBS patients who also have depression or anxiety accompanied by significant pain.

► Bulk Producers

Bulk producers may improve stool passage in IBS-C but are unlikely to have a favorable effect on pain or global IBS symptoms.²⁴ Psyllium may increase flatulence, which may worsen discomfort in some patients. Methylcellulose products are less likely to increase gas production. Although fiber-based supplements are more likely to be useful in IBS-C, these products may be dose adjusted in diarrhea to increase stool consistency. Other laxative products might be used in IBS-C, but most are less desirable than bulking agents due to the potential for unwanted effects.

► Antimotility Agents

Loperamide stimulates enteric nervous system receptors, inhibiting peristalsis and fluid secretion. It improves stool consistency and reduces the number of stools.²⁴ Consequently, it is most useful in patients who have diarrhea as a prominent symptom. However, it does not lessen abdominal pain and can occasionally aggravate the pain.

► Alosetron

Stimulation of 5-HT₃ receptors triggers hypersensitivity and hyperactivity of the large intestine. Alosetron (Lotronex), a selective 5-HT₃ antagonist, blocks these receptors and is used to treat women with severe IBS-D. Eligible patients should have frequent and severe abdominal pain, frequent bowel urgency or incontinence, and restricted daily activities. Alosetron has been shown to improve overall symptoms and quality of life. Alosetron can cause constipation in some patients.

Because alosetron has been associated with ischemic colitis, it can be prescribed only under strict guidelines, including signing of a consent form by both patient and physician. Patients selected for therapy should exhibit severe chronic IBS symptoms and should have failed to respond to conventional therapy.

► Tegaserod Maleate

Tegaserod maleate (Zelnorm) stimulates 5-HT₄ receptors in the GI tract, thereby increasing intestinal secretion, peristalsis, and small bowel transit. It also reduces sensitivity related to abdominal distention. It has been

shown to be more effective than placebo in improving global IBS symptoms and altered bowel habits in IBS-C.²⁴ However, because of a higher risk of heart attack, stroke, and unstable angina (heart/chest pain) in patients treated with tegaserod maleate, the drug has been withdrawn from the market. The FDA can authorize use of tegaserod maleate for emergency situations only. The FDA must also authorize the drug to be shipped.

► Rifaximin

Rifaximin (Xifaxan) is a semisynthetic antibiotic with very low systemic absorption. It is believed that bacterial overgrowth plays a role in some IBS patients and that some antibiotics might be helpful. Rifaximin's lack of absorption reduces the likelihood of adverse effects, and its good antibacterial activity coupled with low microbial resistance make it a promising agent for a segment of the IBS population.²⁵ However, it did not carry FDA-approved labeling for this indication at the time of this writing.

OUTCOME EVALUATION

- Because symptoms vary in intensity and among patients, a specific drug therapy may not lead to equivalent symptom abatement in different patients.
- Monitor for adequate relief of symptoms. Patients whose pain does not respond to drug therapy may have a psychological comorbid condition and may require psychiatric intervention.
- Specifically, monitor for relief of pain if present initially. Monitor patients with symptoms of constipation or diarrhea for frequency, appearance, and size of stools in relationship to their normal characteristics. As stools normalize, associated symptoms such as bloating and abdominal distention should resolve.
- For IBS-C patients taking bulk producers, monitor for relief of constipation. Hard stools should become softer within 72 hours. IBS-M patients may gain relief with these agents as well.
- Monitor antidepressant therapy for relief of lower abdominal pain.
- Antispasmodics may provide limited relief of crampy abdominal pain.
- Assess 5-HT₄ receptor agonists (tegaserod) for relief of crampy abdominal pain and bloating.
- Evaluate 5-HT₃ receptor antagonists (alosetron) for relief of abdominal pain and fecal incontinence.
- Antimotility agents should be expected to reduce stool frequency and control diarrhea.
- Monitor complete blood cell count, serum electrolytes and chemistries, stool guaiac, and erythrocyte

Patient Care and Monitoring for IBS

1. Assess symptoms to determine if patient-directed therapy is appropriate or whether physician evaluation is needed.
2. Determine the type, severity, and frequency of symptoms and possible exacerbating factors.
3. Listen attentively to the patient's complaints and reassure the patient to allay fears about invasive disease.
4. Obtain a thorough current history of prescription, nonprescription, and dietary supplement use.
5. Determine if any IBS treatments have been attempted and how effective they have been.
6. Determine whether the patient has received educational intervention about IBS, health promotion, and symptom prevention measures.
7. Provide patient education about IBS symptoms, lifestyle modifications, and drug therapy for IBS:
 - Explain how to use medications relative to symptom intensity.
 - If taking alosetron, determine nonadherence with special use requirements.
 - Describe potential adverse effects.
 - List drugs that may interact with the therapy.
 - Discuss what to do if red flag symptoms occur.

sedimentation rate yearly for changes that might signal an overlapping organic problem.

- Refer any patient presenting with red flag signs for medical evaluation.

Abbreviations Introduced in This Chapter

BSS	Bismuth subsalicylate
CBT	Cognitive behavioral therapy
EPEC	Enteropathogenic <i>Escherichia coli</i>
ETEC	Enterotoxigenic <i>E. coli</i>
FGID	Functional gastrointestinal disorder
IBS	Irritable bowel syndrome
IBS-C	Irritable bowel syndrome with constipation
IBS-D	Irritable bowel syndrome with diarrhea
IBS-M	Irritable bowel syndrome with constipation and diarrhea (mixed)
ORS	Oral rehydration solution
TCA	Tricyclic antidepressant

Portal Hypertension and Cirrhosis

Laurajo Ryan

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiology of cirrhosis and portal hypertension.
2. Outline the progression of liver damage from excessive alcohol intake.
3. Identify signs and symptoms of liver disease in a given patient.
4. Identify laboratory abnormalities that result from liver disease and describe the pathophysiology of each abnormality.
5. Describe the consequences associated with decreased hepatic function.
6. Create treatment goals for a patient with portal hypertension and its complications.
7. Evaluate patient history and physical examination findings to determine the etiology of cirrhosis.
8. Recommend a specific treatment regimen for a patient with cirrhosis that includes lifestyle changes, nonpharmacologic therapy, and pharmacologic therapy.

KEY CONCEPTS

- 1 Portal hypertension is the precipitating factor for many of the complications of cirrhosis. Lowering portal pressure can reduce the complications of cirrhosis and decrease morbidity and mortality.
- 2 Chronic excessive ethanol intake causes progressive liver damage primarily because both ethanol and its metabolic products are direct hepatotoxins.
- 3 Cirrhosis is irreversible; treatments are directed at limiting disease progression and minimizing complications.
- 4 Nonselective β -blockers are first-line treatment for preventing variceal bleeding; they vasoconstrict the splanchnic bed through multiple mechanisms.
- 5 The goals of treating ascites are to minimize acute discomfort, reequilibrate ascitic fluid, and prevent spontaneous bacterial peritonitis (SBP). Treatment should modify the underlying disease pathology; without directed therapy, fluid will rapidly reaccumulate.
- 6 Cirrhosis is a high aldosterone state; spironolactone is a direct aldosterone antagonist and the primary treatment for ascites.
- 7 Acute variceal hemorrhage is an emergency. It is crucial to control bleeding, decrease risk of rebleeding, and prevent SBP.

- 8 Long-term antibiotic prophylaxis for SBP decreases mortality in patients with a history of SBP or low-protein ascites plus one of the following: serum creatinine (SCr) 1.5 mg/dL (133 μ mol/L) or greater, blood urea nitrogen (BUN) 25 mg/dL (8.9 mmol/L) or greater, serum sodium 130 mEq/L (130 mmol/L) or less, or Child–Pugh score of at least 9, with bilirubin of at least 3 mg/dL (51.3 μ mol/L).
- 9 Lactulose is the foundation of pharmacotherapy to prevent and treat hepatic encephalopathy (HE). It binds ammonia in its ionic form in the gut and facilitates its excretion.

INTRODUCTION

Cirrhosis is the progressive replacement of normal hepatic cells with fibrous scar tissue. This scarring is accompanied by the loss of viable hepatocytes, which are the functional cells of the liver. 1 *Cirrhosis is irreversible and leads to portal hypertension, which is in turn responsible for many of the complications of advanced liver disease. Cirrhotic complications include (but are not limited to) ascites, spontaneous bacterial peritonitis (SBP), hepatic encephalopathy (HE), hepatorenal syndrome (HRS), and variceal bleeding.*¹

EPIDEMIOLOGY AND ETIOLOGY

Cirrhosis is the result of long-term insult to the liver; damage is typically not evident clinically until the fourth decade

of life. Chronic liver disease and cirrhosis combined were the 12th leading cause of death in the United States in 2007. In patients between the ages of 25 and 64 years, damage from excessive alcohol use accounted for over one-half of the deaths.² Alcoholic liver disease and viral hepatitis C are the most common causes of cirrhosis in the United States, whereas hepatitis B accounts for the majority of cases worldwide.³ Once cirrhosis is diagnosed, the disease progression is similar, regardless of the initial insult to the liver.

Estimates vary, but alcoholic cirrhosis can develop with as little as 2 to 3 drinks per day in women and 3 to 4 drinks per day in men, although 5 to 8 drinks per day is more typical.⁴ A standard drink (14 g of ethanol) is equivalent to 1.5 oz (45 mL) of hard liquor, 5 oz (150 mL) of wine, or a 12-oz (360-mL) beer. With equivalent alcohol intake; women usually develop cirrhosis more quickly than men. Differences in alcohol metabolism may account for this gender disparity; women metabolize less alcohol in the GI tract; this allows delivery of more ethanol (which is directly hepatotoxic) to the liver.⁵ Genetic factors also play a role in alcoholic liver disease; some people progress to cirrhosis with much less cumulative alcohol intake than that of a typical cirrhotic patient (either fewer drinks per day or faster disease development), whereas others do not develop the disease even with more excessive intake.

Infection with one or more strains of viral hepatitis causes acute, potentially reversible, hepatic inflammation, whereas chronic infection with hepatitis B or C can lead to cirrhosis. Hepatitis B and C are common in IV drug users (direct blood transmission) or sexual contact (common route of hepatitis B transmission). Many cases of hepatitis C are idiopathic.⁶ See Chapter 24, “Viral Hepatitis,” for a complete discussion of infectious hepatitis.

Between 30% and 40% of patients with cirrhosis can be expected to experience a variceal bleed at some point in their disease.⁷ Variceal bleeding carries a remarkably high mortality rate; 6-week mortality is as high as 30% in patients with advanced disease. Mortality correlates with disease severity; risk factors include poor liver function, large varices, and red signs (wales) on endoscopic examination.⁸ More than two-thirds of patients who survive the first incidence of variceal bleeding experience a repeat episode.

Development of ascites in cirrhotic patients is a particularly ominous marker; 2-year mortality after initial presentation with ascites is approximately 50%.⁹ In addition to the high mortality rate, cirrhosis carries an enormous economic and social burden from hospitalizations, lost wages, and decreased productivity, not to mention the emotional strain of the disease on both patients and families.

Determining the specific cause of cirrhosis requires examination of both physical presentation and a thorough past medical history. An accurate social history is particularly important because few factors in the physical or laboratory examination indicate disease etiology. Identifying the cause of cirrhosis is imperative; disease etiology can affect treatment decisions and therapeutic options.

PATHOPHYSIOLOGY

Portal Hypertension and Cirrhosis

The portal vein is the primary vessel leading into the liver; it receives deoxygenated venous blood from the splanchnic bed (intestines, stomach, pancreas, and spleen) (Fig. 22-1). Portal flow accounts for approximately 75% of blood delivered to the liver (approximately 1 to 1.5 L/min in noncirrhotics). The hepatic artery provides the remaining 25% in the form of oxygenated blood from the abdominal aorta. Normal portal vein pressure is 5 to 10 mm Hg; this maintains liver blood flow of approximately 1 L/min. **Portal hypertension** occurs when portal pressure exceeds 10 to 12 mm Hg.¹⁰

Portal hypertension is a consequence of increased resistance to blood flow through the portal vein. This is often a result of restructuring of intrahepatic tissue (sinusoidal damage) but may also be caused by presinusoidal (prehepatic) injury such as portal vein occlusion from trauma, malignancy, or thrombosis. The third (and least common) cause of portal hypertension is outflow obstruction of the hepatic vein. Hepatic vein obstruction is considered posthepatic; normal liver structure is maintained. This chapter focuses on portal hypertension caused by intrahepatic damage from cirrhosis.

FIGURE 22-1. The portal venous system. (From Sease JM. Portal hypertension and cirrhosis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011:640, with permission.)

FIGURE 22-2. Relationship of sinusoids to hepatocytes and the venous system. (From Sease JM. Portal hypertension and cirrhosis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011:641, with permission.)

Sinusoidal damage from cirrhosis is the most common cause of portal hypertension. The sinusoids are porous vessels within the liver that surround radiating rows of hepatocytes, the functional cells of the liver (Fig. 22-2). Sinusoids transport systemic blood, which contains ingested substances (e.g., food, drugs, and toxins) to the hepatocytes. The liver processes the nutrients (carbohydrates, proteins, lipids, vitamins, and minerals) for either immediate use or storage, while drugs and toxins are broken down through a variety of metabolic processes.

Progressive destruction of hepatocytes and an increase in fibroblasts and connective tissue surrounding the hepatocytes culminate in cirrhosis. Fibrosis and regenerative nodules of scar tissue modify the basic architecture of the liver, disrupting hepatic blood flow and normal liver function.

- Reduced hepatic blood flow can significantly alter normal metabolic processes and decrease protein synthesis within the liver. Hepatic processing of drugs is reduced, resulting in higher drug concentrations and extended

half-life of drugs normally eliminated through first-pass metabolism. Decreased hepatic metabolism can also reduce or delay prodrug activation, which can result in therapeutic failure. The liver also processes metabolic waste products for excretion. In cirrhosis, bilirubin (from the enzymatic breakdown of heme) can accumulate; this causes jaundice (yellowing of the skin), scleral icterus (yellowing of the sclera), and tea-colored urine (urinary bilirubin excreted as urobilinogen).

Changes in steroid hormone production, conversion, and handling are prominent features of cirrhosis. These changes can result in decreased libido, gynecomastia (development of breast tissue in men), testicular atrophy, and features of feminization in men. Another effect of changes in sex hormone metabolism is development of spider angiomas (nevi), which are vascular lesions found mainly on the trunk. The lesions have a central arteriole (body) surrounded by radiating “legs.” When blanched, the lesions fill from the center body outward toward the legs. Spider angiomas are not specific to cirrhosis, but the number and size do correlate

with disease severity; their presence relates to risk of variceal hemorrhage.¹¹

Increased intrahepatic resistance to portal flow increases pressure on the entire splanchnic bed; an enlarged spleen (splenomegaly) is a common finding in cirrhotic patients. Splenic platelet sequestration secondary to splenomegaly is one cause of thrombocytopenia in cirrhotic patients.

Portal hypertension mediates systemic and splanchnic arterial vasodilation through production of nitric oxide and other vasodilators in an attempt to counteract the increased pressure gradient. Nitric oxide causes a fall in systemic arterial pressure; this drop in pressure activates the renin–angiotensin–aldosterone system (RAAS) and the sympathetic nervous system, and increases antidiuretic hormone (vasopressin) production.¹² These systems are activated in an attempt to maintain arterial blood pressure and renal blood flow by increasing sodium and water retention.

Excess sodium and water retention put increased pressure on the vascular system. One consequence is that the umbilical vein, which is usually eradicated in infancy, may become patent, resulting in prominent dilated veins visible on the surface of the abdomen. This phenomenon is called caput medusae because it resembles the head of the mythical Gorgon Medusa.

Ascites

Ascites is the accumulation of fluid in the peritoneal space. It is the most common sign of decompensated cirrhosis (as well as one of the first signs) and portends a dire prognosis.¹³

The pathophysiology of ascites, portal hypertension, and cirrhosis are interrelated (Fig. 22–3). Cirrhotic changes and

FIGURE 22–3. Factors involved in the development of ascites. (From Chung RT, Podolsky DK. Cirrhosis and its complications. In: Kasper DL, Braunwald E, Fauci AS, et al., eds. *Harrison's Principles of Internal Medicine*, 17th ed. New York, NY: McGraw-Hill, 2005:1858–1869, with permission.)

subsequent decreases in synthetic function lead to decreased albumin production (hypoalbuminemia). Albumin is the primary intravascular protein responsible for maintaining oncotic pressure within the vascular system; low serum albumin levels, elevated hydrostatic pressure, and increased capillary permeability allow fluid to leak from the vascular space into body tissues. This results in ascites, peripheral edema, and fluid in the pulmonary system. Obstruction of hepatic sinusoids and hepatic lymph nodes also allows fluid to seep into the peritoneal cavity, further contributing to ascitic fluid formation.

Lowered effective intravascular volume decreases renal perfusion; the kidney reacts by activating the RAAS, increasing plasma renin activity, aldosterone production, and sodium retention. The increase in intravascular volume furthers the imbalance of intravascular oncotic pressure, allowing even more fluid to escape to the extravascular spaces, increasing ascites and peripheral edema. Unchecked, these combined effects enable the cycle of portal pressure and ascites to continue, creating a self-perpetuating loop of ascites formation.

Patients with ascites avidly retain sodium and water, not only through aldosterone mechanisms, but also through increases in antidiuretic hormone and sympathetic nervous system activation. Patients may become hyponatremic if there is a decrease in free water excretion. This is not a result of too little sodium; it is a dilutional effect. Untreated, these factors can lead to a decrease in renal function and the hepatorenal syndrome (HRS).^{4,12}

Hepatorenal Syndrome

Hepatorenal syndrome is a decline renal function in the setting of cirrhosis that is not caused by intrinsic renal disease. Type 1 HRS is characterized by rapid deterioration of renal function (acute kidney injury [AKI]) in the presence of decompensated cirrhosis that is not reversible with volume repletion. Untreated it is rapidly fatal with a 50% mortality rate at 14 days. Renal artery vasoconstriction (stimulated by the sympathetic nervous system) and decreased mean arterial pressure (mediated by nitric oxide) decrease renal perfusion and precipitate renal failure. The kidneys attempt to counteract this drop in renal perfusion through RAAS activation. Production of renin stimulates a cascade that causes fluid retention and peripheral vasoconstriction in an attempt to increase renal blood flow. Prostaglandin E₂ and prostacyclin production are increased to stimulate renal vasodilation. HRS develops when these mechanisms are overwhelmed and renal perfusion drops acutely. SBP is often a trigger for HRS, and nonsteroidal anti-inflammatory drugs (NSAIDs) precipitate HRS by inhibiting prostaglandins. Type 2 HRS has similar pathophysiology to type 1 HRS but is characterized by a less acute decline in renal function.

The traditional renal function monitoring parameters of SCr and blood urea nitrogen (BUN) tend to be low in cirrhotic patients secondary to reduced muscle mass and decreased hepatic urea production, respectively. Because of this, even minor changes in these parameters should be monitored closely; seemingly small changes may represent large changes in renal function.

Varices

The splanchnic system drains venous blood from the GI tract to the liver. In portal hypertension, there is increased resistance to drainage from the originating organ, so collateral vessels (varices) develop in the esophagus, stomach, and rectum to compensate for the increased blood volume. Varices divert blood meant for hepatic circulation back to the systemic circulation, decreasing clearance of medications and potential toxins through loss of first-pass metabolism. Varices are weak superficial vessels; any additional increase in pressure can cause them to rupture and bleed.¹⁴

Spontaneous Bacterial Peritonitis

SBP is an acute bacterial infection of peritoneal (ascitic) fluid in the absence of intra-abdominal infection or intestinal perforation. Estimated SBP prevalence in patients with ascites ranges from 10% to 30%.¹⁵ The peritoneal cavity is usually a sterile space. One proposed mechanism of bacterial contamination is translocation of intestinal bacteria to mesenteric lymph nodes, which then seed the ascitic fluid.¹⁶ Bacterial translocation correlates with the delay in intestinal transit time and increased intestinal wall permeability observed in cirrhotic patients. Another possible mechanism is the hematogenous spread of bacteria into the peritoneal space.¹⁷ Low protein (less than 1 g/dL [10 g/L]) ascites is also associated with increased rates of SBP; presumably low protein is correlated to low antibacterial activity.

Enteric gram-negative aerobes are the most common bacteria isolated from ascitic fluid, usually *Escherichia coli* or *Klebsiella pneumoniae*. *Streptococcus pneumoniae* is the most common gram-positive pathogen associated with SBP.¹⁸ Once a bacterial pathogen has been identified, the antimicrobial spectrum can be narrowed; SBP is rarely polymicrobial.

Hepatic Encephalopathy

Numerous factors, many of them poorly understood, are involved in the development of HE. In severe hepatic disease, systemic circulation bypasses the liver; so many substances normally metabolized by the liver remain in the systemic circulation and accumulate. In excess, these metabolic by-products, especially nitrogenous waste, cause alterations in CNS functioning.¹⁹

Ammonia (NH₃) is just one of the toxins implicated in HE. It is a metabolic by-product of protein catabolism; it is also generated by bacteria in the GI tract. In a normally functioning liver, hepatocytes degrade ammonia to form urea, which is renally excreted. In cirrhosis, the conversion to urea is retarded and ammonia accumulates, resulting in encephalopathy. Patients with HE commonly have elevated serum ammonia concentrations, but ammonia levels do not correlate with the degree of CNS impairment.¹⁹ Decreased urea formation is evident on laboratory assessments as decreased BUN, but BUN levels do not correlate with the degree of HE.

High levels of false neurotransmitters (aromatic amino acids, γ -aminobutyric acid, and endogenous benzodiazepines)

have also been implicated in HE. These substances bind to both the γ -aminobutyric acid and benzodiazepine receptors and act as agonists at the active receptor sites.¹⁹

- Decreased cognition, confusion, and changes in behavior combined with physical signs such as asterixis (characteristic flapping of hands upon extension of arms with wrist flexion) indicate HE. Patients with previously stable cirrhosis who develop acute encephalopathy often have an identifiable precipitating event that can account for the increased production and/or decreased elimination of toxins. Infections, variceal hemorrhage, renal insufficiency, electrolyte abnormalities, and increased dietary protein have all been associated with acute development of HE. Acute HE triggers can often be treated, reversing encephalopathy. Changes of a more chronic, insidious nature are more difficult to treat; patients rarely recover from chronic HE.

Bleeding Diathesis and Synthetic Failure

- Coagulopathies signal end-stage liver disease. The liver manufactures procoagulation and anticoagulant factors essential for blood clotting and maintenance of blood homeostasis. In advanced disease, the liver is unable to synthesize these proteins, resulting in extended clotting times (e.g., prothrombin time) and bleeding irregularities.²⁰

Thrombocytopenia is another coagulation abnormality seen in advanced liver disease. This is a result of decreased platelet production in the bone marrow (triggered by a lack of thrombopoietin stimulation by the liver) as well as the splenic sequestration of formed platelets.

Macrocytic anemia occurs because of decreased intake, metabolism, and storage of folate and vitamin B₁₂. Individuals who continue to drink exacerbate blood abnormalities further; ethanol is toxic to bone marrow.

Alcoholic Liver Disease

- The course of alcoholic liver disease moves through several distinct phases from fatty liver to alcoholic hepatitis and finally cirrhosis. Metabolism of large amounts of ethanol shifts hepatic metabolic processes away from oxidation and toward reduction. These changes in metabolism account for the fatty liver, hypertriglyceridemia, and acidemia observed in alcoholic liver disease. Fatty liver and alcoholic hepatitis may be reversible with cessation of alcohol intake. The scarring of cirrhosis is permanent, but maintaining abstinence from alcohol can decrease complications and slow progression to end-stage liver disease.²¹ Continuing to drink alcohol speeds the advancement of liver dysfunction and cirrhotic complications.

Ethanol metabolism begins prior to absorption; alcohol dehydrogenase (ADH) in the gastric mucosa oxidizes a portion of ingested alcohol to **acetaldehyde**. The remaining alcohol is rapidly absorbed from the GI tract, and because it is highly lipid soluble, it enters the body tissues quite easily. ② ADH oxidizes ethanol in body tissues, primarily the liver, causing inflammation and fibrosis.²² High ethanol levels saturate the ADH enzyme system. When ADH is

overwhelmed, the microsomal ethanol oxidizing system takes over the detoxification process. This system is an inducible cytochrome P-450 (CYP 450) enzyme system; it participates in phase I metabolism and like ADH, produces acetaldehyde as its end product.²³ Acetaldehyde exerts direct toxic effects on the liver by damaging hepatocytes, inducing fibrosis, and directly coupling to proteins, interfering with their intended actions.

Less Common Causes of Cirrhosis

Genetics and metabolic risk factors mediate other less common causes of cirrhosis. These diseases vary widely in prevalence, disease progression, and treatment options.

Primary biliary cirrhosis is characterized by progressive inflammatory destruction of the bile ducts. This immune-mediated inflammation of the intrahepatic bile ducts causes remodeling and scarring, resulting in retention of bile in the liver, hepatocellular damage, and cirrhosis. The number of patients affected with primary biliary cirrhosis is difficult to estimate because it is often asymptomatic and people may be diagnosed incidentally during a routine healthcare visit.

Nonalcoholic fatty liver disease (NAFLD) begins with asymptomatic fatty liver but can progress to cirrhosis. NAFLD is a diagnosis of exclusion; viral, genetic, or environmental causes must be eliminated prior to making this diagnosis. NAFLD is directly related to numerous metabolic abnormalities. Risk factors include diabetes mellitus, dyslipidemia, obesity, insulin resistance, and other conditions associated with increased hepatic fat.²⁴

Hereditary hemochromatosis is an autosomal recessive disease that causes increased intestinal iron absorption and subsequent deposition in hepatic, cardiac, and pancreatic tissue. Hepatic iron overload results in fibrosis, hepatic scarring, cirrhosis, and hepatocellular carcinoma. Repeated blood transfusions can also cause hemochromatosis, but this mechanism rarely leads to cirrhosis.

Wilson's disease is an autosomal recessive disease that leads to cirrhosis through protein abnormalities. The protein responsible for facilitating copper excretion in the bile is faulty, so copper accumulates in hepatic tissue. High copper levels are toxic to hepatocytes. Fibrosis and cirrhosis may develop in untreated patients. Patients with Wilson's disease usually present with symptoms of liver and/or neurologic disease while still in their teens.

A third autosomal recessive genetic disease is α_1 -antitrypsin deficiency. Abnormalities in the α_1 -antitrypsin protein impair its secretion from the liver. α_1 -Antitrypsin deficiency causes cirrhosis in children as well as adults; adults usually have concomitant pulmonary disease such as chronic obstructive pulmonary disease.

CLINICAL PRESENTATION AND DIAGNOSIS

See the clinical presentation text box on the next page for the symptoms, signs, and laboratory abnormalities associated with cirrhosis.

Diagnosis of Cirrhosis

In some cases, cirrhosis is diagnosed incidentally before the patient develops symptoms or acute complications, but many patients have decompensated cirrhosis at initial presentation. Patients may present with variceal bleeding, ascites, SBP, or HE. At diagnosis, patients may have some, all, or none of the laboratory abnormalities and/or signs and symptoms that are associated with cirrhosis (see clinical presentation text box).²⁵

Liver biopsy is the only way to definitively diagnose cirrhosis, but this is often deferred in lieu of a presumptive diagnosis. Ultrasound and computed tomography are used routinely to evaluate cirrhosis; a small nodular liver with increased echogenicity is consistent with cirrhosis. The modified Child–Pugh and Model for End-Stage Liver Disease (MELD) classification systems (Table 22–1) are used to classify disease severity and evaluate the need for transplantation.

Patients with ascites or known varices are presumed to have portal hypertension. Direct measurements of portal

Table 22–1

Child–Pugh and MELD Classifications for Determining Severity of Liver Damage

Child–Pugh Classification^a

Variable	1 Point	2 Points	3 Points
Bilirubin (mg/dL) (μmol/L)	Less than 2	2–3	Greater than 3
	Less than 34	34–51	Greater than 51
Albumin (g/dL) (g/L)	Greater than 3.5	2.8–3.5	Less than 2.8
	Greater than 35	28–35	Less than 28
Prothrombin time (seconds prolonged) or INR	1–3	4–6	Greater than 6
	Less than 1.8	1.8–2.3	Greater than 2.3
Ascites	None	Slight	Moderate
Encephalopathy	None	Grade 1–2	Grade 3–4

MELD Classification

The formula for the MELD score is $3.8 \times \ln(\text{bilirubin [mg/dL]}) + 11.2 \times \ln(\text{INR}) + 9.6 \times \ln(\text{creatinine [mg/dL]}) + 6.4 \times (\text{etiology: 0 if cholestatic or alcoholic, 1 otherwise})$.

Using SI units, the MELD score is $3.8 \times \ln(\text{bilirubin } [\mu\text{mol/L}]/17.1) + 11.2 \times \ln(\text{INR}) + 9.6 \times \ln(\text{creatinine } [\mu\text{mol/L}]/88.4) + 6.4 \times (\text{etiology: 0 if cholestatic or alcoholic, 1 otherwise})$.

INR, international normalized ratio; MELD, Model for End-Stage Liver Disease; Ln, natural logarithm.

^aClass A: 1 to 6 total points; B: 7 to 9 points; C: 10 to 15 points.

Clinical Presentation of Cirrhosis and Complications of Portal Hypertension

General

- Most signs and symptoms are specific to the complication the patient is experiencing at the time of presentation.

Symptoms

- Patients with cirrhosis may be asymptomatic until acute complications develop.
- Nonspecific symptoms may include anorexia, fatigue, weakness, and changes in libido and sleep patterns.
- Patients may experience easy bruising and may bleed from minor injuries.
- Pruritus may be present, particularly with biliary involvement.
- Patients with ascites may complain of abdominal pain, nausea, increasing tightness and fullness in the abdomen, shortness of breath, and early satiety.
- Hemorrhage from esophageal or gastric varices may be associated with melena, pallor, fatigue, and weakness from blood loss. Patients often present with nausea, vomiting, and hematemesis because blood in the GI tract is nauseating. Bleeding from rectal varices may present as **hematochezia**.
- In patients with bleeding varices, digestion of swallowed blood represents a high protein load; this causes nausea and can precipitate symptoms of HE.
- In patients with HE, neurologic changes can be overwhelming or so subtle that they are not clinically apparent except during a targeted clinical evaluation.
- Patients with HE may complain of disruption of sleep patterns and day-to-night inversion; patients have delayed bedtime and wake times, which may progress to complete inversion of the normal diurnal cycle.
- If SBP occurs, symptoms of infection may include fever, chills, abdominal pain, and mental status changes.

Signs

- Nonspecific signs on physical examination include jaundice, scleral icterus, tea-colored urine, bruising, hepatomegaly, splenomegaly, spider angiomas, caput medusae, palmar erythema, gynecomastia, and testicular atrophy.
- Ascites can be detected by increased abdominal girth accompanied by shifting dullness and a fluid wave.
- Signs of variceal bleeding depend on the degree of blood loss and abruptness of onset. Rapid and massive blood loss is more likely to result in hemodynamic instability than slow, steady bleeding. Signs of acute bleeding may include pallor, hypotension, tachycardia, mental status changes, and hematemesis.
- Markers of hepatic encephalopathy (HE) include decreased cognition, confusion, changes in behavior, and asterixis.
- Patients with SBP may present with fever, painful tympanic abdomen, and changes in mental status.
- Decreases in clotting factors may manifest as abnormal bruising and bleeding.

- Dupuytren's contracture is a contraction of the palmar fascia that usually affects the fourth and fifth digits. It is not specific to cirrhosis and can also be seen in repetitive use injuries.

Laboratory Abnormalities

- Hepatocellular damage manifests as elevated alanine aminotransferase (ALT) and aspartate aminotransferase (AST). The degree of transaminase elevation does not correlate with the remaining functional metabolic capacity of the liver. An AST level twofold higher than ALT suggests alcoholic liver damage.
- Elevated alkaline phosphatase is nonspecific and may correlate with liver or bone disease; it tends to be elevated in biliary tract disease.
- γ -Glutamyl transferase (GGT) is specific to the bile ducts, and in conjunction with an elevated alkaline phosphatase, it suggests hepatic disease. Extremely elevated GGT levels further indicate obstructive biliary disease. GGT is also elevated in individuals who drink three or more alcoholic drinks daily.
- Increased total, direct, and indirect bilirubin concentrations indicate defects in transport, conjugation, or excretion of bilirubin.
- Lactate dehydrogenase (LDH) is a nonspecific marker of hepatocyte damage; a disproportionate elevation of LDH indicates ischemic injury.
- Thrombocytopenia may occur because of decreased platelet production and splenic platelet sequestration.
- Anemia (decreased hemoglobin and hematocrit) occurs as a result of variceal bleeding, decreased erythrocyte production, and hypersplenism.
- Elevated prothrombin time (PT) and international normalized ratio (INR) are coagulation derangements that indicate loss of synthetic capacity in the liver and correlate with functional loss of hepatocytes.
- Decreased serum albumin and total protein occur in chronic liver damage due to loss of synthetic capacity within the liver.
- The serum albumin-to-ascites gradient is 1.1 g/dL (11 g/L) or greater caused by portal hypertension.
- Increased blood ammonia concentration is characteristic of HE, but levels do not correlate well with the degree of impairment.
- Increased serum creatinine signaling a decline in renal function may be seen with hepatorenal syndrome.
- Signs and symptoms of SBP in a patient with cirrhosis and ascites should prompt a diagnostic paracentesis (Fig. 22–5). In SBP, there is decreased total serum protein, elevated white blood cell count (with left shift), and the ascitic fluid contains at least 250 cells/mm³ (250 × 10⁶/L) neutrophils. Bacterial culture of ascitic fluid may be positive, but lack of growth does not exclude the diagnosis.

pressure require invasive procedures and increase the risk of bleeding; this is usually deferred in lieu of presumptive therapy.

Diagnosis of Ascites

In obese patients or those with only small amounts of fluid accumulation, ultrasound evaluation may be necessary to detect ascites. Analysis of ascitic fluid obtained during **paracentesis** provides diagnostic clues to the etiology of the ascites. Diagnostic evaluation should include cell count with differential, albumin, total protein, Gram stain, and bacterial cultures. In patients without an established diagnosis of liver disease, the serum ascites-albumin gradient (SAAG) is used to determine if the ascites is caused by portal hypertension.²¹ SAAG compares serum albumin concentration to ascitic fluid albumin concentration:

$$\text{Alb}_{\text{serum}} - \text{Alb}_{\text{ascites}} = \text{SAAG}$$

A value of 1.1 g/dL (11 g/L) or greater identifies portal hypertension as the cause of the ascites with 97% sensitivity.²¹ In portal hypertension, the ascitic fluid is low in albumin; this balances the oncotic pressure gradient with the hydrostatic pressure gradient of portal hypertension. The differential diagnoses for SAAG values less than 1.1 g/dL (11 g/L) include peritoneal carcinoma, peritoneal infection (tuberculosis, fungal, or cytomegalovirus), and nephrotic syndrome. Serum albumin measurements should be made at the time of paracentesis for an accurate comparison.²¹

TREATMENT OF PORTAL HYPERTENSION, CIRRHOSIS, AND COMPLICATIONS

Desired Outcomes

Recognizing and treating the cause of cirrhosis is paramount. **3** *Cirrhosis is irreversible; treatments are directed at limiting disease progression and minimizing complications.* The immediate treatment goals are to stabilize acute complications such as variceal bleeding and prevent SBP. Once life-threatening conditions have stabilized, the focus shifts to preventing complications and further liver damage. Preventing complications involves both primary and secondary prophylaxis. To determine appropriate prophylactic therapy, a careful analysis of patient characteristics and disease history is mandatory. The sections that follow concentrate on treatment and prevention of cirrhotic complications.

Nonpharmacologic Therapy

Lifestyle modifications can limit disease complications and slow further liver damage. Avoiding additional hepatic insult is critical for successful cirrhosis treatment. The only proven treatment for alcoholic liver disease is immediate cessation of alcohol use. Patients with cirrhosis from causes other than alcohol also benefit from avoiding alcohol;

Patient Encounter Part 1

LT is a 49-year-old woman who is brought to the emergency department by her husband. This evening when he returned home from work, he found LT asleep in the living room. He attempted to wake her up, but she was “out of it,” so he brought her for medical attention.

Chief complaint: Not obtained; minimal response to stimuli

HPI: Husband states that LT had complained of weakness and fatigue for approximately 2 days

PMH: Four pregnancies, four live births; skull fracture 4 years ago secondary to a fall, type 2 diabetes (diet controlled)

PSH: Cesarean section, tubal ligation

SH: Married, lives with her brother, her husband, and their four children; works as a bartender; drinks “socially” per husband; no tobacco or illicit drug use

FH: Mother with osteoporosis, hypothyroidism, depression, and hypertension; father’s medical history is unknown; two brothers with type 2 diabetes

Outpatient meds: No prescriptions; OTC acetaminophen for frequent headaches

ROS: (+) weakness and fatigue per husband

PE:

VS: BP 77/31 mm Hg, P 118 bpm, T 99.1°F (37.3°C), RR 22 breaths/min, oxygen saturation 96% (0.96) on room air, height 61” (155 cm), weight 68 kg, BMI 28.3 kg/m²

HEENT: PERRL, EOMI, (+) scleral icterus, mild jaundice

CV: Tachycardic; RR; no murmurs, rubs, or gallops

Chest: CTA bilaterally, no crackles or wheezes

Abd: Soft, nontender, slightly distended abdomen, normal bowel sounds, mild hepatosplenomegaly, possible small ascites

Ext: 2+ pedal pulses, mild to moderate pitting edema

Based on the current information, what is the most likely cause of her mental status changes?

What signs and symptoms does this patient have that are consistent with cirrhosis?

What risk factors does she have for cirrhosis?

regardless of the etiology, all cirrhotic patients should abstain from alcohol to prevent further liver damage.

Patients with ascites require dietary sodium restriction. Intake should be limited to less than 800 mg sodium (2 g sodium chloride) per day. More stringent restriction may cause faster mobilization of ascitic fluid, but adherence to such strict limits is very difficult. Ascites usually responds well to sodium restriction accompanied by diuretic therapy.^{13,21} A spot urine sodium-to-potassium ratio greater than 1 indicates nonadherence to dietary sodium goals.

Medication use must be monitored carefully for potential hepatotoxicity. Hepatically metabolized medications have the potential to accumulate in patients with liver disease. Little guidance is available on drug dosing in hepatic impairment because these patients have historically been excluded from drug trials. Daily acetaminophen use should not exceed 2 g. Dietary supplements, herbal remedies, and nutraceuticals have not been well studied in hepatic impairment and cannot be recommended.

In patients with variceal bleeding, nasogastric (NG) suction reduces the risk of aspirating stomach contents. Aspiration pneumonia is a major cause of death in patients with variceal bleeding. NG suction can also decrease vomiting by removing blood from the GI tract during acute episodes of variceal bleeding; blood in the GI tract is very nauseating.

Endoscopic band ligation (application of a stricture around the varix) is used to stop acutely bleeding varices. Band ligation has replaced sclerotherapy (injection of a caustic substance into the varix) as the preferred endoscopic treatment and is effective in stopping acute variceal bleeding in up to 90% of patients.²⁶ It is the standard of care for secondary prophylaxis of repeat bleeding in patients with a history of either esophageal or gastric variceal bleeding. Band ligation is best used in conjunction with pharmacologic treatment.^{27–29}

Balloon tamponade involves the application of direct pressure to the area of bleeding with an inflatable balloon attached to an NG tube. It is an option when drug therapy and band ligation fail to stop variceal bleeding. Balloon tamponade is used only for rescue therapy. Once the direct pressure of the balloon is removed, rebleeding often occurs, so balloon tamponade is only a temporary measure prior to more definitive treatment such as shunting.¹⁰

During episodes of acute HE, temporary protein restriction to decrease ammonia production can be a useful adjuvant to pharmacologic therapy. Long-term protein restriction in cirrhotic patients is not recommended. Cirrhotic patients are already in a nutritionally deficient state, and prolonged protein restriction will exacerbate the problem.¹⁹

Hepatitis A and B vaccination is recommended in patients with cirrhosis to prevent additional liver damage from an acute viral infection.³⁰ Pneumococcal and influenza vaccination may also be appropriate and can reduce hospitalizations.

Shunts are long-term solutions to decrease elevated portal pressure. Shunts divert blood flow through or around the diseased liver, depending on the location and type of shunt employed. Transjugular intrahepatic portosystemic shunts (TIPS) create a communication pathway between the intrahepatic portal vein and the hepatic vein. TIPS procedures have an advantage over surgically inserted shunts because they are placed through the vascular system rather than through more invasive surgical procedures, but they still carry a risk of bleeding and infection. TIPS placement is associated with improvement in HRS but also with an increased incidence of HE.³¹ HE associated with TIPS placement results from decreased detoxification of nitrogenous waste products because the shunt allows blood to evade metabolic processing.

Pharmacologic Therapy

Drug therapy targeted to reduce portal hypertension and cirrhosis can alleviate symptoms and prevent complications but cannot reverse cirrhosis.

► Portal Hypertension

- 4 *Nonselective β -blockers such as propranolol and nadolol are first-line treatments to reduce portal hypertension. They reduce bleeding and decrease mortality in patients with known varices. Use of β -blockers for primary prevention of variceal formation is controversial.*

Only nonselective β -blockers (those that block both β_1 and β_2 receptors) reduce bleeding complications in patients with known varices. Blockade of β_1 receptors reduces cardiac output and splanchnic blood flow. β_2 -Adrenergic blockade prevents β_2 -receptor-mediated splanchnic vasodilation while allowing unopposed α -adrenergic effects; this enhances vasoconstriction of the systemic and splanchnic vascular beds. The combination of β_1 and β_2 blockade makes the nonselective β -blockers preferable to cardioselective agents (those blocking primarily β_1 receptors) in treating portal hypertension.^{1,27,32,33} Although cardioselective β -blockers do lose their cardioselectivity at higher doses, most patients with cirrhosis cannot tolerate the high doses.

Because β -blockers decrease blood pressure and heart rate, they should be started at low doses to increase tolerability; cirrhotic patients often already have low blood pressure and heart rate. Propranolol is hepatically metabolized; initial concentration, half-life, and pharmacologic effects are prolonged in portal hypertension. A reasonable starting dose of propranolol is 10 mg once or twice daily.

Doses should be titrated as tolerated with the goal of decreasing heart rate by 25% or to approximately 55 to 60 bpm.^{10,27} Heart rate is not an accurate predictor of portal pressure reduction, but it is the acknowledged surrogate marker for effectiveness because there are no other acceptable alternatives.

Nitrates have been suggested for patients who do not achieve therapeutic goals (heart rate reduction) with β -blocker therapy alone. Nitrates (e.g., isosorbide mononitrate), both alone and in combination with β -blockers, show enhanced reduction of portal pressure in clinical trials; however, there is an increase in mortality when nitrates are used alone. Patients treated with the combination of nonselective β -blockers and nitrates have significantly more adverse events compared with β -blocker monotherapy.^{34,35} Current evidence only supports use of the combination to prevent rebleeding, not for primary prophylaxis. Unfortunately, β -blockers either alone or in combination may be intolerable for many patients with cirrhosis.

► Ascites

- 5 *The goals of treating ascites are to minimize acute discomfort, reequilibrate ascitic fluid, and prevent SBP. Treatment should modify underlying disease pathology; without directed therapy, fluid will rapidly reaccumulate.*

Acute discomfort from ascites may be ameliorated by therapeutic paracentesis. Often the removal of just 1 to 2 L of ascitic fluid provides relief from pain and fullness. For large volume “taps” (5 L or more), volume resuscitation should be provided with 6 to 8 g of IV albumin per liter of fluid removed. Albumin 25% should be used because it has one-fifth the volume of the 5% product. Large-volume paracentesis without albumin administration is known to precipitate HRS through decreased perfusion. If less than 5 L of fluid is removed in a hemodynamically stable patient, albumin use is not warranted.²¹

► Diuretics

Diuretics are usually required in addition to sodium restriction (see Nonpharmacologic Therapy). **6** *Cirrhosis is a high aldosterone state; spironolactone is an aldosterone antagonist and counteracts the effects of activation of the RAAS. Spironolactone with or without furosemide forms the basis of pharmacologic therapy for ascites.* In hepatic disease, not only is aldosterone production increased, but its half-life is prolonged because of decreased hepatic metabolism. Spironolactone also conserves potassium that would otherwise be excreted because of elevated aldosterone levels.

Spironolactone is typically used with a loop diuretic (e.g., furosemide) for more potent diuresis. A ratio of 40 mg furosemide (the most commonly used loop diuretic) to each

100 mg spironolactone can usually maintain serum potassium concentrations within the normal range. Therapy is commonly initiated with oral spironolactone 100 mg and furosemide 40 mg/day.

Doses should be titrated at intervals no more frequent than every 2 to 3 days. Because spironolactone is used for its antialdosterone effects, higher doses (up to 400 mg/day) are used compared with doses used to treat hypertension. If intolerable side effects such as painful gynecomastia occur with spironolactone, other potassium-sparing diuretics may be used, but clinical trials have not shown equivalent efficacy.²¹

The maximum ascitic fluid that can be removed through diuresis is approximately 0.5 L/day.²¹ Because ascites equilibrates with vascular fluid at a much slower rate than does peripheral edema, aggressive diuresis is associated with intravascular volume depletion rather than depletion of peritoneal fluid. Aggressive diuresis should be avoided unless patients have concomitant peripheral edema. Patients with peripheral edema in addition to ascites may require increasing furosemide doses until euvolemia is achieved; IV diuretics are often necessary.²¹ Diuretic therapy in cirrhosis is typically lifelong.

► Varices

Variceal bleeding is common in cirrhotic patients; it accounts for up to 10% of all cases of upper GI hemorrhage. **7** *During acute variceal hemorrhage, it is crucial to control bleeding,*

Patient Encounter, Part 2

Laboratory results for LT showed the following:

Sodium 126 mEq/L (126 mmol/L)	Albumin 2.3 g/dL (23g/L)
Potassium 2.9 mEq/L (2.9 mmol/L)	Total bilirubin 1.9 mg/dL (32.5 μmol/L)
Chloride 97 mEq/L (97 mmol/L)	Alk phos 213 IU/L (3.55 μkat/L)
Bicarbonate 18 mEq/L (18 mmol/L)	AST 137 IU/L (2.28 μkat/L)
BUN 12 mg/dL (4.3 mmol/L)	ALT 66 IU/L (1.10 μkat/L)
SCr 0.8 mg/dL (71 μmol/L)	INR 1.4
Glucose 114 mg/dL (6.3 mmol/L)	PT 19 seconds
Hemoglobin 7.6 g/dL (76 g/L; 4.7 mmol/L)	GGT 163 IU/L (2.72 μkat/L)
Hematocrit 23% (0.23)	LDH 187 IU/L (3.12 μkat/L)
WBC $5.4 \times 10^3/\text{mm}^3$ ($5.4 \times 10^9/\text{L}$)	Serum NH_3 72 mcg/dL (42 μmol/L)
Platelets $109 \times 10^3/\text{mm}^3$ ($109 \times 10^9/\text{L}$)	Blood alcohol undetectable

Which laboratory values suggest a diagnosis of cirrhosis?

What is the likely cause of LT's mental status change? Are there other conditions that may have contributed to the mental status change?

What is a likely trigger for LT's mental status change?

How does this relate to her complaints of weakness and fatigue?

ALT, alanine aminotransferase; AST, aspartate aminotransferase; GGT, γ-glutamyl transferase; INR, international normalized ratio; IU, international units; LDH, lactate dehydrogenase; PT, prothrombin time.

FIGURE 22-4. Treatment algorithm for active GI bleeding resulting from portal hypertension. (Adapted from Schiano TD, Bodenheimer HC. Complications of chronic liver disease. In: Friedman SL, McQuaid KR, Grendell JH, eds. *Current Diagnosis and Treatment in Gastroenterology*, 2nd ed. New York, NY: McGraw-Hill, 2003:649, with permission).

prevent rebleeding, and avoid acute complications such as SBP. Acute mortality is approximately 20%, with 1-year mortality greater than 60% in patients with very elevated portal pressure; patients must be treated aggressively.⁸ A treatment algorithm for acute variceal bleeding is depicted in [Figure 22-4](#).

Octreotide is a synthetic somatostatin analog; it causes selective vasoconstriction of the splanchnic bed, decreasing portal venous pressure with few serious side effects. The recommended octreotide dose is a 50- to 100-mcg IV loading dose followed by a 25 to 50 mcg/h continuous IV infusion. Therapy should continue for at least 24 to 72 hours after bleeding has stopped. Some clinicians continue octreotide for a full 5 days because this is the time frame during which the risk of rebleeding is highest. Octreotide combined with endoscopic therapy results in decreased rebleeding rates and transfusion needs when compared with endoscopic treatment alone.²⁸

► Spontaneous Bacterial Peritonitis

Prophylactic antibiotic therapy is recommended during acute variceal bleeding to prevent SBP; this is typically

initiated with a third-generation cephalosporin (1 g IV ceftriaxone daily) or a fluoroquinolone (norfloxacin 400 mg orally twice daily, ciprofloxacin 500 mg orally twice daily, or ciprofloxacin 400 mg IV twice daily) for 7 days. If the patient is actively bleeding, consider IV instead of oral therapy. Avoid fluoroquinolone therapy in patients who have used this drug class for long-term prophylaxis; they may have developed fluoroquinolone resistance. Prophylactic antibiotic therapy reduces in-hospital infections and mortality in patients hospitalized for variceal bleeding.³⁴

If SBP is suspected, empiric antibiotic therapy should be initiated with a broad-spectrum anti-infective agent after ascitic fluid collection, pending cultures and susceptibilities ([Fig. 22-5](#)).^{36,37} In the setting of presumed infection, delaying treatment while awaiting laboratory confirmation is inappropriate and may result in death. The initial antibiotic should be an IV third-generation cephalosporin (e.g., cefotaxime 2 g every 8 hours, ceftriaxone 1 g every 24 hours), an IV extended-spectrum penicillin (e.g., piperacillin-tazobactam 3.375 g every 6 hours or 4.5 g every 8 hours), or an IV fluoroquinolone (e.g., ciprofloxacin 400 mg IV every 12 hours; only if the patient has not received long-term prophylaxis with

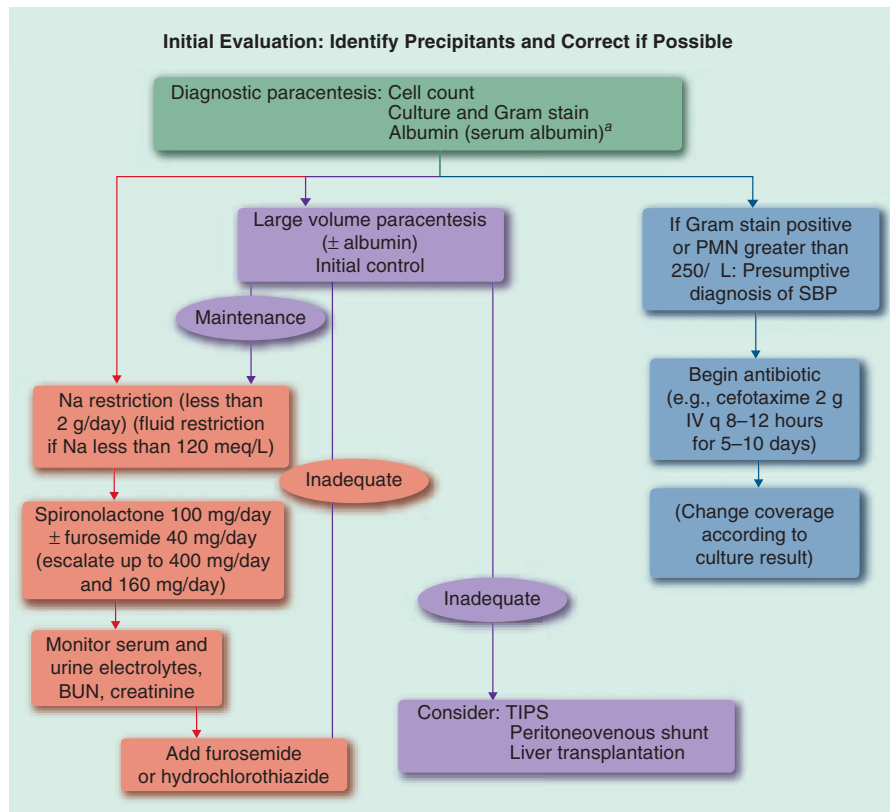

FIGURE 22-5. Approach to the patient with ascites and spontaneous bacterial peritonitis (SBP). (BUN, blood urea nitrogen; Na, sodium; PMN polymorphonuclear leukocyte; TIPS, transjugular intrahepatic portosystemic shunt.) (From Chung RT, Podolsky DK. Cirrhosis and its complications. In: Kasper DL, Braunwald E, Fauci AS, et al., eds. *Harrison's Principles of Internal Medicine*, 17th ed. New York, NY: McGraw-Hill, 2005:1858–1869, with permission.)

^aIf PMN is greater than 250/ μ L ($250 \times 10^6/L$) but culture is negative (culture-negative neutrocytic ascites), begin empiric antibiotics and retap after 48 hours. If culture is positive but PMN less than 250/ μ L ($250 \times 10^6/L$), treat as if PMN greater than 250/ μ L ($250 \times 10^6/L$) (presumed SBP). If polymicrobial infection exists, exclude SBP.

a fluoroquinolone). These agents cover the most common gram-negative and gram-positive agents implicated in SBP. Third-generation cephalosporins are usually recommended as first-line therapy. Local resistance patterns must be taken into account when choosing empiric antibiotic therapy. Once a bacterial pathogen has been identified, coverage may be narrowed to an agent that is highly active against that particular organism. SBP is rarely polymicrobial.

SBP has been identified as a cause of HRS. The risk of renal failure is reduced with IV albumin therapy, dosed at 1.5 g/kg of body weight initially, followed by 1 g/kg of body weight on day 3 of SBP therapy.³⁸

8 Long-term antibiotic prophylaxis for SBP decreases mortality and is recommended in patients with a history of SBP or low-protein ascites (ascitic fluid albumin less than 1.5 g/dL [15 g/L]) plus one of the following: SCr 1.5 mg/dL (133 μ mol/L) or greater, BUN ≥ 25 mg/dL (8.9 mmol/L) or greater, serum sodium 130 mEq/L (130 mmol/L) or less, or Child–Pugh score of at least 9, with bilirubin of at least 3 mg/dL (51.3 μ mol/L). Recommended oral regimens include one trimethoprim–sulfamethoxazole double-strength tablet daily, norfloxacin 400 mg daily, or ciprofloxacin 750 mg daily.¹⁸

► Encephalopathy

Lactulose **9** Lactulose is the foundation of pharmacologic therapy to prevent and treat HE. It is a nondigestible synthetic disaccharide laxative that is hydrolyzed in the gut to an osmotically active compound that draws water into the colon and stimulates defecation. Lactulose lowers colonic pH, which favors the conversion of ammonia (NH_3) to ammonium (NH_4^+).³⁹ Ammonium is ionic and cannot cross back from the gut into systemic circulation; it is eliminated in the feces. Lactulose is usually initiated at 15 to 30 mL two to three times per day and titrated to a therapeutic goal of two to four soft bowel movements daily.^{19,40,41}

Antibiotic Therapy Rifaximin is a nonabsorbable antibiotic that is used extensively in Europe as first-line therapy for HE. Rifaximin decreases urease-producing gut bacteria, which decreases ammonia production. Rifaximin therapy has been shown to be both efficacious and well tolerated, but its expense in the United States (it is only licensed for HE prophylaxis, not treatment) may be prohibitive for long-term use. The rifaximin dose is 550 mg twice daily given with lactulose. At this dose it costs approximately 10-fold more

Patient Encounter, Part 3

While in the ED, LT was given 3 units of packed red blood cells and ceftriaxone 1 g IV. She was taken for an endoscopy, but she did not have any actively bleeding varices. She developed mild itching, and the antibiotic was discontinued. About 6 hours later LT is awake and oriented. When her husband is out of the room, she does admit to heavy alcohol use. She also states that she has had dark tarry stools for about a week, and 3 days prior to admission she began vomiting. She states that the emesis “looked like coffee grounds.”

What pharmacologic and nonpharmacologic interventions are needed to prevent progression of cirrhosis and future decompensation?

than lactulose. Another commonly used regimen is 400 mg every 8 hours for 5 to 10 days.

Metronidazole and neomycin have also been used to treat hepatic encephalopathy but are not generally recommended because of toxicity; metronidazole is associated with peripheral neuropathy with prolonged use, and although neomycin is classified as a nonabsorbable antibiotic, patients with cirrhosis have detectable plasma concentrations. This is thought to be due to decreased integrity of the intestinal mucosa and may lead to nephrotoxicity. Neomycin should not be used.

Flumazenil Evidence for false transmitters as the cause of encephalopathy is demonstrated by the fact that administration of flumazenil (a benzodiazepine antagonist) has resulted in functional improvement. Unfortunately, long-term benefit has not been shown, and because flumazenil can only be administered parenterally, it is not an appropriate choice for clinical use. Flumazenil use is limited to the research setting.

Hepatorenal Syndrome

HRS is a life-threatening complication of cirrhosis. Targeted treatment increases central venous system volume. Peripheral vasoconstriction redistributes fluid from the periphery to the venous system; fluid is retained in the vascular space by administering albumin (to increase oncotic pressure). The ultimate goal is to increase renal perfusion.

A common regimen involves giving albumin 1 g/kg on day 1, followed by 20 to 40 g on subsequent treatment days. This regimen is used in combination with midodrine (an α -agonist) and octreotide. Midodrine is typically initiated at 7.5 mg orally three times daily, and octreotide is administered subcutaneously (as opposed to IV during variceal bleeding) 100 mcg three times daily. Both drugs can be titrated as tolerated to achieve increases in mean arterial pressure of 15 mm Hg or greater.

Terlipressin, a vasopressin analog available in Europe, has been used with success in patients with HRS, but it is not currently available in the United States.

Patient Encounter, Part 4

The next day, LT’s mental status declines; she becomes somnolent and irritable. On physical examination her abdomen is tender to mild palpation.

VS: BP 98/70 mm Hg, P 102 bpm, T 101.9°F (38.8°C), RR 18 breaths/min, oxygen saturation 98% (0.98) on room air.

The medical resident suspects SBP and orders a paracentesis. The ascitic fluid shows PMN 300 cells/ μ L (300×10^6 /L), gram stain negative, SAAG 1.4 g/dL (14 g/L).

What is the implication of the ascitic fluid findings?

Should you wait for the culture results to be sure there is actually an infection before starting antibiotics?

If antibiotics are indicated, what drug(s) and regimen(s) would you recommend?

What additional treatment should she receive?

If SBP is not treated appropriately, what are potential clinical consequences?

Is LT a candidate for long-term antibiotic prophylaxis?

What are the feasible options for long-term antibiotic prophylaxis?

► Coagulation Abnormalities

Vitamin K is essential to produce active coagulation factors in the liver. Elevated clotting time resulting from decreased protein synthesis is indistinguishable from that produced by low vitamin K levels secondary to malnutrition or poor intestinal absorption. When given subcutaneously (10 mg for 3 days), Vitamin K₁ (phytonadione) can replete stores and establish if coagulation abnormalities are secondary to decreased synthetic function alone. It is unusual to completely reverse clotting abnormalities, but most patients experience a decrease in international normalized ratio (INR), conferring a decreased risk of bleeding. Because cirrhotic patients may have decreased bile production resulting in decreased absorption of fat-soluble vitamins, phytonadione should be given subcutaneously instead of orally to ensure absorption.

OUTCOME EVALUATION

- Reevaluate the pharmacotherapy regimen at each visit to assess adherence, effectiveness, adverse events, and need for drug titration.
- Determine adherence to lifestyle changes such as cessation of ethanol intake and avoidance of over-the-counter medications (particularly NSAIDs and acetaminophen) and herbal remedies that may exacerbate complications of cirrhosis.
- Assess the effectiveness of β -blocker therapy by measuring heart rate. Heart rate reduction of 25% from baseline or to 55 to 60 bpm is desirable. Ask the patient specific, directed questions regarding adverse effects

- of β -blockers; inquire about symptoms of orthostatic hypotension (e.g., lightheadedness, dizziness, or fainting).
- Evaluate effectiveness of diuretic therapy with regard to ascitic fluid accumulation and development of peripheral edema. Ask the patient directed questions regarding abdominal girth, fullness, tenderness, and pain. Weigh the patient at each visit, and ask the patient to keep a weight diary. Assess for peripheral edema at each visit.
 - Assess dietary sodium intake by patient food recall. Measure dietary sodium adherence using spot urine sodium-to-potassium ratio. Assess for appropriate sodium excretion.
 - Obtain complete blood count and prothrombin time (PT)/INR to assess for anemia, thrombocytopenia, or coagulopathy. Ask about bruising, bleeding, hematemesis, hematochezia, and melena to assess for bleeding.
 - Review biopsy reports and laboratory data. Hepatic transaminases and blood ammonia levels do not correlate well with disease progression, but increased coagulation times are markers of loss of synthetic function.
 - Evaluate for signs and symptoms of HE. Mental status changes may be subtle; questioning family members

or caregivers about confusion or personality changes may reveal mild HE even if the patient is unaware of deficits.

- In patients taking lactulose therapy, titrate the dose to achieve two to four soft bowel movements daily.

Abbreviations Introduced in This Chapter

ADH	Alcohol dehydrogenase
ALT	Alanine aminotransferase
AST	Aspartate aminotransferase
BUN	Blood urea nitrogen
CYP450	Cytochrome P-450 isoenzyme
GGT	γ -Glutamyl transpeptidase
HE	Hepatic encephalopathy
HRS	Hepatorenal syndrome
INR	International normalized ratio
LDH	Lactate dehydrogenase
MELD	Model for End-Stage Liver Disease
NAFLD	Nonalcoholic fatty liver disease
NG	Nasogastric
NH ₃	Ammonia
NH ₄ ⁺	Ammonium
NSAID	Nonsteroidal anti-inflammatory drug
PT	Prothrombin time
RAAS	Renin-angiotensin-aldosterone system
SAAG	Serum ascites-albumin gradient
SBP	Spontaneous bacterial peritonitis
TIPS	Transjugular intrahepatic portosystemic shunt

Patient Care and Monitoring

1. Obtain a complete history of alcohol intake and hepatotoxic drug use, including over-the-counter products and dietary supplements.
2. At each encounter, ask the patient specific questions about adherence to prescribed therapy, dietary restrictions, and cessation of alcohol intake.
3. At each visit, evaluate the pharmacotherapy regimen for appropriate drug choice and dose, nonprescription drug use, adverse effects, and use of potentially hepatotoxic medications.
4. Question the patient about adverse effects because hepatically metabolized medications may accumulate and cause adverse effects.
5. Consider antibiotic prophylaxis for SBP in patients with low-protein ascites or prior SBP.
6. Conduct a review of systems and physical examination at each visit to determine if the patient has had progression of complications.
7. Ask specific questions about bleeding, bruising, and fatigue. There is a direct link between loss of synthetic function and disease progression.
8. Refer the patient to substance abuse counseling for education about alcohol cessation if appropriate.
9. Provide education regarding dietary sodium restriction at each visit; consider referral to a dietician if appropriate.

Pancreatitis

Janine E. Then and Heather M. Rouse

LEARNING OBJECTIVES

● Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of acute and chronic pancreatitis.
2. Differentiate acute from chronic pancreatitis.
3. Discuss the clinical implications of pancreatic fluid collections, pancreatic abscess, and pancreatic necrosis in acute pancreatitis.
4. Formulate care plans for managing acute pancreatitis.
5. Identify pharmacologic and nonpharmacologic means of preventing repeat episodes of chronic pancreatitis.
6. Choose appropriate pancreatic enzyme supplementation for patients with chronic pancreatitis.

KEY CONCEPTS

- 1 The most common causes of acute and chronic pancreatitis in adults are ethanol abuse and biliary stones.
- 2 Pancreatic necrosis occurs within the first 2 weeks of acute pancreatitis and develops in 10% to 20% of patients with acute pancreatitis.
- 3 Therapy of acute pancreatitis is primarily supportive unless a specific etiology is identified. Supportive therapy involves fluid repletion, nutrition support, and analgesia.
- 4 Medications aimed at decreasing pancreatic enzyme release, nasogastric suction, and anticholinergic medications have not shown benefit in the treatment of acute pancreatitis.
- 5 Long-term sequelae of chronic pancreatitis include dietary malabsorption, impaired glucose tolerance, cholangitis, and potential addiction to opioid analgesics.
- 6 Treatment of chronic pancreatitis is aimed at removing the cause (ethanol abuse, cigarette smoking, or biliary stones), providing analgesia, supplementing with pancreatic enzyme preparations, and implementing dietary restrictions.

INTRODUCTION

The pancreas is a gland in the abdomen lying in the curvature of the stomach as it empties into the duodenum. The pancreas

functions primarily as an exocrine gland, although it also has endocrine function. The exocrine cells of the pancreas are called **acinar cells** that produce and store various digestive enzymes that mix with a bicarbonate-rich solution released from duct cells to produce pancreatic juice. This pancreatic juice is released through the **ampulla of Vater** into the duodenum to aid in the digestive process as well as buffer acidic fluid released from the stomach (**Fig. 23–1**).¹

These enzymes are produced and stored as inactive proenzymes within **zymogen** granules to prevent autolysis and digestion of the pancreas. The zymogen granules are also responsible for enzyme transport to the pancreatic duct. Amylase and lipase are released from the zymogen granules in the active form, whereas the proteolytic enzymes are activated in the duodenum by enterokinase. Enterokinase triggers the conversion of trypsinogen to the active protease **trypsin**, which then activates the other proenzymes to their active enzymes. The pancreas contains a trypsin inhibitor to prevent autolysis.

ACUTE PANCREATITIS

EPIDEMIOLOGY AND ETIOLOGY

1 *In the Western Hemisphere, acute pancreatitis is caused mainly by ethanol use/abuse and gallstones (cholelithiasis). Ethanol use accounts for about 30% of acute pancreatitis cases and gallstones about 30% to 40% of cases. Other common causes of acute pancreatitis include hypertriglyceridemia,*

FIGURE 23-1. Anatomical structure of the pancreas and biliary tract. (From Bolesta S, Montgomery PA. Pancreatitis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011; Figure 46-1, with permission.)

endoscopic retrograde cholangiopancreatography (ERCP), pregnancy, and autodigestion due to early activation of pancreatic enzymes. Numerous medications have also been implicated as causes of acute pancreatitis, but other causes should be ruled out before discontinuing a medication indefinitely (Table 23-1).²

PATHOPHYSIOLOGY

Ethanol abuse may cause precipitation of pancreatic enzymes in the ducts of the pancreas, leading to chronic inflammation

Table 23-1

Selected Medications Associated with Acute Pancreatitis

Definite Association	Probable Association
5-Aminosalicylic acid	Angiotensin-converting enzyme inhibitors
Asparaginase	HMG-CoA reductase inhibitors
Azathioprine	Cimetidine
Corticosteroids	Didanosine
Didanosine	Cisplatin
Estrogens	Clozapine
Furosemide	Ethacrynic acid
6-Mercaptopurine	Indinavir
Cytarabine	Interferon α -2b
Pentamidine	Lamivudine
Sulfonamides	NSAIDs
Sulindac	Propofol
Tigecycline	Salicylates
Valproic acid/salts	Thiazide diuretics
	Zalcitabine

Adapted from Bolesta S, Montgomery PA. Pancreatitis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. *Pharmacotherapy: A Pathophysiologic Approach*, 8th ed. New York, NY: McGraw-Hill, 2011; Table 46-2, with permission.

and fibrosis resulting in loss of exocrine function. Ethanol itself may be directly toxic to the pancreatic cells and may lead to an upregulation of enzymes that produce toxic metabolites leading to further damage.³ Gallstones can obstruct the ampulla of Vater causing pancreatic enzymes or bile to move in a retrograde fashion into the pancreas. This retrograde movement may be responsible for pancreatic autolysis.¹

Autolysis of the pancreas can occur when zymogens are activated in the pancreas before being released into the duodenum. Acute pancreatitis can result from the initial injury to the zymogen-producing cells, which is followed by neutrophil, lymphocyte, and macrophage invasion of the pancreas and further activation of enzymes within the pancreas. This cascade of events is destructive to the pancreas and harmful to the patient.
