Vaugeois et al. (1996) described a genetic mouse model of helplessness sensitive to imipramine. Lines of mice were selectively bred to diverge in their spontaneous helplessness in the tail-suspension test. By the second generation of selection, only mice of the helpless line were sensitive to the antidepressant imipramine.

Mayorga and Lucki (2001) demonstrated limitations on the use of the C57BL/6 mouse in the tail-suspension test. Under baseline conditions, the majority of C57BL/6 mice climbed up their tails during the 6-min test session. The occurrence of this behavior was not found in other strains of mice.

Liu and Gershenfeld (2001) found genetic differences in the tail-suspension test among 11 inbred strains of mice as far as basal immobility was concerned. Surprisingly, the reduction of immobility by imipramine was independent of basal immobility.

Ripoli et al. (2003) tested antidepressant-like effects in various mice strains in the tail-suspension test and found considerable differences depending on strain and test drug.

Shearman et al. (2003) tested antidepressant-like effects of a cannabinoid CB1 receptor inverse agonist in mice using an automated tail-suspension apparatus (TSE Systems, Bad Homburg, Germany) with a tail hanger connected to a precision load cell. Mice remained suspended by the tail, at a height of 35 cm from the tabletop, for 6 min. During this time the load cell recorded the mouse's movements and transmitted the information to a computer, which then recorded the rate of immobility within the course of the session, and calculated total duration of immobility.

E.6.2.4 Learned Helplessness in Rats

PURPOSE AND RATIONALE

Animals exposed to inescapable and unavoidable electric shocks in one situation later fail to escape shock in a different situation when escape is possible (Overmier and Seligman 1967; Maier and Seligman 1976). This phenomenon was evaluated as a potential animal model of depression (Sherman et al. 1979; Martin et al. (1986), Christensen and Geoffroy 1991; Tejedor del Real et al. 1991; Weiss and Kilts 1998).

PROCEDURE

Learned helplessness is produced in male Sprague-Dawley rats (300 g) by exposure to electric shock (0.7 mA) for 1 h on a schedule of 10 s of shock/min. The apparatus is a $30 \times 45 \times 30$ cm box with a grid floor. At a height of 20 cm above the floor, a platform (7.5×7.5 cm) can be inserted through one side wall to allow a jump-up escape response. The platform is not available during training. After the appropriate treatment, the animals are tested for acquisition of a jump-up escape in the same apparatus. At the beginning of a trial, the platform is pushed into the box and a 0.4 mA shock initiated. Shock is terminated in 10 s if the animal has not escaped onto the platform by this time. If an escape response occurred, the animal is allowed to remain on the platform for the duration of 10 s, then returned to the grid floor. Ten such trials with an intertrial interval of 20 s are given. In a naive control group of rats, this training resulted in 80% acquiring learned helplessness behavior. Drugs are given before the training and the test period.

EVALUATION

A drug is considered to be effective, if the learned helplessness is reduced and the number of failures to escape is decreased. Imipramine was found to be active only after repeated applications. A benzodiazepine was effective, whereas chlorpromazine was ineffective.

CRITICAL ASSESSMENT OF THE METHOD

The "learned helplessness" in the rat can be regarded as an additional measure for antidepressant activity in addition to other tests. The test is time consuming and its specificity is questionable. The major drawback of the model is that most of the depression-like symptomatology does not persist beyond 2–3 days following cessation of the uncontrollable shock.

MODIFICATIONS OF THE METHOD

Vaccheri et al. (1984) used an apparatus with an lever to be pressed to interrupt the shock. Giral et al. (1988), Porsolt et al. (1990) Simiand et al. (1992) used shuttle-boxes for escape.

Curzon et al. (1992) described a similar rat model of depression. Rats were tested in an open field after being restrained by taping them to wire grids for two h on the preceding day. The reduced activity is antagonized by antidepressant drugs.

A modification of the test incorporating aspects of chronic mild stress paradigm was described by Gambarana et al. (2001) A model of anhedonia is based on the finding that exposure to repeated unavoidable stress prevents the development of an appetitive behavior induced and maintained by a highly palatable food (vanilla sugar) in rats fed ad libitum (Ghiglieri et al. 1997).

The chronic stress procedure involves restraint and novel housing, and avoids the problems associated with food deprivation (Reid et al. 1997).

Vollmayr et al. (2001) studied brain-derived neurotrophic factor (BDNF) stress responses in rats bred for learned helplessness in a system provided by TSE Systems, Bad Homburg, Germany. Two strains of rats were bred, one which reacts with congenital helplessness to stress, and one which congenitally does not acquire helplessness when stressed. In rats with congenital helplessness, acute immobilization stress does not induce a reduction of BDNF expression in the hippocampus, which is observed in Sprague Dawley rats that do not acquire helplessness.

Vollmayr and Henn (2001) proposed key factors that can be manipulated to enhance both the usability and the reliability of the rat helplessness paradigm.

Rats bred for congenital learned helplessness (King et al. 1993; Shumake et al. 2000) responded less to sucrose but did not show deficits in activity or learning (Vollmayr et al. 2004).

E.6.2.5 Muricide Behavior in Rats

PURPOSE AND RATIONALE

Horovitz et al. (1965) described a selective inhibition of mouse-killing behavior in rats (Karli 1956; Karli et al. 1969) by antidepressants. The test can be used to evaluate antidepressants such as tricyclics and MAO-inhibitors.

PROCEDURE

Male Sprague-Dawley rats (300–350 g) are isolated for 6 weeks in individual cages. They have access to food and water ad libitum. One mouse is placed into the rat's cage. About 10 to 30% of rats kill the mouse by biting the animal through the cervical cord. Only rats consistently killing mice within 5 min after presentation are used for the test. The mice are removed 15 to 45 s after they have been killed in order to prevent the rats from eating them. Drugs are injected i.p. to the rats before the test. Mice are presented 30, 60 and 120 min after drug administration.

EVALUATION

Failure to kill a mouse within 5 min is considered inhibition of muricidal behavior. Performing dose-response experiments, the ED_{50} is defined as the dose which inhibits mouse killing in 50% of the rats.

MODIFICATIONS OF THE METHOD

Injections of 5,7-dihydroxytryptamine into the lateral hypothalamus increased mouse-killing behavior in rats (Vergnes and Kempf 1982).

Molina et al. (1985) considered rats isolated for at least one month which do not kill mice in a 30 min test period as spontaneous non-killer rats. In these animals, mouse-killing behavior could be induced by i.p. injection of 150 mg/kg p-chlorophenylalanine daily for 2 days or by electrolytic lesions in the dorsal and median raphe.

McMillen et al. (1988) studied the effects of housing and muricidal behavior on serotonergic receptors and interactions with novel anxiolytic drugs.

CRITICAL ASSESSMENT OF THE METHOD

The mouse-killing behavior is inhibited not only by anti-depressants but also by central stimulants like d-amphetamine (Horovitz et al. 1966; Sofia 1969a, b), some antihistamines (Barnett et al. 1969), and some

cholinergic drugs (McCarthy 1966; Vogel and Leaf 1972; Wnek and Leaf 1972). Neuroleptics and benzodiazepines are active only in doses which impair motor performance.

E.6.2.6 Behavioral Changes After Neonatal Clomipramine Treatment

PURPOSE AND RATIONALE

Vogel et al. (1988, 1990a), Hartley et al. (1990) reported that neonatally administered clomipramine produces changes in adult rats that resembles endogenous depression in man, based on earlier observations by Mirmiran et al. (1981), Rodriguez-Echandia and Broitman (1983). This phenomenon has been studied by several research groups in many respects (Neill et al. 1990; Vogel et al. 1990b–e, 1996a, b; Velazquez-Moctezuma and Diaz-Ruiz 1992; Yavari et al. 1993; Maudhuit et al. 1995, 1996; Prathiba et al. 1995, 1997, 1998, 1999; Feenstra et al. 1996; Kinney et al. 1997; Bonilla-Jaime et al. 1998; Dwyer and Rosenwasser 1998).

PROCEDURE

Three days after birth, all male pups of Sprague Dawley mother rats are cross-fostered and all female pups are killed. Cross-fostering consists of removing all pups from their biological mothers and placing them with another lactating female (the non-biological foster mother). Each litter is divided into two groups of approximately equal number. Each half of the litter is placed with a different lactating female (the foster mother), and each foster mother receives half the pups from two litters. All pups with each foster mother receive the same treatment (clomipramine or saline) and the two pup groups of each original litter are assigned to different treatments. Thus, each original pup litter contributes equally to experimental and control groups. Each pup is injected subcutaneously between the shoulder blades with 15 mg/kg clomipramine hydrochloride or saline vehicle twice daily on postnatal days 8 through 21. At one month of age the pups are weaned and housed as litters until approximately 3 weeks prior testing, at which time they are individually housed.

All testing is conducted in a Coulbourn operant conditioning chamber (Lehigh Valley, PA) placed in a quiet area. The floor rods are connected with a shock generator and a shock scrambler.

Behavioral testing is commenced at 3 months postnatally. Each test pair consists of one clomipramine-treated and one vehicle-treated rat. Prior to testing, all clomipramine- and saline-treated rats are paired by body weight (within 5 grams) to diminish size differences that could affect behavioral results. Pairs remain the same throughout the testing.

For evaluation of drugs, clomipramine-treated rats are administered subcutaneously for 4 days twice daily saline, or standard drug (10 mg/kg imipramine), or test drug.

Tests are done daily for 4 days. On the first day, the animals are placed in the chamber for 12 min habituation. On days 2–4, the sessions start with a 2 min

habituation period followed by 10 min of shock delivery. Shocks (1.33 mA, 0.5 s duration) are delivered on a variable schedule with a minimum of 5 and a maximum of 10 s shock intervals. This results in a total of 70–80 shocks within the 10-min session.

Two observers score simultaneously. Each watches one rat of the pair. The rats are identified by a red mark on the fur. The behaviors produced are almost totally in response to shock delivery; both animals are almost immobile between the shocks. Both observers are blind to the treatment conditions of the animals.

Offensive and defensive behaviors are scored including the following 4 behaviors:

1. An upright position which is part of a mutual upright posture in which the dominant rat towers over the submissive rat. The submissive rat rears on its hindlegs, with the head positioned at an upward angle, the forepaws extended toward the attacking animal, and the ventral surface of the body continually facing the opponent.
2. In the offensive crouch, the dominant animal turns its flank towards the subordinate; the submissive crouch is characterized by freezing in a motionless crouching position.
3. Mounting behavior is frequently seen and is the same as seen in the male prior to copulating with a female.
4. Leaps in response to the shock which are directed to the other rat are scored as aggressive responses.

Three defensive or submissive behaviors were observed:

1. Defensive upright posture;
2. submissive crouch;
3. a supine position in submission to the dominant rat.

In this system each offensive behavior by one rat is partly defined by a defensive behavior of the other rat and vice versa.

EVALUATION

The individual behaviors of the treatment and control groups are listed for offensive and defensive behavior on days 1, 2, and 3 and the total of scores calculated for each group. Analysis of variance is applied to offensive, defensive, difference (offensive minus defensive) and total (offensive plus defensive behavior scores. Rats treated postnatally with clomipramine have significantly fewer offensive and significantly more defensive behaviors. This effect is ameliorated by treatment with antidepressant drugs.

CRITICAL ASSESSMENT OF THE TEST

Not only clomipramine, but also other psychotropic drugs induce changes in behavior of adult rats after treatment in neonatal age (Drago et al. 1985; Frank and Heller 1997; Hansen et al. 1998), however, clomipramine induces the most pronounced effects (Velazquez-Moctezuma et al. 1993; Vogel and Hagler 1996; Hansen et al. 1997). Specificity of the procedure to evaluate potential antidepressant compounds remains to be established.

MODIFICATIONS OF THE METHOD

Neonatal treatment with clomipramine not only reduces shock induced aggression, but also induces REM sleep abnormalities (Mirmiran et al. 1981; Vogel et al. 1990b,c; Frank and Heller 1997), decreases intracranial self-stimulation (Vogel et al. 1990d), increases activity in open-field tests in adulthood (Hartley et al. (1990, Prathiba et al. 1997), increases immobility in the forced swim test (Velazquez-Moctezuma and Diaz-Ruiz 1992), reduces adult male rat sexual behavior (Neill et al. 1990; Velazquez-Moctezuma et al. 1993; Vogel et al. 1996; Bonilla-Jaime et al. 1998,), influences the hypothalamic-pituitary-adrenal axis in adult rats (Feenstra et al. 1996; Prathiba et al. 1998, 1999). Vázquez-Palacios et al. (2005) studied antidepressant effects of nicotine and fluoxetine in the animal model of depression induced by neonatal treatment with clomipramine.

E.6.2.7 Chronic Stress Model of Depression

PURPOSE AND RATIONALE

The chronic mild stress paradigm was developed in order to simulate in animals the symptom of anhedonia, a major feature of depression (Willner et al. 1987, 1992; Forbes et al. 1996; Willner 1997; Willner and Mitchell 2002; Grippo et al. 2003; Konkle et al. 2003; Pijlman et al. 2003; Strekalova et al. 2004). The model has been used to test compounds with antidepressant activity (Moreau et al. 1996; Kopp et al. 1999; Papp and Wieronska 2000; Harkin et al. 2002; Ducottet et al. 2003; Gabriel et al. 2005).

The stress regime was modified by several authors.

The stress regimen used by Moreau et al. (1996) consisted of exposing male Wistar rats each week to a variety of unpredictable, mild stressors such as repeated 1-h periods of confinement to small cages with bells ringing every 10 min, one period of overnight illumination, one overnight period of food and water deprivation immediately followed by 2 h of access to restricted food, one overnight period of water deprivation followed by 1 h exposure to an empty bottle, and one overnight period of group housing in a damp cage.

Grippo et al. (2003) exposed male Sprague Dawley rats to the following stressors in random order: continuous overnight illumination, 40° cage tilt along the vertical axis, paired housing, soiled cage, exposure to an empty water bottle immediately following a period of acute water deprivation, stroboscopic illumination, and white noise.

Ducottet et al. (2003) studied the effects of a selective non-peptide corticotropin-releasing factor receptor 1 antagonist in a mild stress model of depression in **mice**. The method is based on a regimen published by Kopp et al. (1999) and by Griebel et al. (2002a, 2002b).

PROCEDURE

Male BALB/cByJIco mice, aged 9 weeks at the beginning of chronic mild stress experiments, were housed for 1 week individually in small cages with food and water ad libitum at a 12/12 h light/dark cycle and 21°C. The chronic mild stress procedure consists of restraint in a small tube for 1 h, forced bath in water at 32°C for 30 min, water and food deprivation for 15 h, paired housing in damped sawdust for 18 h, food restriction for 3 h, access to an empty water bottle for 2 h, and inversion of the light/dark cycle. Over 3 weeks, four to six of these procedures were applied every day in random order. Physical state was controlled weekly using a scale from 1 to 3 using piloerection, dirty fur, and body weight as symptoms. At the end of the experiment, the mice were subjected to a light/dark test.

Treatment started at week 5, while the stress regimen was continuing. Mice were divided into three groups ($n = 20$) each subjected to a 5-week period of chronic mild stress before being administered during a 4-week period with one of the following treatments: vehicle, daily i.p. injections of 10 mg/kg fluoxetine as standard, or test drug.

EVALUATION

Data were analyzed using non-parametric exact analyses including the Monte Carlo correction. Data of physical state were analyzed with a Friedman test, followed by a Wilcoxon signed ranks test comparing initial week with chronic mild stress weeks and treatment weeks. Data of body weight were treated with a Kruskal-Wallis test for each week followed by a permutation test for two independent samples. The light/dark test was submitted to a Kruskal-Wallis test followed by an a posteriori permutation test.

MODIFICATIONS OF THE METHOD

Since the incidence of clinical depression is significantly higher in woman than in men, Konkle et al. (2003) compared the effects of 6 weeks of chronic mild stress administration among female and male rats of Sprague Dawley and of Long Evans strains.

Matthews and Robbins (2003) reported that a specific periodic neonatal maternal separation procedure leads to a robust constellation of behavioral changes in the adult rat that resembles core aspects of anhedonia in men.

Sammut et al. (2001, 2002) studied antidepressant reversal of interferon-α-induced anhedonia utilizing a three-bottle test (Muscat et al. 1991). A drinking and feeding monitoring system (TSE, Systems Bad Homburg, Germany) was used. In this test, three concentrations of sucrose (1%, 8%, and 32%) are simultaneously presented to each individually caged rat. The three-bottle test allows demonstration of the monotonic relationship between intake and hedonic value as is characteristic of human studies.

E.6.2.8 Novelty-Induced Hypophagia Test

PURPOSE AND RATIONALE

The onset of the therapeutic response to antidepressant treatment exhibits a characteristic delay. While acute antidepressant treatment increases synaptic monoamines within minutes to hours, weeks of sustained treatment are required to induce therapeutic effects (Blier 2003). Few models have been developed in which chronic, but not acute, antidepressant treatment alters behavior (Brodnoff et al. 1988, 1989; Borsini et al. 2002; Cyran et al. 2002; Cyran and Mombereau 2004). Dulawa et al. (2004) and Dulawa and Hen (2005) used the novelty-induced hypophagia test to study chronic antidepressant effects in mice.

PROCEDURE

For chronic testing, male Balb/cL mice were given various doses of test compound in the drinking water. On day 23 of treatment, mice were singly housed. They were trained to drink sweetened condensed milk for three consecutive days presented for 30 min each day in 10-ml serological pipettes with sippers attached with parafilm. Home cage testing occurred on day 28 when mice were briefly removed from their cages to position pipettes containing milk, and testing began when mice were returned to their home cages. The latency to drink and the volume consumed were recorded every 5 min for 30 min. Home cage testing occurred under dim lighting. Novel cage testing occurred on day 29, when mice were placed into new clean cages with the same dimensions but without shavings, with pipettes containing the milk positioned. Novel cage testing occurred under bright lighting with white paper under cages to enhance aversiveness. Again, the latency to drink and the volume consumed were recorded every 5 min for 30 min. For latency scores, a maximum cutoff of 600 s was used.

EVALUATION

Two-factor ANOVA with the home/novel cage condition as a within-subjects factor was applied to latency values. For consumption data, a three-factor ANOVA with block (5-min intervals) and the home/novel cage condition as within-subject factors and drug as a between-subject factor was used to assess whether the novel cage was sufficiently anxiogenic to reduce consumption.

E.6.2.9 Reduction of Submissive Behavior

PURPOSE AND RATIONALE

Pairs of rats competing for food develop a dominant/submissive behavior, which can be measured in a competition test as the relative success of two food-restricted rats to gain access to a sweetened milk supply. Submissive behavior for one subject can be objectively measured as the amount of time spent at the feeder relative to that by the paired dominant animal. Malatynska and Kostowski (1984), Malatynska et al.

(1995, 2002), and Knapp et al. (2002) described reduction of submissive behavior in rats as a test for antidepressant drug activity.

PROCEDURE

Drugs were given by i.p. injection once a day during the treatment period (including weekends). On weekdays, drugs were administered 1 h before behavioral testing. The testing apparatus and the reduction of submissive behavior model procedure are described by Malatynska et al. (2002).

The apparatus was constructed at OmniTech (Columbus, OH) according to a design by Malatynska and Kostowski (1984). The transparent Plexiglas apparatus consisted of two identical chambers ($24 \times 17 \times 14$ cm) connected by a $4.5 \times 4.5 \times 52$ cm passage. In the middle of the passage, a 10-ml glass beaker was placed into a hole cut in the floor of the passage. Prior to behavioral testing, the beaker was filled with sweetened milk (10 g sucrose/cup) through a hinged door in the ceiling of the passage.

The animals were randomly assigned to pairs prior to testing. They were group-housed four to a cage between testing sessions so that paired animals were always separated. Behavioral testing was performed once a day for a 5-min period on weekdays. During the testing period, an animal received one point when it was observed drinking milk during each 5-s interval of the 5-min period. Four different observers contributed to scoring different animal pairs and all were blinded to the treatment animals received. The design of the apparatus permits only one animal to drink at a time but it is possible for both animals to have consumed milk during an interval. At the end of the 5-min period, the animals were returned to their home cages and given free access to food for 1 h. The animals were also given free access to food from the Friday afternoon following testing to the Sunday afternoon when they were once again food-deprived. The animals showed normal weight gain during the course of the study.

EVALUATION

Each animal of the pair was scored on each testing day for 2 weeks. Week 2 data for the two animals of a pair were tested for significant differences using the two-tailed *t*-test assuming unequal variance. The member of a pair having a significantly lower drinking score ($p < 0.05$) was defined as "submissive" and the partner as "dominant." Any pairs not showing significant dominant–submissive relationship were dropped from the study. Submissive animals were treated with drugs or vehicle and dominant animals were treated with vehicle for the next 3–4 weeks.

The data used for subsequent analyses are referred to as dominance level values. They are calculated as the difference in daily drinking scores between paired rats. The daily dominance level values were averaged over each week starting with the 2nd week of testing for each pair selected. The *n* used for statistical purposes in the study was the averaged weekly dominance level value for a single pair of animals. The effect of treatment on dominance level values for animal pairs within a treatment group was tested for statistical significance by comparing dominance level values during the 2nd week of testing (control period) to values measured during subsequent weeks of testing (treatment period) by analysis of variance (ANOVA) followed by post hoc unpaired *t*-tests for significance between control and treatment data. A *p*-value of less than 0.05 was used as the cutoff for significance. This approach gives information for the time of effect onset and effect for a selected period. Effect onset is defined as the period (weeks) at which the drug-induced reduction of the dominance level becomes significant relative to the control value measured after the 2nd week before treatment is initiated. The relative effect of two treatments is determined for the same treatment period. This is done for the 3rd week of treatment after all drugs have passed the onset of activity.

MODIFICATIONS OF THE METHOD

Pinhasov et al. (2005) used automatic scoring by a multiple-subject video-tracking system for antidepressant activity testing of the reduction of submission behavior.

Leo et al. (2005) applied nuclear magnetic resonance-based metabonomics to the dominant-submissive rat behavioral model. Principal component analysis revealed a metabolite from milk sugar, galactose, as a discriminating factor between rats classified as dominant and those classified as submissive.

Malatynska et al. (2005) described submissive behavior in **mice** as a test for antidepressant drug activity.

E.6.2.10 Animal Models of Bipolar Disorder

PURPOSE AND RATIONALE

Bipolar disorder is a psychiatric condition characterized by episodes of mania, depression, and underlying mood instability. The disease is distinguished by its cyclicity. Several attempts have been made to induce cyclic symptoms in animals. Preclinical studies with animal models of mania and depression have been developed to evaluate the potential efficacy of new psychotropic drugs. The main problem is to find a model that mimics mood cyclicity, which is a hallmark of bipolar disorder (Machado-Vieira et al. 2004). Antelman et al. (1995, 1998), Caggiula et al. (1998a, 1998b), and Kucinski et al. (1999) reported that repeated exposure to cocaine or other stressors can induce an oscillation or cycling in various physiological systems.

Cao and Peng (1993) and Arban et al. (2005) described a rodent model of mania, in which hyperactivity is induced by the combination of D-amphetamine and chlordiazepoxide.

PROCEDURE

Male CDI mice weighing 22–26 g were group housed at 21±2°C with 45%–70% humidity on a 12/12 h light/dark cycle. Test drugs were administered orally 60 min before the test. D-amphetamine sulfate (1.25 mg/kg i.p.) and chlordiazepoxide (6.25 mg/kg i.p.) were injected 30 min before the session. Locomotor activity was recorded using a Digiscan Analyzer (Model RXYZCM-8, Omnitech). Animals were individually placed in Plexiglas cages equipped with 48 photocells, and the total distance traveled (cm) by each mouse over a 30-min period was determined.

EVALUATION

Statistical analysis was carried out using an ANOVA followed by Dunnett's test. Results are expressed as mean ± SEM of the total distance traveled (in cm), with group size ranging from 9 to 12 mice.

MODIFICATIONS OF THE METHOD

Petty and Sherman (1981) proposed hyperactivity in rats induced by intraventricular injection of 6-hydroxydopamine as a pharmacological model of mania.

Gould et al. (2001) reported differential sensitivity to lithium's reversal of amphetamine-induced open-field activity in two inbred strains of mice.

Gessa et al. (1995) studied sleep deprivation in rats by the platform method as a possible animal model of mania.

Gambarana et al. (2000) found that long-term lithium administration abolishes the resistance to stress in rats sensitized to morphine and discussed this as a model of mania.

Shaldubina et al. (2002) induced a biphasic locomotor response starting with inhibition and followed by excitation by quinpirole, a D_2/D_3 agonist, and recommended this as a model of bipolar disorder.

D'Aquila et al. (2004) treated rats for 4 weeks with imipramine. After a withdrawal time of 40 days, the animals showed a depressive-like behavior indicated by an increase of immobility in the forced swimming test.

El Mallak et al. (1995, 2003) and Decker et al. (2000) administered intracerebroventricularly 5 µl of ouabain (10^{-3} M) to rats, which induced hyper- and hypoactivity and recommended this as a model of bipolar illness.

Wei et al. (2004) generated transgenic mice overexpressing the glucocorticoid receptor specifically in the forebrain. These mice display a significantly increased emotional lability and depressive-like behavior relative to wild type.

E.6.2.11
Animal Models of Obsessive-Compulsive Disorder

PURPOSE AND RATIONALE

Obsessive-compulsive disorder (OCD) is characterized by recurrent intrusive thoughts, feelings or ideas (obsessions) and ritualistic actions (compulsions) which cause significant distress and dysfunction. The disease has gained increasing attention (Stein 2000, 2002). The relevance of ethologic (naturally occurring) animal models (dogs: Stein et al. 1998; Overall 2000; birds: Woods-Kettelberger et al. 1997; horses: Nurnberg et al. 1997) has been discussed. Clinical studies and pharmacological experiments, mostly performed in rats (Joel et al. 2005; Tsaltas et al. 2005; Joel 2006), indicate the involvement of the serotoninergic system.

Deficits in spontaneous alterations produced by 8-OH-DPAT in rats were used as animal model of obsessive-compulsive behavior by Yadin et al. (1991), Fernández-Guasti et al. (2003), van Kuyck et al. (2003), Ulloa et al. (2004a, 2004b), and Agrati et al. (2005).

PROCEDURE

Apparatus

The testing apparatus for spontaneous alterations was a Plexiglas T maze with goal boxes characterized by distinctive cues. All arms (including the main arm and the two goal boxes) measured 50 × 10 cm. Guillotine doors separated the main arm and the goal boxes from the main body of the maze. Small plastic cups were placed in the corners of both goal boxes. The maze was covered with clear Plexiglas lids.

Experimental Procedure

Wistar rats weighing 250–300 g are exposed to three training sessions. On the first training day, animals were habituated to the maze for 20 min during which time they were allowed to explore the entire area. Thereafter, they were exposed to chocolate milk in their home cages, in order to acquaint them to the novel stimulus. On the second training day, animals were confined for 5 min to each goal arm, where chocolate milk was available. On the third training day, animals were placed in the main arm, the guillotine doors were lifted and rats were allowed to choose between the two goal arms, each one baited with chocolate milk. When the animal placed all four paws in a goal arm it was confined to it for 30 s and the entry was considered as a choice. Thereafter, the animals were removed and placed in a holding cage for 10 s. This procedure was repeated for a total nine runs.

Drug treatment (clomipramine or test drugs) was started on three consecutive days before the experimental sessions. One day before, the animals were deprived of food for 24 h.

Thereafter, they were injected i.p. with 1 mg/kg of the selective 5-HT_{1A} agonist 8-OH-DPAT and 15 min later they were placed in the main arm and allowed to choose between the two goal arms. The procedure was repeated up to seven runs or until they alternated their election. The choice made by the animal (right or left) was recorded. The number of repetitive choices until an alternation occurs indicates compulsive-like behavior. Additionally, the animals that chose the same alley in three consecutive occasions were defined as highly perseverative.

EVALUATION

The number of consecutive entries to the same alley of the T-maze is presented as the median and the number of highly perseverative per group is expressed as a percentage. Data were analyzed by means of nonparametric tests.

MODIFICATIONS OF THE METHOD

Joel and Avisar (2001) proposed excessive lever pressing following post-training signal attenuation in rats: a possible animal model of obsessive-compulsive disorder.

Szechtman et al. (2001) discussed compulsive checking behavior of quinpirole-sensitized rats as an animal model of obsessive-compulsive disorder.

Berridge et al. (2005) proposed sequential superstereotypy of an instinctive fixed action pattern in hyper-dopaminergic mutant **mice** as a model of obsessive-convulsive disorder.

E.6.2.12 Antidepressant-Like Activity in Differential-Reinforcement of Low Rate 72-Second Schedule

PURPOSE AND RATIONALE

The differential-reinforcement of low-rate (DRL) 72-s schedule has been recommended for evaluation of antidepressant drugs (O'Donnell and Seiden 1983).

PROCEDURE

Male Sprague Dawley rats weighing 350–450 g are housed in suspended wire cages in rooms maintained at 21–23°C and 30% to 40% relative humidity having free access to laboratory chow except during experimental sessions. Water is provided after each daily session in order to maintain body weights.

Apparatus

Model C Gerbrand operant-conditioning chambers (O'Donnell and Seiden 1983) or Coulbourn operant chambers (Pollard and Howard 1986) are used. A lever that operates a microswitch is mounted on one wall 3 cm from the side, 2.5 cm above a grid floor and 6.5 cm from an access port for a dipper that provides 0.025 ml of water. A houselight is mounted on the opposite wall. A downwards force equivalent to approximately 15 g operates the lever, constituting a response. When the schedule requirements are met, the dipper is lifted from a water trough to an opening in the floor of the access port for 4 s, constituting a reinforcer.

Rats are water-deprived for 22 h before each session. Each rat is initially trained under an alternative fixed-ratio 1, fixed-time 1-min schedule for water reinforcement. Thus, each response is reinforced, and reinforcement is also provided every min if no responding occurs. All rats are then placed under a DRL (differential-reinforcement-of-low-rate) 18 s schedule for 3 weeks. The schedule requirement is then increased to 72 s (DRL 72-sec). When performances on the DRL 72-sec schedule are stabilized (approximately 6 weeks), drug treatments are initiated.

Each group of 6 to 10 rats is subjected to a dose-response determination for one ore more drugs. Drugs are administered one h before testing by intraperitoneal injection.

EVALUATION

Data are expressed as percentages of non-injected controls. The control values are the response and reinforcement rates on those days immediately preceding the test day. The number of responses and reinforcers per session at each drug dose are tested for statistically significant differences from control values with paired *t*-tests using a two tailed criterion of statistical significance.

CRITICAL ASSESSMENT OF THE TEST

The method is rather time consuming. Moreover, the specificity as screening method for antidepressants has been challenged (Pollard and Howard 1986).

E.6.3 Tests for Antidepressant Activity Based on the Mechanism of Action

E.6.3.1 Potentiation of Norepinephrine Toxicity

PURPOSE AND RATIONALE

Antidepressants block the re-uptake of biogenic amines into nervous tissue. In this way, the toxic effects of norepinephrine are potentiated.

PROCEDURE

Male NMRI mice (22–25 g) are randomly assigned to test groups of 10 subjects. The test drug, the standard or the vehicle are given orally 1 h prior to the s.c. injection of the sublethal dose of 3 mg/kg noradrenaline. The groups of 10 mice are placed into plastic cages with free access to food and water.

EVALUATION

The mortality rate is assessed 48 h post-dosing. ED_{50}, or dose which causes death of 50% of the treated subjects, is calculated by means of linear regression analysis.

CRITICAL ASSESSMENT OF THE METHOD

Several antidepressants block not only the uptake of noradrenaline, but also of dopamine and of serotonin.

By definition, this test can only measure the noradrenaline-uptake inhibition.

One of the earliest observations on the pharmacology of antidepressants was by Sigg (1959), who showed that imipramine, as distinguished from other tricyclic substances known at this time, produced a profound potentiation of the cardiovascular effects of exogenously administered catecholamines in animals.

E.6.3.2 Compulsive Gnawing in Mice

PURPOSE AND RATIONALE

In man and in other species, like dogs, apomorphine induces emesis. Treatment of rodents with apomorphine causes compulsive gnawing instead of vomiting. The compulsive gnawing in mice induced by apomorphine is due to dopaminergic stimulation. Centrally acting anticholinergics shift the balance between acetylcholine and dopamine resulting in an enhancement of the apomorphine effect. Therefore, many compounds with psychotropic activity are known to have an apomorphine-synergistic effect. This enhancement is also found after administration of tricyclic antidepressants (Ther and Schremm 1962).

PROCEDURE

NMRI mice with a body weight between 18 and 20 g are injected s.c. with 10 mg/kg apomorphine. At the same time they are treated i.p. or s.c. with the test drug or the vehicle. For testing oral activity the animals are treated 30 min prior to apomorphine injection. Immediately after apomorphine injection 6 mice are placed into a cage $45 \times 45 \times 20$ cm with a wired lid. The bottom of the cage is covered with corrugated paper, the corrugation facing upwards. The mice start to bite into the paper causing fine holes or tear the paper. This behavior is enhanced by antidepressants. The mice remain 1 h in the cage.

EVALUATION

The number of bites into the corrugated paper is evaluated by placing a template upon the paper. The template has 10 rectangle windows divided into 10 areas of the same size. In a total of 100 areas the number of bites is checked. In this way percentage of damaged paper in calculated. Ten mg/kg apomorphine does not increase the biting rate of 5–10% which also occurs in normal animals. Likewise, atropine in doses of 40 and 80 mg/kg s.c. alone does not increase the biting behavior. In contrast, the combination of apomorphine and atropine greatly enhances the occurrence of gnawing. The same is true for antidepressants. For example, a dose of 25 mg/kg imipramine increases the damaged area by 40–70%. Percent gnawing of the test compound is compared with that of the standard.

CRITICAL ASSESSMENT OF THE TEST

Not only antidepressants, but also centrally acting anticholinergics and antihistaminics are active in this test. However, the test has the advantage of simplicity without any pretraining of the animals.

MODIFICATIONS OF THE METHOD

De Feo et al. (1983) reported on possible dopaminergic involvement in biting compulsion of mice induced by large doses of clonidine.

Stereotyped gnawing in mice is induced by methylphenidate (Pedersen and Christensen 1972). The phenomenon is potentiated by various drugs, such as benzodiazepines (Nielsen et al. 1991).

Stereotyped behavior in **guinea pigs** induced by apomorphine or amphetamine consisting in continuous gnawing and sniffing of the cage floor was described by Klawans and Rubovits (1972) and used as an experimental model of tardive dyskinesia.

Molander and Randrup (1974) investigated the mechanisms by which L-DOPA induces gnawing in mice.

E.6.3.3 Apomorphine-Induced Hypothermia in Mice

PURPOSE AND RATIONALE

Apomorphine induces hypothermia in mice which can be prevented by antidepressants.

PROCEDURE

Male NMRI mice (20–22 g) are used and randomly assigned to test groups of 6 subjects. One hour after oral administration of the test compounds or the vehicle a dose of 16 mg/kg apomorphine is injected s.c. The rectal temperature of each mouse is measured by an electronic thermometer immediately prior to apomorphine administration and 10, 20 and 30 min later. During the entire experiment, subjects are housed in groups of three in glass jars at room temperature.

EVALUATION

A time curve is constructed by plotting the temperature (mean of each group) against time in min. The AUC is calculated for all groups and converted into percent inhibition of apomorphine-induced hypothermia in the control group. An ED_{50} can be calculated by linear regression analysis.

CRITICAL ASSESSMENT OF THE METHOD

Antagonism against apomorphine-induced hypothermia can be regarded as a hint for antidepressant activity. Compounds with a marked noradrenergic or dopaminergic component are active against apomorphine-induced hypothermia but not antidepressants acting mainly through serotoninergic mechanisms.

MODIFICATIONS OF THE METHOD

Cox and Lee (1981) induced hypothermia in rats by intrahypothalamic injection of 5-hydroxytryptamine and recommended this as a model for the quantitative study of 5-hydroxytryptamine receptors.

E.6.3.4 Tetrabenazine Antagonism in Mice

PURPOSE AND RATIONALE

Tetrabenazine (TBZ) induces a depletion of biogenic amines (e. g. noradrenaline, dopamine, serotonin) without affecting their de novo synthesis. TBZ depletes noradrenaline from nerve terminals and prolongs re-uptake into the granula. Noradrenaline is degraded by monoamino-oxydase. Antidepressants inhibit the re-uptake of noradrenaline into the nerve terminals and increase thereby the noradrenaline concentration at the receptor site. In this way, the effect of TBZ is antagonized. Therefore, both MAO-inhibitors and tricyclic antidepressants are known to prevent or to antagonize these effects. The prevention of TBZ induced ptosis and catalepsy can be used for evaluation of antidepressants.

PROCEDURE

Groups of 5–10 male NMRI mice (20–22 g) are used. Sixty min after oral or 30 min after i.p administration of the test compound or the vehicle 40 mg/kg i.p. TBZ are injected. The animals are placed into individual cages. The test is started 30 min after TBZ administration and repeated every 30 min up to 2 h. Catalepsy and ptosis are used as criteria. A stair is formed with 2 cork stoppers having 2 steps of 3 cm height. The animals are placed head downwards with their hindlegs upon the top cork. As long as TBZ exerts its cataleptic effect the animals remain in this catatonic state. If the cataleptic effect is not antagonized after a limit of 60 s the animals are placed into a normal position.

EVALUATION

Thirty days after replacement the degree of ptosis is scored: eyes closed = 4, eyes 3/4 closed = 3, eyes 1/2 closed = 2, eyes 1/4 closed = 1, eyes open = 0. (Rubin et al. 1957) Similarly, the cataleptic effect is scored according to the duration of catalepsy. Catalepsy more than 60 s = 5, between 30 and 60 s = 4, between 10 and 30 s = 3, between 5 and 10 s = 1, less than 5 s = 0. The scores of the TBZ controls are taken as 100% and the percentage is calculated for the treated animals.

Imipramine was found to be effective at a dose of 10 mg/kg s.c. or 20 mg/kg orally.

CRITICAL ASSESSMENT OF THE METHOD

The TBZ antagonism has been found to be a simple and reliable test for evaluation of classical antidepressants.

MODIFICATIONS OF THE METHOD

Ptosis in mice can be induced in a similar way by treatment with reserpine. Mice receive a single oral dose of the test compound followed by subcutaneous administration of 5 mg/kg reserpine 30 min later. Ptosis is observed for the next 1 or 2 h and scored in a similar way as in the TBZ test.

TBZ ptosis can also be elicited in rats. The test procedure and the evaluation is the same as in mice. Tetrabenazine-induced hyperthermia in mice has been proposed as test for antidepressant activity by Gylys et al. (1963).

E.6.3.5 Reserpine-Induced Hypothermia

PURPOSE AND RATIONALE

Depletion of biogenic amines (noradrenaline, 5-hydroxytryptamine, dopamine) in the brain induces not only catalepsy and ptosis but also hypothermia in rodents. The decrease of body temperature induced by reserpine is antagonized by antidepressants, MAO-inhibitors and central stimulants. The subcutaneous administration of 2 mg/kg reserpine leads to a decrease of core temperature in mice to 20–23°C after 18 h. The fall in temperature can be antagonized by antidepressants, but also by amphetamine-like drugs. However, the time course is different: tricyclic antidepressants have a slow onset of action and a long lasting effect, whereas amphetamine-like drugs have a quick onset of action and a short-lasting effect.

PROCEDURE

Groups of 5 male NMRI mice (19–21 g body weight) are used. On the day before testing, they are dosed with 2 mg/kg reserpine s.c. They are housed in a climate-controlled animal colony and have free access to food and water. Eighteen hours after reserpine administration, the animals are placed into individual cages. The initial rectal temperature is determined by insertion of an electronic thermometer (e. g. Ellab T-3) to a constant depth of 2 cm. Following administration of the test compound (either i.p. or p.o.), the rectal temperature is measured again at 60 min intervals for 7 h.

EVALUATION

Rectal temperature is recorded every hour. The difference in temperature from vehicle controls is calculated for each time and the maximal difference is scored. The differences are then statistically compared using the *t*-test.

MODIFICATIONS OF THE METHOD

The time course and the administration route can be changed. Male mice are treated with the test drug or the standard 1 h prior to intravenous injection of 2 mg/kg reserpine. Rectal temperature is measured by a rectal thermometer prior and every 60 min up to 6 h The animals are kept in groups of 3 in glass jars at a controlled temperature of 20–21°C. Using a computer program the area under the curve is calculated by plotting the temperature (mean of each group) before and the decrease after reserpine against time in hours. Areas of treated groups are converted to percentage of controls.

Colpaert et al. (1975), Niemegeers (1975) described the antagonism of antidepressants and other drugs against Ro-4–1284, a benzoquinolizine derivative which by itself exhibits reserpine-like activities.

CRITICAL ASSESSMENT OF THE METHOD

The test has been proven as a simple and reliable method to detect antidepressant activity. However, the

reversal of hypothermia is not specific for antidepressants. The fall in body temperature can also be antagonized by amphetamines, and some antipsychotic agents (chlorpromazine). The different time course of antidepressants (slow onset of action, long-lasting effect) and amphetamine-like drugs (quick onset of action, short-lasting effect) allows differentiation between the two groups of drugs.

E.6.3.6 5-Hydroxytryptophan Potentiation in Mice

PURPOSE AND RATIONALE

According to the monoamine hypothesis of depression compounds exert antidepressant activity because they are capable of enhancing central noradrenergic and/or serotoninergic functions. Several antidepressant agents potentiate serotonin effects by a block of the re-uptake of serotonin. DL-5-Hydroxytryptophan is used as the precursor of serotonin. Enzymatic breakdown is inhibited by the MAO-inhibitor pargyline. In mice the characteristic symptom of head-twitches is observed.

PROCEDURE

Groups of 6 male mice (18–30 g) are used. They are treated i.p with the test drug or the vehicle. Thirty min later, the mice receive 75 mg/kg pargyline HCl s.c. Ninety min after pargyline the animals are injected wit 10 mg/kg DL-5-hydroxytryptophan (5-HTP) i.v.

EVALUATION

Animals positively influenced show a characteristic behavior of head twitches. A animal is considered to be positive if it shows head twitches 15 min after 5-HTP injection. Enhancement is observed after treatment with serotonin uptake blockers relative to animals pretreated with pargyline only.

CRITICAL ASSESSMENT OF THE METHOD

The test can be considered as additional evidence for antidepressant activity based on uptake inhibition.

MODIFICATION OF THE METHOD

The head-twitch in mice can also be elicited without a MAO-inhibitor by using higher doses (200 mg/kg) of DL-5-hydroxytryptophan.

Moser and Redfern (1988) studied the effects of four benzodiazepines on the head-twitch response induced in mice by several 5-HT receptor agonists.

Meert et al. (1988) studied partial and complete blockade of 5-hydroxytryptophan (5-HTP)-induced head twitches in the *rat* by serotonin S_2 antagonists.

Niemegeers et al. (1983), Awouters et al. (1988) used *mescaline* induced head twitches in the rat as an *in vivo* method to evaluate serotonin S_2-antagonists. Head twitches were counted for 15 min after intravenous injection of 20 mg/kg mescaline. Twitch counts of less than 2 were considered as inhibition and of less than 2 as blockade of the mescaline response.

E.6.3.7
5-Hydroxytryptophan Potentiation in Rats

PURPOSE AND RATIONALE

The inhibition of serotonin re-uptake by some anti-depressants can be tested *in vivo* in rats by administration of the precursor 5-hydroxytryptophan and inhibition of its breakdown by the MAO-inhibitor pargyline. In contrast to mice exhibiting head twitches, rats show other symptoms such as continuous forelimb clonus.

PROCEDURE

Groups of 6 male Wistar rats weighing 150–200 g are used. Four hours prior to testing pargyline HCl is injected sc. at a dose of 75 mg/kg. Thirty min before i.p. injection of 1 mg/kg L-5-hydroxytryptophan, test compounds or standards are administered intraperitoneally. Fifteen min after the 5-hydroxytryptophan injection, the animals are observed for 15 min. An animal is considered to be positive if is exhibits continuous forelimb clonus.

EVALUATION

Enhancement is expressed as normalized percent increase relative to the vehicle control. Using various doses, ED_{50} values with 95% confidence limits can be determined by probit analysis.

MODIFICATIONS OF THE METHOD

Hallberg et al. (1985) developed a registration device based on accelerometry in order to accomplish an objective quantification of tremors in conscious unrestrained rats. Tremor intensity was continuously recorded by a small piecoresistive accelerometer mounted on the back of the freely moving rat. The accelerometer was connected to a Grass Polygraph. The integrated signals were further analyzed by a desk-top computer.

The behavior in rats induced by 10 mg/kg L-5-hydroxytryptophan i.p. can be antagonized by compounds having 5-HT_2 antagonist properties (Colpaert and Janssen 1983).

E.6.3.8
Yohimbine Toxicity Enhancement

PURPOSE AND RATIONALE

Yohimbine occupies central α_2-receptors, and prevents noradrenaline from binding to these receptors. Compounds with antidepressant properties are known to inhibit physiological inactivation of noradrenaline and other biogenic amines by blocking the re-uptake at nerve terminals. Administration of a test compound with antidepressant properties leads to an increase in noradrenaline concentration. Following the simultaneous administration of yohimbine and antidepressants the animals die of noradrenaline poisoning.

PROCEDURE

Groups of 10 male NMRI mice (25–28 g) are used. Mice are placed in plastic cages and receive the test compound or the vehicle by oral or i.p. administration.

Thirty min later, a dose of 25 mg/kg yohimbine (a sublethal dose) is given s.c.

EVALUATION

Mortality rate is assessed 1 h, 2 h, 3 h, 4 h, 5 h, and 24 h after dosing. Lethality in the control group (Yohimbine only) is less than 10%, whereas 10 mg/kg desipramine-HCl causes death in about 90%. Using various doses ED_{50}-values can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

The test has been proven as a simple method to detect antidepressants with monoamine uptake inhibiting properties.

E.6.3.9 Tryptamine Seizure Potentiation in Rats

PURPOSE AND RATIONALE

Monoamine oxidase (MAO) inhibitors like iproniazid enhance seizures in rats caused by an intravenous infusion of tryptamine HCl. This procedure can be used to elucidate the *in vivo* MAO inhibiting properties of compounds.

PROCEDURE

Groups of 5 male Wistar rats weighing 150–200 g are used. Test compounds, standard or vehicle controls are administered intraperitoneally 0.5; 1; 2; and 4 h prior testing. At the time of testing 5 mg/kg tryptamine HCl freshly dissolved in saline are injected intravenously. Immediately after tryptamine HCl administration, the animals are observed individually for three min for the appearance of clonic "pedalling" movements of the forepaws which is considered a positive response. Frequently, these clonic seizures are preceded by a kyphotic curvature of the spine but this sign does not constitute a positive response.

In addition to the vehicle control group, a series of five positive control animals receiving tranylcypromine at 5 mg/kg i.p. with a 0.5 h pretreatment time are subjected to the test in order to check the effectiveness of the tryptamine HCl solution which is relatively unstable. A 100% response is expected. Fresh tryptamine HCl solution should be prepared hourly as needed.

EVALUATION

The normalized percent potentiation is calculated as follows:

$$100 \times \left[\frac{\%\ \text{animals potent. in drug group}}{1 - \%\ \text{animals potent. in vehicle group}} - \frac{\%\ \text{animals potent. in vehicle}}{1 - \%\ \text{animalspotent. in vehicle group}} \right]$$

A dose-response is obtained in the same manner at the peak time of drug effect except that a group size of 10 animals is used and four different doses are tested in addition to the vehicle and the tranylcypromine groups.

An ED_{50} is calculated using probit analysis.

MODIFICATIONS OF THE METHOD

E.6.3.10 Serotonin Syndrome in Rats

PURPOSE AND RATIONALE

Compounds which stimulate serotonin receptors cause a series of behavioral changes in rats which is called the serotonin syndrome (Jacobs 1976; Green and Heal 1985; Tricklebank 1985) such as head weaving, increased locomotion, forepaw treading, flat posture and lower lip retraction. With increasing knowledge about the subtypes of serotonin receptors these symptoms were defined to be associated with 5-HT_{1A} receptors and their specific agonists (Smith and Peroutka (1986), Blanchard et al. 1993; Yu and Lewander 1997).

PROCEDURE

Time- and dose-dependence of **forepaw treading**, which is scored at 15, 30, 45, and 60 min according to a 3-point scale (0 = absent; 1 = periodic and weak; 2 = continuous) according to Arnt and Hyttel (1989) and Porsolt et al. (1992),

was measured by Deakin and Green (1978), Green et al. (1983), Goodwin and Green (1985), Goodwin et al. (1986), Berendsen and Broekkamp (1990), Schoeffter et al. (1993), Andersson and Larsson (1994), Forster et al. (1995), Kofman and Levin (1995), Lu and Nagayama (1996), O'Connell and Curzon (1966), Gaggi et al. (1997), Kleven et al. (1997), Yu and Lewander (1997),

of **flat body posture** by Deakin and Green (1978), Goodwin and Green (1985), Goodwin et al. (1986), Blanchard et al. (1993), Schoeffter et al. (1993), Andersson and Larsson (1994), Foreman et al. (1993, 1994, 1995), Forster et al. (1995), Kofman and Levin (1995), O'Connell and Curzon (1966), Gaggi et al. (1997), Kleven et al. (1997), Wolff et al. (1997), Yu and Lewander (1997),

of **hind limb abduction** by Deakin and Green (1978), Green et al. (1983), Goodwin and Green (1985), Goodwin et al. (1986), Kofman and Levin (1995),

of **increased motility** by Tricklebank (1985), Forster et al. (1995), Gaggi et al. (1997), O'Neill and Parameswaran (1997),

of **decreased body temperature** by Martin et al. (1992), Schoeffter et al. (1993), Simiand et al. (1993), Foreman et al. (1993, 1994, 1995), Forster et al. (1995), O'Connell and Curzon (1966), Bagdy and To (1997), Wolff et al. (1997), Yu and Lewander (1997),

of **head twitches** by Deakin and Green (1978), Green et al. (1983), Goodwin and Green (1985), Goodwin et al. (1986), Meert et al. (1988), Berendsen and Broekkamp (1990,) Kofman and Levin (1995), Gaggi et al. (1997), Kleven et al. (1997),

of **lower lip retraction**, which is scored according to Berendsen et al. (1989) after 15, 30, 45 min as follows: 0 = lower incisors not or hardly visible (not different from nontreated animals), 0.5 = partly visible, 1 = completely visible,

by Smith and Peroutka (1986), Berendsen et al. (1994, 1997), Porsolt et al. (1992), Blanchard et al. (1993), Andersson and Larsson (1994), Foreman et al. (1993, 1994, 1995), Moore et al. (1993), De Boer et al. (1995), Berendsen et al. (1966), Bagdy and To (1997), Groenink et al. 1997; Kleven et al. (1997), Wolff et al. (1997).

EVALUATION

Scores of each symptom are registered for each test animal. Average values of treated animals are compared with controls treated with vehicle alone. Dose-response and time response curves are evaluated.

CRITICAL ASSESSMENT OF THE TEST

Among the many symptoms of the serotonin syndrome in rats, forepaw treading, flat body posture and lower lip retraction were used by most authors to characterize agonists and antagonists of 5-HT_{1A} receptors.

MODIFICATIONS OF THE METHOD

Trulson et al. (1976) used the serotonin syndrome to test the supersensitivity after destruction of central serotonergic nerve terminals by intracerebral injection of 5,7-dihydroxytryptamine.

Blanchard et al. (1997) described the symptoms of selective activation of 5-HT_{1A} receptors in **mice**.

Locomotor activity of **guinea pigs** was increased in a dose-dependent manner by 5-HT_{1A} receptor agonists (Evenden 1994).

E.6.3.11 Hypermotility in Olfactory-Bulbectomized Rats

PURPOSE AND RATIONALE

Bilateral olfactory bulbectomy in the rat is associated with changes in exploratory behavior that are reversed by chronic, but not acute treatment with antidepressant drugs (Cairncross et al. 1978, 1979; Leonard and Tuite 1981; Janscár and Leonard 1981). The olfactory bulbectomized rat is used as an animal model of depression. Several behavioral changes have been observed following bilateral olfactory bulbectomy: hyperactivity in a closed arena, such as the open field; enhanced nocturnal activity; deficits in memory as shown by passive avoidance behavior and in the Morris water maze and the radial maze; increased open-arm entries in the elevated-plus maze, and changes in food-motivated and conditioned taste aversion behavior. Alteration in the noradrenergic, serotonergic, cholinergic, GABAergic, and glutamatergic neurotransmitter systems are also associated with olfactory bulbectomy (Wren et al. 1977; Van Riezen and Leonard 1990; Kelly et al. 1997).

PROCEDURE

Male Sprague Dawley rats are anesthetized with intraperitoneal injection of 2.5% tribromo-ethanol solution (Cairncross et al. 1977). Following exposure of the skull, a burr hole is drilled at points 7 mm anterior to the bregma and 2 mm either side of the midline at a point corresponding to the posterior margin of the orbit of the eye. The olfactory bulbs are removed by suction and the burr holes filled with hemostatic sponge. Tetramycin powder is then applied to the wound and the skin closed by surgical clips. Sham-operated animals are treated in the same way but although the dura above the bulbs is cut, the bulbs are left intact. The animals are allowed to recover for 14 days after surgery.

For drug evaluation the animals are treated subcutaneously with the test drug or the standard or the vehicle once daily at 09:00 for 14 days. In each experiment sham-operated controls treated with test drug, standard and vehicle are included.

The behavior of the animals is tested from the 12th day onwards. The rats are placed singly in the center of an open field apparatus. Ambulation (no. of squares crossed), rearing (forepaws raised from the floor), grooming and defecation (no. of fecal boli) scores are recorded for an 3 min period of observation.

EVALUATION

The results are analyzed statistically using Student's *t*-test (2 tail test), the significance being set at $P < 0.05$.

CRITICAL ASSESSMENT OF THE METHOD

The bulbectomized rat model has been shown to be highly selective for both typical and atypical antidepressants, however, the procedure is quite time consuming.

MODIFICATIONS OF THE METHOD

Various authors used this model to demonstrate antidepressant-like activity: such as Briley et al. (1996) for milnacipran, a serotonin and noradrenaline uptake inhibitor, Hancock et al. (1995) for A-80426, an α_2-adrenoceptor antagonist with serotonin uptake blocking activity, McNamara et al. (1995) for the centrally active serotonin agonist 8-hydroxy-2-(di-n-propylamino) tetralin (8-OH-DPAT), Redmont et al. (1997) for dizocilpine (MK-801), Song and Leonard (1994) for the serotonin reuptake inhibitors fluvoxamine and sertraline, Song et al. (1996a) for centrally administered neuropeptide Y, Song et al. (1996b) for the H_1 receptor antagonist terfenadine.

Kelly and Leonard (1994, 1995) studied the effects of potential antidepressants, such as selective serotonin reuptake inhibitors, in olfactory bulbectomized rats. Kelly et al. (1997) anesthetized male Sprague Dawley rats weighing 230–280 g with 375 mg/kg i.p. chloral hydrate. The surgical procedure involves drilling two burr holes (2 mm diameter, 8 mm anterior to bregma) either side, 2 mm from the midline of the frontal bone overlying the olfactory bulbs. The olfactory bulbs can be visualized through these burr holes and can be aspirated by means of a blunt hypodermic needle attached to a water pump, taking care not to cause damage to the frontal cortex. Prevention of blood loss from the burr holes is achieved by filling them with hemostatic sponge. Antibiotic powder is applied to the wound, prior to closing with 7.5-mm surgical clips. A period of 2 weeks allows for the recovery from the surgical procedure and is optimal for the development of the bulbectomy syndrome.

Potential antidepressant drugs are preferably administered for a period of 2 weeks. Various procedures can be used to test the drug's effect in olfactory bulbectomized rats, such as open field (Cryan et al. 1999; Slotkin et al. 1999), home cage activity (Redmont et al.

1997), forced swim test (Kelly and Leonard 1999), elevated plus maze (McGrath and Norman 1999), passive avoidance (Martin et al. 1998; Nowak et al. 2003), and olfactory bulbectomy-induced hyperemotionality (Chaki et al. 2004).

Redmont et al. (1995) studied the effect of chronic antidepressant administration on the conditioned taste aversion to 8-OHDPAT in the olfactory bulbectomized rat.

Kelly et al. (1997) gave an update of the olfactory bulbectomized rat as a model of depression. Tricyclic antidepressants (amitryptiline, desimipramine), atypical agents (mianserin), selective serotonin reuptake inhibitors (paroxetine, sertraline, fluvoxamine), reversible inhibitors of monoamine oxidase A (moclobemide), as well as putative antidepressants, such as 5-HT_{1A} agonists (zalospirone, ipsapirone), noncompetitive NMDA antagonists (MK-801) and triazolobenzazepines (alprazolam, adinazolam), have demonstrated antidepressant-like activity in this model.

Zhou et al. (1998) found serotoninergic hyperinnervation of the frontal cortex in the bulbectomized rat.

Increases in the concentrations of the neuropeptides corticotropin-releasing factor, thyrotropin-releasing factor, somatostatin (Bissette 2001), and neuropeptide Y (Holmes et al. 1998), which may play a role in mediating the antidepressant-sensitive behaviors, have been demonstrated.

Comparing the behavioral and biochemical effects of bulbectomy in young versus aged rats, Slotkin et al. (1999) suggested that this test might provide a useful animal model with which to test therapeutic intervention for geriatric depression.

Ho et al. (2000) demonstrated increased striatal glutamate release during novelty exposure-induced hyperactivity in olfactory bulbectomized rats that may have a modulatory role in the antidepressant-sensitive response.

Wrynn et al. (2000) performed an *in vivo* magnetic resonance imaging study in olfactory bulbectomized rats and demonstrated alterations in signal intensities in cortical, hippocampal, caudate and amygdaloid regions.

Holmes et al. (1998) studied the effects of olfactory bulbectomy on neuropeptide gene expression in the rat olfactory system.

Bilkei-Gorzo et al. (2002) and Zueger et al. (2005) tested alterations in locomotor activity and exploratory behavior after olfactory bulbectomy in **mice** (using systems provided by TSE Systems, Bad Homburg, Germany).

E.6.3.12 Sexual Behavior in Male Rats

PURPOSE AND RATIONALE

Sexual behavior in male rats is stimulated by 5-HT_{1A} receptors agonists (Ahlenius et al. 1981; Gorzalka et al. (1990), Foreman et al. 1993, 1994, 1995; Anderson and Larsson 1994; Tallentire et al. 1996; Ahlenius and Larsson 1997; Fernández-Guasti and Rodriguez-Manzo 1997) and inhibited by serotonin receptor antagonists (Mendelson and Gorzalka 1981) and by 5-HT_{1B} receptors antagonists (Fernández-Guasti et al. 1989). The test procedure was described in detail by Arnone et al. (1995).

PROCEDURE

Adult male and ovarectomized female Sprague Dawley rats are housed in sex-separated rooms at 21 ± 1°C in a reversed light-dark cycle with free access to food and water.

Mating Behavior

Male rats of two levels of sexual performance are selected for drug testing: sexually naive and sexually experienced. The latter are given 4 mating pretests, twice a week. Only sexually active males that achieve at least two ejaculations per test, are included in the experiments.

The mating tests are performed between 12:30 and 17:00, during the dark phase of the lighting cycle. Drug is administered orally 1 h before the test to the male rat. The animal is allowed to adapt to the test area (60 cm diameter, 50 cm high) illuminated with a dim red light. Each behavioral test starts with the introduction of a stimulus female brought into sexual receptivity by s.c. treatment with estradiol benzoate (10 µg/rat), followed 48 h later by progesterone (500 µg/rat), 4–5 h before testing. The tests end either 20 min later or after the first post-ejaculatory mount (or 2 h later for sexual satiation).

The following behavioral parameters are recorded:

- **Mount and intromission latencies:** time interval from the first introduction of the female to the first mount or intromission, respectively. Mounts are accompanied by an average of three or four brief shallow thrusts, while the intromission, which succeeds

this event, is marked by a single deep thrust indicative of penile insertion.
- **Mount frequency:** total number of pre-ejaculatory mounts with and without intromission.
- **Intromission frequency:** total number of pre-ejaculatory intromissions.
- **Ejaculatory latency:** time interval from the first intromission to ejaculation. A total of 1200 s is scored for the latencies of rats failing to mount, intromit or ejaculate.

Sexual Satiation

The mating pattern of the male rat consists of repeated mounts and intromissions, culminating in an ejaculation. The ejaculation is followed by a period of 4–5 min during which time the male remains refractory to sexual stimulation by the female. The sexual activity is thereafter resumed with a new series of mounts and intromissions followed by ejaculation. If uninterrupted, the rat may achieve five to six ejaculations before sexual satiation sets in. Sexually experienced male rats are allowed to copulated with a receptive female for 2 h. The behaviors are recorded on a videotape. The criterion for satiation is that the male fails to mount within 20 min post ejaculation. The latency to satiation and the number ejaculations are recorded.

Finally, for each ejaculatory series, the following parameters are recorded:

- **Copulation duration:** time interval between the first mount and the ejaculation.
- **Post ejaculatory interval:** time interval from the ejaculation to the first mount of the next series.

Penile Erections

One hour before the experiment, male rats are allowed to adapt to the quiet observation room. One hour after oral drug administration, rats are placed in individual plastic cages ($10.5 \times 24 \times 16$ cm). Series of nine rats comprising, at random, control and drug-treated animals, are observed simultaneously for 45 min and the number of penile erections is counted. Penile erection is defined as a period of pelvic thrusting followed by an upright position with genital grooming and the display of the engorged penis. Animals are used only once.

EVALUATION

Data are analyzed using non-parametric statistics. The Fisher test is used for percentage responding. For quantified behavioral parameters, the Kruskal-Wallis test, followed by the Mann-Whitney *U*-test corrected by Holm's method is used for comparisons versus the control group. The Mann-Whitney *U*-test is used for comparison of a single treated group versus its own control group.

MODIFICATIONS OF THE METHOD

Barr et al. (1999) subjected male rats to a 4-day escalating dose schedule of d-amphetamine. Twelve hours after the final dose the rats were tested for sexual behavior. Withdrawal from the amphetamine was associated with decrements in several motivational components of sexual behavior. The procedure was recommended as a rodent model of depression.

Pomerantz et al. (1993) studied the influence of 5-HT receptor agonists on male sexual behavior of **rhesus monkeys**.

E.6.4 Genetic Models of Depression

E.6.4.1 Flinders Sensitive Line of Rats

The **Flinders Sensitive Line of rats** was established by genetically selecting (breeding) Sprague Dawley rats for a behavioral trait, supersensitivity to cholinergic agents (Overstreet and Russell 1982; Overstreet 1986; Overstreet et al. 1986, 1990, 1992; Daws and Overstreet 1999). The name Flinders refers to University of Flinders, Australia, where the line was first selected. The usefulness of the Flinders Sensitive Line of rats as an animal model for depression is evident because it exhibits behavioral features characteristic of depression in humans and responds to chronic, but not acute, treatment with antidepressants (Overstreet 1993; Overstreet et al. 1995; Yadid et al. 2000; Overstreet and Griebel 2004; Overstreet et al. 2004; Dremencov et al. 2005).

Vasquez et al. (2000) tested the effects of electroconvulsive stimuli and d-amphetamine on neuropeptide Y concentrations in brain and on locomotion in the Flinders Sensitive Line rat.

Ferreira-Nuño et al. (2002) studied masculine sexual behavior features in Flinders sensitive and resistant line rats.

Shayit et al. (2003) demonstrated 5-HT_{1A} receptor subsensitivity in infancy and supersensitivity in adulthood in the Flinders Sensitive Line rat.

Dremencov et al. (2004) showed in the Flinders Sensitive Line of rats that the serotonin–dopamine interaction is critical for the fast-onset action of antidepressant treatment. Seven-day treatment with nefazodone (a putative fast-onset antidepressant) but not with desipramine (a classical antidepressant) normalized immobility time in the swim test in Flinders Sensitive Line rats. Serotonin-induced dopamine release but not basal dopamine levels correlated with the improvement of depressive-like behavior.

Lavi-Avnon et al. (2005) showed an abnormal pattern of maternal behavior in the Flinders Sensitive Line of rats.

Maayan et al. (2005) demonstrated the involvement of dehydroepiandrosterone and its sulfate ester in blocking the therapeutic effect of electroconvulsive shocks in the Flinders Sensitive Line of rats.

King and Edwards (1999), King et al. (2001), and Shumake et al. (2003) bred **congenital learned helpless rats**, which exhibit physiological symptoms of analgesia, cognitive deficits and hyporesponsivity of the hypothalamic–pituitary–adrenal axis similar to those observed in human subjects with post-traumatic stress disorder.

Will et al. (2003) described **selectively bred Wistar–Kyoto rats** as an animal model of depression and hyper-responsiveness to antidepressants. Based on the significant decrease in investigative behavior of male rats towards a female intruder, reflecting the presence of anhedonia, Paré (2000) concluded that the Wistar–Kyoto rat strain represents a useful animal model of depressive behavior.

E.6.4.2 Genetically Altered Mice as Models of Depression

Cryan et al. (2002) published a survey on the use of genetically altered mice to assess antidepressant-related phenotypes. Cyran and Mombereau (2004) discussed the utility of models for studying depression-related behavior in genetically modified mice.

Cases et al. (1995) found aggressive behavior and altered amounts of brain serotonin and epinephrine in mice lacking **MAO_A**. Pup behavioral alterations including trembling, difficulties in righting, and fearfulness were reversed by the serotonin inhibitor parachlorophenylalanine. Adults manifested a distinct behavioral syndrome, including enhanced aggression in males.

Lijam et al. (1997) created mice deficient in *Dvl1*, one of the three mouse homologs of the *Drosophila* polarity gene *Dishevelled*, by gene targeting. These mice exhibited reduced social interaction and sensorimotor gating abnormalities.

Grimsby et al. (1997) reported an increased stress response and increased levels of α-phenylethylamine in **MAO_B**-deficient mice. In addition, mutant mice were resistant to the neurodegenerative effects of 1-methyl 4-phenyl 1,2,3,6-tetrahydropyridine (MPTP), a toxin that induces a condition reminiscent of Parkinson's disease.

Sallinen et al. (1999) reported that general alteration of the **α_2-adrenoceptor subtype c** in mice affects the development of behavioral despair and stress-induced increases in plasma corticosterone levels. α_{2c}-Adrenoceptor overexpression increased, and the lack of α_{2c}-adrenoceptors, decreased the immobility of mice in the forced swimming test.

Cyran et al. (2001) used **dopamine-beta-hydroxylase-deficient** mice to determine the role of norepinephrine in the mechanisms of action of antidepressant drugs. The dopamine-beta-hydroxylase-deficient mice failed to demonstrate antidepressant-like behavioral effects following the administration of several classes of antidepressants.

Mayorga et al. (2001) studied antidepressant-like behavioral effects in **5-hydroxytryptamine$_{1A}$and 5-hydroxytryptamine$_{1B}$receptor mutant mice**. The results suggested, that 5-HT_{1A} and 5-HT_{1B} receptors have different roles in the response to antidepressant drugs in the tail-suspension test.

Froger et al. (2001) found that 5-hydroxytryptamine$_{1A}$ autoreceptor adaptive changes in **substance P (neurokinin 1) receptor knockout mice** mimic antidepressant-induced desensitization. The constitutive lack of NK_1 receptors appeared to be associated with a downregulation/functional desensitization of 5-HT_{1A} autoreceptors resembling that induced by chronic treatment with antidepressants.

Jaber et al. (1997) inactivated the expression of the **dopamine transporter** in mice. The authors claimed that these genetically altered mice offer a unique model to test the specificity and selectivity

of dopamine-transporter-acting drugs and provide new concepts related to clinical conditions such as Parkinson's disease, schizophrenia, and drug addiction.

Xu et al. (2000) reported that mice lacking the **norepinephrine transporter** are supersensitive to psychostimulants. Disruption of the norepinephrine transporter (NET) gene prolonged the clearance of norepinephrine and elevated extracellular levels of this catecholamine. In a classical test for antidepressant drugs, the NET-gene-deficient mice behaved like antidepressant-treated wild-type mice.

Holmes et al. (2001) characterized the **dopamine receptor D_5null mutant** of mice in behavioral tests.

Based on pharmacology of adenosine A_{2A} receptor antagonists and results with **A_{2A}receptor knockout mice**, El Yacoubi et al. (2001) claimed that adenosine A_{2A} receptor antagonists are potential depressants.

MacQueen et al. (2001) investigated the performance of heterozygous **brain-derived neurotrophic factor knockout mice** on behavioral analogs of anxiety, nociception, and depression.

Conti et al. (2002) reported that cAMP-response-element-binding protein is essential for the upregulation of **brain-derived neurotrophic factor** transcription, but not the behavioral or endocrine responses to antidepressant drugs. cAMP-response-element-binding-protein-deficient mice were used to study the effects of desipramine and fluoxetine in behavioral, endocrine and molecular analyses.

Stork et al. (2000) studied postnatal development of a GABA deficit and disturbance of neural functions in mice lacking GAD65. Adult **GAD65(–/–) mice** showed a largely abnormal neural activity with frequent paroxysmal discharges and spontaneous seizures. They furthermore displayed increased anxiety-like behavior in a light/dark avoidance test and reduced inter-male aggression, as well as reduced forced-swimming-induced immobility indicative of an antidepressant-like behavior.

Svenningsson et al. (2002) studied the involvement of striatal and extrastriatal DARPP-32, a cAMP-regulated phosphoprotein, in biochemical and behavioral effects of fluoxetine using **DARPP-32 knockout mice**.

Calapai et al. (2001) used **interleukin-6 knockout mice** to characterize the antidepressant action of *Hypericum perforatum*.

Porsolt (2000) reviewed the utility of animal models of depression for transgenic research.

El Yacoubi et al. (2003) published the behavioral, neurochemical, and electrophysiological characterization of a genetic mouse model of depression.

Wei et al. (2004) generated mice overexpressing glucocorticoid receptor specifically in forebrain. These mice display a significant increase in anxiety-like and depression-like behaviors relative to wild type.

E.7 Anti-Parkinsonism Activity

E.7.0.1 General Considerations

A fundamental lesion in Parkinson's disease is a marked deficiency in the dopaminergic innervation of the basal ganglia owing to degeneration of neurons in the substantia nigra. Enhancement of dopaminergic transmission restores motor function at least partially. The decrease in dopaminergic activity in the basal ganglia results in a relative excess of cholinergic influence. Therefore, dopaminergic agonists, such as levodopa a precursor of dopamine, and cholinergic (muscarinic) antagonists can be combined in the treatment of Parkinson's disease. Parkinson-like syndromes also occur after depletion of central stores by reserpine and after treatment with phenothiazines and other antipsychotic drugs blocking dopamine receptors. (Vernier 1964; Marsden et al. 1975; Duvoisin 1976; Hornykiewicz 1975; Miller and Hiley 1975). The pathology of Parkinson's disease is typified by the presence of cytoplasmic inclusions (Lewy bodies). The formation of these proteinaceous inclusions involves the interaction of several proteins, including α-synuclein, synphilin, parkin and ubiquitin carboxyl-terminal hydrolases (Goldberg and Lansbury 2000; Shimohama et al. 2003; Le and Appel 2004; Meredith et al. 2004; Snyder and Wolozin 2004; von Bohlen und Halbach et al. 2004). Orr et al. (2002) gave a review on inflammatory aspects of Parkinson's disease and highlighted the cell-to-cell interactions and immune regulations critical for neuronal homeostasis and survival. Parkinson's disease and related synucleinopathies are considered as a new class of nervous system amyloidoses (Trojanowski and Lee 2002; Dev et al. 2004; Liu et al. 2005).

E.7.1 In Vitro Methods

E.7.1.1 Culture of Substantia Nigra

PURPOSE AND RATIONALE

Although *in vivo* animal studies have been used to examine the effects of a number of Parkinson-inducing compounds, there is little information on reliable *in vitro* methodologies that can recapitulate the previously observed in *vivo* results. Cardozo (1993) and Smeyne and Smeyne (2002) described details of a method for generating mixed and chimeric neuron/glial cultures of postnatal substantia nigra (SN), independent of other monoaminergic nuclei in the ventral midbrain. Since many toxins do not affect regions of the midbrain except the SN, use of whole ventral midbrain from embryos can dilute any measurement of cell death. By specifically culturing ventrolateral midbrain containing the SN, one can more directly target the effects of dopaminergic toxins. In addition, this method can be used to test potential therapies for amelioration of Parkinson's disease.

PROCEDURE

Generation of SN Cultures

1. Postnatal day 2–5 C57Bl/6 mice and/or Swiss-Webster (SWR) mice (Harlan) are placed on ice for 2–3 min to achieve an appropriate plane of anesthesia.
2. Animals are quickly decapitated and ≈ 8–10 brains from P2–P5 C57BL/6 or SWR matings are removed and placed in a freshly prepared dissociation media (= DM containing 12.8 g sodium sulfate; 5.2 g potassium sulfate; 0.036 g calcium chloride· $2H_2O$; 1.18 g magnesium chloride· $6H_2O$; 1.8 g glucose anhydrous; 0.238 g HEPES in 1 l deionized water, adjusted to pH 7.4 with NaOH).
3. Brains are placed on their ventral surface and a slice of midbrain rostral to the cerebellum and caudal to the hippocampus is isolated. This removed brain slab is placed flat in DM and either the entire midbrain or the ventrolateral midbrain containing the SN is dissected and minced into small pieces.
4. The minced SN or midbrain is then incubated in papain and DNAase (Dissociation Kit, Worthington Biochemical, Freehold, N.J., USA, follow kit instructions) for 30 min at 37°C. A second incubation with fresh papain solution (30 min, 37°C) is followed by three rinses in DM, and one rinse in plating media (PM).
5. Tissue is triturated in 5 ml PM and the cell suspension is added to 2 ml (1 ml of BSA stock and 1 ml ovalbumin stock).
6. The cell suspension is spun 1400 rev/min for 8 min and the pellet is then resuspended in 1.0 ml plating media containing 2% rat serum.
7. Once resuspended, cells are counted using trypan blue (0.4%) to determine cell viability.
8. Cells are adjusted to 1.2×10^6 cells/ml and plated at ≈ 200,000 cells/cm^2 in Lab-Tek 4-well Permanox™ chamber slides that were previously coated with laminin (200 mg/ml, Collaborative Biomedical Products) and poly-D-lysine (200 mg/ml, Collaborative Biomedical Products) 1:1 (v:v) and rinsed once with deionized water. Cells are maintained in an incubator at 37°C, 5% CO_2, and fed 2–3 times per week with feeding media complete with 2% rat serum (RS) by exchanging approximately one-fifth of the media (100 µl).

Chimeric Neuron/Glial Cultures

1. SNpc cells plated on pre-plated SNpc glia are produced using a variation of the previously described methods. SNpc glial feeder layers from P2–5 C57BL/6 or SWR mice are produced using the above described method, but cells are plated at 20,000–50,000 cells/cm^2 and fed with plating media containing 2% rat serum and 8% fetal bovine serum to promote glial proliferation and neuronal death.
2. For astrocyte cultures, this is the final step.
3. To generate mixed neuron/glial cultures, 3–4 weeks after the initial SNpc cells are plated, the glial feeder layers are rinsed once with plating media without serum, and 0.5 ml of plating media with 2% rat serum (RS) are added.
4. SNpc cells from C57BL/6 or SWR mice are isolated (as above) and plated at 250,000 cells/well on the previously generated glial feeding layers.
5. Twenty-four hours after plating of neurons onto the glial feeder layers, the cultures are fed with feeding media complete with 2% RS by an exchange of approximately one-fifth of the medium (100 µl) and cytosine β-D-arabinofuranoside (Ara-C, 2 µM) to prevent glial proliferation of the freshly plated cells. Thereafter, Ara-C (10 µM, final concentration) is added at each feeding.

MPTP Treatment

1. 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is added to cultures 7–10 days after the neurons are plated onto glia. The MPTP is prepared by dissolving MPTP in feeding media for a 1-mM stock, then diluting to a 1-μM stock with feeding media complete with 2% rat serum and adding this directly to the cultures. The final concentration of the MPTP in media is 50 nM. Two feedings of MPTP, in 2 days, are necessary to achieve the desired toxic effect.
2. Seven days after MPTP is added, the cultures are rinsed 3× with TBS, fixed in 4% buffered paraformaldehyde for 10 min, and rinsed 3× with TBS.

EVALUATION

Identification of SN Cells

1. To determine the number of SN cells, cultures are immunostained for expression of tyrosine hydroxylase. First, endogenous peroxidase activity is quenched by rinsing with 0.3% hydrogen peroxide in methanol in 1 × TBS for 2 × 15 min. Cells are permeabilized with 0.1% Triton X-100, 5% goat serum in TBS for 2 × 15 min. Cultures are covered in 400 μl of a polyclonal antibody directed against tyrosine hydroxylase (Eugene Tech International, Ramsey, N.J., USA or Pel-Freeze, Burlingame, Calif., USA: each 1:500) and incubated in this solution overnight at 4°C. The next day, cultures are rinsed three times with TBS followed by application of secondary antibody (goat α-rabbit) and amplification with Avidin–Biotin (ABC Elite Peroxidase kit, Vector Labs, Burlingame, Calif., USA). Final visualization of the immunopositive neurons is made using diaminobenzidine (DAB kit, Vector Labs) as a chromagen.
2. All TH-positive cells having the previously described characteristics of SNpc neurons (TH-positive cytoplasm surrounding a pale unstained nucleus, Hamre et al. 1999) from each culture are counted at a magnification of 200×. Note: to control for variability between cultures, all MPTP treatments are performed on matched cultures present on one single slide. Once cells are counted in each well, the number of TH-positive cells in the MPTP-treated cultures from each genotype is compared to the adjacent non-treated culture. Since an identical number of cells generated from the same brains was plated on a single slide, these cultures are directly compared to determine the percentage cell loss following MPTP. The percentage cell loss data following MPTP are then pooled from all C57Bl/6, SWR or mixed cultures.

E.7.1.2 Inhibition of Apoptosis in Neuroblastoma SH-SY5Y Cells

PURPOSE AND RATIONALE

A dopamine-derived neurotoxin, 1(*R*), 2(*N*)-dimethyl-6,7-dihydroxy-1,2,3,4-tetrahydroisoquinoline [*N*-methyl(*R*)salsolinol] was found to cause parkinsonism in rats and to deplete selectively dopamine neurons in the substantia nigra after infusion in the striatum. This isoquinoline occurs enantio-specifically in the nigra-striatum of human brains. The biosynthesis from dopamine is catalyzed by two enzymes, (*R*)salsolinol synthase and (*R*)salsolinol *N*-methyltransferase. The isoquinoline increases in the cerebrospinal fluid from parkinsonian patients, and the increase is ascribed to high activity of its synthesizing neutral (*R*)salsolinol *N*-methyltransferase, as shown by analyses in lymphocytes. The cell death caused by this neurotoxin in dopaminergic human neuroblastoma SH-SY5Y cells proved to be apoptotic. Apoptosis by this neurotoxin is mediated by intracellular sequential process, loss of mitochondrial membrane potential, activation of caspases and DNA fragmentation (Maruyama et al. 1997; Naoi et al. 1996, 1997, 2000, 2002).

Neuroprotection to halt progressive cell death of neurons has been proposed as a future therapy for neurodegenerative disorders. In these disorders, such as Parkinson's disease and Alzheimer's disease, apoptosis contributes to neuronal death in most cases (Tatton 2000). The well-regulated and relatively slow apoptotic process was proposed as a target of neuroprotection (Thompson 1995; Naoi and Maruyama 2001). Apoptosis is induced in neurons by various insults: oxidative stress, metabolic compromise, excitotoxicity, and neurotoxins. Apoptotic signaling is a multi-step pathway induced by opening a mitochondrial mega-channel called permeability transition (PT) pore, followed by decline in membrane potential, $\Delta\Psi m$, re-

lease of apoptosis-inducing factors, activation of caspases and fragmentation of nuclear DNA. Mitochondrial PT pore is regulated by Bcl-2 protein family, preventively by Bcl-2 and Bcl-xL and in a promotive way by BAX and BAD. Several papers describe the neuroprotective-antiapoptotic action of the anti-Parkinson drug rasagiline (Akao et al. 2002a, 2002b; Youdim et al. 2003; Maruyama et al. 2002, 2004b).

Maruyama et al. (2004a) described the neuroprotective function of *R*-(–)-1-(benzofuran-2-yl)-2-propylaminopentane, [*R*-(–)-BPAP], against apoptosis induced by *N*-methyl(*R*)salsolinol, an endogenous dopaminergic neurotoxin, in human dopaminergic neuroblastoma SH-SY5Y cells.

PROCEDURE

SH-SY5Y cells were cultured in Cosmedium-001 tissue culture medium (CosmoBio, Tokyo, Japan), supplemented by 5% fetal calf serum in an atmosphere of 95% air /5% CO_2.

Assessment of Apoptosis Induced by NM(R)Sal and the Protection by BPAP Derivatives

Apoptosis was quantitatively measured by fluorescence-augmented flow cytometry (FACS) with FACScan and CellQuest software (Becton Dickinson, San Jose, Calif., USA). Cells cultured in a 6-well poly-L-lysine-coated culture flask were incubated with or without 1 μM to 1 nM (−)-BPAP analogs at 37°C for 30 min, and then for 24 h with 250 μM *N*M(*R*)Sal in Cosmedium-001 culture medium supplemented with fetal calf serum. The cells were treated with trypsin, gathered, washed with the culture medium and twice with phosphate-buffered saline (PBS). The cells were incubated with 100 nM test drugs solution in an ice-bath for 30 min, washed and suspended in PBS, then subjected to FACS analysis.

Measurement of Changes in $\Delta\Psi$m

Decline in $\Delta\Psi$m induced by *N*M(*R*)Sal was quantified by measuring the reduction of Rhodamine 123 fluorescence pre-loaded in the cells (Patarino et al. 1996), as reported by Akao et al. (2002b). To examine the effects of (−)-BPAP analogs, the cells cultured in 6-well poly-L-lysine-coated tissue culture flasks were stained with 5 μM Rhodamine 123 in DMEM for 30 min at 37°C. After being washed twice with PBS, the cells were suspended in DMEM, incubated with 1 μM to 1 nM BPAP derivatives for 30 min, then with 250 μM *N*M(*R*)Sal for 1 h. After being washed and gathered by treatment with trypsin, the cells were suspended in PBS and the fluorescence at 535 nm was measured with excitation at 505 nm in a Shimadzu spectrofluorophotometer, RF-5000 (Kyoto, Japan).

Measurement of bcl-2 mRNA Level in the Cells Treated with BPAP Derivatives

SH-SY5Y cells were cultured in the presence of various concentrations (100 nM to 10 pM) of (−)-BPAP analogs for 24 h, and mRNA levels of bcl-2 were quantitatively assessed by RT-PCR (Akao et al. 2002a, 2002b). The cells were gathered and washed with PBS, and the total RNA was extracted by the phenol/guanidinium thiocyanate method. cDNA was generated by reverse transcription of 2 μg of the total RNA, and the cDNA fragments were amplified using the PCR primers. The linearity of the relationship of the amount of PCR product to the time of PCR amplification was confirmed under the conditions used in this study. PCR products were analyzed by electrophoresis on 3% agarose gels, and α-actin was used as an internal standard. The amounts of mRNA were quantified using NIH imaging software (version 1.62, developed at the U.S. National Institute for Health).

Measurement of Bcl-2 Levels in the Cells Treated with (–)-BPAP Derivatives

SH-SY5Y cells treated with 1 μM to 1 pM (–)-BPAP analogs for 24 h, and the cells were gathered, washed with PBS and suspended in RIPA buffer (10 mM Tris-HCl buffer, pH 7.5, containing 1% NP-40, 0.1% sodium deoxycholate, 0.1% sodium dodecylsulfate, 150 mM NaCl and 1 mM EDTA 2Na). The lyzed protein (5 μg) was separated by SDS-PAGE using a 10%–20% gradient polyacrylamide gel (Bio-Rad, Hercules, Calif., USA) and electroblotted onto PVDF membranes (Du Pont, Boston, Mass., USA). After blockage with 5% nonfat milk in PBS containing 0.1% Tween 20, the membrane was incubated overnight at 4°C with anti-human Bcl-2 (100) antibody (Santa Cruz Biotechnology, Santa Cruz, Calif., USA), or anti-β-actin antibody as control (Sigma, St. Louis, Mo., USA). The membranes were incubated further with alkaline phosphatase-conjugated goat anti-mouse antibody (Promega, Madison, Wis., USA) at room temperature. The immunoblots were visualized by use of an enhanced chemiluminescence detection kit (New England Biolabs, Beverly, Mass., USA), and quantified by computer-assisted image analysis with the NIH imaging software.

EVALUATION

Experiments were repeated four to eight times, and the results were expressed as the mean and SD. Differences were statistically evaluated by analysis of variance (ANOVA) followed by Sheffe's *F*-test. A p value less than 0.05 was considered to be statistically significant.

MODIFICATIONS OF THE METHOD

Maruyama et al. (2000) found that dopaminergic neurotoxins, 6,7-dihydroy-1-(3′,4′-dihydroxybenzyl)-isoquinolines, cause different cell death in SH-SY5Y cells: apoptosis was induced by oxidized papaverolines and necrosis by reduced tetrahydropapaverolines.

Maruyama et al. (2003) described the anti-apoptotic action of an anti-Alzheimer drug, TV3326 [(N-propargyl)-(3R)-aminoindan-5-yl)-ethyl methyl carbamate], a novel cholinesterase-monoamine oxidase inhibitor.

E.7.2 In Vivo Methods

E.7.2.1 Tremorine and Oxotremorine Antagonism

PURPOSE AND RATIONALE

The muscarinic agonists tremorine and oxotremorine induce parkinsonism-like signs such as tremor, ataxia, spasticity, salivation, lacrimation and hypothermia. These signs are antagonized by anticholinergic drugs.

PROCEDURE

Groups of six to ten male NMRI mice weighing 18–22 g are used. They are dosed orally with the test compound or the standard (5 mg/kg benzatropine mesilate) 1 h prior to the administration of 0.5 mg/kg oxotremorine s.c. Rectal temperature is measured before administration of the compound (basal value) and 1, 2 and 3 h after oxotremorine injection. Tremor is scored after oxotremorine dosage in 10-s observation periods every 15 min for 1 h.

Tremor	Score
absent	0
slight	1
medium	2
severe	3

Salivation and lacrimation are scored 15 and 30 min after oxotremorine injection.

absent	0
slight	1
medium	2
severe	3

EVALUATION

Hypothermia

The differences of body temperature after 1, 2 and 3 h versus basal values are summarized for each animal in the control group and the test groups. The average values are compared statistically.

Tremor

The scores for all animals in each group at the three observation periods are summarized. The numbers in the treated groups are expressed as percentage of the number of the control group.

Salivation and Lacrimation

The scores for both symptoms for all animals in each group are summarized at the two observation periods. The numbers in the treated groups are expressed as a percentage of the number of the control group.

CRITICAL ASSESSMENT OF THE METHOD

The oxotremorine antagonism has been proven to be a reliable method for testing central anticholinergic activity. The overt isomorphism between the animal model and the symptoms of Parkinson's disease recommend this test for screening of anti-Parkinson drugs (Cho et al. 1962; Vernier 1964; Everett 1964; Turner 1965; Bebbington et al. 1996; Frances et al. 1980; Ringdahl and Jenden 1983). However, the model measures only central anticholinergic activity (Duvoisin 1976).

MODIFICATIONS OF THE METHOD

Matthews and Chiou (1979) developed a method for quantifying resting tremors in a rat model of limb dyskinesias. The model involved permanent cannulation of the caudate nucleus for the introduction of carbachol. Tremors were quantified with a small transducer and an electronic data collecting system. The system allows the construction of dose–response curves for tremor inhibition by potential antiparkinsonism drugs.

Johnson et al. (1986) developed a procedure for quantifying whole-body tremors in mice. Displacement of a free floating platform by animal movement created a change in resistance across a strain gauge. Administration of oxotremorine, 2.5 mg/kg, i.p, produced numerous high-frequency, high-intensity peaks within 5 min.

Clement and Dyck (1989) constructed and tested a tremor monitor that quantitates soman- and oxotremorine-induced tremors. The device consisted of a force transducer, from which a plastic beaker was suspended containing a mouse. The signal from the force transducer was fed into a tremor monitor and quantitated using the Applecounter from Columbus Instruments.

Coward et al. (1977) recommended *N*-carbamoyl-2-(2,6-dichlorophenyl)acetamidine hydrochloride (LON-954), a tremorigenic agent, as an alternative to oxotremorine for the detection of anti-Parkinson drugs.

Rats treated with 3-acetylpyridine show a selective degeneration of neurons in the inferior olive nucleus and the olivo-cerebellar tract with characteristic motor inco-ordination and ataxia (Denk et al. 1968; Watanabe et al. 1997; Kinoshita et al. 1998). Similar motor dysfunction is seen in patients with olivo-ponto-cerebellar atrophy. To measure the effect of 3-acetylpyridine and the ameliorating effect of TRH agonists in rats the maximal height of vertical jump after stimulation by a foot shock was measured.

Stanford and Fowler (1997) used a special technique for measuring forelimb tremor in rats induced by low doses of physostigmine. The rats pressed a force-sensing operandum while a computer measured force output and performed Fourier analyses on resulting force–time waveforms.

Several studies indicate that the exposure to the pesticide **rotenone** causes highly selective dopaminergic degeneration and α-synuclein aggregation in rats (Betarbet et al. 2000; Sherer et al. 2003a, 2003b).

Tremulous jaw movements in rats induced by tacrine (Mayorga et al. 1997; Cousins et al. 1999) are considered to reflect symptoms in Parkinson's disease. The are suppressed by dopamine agonists (Salamone et al. 2005).

E.7.2.2 MPTP Model of Parkinson's Disease

PURPOSE AND RATIONALE

MPTP (*N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) has been shown to cause symptoms of Parkinson's disease in exposed individuals. The first observation was made in a relatively young, drug-abusing population. This initiated many clinical and experimental studies (Chiba et al. 1984; Heikkila et al. 1984; Kindt et al. 1988; Review by Special 2002). When administered to primates this compound causes a partial destruction of basal ganglia and a syndrome that resembles Parkinson's disease.

PROCEDURE

Burns et al. (1983) treated eight adult rhesus monkeys weighing 5–8 kg over a period of 5–8 days with cumulative intravenous doses of *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (N-MPTP) up to 10–18 mg/kg. These animals showed a parkinsonism-like disorder (akinesia, rigidity, postural tremor, flexed posture, eyelid closure, drooling) which was reversed by the administration of L-dopa. The pathological and biochemical changes produced by N-MPTP are similar to the well established changes in patients with Parkinsonism.

The N-MPTP intoxication was applied using marmosets by Nomoto et al. (1985, 1988), Temlett et al. (1989) and by Kebabian et al. (1992) to evaluate potential antiparkinson drugs.

EVALUATION

The severity of parkinsonian symptoms is rated by trained observers using a scale of 0 (normal) to 17 (maximum severity) that assesses movement (0: normal; 1: reduced; 2: sleepy), checking movements (0: present; 1: reduced; 2: absent), attention and blinking (0: normal; 1: abnormal), posture (0: normal; 1: abnormal trunk; 2: abnormal trunk and tail; 3: abnormal trunk, tail, and limbs; 4: flexed posture), balance and coordination (0: normal; 1: impaired; 2: unstable;

4: falls), reactions (0: normal; 1: reduced; 2: slow; 3: absent) and vocalizations (0: normal; 1: reduced; 2: absent).

MODIFICATIONS OF THE METHOD

Close and Elliott (1991) studied the behavioral effects of anti-Parkinsonian drugs in normal and MPTP-treated marmosets following central microinfusions.

Kebabian et al. (1992) tested a selective D_1 receptor agonist with antiparkinsonian activity in MTPT-treated marmosets.

Domino and Sheng (1993) studied the relative potency of some dopamine agonists with varying selectivities for D_1 and D_2 receptors in MPTP-induced hemi-parkinsonian monkeys.

Gnanalingham et al. (1995) used MTPT-treated marmosets and found differential effects with D_1 dopamine antagonists as compared with the effects in rats with unilateral 6-OGDA-induced lesions, where 6-OGDA is 6-hydroxydopamine.

Doudet et al. (1993) used intravenous administration of ^{15}O-labeled water and 6-(^{18}F)-L-fluorodopa to assess abnormal striatal activity in monkeys after long-term recovery of unilateral lesions of the dopaminergic nigro-striatal system induced by MPTP. Positron emission tomography (PET) data were examined in relation to behavioral and biological parameters, such as cerebral blood flow.

Belluzzi et al. (1994) induced a hemiparkinsonian syndrome in *Macaca nemestrina* **monkeys** by unilateral infusion of MPTP into the right coronary artery.

Raz et al. (2000) recorded hand tremor and simultaneous activity of several neurons in the external and internal segments of the globus pallidus in **vervet monkeys** before and after treatment with MPTP.

Rollema et al. (1989) compared the effects of intracerebrally administered MPP^+ (1-methyl-4-phenylpyridinium) in three species (**mouse, rat** and **monkey**) by microdialysis determinations of dopamine and metabolites in the striatum.

Asin et al. (1997) tested a selective D_1 receptor agonist in **rats** previously given unilateral 6-hydroxydopamine injections and in **macaques** previously given unilateral, intracarotid infusions of MPTP.

Lange (1989, 1990) described circling behavior in old **rats** after unilateral intranigral injection of MPTP.

Fuxe et al. (1992) studied the protection against MPTP-induced degeneration of the nigrostriatal dopamine neurons in the **black mouse**.

There are marked species differences in susceptibility to the neurotoxic effects of MTPT (Giovanni et al. 1994; Schober 2005).

Grünblatt et al. (2001) described gene expression analysis of mice in the MPTP model of Parkinson's disease using cDNA microarray.

Mandel et al. (2003) reviewed the use of cDNA microarrays to assess Parkinson's disease models and the effects of neuroprotective drugs.

Hamre et al. (1999) performed a quantitative analysis in seven strains of **mice** and found that differential strain susceptibility following MPTP administration acts in an autosomal fashion.

Sedelis et al. (2001) described behavioral phenotyping of the MPTP mouse model on Parkinson's disease.

Muramatu et al. (2003) published an immunocytochemical study on cerebral alterations in an MPTP mouse model of Parkinson's disease.

E.7.2.3 Reserpine Antagonism

PURPOSE AND RATIONALE

Reserpine induces depletion of central catecholamine stores. The sedative effect can be observed in mice shortly after injection, followed by signs of eyelid ptosis, hypokinesia, rigidity, catatonia, and immobility. These phenomena can be antagonized by dopamine agonists.

PROCEDURE

Male NMRI mice of either sex weighing 20–25 g are used. They are injected intraperitoneally with 5 mg/kg reserpine and tested 24 h later. The test compounds are injected 30 min prior to observation. The animals are placed singly onto the floor of a Perspex container (30 × 26 cm, 20 cm high), situated on a Panlab proximity sensor unit. Horizontal movements are recorded for 10 min. Moreover, rearings and grooming episodes are recorded by an experienced observer.

EVALUATION

Locomotor activity and grooming scores of drug-treated animals are compared with controls treated with reserpine and vehicle only by analysis of variance.

MODIFICATIONS OF THE METHOD

Rats treated with reserpine develop spontaneous orofacial dyskinesia that has features similar to tardive dyskinesia in humans (Abbot et al. 1991; Nisewander et al. 1994). The incidence of tongue protrusions was recorded to quantify the occurrence of oral dyskinesia.

E.7.2.4 Circling Behavior in Nigrostriatal Lesioned Rats

PURPOSE AND RATIONALE

Unilateral lesion of the dopaminergic nigrostriatal pathway in the rat by the neurotoxin 6-hydroxydopamine (6-OHDA) induces hypersensitivity of the postsynaptic dopaminergic receptors in the striatum of the lesioned side (Ungerstedt 1971). The rats rotate in a direction towards the lesioned side (ipsilateral) when an indirect acting compound such as amphetamine is administered, but to the opposite direction (contralateral) when a directly acting dopamine agonist, e. g., apomorphine, or the dopamine precursor L-dopa is given. Therefore, this test can be used for the study of central dopamine function and the evaluation of dopamine antagonists and agonists, particularly the activity of novel antiparkinsonian drugs.

PROCEDURE

Male Wistar rats weighing 200–250 g at the time of surgery are used. The are housed individually in a controlled environment with free access to food and water.

The animals are anesthetized with sodium pentobarbital. The head is placed in a stereotaxic device (DKI 900) and positioned according to the atlas of König and Klippel (1963). After a sagittal cut is made in the skin of the skull, a 2-mm-wide hole is drilled with an electrical trepan drill. Care is taken not to lesion the meninges. A 30-gauge stainless-steel cannula connected to a Hamilton syringe is aimed at the anterior zona compacta of the substantia nigra (coordinates anterior 4.1, lateral 1.0 and dorso-ventral –2.5 from instrument zero). A total of 8 µg of 6-OHDA in 4 γ/l of saline is injected at a rate of 1 γ/4 min. After the intracranial injection the wound is closed. The animal is allowed several weeks for recovery and for development of the lesion.

Specially constructed opaque plastic spheres attached to solid-state programming equipment serve as test chambers. The number of full turns, either ipsilateral or contralateral to the lesion, is recorded on an automatic printout counter every 15 min for 1- or 2-h test sessions.

To determine the control values for ipsilateral turning, each subject is administered 2.5 mg/kg of d-amphetamine and immediately placed in the circling chamber for 2 h. Control values for contralateral circling are determined by injecting apomorphine at 1 mg/kg s.c. and recording the rat's circling for 1 h.

Test compounds are given i.p or s.c. and the animals placed into the circling chambers. Circling is recorded over a 1-h period.

EVALUATION

Percent change of drug turns from control turns is recorded. Using various doses ED_{50} values can be calculated.

MODIFICATIONS OF THE METHOD

Etemadzadeh et al. (1989) described a computerized rotometer apparatus for recording circling behavior. The digital pulses derived from the infrared photocell detector induced by the animal rotations were fed directly to a 20-megabyte microcomputer for online recording and were processed further to the Digital Equipment Corporation's VAX computer with the SAS software system for statistical and graphical analysis.

Hudson et al. (1993) described a 16-channel automated rotometer system for reliable measurement of turning behavior in 6-hydroxydopamine-lesioned and transplanted rats. The system is preferable to more tedious methods such as videotaping and subsequent manual analysis or various other mechanical systems.

A rotometer differentiating between clockwise and counter-clockwise rotations with computerized evaluation is available from Technical and Scientific Equipment (Bad Homburg, Germany; Schwarz et al. 1978).

Carey (1989) tested stimulant drugs as conditioned and unconditioned stimuli in a classical conditioning paradigm using drug-induced rotational behavior in rats with unilateral lesions of dopamine neurons.

The production of asymmetry and circling behavior following unilateral, intrastriatal administration of neuroleptics was discussed by Costall et al. (1983).

Rotational behavior produced by intranigral injections of bovine and human β-casomorphins in rats was described by Herrera-Marschitz et al. (1989).

Perese et al. (1989) created a hemiparkinsonian model in rats in which there is 6-OHDA-induced destruction of the dopaminergic nigrostriatal pathway but sparing of the dopaminergic mesolimbic pathway.

Sauer and Oertel (1994) published a retrograde tracing and immunocytochemical study on the pro-

gressive degeneration of nigrostriatal dopamine neurons following intrastriatal terminal lesions with 6-hydroxydopamine in the rat.

Garrett and Holtzman (1996) compared the effects of apomorphine, d-amphetamine, cocaine and caffeine on locomotor activity and rotational behavior in rats with unilateral 6-OHDA-induced lesions of the nigrostriatal tract.

McElroy and Ward (1995) reported that the high-affinity and selective dopamine D_3 receptor ligand, 7-OH-DPAT, caused 6-OHDA-lesioned rats to rotate in a direction contralateral to the lesioned side similarly to the direct-acting dopamine agonist apomorphine.

Haque et al. (1996) directly infused the neurotrophins NT3 and NT4/5 intraparenchymally in close proximity to transplanted nigral tissue placed in the dopamine-depleted striatum of 6-hydroxydopamine-lesioned rats.

A survey on the unilateral 6-hydroxydopamine lesion model in behavioral brain research was prepared by Schwarting and Huston (1996).

DSP-4 [*N*-(2-chloroethyl)-*N*-ethyl-2-bromobenzylamine] is highly toxic to noradrenergic neurons (Finnegan et al. 1999). Srinivasan and Schmidt (2003, 2004) showed that parkinsonian symptoms in 6-hydroxydopamine-induced partial degeneration of substantia nigra in rats are potentiated after depletion of nucleus coeruleus noradrenaline by intraperitoneal treatment with DPS-4.

Harro et al. (2003) studied the effect of denervation of the locus coeruleus projections by DSP-4 treatment on [^{3}H]-raclopride binding to dopamine D_2 receptors and D_2 receptor–G protein interaction in rat striatum.

Löscher et al. (1996) described a mutant rat strain (*CI*) with abnormal circling behavior reminiscent of 6-hydroxydopamine-lesioned rats.

Mele et al. (1997) studied alterations in striatal dopamine overflow by *in vivo* microdialysis during rotational behavior of rats induced by amphetamine, phencyclidine and MK 801.

Smith et al. (1996) reported contralateral turning in chronically cannulated rats after stimulation of glutamate receptors by unilateral intrastriatal injections of glutamate receptor agonists, such as kainate or AMPA.

Spooren et al. (2000) tested the effects of a prototypical $mGlu_5$ receptor antagonist on rotarod locomotor activity and rotational responses in unilateral 6-OHDA-lesioned rats using an accelerated rotarod and automated rotameter cylinders (TSE Systems, Bad Homburg, Germany).

Using the same equipment, Breysse et al. (2002) reported that chronic but not acute treatment with a metabotropic glutamate 5 receptor antagonist reverses the akinetic deficits in rats with 6-hydroxydopamine lesions.

Using automated rotameter bowls (TSE Systems, Bad Homburg, Germany), Meissner et al. (2002) found that deep brain stimulation of subthalamic neurons induces contralateral circling in freely moving 6-hydroxydopamine-lesioned rats.

With this equipment, Lebsanft et al. (2005) found, that 3,4-methylenedioxymethylamphetamine counteracts akinesia enantioselectively in rat rotational behavior.

O'Neill et al. (2004) described neurotrophic actions of an AMPA receptor potentiator, which may increase brain-derived neurotrophic factor expression, in rodent models of Parkinson's disease.

Inhibition of sinistrotorsion induced in **guinea pigs** by injection of physostigmine into the right carotid artery was proposed as a method of screening central anticholinergic activity by De Jonge and Funcke (1962).

Behavioral quantification of striatal dopaminergic supersensitivity after bilateral 6-hydroxydopamine lesions in the **mouse** was reported by Mandel et al. (1992).

Worms et al. (1986) and Poncelet et al. (1993) studied turning behavior in mice induced by intrastriatal injection of neuropeptides.

Fitzgerald et al. (1992) recommended the **chakragati mouse (ckr)**, a transgenic insertional mutant which displays lateral circling, locomotor hyperactivity and hyperreactivity, as a model to study aspects of neuropsychiatric disorders associated with dopaminergic abnormalities.

Emonds-Alt et al. (1995) injected 0.3 pg senktide into the striatum of **gerbils** inducing contralateral rotations which were antagonized by intraperitoneal or oral administration of a tachykinin NK_3 receptor antagonist.

Vernier and Unna (1963) tested drugs against the tremor induced by stereotactically oriented electric lesions in the region of the subthalamus or the mesencephalic reticular formation in **monkeys**.

E.7.2.5 Elevated Body Swing Test

PURPOSE AND RATIONALE

Borlongan and Sanberg (1995); Borlongan et al. (1995) proposed the elevated body swing test as a measure of asymmetrical motor behavior of hemiparkinsonian animals in a drug-free state.

PROCEDURE

Male, 8-week-old Sprague Dawley rats are anesthetized with sodium pentobarbital (60 mg/kg i.p.) and mounted in a Kopf stereotaxic frame. They are lesioned by injection of 8 µg 6-hydroxydopamine in 4 µl saline containing 0.02% ascorbic acid in the left substantia nigra (AP – 5.0, ML+1.5, DV – 8.0). The solution is injected over a 4-min period and the needle left in place for an additional 5 min before retraction.

Seven days after the lesion, behavioral testing is performed. The animal is allowed to habituate in a Plexiglas box and attain a neutral position having all four paws on ground. The rat is held about 2.5 cm from the base of its tail and elevated 2.5 cm above the surface on which it has been resting. A swing is recorded whenever the animal moves its head out of the vertical axis to either side. Before attempting another swing, the animal must return to the vertical position for the next swing to be counted. Swings are counted for 60 s over four consecutive 15-s segments. The total number of swings made to each side is divided by the overall total number of swings made to both sides to get percentages of left and right swings. The criterion of biased swing is set at 70% or higher. At 30 and 45 s, 6-OHDA-lesioned rats exhibit right-biased swings of 70% or higher compared to normal rats.

EVALUATION

A two-way ANOVA is used to analyze swing behavior data across the 15-s segments.

E.7.2.6 Skilled Paw Reaching in Rats

PURPOSE AND RATIONALE

Montoya et al. (1990, 1991), Abrous et al. (1993), Abrous and Dunnett (1994), Nikkhah et al. (1993), and Barnéoud et al. (1996) used the skilled paw reaching test as a model of Parkinson's disease in the rat. The term "staircase test" mentioned in this context has nothing to do with the staircase test described by Thiebot et al. (1973) for evaluating anxiolytic activity in rats (see E.2.4.6).

Unilateral injection of 6-OHDA into the medial forebrain bundle results in an impairment of paw reaching on both sides which can be ameliorated by drug treatment or transplantation of a nigral cell suspension.

The apparatus has been developed after earlier studies by Whishaw et al. (1986) who investigated the contributions of motor cortex, nigrostriatal dopamine and caudate-putamen to skilled forelimb use in the rat.

PROCEDURE

Apparatus

The apparatus consists of a clear Perspex chamber with a hinged lid. A narrower compartment with a central platform running along its length, creating a trough

on either side, is connected to the chamber. The narrowness of the side compartment prevents rats from turning around, so they can use only their left paw for reaching into the left trough and their right paw for reaching into the right trough. A removable double staircase is inserted into the end of the box, sliding into the troughs on either side of the central platform. Each of the steps of the staircase contains a small well, and two 45-mg saccharin-flavored pellets are placed in each well.

Learning Procedure

The week before the start of the training period, the rats are deprived of food and their body weight is stabilized at 85% of the weight of non-deprived rats. At the same time, they are gently manipulated and familiarized with the appetitive saccharin-flavored pellets.

The animals then begin to learn the paw reaching task. For 4 weeks they are placed in the test boxes once per day for 10–15 min. The number of pellets eaten during the test period indicates the rat's success in grasping and retrieving the pellets; the number of steps from which pellets have been removed provides an index of the attempts to reach the food and how far the rat can reach; the number of missed pellets remaining at the end of the test on the floor of the side compartment indicates a lack of sensorimotor coordination in grasping and retrieving the pellets. In addition to these three parameters, it is noted which forepaw the rat used for the first movement to reach the pellet on each test day. A first choice score of +1 corresponds to the paw contralateral to the lesion, a score of –1, to the paw ipsilateral to the lesion. Because rodents exhibit a "pawedness," it must be noted whether there is a preference for one paw.

Lesions

The mesotelencephalic system is lesioned by a stereotaxic unilateral injection of 6-OHDA into the medial forebrain bundle under equithesin anesthesia. 6-OHDA is injected in a volume of 1.5 µl and at a concentration of 4 µg/µl of 0.9% saline and 0.01% ascorbic acid twice over 3 min via a 30-gauge stainless steel cannula at the stereotaxic coordinates: $L = 1.6$ mm, $AP = 0$ mm, $V = -7.6$ mm and $L = 1.6$ mm, $AP = -1$ mm, $V = -8$ mm. The coordinates AP and L are estimated relative to the bregma, and V is measured from the level of the dura, with the incisor bar set 5 mm above the interaural line. Following each injection, the cannula is left in place for an additional 4 min to allow the diffusion of the neurotoxin away from the injection site. The sham-operated group receives sham lesions by identical injection of ascorbate-saline solution alone.

Drug Treatment

The animals are injected i.p. with the test drug or saline 30 min before the unilateral 6-OHDA lesion and 24 h thereafter.

EVALUATION

Test sessions are performed 4, 5, 7, and 8 weeks after 6-OHDA lesion. The parameters success, attempts and sensorimotor coordination are subjected to a two-way ANOVA with group as the independent measure and weeks as the dependent measure.

MODIFICATIONS OF THE METHOD

Fricker et al. (1996) investigated the effect of unilateral ibotenic acid lesions in the dorsal striatum, placed at anterior, posterior, medial, or lateral loci, in the staircase test of skilled forelimb use.

Nakao et al. (1996) studied paw reaching ability in rats with unilateral quinolinic acid lesions of the striatum as an animal model for Huntington's disease.

Barnéoud et al. (1996) evaluated the neuroprotective effects of riluzole using impaired skilled forelimb use, circling behavior, and altered dopaminergic metabolism of the mesotelencephalic system in unilaterally 6-OHDA-lesioned rats.

Fricker et al. (1997) studied the correlation between positron emission tomography, using ligands to the D_1 and D_2 receptors, and reaching behavior in rats with ibotenic acid lesions and embryonic striatal grafts.

Grabowski et al. (1993), Marston et al. (1995), and Sharkey et al. (1996) tested drug effects on skilled motor deficits produced by middle cerebral artery occlusion in rats using the paw reaching test.

Meyer et al. (1997) described a revolving food pellet test for measuring sensorimotor performance in rats.

E.7.2.7 Stepping Test in Rats

PURPOSE AND RATIONALE

Schallert et al. (1992),Olsson et al. (1995) and Rosenblad et al. (1997) introduced the stepping test as a clinically relevant unilateral model of Parkinsonian akinesia. The 6-OHDA lesion induced marked and long-lasting impairments in the initiation of stepping movements with the contralateral paw which can be ameliorated by the systemic application of drugs.

PROCEDURE

6-OHDA Lesion Surgery

Female Sprague Dawley rats receive two stereotaxic injections of 6-OHDA (3.6 µg/µl in 0.2 µg/ml ascorbate-saline) into the right ascending mesostriatal dopamine pathway using a 10-µl Hamilton syringe at the following coordinates (in mm, with reference to bregma and dura):

1. 2.5 µl at AP –4.4, L 1.2, V 7.8, tooth bar –2.4;
2. 3.0 µl at AP –4.0, L 0.8, V 8.0, tooth bar +3.4 at an injection rate of 1 µl/min.

The cannula is left in place for an additional 5 min before slowly retracted.

Experimental Setup for Stepping Test

The tests monitoring initiation time, stepping time and step length are performed using a wooden ramp with a length of 1 m connected to the rat's home cage. A smooth-surfaced table is used for measuring adjusted steps.

During the first 3 days the rats are handled by the experimenter to familiarize them with the experimenter's grip. During the subsequent 1–2 days the rats are trained to run spontaneously up the ramp to the home cage.

The stepping test comprises two parts: first, the time to initiation of a movement of each forelimb, the step length, and the time required for the rat to cover a set distance along the ramp with each forelimb; and second the initiation of adjusting steps by each forelimb when the animal was moved sideways along the bench surface. Each test consists of two tests per day for three consecutive days and the mean of six subtests is calculated.

Initiation Time, Stepping Time, and Step Length

The rat is held by the experimenter with one hand fixing the hindlimbs and slightly raising the hind part above the surface. The other hand fixes the forelimb not to be monitored. Time is measured until the rat initiates movement with the forelimb not fixed by the experimenter, using 180 s as break-off point. Stepping time is measured from initiation of movement until the rat reaches the home cage. Step length is calculated by dividing the length of the ramp by the number of steps required for the rat to run up the ramp. The sequence of testing is right paw testing followed by left paw testing, repeated twice.

Adjusting Steps

The rat is held in the same position as described above with one paw touching the table, and is then moved

slowly sideways (5 s for 0.9 m) by the experimenter, first in the forehand and then in the backhand direction. The number of adjusting steps is counted for both paws in the backhand and forehand directions of movement. The sequence of testing is right paw forehand and backhand adjusting stepping, followed by left paw forehand and backhand directions. The test is repeated twice each day.

The paw contralateral to the lesion is passively dragging when the rat is moved in the forehand direction, while the ipsilateral paw performs frequent stepping movements.

Drug Application

Stepping tests are repeated to determine the baseline weekly after the 6-OHDA lesion. The drug tests are administered for 1 day only. Various drugs can be evaluated in weekly intervals.

EVALUATION

Results are expressed as means ± SEM. For statistical evaluation, the data are subjected to one-factor analysis of variance (ANOVA) and Fisher post hoc test.

MODIFICATIONS OF THE METHOD

Schallert et al. (2000), Picconi et al. (2003, 2004), and Centonze et al. (2005) described the limb-use asymmetry test to measure motor performance in rats with 6-OHDA-induced lesions. Forelimb use during exploratory activity was analyzed in a transparent cylinder (20 cm diameter and 30 cm height) for 3–10 min depending on the degree of movement maintained during the trial. The number of supporting wall contacts executed independently with the right of the left forelimb was counted. The percentage of wall contacts executed by the impaired forelimb (contralateral to the lesion) was then subtracted from the percentage of contacts with the non-impaired forelimb to obtain a limb-use asymmetry score.

E.7.2.8 Transgenic Animal Models of Parkinson's Disease

PURPOSE AND RATIONALE

New insight in the pathobiology of Parkinson's disease has led to the development of transgenic animal models (Gonzalez-de Aguilar et al. 2003; Kirik and Björklund 2003; Levine et al. 2004).

The most prominent models are related to **α-synuclein**. The first transgenic mice that express human α-synuclein were generated by Masliah et al. (2000). These mice displayed a progressive accumulation of α-synuclein and ubiquitin-immunoreactive inclusions in neurons of the neocortex, hippocampus, and substantia nigra. These alterations were associated with a loss of dopaminergic terminals in the basal ganglia and with motor impairments. Since then, several studies on transgenic α-synuclein mice have been performed (van der Putten et al. 2000; Masliah et al. 2001; Giasson et al. 2002; Kirik et al. 2002; Gispert et al. 2003; Hashimoto et al. 2003; Fernagut and Chesselet 2004; Martin-Clemente et al. 2004; Cabin et al. 2005; Frasier et al. 2005; Poon et al. 2005). Masliah and Hashimoto (2002) discussed the possible role of **β-synuclein** for development of new treatments for Parkinson's disease using transgenic animal models.

Ubiquitin carboxyl-terminal hydrolase L1 (**UCH-L1**) is a neuron-specific ubiquitin recycling enzyme, which may be implicated in the pathogenesis of Parkinson's disease (Leroy et al. 1998). Lindsten et al. (2003) developed a model for *in vivo* analysis of the ubiquitin/proteasome system by generating mouse strains transgenic for a green fluorescence protein reporter carrying a constitutively active degradation signal.

Loss-of-function mutations in **parkin** are the major cause of early-onset familial Parkinson's disease. To investigate the pathogenic mechanism by which loss

of parkin function causes Parkinson's disease, Goldberg et al. (2003) generated a mouse model bearing a germline disruption in parkin. In addition to PARK1 (representing the α-synuclein gene) and PARK2 (representing the UCH-L1 gene), other monogenic forms of Parkinson's disease have been described (Lansbury and Brice 2002; von Bohlen und Halbach et al. 2004).

The ***weaver*** **mutant mouse** has been proposed as another model of Parkinson's disease (Bankiewicz et al. 1993; Bandmann et al. 1996; Cheng et al. 1997; Ebadi et al. 2005).

MODIFICATIONS OF THE METHOD

Lo Bianco et al. (2002) studied α-synucleinopathy and selective dopaminergic neuron loss in a **rat** lentiviral-based model of Parkinson's disease.

Kirik et al. (2003) described nigrostriatal α-synucleinopathy induced by viral vector-mediated overexpression of human α-synuclein using a primate (adult **marmosets**) model of Parkinson's disease.

Transgenic **Drosophila** models expressing human α-synuclein were described by Feany and Bender (2000), Pendleton et al. (2002), and Scherzer et al. (2003).

Brown et al. (2002) published multiplex three-dimensional brain gene expression mapping in a mouse model of Parkinson's disease.

Son et al. (2003) described cloning and expression analysis of the Parkinson's disease gene, **UCH-L1**, and its promoter in **zebrafish**.

E.7.2.9 Cell Transplantations into Lesioned Animals

PURPOSE AND RATIONALE

Human embryonic stem cells may potentially serve as a renewable source of cells for transplantation. In Parkinson's disease, embryonic stem-cell-derived dopaminergic neurons may replace the degenerated neurons in the brain. To substantiate this goal, numerous animal experiments were performed. Most authors used rats rendered hemi-Parkinsonian by injection of 6-OHDA into the substantia nigra as recipients (Zawada et al. 1998; Mendez et al. 2000; Sawamoto et al. 2001; Björklund et al. 2002; Hao et al. 2002; Kim et al. 2002; Ben-Hur et al. 2004; Burnstein et al. 2004; Jollivet et al. 2004; Levy et al. 2004; Yoshizaki et al. 2004; Rafuse et al. 2005; Richardson et al. 2005).

Takagi et al. (2005) reported that dopaminergic neurons generated from cynomolgus monkey embryonic stem cells functioned in the MPTP primate model of Parkinson's disease. However, complications were reported by Blanchet et al. (2003) using a similar approach.

In spite of almost 20 years of experimental experience, clinical trials with cell transplantation for Parkinson's disease have had disappointing results (Drucker-Colin and Verdugo-Diaz 2004; Linazaroso 2004; Roitberg et al. 2004).

E.7.2.10 Transfer of Glial Cell Line-Derived Neurotrophic Factor (GDNF)

PURPOSE AND RATIONALE

Recombinant viral vectors derived from adenovirus, adeno-associated virus or lentivirus have been developed into highly effective vehicles for gene transfer to the adult central nervous system. These vectors have been shown to be effective for long-term delivery of glial cell-line derived neurotrophic factor (GDNF) in the nigrostriatal system. GDNF is a strong candidate agent in the neuroprotective treatment of Parkinson's disease. The injection of adeno-associated virus encoding rat glial cell line-derived neurotrophic factor protected nigral neurons in the 6-OHDA-induced degeneration model of Parkinson's disease in rats (Yoshimoto et al. 1995; Bilang-Bleuel et al. 1997; Lapchak et al. 1997; Mandel et al. 1997; Björklund et al. 2000; Chen et al. 2003; Wang et al. 2002; Thi et al. 2004). Jollivet et al. (2004) used intra-striatal glial cell line-derived neurotrophic-factor-releasing microspheres. Yasuhara et al. (2005) reported the use of glial cell line-derived neurotrophin-factor-producing cells encapsulated into hollow fibers. Kojima et al. (1997) and Cheng et al. (1998) found that glial cell-line-derived neurotrophic factor protects against MPTP-induced neurotoxicity in **mice**. Kordower et al. (2000) reported that neurodegeneration was prevented by lentiviral vector delivery of GDNF in primate models (**rhesus monkeys** treated with MPTP) of Parkinson's disease.

E.8
Animal Models of Neurological Disorders

E.8.1
Huntington's Disease

E.8.1.1
General Considerations

PURPOSE AND RATIONALE

Huntington's disease is a neurological disorder characterized by loss of striatal neurons and the motor signs of dyskinesia, dystonia and chorea, as well as complex neuropsychiatric changes (Hayden 1981). Brouillet et al. (1999) reviewed the different aspects of the replicating Huntington's disease phenotype in experimental animals. There is at present no effective therapy against this disorder. The gene responsible for the disease has been cloned and the molecular defect identified as an expanded polyglutamine tract in the N-terminal region of a protein, named huntingtin (Landles and Bates 2004; Li and Li 2004). Huntingtin interacts with a number of proteins and it has been suggested that alterations in glycolysis, vesicle trafficking or apoptosis play a role in the pathophysiology of Huntington's disease.

E.8.1.2
3-Nitropropionic Acid Animal Model of Huntington's Disease

PURPOSE AND RATIONALE

An animal model of **Huntington's disease** was recommended by Beal et al. (1993), Brouillet et al. (1993), and Borlongan et al. (1995, 1997a, 1997b). Administration of 3-nitropropionic acid, an inhibitor of the mitochondrial citric acid cycle, produces a very selective striatal degeneration and results in a progressive locomotor deterioration in rodents resembling that of Huntington's disease.

PROCEDURE

Borlongan et al. (1995) injected male Sprague Dawley rats i.p. with 10 mg/kg of 3-nitropropionic acid once every 4 days for 28 days and measured passive avoidance in a step-down apparatus and locomotor activity using the Digiscan Animal Activity Monitor System. Using the same system, Borlongan et al. (1997b) found hyperactivity after two injections, whereas four injections or more lead to hypoactivity.

Lee et al. (2000) evaluated the neuroprotective effect of lamotrigine and MK-801 on rat brain lesions induced by 3-nitropropionic acid by magnetic resonance imaging and *in vivo* proton magnetic resonance spectroscopy.

Male Sprague Dawley rats received daily i.p. injections of 15 mg/kg of 3-nitropropionic acid for five consecutive days. Test drugs were injected daily before 3-nitropropionic acid injections.

Behavioral changes were recorded daily, and immediately before sacrifice, graded according to the neurological scale described by Guyot et al. (1997). A total of 6 grades included: Grade 0, normal behavior; grade 1, general slowness in movement due to mild hind-limb impairment; grade 2, prominent gait abnormality with poor coordination; grade 3, nearly complete hind-limb paralysis; grade 4, incapability to move due to four-limb impairment; and grade 5, recumbency.

Magnetic resonance measurements were performed on the sixth day under anesthesia with 60 mg/kg i.p. pentobarbital. An endotracheal tube was set for artificial ventilation with an animal ventilator. The expiratory CO_2 concentration was maintained between 3.5% and 4.5% by adjusting the ventilator. Magnetic resonance measurements were performed on a Biospec 4.7 T spectrometer with an active shielding gradient at 6.9 Gy/cm in 500 µs. The rats were placed in a prone position with a custom-designed head-holder. A 20-cm birdcage coil was used for RF excitation, and a 2-cm-diameter surface coil placed directly over the head was used for signal receiving. After magnetic field optimization, a multi-slice multi-echo image was obtained with the following parameters: field of view = 5 cm, four slices (2 mm thick with a 1-mm gap), matrix 256 × 128, TR = 4,000 ms, and initial TE = 20 ms with an echo spacing of 20 ms for six echos. Pixel-by-pixel T2 maps were obtained

with commercial analysis software. The average of T2 values of bilateral hippocampus or striatum calculated from multi-echo images was applied for statistical analysis.

The point-resolved spectroscopy (PRESS) sequence preceded by three consecutive chemical shift selective saturation (CHESS) pulses for water suppression was used to acquire the localized proton spectra over the striatum. After manually adjusting the transmitter and receiver, magnetic field shimming of the striata and maximizing the suppression of the water signal, spectral data were obtained with the following parameters: TR = 2000 ms, TE = 136 ms, scan no. = 256, spectral width = 4000 Hz. The peak areas of *N*-acetyl-aspartate, choline, creatine, succinate, and lactate were recognized. The ratios of cerebral metabolites relative to creatine were used for statistical analysis.

EVALUATION

The data were expressed as means ± SD. One-way ANOVA followed by a Tukey test was used for evaluating significant difference among sham controls and various treatment groups.

MODIFICATIONS OF THE METHOD

Matthews et al. (1998) found neuroprotective effects of creatine and cyclocreatine against lesions induced by malonate or 3-nitropropionic acid.

Quary et al. (2000) demonstrated major strain differences in response to chronic systemic administration of the mitochondrial toxin 3-nitropropionic acid in rats.

Pubill et al. (2001) reported that orphenadrine (an anticholinergic drug with NMDA receptor antagonist properties) prevented 3-nitropropionic-acid-induced neurotoxicity *in vitro* and *in vivo*.

Lastres-Becker et al. (2003) found that compounds acting on the endocannabinoid and/or endovanilloid systems reduce hyperkinesia in rats induced by bilateral intrastriatal injection of 3-nitropropionic acid.

Lee and Chang (2004) used magnetic resonance imaging and spectroscopy to assess 3-nitropropionic-acid-induced brain lesions in rats.

Tunez et al. (2004) described a protective effect of melatonin on 3-nitropropionic-acid-induced oxidative stress in synaptosomes in rats.

Hantraye et al. (1992) reported that intrastriatal transplantation of cross-species fetal striatal cells reduced abnormal movements in **baboons** injected with the neurotoxin ibotenic acid.

Palfi et al. (1996) showed that chronic 3-nitropropionic acid treatment replicates the cognitive and motor deficits in Huntington's disease also in **baboons.**

Mittoux et al. (2000) reported restoration of cognitive and motor function by ciliary neurotrophic factor in a primate model (***Macaca fascicularis***) of Huntington's disease.

E.8.1.3 Quinolinic Acid Rat Model of Huntington's Disease

PURPOSE AND RATIONALE

Intrastriatal injection of quinolate, an NMDA receptor agonist, replicates many neurochemical, histological, and behavioral features of Huntington's disease (Beal et al. 1986, 1988, 1991; DiFigla 1990; Burns et al. 1995; Pérez-Navarro et al. 2000a).

Araujo and Hilt (1997) found that the glial cell-line-derived neurotrophic factor attenuates the behavioral and neurochemical deficits induced by quinolinic acid in rats.

PROCEDURE

Female Sprague Dawley rats were anesthetized with pentobarbital (50 mg/kg) before being placed in a stereotaxic apparatus (Kopf). A small hole was made on the left side of the skull 3.0 mm lateral to the midline, through which a hypodermic needle attached to a Hamilton syringe was lowered 5 mm below the dura into the striatum. For each lesioned rat, 200 nmol of quinolinic acid dissolved in 2 µl of phosphate-buffered saline was injected over a 1-min interval through the needle into two sites (0.7 and 1.4 mm anterior to the bregma) in the left striatum, while the contralateral striatum was left intact.

Neurotrophic factors were given 30 min prior to the toxin injections. Recombinant glia-cell-derived neurotrophic factor (Lin et al. 1993; Lapchak et al. 1997), brain-derived neurotrophic factor or neurotrophin-3 was administered intraventricularly. For i.c.v. treatment, a Hamilton syringe or an infusion cannula was lowered through a hole drilled in the skull of anesthetized rats at the following coordinates: 1.4 mm posterior to the bregma, 2 mm lateral to the midline, and 3.5 mm below the dura.

Rotational Behavior

The effects of quinolinic acid lesions and neurotrophic factor treatment on rotational behavior were assessed using a Rota-Count 8 automated rotor system (Columbus Instruments), which monitors both clockwise and counterclockwise turning behavior. One week following surgery, rats were given 5 mg/kg amphetamine i.p. 15 min prior to placement into the apparatus. The total number of turns in successive 10-min intervals was measured in a 1-h period.

Histology

The extent of the lesion produced by quinolinic acid was illustrated using Nissl-stained coronal sections.

D_1 and D_2 dopamine receptor binding was evaluated in homogenized lesioned and unlesioned striata.

Striatonigral [^{3}H]neurotransmitter uptake was measured in synaptosomes from striatal tissue containing putamen-pallidum as well as a portion of the globus pallidus.

Striatal choline acetyltransferase activity was determined in striatal homogenates using a radiochemical assay.

Neuropeptide levels in tissue homogenates were measured using commercial radioimmunoassay kits.

EVALUATION

Results are expressed as mean ± SEM of the number of rats, where each sample was the average of duplicate or triplicate measures. Statistical significance was assessed using a one-way ANOVA, followed by post hoc Bonferroni or Dunnett's Multiple Comparisons analysis.

MODIFICATIONS OF THE METHOD

Anderson et al. (1996) reported that the ciliary neurotrophic factor protects striatal output neurons in the quinolinic acid rat model.

Nakao et al. (1996) studied paw reaching ability in rats with unilateral quinolinic acid lesions of the striatum.

Shear et al. (1998) compared intrastriatal injections of quinolinic acid and 3-nitropropionic acid for use in animal models of Huntington's disease.

Hughes et al. (1999) found that administration of recombinant human activin-A has powerful neurotrophic effects on selected striatal phenotypes in the quinolinic acid lesion model.

Pérez-Navarro et al. (1999) reported that intrastriatal grafting of a glia cell-line-derived neurotrophic-factor-producing cell line protects striatonigral neurons from quinolinic acid excitotoxicity *in vivo*.

Reggio et al. (1999) found that the intrastriatal injection of an adenosine A_2 receptor antagonist prevents frontal cortex EEG abnormalities in the quinolinic acid rat model.

Nakao et al. (1999) reported that embryonic striatal grafts restore neuronal activity of the globus pallidus in the quinolinic acid rat model.

Pérez-Navarro et al. (2000b) found that neurturin protects striatal neurons but not interneurons in the quinolinic acid rat model.

Bensadoun et al. (2001) found a neuroprotective effect of interleukin-6 and IL6/IL6R chimera in the quinolinic acid rat model.

Gianfriddo et al. (2003) found that adenosine A_{2A} antagonism increases striatal glutamate outflow in the quinolinic acid rat model.

Ryu et al. (2003) described neuroprotective effects of pyruvate in the quinolinic acid rat model.

Scattoni et al. (2004) reported progressive behavioral changes in the spatial open-field in the quinolinic acid rat model.

E.8.1.4 Transgenic Animal Models of Huntington's Disease

PURPOSE AND RATIONALE

Several **transgenic models** of Huntington's disease are described, among them:

The **R6/2 HD mouse model** (Ona et al. 1999; Hickey and Morton 2000; Hemlinger et al. 2002; Keene et al. 2002; Hockly et al. 2003a, 2003b; Zucker et al. 2004; Chou et al. 2005);

the **yeast artificial chromosome (YAC) mouse** (Ainscough et al. 2001; Slow et al. 2003; Al Mahdawi et al. 2004);

the **TgCAG100 mouse** (Laforet et al. 2001; Ariano et al. 2005);

the **Hdh^{Q111}mouse** (Gines et al. 2003).

A **transgenic rat model** of Huntington's disease was described by Von Hörsten et al. (2003). Behavioral phenotyping was performed using computerized systems from TSE Systems (Bad Homburg, Germany).

Segalat and Neri (2003) recommended *Caenorhabditis elegans* as a model for human inherited degenerative disorders, such as Duchenne's muscular dystrophy and Huntington's disease.

A **transgenic *Drosophila* model** of Huntington's disease was recommended by Lee et al. (2004) and Agrawal et al. (2005).

E.8.2 Amyotrophic Lateral Sclerosis

E.8.2.1 General Considerations

PURPOSE AND RATIONALE

Amyotrophic lateral sclerosis is an adult-onset neurological disease characterized by the selective loss of motor neurons. The early symptoms, principally limb and bulbar muscle weakness, begin in middle life and progress usually rapidly to death within 2 or 3 years. Clinical subtypes of the disease are defined according to the predominant site of weakness and whether upper or lower motor neurons are primarily involved (Rowland and Shneider 2001; Morrison 2002; Waldmeier 2003). Several experimental models for amyotrophic lateral sclerosis have been developed (Kaal et al. 1999; Anger 1991; Senior 2002).

E.8.2.2 Transgenic Animal Models of Amyotrophic Lateral Sclerosis

PURPOSE AND RATIONALE

Most of the transgenic mouse models are based on familial superoxide dismutase 1 (SOD1) mutations. Of these, the **G93A** mouse is the most investigated (Gurney et al. 1994; Kostic et al. 1997; Trieu and Uckun 1999; Vukosavic et al. 1999, 2000; Azzouz et al. 2000; Li et al. 2000; Spooren and Hengerer 2000; Andreassen et al. 2001; Canton et al. 2001; Jung et al. 2001; Wendt et al. 2002; Azari et al. 2003; Copray et al. 2003; Maragakis et al. 2003; Snow et al. 2003; van Damme et al. 2003; Raiteri et al. 2004; Raman et al. 2004; Waibel et al. 2004). These mice express mutant human SOD1 with a substitution of glycine to alanine in position 93, which induces a severe, progressive motoneuron disease. Several studies were performed with **G37R** (Nguyen et al. 2001; Farah et al. 2003; Robertson et al. 2003, 2003), **H46R** (Nagai et al. 2001), and **G85R** (Bruijn et al. 1998; Amedola et al. 2004) mutant mice. Pasinelli et al. (1998) reported cleavage and activation of caspase-1 in these animals, and Lee et al. (2001) found increased vulnerability of cells transfected with these mutant forms of SOD1 to apoptotic stimuli and protection by overexpression of Bcl-2.

Van Damme et al. (2003) tested the AMPA receptor antagonist NBXQ for survival in a transgenic mouse model of amyotrophic lateral sclerosis. Canton et al. (2001) described the pharmacological properties and activity in the SOD1-G53A animal model of amyotrophic lateral sclerosis of a synthetic AMPA antagonist.

PROCEDURE

Transgenic mice [B6SJL-TgN(SOD1-G93A)G1H] heterozygous for the deficient SOD1 gene and wild-type littermates were identified by polymerase chain reaction. Animals were treated starting on the 50th day of life, until their death with various subcutaneous doses of the test compound.

The following parameters were examined:

Muscle strength: Animals were tested for muscle strength at intervals using a muscle strength meter. Each mouse was held by the tail and pulled steadily over a metal grill three times in rapid succession. The force was recorded on a force meter. The highest score for muscle strength was taken.

Glutamate uptake: Animals were sacrificed at 150 days and spinal cord rapidly dissected for synaptosomal preparations and high-affinity Na^+-dependent glutamate uptake was measured. Spinal cords were homogenized in 20 volumes of sucrose (0.32M) and the homogenate centrifuged at 800 *g* for 10 min. After centrifugation of the supernatant at 20,000 *g* for 20 min, the pellet was resuspended and washed in 50 volumes of sucrose buffer. Transport assays were performed in Krebs-HEPES buffer. Duplicate samples, with or without sodium chloride, were incubated at 37°C for 3 min in the presence of [^{3}H]L-glutamate after appropriate isotopic dilution. The reaction was stopped by addition of ice-cold buffer containing choline and followed by filtration and scintillation counting of the radioactivity retained on filters. High-affinity Na^+-dependent uptake was calculated by subtracting results obtained in choline buffer from that obtained with Na^+ buffer.

Life expectancy: Remaining mice were treated until day of death, which was noted.

EVALUATION

Statistical significance of the biochemical and behavioral data was assessed using Kruskal-Wallis non-parametric analysis of variance followed by Dunn's multiple comparison test.

MODIFICATIONS OF THE METHOD

Haase et al. (1998) described therapeutic effects and mechanism of action of adenovirus-mediated transfer of the neurotrophin-3 gene into skeletal muscle of pmn (progressive motor neuropathy) mice.

Schmalbruch et al. (1991) described an autosomal-recessive mouse mutant with progressive motor neuropathy. Homozygotes develop paralysis of the hindlimbs during the third week of life. Soon thereafter the forelimbs also become weak, and all mice die 6–7 weeks after birth.

Zhu et al. (2002) reported that minocycline inhibits cytochrome c release and delays progression of amyotrophic lateral sclerosis in transgenic mice.

Howland et al. (2002) described focal loss of the glutamate transporter EAAT2 in a transgenic **rat** model of SOD1 mutant-mediated amyotrophic lateral sclerosis.

Bordet et al. (1999, 2001) reported protective effects of cardiotrophin-1 adenoviral gene transfer on neuromuscular degeneration in transgenic amyotrophic lateral sclerosis mice overexpressing a mutated form of human superoxide dismutase-1 with a $Gly^{93}Ala$ substitution.

Ralph et al. (2005a, 2005b) reported that a silencing mutant SOD1 using interfering RNA protects against neurodegeneration and extends survival in the G93A model of amyotrophic lateral sclerosis.

Pharmacology and mechanism of action of riluzole, which has demonstrated beneficial effects in amyotrophic lateral sclerosis in clinical studies, have been investigated in several preclinical studies (Doble 1996; Gurney et al. 1998; Jimonet et al. 1999; Snow et al. 2003).

E.8.3 Spinal Muscular Atrophy

E.8.3.1 General Considerations

PURPOSE AND RATIONALE

Spinal muscular atrophy is a common genetic disease of the motor neuron with a high mortality during infancy (Strober and Tennekoon 1999; Iannaccone et al. 2004; Ogino and Wilson 2004). Among the group of clinically and genetically heterogeneous spinal muscular atrophies, the autosomal recessive proximal types I–III are the most frequent (Schara and Mortier 2004). They are caused by mutations of the telemetric copy of the survival motor neuron gene (SMN1) on chromosome sq while loss of the centromeric copy (SMN2) does not lead to spinal muscular atrophy (Talbot and Davis 2001; Frugier et al. 2002; Wirth 2002; Nicole et al. 2002).

Transgenic mouse models have been developed for these types of disease.

E.8.3.2 Transgenic Animal Models of Spinal Muscular Atrophy

PURPOSE AND RATIONALE

Several mouse models of spinal muscular atrophy are described (Bergin et al. 1997; Deniselle et al. 1997;

DiDonato et al. 1997, 2001; Schrank et al. 1997; Fricker 2000; Frugier et al. 2000; Hsieh-Li et al. 2000; Jablonka et al. 2000, 2001; Monani et al. 2000a, 2000b, 2003; Cifuentes-Diaz et al. 2001, 2002; Melki 2001; Tucker et al. 2001; Ferri et al. 2003, 2004; Rossoll et al. 2003; Azzouz et al. 2004; Grohmann et al. 2004; Le et al. 2005). These studies are intended to mimic spinal muscular atrophy in humans resulting from loss-of-function mutations in the survival motor neuron gene (Smn). Mice carrying a homozygous deletion of Smn exon 7 display a dramatic and progressive loss of motor axons involving both proximal and terminal regions. The human centromeric survival motor neuron gene (*SMN2*) rescues embryonic lethality in $Smn^{-/-}$ mice. SMNDelta7, the major product of the centromeric survival motor neuron (SMN2) gene, extends survival in mice with spinal muscular atrophy.

Chang et al. (2001) reported treatment of spinal muscular atrophy in transgenic mice by sodium butyrate.

PROCEDURE

Cell Culture

Epstein-Barr-virus-transformed lymphoid cell lines from different SMA-type patients with deleted *SMN1* genes were established. Lymphocytes were collected from the whole blood of patients by Ficoll hypaque separation. The buffy coat was collected and washed twice with 5 ml PBS. The pellet was resuspended in 5 ml RPMI medium containing 0.5 ml Epstein-Barr virus, 50 µl phytohemagglutinin (0.5 mg/ml), and 50 µl ciclosporin (0.2 mg/ml). Cells were incubated at 37°C with 5% CO_2 until they became viable.

Mice

Five independent human *SMN2* gene transgenic mice were generated and crossed with mice heterozygous for the *Smn* locus knockout. Transgenic mice that were also homozygous for the knockout alleles ($Smn^{-/-}SMN2$) were then generated by crossing with the above mice. These knockout transgenic mice developed progressive motor neuron disease similar to that in human SMA patients. The SMA-like mice were classified into three groups based on their phenotypes, which were judged by three independent observers. Mice with the most severe pathological form (type 1) did not develop furry hair and died before postnatal day 10; mice with intermediate severity (type 2) showed poor activity and variable symptoms and died at 2–4 weeks; the type 3 mice survived and bred normally, but had short and enlarged tails (Hsieh-Li et al. 2000). SMA-like mice (non-pregnant and pregnant) were supplied with sterile water ad libitum and rodent pellets. The sodium butyrate-treated group received sodium butyrate at a concentration of 0.8 mg/ml or 8 mg/ml in distilled water, beginning immediately after diagnosis or after 15 days gestation in SMA-like pregnant mice. Both groups consumed about 5–10 ml per day per mouse. After 1–12 weeks of treatment, the mice were sacrificed, and their organs or tissues were quickly removed and frozen in liquid nitrogen.

Reverse Transcriptase-PCR Analysis

Reverse transcriptase-PCR analysis was performed according to Hsieh-Li et al. (2000) and Jong et al. (2000).

Subcellular Fractionation

Fresh frozen spinal cord, brain, and skeletal muscle samples (500 mg) from different types of SMA mice were fractionated. Tissues were homogenized with a tight-fitting glass pestle in ice-cold buffer. The nuclei were pelleted by centrifugation at 800 *g* for 3 min. The nuclear pellet was resupended by trituration in 100 µl of buffer and kept on ice for 15 min followed by centrifugation at 15,000 *g* for 10 min ar 4°C. The supernatant (soluble nuclear extract) was removed, and the insoluble nuclear pellet was further sonicated in sonication buffer.

Western Blot Analysis

Synthetic peptides containing part of human SMN exon 7 (amino acids 279–288) and exon 2 (amino acids 72–84) were used to immunize rabbits and to purify specific antibodies(H2 and H7) from rabbit crude sera with an EAH Sepharose 4B column. Two mouse anti-SR protein antibodies (anti-SRp20 and 16H3) were used to detect the human SR proteins. Proteins were loaded on a 5% polyacrylamide stacking gel above a 12% separating gel, and the the gel was run with a discontinuous buffer using Laemmli's method. After electrophoresis, proteins were transferred electrophoretically to poly-(vinylidene difluoride) membranes. After the transfer, the membranes were blocked with TBST containing 4% BSA for 2 h at room temperature. The blots were washed for three 20-mim periods in TBST and then incubated with a 1:32,000 dilution of an anti-rabbit IgG alkaline phosphatase conjugate in TBST for 1 h at room temperature. The reaction was detected by adding 1.5% 5-bromo-4-chloro-3-indolyl phosphate and 3% nitro blue tetrazolium in a developing buffer.

Histopathological Analysis

Histopathological analysis was performed according to Hsieh-Li et al. (2000).

EVALUATION

Results from multiple experiments were expressed as mean ± standard error. Survival data of treated and untreated mice are presented as a Kaplan-Meier plot using the log rank test. A standard χ_2 test was used to assess differences in the frequency of mild or severe phenotype in the SMA-like mice born from treated and untreated mothers, which analyzed the percentage of type 1 (or 2+3) newborn mice as a fraction of the total number of pups.

MODIFICATIONS OF THE METHOD

Lesbordes et al. (2003) reported therapeutic benefits of cardiotrophin-1 gene transfer in a mouse model of spinal molecular atrophy.

Andreassi et al. (2001) found that aclarubicin treatment restored SMH levels to cells derived from type I spinal muscular atrophy patients.

Haddad et al. (2003) reported that riluzole attenuates spinal muscular atrophy disease progression in a mouse model.

He et al. (2005) described an inherited motor neuron disease in domestic cats as a model of spinal muscular atrophy.

E.8.4
Spinal and Bulbar Muscular Atrophy

E.8.4.1
General Considerations

PURPOSE AND RATIONALE

Spinal and bulbar muscular atrophy is a late-onset motor neuron disease characterized by proximal muscle atrophy, weakness, contraction fasciculations, and bulbar involvement. The disease exclusively affect males, while females are usually asymptomatic (Katsuno et al. 2003, 2004).

REFERENCES AND FURTHER READING

E.8.4.2
Transgenic Animal Models of Spinal and Bulbar Muscular Atrophy

PURPOSE AND RATIONALE

Spinal and bulbar muscular atrophy is a polyglutamine disease caused by expansion of a CAG repeat in the androgen receptor gene (Adachi et al. 2001; Katsuno et al. 2002; Walcott and Merry 2002). Several transgenic mouse models were developed (Bates and Davies 1997; Abel et al. 2001; MacManamny et al. 2002).

Katsuno et al. (2003) reported that leuprolin rescues polyglutamine-dependent phenotypes in a transgenic mouse model of spinal and bulbar muscular atrophy.

PROCEDURE

Animals

Transgenic mice were generated carrying a full-length androgen receptor containing 97 CAGs (Katsuno et al. 2002). A full-length human androgen receptor fragment was subcloned containing 24 or 97 CAG repeats (Kobayashi et al. 1998) into a pCAGGS vector (Niwa et al. 1991) digested with *Hind*III. The result was microinjected into fertilized eggs of BDF1 mice. Five founders with AR-97Q were obtained. These mouse lines were maintained by back-crossing with CS7B1/6 mice.

Neurological status was measured with the Rotarod test (Columbus Instruments) and cage activity with the AB system (Neuroscience, Tokyo).

Hormonal Treatment

Leuprolin acetate was injected subcutaneously at a dose of 25, 50 or 100 µg per mouse every 2 weeks from 5 weeks of age. Control mice were treated with vehicle. Leuprolin-treated AR-97Q mice were given either leuprolin only or leuprolin plus 20 µg testosterone enanthate dissolved in sesame oil s.c. weekly from the age of 13 weeks. Flutamide was injected at a dose of 1.8 mg per mouse once every second day.

Serum testosterone was assayed with a radioimmunoassay.

Protein Expression Analysis

Mice were sacrificed by anesthesia and exsanguination and their tissues snap-frozen with powdered CO_2 in acetone. Tissues were homogenized in 50 mM TRIS, pH 8.0, 150 mM NaCl, 1% Nonidet-P40, 0.5% deoxycholate, 0.1% SDS and 1 mM 2-mercaptoethanol with 1 mM PMSF and 6 µg/ml aprotinine and centrifuged at 2,500 *g* for 15 min at 4°C. Each lane of a 5%–20% SDS-PAGE gel was loaded with 160 µg protein from nerve tissue and 80 µg for muscle from the respective supernatant fraction. This was transferred on Hybond-P membranes in a transfer buffer of 25 mM TRIS, 192 mM glycine, 0.1% SDS and 10% methanol. After immuno-probing with a rabbit antibody to the androgen receptor, a secondary antibody probing and detection with the ECL Plus kit (Amersham) was performed. The signal intensity of the bands was quantified using the NIH Image program. The quantita-

tive data of three independent Western blots were expressed as mean ± SD.

Immunohistochemistry and Histology

Deeply anesthetized mice were perfused through the left cardiac ventricle with 20 ml of a 4% paraformaldehyde fixative in phosphate buffer. The tissues were post-fixed overnight in 10% phosphate-buffered formalin and processed for paraffin embedding. De-paraffinized tissue sections 4 µm in thickness were dehydrated in alcohol, treated with formic acid for 5 min at room temperature and stained with the polyglutamine-specific antibody 1C2 (1:10,000 dilution) (Holmberg et al. 1998). After formalin fixation, tail specimens were washed with 70% alcohol and decalcified with 7% formic acid and 70% ethanol for 7 days followed by paraffin embedding. To assess 1C2-positive cells in muscle, the number of 1C2-positive cells in more than 500 fibers in the entire area was calculated and expressed as the number per 100 muscle fibers. The air-dried cryostat sections (6 µm in thickness) of gastrocnemius muscles were stained with hematoxylin-eosin.

EVALUATION

Data were analyzed using the unpaired *t*-test.

MODIFICATIONS OF THE METHOD

Adachi et al. (2003) reported that heat shock protein 70 chaperone overexpression ameliorates phenotypes of the spinal and bulbar muscular transgenic mouse model by reducing nuclear localized mutant androgen receptor protein.

Chevalier-Larsen et al. (2004) found that castration restores the function and neurofilament alterations of aged symptomatic males in a transgenic mouse model of spinal and bulbar muscular atrophy.

Minamiyama et al. (2004) reported that sodium butyrate ameliorates phenotypic expression in a transgenic mouse model of spinal and bulbar muscular atrophy.

E.8.5 Models of Down Syndrome

PURPOSE AND RATIONALE

Down syndrome, the most common known genetic cause of mental retardation, is the result of trisomy of chromosome 21. Although the degree of cognitive impairment in Down syndrome can be quite variable, individuals with Down syndrome have significantly lower IQs with impaired speech and language skills as well as specific difficulties in auditory and visual memory, in spatial memory and in the acquisition of conditioned and operant responses. Down syndrome is considered to be caused by trisomy of the human chromosome 21.

Several attempts have been made to find animal models for Down disease. Since the mouse chromosome 16 is homologous to the human chromosome 21, mice with trisomy of chromosome 16 were created. Cox et al. (1984) reported production of a viable trisomy 16 diploid mouse chimera as a model of human trisomy 21 (Down syndrome). This model has been extensively used (Epstein et al. 1985; Sweeney et al. 1989; Holtzman et al. 1992; Shetty et al. 1996). However, the value of this model is limited to some extent because trisomy 16 mouse fetuses do not survive as live-born animals.

The **Ts65Dn mouse** carries only a partial trisomy for mouse chromosome 16 in a region that has highly homology to the Down syndrome region of human chromosome 21. These mice survive until adulthood and have therefore been used as animal model for Down syndrome in more recent studies (Davisson et al. 1993; Coussons-Read and Crnic 1996; Klein et al. 1996; Kola and Hertzog 1997; Costa et al. 1999; Cooper et al. 2001; Galdzicki et al. 2001; Granholm et al. 2002; Bimonte-Nelson et al. 2003; Stasko and Costa 2004).

Ema et al. (1999) described an animal model of Down syndrome in mice overexpressing the *mSim2* gene located on chromosome 16. Borella et al. (2003) characterized social behaviors and oxytoninergic neurons in the S-100β overexpressing mouse model of Down syndrome originally described by Friend et al. (1992).

A number of experimental compounds have been developed that result in improved cognitive performance in animal models. Moran et al. (2002) described the effects of piracetam on cognitive performance in a mouse model of Down syndrome.

PROCEDURE

Male 5-week-old Ts65Dn and euploid littermate control mice received daily injection of one of three dose of piracetam (75, 150, and 300 mg/kg) or saline vehicle. Piracetam treatment continued for 4 weeks prior to and throughout the 4-week testing period. Testing consisted of assessments of performance on the visible- and hidden-platform components of the Morris maze task and assessment of spontaneous activity within computerized activity chambers.

EVALUATION

Significant effects were explored with two-way ANOVA, analysis of main effects, and paired *t* comparisons.

MODIFICATIONS OF THE METHOD

Cardenas et al. (2002) established and characterized immortal neuronal cell lines derived from the spinal cord of normal and trisomy 16 fetal mice.

E.8.6 Models of Wilson's Disease

PURPOSE AND RATIONALE

Wilson disease is an **inherited disorder of copper metabolism** caused by autosomal recessive mutations of the *ATP7B* gene. The mutant ATP7B proteins lead to an impaired copper efflux, a decreased copper incorporation into ceruloplasmin and to hepatic copper accumulation, resulting in hepatocellular injury and deposition of copper in extra-hepatic tissues. Patients suffer from chronic or acute liver disease, psychiatric symptoms and neurological abnormalities with extrapyramidal symptoms, such as tremor and ataxia. D-penicillamine has been used for treatment of patients with Wilson disease, but more recently ammonium tetrathiomolybdate has been recommended (Stremmel et al. 1991; Silva et al. 1996; Brewer et al. 2003).

The **Long-Evans Cinnamon rat** has a mutation homologous to the human Wilson disease gene, leading to gross copper accumulation and development of hepatitis. This rat strain has ben extensively used as animal model for Wilson disease (Yamaguchi et al. 1994; Suzuki 1995; Adachi et al. 1997; Kodama et al. 1998; Nagano et al. 1998; Nomiyana et al. 1999; Terada and Sugiyama 1999; Klein et al. 1998, 2000, 2004; Komatsu et al. 2000, 2002; Meng et al. 2004).

Klein et al. (2004) reported the effects of tetrathiomolybdate in the treatment of acute hepatitis in Long-Evans Cinnamon rats.

PROCEDURE

Female Long-Evans Cinnamon rats (Charles River, Japan) at an age of between 60 and 100 days were used, whereas female Long-Evans Aguti rats served as controls. Long-Evans Cinnamon (LEC) rats were randomly divided in different groups:

LEC rats without any treatment and without signs of liver disease,

jaundiced LEC rats without any treatment,

jaundiced LEC rats treated once intraperitoneally with 10 mg/kg tetrathiomolybdate.

The tetrathiomolybdate-treated rats were sacrificed either 1 or 4 days after treatment.

Tissue Preparation and Subcellular Fractionation

Livers were flushed *in situ* with ice-cold 0.9% NaCl in order to remove the blood. A part of the liver was fixed in 4% neutral formalin, embedded in paraffin, and sections were stained for light microscopy. From homogenates lysosomal and mitochondrial fractions were prepared (Klein et al. 1998, 2000). Electron microscopy and X-ray microanalysis were performed. Metals and metallothionein were quantified.

EVALUATION

Student's *t*-test was used for statistical evaluation.

OTHER DISORDERS OF COPPEER METABOLISM

Besides Wilson's syndrome, other inherited diseases of cellular copper metabolism are known, such as Menkes disease and the toxic milk syndrome in mice (Palida and Ettinger 1991; La Fontaine et al. 2001).

Menkes' syndrome is an X-linked recessive disorder associated with copper deficiency, lethal in early childhood. Menkes' children show impaired synthesis of collagen and elastin. Furthermore, they are severely mentally retarded. Diffuse atrophy, focal degeneration of gray matter and prominent neuronal loss have been detected in the cerebellum. The molecular basis of this syndrome has been identified as a mutated gene (*ATP7A*) encoding for a P-type cation-transporting ATPase (Kodama and Murata 1999; Tumer et al. 1999; Rossi et al. 2001).

The mutant **macular** mouse has been used as animal model for Menkes' disease (Tanaka et al. 1990; Murata et al. 1997, 1998; Suzuki-Kurasaki et al. 1997). The **brindled mouse mutant** (Mo^{br}) is considered to be the closest model to Menkes' disease (Grimes et al. 1997; Rossi et al. 2001). The mutant mice are hypopigmented and die at around 15 days after birth, but can be saved by treatment with copper before the 10th postnatal day.

E.8.7
Models of Cerebellar Ataxia

The pathology mechanisms underlying the signs of hereditary cerebellar ataxia in humans are not well understood (Harding 1984).

Kato et al. (1982) and Yamaguchi et al. (1992) regarded the rolling mouse Nagoya as an animal model of hereditary cerebellar ataxia.

Niimi et al. (1982) made an animal model of cerebellar ataxia by injections of kainic acid into both sides of the cerebellar hemispheres of male rats.

Grüsser-Cornehls et al. (1999) recommended Weaver mutant mice as an animal model of cerebellar ataxia.

Fernandez et al. (1998) induced ataxia in adult rats either with intraperitoneal injection of 50–65 mg/kg 3-acetylpyridine or by bilateral electrocoagulation of the inferior olive. Insulin-like growth factor 1 restored motor coordination in this rat model of cerebellar ataxia.

Ataxia-telangiectasia is a complex multiparametric disease associated with oculocutaneous telangiectasias, cerebellar ataxia, elevated chromosomal aberration frequency, and varied degrees of immunodefi-

ciency. Kaiserlian et al. (1986) described the wasted mouse as a model of this disease.

Clark et al. (2000) reported X-linked transmission of the *shake*r mutation in rats with hereditary Purkinje cell degeneration and ataxia.

Sausbier et al. (2004) described cerebellar ataxia and Purkinje cell dysfunction in mice caused by Ca^{2+}-activated K^+ channel deficiency

E.8.8 Models of Niemann-Pick Syndrome

PURPOSE AND RATIONALE

Niemann-Pick disease type C is a progressive neurodegenerative disorder caused by mutations in the *NPC1* gene and characterized by intracellular accumulation of cholesterol and sphingolipids.

Pentchev et al. (1980, 1984) described a genetic storage disorder in BALB/C mice with metabolic block in esterification of exogenous cholesterol. The murine model of Niemann-Pick C disease with mutation in a cholesterol homeostasis gene (**npc1^{-}/$^{-}$mutant mice**) has been used in several studies (Weintraub et al. 1985, 1987; Higashi et al. 1993; Loftus et al. 1997; Erickson et al. 2000; Bascunan-Castillo et al. 2004). Some attempts have been made to improve the clinical course of the Niemann-Pick C disease mouse (Liu et al. 2000). Treatment with cyclodextrins had variable effects in delaying neurological symptoms and in decreasing liver cholesterol storage (Camargo et al. 2001). Zhan et al. (2004) showed that cyclin-dependent kinase inhibitors attenuate protein hyperphosphorylation, cytoskeletal lesion formation, and motor defects in Niemann-Pick type C mice.

MODIFICATIONS OF THE METHOD

Sym et al. (2000) described a model for Niemann-Pick type C disease in the nematode *Caenorhabditis elegans*.

E.8.9 Models of Gangliosidosis

PURPOSE AND RATIONALE

The glycosphingolipid lysosomal storage diseases are inherited metabolic diseases in which a gene encoding a lysosomal hydrolase or one of their co-factors is mutated. Two classes of glycosphingolipid storage diseases are known, those in which the storage glycosphingolipid is neutral (**Gaucher** and **Fabry** disease) and the gangliosidoses in which the storage lipid is a ganglioside (glycosphingolipid containing one or more sialic acid residues). The gangliosidoses include the G_{M2} storage disorders, **Tay-Sachs** and **Sandhoff disease** (O'Dowd et al. 1986; Paw et al. 1989; Koller and Sandhoff 1998; Schröder et al. 1991; Glaros et al. 2005), and the G_{M1} storage disorder termed G_{M1} gangliosidosis or **Morquio** B disease (Matsuda et al. 2003).

Spontaneous gangliosidosis has been described in several animal species, such as **dogs** (Singer and Cork 1989; Kaye et al. 1992; Wang et al. 2000; Yamato et al. 2003, 2004b; Kreutzer et al. 2005), **cats** (Cork et al. 1977; Neuwelt et al. 1985; Muldoon et al. 1994; Kroll et al. 1995; Yamato et al. 2004a; Martin et al. 2005), **sheep** (Skelly et al. 1995; Ryder and Simmons 2001), **deer** (Fox et al. 1999), and **pigs** (Kosanke et al. 1978).

***β*-Galactosidase-deficient mice** were described as an animal model for G_{M1}-gangliosidoses (Hahn et al. 1997; Matsuda et al. 1997a, 1997b; Oshima 1998; Callahan 1999; Itoh et al. 2001). Mouse models of G_{M2} gangliosidosis are reported by Huang et al. (1997) and Jeyakumar et al. (2003).

No effective treatment of patients is known as yet, but Jeyakumar et al. (1999) found delayed symptom onset and increased life expectancy in Sandhoff disease mice treated with *N*-butyldeoxynojirimycin. Yamaguchi et al. (2003) reported that plasmid-based gene transfer ameliorates visceral storage in a mouse model of Sandhoff disease. Martino et al. (2002) described restoration of the G_{M2} ganglioside metabolism in bone-marrow-derived stromal cells from a Tay–Sachs disease mouse model. Furthermore, Martino et al. (2005) reported that a direct gene strategy via brain internal capsule reverses the biochemical defect in Tay–Sachs disease.

E.8.10 Models of Mucopolysaccharidosis

PURPOSE AND RATIONALE

Mucopolysaccharidosis type IIIA or **Sanfilippo syndrome** is a lysosomal storage disorder characterized by progressive neurological pathology. Patients exhibit aggression, disturbed sleep, hyperactivity and mental decline ultimately resulting in inanition and death. Four mucopolysaccharidosis subtypes result from deficiencies in different lysosomal enzymes that sequentially degrade heparin sulfate: sulfamidase (MPS IIIA), α-*N*-acetylglucosaminidase (MPS IIIB), acetyl-CoA:α-glucosamidine *N*-acetyltransferase (MPS IIIC), and glucosamine-6-sulfatase (MPS IIID).

Mucopolysaccharidosis III has been described in several animal species, such as mice (Li et al. 1999, 2002; Yu et al. 2000; Gografe et al. 2003; Garbuzova-Davis et al. 2005), dogs (Fischer et al. 1998; Aronovich et al. 2000; Ellinwood et al. 2003), emus (Giger et al. 1997; Aronovich et al. 2001), and goats (Thompson et al. 1992).

A naturally occurring mouse model of MPS-IIIA has been discovered (Bhaumik et al. 1999; Bhattacharyya et al. 2001), with pathophysiology and symptoms that resemble the human conditions (Glid-

don and Hopwood 2004; Hemsley and Hopwood 2005).

No effective drug treatment for patients with Sanfilippo disease is available; however, experiments in mice showed beneficial effects after transplantation of human umbilical cord blood cells (Garbuzova-Davis et al. 2005), or treatment with lentiviral NAGLU vector (Di Natale et al. 2005) or enzyme replacement (Yu et al. 2000; Gliddon and Hopwood 2004).

E.9 General Anesthesia

E.9.1 Intravenous Anesthesia

E.9.1.1 General Considerations

PURPOSE AND RATIONALE

The first agents which could be used as intravenous anesthetics were **barbiturates**. Barbiturates with a duration of action appropriate to the requirements of surgery became available with the introduction of hexobarbital and thiopental (Volwiler and Tabern 1930; Miller et al. 1936). The studies with barbiturates were extended (Butler and Bush 1942; Christensen and Lee 1973). Intravenous anesthetics from other chemical groups were developed, such as **acetamidoeugenol** (Estil, Domenjoz 1959), steroid derivatives (Presuren = **hydroxydione sodium**, Laubach et al. 1955; **alfaxolone**, CT1341, Child et al. 1971), **propanidid** (Epontol, Goldenthal 1971), **ketamine** (CI-581, Chen et al. 1966; Reich and Silvay 1989), **etomidate** (Janssen et al. 1975), **propofol** (ICI 35868, Glen 1980), **midazolam** (Pieri 1983; Reilly and Nimmo 1987).

E.9.1.2
Screening of Intravenous Anesthetics

PURPOSE AND RATIONALE

Screening of intravenous anesthetics or hypnotics is performed mostly in mice or rats. Doses for loss of righting reflex and lethal doses are determined. Onset of action and duration of action are the secondary parameters.

PROCEDURE

Male mice weighing 18–22 g are injected intravenously via the tail vein. The anesthetic activity is estimated from the number of animals that loose their righting reflex. The righting reflex is considered lost when the mouse, placed on its back, fails to recover from this position within 1 min. The acute toxicity is based on lethality within a 24-h observation period.

To determine onset and duration of action groups of 20 mice are used. They are placed in individual observation cages maintained at room temperature (24 ± 1°C). They are not stimulated during the interval between loss and recovery of the righting reflex. The onset is defined as the complete loss of the righting reflex, i. e., no attempt to move the head or body. Recovery is considered to have occurred when the animal after spontaneous righting would re-right itself within 15 s when placed on its back.

EVALUATION

The median anesthetic dose (AD_{50}) and the median lethal dose (LD_{50}) are determined from dose-response curves with at least 4 doses by the method of Litchfield and Wilcoxon (1949).

The data for onset and duration of action are analyzed statistically by Student's *t*-test.

MODIFICATIONS OF THE METHOD

Volwiler and Tabern (1930) determined the minimum effective dose in rats after subcutaneous injection of various barbiturates not being awakened when outer ear passage was tickled with a straw.

Büch et al. (1968) studied the distribution, anaesthetic potency and metabolic elimination of the optical isomers of methylphenobarbital in rats.

Glen (1977) described a method for the laboratory evaluation of the speed of onset of i.v. anesthesia in **mice**. Various clinically used intravenous anesthetics were compared. The technique involves a) determination of the medium hypnotic dose (HD_{50}) by plotting the probit value of the mice sleeping against dose on a logarithmic scale, b) plotting mean induction time over a range of doses against the logarithm of the dose and c) comparison of induction times at 1.25 HD_{50}. All doses were given over 1 s or 10 s. A 1-s injection was thought to be of most value in the of structure activity effects.

Chen et al. (1966) tested the anesthetic activity and the neuropharmacological spectrum of ketamine (CI-581) in mice, pigeons and monkeys.

Child et al. (1971) tested the anesthetic activity of alfaxolone (CT1341) in **mice, rats, rabbits, cats, dogs** and **monkeys**.

Janssen et al. (1975) tested onset and duration of anesthesia after etomidate in mice, rats, guinea pigs and dogs.

New intravenous anesthetics were reviewed by Reilly and Nimmo (1987).

The anesthetic potency of remifentanil in dogs in terms of reduction of enflurane *MAC* was tested by Michelsen et al. (1996).

Dingwall et al. (1993) described the tolerometer as a fast, automated method for the measurement of righting reflex latency.

E.9.1.3 EEG Threshold Test in Rats

PURPOSE AND RATIONALE

The electroencephalographic (EEG) threshold test has been used to determine and compare the potency of several CNS depressant agents (Bolander et al. 1984; Koskela and Wahlström 1989; Norberg and Wahlström 1988; Norberg et al. 1987). Korkmaz and Wahlström (1997) described in detail the protocol of the EEG burst suppression threshold test for the determination of CNS sensitivity to intravenous anesthetics in rats.

PROCEDURE

Adult Sprague-Dawley rats are housed at a reversed light/dark cycle and an ambient temperature of 23 ± 1°C. Twenty four hours prior to the EEG threshold test, the rats are placed in a tube restrainer. Twisted stainless steel wire and suitable surgical needles are used to sew the electrodes to the scalp above the frontal cortex. Since generalized changes in EEG recordings are used, this stainless steel material is adequate for recording purposes. Care is taken to prevent irritation of periosteal tissue. Since this procedure causes little discomfort, the use of local anesthetics and general anesthesia can be avoided.

For EEG threshold testing, the rat is placed on a warm cloth and held gently by the assistant. A needle is placed on one lateral tail vein and connected with an infusion pump. Crocodile clips are used to connect the electrodes to the EEG recorder and a crocodile clip is attached to one of the ears of the rats as a signal ground.

The EEG recording is closely observed by the technician. The changes in the EEG induced by the anesthetic agent are used to measure drug effects on the CNS. The normal EEG in an awake rat has a low amplitude and a frequency of approx. 30 cycles/s. During the first part of infusion, an increase in amplitude and a slight decrease in frequency are observed. At this stage of infusion, dependent on the anesthetic agent, jerks or sometimes convulsive episodes may occur. As the infusion continues, the frequency decreases and burst suppression periods appear. The loss of righting reflex occurs at this stage. When a burst suppression lasts one second or, the threshold criterion which is called ‘silent second’ is reached and the time is recorded. After the threshold determination, the rats are placed in the recovery room.

EVALUATION

The threshold dose is calculated by multiplying the time required to reach the threshold criterion with the dose administration rate. Threshold doses are determined for each anesthetic at various dose administration rates indicating the optimal dose administration rate.

MODIFICATIONS OF THE METHOD

Wauquier et al. (1988) studied relationships between quantitative EEG measures and pharmacodynamics of alfentanil in dogs. Before, during and up to 3 h after infusion, the effects of 3 doses on 6 quantitative EEG measures (zero-crossing frequency, root mean square amplitude, spectral edge, relative delta, alpha and beta power) were assessed.

E.9.1.4 Efficacy and Safety of Intravenous Anesthetics

PURPOSE AND RATIONALE

Besides determination of the ratio between anesthetic and lethal dose, intravenous anesthetics have to be tested for their influence on the cardiovascular and pulmonary system. Borkowski et al. (1990 described a method to compare intravenous anesthetics in rabbits.

PROCEDURE

Adult New Zealand White rabbits with a mean weight of 4.5 kg are used. To provide access for direct blood pressure measurement and arterial blood samples, an 18-gauge catheter is implanted into the left carotid artery under halothane anesthesia. Following a minimum 24-h recovery period, the rabbit is placed in a sling and a pneumograph is fitted around the rabbit's caudal thorax at the level of 10th to 12th ribs to monitor respiratory rate and pattern. From the arterial catheter blood is withdrawn for blood gas analysis. Then the catheter is connected to a blood-pressure transducer. A 10-min acclimatization period is allowed before control measurements are recorded. Each rabbit serves as its own control in that cardiopulmonary parameters and responses to noxious stimuli are determined before anesthesia is induced. The right marginal ear vein is catheterized with a 22-gauge catheter, which is secured with adhesive tape, flushed with physiologic sterile saline and used for the administration of the anesthetic agents.

One third of the dose of the anesthetic to be tested is injected manually over a 1-min period. When the rabbit is relaxed it is removed from the sling and is placed in left lateral recumbence on a heating blanket. The degree of muscle tension and reaction to noxious stimuli are determined while the rabbit is in the sling and at 15 min intervals following anesthesia. The assessments performed include those of jaw tone, leg muscle tone, palpebral reflex, corneal reflex, ear pinch reflex and pedal withdrawal reflex. Jaw tone is evaluated subjectively by pulling the lower jaw open by an index finger. Leg muscle tone is evaluated by flexion and extension of the right rear leg according to subjective scores. The corneal reflex is tested by placing a moistened cotton swab on the cornea. The palpebral reflex is tested by touching the medial canthus with a dry cotton swab. Assessment of the ear pinch reflex is performed by applying a compression force with an alligator clip. The pedal withdrawal reflex is determined by applying the same clip on the right rear fifth digit at the distal phalanx.

Cardiopulmonary parameters and rectal body temperature are determined while the rabbit is in the sling and also at 15 min intervals following induction of anesthesia with the rabbit in lateral recumbency. Heart rate, mean arterial blood pressure, respiratory rate and respiratory pattern are calculated from tracings from the physiological recorder. Arterial blood pH, partial pressure of oxygen (PaO_2), and partial pressure of carbon dioxide ($PaCO_2$) are determined from arterial blood samples.

EVALUATION

The heart rate, mean arterial blood pressure, respiratory rate, pH, PaO_2 and $PaCO_2$ are analyzed using a two-factor analysis on repeated measures. The control values are treated as covariate to allow standardization of the inherent variation between rabbits. The single *t*-test for paired differences is used to compare control values to data obtained during the later testing intervals. The standard error of the mean (SEM) is calculated for each variable at each time interval. Data for muscle tone and responses to noxious stimuli are calculated as frequency percentages. The Fisher's Exact test is used to compare between treatments. For all of the statistical analyses, a *p*-value of less than 0.05 is considered significant.

MODIFICATIONS OF THE METHOD

Details of anesthesia in the rabbit were also described by Murdock (1969).

Peeters et al. (1988) performed a comparative study of four methods for general anesthesia in rabbits.

Glenn (1980) examined the anesthetic activity of propofol (ICI 35868) in mice, rats, rabbits, cats pigs and monkeys including cardiovascular and respiratory parameters and EEG studies.

E.9.2 Inhalation Anesthesia

E.9.2.1 General Considerations

PURPOSE AND RATIONALE

The efficacy and safety of new inhalation anesthetics has to be evaluated in pharmacological experiments. Robbins (1946) defined the anesthetic AD_{50} as the concentration of anesthetic at which 50% of mice failed to right themselves for 15 s when placed in a rotating bottle with a known concentration of anesthetic. The concentration of the anesthetic that caused apnea in 50% of the mice in 10 min was defined as the LD_{50} and the ratio LD_{50}/AD_{50} as and an index of safety.

Wolfson et al. (1972) recommended brain anesthetic concentration for construction of anesthetic indices.

E.9.2.2 Screening of Volatile Anesthetics

PURPOSE AND RATIONALE

A simple technique for preliminary testing of anesthetic agents is the introduction of a measured amount of volatile liquid into a covered glass container of known volume. If the density and molecular weight of the liquid are known, the volume % concentration of the anesthetic mixture can be calculated (assuming 1 mol of vapor = 22.4 l). Mice or rats are introduced into the chamber and the quality of anesthesia is noted. Conditions are then adjusted until the anesthetic concentration has been established.

PROCEDURE

Male NMRI mice weighing 20–25 g or male Wistar rats weighing 250–300 g are used. A wide-mouth, screw-cap glass jar of 3 Liter volume is flushed with oxygen for 1 min and a measured amount of the volatile substance is placed on the bottom through a suitable syringe. The amount is calculated to give 1.25 vol% concentration of vapor in the jar (or a logarithmic multiple of 1.25%, i. e., 0.63, 2.5, 5.0, 10.0). The jar is closed and evaporation of the substance is facilitated by gentle rotation of the jar. One rat or 5 mice are quickly placed from a beaker into the jar, and the jar is immediately closed. Every 15 s the jar is gently rotated and the time noted for each animal to become anesthetized (loss of righting reflexes). The procedure is repeated until all animals are anesthetized. Induction should occur not sooner than 30 s and not later than 5 min. The animals are allowed to remain in the anesthesia jar for 10 min, with testing of righting reflexes until they are quickly removed into room air. The time of recovery to righting or walking is recorded for each animal. Postanesthetic analgesia is tested by gently pressing the base of the tail every min until recovery has occurred. Recovery time is defined as the time in min until the mouse spontaneously moves in upright position. If induction time is shorter than 30 s or longer than 10 min, the concentration of anesthetic is decreased or increased until the proper concentrations is found.

EVALUATION

The results are reported as mean induction time and mean recovery time. Twenty-four-hour survival rate is recorded for latent toxicity.

MODIFICATIONS OF THE METHOD

Burns et al. (1961) used a simplified mouse test apparatus with a small container and an open circuit technique.

Raventós (1956) used cats, dogs and monkeys to evaluate the cardiovascular effects of fluothane.

E.9.2.3 Determination of Minimal Alveolar Anesthetic Concentration (MAC)

PURPOSE AND RATIONALE

The term **"minimum alveolar anesthetic concentration" (MAC)** was coined by Merkel and Eger (1963) as an index to compare various anesthetic agents.

The use of *MAC* which represents the partial anesthetic pressure in the brain has gained wide acceptance (Eger et al. 1965; Quasha et al. 1980).

For **man**, Saidman and Eger (1964) defined *MAC* as the point at which 50% of the patients moved in response to a surgical incision.

A method for determining minimum alveolar concentration of anesthetic in the **rat** was published by Waizer et al. (1973). Kashimoto et al. (1997) determined the minimum alveolar concentration of sevoflurane in rats. Eger et al. (1999) studied maximum alveolar anesthetic concentration of fluorinated alkanols in rats and dicussed the relevance to theories of narcosis. Eger et al. (2003) studied additive minimum alveolar concentration (MAC) effects o halothane and isofluroane in rats.

Issues in the design and interpretation of minimum alveolar anesthetic concentration (MAC) studies were discussed by Sonner (2002).

PROCEDURE

Minimum alveolar anesthetic concentrations (MAC) are determined in Sprague Dawley rats weighing 300–450 g. Each rat is placed in an individual gas tight plastic cylinder closed at both ends by rubber stoppers. The stoppers are pierced with holes for various purposes. A rectal temperature probe (temperature maintained between 36°C and 38.5°C) and the rat's tail are drawn separately through holes in the rubber stopper closing the distal end of the cylinder. Delivered gases at an average inflow rate of 1L/min to each rat enter through ports at at the head (proximal) end of the cylinder and exit at the tail (distal end), a flow to minimize rebreathing (inspired $CO_2 < 10$ mm Hg). Exiting gases are scavenged.

The anesthetics are introduced from conventional vaporizers. For the determination of MAC, an initial concentration is used that permits movement of the rats in response to noxious stimulation. A tail clamp is applied for 1 minor until the animal moves, and the anesthetic partial pressure is measured by gas chromatography. If the animal moves, the partial pressure is increased by 0.2% or 0.3% atmospheres. After equilibration for 30 min, the tail clamp is appliedagaion and the anesthetic partial pressure measured by gas chromatography. This procedure is repeated until the partial pressures bracketing movement-nonmovement are determined for each rat.

EVALUATION

MAC is defined as the average of the partial pressures that just prevented movement in response to clamping of the tail. Differences between anesthetics are accepted at $P < 0.05$.

MODIFICATIONS OF THE METHOD

Fang et al. (1997) found that maturation decreases ethanol minimum alveolar anesthetic concentration (*MAC*) more than desflurane *MAC* in **rats**.

Gong et al. (1998) assessed the effect of rat strain on susceptibility to anesthesia and convulsions produced by inhaled compounds.in five different rat strains. Strain minimally influenced anesthetic and convulsant requirements of inhaled compounds in rats.

Doquier et al. (2003) studied the minimum alveolar anesthetic concentration of volatile anesthetics in rats as tools to assess antinociception in animals.

Determination of the minimal alveolar concentration (*MAC*) of halothane in the white New Zealand **rabbit** was published by Davis et al. (1975).

Determination of an anesthetic index (Apnea/*MAC*) in experiments in **dogs** has been proposed by Regan and Eger (1967).

Murphy and Hug (1982), Hall et al. (1987) used the reduction of enflurane *MAC* values in **dogs** as parameter for the anesthetic potency of fentanyl or sufentanyl, respectively.

Seifen et al. (1987) used *MAC* values for comparison of cardiac effects of enflurane, isoflurane, and halothane in the **dog heart-lung preparation**.

Ide et al. (1998) used airway occlusion in **cats** as a noxious respiratory stimulus that induces a visceral sensation of choking for determination of minimum alveolar anesthetic concentrations during halothane, isoflurane, and sevoflurane anesthesia. These values were compared with *MAC* values for somatic noxious stimuli such as toe pinch or tetanic stimulus. The authors recommended this method as a new concept for *MAC* determination.

Eger et al. (1988) determined minimum alveolar concentration of fluorinated anesthetics in **pigs**.

E.9.2.4 Efficacy and Safety of Inhalation Anesthetics

PURPOSE AND RATIONALE

To assess the safety margin of a inhalation anesthetic not only the ED_{50} values but also the maximally effective dose and the dose with a minimal danger of fatal outcome should be determined. In particular, *cardiovascular parameters* are observed (Kissin et al. 1983).

PROCEDURE

Male Sprague Dawley rats weighing 300–350 g are placed into a clear chamber with the tail protruding from a special opening. An anesthetic-oxygen non-humidified mixture is directed into the chamber at a rate of 4 l/min. The inhalation anesthetics, e. g., halothane or isoflurane, are vaporized in Draeger vaporizers and the level in the chamber is monitored with a gas analyzer which is calibrated with a mass spectrometer. Rectal temperature is monitored and maintained at 37°C with a heating pad. Each rat is exposed to only one pre-determined concentration of anesthetic for 30 min, at which time the presence or absence of the end point of anesthesia is determined. For the lethal end point, rats are tracheotomized and ventilated at 60 strokes/min through an endotracheal catheter. Tidal volume is adjusted to maintain Pa_{CO2} at 40 ± 5 mm Hg.

As endpoints of anesthesia are used:

- Loss of righting reflex. The test is regarded as positive if the animal fails to right itself with all four feet on the floor within 15 s after being placed in a side position.
- Prevention of purposeful movements response to a noxious stimulus. The animals are stimulated for 60 s by placement of a 1-kg weight on the middle of the tail. Only the purposeful movement of the head or legs is considered to be a response.
- Prevention of the heart rate increase to a noxious stimulus (ECG signals). An increase in heart rate of greater than 1% is regarded as a positive response.
- The end point for the lethal effect is 7 mm Hg in the femoral artery with artificial respiration.

With each of the anesthetics, four series of experiments are performed: to determine the righting reflex, purposeful movement response, heart rate response,

and lethal effect. The concentrations of the test compounds and the standard are spaced equally between the above-mentioned doses.

After determination of the heart rate effect and the lethal effect, the rats are sacrificed for determinations of brain tissue concentrations. The whole brain is removed and tissue anesthetic concentration is determined by gas chromatography.

EVALUATION

For calculation of the dose-effect curves, the probit method of statistical analysis is used.

For the assessment of anesthetic safety, not only the therapeutic ratio (LD_{50}/ED_{50}) but also the standard safety margin

$$SSM = (LD_5 - ED_{95})/ED_{95} \times 100$$

is used. This represents the percentage by which the ED_{95} has to be increased before LD_5 is reached.

CRITICAL ASSESSMENT OF THE METHOD

The standard safety margin has definitive advantages over therapeutic ratio. In contrast to the LD_{50}/ED_{50} index, the standard safety margin is influenced not only by the distance between central points of the anesthetic and lethal dose-effect curves, but also by the slope of these curves.

MODIFICATIONS OF THE METHOD

A similar concept, based on response to tail clamping, respiratory arrest and cardiovascular failure in the **rat** was published as anesthetic index by Wolfson et al. (1973).

An other attempt to determine anesthetic requirements in rats was published by White et al. (1974).

Kissin et al. (1984) studied the morphine-halothane interaction in rats.

Fukuda et al. (1996) investigated the effects of sevoflurane and isoflurane on bupivacaine-induced arrhythmias and seizures in rats.

Kanaya et al. (1998) Compared myocardial depression by sevoflurane, isofluorane, or halothane in **cultured neonatal rat ventricular myocytes**. Changes in beating rate and amplitude during exposure to the anesthetics were measured.

Chaves et al. (2003) used non-invasive electrocardiography in **mice** to study the effects of intravenous and inhalation anesthetics and of age.

Krantz et al. (1941, 1953) described an anesthetic index between surgical anesthesia (cornea and wink reflexes abolished) and respiratory failure in **dogs**.

Van Poznak and Artusio (1960a, b) determined the anesthetic properties of fluorinated compounds in dogs using a face mask for the induction of anesthesia and a cuffed endotracheal tube later on. ECG (lead II) and EEG were monitored.

Steffey and Howland (1978) determined the potency of enflurane in dogs in comparison with halothane and isoflurane.

Johnson et al. (1998) compared isoflurane with sevoflurane for anesthesia induction and recovery in adult dogs.

Salmempera et al. (1992) studied in dogs the potency of remifentanil, a short acting opioid analgesic, which is used as anesthetic adjunct by variable-rate infusion. Enfluorane minimal alveolar concentration was measured by the tail-clamp method in dogs before and after sequential infusion of various doses of remifentanil. The plasma concentration causing a 50% reduction of enfluorane minimal alveolar concentration was determined.

Kataoka et al. (1994) studied the negative inotropic effects of sevoflurane, isoflurane, enflurane and halothane in canine blood-perfused papillary muscles.

Hirano et al. (1995) compared the coronary hemodynamics during isoflurane and sevoflurane anesthesia in dogs.

Mutoh et al. (1997) compared the cardiopulmonary effects of sevoflurane with those of halothane, enflurane, and isoflurane, in dogs.

Hashimoto et al. (1994) examined the effects of sevoflurane and halothane on the effective refractory period and ventricular activation in a canine myocardial infarction model.

The effects of desflurane, sevoflurane and halothane on postinfarction spontaneous dysrhythmias in dogs were examined by Novalija et al. (1998).

Cardiopulmonary effects in **cats** were studied for desflurane by McMurphy and Hodgson (1996), for sevoflurane by Hisaka et al. (1997).

Saeki et al. (1996) determined the effects of sevoflurane, enflurane, and isoflurane on baroreceptor-sympathetic reflex in **rabbits**.

Hanagata et al. (1995) found that isoflurane and sevoflurane produce a dose-dependent reduction in the shivering threshold in rabbits.

Antognini and Eisele (1993) determined anesthetic potency and cardiopulmonary effects of enfluorane, halothane, and isofluorane in **goats.**

The effects of multiple administrations of sevoflurane to cynomolgus **monkeys** were evaluated by Soma et al. (1995).

The effect of inhalation anesthetics on the **respiratory system** was investigated in several studies:

Mazzeo et al. (1996) compared the relaxing effects of desflurane and halothane at various *MAC*s on isolated proximal and distal airways of dogs precontracted with acetylcholine.

Hashimoto et al. (1996) compared the bronchodilating effect of sevoflurane, enflurane and halothane in dogs using a superfine fiberoptic bronchoscope. The dogs were anesthetized with pentobarbital, paralyzed with pancuronium, and the lungs were mechanically ventilated. The endotracheal tube had an additional lumen to insert the superfine fiberoptic bronchoscope (outer diameter 2.2 mm) which was located between a second and third bronchial bifurcation to continuously monitor the bronchial cross-sectional area of third or forth generation bronchi. Bronchoconstriction was produced by histamine injection and infusion. The bronchial cross-sectional area was printed out by a video-printer at the end of expiration and was calculated on a computer using an image program after various *MAC*s of the different inhalation anesthetics.

Mitsuhata et al. (1994) induced systemic anaphylaxis in dogs sensitized to Ascaris suum by intravenous injection of the antigen and measured pulmonary resistance and dynamic pulmonary compliance. Sevoflurane was as effective as isoflurane in attenuating bronchoconstriction associated with anaphylaxis in dogs.

Cervin and Lindberg (1998) examined the short-term effects of halothane, isoflurane and desflurane on mucociliary activity in the rabbit maxillary sinus *in vivo*.

E.10 NMRI Methods in Psychoneuropharmacology

E.10.1 General Considerations

PURPOSE AND RATIONALE

Magnetic resonance imaging (MRI) is the preferred technique for the visualization of lesions in the brain and spinal cord of patients with MS. It visualizes the resonance signals of tissue protons when they are placed in a time-varying strong magnetic field. The most frequently used parameters measured in MS are the spin-lattice relaxation time (T_1) and the spin-spin relaxation time (T_2). MRI is routinely used as a tomographic imaging technique, where anatomical pictures are created of 1-mm-thick tissue sections. The contrast differences between brain structures in most MRI techniques are determined by the different densities and diffusion of protons, as well as differences in relaxation times. T_2 images are sensitive to water and, because all pathological alterations in MS brains are associated with altered distribution of tissue water (edema), this technique is highly useful for visualization of the spatial distribution of lesions. Contrast in T_1 images is determined mainly by different lattice densities. Dense structures, such as compact white matter, have low T_1 values, whereas relatively loose structures, such as gray matter or lesions, have higher T_1 values.

To distinguish inflammatory active from inactive lesions, the paramagnetic dye gadolinium-DTPA is intravenously injected (0.1–0.3 mmol/kg) and, in areas of increased blood–brain barrier permeability, leaks into the brain parenchyma, causing local enhancement of the T_1-weighted signal intensity.

A third important MRI technique in MS is magnetization transfer ratio (MTR) imaging. The MTR of a given tissue is defined as the ratio of free protons versus protons bound to tissue macromolecules.

Besides general applications to body composition in animals (Mitchell et al. 2001; Changani et al. 2003; Mirsattari et al. 2005) NMR studies contributed to evaluation of drugs in psychoneuropharmacology.

E.10.2 NMRI Psychopharmacological Studies in Rats

E.10.2.1 NMRI Study of Experimental Allergic Encephalomyelitis in Rats

PURPOSE AND RATIONALE

Duckers et al. (1997) studied the effect of a neurotropic treatment on cortical lesion development in experimental allergic encephalomyelitis in rats by longitudinal *in vivo* magnetic resonance imaging methods.

PROCEDURE

Animals

Female Lewis rats weighing approximately 190 g were used for*in vivo* proton MRI. The rats were housed individually in Macrolon cages and had free access to rat chow and water during the 5-month study. The rats were divided at random into three groups. In two groups of rats chronic experimental allergic encephalomyelitis was induced by s.c. injection of myelin/adjuvant. The third group was injected with vehicle.

Immunization of Animals

Two hours before inoculation, spinal cords from Duncan Hartley guinea pigs were dissected and homogenized in an equal volume of phosphate-buffered saline (PBS) (pH 7.3; 1 g spinal cord in 1 ml PBS). Equal parts of guinea pig spinal cord homogenate in PBS and complete Freund's adjuvant (CFA) were mixed as described by Lassmann (1983) and Wisniewski and Keith (1977).

Anesthetized rats were sensitized by injecting 0.3 ml of the CNS emulsion in the dorsum pedis of the hindlimbs. Age-matched controls were challenged

similarly except that the emulsion solely contained PBS in CFA. The day of inoculation was designated day 0 post-inoculation (dpi 0).

Peptide Treatment

For the neurotrophic treatment, an $ACTH_{4–9}$ analog devoid of corticotrophic activity [Org2766, H-Met(O_2)-Glu-His-Phe-D-Lys-Phe-OH] was used. The heptapeptide has well-documented neurotrophic properties, as demonstrated previously in different animal models for peripheral and central nerve damage (Bär et al. 1990; Stand et al. 1991). The rats with chronic experimental allergic encephalomyelitis were given s.c. injections, in the neck, of either the $ACTH_{4–9}$ analog (75 µg/kg in 0.5 ml saline) or 0.5 ml saline every 48 h. Age-matched control animals received saline injections every 48 h. Treatment was started on the day of inoculation and continued until the experiment ended 21 weeks after inoculation.

Neurological Status of the Rats

The clinical status of the rats was evaluated every 48 h by weighing the rats and scoring their neurological status on a 0–9 ordinal scale. The scores represent the following neurological symptoms: grade 0, no visible neurological symptoms; grade 1, loss of tail tip reflex; grade 2, flaccid tail; grade 3, moderate paraparesis, manifested as minor locomotion disturbances; grade 4, severe paraparesis accompanied by lordosis, severe disturbed locomotion and severe weight loss; grade 5, one paralysed hindlimb; grade 6, complete paralysis; grade 7, paralysis from diaphragm upwards; grade 8, tetraplegia, only head movements possible; grade 9, death due to chronic experimental allergic encephalomyelitis.

T2-Weighted and Short Tau Inversion Recovery Magnetic Resonance Imaging

Animals were examined by using MRI at 5, 10, and 20 weeks post-inoculation. The rats were anesthetized with Hypnorm (containing 10 mg/ml fluanisone and 0.315 mg/ml fentanyl citrate, dose 0.6 ml/kg s.c.) and Stesolid (diazepam). After intubation, the rats were mechanically ventilated with 70% oxygen and 30% N_2O with 0.5% v/v halothane.

The ^{1}H-MRI experiments were performed with a SISCO 200/400 system (SISCO, Palo Alto, Calif., USA) operating at 4.7 T and equipped with actively shielded gradients (max. gradient 18 Mt/m). In all experiments, an Alderman-Grant type radio frequency coil with an inner diameter of 5 cm was used. For accurate and reproducible positioning, animals were mounted in a stereotaxic holder positioned on the coil support. For each animal, a sagittal T1W scout image [echo time (TE) 20 ms, repetition time (TR) 600 ms] outlined the start (border of frontal lobe and olfactory bulb) and endpoint (border of cerebellum–spinal cord) for subsequent coronal multislice experiments used to quantify the extent of tissue damage.

All MRI experiments were based on a spin-echo sequence with 5-ms sinc-modulated radiofrequency pulses. A total of 11 T2W coronal multislice images per animal was obtained (slice thickness 1.1 mm, interslice gap 0.7 mm), using a TR of 2 s and a TE of 60 ms; two transients were averaged. The field of view was $5 \times 5\,cm^2$; 128 points were acquired in the phase encoding direction and 512 points in the read-out direction. After processing, these were presented in a square matrix of 512×512 pixels.

Subsequently, multislice coronal short tau inversion recovery (STIR) images were recorded as described above (TR/TE 2000/60, number of transients 2), except that the spin echo sequence was preceded by a 180° inversion pulse followed by an inversion time of 250 ms. In pilot experiments, this inversion time was found to yield optimal contrast between compromised and healthy brain tissue.

In order to measure the coronal relaxation time T2 on a pixel-by-pixel basis, six rats (two age-matched control rats and four rats with chronic experimental allergic encephalomyelitis) were used in a series of T2W imaging experiments with a TE of 20 ms, 40 ms, 60 ms, and 80 ms and a TR of 6 s. In this experiment, which was performed at week 21 post-inoculation, all other parameters were identical to those of the above-mentioned T2W imaging experiment. The series of T2W images at a given slice position were used to reconstruct a two-dimensional map of T2 by fitting the data on a pixel-by-pixel basis to monoexponential decay functions. T2 values of cortex tissue, thalamus and ventricles were read from the T2 map and averaged among animals. T2 values of lesioned tissue were calculated for lesions which extended throughout the thickness of the MRI slice.

All MRI data were analysed using MRI specific software (Image Browser, SISCO, Sunnyvale, Calif., USA) by two different investigators who were blind to the treatment given to the animals. A filter was positioned over the region of interest (cortex and subcortical regions) in MRI slices. The filters were preset at fixed values, which appeared to yield an optimal differentiation between areas of relatively low and high signal intensity in pilot experiments. Pixels with relatively high signal intensities (e. g., higher than the fil-

ter setting) were added to obtain the total surface area of the brain regions with high signal intensities in that given slice. These surface areas with high signal intensity were summed for all slices for each animal and converted to total lesion volume (in µl). In the analysis, interslice gaps were not included in the calculation of the total lesion volume.

EVALUATION

Application of the drugs, evaluation of the clinical status and the MRI were all performed by different investigators who were blind to the treatment given to the animals. Treatment codes were broken at the end of the experiment after data analysis had been completed. The distribution of clinical scores in the different treatment groups was analyzed using a nonparametric Wilcoxon Rank Sum test. Treatment effects on lesion volume measured by MRI were tested by an analysis of variance for repeated measurements (MANOVA) followed by additional Student's *t*-tests (two-paired). $P < 0.05$ was considered to be significantly different.

E.10.2.2 NMRI Study of 3-Nitropropionic Acid-Induced Neurodegeneration in Rats

PURPOSE AND RATIONALE

Effective clinical therapies for neurodegenerative diseases are currently lacking because the precise mechanisms underlying cell death are still obscure. It is hypothesized that a defect in mitochondrial energy metabolism may be the basis of secondary excitotoxic neuronal death in neurodegenerative diseases. 3-Nitropropionic acid is an irreversible succinate dehydrogenase inhibitor which blocks both the Krebs' cycle and mitochondrial electron transport. 3-Nitropropionic-acid-intoxicated rats serve as the animal model for one neurodegenerative disease, Huntington's disease. Chyi and Chang (1999) applied noninvasive diffusion- and T_2-weighted magnetic resonance imaging to study the temporal evolution and spatial distribution of brain lesions which were produced by intravenous injection of 3-nitropropionic acid in rats.

PROCEDURE

Animal Preparation

Male Sprague Dawley rats were anesthetized intraperitoneally with sodium pentobarbital (60 mg/kg). Anesthesia was maintained by serial supplement of pentobarbital (5 mg/50 min, i.v.) 2 h after the initial injection. One femoral vein was cannulated for chemical administration, and an endotracheal tube was set for artificial ventilation with an animal ventilator. A muscle relaxant, gallamine was injected intravenously to avoid spontaneous ventilation and movement during the image-acquisition period. The initial dose of gallamine was 12 mg and the maintaining dose was 6 mg/h. A bolus injection of 3-nitropropionic acid was intravenously administered.

Image Acquisition

Experiments were performed on a 4.7 T spectrometer (Spectrospin, Biospec 4.7 T, Fällanden, Switzerland) with an active shielding gradient at 5.6 G/cm in 500 µs. A 70-mm birdcage RF coil was used, and rats were placed in a prone position with a custom-designed head-holder. Four transverse images (2-mm-thick) along anterior–posterior direction were obtained using a 5-cm field of view and 128×256 matrix. The offsets were set corresponding to the sections −4.3, −1.8, +0.7, and +3.2 mm to the bregma. A fast spin-echo sequence was applied for T_2-weighted images (T_2WIs) with relaxation TIME = 4000 ms, effective echo TIME = 80 ms, and echo train LENGTH = 8. For diffusion-weighted images (DWIs), the pulsed field gradient method was employed with a relaxation time of 2000 ms, echo time of 59 ms, δ of 20 ms, Δ of 27 ms, and b-value of 1300 s/mm^2. The diffusion-sensitive gradients were applied in the read (x) direction before and after the 180° pulse. The controlled T_2WIs and DWIs were acquired prior to 3-nitropropionic administration. Then 2.5 min after the injection of 3-nitropropionic, sequential T_2WIs and DWIs were continuously performed for 8 h.

In a separate preparation, DSC MRI was performed immediately after diffusion-weighted MRI at 5 min be-

fore and 4 h after 3-nitropropionic acid administration. A 2-mm-thick transverse single-slice was chosen and centered at 0.5 mm anterior to the bregma where the striatal lesion sites were easily observed on the DWIs. A series of 30 gradient-echo images with a 64×256 matrix size, relaxation TIME = 30 ms, echo TIME = 10 ms, and $\alpha = 15°$ were acquired. The acquiring time for each gradient echo image was 1.92 s. The bolus of susceptibility contrast agent, gadopentic acid (0.3 mmol/kg, Schering, Berlin, Germany), was injected intravenously 10 s after the start of image acquisition.

EVALUATION

Data processing was performed using a commercially available image analysis software (MRVision, MRVision, Menlo Park, Calif., USA). According to Paxinos and Watson (1986), selected regions of interest (ROIs) in the striatum, hippocampus, cortex, and corpus callosum were defined. A signal-to-noise ratio (SNR) of a ROI was defined as the ratio of the mean signal intensity (SI) in this ROI to the mean SI in an adjacent background area. The relative contrast of a ROI was calculated according to the following formula: $|SI_A - SI_C| / SI_C$, where SI_A is the mean SI in this ROI and SI_C is the mean SI in the cortical ROI on the same image (Knowles and Markisz 1988). The SI_C was selected as reference because its SNR remained constant throughout the experimental period. The rCBV maps were generated by the integral under the ΔR_2^* transit curves on a pixel-by-pixel basis. The SNR, relative contrast, and regional rCBV determined from the rCBV map were all unit-less ratios.

Results were presented as means ± SEM. Statistical analyses were performed using paired Student's *t*-test to compare controlled and 3-nitropropionic-acid-treated data. $P < 0.01$ was considered statistically significant.

MODIFICATIONS OF THE METHOD

Using magnetic resonance imaging and *in vivo* proton magnetic resonance spectroscopy, Lee et al. (2000) evaluated the neuroprotective effect of lamotrigine and MK-801 on rat brain lesions induced by 3-nitropropionic acid.

E.10.2.3 NMRI Studies of Brain Activation in Rats

PURPOSE AND RATIONALE

Brain functional magnetic resonance imaging (fMRI) is capable of revealing *in vivo* biochemical, structural, and functional information that reflects the physiological integrity of the brain (Jenkins et al. 1996). In general, brain fMRI includes four different aspects of MR methods including tissue water movement (diffusion-weighted MRI) (Le Bihan et al. 1986), capillary flow (perfusion-weighted MRI) (Williams et al. 1992; Kim 1995), neuronal activation (blood oxygenation level-dependent, BOLD, MRI) (Ogawa et al. 1992), and cerebral metabolites (magnetic resonance spectroscopy) (Brown et al. 1982). In all of these methods, the BOLD effect, based on the difference in magnetic susceptibility between paramagnetic blood deoxyhemoglobin and surrounding tissues, is frequently employed to *in vivo* map functional changes during brain activation (McCarthy et al. 1993; Turner et al. 1993).

Chang and Shyu (2001) described a functional magnetic resonance imaging (fMRI) study of brain activations during non-noxious and noxious electrical stimulation of the sciatic nerve of rats.

PROCEDURE

Male Sprague Dawley rats were initially treated with atropine (6 mg/kg, i.p.), and then anesthetized with methohexital sodium, 65 mg/kg, i.p. A PE-240 tube was inserted via tracheotomy for artificial ventilation. A PE-50 catheter was placed in the femoral vein for the administration of drug. α-Chloralose (50 mg/kg) was given intravenously. After the sciatic nerve was exposed and isolated, a cuff electrode made from silicon tube and stainless steel wires was placed around the nerve. The surrounding muscle and skin were carefully sutured, and paraffin oil was filled around the electrode to prevent short-circuiting. Artificial ventilation was applied and CO_2 concentration was monitored and controlled within the range of 3.5%–4.5%. Rectal temperature was measured and maintained at about 37°C by a feedback-controlled warm-air system. After the

head-holder was in place, muscle relaxant (gallamine triethiodide, 50 mg/kg, i.v.) was given for muscle relaxation.

Electrophysiological Experiment

Laminectomy was performed between T12 and L5. Dorsal roots at L4 and L5 level were carefully isolated and cut. Each of the peripheral ends of the roots was ligated with a cotton thread previously soaked with normal saline. A silver–silver chloride electrode hooked on the end of the root was used to record the evoked field potentials extracellularly ipsilateral to the stimulating sites. The extracellular field potentials were amplified by a high-input impedance amplifier. All analog signals were displayed on either an analog or digital storage oscilloscope. Twenty sweeps of evoked compound potentials were averaged for each stimulus intensity. The threshold current for inducing minimal muscle twitch was tested before applying the muscle relaxant. The electrical current was delivered by a constant current pulse generator. The electrical pulse was a square wave, 0.5 ms duration, 2 Hz. This muscle twitch threshold current was used to compare with the threshold for inducing the minimal compound action potentials. The intensity was increased as a multiple of the threshold current value.

Imaging Acquisition in fMRI Experiments

MR experiments were performed on a Biospec BMT 47/40 4.7 T system equipped with an actively shielded gradient system (up to 5.9 G/cm in 500 μs). A 70-mm birdcage RF coil was used, and rats were placed in a prone position with a custom-designed head-holder. T1-weighted spin-echo images were scanned in transverse and sagittal planes to position the animal properly so that images were centered 1 mm posterior to the bregma. For identifying anatomical location, T_2-weighted spin-echo images with four slices in the transverse plane were acquired using a repetition time (TR) of 4 s, an echo time (TE) of 80 ms, a field of view (FOV) of 5 cm, and a slice thickness (SLTH) of 2 mm. The acquisition matrix was 256×128 with a matrix of 256×256 after zero-filling. Thus, the images covered the rat brain from 3 mm anterior to the bregma to 5 mm posterior to the bregma. At the same locations of T_2-weighted spin-echo images, a series of 40 gradient-echo images per slice for four slices in the transverse plane were collected for baseline and stimulation sets with a TR of 180 ms, an TE of 20 ms, a flip angle of 22.5°, a FOV of 5 cm and a SLTH of 2 mm. The acquisition matrix was 256×64 with a matrix of 256×256 after zero-filling. The total scanning time for each image was 23 s. In the baseline set, the stimulation was turned off during the first eight image acquisitions. The electrical stimulation was switched on in two stimulation sets during acquisition of images 9–16 and 25–32. The stimulator was switched off for the rest of the period. The stimulation consisted of rectangular pulses of 0.5 ms duration and a 2 Hz frequency current. The same muscle twitch measurement as described in the electrophysiological study session was conducted to determine the intensity of the threshold current. In each image acquisition session, only one stimulation intensity was used. Stimuli with varied threshold-multiplied intensities were applied randomly in three different sessions in each rat. At least 30 min waiting time was allowed between each acquisition session.

Physiological Data Acquisition System in fMRI Experiments

Inside the magnet, animals were placed in an acrylic head-holder for accurate positioning of the location of brain structures. The integrated physiological data acquisition system we used was processed and controlled by a program written in Microsoft BASIC language on an IBM personal computer (Shyu et al. 1996). The data acquisition and control signals were channeled through serial ports and a PCL-818 (Advantech, A/D converter and digital input/output) interface card. All digitized physiological data, timing events and trigger pulses from each image acquisition were displayed in real time to view the animal's condition. The same data were placed in a data array and stored on a hard disk for off-line analyses, plotting, and printing.

EVALUATION

Image data processing and analyses of significance of signal changes were performed using MRVision (MRVision, USA) running on a Silicon Graphics INDY workstation. The series of multi-sliced images were realigned in the vertical and horizontal direction related to the first image in the series. The analyses of the aligned data were based on the cross-correlation processing strategy (Bandettini et al. 1993). The correlation coefficient between each pixel of the series of images and a model of a square wave (whose OFF–ON–OFF–ON–OFF period was the same as the stimulation pattern) was calculated. An associated *t*-statistic image was generated by the fitting function. The *t*-statistic image was used to determine whether the correlation coefficient for each pixel was significantly different from zero. The same analysis procedure was carried out in each slice of the four slices. A critical *t*-value for each pixel for the desired level

of significance (e. g., $P < 0.01$) and degrees of freedom (total images-2) was calculated and an output image, an activated map consisting of clusters of pixels whose values exceeded the level of significance, was generated. This image, white color in appearance, was then overlaid with a high-resolution T_2-weighted image, resulting in an image showing the significantly activated region in white overlapping the anatomical image. The region of interest (ROI) from the *t*-statistic image was selected according to its corresponding location in the T_2-weighted image. The stereotaxic atlas of the rat (Paxinos and Watson 1998) was used as the reference for determining the corresponding anatomical structures in T_2-weighted images. The time course of signal intensities of 40 images of each of the four slices was obtained in the selected ROI. The extent of the functional activation was obtained by calculating the percentage change of averaged signals between the OFF period and the first and the second ON periods. Each chosen ROI corresponded to an anatomical structure that appeared in different slices, thus the signal intensity changes of each ROI in different slices could be averaged. The area of each ROI as depicted by pixel numbers appearing in different slices was summed. The mean percent signal increases and total area of each ROI activated by different intensities were compared using one-way ANOVA with $P < 0.05$ or < 0.001 considered to be significant. Post-hoc examination of the difference between groups was performed by the Student–Newman–Keuls test.

MODIFICATIONS OF THE METHOD

Kerskens et al. (1996) compared ultrafast perfusion-weighted MRI of functional brain activation in rats during forepaw stimulation with $T2^*$-weighted MRI.

Several other studies using MRI were performed in rats:

Wrynn et al. (2000) reported an *in vivo* magnetic resonance imaging study of the olfactory bulbectomized rat model of depression. The magnetic resonance imaging (MRI) investigation demonstrated alterations in signal intensities in cortical, hippocampal, caudate and amygdaloid regions in olfactory bulbectomized animals, but not in sham-operated controls. Ventricular enlargement was also evident in olfactory bulbectomized animals.

Itoh et al. (2004) described magnetic resonance and biochemical studies during pentylenetetrazole-kindling development and the relationship between nitric oxide, neuronal nitric oxide synthase and seizures. The daily administration of pentylenetetrazole was associated with an increase in the amount of neuronal nitric oxide synthase (nNOS). NO generation was measured directly by *in vivo* and *ex vivo* electron paramagnetic resonance on rats undergoing progressive convulsions. Morphological changes in the brain structure of rats were measured by magnetic resonance imaging during epileptic convulsions induced by repetitive administration of pentylenetetrazole.

Watanabe et al. (2006) described mapping of the habenulo-interpeduncular pathway in living **mice** using manganese-enhanced 3D MRI. Six hours after intracerebroventricular microinjection of $MnCl_2$, T1-weighted 3D MRI (2.35 T) at 117 µm isotropic resolution revealed a continuous pattern of anterograde labeling from the habenula via the fasciculus retroflexus to the interpeduncular nucleus.

Hasegawa et al. (2003) described diffusion-weighted imaging in kainic-acid-induced complex partial status epilepticus in **dogs**. A cannula was stereotactically inserted into the left amygdala. One week after surgery, all dogs were imaged using MRI. Pre-injection imaging consisted of T2-weighted (T2W) imaging, fluid attenuated inversion recovery (FLAIR), and DWI. Two weeks after surgery, five dogs received intra-amygdaloid KA microinjections. MRI was carried out at 3, 6, 12, 24, and 48 h after onset of complex partial status epilepticus.

E.10.3 NMRI Psychoneuropharmacological Studies in Primates

E.10.3.1 Functional NMRI Studies in the Brain of Rhesus Monkeys

PURPOSE AND RATIONALE

Zhang et al. (2000) and Andersen et al. (2002) published methodological details for functional MRI studies in awake rhesus monkeys.

PROCEDURE

Adult female rhesus monkeys (*Macaca mulatta*) were maintained on a 12-h light:12-h dark cycle in individual cages with water available ad libitum. They had to be adapted to an MRI environment.

The goal was to elicit cooperative involvement of the rhesus monkeys through positive reinforcement. The animals were first acclimated to working with the trainers in their home cage room. Visual contact, vocal familiarity and positive reinforcements (juice rewards and preferred foods) were used to promote bonding and establish a working relationship between subject and trainer. A pole-and-collar system was used to handle and train monkeys. The monkeys were trained to voluntarily exit their home cages with use of positive reinforcements and the pole-and-collar system. After subjects were sufficiently trained, they were introduced to the primate-training chair. Food was removed from the subject's home cage approximately 20 h prior to a training session. Training sessions lasted 45–75 min and were conducted at least twice a week per subject until no major movements were observed.

Apparatus

The animals were adapted to the MRI-compatible chair constructed from non-ferromagnetic materials and designed to comfortably position an adult rhesus monkey in a prone, sphinx-like position within the magnet bore. The head-holder was designed to restrict head motion without having to surgically attach a head-holder to the skull. The head frame was placed over the monkey's head and secured to the training chair using four nylon screws. The monkey's head rested comfortably on a padded chin support that acted as a stabilizer and cushion. Its nose and mouth were positioned outside the head-holder for comfort and ease of breathing. Under local anesthesia (1% lidocaine, 2.0 ml on each side), two MRI-compatible pins were inserted through the overlying skin and connective tissue to contact the bony cranium. Earbars/earplugs were constructed that followed the natural angle of the rhesus ear canal and secured firmly to the chair-mounted head-holder. Earbars/earplugs were used both for MRI and training sessions to reduce head movement and protect the animals from the high ambient MRI noise levels. Two separate boxes in front of the MRI-compatible chair accommodated the front limbs of the monkey.

fMRI Procedures

The scans were conducted on a Siemens VISION (VB33A) 1.5T MRI scanner using the body coil to transmit radio frequency and an 8-cm surface coil placed above the monkey's head for RF signal reception. The anatomic structures of interest were visualized using a 3D FLASH sequence with 1 mm isotropic resolution (TR/TE = 21/6 ms, flip ANGLE = 30°, image matrix SIZE = 128 × 128 × 90, field of VIEW = 128 mm, BANDWIDTH = 195 Hz per pixel). No correction was made for the fall-off in signal intensity with distance from the surface coil in the anatomic images, but sufficient sensitivity was

available to accurately visualize anatomic structures throughout the entire slice.

Functional MR images were acquired continuously using a FLASH 2D multiple gradient-recalled-echo (MGRE) navigator sequence. Slices were acquired interleaved for three non-contiguous positions in the coronal plane: the first slice covering the area of the putamen and the caudate, the second one covering globus pallidus, and the last one included the substantia nigra (Zhang et al. 2000). An 11-echo MGRE sequence was used to map on a pixel-by-pixel basis the local transverse relaxation rate R_2^* Menon; Andersen; Chen and Chen). R_2^* is the local transverse relaxation rate for the measured MR signal intensity, $S(\mathrm{TE}) = S_0 \exp(-R_2^* \mathrm{TE})$, where TE is the echo delay time. It is the parameter that affects contrast in a T_2^*-weighted image sensitized to local susceptibility effects such as those caused by changes in the blood oxygenation level. Darker regions in T_2^*-weighted images have larger baseline R_2^* values reflecting a more rapid MR signal decay rate ($R_2^* = 1/T_2^*$). The increase in blood oxygenation level associated with brain "activation" causes a decrease in the value of the R_2^* parameter. There are several advantages of using R_2^*. As an intrinsic MR parameter, its value is not affected by the non-uniform sensitivity pattern of the surface coil used for signal reception, provided the images at all echo times TE have sufficient signal level, well above the intrinsic noise floor. Also, R_2^* is insensitive to changes in the absolute image intensity, S_0, that may occur over the duration of a long scan. A disadvantage is that the rate of acquisition is slower, although a single-shot multi-echo EPI method was recently developed for quantitative R_2^* mapping in functional MR imaging (Posse et al. 1999).

The last TE images were acquired without phase encoding gradients to serve as a navigator echo for detection of head motion occurring during the acquisition of data for reconstruction of single R_2^* images. The FLASH 2D acquisition parameters were: TR = 250 ms, TE = 7–75 ms, image acquisition matrix SIZE = 112 × 128, rectangular field of VIEW = 112 × 128 mm, slice THICKNESS = 3 mm, flip ANGLE = 40°, BANDWIDTH = 156 Hz per pixel. Local shimming of the static magnetic field B_0 in the basal ganglia was used to optimize sensitivity to the BOLD effect. For each animal, 20 min of baseline fMRI data were collected, after which 0.1 mg/kg apomorphine was injected subcutaneously. Data collection then resumed for another 20 min. In cases where replicate scans were obtained in the same animal, there was at least a 1-week interval between scans.

EVALUATION

The calculation of R_2^* values was carried out on a pixel-by-pixel basis by fitting the gradient echo signal decay to a first-order model $\ln(S) = \ln(S_0) - R_2^* \mathrm{TE}$. The corresponding percentage signal changes, $\Delta S/S$, reported in our activation studies are determined from ΔR_2^* as the values that would have been observed at a representative single echo time of TE = 45 ms (Blamire et al. 1992; Menon et al. 1993). The latter time is chosen to match the relaxation time T_2^* in brain tissue for maximum contrast [assuming the signal intensity S is maintained constant across studies ($\Delta S/S \approx -\Delta R_2^* \mathrm{TE}$)]. While R_2^* itself does not report on the BOLD effect directly (only the temporal contrast due to changes ΔR_2^* does), repeatability in the measurement of baseline R_2^* values in specific brain regions of a given animal helps ensure consistency during replicate scans over a period of months. However, the baseline R_2^* in some tissues, such as the globus pallidus, does change slowly over a period of years due to metal deposition (e. g., iron) with aging. While there are differences between brain areas in their baseline R_2^* value, we have not seen a significant correlation between baseline and drug-evoked changes (ΔR_2^*). Thus, quantitative measures of changes in R_2^* can be detected regardless of baseline values. Additionally, any departure from a log-linear signal decay behavior can be mapped to help yield information about the intra- or extra-vascular origin of the signal (Chen et al. 1996). All of the analyses have been conducted using MAT:LAB software on Unix/Linux workstations (Mathworks, Natick, Mass., USA).

The fMRI data needed for computation of the R_2^* maps were acquired at a rate of one set consisting of three image slices every 30 s. Rigid-body motion between successive time points was not corrected since most effects were in the through-slice direction. Prior to administration of any drug, a total of 40 time frames were collected over 20 min for the baseline state. Following the injection of drug, an additional 40 images were collected to track the dynamic response. First, the time-course data for each pixel were adjusted by centering so as to have a zero mean during the baseline period comprising the first 40 time frames. The sample covariance matrix of dimension 80 × 80 was then computed from the measured R_2^* response for all image voxels in the brain, and the principal component time-course profiles were determined as the eigenvectors. The associated pixel-wise scores across the slice images represented the spatial modes/patterns.

Information in the navigator echo data from all three slices was used to detect line-to-line changes and sub-

sequently discard image time frames where motion had occurred during the acquisition. Additionally, formal statistical methods of influence analysis for PCA were used to flag and subsequently remove outlying observations that exerted undue influence and contributed disproportionately in the partitioning of variance (Andersen et al. 2002). These observations typically corresponded to spikes at points in the time series data and present as artifacts in the corresponding R_2^* maps. In a typical fMRI study of an awake rhesus monkey, on the order of 5–10 time frame observations out of a total of 80 would be detected by the navigator echo and 10–20 would be flagged as statistical outliers in the influence analysis for PCA. From the trimmed data set, the sample covariance matrix and principal component time course profiles were then recomputed yielding a far more robust representation.

The first principal component, which also represents the largest source of variance in the data, was then used to model the temporal response in each voxel across the brain image slices. This approach of filtering and fitting enables both an analysis of the dynamic nature of the temporal response to administration of a drug in a single animal and the development of an unbiased measure of activation that can be used in the analysis of data combined across multiple animals. From the filtered data, the change ΔR_2^* representing the fMRI activation response to a drug was determined as the difference between the mean R_2^* value across 20 images post drug administration during the period of peak response and the mean value within the 40 images acquired as baseline prior to administration.

MODIFICATIONS OF THE METHOD

Stefanacci et al. (1998) and Dubowitz et al. (2001) reported MRI studies in conscious monkeys.

Howell et al. (2001) described an apparatus and behavioral training protocol to conduct positron emission tomography (PET) neuroimaging in conscious rhesus monkeys reporting the development and standardization of PET neuroimaging protocols in conscious rhesus monkeys and their application to the characterization of the acute effects of cocaine on cerebral blood flow. Specific attention was devoted to the development of an effective and comfortable head restraint device to be used in the imaging of conscious monkeys. The restraint device was designed to attach to a standard primate chair to facilitate frequent immobilization. Subjects received extensive behavioral training prior to neuroimaging in order to ensure their comfort and minimize potential stress associated with the imaging protocols. Functional changes in cerebral blood flow were characterized in three subjects with the positron-emitting tracer ^{15}O water following acute i.v. administration of cocaine. Regions of interest were defined on MRI scans with a high degree of accuracy.

E.10.3.2 Functional NMRI Studies in the Brain of Common Marmosets

PURPOSE AND RATIONALE

Massacesi et al. (1995) and Genain and Hauser (1997) described actively and passively induced experimental autoimmune encephalomyelitis in common marmosets as a model of multiple sclerosis. ‘t Hart et al. (1998, 2004) used this model for detailed MRI studies with histopathological characterization of MRI-detectable white matter lesions.

PROCEDURE

Eleven marmosets (*Callithrix jacchus*) were used for this study. The body weight of the monkeys at the start

of the experiment ranged between 295 and 320 g. During the experiments, the monkeys were individually housed in spacious cages with padded shelter on the bottom. The daily diet consisted of commercial food pellets for non-human primates, supplemented with rice and fresh fruit. Drinking water was provided ad libitum

Induction of Experimental Autoimmune Encephalomyelitis (EAE)

Myelin was isolated from human brain white matter, which was kindly provided by Dr. Rivka Ravid of the Dutch Brain Bank (Amsterdam, The Netherlands). The myelin concentration in the stock solution was 30 mg/ml on a dry-weight basis and 1.3 mg/ml protein on a protein basis as measured according to Bradford (1976).

In a first group of five monkeys the myelin stock solution was emulsified in an equal volume of enriched complete adjuvant. Enriched complete adjuvant was prepared by mixing incomplete adjuvant (DIFCO Laboratories, Detroit, Mich., USA) with 6 mg/ml desiccated mycobacteria (*Mycobacterium tuberculosis*, H37A, DIFCO) followed by brief sonication. Under ketamine anesthesia, each monkey was injected intradermally on the back with 600 µl of emulsion divided over four spots, two in the inguinal and two in the axillary region. In addition, 1 ml phosphate-buffered saline (pH 7.4) containing 1010 heat-inactivated *Bordatella pertussis* particles was injected immediately after immunization and 48 h later.

In a second group of six monkeys, the original immunization protocol was modified in two respects. First, the *Mycobacterium* concentration in the antigen-adjuvant emulsion was reduced from 1.5 to 0.5 mg/ml to diminish the severity of ulceration around the injection sites. Secondly, *B. pertussis* administration as second adjuvant was omitted to obtain a milder EAE in which patterns of EAE reactivity can be associated with the presence of certain mhc alleles and cytokine profiles.

Clinical Diagnosis

The clinical course of EAE was recorded daily by a trained observer using semiquantitative scoring: 0 = no clinical signs; 0.5 = apathy, loss of appetite, altered walking pattern without ataxia; 1 = lethargy and/or anorexia; 2 = ataxia; 2.5 = para- or monoparesis and/or sensory loss and/or brainstem syndrome; 3 = para- or hemiplegia; 4 = quadriplegia; 5 = spontaneous death attributable to EAE. The highest per-day scores were averaged over 1 week. Moreover, each monkey was weighed at least three times per week to obtain a more objective score of the clinical wellbeing.

MRI

MRI was performed at the Bijvoet Center of Utrecht University, the Netherlands. For each monkey, T2- and T1-weighted magnetic resonance (MR) images were recorded, the latter also with contrast enhancement after intravenous injection of gadolinium-diethylenetriamine-penta-acetic acid (DTPA) (triple dose). The time points for performing MRI after immunization were chosen during periods of clinically active EAE

In Vivo MRI

In preparation for the experiment, the monkeys were anesthetized with ketamine/Vetranquil (9/1 v/v). During scanning, each monkey was placed on a 37°C water-filled heating pad to prevent hypothermia. The head of the monkey was fixed in a custom-built stereotaxic apparatus made of metal-free plastics to ensure reproducible positioning in the magnetic field and to minimize movement artifacts. The stereotaxic apparatus was placed inside a saddle-type radiofrequency coil.

MRI was performed on a SISCO 200-MHz spectrometer (Varian, Palo Alto, Calif., USA) equipped with an actively shielded gradient (maximum gradient 3.2 G/cm, 33 cm inner diameter).

Postmortem MRI

T2-weighted MR images were recorded from formalin-fixed brains to enable the determination of the exact localization of the lesions that were detected *in vivo*. In both scannings the same orientation points were chosen for slice localization. Because movement artifacts were absent and long acquisition times can be used, images of very high contrast can be obtained.

Slice Orientation and Scanning Procedure

First, a sagittal scout scan was made. The posterior and anterior positions of the corpus callosum were chosen as orientation markers for precise localization of the slices for the *in vivo* and postmortem MRI. A T2-[echo time (TE)/repetition time (TR), 60/2500 ms-] weighted multislice scan (20 slices of 1 mm thickness) was obtained followed by a T1-weighted scan (TE/TR, 25/1000 ms) with the same spatial prescription. Gadolinium-DTPA (Magnevist; Schering, Berlin, Germany) was injected intravenously (0.3 mmol/kg)

and allowed to circulate for 10 min to ensure adequate distribution. Next, the T1-weighted MRI was repeated to attain a post-contrast data set. Each slice was recorded with a matrix of 256 × 128 data points and a field of view of 5 × 5 cm. The data set was analyzed on an Apple Macintosh Performa 630 using the public domain NIH Image program.

The T1-weighted MR images had an unexpected gray-white matter contrast. In images recorded with the NMR machines that are now used in clinical settings, which are 1.5 T or less, a contrast conversion of the white and gray matter is normally seen on T1-weighted versus T2-weighted images. In T1-weighted images the NMR signal of the white matter is hyperintense in comparison with that of the gray matter, whereas in T2-weighted images the white matter signal is hypointense compared with that of the gray matter.

In both the T1- and T2-weighted images recorded on our 4.7-T machine, white matter is hypointense as compared with gray matter, and lesions are visible as hyperintensities. This is not a unique feature of the marmoset brain, given that it was also observed in cat brains. The most likely explanation for this discrepancy is that with the high magnetic field used, T1 values of gray and white matter converge, whereas T2 values are unaffected by the strength of the field. In our T1-weighted images, the intensities of white and gray matter are most likely determined by the longer T2 value of gray matter and the different proton densities of both tissues. This phenomenon did not affect the detection of gadolinium enhancement, because even in long TR/short TE images ("proton-density" weighted) contrast enhancement can be observed.

Chapter F
Drug Effects on Learning and Memory[1]

[1] With contributions by F.J. Hock, F.P. Huger, W.H. Vogel, J.D. Brioni, J.L. McGaugh and E. Dere

F.1 Introduction

It is easily understood that behavioral psychopharmacologies faced with the task of dealing with extremely complex behavioral disturbances. This holds true for both patient groups: young people with learning and memory problems and elderly patients with memory deficits. For the elderly, difficulties arise in designing appropriate animal models of human aging or the deficits occurring during human aging. One of the major problems for experimental behavioral pharmacology is whether or not old animals are the appropriate models. At the first view it seems obvious that the study of potential geronto-psychopharmacologic drugs should be performed in old animals. However, the problem is much more complicated. Laboratory animals are not a homogenous population, especially when old. Most of these old animals, which are one-third survivors of a population, have an individually different pathological history that is mostly unknown to the investigators. Some animals may be arthritic others may have bronchitis or cardiac deficiencies. If, for example, an arthritic rat is given a performance task associated with lever pressing, the animals may fail because of his rigid and painful joints and not because of a brain deficit or of the ineffectiveness of the test compound. Similar effects can be observed with old animals having a cataract in a visual discrimination task. Failure to perform a task may even be the result of both central and peripheral disturbances. Consequently it is impossible to describe the failure of one animal to perform the task to deficits in some parts of the brain or to pathological changes in the body.

Considerable evidence indicates that there are age-related changes in learning and memory (Gold and McGaugh 1975; Gold et al. 1975). Myslivecek (1997) described ontogeny of memory and learning in rats. For certain kinds of learning, there are specific developmental periods at which acquisition and retention are optimal; for example, imprinting in animals (Hess 1972; Scheich 1987) and language acquisition in humans (Lennenberg 1967). For other forms of learning and memory, acquisition and long-term retention in animals mature gradually with development (Campbell and Spear 1972). There is some evidence that aged organisms have impaired memory function. For example, in humans, performance on recent memory tasks appears to decay at shorter training-test intervals and is more susceptible to retroactive interference in elderly subjects than in young adult subjects (Craik 1977; Kubanis and Zornetzer 1971). Recent memory also appears to be deficient in aged non-human primates (Bartus et al. 1980).

Although drug discovery is based upon many factors, animal models provide a crucial part in identifying chemical compounds with potential for clinical efficacy. A number of important animal models of human disease have come into existence based upon "serendipitous" discoveries of their ability to identify chemicals with a particular set of therapeutic actions. However, in the absence of truly effective therapeutic agents for age-associated dementia to serve as standards, the development of appropriate animal models for dementia represents a serious challenge. In the case of Alzheimer's disease or age-associated memory impairment, successful development of animal models may well depend upon our ability to accurately reproduce specific pathophysiological or etiologic factors.

It is generally agreed that an ideal animal model of human dementia would exhibit some or all the behavioral and neurological dysfunctions known to be associated with the clinical disorder, as well as the pathological processes leading to the demented condition. An early approach was the measurement of the spinal cord fixation time in rats as described by Giurgea and Mouravieff-Lesiusse (1971), Giurgea and Salama (1977).

McDonald and Overmier (1998) presented a critical review of animal models of the mnemonic impairments in Alzheimer's disease. Socci et al. (1995) could show that chronic antioxidant treatment improves cognitive performance of aged rats. Several authors discussed chronic alcohol intoxication in rats and mice as a model for neurodegeneration (Ahrendt et al. 1988; Fadda and Rossetti 1998; Raghavendra and Kulkarni 2001; Wozniak et al. 2004).

Miller et al. (1999) and McClearn (1999) discussed the use of inbred strains for gerontological research. There are limitations on research with uniform genotypes and advantages of heterogeneous populations. However, for specific purposes, the uniformity and stability of inbred strains are extremely valuable attributes.

Since cholinesterase inhibitors, such as physostigmine (Christie et al. 1981; David and Mohs 1982; Thal et al. 1983) and tacrine (Summers et al. 1986) have been shown to improve cognitive function in

patients with Alzheimer's type dementive disorders and based on analytical data in brains of aged subjects, the cholinergic hypothesis of geriatric memory dysfunction has been established. Numerous attempts have been made to study the influence of potential drugs on the central cholinergic system, e. g., inhibition of acetylcholinesterase activity in rat striatum *in vitro*, differentiation of this activity versus the inhibition of butyrylcholinesterase activity, *ex vivo* cholinesterase inhibition in rat striatum, release of acetylcholine from rat brain slices after electrical stimulation, binding to muscarinic cholinergic receptors in rat forebrain, stimulation of phosphatidyl-inositol turnover via muscarinic receptors, binding to nicotinic cholinergic receptors in rat frontal cortex. Presynaptic cholinergic markers include choline acetyl-transferase and acetylcholinesterase activities, high-affinity transport of choline, acetylcholine synthesis, and muscarinic receptor binding. The high-affinity transport of choline is influenced by a cholinotoxin, ethylcholine aziridinium (AF64A) that induces *in vivo* a persistent central cholinergic hypofunction of presynaptic origin (Fisher and Hanin 1986).

Changeux et al. (1998) discussed the role of nicotinic acetylcholine receptors in the brain in learning and reinforcement.

These approaches may give hints for the discovery of new antidementic drugs. The "cholinergic hypothesis" (Bartus et al. 1982, 1987) is not unequivocal in the pathophysiology of Alzheimer's disease (Francis et al. 2005). The role of other transmitters has to be studied (Nordberg 1990). *In vitro* and *in vivo* studies have to be performed in parallel in order to find new approaches to treat Alzheimer's disease or Alzheimer's type dementia.

The **amyloid cascade hypothesis** has gained much interest (Thorsett and Latimer 2000; Yamada and Nabeshima 2000; Emre and Qizilbash 2001; Sommer 2002; Lichtenthaler and Haass 2004).

As early as 1907, Alzheimer described the appearance of plaques and neurofibrillary tangles (Alzheimer 1907). Senile plaques are extracellular insoluble, congophilic protein aggregates composed of amyloid β, a 39- to 43-amino-acid peptide. Neurofibrillary tangles are intracellular lesions consisting of paired helical filaments from the hyperphosphorylated cytoskeletal protein τ, which is a microtubule-associated protein that is involved in microtubule assembly and stabilization. In Alzheimer's disease, τ is abnormally phosphorylated, aggregates into paired helical filaments, and loses its ability to stabilize axonal microtubules (Mandelkow and Mandelkow 1998).

Goedert and Hasegawa (1999) discussed the tauopathies as an experimental animal model for Alzheimer's disease and other dementing disorders.

The discovery of autosomal dominant mutations in the gene encoding the amyloid precursor protein that were causal for early-onset familial Alzheimer's disease strongly suggested amyloid β to be the prime suspect in the pathogenesis of Alzheimer's disease, resulting in the formulation of the amyloid cascade hypothesis (Hardy and Higgins 1992).

In line with the amyloid cascade hypothesis, a strategy for disease-modifying pharmacological intervention would be the selective inhibition of β- and γ-secretase, the proteases that process amyloid precursor protein to amyloid β.

Bartzokis (2004) presented age-related myelin breakdown as a hypothetical model of cognitive decline and Alzheimer's disease.

F.2 In Vitro Methods

F.2.0.1 In Vitro Inhibition of Acetylcholine-Esterase Activity in Rat Striatum

PURPOSE AND RATIONALE

The purpose of this assay is to screen drugs for inhibition of acetylcholine-esterase activity. Inhibitors of this enzyme may be useful for the treatment of Alzheimer's disease.

Acetylcholinesterase (AChE), which is sometimes called true or specific cholinesterase, is found in nerve cells, skeletal muscle, smooth muscle, various glands and red blood cells (Nachmansohn and Rothenberg 1945; Koelle et al. 1950; Ellman et al. 1961). AChE may be distinguished from other cholinesterases by substrate and inhibitor specificities and by regional distribution. Its distribution in brain roughly correlates with cholinergic innervation and subfractionation shows the highest level in nerve terminals.

It is generally accepted that the physiological role of AChE is the rapid hydrolysis and inactivation of acetylcholine. Inhibitors of AChE show marked cholinomimetic effects in cholinergically-innervated effector organs (Taylor 1996) and have been used therapeutically in the treatment of glaucoma, myasthenia gravis and paralytic ileus. However, recent studies (Christie et al. 1981; Summers et al. 1981; Davies and Mohs 1982; Atak et al. 1983) have suggested that AChE inhibitors may also be beneficial in the treatment of Alzheimer's dementia.

Augustinsson (1971) reviewed a number of methods for assaying cholinesterase activity and concluded that the method described by Ellman et al. (1961) was one of the best. The method described is a modification of Ellman's procedure.

PROCEDURE

Reagents

1. 0.05 M Phosphate buffer, pH 7.2
   a) 6.85 g $NaH_2PO_4 \cdot H_2O$/100 ml distilled H_2O
   b) 13.40 g $Na_2HPO_4 \cdot 7H_2O$/100 ml distilled H_2O
   c) add a) to b) until pH reaches 7.2
   d) Dilute 1:10
2. Substrate in buffer
   a) 198 mg acetylthiocholine chloride (10 mM)

b) q.s. explain to 100 ml with 0.05 M NaH_2PO_4, pH 7.2 (reagent 1)

3. DTNB in buffer
   a) 19.8 mg 5,5-dithiobisnitrobenzoic acid (DTNB) (0.5 mM)
   b) q.s. to 100 ml with 0.05 M NaH_2PO_4, pH 7.2 (reagent 1)
4. A 2 mM stock solution of the test drug is made up in a suitable solvent and q.s. to volume with 0.5 mM DTNB (reagent 3). Drugs are serially diluted (1:10) such that the final concentration (in cuvette) is 10^{-4} M and screened for activity. If active, IC_{50} values are determined from the inhibitory activity of subsequent concentrations.

Tissue Preparation

Male Wistar rats are decapitated, brains rapidly removed, corpora striata dissected free, weighed and homogenized in 19 volumes (approximately 7 mg protein/ml) of 0.05 M NaH_2PO_4, pH 7.2 using a Potter-Elvejhem homogenizer (Kontes, Vineland, NJ). A 25 µl aliquot of this suspension is added to 1 ml of the vehicle or various concentrations of the test drug and reincubated for 10 min at 37°C.

Assay

Enzyme activity is measured with the Beckman DU-50 spectrophotometer. This method can be used for IC_{50} determinations and for measuring kinetic constants.

Reagents are added to the blank and sample cuvettes as follows:

Blank: 0.8 ml PO_4 buffer/DTNB
0.8 ml buffer/Substrate

Control: 0.8 ml PO_4 buffer/DTNB/Enzyme
0.8 ml PO_4 buffer/Substrate

Drug: 0.8 ml PO_4 buffer/DTNB/Drug/Enzyme
0.8 ml PO_4 buffer/Substrate

Blank values are determined for each run to control for non-enzymatic hydrolysis of substrate and these values are automatically subtracted by the kin-data program available on kinetics soft-pac module. This program (Beckman DU-50 series spectrophotometer, kinetics Soft-Pac™ module operation instructions: 1–7 also calculates the rate of absorbance change for each cuvette.

EVALUATION

For IC_{50} determinations: Substrate concentration is 10 mM diluted 1:2 in an assay yielding a final concentration of 5 mM. DTNB concentration is 0.5 mM yielding 0.25 mM final concentration

$$\% \text{ Inhibition} = \frac{\text{slope control} - \text{slope drug}}{\text{slope control}} \times 100$$

IC_{50} values are calculated from log-probit analysis.

F.2.0.2 In Vitro Inhibition of Butyrylcholine-Esterase Activity in Human Serum

PURPOSE AND RATIONALE

This assay can be used in conjunction with the acetylcholine-esterase assay to determine the enzyme selectivity of various cholinesterase inhibitors.

Butyrylcholine-esterase (BChE), which is sometimes called pseudocholinesterase, preferentially hydrolyzes butyrylcholine. This enzyme is found in the highest amounts in serum, but its physiological role is not known (Chemnitius et al. 1983; Walker and Mackness 1983). Ethopropazine and tetra-isopropyl pyrophosphoramide (ISO-OMPA) are selective inhibitors of butyrylcholinesterase. In an *ex vivo* experiment with the selective BChE inhibitor, ISO-OMPA, it was shown that inhibition of butyrylcholinesterase was not correlated with any significant acute cholinomimetic effects.

PROCEDURE

Reagents

1. 0.05 M phosphate buffer, pH 7.2
   a) 6.85 g $NaH_2PO_4 \cdot H_2O$/100 ml distilled H_2O
   b) 13.40 g $Na_2HPO_4 \cdot H_2O$/100 ml distilled H_2O
   c) Add (a) to (b) until pH reaches 7.2
   d) Dilute 1:10
2. Substrate in buffer
   a) 225.8 mg s-butyrylthiocholine chloride
   b) q.s. to 100 ml with 0.05 M phosphate buffer, pH 7.2 (reagent 1)
3. DTNB in buffer
   a) 19.8 mg 5,5-dithiobisnitrobenzoic acid (DTNB) (0.5 mM)
   b) q.s. to 100 ml with 0.05 M phosphate buffer, pH 7.2 (reagent 1)
4. A 2 mM stock solution of the test drug is made up in a suitable solvent and q.s. to volume with 0.5 mM DTNB (reagent 3). Drugs are serially diluted (1:10) such that determined from the inhibitory activity of subsequent concentrations.

Enzyme Preparation

A vial of lyophilized human serum (Precilip, Biodynamics, Houston, Texas) is reconstituted in 3 ml of distilled water. A 25 ml aliquot of this suspension is added to 1 ml of the vehicle or various concentrations of the test drug and pre-incubated for 10 min at 37°C.

Assay

Enzyme activity is measured with the Beckman DU-50 spectrophotometer. This method can be used for IC_{50} determinations and for measuring kinetic constants.

Reagents are added to the blank and sample cuvettes as follows:

Blank: 0.8 ml PO_4 buffer/DTNB
0.8 ml buffer/Substrate

Control: 0.8 ml PO_4 buffer/DTNB/Enzyme
0.8 ml PO_4 buffer/Substrate

Drug: 0.8 ml PO_4 buffer/DTNB/Drug/Enzyme
0.8 ml PO_4 buffer/Substrate

Blank values are determined for each run to control for non-enzymatic hydrolysis of substrate and these values are automatically subtracted by the kindata program available on kinetics soft-pac module. This program also calculates the rate of absorbance change for each cuvette.

EVALUATION

For IC_{50} determinations: Substrate concentration is 10 mM diluted 1:2 in assay yielding final concentration of 5 mM. DTNB concentration is 0.5 mM yielding 0.25 mM final concentration

$$\% \text{ Inhibition} = \frac{\text{slope control} - \text{slope drug}}{\text{slope control}} \times 100$$

IC_{50} values are calculated from log-probit analysis.

F.2.0.3 Ex Vivo Cholinesterase Inhibition

PURPOSE AND RATIONALE

This assay is used to determine the dose-response relationship and duration of action of cholinesterase inhibitors *in vivo*.

Cholinesterase inhibitors, including physostigmine (Christie et al. 1981; David and Mohs 1982; Thal et al. 1983) and tacrine (Summers et al. 1986) have been shown to improve cognitive functions in Alzheimer's disease. Physostigmine is a potent, but nonselec-

tive inhibitor of cholinesterase (Taylor 1996) and has a short duration of action. Tacrine also inhibits both acetylcholine-esterase (true) and butyrylcholine-esterase (pseudo), but is more potent as an inhibitor of the pseudo-enzyme (Heilbronn 1961).

The mechanism of inhibition of these two drugs is quite different. Physostigmine is a competitive inhibitor and blocks the active site of the enzyme by carbamylation of a serine hydroxyl group at the esteratic site of the enzyme (Taylor 1996; O'Brien 1969). This covalently bound carbamyl group then dissociates from the enzyme much more slowly than the acetyl group left by the natural substrate, but the inhibition is not irreversible like that of the organophosphates. The inhibition characteristics of physostigmine, i. e., submicromolar affinity for the enzyme and covalent binding of the inhibiting group, are ideal for *ex vivo* studies. Tacrine, however, is a mixed competitive inhibitor of cholinesterase (Heilbronn 1961), with lower apparent affinity than physostigmine for the enzyme (based on IC_{50} values at saturated substrate concentrations). Tacrine binds to the anionic site of cholinesterase through weak hydrophobic interactions (Steinberg et al. 1975).

Ideally, a dose-response for cholinesterase inhibition is determined first. Then a dose which gives a reasonable effect (> 50% inhibition if possible) is chosen to do the time-course experiment. The effects on brain acetylcholinesterase activity are examined in striatal tissue, using 5 mM acetylthiocholine as a substrate (Ellman et al. 1961). Effects on butyrylcholine-esterase activity may be determined in plasma samples, with 5 mM butylthiocholine used as a substrate.

PROCEDURE

Reagents

1. 0.05 M Phosphate buffer, pH 7.2
   a) 6.85 g $NaH_2PO_4 \cdot H_2O$/100 ml distilled H_2O
   b) 13.40 g $Na_2HPO_4 \cdot 7H_2O$/100 ml distilled H_2O
   c) add a) to b) until pH reaches 7.2
   d) Dilute 1:10
2. DTNB in buffer
   a) 19.8 mg 5,5-dithiobisnitrobenzoic acid (DTNB) (0.5 mM)
   b) q.s. to 100 ml with 0.05 M phosphate buffer, pH 7.2 (reagent 1)
3. Substrate in buffer
   a) 198 mg acetylthiocholine chloride (10 mM)
   b) q.s. to 100 ml with 0.05 M phosphate buffer, pH 7.2 (reagent 1)

Drug Treatment

Groups of four male Wistar rats are dosed i.p. or p.o. with vehicle or the test drug. For the initial dose response study, the rats are given varying doses of drug based on toxicity reported in primary overt effects testing and sacrificed at either 30 min or 1 h after dosing. The animals are observed and the occurrence of cholinergic signs is noted (piloerection, tremors, convulsions, salivation, diarrhea and chromodacryorrhea). For the time-course study, a dose of the test drug is given which gave significant inhibition of cholinesterase activity.

Tissue Preparation

Male Wistar rats are decapitated, brains rapidly removed, corpora striata dissected free, weighed and homogenized in 4 volumes of 0.05 M phosphate buffer, pH 7.2 using a Potter-Elvehjem homogenizer (Kontes, Vineland, NJ). A 12.5 ml aliquot of the homogenate is added to 1 ml 0.05 M phosphate buffer, pH 7.2/DTNB (reagent 2).

Assay

1. Enzyme activity is measured with the Beckman DU-50 spectrophotometer.
   Reagents are added to the blank and sample cuvettes as follows:

   Blank: 0.8 ml PO_4 buffer/DTNB (reagent 2)
   0.8 ml PO_4 buffer/Substrate (reagent 3)

   Control: 0.8 ml PO_4 buffer/DTNB/Enzyme from control animal
   0.8 ml PO_4 buffer/Substrate

   Drug: 0.8 ml PO_4 buffer/DTNB/Enzyme from treated animal
   0.8 ml PO_4 buffer/Substrate

   Blank values are determined for each run to control for non-enzymatic hydrolysis of substrate and these values are automatically subtracted by the kin-data program available on kinetics soft-pac module. This program also calculates the rate of absorbance change for each cuvette.
2. Substrate concentration is 10 mM diluted 1:2 in the assay yielding final concentration of 5 mM. DTNB concentration is 0.5 mM yielding 0.25 mM final concentration.

EVALUATION

The percent inhibition at each dose or time is calculated by comparison with the enzyme activity of the

vehicle control group.

$$\% \text{ Inhibition} = \frac{\text{slope control} - \text{slope drug}}{\text{slope control}} \times 100$$

Ex vivo time course experiments for physostigmine

	Physostigmine, 0.3 mg/kg, i.p.	
Time (h)	% Inhibition striatum	Cholinergic signs
0.25	48.6	P,T,D
0.5	28.5	P,T,D
1.0	27.0	P,T
2.0	7.6	P,T
4.0	1.4	P,T

P = piloerection, T = tremors, D = diarrhea.

MODIFICATIONS OF THE METHOD

Antagonism of physostigmine-induced lethality in mice has been used by Gouret (1973) as a general indicator of central or peripheral anticholinergic activity. A low dose of physostigmine can be used for detecting procholinergic activity.

F.2.0.4 Molecular Forms of Acetylcholinesterase from Rat Frontal Cortex and Striatum

PURPOSE AND RATIONALE

Different molecular forms of acetylcholinesterase can be isolated from animal tissues after solubilization in buffers containing various detergent and salt concentrations. The number of forms isolated, their relative amounts and molecular characteristics depend on the tissue source and the conditions used for solubilization of the membrane bound enzyme (McIntosh and Plummer 1973; Reiger and Vigny 1976; Trevor et al. (1976). Bon et al. (1979) have classified these forms as globular (G_1, G_2 and G_4) and asymmetric (A_4, A_8 and A_{12}), where the subscripts indicate the number of catalytic subunits. The G_1 and G_4 forms, having sedimentation coefficients of approximately 4S and 10S, respectively, are the major forms contained in bovine caudate nucleus (Grassi et al. 1982). Under conditions of high salt concentrations and detergent, AChE is quantitatively extracted from rat brain, with 10S form being the predominant component (Reiger and Vigny 1976). After solubilization, the molecular forms may be separated according to sedimentation properties by density gradient centrifugation, molecular weight by gel filtration or by electrophoretic mobility.

Although most of these studies on molecular forms of AChE have focused on the physical differences, Chan et al. (1972) reported some difference in sensitivity of the low molecular weight form to physostigmine and fluoride ion, while Lenz and Maxwell (1981) showed differential sensitivity to soman of forms separated by isoelectric focusing. Studies showing selective increases in the 10S form during development (Muller et al. 1985) and selective loss in Alzheimer's disease (Atack et al. 1983) suggest that this form of the enzyme may be developmentally and functionally more important. Cortical and striatal areas show different patterns of cholinergic innervation; the cortex having primarily extrinsic innervation, while the striatal cholinergic pathways are predominantly intrinsic (Ceullo and Sofroniew 1984).

The purpose of this procedure is to determine the effects of various cholinesterase inhibitors on the two major molecular forms of acetylcholinesterase isolated from rat striatum and cerebral cortex.

PROCEDURE

The procedure is divided into three main parts:

I. Preparation and isolation of molecular forms of AChE,

II. Assays for the marker enzymes,

III. Enzyme inhibition studies.

I.a Preparation of molecular forms of AChE

Male Wistar rats (200–250 g) are sacrificed, their brains rapidly removed and frontal cortices or corpora striata removed. The brain areas are weighed and homogenized in 5 volumes (wt/vol) of 10 mM phosphate buffer, pH 7.1, containing 1 M NaCl and 1% Triton X-100, except were indicated. The homogenates are centrifuged at 20,000 *g* for 20 min at 4°C. The supernatant is aspirated and marker enzymes for 16S (*E. coli* β-galactosidase), 11.3S (bovine catalase) and 4.8S (horse liver alcohol dehydrogenase) fractions are added. The supernatant is then centrifuged at 37,000 rpm (140,000 *g* max) for 17.5 h in a Beckman L5–65 ultracentrifuge with a SW-60 rotor. 15-drop fractions are collected for each centrifuge tube and assayed for protein, β-galactosidase, catalase, alcohol dehydrogenase and acetylcholinesterase activity. In addition, butyrylcholinesterase can be measured.

A 400 µl sample of the 20,000 *g*-supernatant is carefully layered on top of a 5–20% continuous sucrose gradient. This gradient is made up in a centrifuge tube from 1.65 ml of 20% sucrose and 1.65 ml of 5% sucrose in homogenizing buffer by means of a gradient maker. A 50% sucrose cushion (0.5 ml) is placed at the bottom of the tube.

Fractions are collected from the bottom of the tube, i.e, the densest fractions are collected first. Each fraction is 15 drops or approximately 24 fractions are collected per centrifuge tube.

I.b Analysis of fractions

β-Galactosidase, catalase and alcohol dehydrogenase are determined by enzymic activity (Hestrin et al. 1955; Chance and Maehly 1955; Bonnichsen and Brink 1955). Protein concentrations are determined by the method of Lowry et al. (1951). Acetylcholinesterase activity or butyrylcholinesterase activity are determined by a modification of the method of Ellman et al. (1961). Briefly, 10 µl aliquots of the fractions are added to 0.25 mM dithionitrobenzoic acid (DTNB) and 5 mM acetylthiocholine or 5 mM butyrylthiocholine in 0.05 M phosphate buffer, pH 7.2 and the absorbance is measured at 412 nm. Fractions of peak acetylcholinesterase activity are characterized by their sedimentation characteristics relative to the marker enzymes and peak fractions are pooled for enzyme inhibition studies or determination of kinetic constants.

II. Assays for marker enzymes

A Equine liver alcohol dehydrogenase (ADH), sedimentation coefficient 4.8 S

1. Enzyme: alcohol dehydrogenase from equine liver, crystallized and lyophilized (Sigma Chem. Co.)
2. Reagents:
   a) β-nicotinamide adenine dinucleotide (NAD) (Sigma Chem. Co.)
   b) 0.1 M glycine-NaOH buffer, pH 9.6
   c) absolute ethanol
   d) buffer-substrate-NAD mixture:
   875 µl NAD+875 µl ethanol+18.75 ml
   0.1 M glycine-NaOH buffer, pH 9.6
3. Assay
   10 µl enzyme fraction and
   850 µl mixture (reagent 2d)
   are incubated for 5 min at room temperature. The reaction is stopped by adding:
   300 µl 1.5 M $ZnSO_4$
   Absorbance is read at 340 nm and enzyme units are determined from a standard curve using values of 1.25, 2.5, 5, 10 and 20 mU of ADH.

B Bovine liver catalase, sedimentation coefficient 11.3 S

1. Enzyme: catalase from bovine liver, purified powder (Sigma Chem. Co., C-10)
2. Reagents:
   a) 30% hydrogen peroxide
   b) 0.05 M sodium phosphate buffer, pH 7.0
   c) mixture: 111 µl 30% hydrogen peroxide + 100 ml buffer, yielding 0.033% peroxide.
3. Assay
   10 µl enzyme fraction
   2990 µl peroxide-buffer mixture (reagent 2c)

Wavelength is set to 240 nm, absorbance is adjusted to 0.480 units. The amount of time is recorded for absorbance to decrease from 0.450 to 0.400. This corresponds to 3.45 µmol of hydrogen peroxide in 3 ml solution. Total catalase activity in 3 ml is 3.45 µMol/min.

C *E. coli* β-galactosidase, sedimentation coefficient 16.0 S

1. Enzyme: β-galactosidase from *E. coli*, grade VI, partially purified, lyophilized (Sigma Chem. Co)
2. Reagents:
   a) substrate: 15 mg/ml O-nitrophenyl-β-D-galacto-pyranoside (Sigma Chem. Co.) in water
   b) 0.6 M Na_2CO_3, pH 7.25
   c) 1 M $NaCO_3$
3. Assay
   10 µl enzyme fraction,
   150 µl 0.6 M phosphate buffer, pH 7.25, and
   50 µl O-Nitrophenyl-β-D-galactopyranoside
   (12 mM in assay) are incubated for 25 min at 30°C. The reaction is stopped by adding:
   500 µl 1 M Na_2CO_3, 1.75 ml water.
   Absorbance is read at 420 nm and enzyme units are determined from a standard curve using values of 0.015, 0.030, 0.525, 0.125 and 0.250 U of β-galactosidase.

III. Enzyme inhibition studies

For the enzyme inhibition studies, 25 µl aliquots of the enzyme preparation are preincubated with varying concentrations of the inhibitor for 10 min at 25°C and acetylcholinesterase activity is determined as previously described.

EVALUATION

Values for the IC_{50} are determined by log-probit analysis of the inhibition data using six to seven concentrations of the inhibitor and represent the means of 3 separate experiments.

F.2.0.5 Release of [^{3}H]ACh and Other Transmitters from Rat Brain Slices

PURPOSE AND RATIONALE

Electrically stimulated release of [^{3}H]ACh is used as a biochemical screen for agents which may possibly enhance or inhibit release of [^{3}H]ACh through a direct muscarinic interaction or other indirect interactions.

Muscarinic autoreceptors have been shown to have a role in the regulation of ACh release in several areas of the CNS (Hadhazy and Szerb 1977; DeBelleroche and Gardiner 1982; Strittmatter et al. 1982; James and Cubeddu 1984). Direct stimulation of muscarinic receptors with muscarinic agonists or indirect stimulation with acetylcholinesterase inhibitors decreases ACh release evoked by either increased potassium concentration or electrical stimulation. Muscarinic antagonists can either block their inhibition, or, under certain conditions, enhance ACh release (James and Cubeddu 1987; Sethy et al. 1988). Furthermore, other

neurotransmitters, most notably 5-HT and DA, can also inhibit [^{3}H]ACh release via interaction with 5-T_2 and D_2 heteroreceptors (Robinson 1983; Jackson et al. 1988; Muramatsu et al. 1988; Drukarch et al. 1989) and this inhibition can be reversed by the appropriate receptor antagonists. A compound's effect on [^{3}H]ACh release may provide evidence for a wide variety of releasing activities.

The advantages of using the electrically stimulated release technique on tissue slices have been described by Zahniser et al. (1986). This technique measures only presynaptic effects of test compounds.

PROCEDURE

This assay is based on the methods described by James and Cubeddu (1984, 1987).

Reagents

1. Krebs-Henseleit bicarbonate buffer, pH 7.4 (KHBB)
   Make a 2 liter batch, containing the following salts:

NaCl	13.84 g	118.4 mM
KCl	0.70 g	4.7 mM
$MgSO_4 \cdot 7H_2O$	0.58 g	1.2 mM
KH_2PO_4	0.32 g	2.2 mM
$NaHCO_3$	4.20 g	24.9 mM
$CaCl_2$	0.28 g	1.3 mM
Prior to use, add:		
Dextrose	4.00 g	11.1 mM

   Aerate for 60 min with 95% O_2/5% CO_2 on ice and check pH.
2. [Methyl-^{3}H]-choline chloride (80–90 Ci/mmol) is obtained from New England Nuclear. The final desired concentration of [^{3}H]choline is 100 nM. Add 0.25 nmol of [^{3}H]choline to 2.5 ml KHBB.
3. For most assays, a 10 mM stock solution of the test compound is prepared in a suitable solvent and diluted such that the final concentration in the assay is 10 µM. Higher or lower concentrations may be used depending on the potency of the test compound.
4. Hemicholinium-3 or HC-3 (Sigma): Make a 10 mM stock solution in H_2O. Two milliliters of this stock are then diluted to one liter in KHBB to give a final concentration of 20 µM.

Tissue Preparation

Male Wistar rats (100–150 g) are decapitated, and cortical, striatal, or hippocampal tissue removed on ice and 0.4 mm slices are prepared with a McIlwain tissue slicer. The slices are made individually, placed in cold, oxygenated buffer (10–20 ml) and incubated at 35°C for 30 min under oxygen. After this incubation, the buffer is decanted, leaving the slices behind. Then 2.5 ml of cold oxygenated buffer is added, and enough [^{3}H]choline to bring the final concentration to 100 nM. This is then incubated and shaken for 60 min at 35°C under oxygen. After this step, the buffer is decanted and the "loaded" slices are immediately placed on nylon mesh in the stimulation chambers.

Assay

Control buffer is pumped through the chamber for 42 min at a flow rate of 0.7 ml/min, to establish a stable baseline. Under these conditions released [^{3}H]ACh is subject to hydrolysis by acetylcholinesterase. The perfusion buffer is changed to fresh KHBB containing 20 µM HC-3. The potent choline uptake inhibitor HC-3 is included to prevent the re-uptake of any [^{3}H]choline formed from the hydrolysis of released [^{3}H]ACh. This maintains the stoichiometry of the stimulated release. The evoked release has been shown to be mostly [^{3}H]ACh rather than [^{3}H]choline, whereas spontaneous release under control, drug-free conditions is mostly [^{3}H]choline (Richardson and Szerb 1974; Szerb et al. 1977; Supavilai and Karobath 1985; Saijoh et al. 1985; Nishino et al. 1987).

SPECIAL CONDITIONS

1. Stimulation parameters are set at 2 Hz (2 ms duration) for 120 s, with 1 ms delay and voltage setting of 750 SIU (250 Ω). Agonists are more potent modulators of [^{3}H]ACh release at low stimulation frequencies (5).
2. For striatal slices, 2 µM sulpiride is present in the buffer to prevent DA inhibition of ACh release.
3. In some experiments, 5 µM methysergide is present in the buffer to prevent the serotonergic inhibition of ACh release mediated by 5-HT_2 receptors.
4. In order to determine the muscarinic regulation of [^{3}H]ACh release, 10 µM atropine can be included in some experiments.
5. In some experiments, physostigmine is added to the perfusion buffer. This causes a marked inhibition of stimulated release via feedback at pre-synaptic receptors. Under these conditions, receptor antagonists enhance [^{3}H]ACh release.

After the experiment is completed, the chambers are washed with distilled water for at least 20 min, 200 ml of 20% methanol in distilled water and again with distilled water for at least 20 min.

EVALUATION

After conversion of dpm, percent fractional release is calculated for each fraction, using a Lotus program.

Percent fractional release is defined as the amount of radiolabeled compound released divided by the amount present in the tissue. "Spontaneous Release" (SP) values are the average of the two fractions preceding and the first fraction in that range after the stimulation period. "Stimulated" (S) values are the summed differences between the percent fractional release during stimulation and the appropriate SP value.

The effects of drugs can be reported as S_2/S_1 ratios. To normalize the data, drug effects can be estimated by first calculating S_2/S_1 values for control and drug-treated slices and then expressing the S_2/S_1 value for the drug-treated slices as a percentage of the S_2/S_1 value for the control slices for each experiment. Each condition should be tested in slices from the same animal.

MODIFICATIONS OF THE METHOD

Release of Other Neurotransmitters From Brain Tissue in Vitro

Several authors (Harms et al. 1979; de Belleroche and Gardiner 1982; James and Cubeddu 1984; Raiteri et al. 1984; Zahniser et al. 1986; Smith et al. 1984, 1994) studied the release of neurotransmitters from brain tissue *in vitro*.

Raiteri et al. (1974) described a simple apparatus for studying the release of neurotransmitters from synaptosomes.

De Boer et al. (1988) determined the release of noradrenaline and serotonin in synaptosomes from rat cerebral cortex.

Saijoh et al. (1985) studied the influence of hypoxia on release and uptake of the neurotransmitters dopamine and acetylcholine in guinea pig striatal slices.

PROCEDURE

[^{3}H] Norepinephrine Release from Cortical Slices

Cortical slices (0.4 mm) from male Wistar rats are preincubated in Krebs buffer saturated with 95% O_2/5% CO_2, pH 7.4 for 30 min at 35°C, and then incubated in fresh buffer containing 25 nM [^{3}H]NE (35 Ci/mmol) for 30 min at 35°C. The slices are then placed in glass superfusion chambers containing platinum electrodes and perfused at 0.75 ml/min. Fractions are collected at 7 min intervals. Slices are electrically stimulated with unipolar pulses (15–30 mA) of 2 ms duration at 5 Hz for 60 s. Two rounds of stimuli are applied, separated by 10 fractions. Test compound is applied at fraction 14 (28 min after the first stimulation).

The fractions collected are counted for tritium in 10 ml of Liqiscint scintillation fluid and corrected for quench. For measurement of remaining tritium, slices are dissolved overnight in 0.5 ml of Protosol, buffered with 1 ml of Tris HCl, and counted. Percent fractional release is defined as the ratio of tritium released versus the amount present in the tissue.

[^{3}H] Norepinephrine Release from Cortical Synaptosomes

Cortices from male Wistar rats are homogenized in 9 volumes of 0.32 M sucrose in a Potter-Elvejhem homogenizer and then centrifuged at 1000 *g* for 10 min at 4°C. The supernatant is recentrifuged at 17000*g* for 20 min, and the pellet is resuspended in 0.32 M sucrose at the original volume.

The freshly prepared synaptosomes are incubated with 50 nM [^{3}H]NE in Krebs buffer containing 10 mM pargyline for 10 min at 37°C. The ratio of buffer to tissue suspension is 80:20. The [^{3}H]NE-loaded synaptosomes are then separated by centrifugation (17000 *g* for 20 min), washed with buffer containing pargyline, recentrifuged, and then finally resuspended in 0.32 M sucrose at their original volume. The assay mixture consists of 900 ml Krebs buffer containing 10 mM pargyline, 100 ml of [^{3}H]NE-loaded synaptosomes, and 10 ml of vehicle or drug. This mixture is then vortexed and incubated for 5 min at either 37°C or 0°C (to define total versus non-specific release). After a 10 min centrifugation (3000 *g*), the pellets are solubilized in a Triton X-100/ethanol mixture and transferred to scintillation vials, and counted in 10 ml of Liquiscint.

The net disintegrations for the 37°C and 0°C incubations are calculated, and % increase values determined as [(control–drug)/control] × 100.

Several chemical methods to measure acetylcholine (Israël and Lesbats 1982; Damsa et al. 1985; Stadler and Nesselhut 1986), or catecholamines and serotonin (Wagner et al. 1979; Magnusson et al. 1980; Nielsen and Johnston 1982; Wagner et al. 1982) are available.

F.2.0.6 [^{3}H]Oxotremorine-M Binding to Muscarinic Cholinergic Receptors in Rat Forebrain

PURPOSE AND RATIONALE

The muscarinic receptors are members of the superfamily of G-protein-coupled receptors. They are relatively abundant and mediate the diverse action of acetylcholine in the CNS, as well as throughout nonnervous tissues innervated by the parasympathetic nervous system. Five separate genes (m1–m5) encode muscarinic receptor proteins exhibiting the rhodopsin-like structural motif containing seven transmembrane domains. They show strong sequence homology with each other and with related G-protein-coupled receptors within the transmembrane spanning domains, but each receptor has unique amino acid sequences located at the extracellular amino end and in the third intracellular loop (Caulfield 1993; Jones 1993; McKinney 1993; Wess 1996).

The purpose of this assay is to determine the binding affinity of potential cholinomimetic drugs for muscarinic receptors in brain, using an agonist ligand.

Oxotremorine is a potent centrally and peripherally acting muscarinic cholinergic agonist (Chao et al. 1962; Bebbington et al. 1966), which has been shown to be active in isolated tissue preparations as well as *in vivo* (Rindahl and Jenden 1983). Both central and peripheral effects of oxotremorine are blocked by anti-muscarinic drugs such as atropine (Chao et al. 1962; Bebbington et al. 1966). Structural modification of the oxotremorine molecular yields compounds which are full agonists, partial agonists and antagonists at muscarinic receptors (Rindahl and Jenden 1983). Oxotremorine-M (oxo-M), a quaternary nitrogen analog of oxotremorine, is a full agonist for the phosphatidyl-inositol response, while oxotremorine is a partial agonist (Fisher et al. 1984). Both oxotremorine and oxo-M are full agonists for inhibition of adenylate cyclase (Ehlert 1985; Olianas et al. 1983; Brown and Brown 1984). Of the muscarinic agonists, oxotremorine is the most potent inhibitor of [^{3}H]QNB binding, however, the IC_{50} is still only in the micromolar range. The apparent low affinity of agonist competition for [^{3}H]-antagonist binding sites is a common phenomena and is due to the existence of multiple agonist affinity states of the receptor, as described by Birdsall et al. (1978). For this reason, it is desirable to use an agonist ligand to measure the binding affinities of potential agonists.

Molecular methods have disclosed the existence of five muscarinic receptors which are coupled to different second messenger systems. At least four of them are expressed as functional receptor proteins in the neocortex and hippocampus formation (McKinney and Coyle 1991).

PROCEDURE

Reagents

1. 0.5 M Tris buffer, pH 7.4
   66.1 g of Tris HCl
   9.7 g of Tris base
   q.s. to 1 liter with deionized water
2. 0.05 M Tris buffer, pH 7.4
   (10-fold dilution of reagent 1)
3. [Methyl-^{3}H]-oxotremorine acetate (specific activity 83–85 Ci/mmol) is obtained from New England Nuclear.
   For IC_{50} determinations: [^{3}H]Oxotremorine-M is made up to a concentration of 100 nM. Fifty µl of this solution is added to each assay tube (yields a final concentration of 5 nM).
4. Atropine sulfate is obtained from Sigma Chemical Company. A 2 mM stock solution is made up in distilled water. Twenty µl is added to 3 tubes for determination of non-specific binding (yields a final concentration of 40 µM).
5. A 0.5% (w/v) solution of polyethylene-imine is prepared in distilled water. GF/C filters are soaked in this solution for at least three hours at room temperature. This is done to reduce the binding of the ligand to the filter strips.
6. Test compounds: For most assays, a 10 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 2×10^{-4} to 2×10^{-7} M.

Tissue Preparation

Male Wistar rats are decapitated and their brains rapidly removed. The forebrains (all tissue forward of a vertical cut in front of the hypothalamus) are weighed (400–500 mg each) and homogenized in 10 volumes of 0.05 M Tris buffer, pH 7.4 (reagent 2) using a Potter-Elvehjem glass homogenizer fitted with a Teflon pestle. The homogenate is centrifuged at 1000 *g* for 10 min. The supernatant is then centrifuged at 50,000 *g* for 60 min. The supernatant from this centrifugation is discarded and the pellet resuspended in the original volume of 0.05 M Tris buffer, pH 7.4, on the Polytron to 100 mg/ml (wet weight). Specific binding is roughly 1% of total added and 50% of total bound.

Binding Assay

50 µl	0.5 M Tris buffer, pH 7.4 (reagent 1)
380 µl	H_2O
20 µl	drug or 2 mM atropine
50 µl	^{3}H-oxotremorine-M (reagent 3)
500 µl	tissue

Tubes are vortexed and incubated at 30°C for 45 min (2). Bound [^{3}H]-oxotremorine-M is captured by filtration under reduced pressure. The incubation mixture is diluted with approximately 4 ml ice-cold 0.05 M Tris buffer, pH 7.4 (reagent 2), then exposed to vacuum, and tubes washed once more with approximately 5 ml of reagent 2. The filters (GFC in 0.5% polyethylene-imine for more than 3 h, reagent 5) are then counted in 10 ml Liquiscint scintillation fluid.

EVALUATION

Specific binding is the difference between total bound (in presence of vehicle) and that bound in the presence of 40 µM atropine. Percent inhibition of specific [^{3}H]-oxotremorine-M is calculated for each concentration of test drug and IC_{50} values determined by computer-derived log probit analysis. The percent inhibition at each drug concentration is the mean of duplicate or triplicate determinations. Some day-to day variability is present in this assay, and IC_{50} values should be confirmed by repeat analysis.

MODIFICATION OF THE METHOD

[^{3}H]Pirenzepine has been used to identify muscarinic receptor subtypes in the brain (Watson et al. 1983a, b).

F.2.0.7 [^{3}H]N-Methylscopolamine Binding in the Presence and Absence of Gpp(NH)p

PURPOSE AND RATIONALE

G-protein-linked muscarinic receptors are converted by guanine nucleotides from a high-affinity bind-

ing state to a low-affinity binding state for muscarinic agonists (Gilman 1986), while the binding of muscarinic antagonists to the receptor is not affected. The effects of guanine nucleotides on muscarinic agonist affinity are brain region- and temperature-dependent (Aronstram and Narayanan 1988). Therefore, incubation of cerebellar membranes with 50 µM 5′-guanylylimidophosphate (Gpp(NH)p), the non-hydrolyzable analog of GTP, causes a shift to the right (decreased affinity) of the muscarinic agonist inhibition curves when ^{3}H-NMS is used as the ligand.

The assay differentiates the interaction of muscarinic agonists and muscarinic antagonists with ^{3}H-N-me-thylscopolamine (^{3}H-NMS)-labeled receptors in cerebellar tissue based on the selective effect of guanine nucleotides on the affinity of muscarinic agonists for the receptor.

PROCEDURE

The procedure is based on ^{3}H-NMS rat brain binding assay described by Aronstram and Narayanan (1988).

Reagents

1. 0.5 M Tris-HCl buffer, pH 7.4
2. 0.05 M Tris-HCl buffer, pH 7.4
3. 0.05 M Tris-HCl buffer, pH 7.4 + 2 mM $MgCl_2$
4. 0.05 M Tris-HCl buffer, pH 7.4 + 2 mM $MgCl_2$ + 100 µM phenylmethylsulfonyl fluoride
5. Atropine sulfate is made up to 1 mM in distilled water and 20 µl is added to a 2 ml reaction mixture. This yields a final concentration of 10 µM. Atropine is used for nonspecific binding.
6. 5′-Guanylylimidodiphosphate (Gpp(NH)p) is made up to 2 mM in distilled water. The final concentration in the reaction mixture is 50 µM.
7. ^{3}H-N-Methylscopolamine (NMS) is obtained from Amersham and diluted to 4 nM in distilled water. The final concentration in the reaction mixture is 0.1 nM.
8. Test compounds
   For most assays, a 10 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-4} to 10^{-7} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used depending on the potency of the drug.

Tissue Preparation

Male Wistar rats are decapitated and their brains rapidly removed. The cerebella are dissected, weighed and homogenized in 10 volumes of 0.05 M Tris-HCl buffer, pH 7.4 + 2 mM $MgCl_2$+100 µM phenylmethylsulfonyl fluoride (buffer 4), using a Potter-Elvehjem glass homogenizer fitted with a Teflon pestle. The homogenate is centrifuged at 20,000 *g* for 20 min. The pellet is resuspended in 10 volumes of 0.05 M Tris-HCl buffer+2 mM $MgCl_2$ (buffer 3).

Binding Assay

1000 µl	0.05 M Tris buffer + 2 mM $MgCl_2$
780 µl	H_2O
20 µl	vehicle or 1 mM atropine or appropriate drug concentration
50 µl	H_2O or Gpp(NH)p
50 µl	[^{3}H]NMS
100 µl	tissue suspension

Tubes are incubated at 20°C for 90 min. Bound [^{3}H]NMS is captured by vacuum filtration. The filters are washed three times with 5 ml aliquots of 0.05 M Tris buffer, pH 7.4. Filters are counted in 10 ml Liquiscint scintillation fluid.

EVALUATION

Specific binding of [^{3}H]NMS is the difference between total bound (in the presence of vehicle) and that bound in the presence of 1 mM atropine. Percent inhibition of specific [^{3}H]NMS binding is calculated for each concentration of test drug and IC_{50} values are determined by computer-derived log-probit analysis. The percent inhibition at each drug concentration is the mean of triplicate determinations.

F.2.0.8 Stimulation of Phosphatidylinositol Turnover in Rat Brain Slices

PURPOSE AND RATIONALE

The purpose of this assay is to determine the ability of test compounds to stimulate the turnover of phosphatidylinositol (PI) in brain tissue. This assay can be used to determine agonist activity at a number of CNS receptors known to be linked to the PI response. A major interest is the evaluation of muscarinic cholinergic receptors.

Receptor-activated hydrolysis of inositol phospholipids is now recognized as an important second messenger system for muscarinic, alpha-adrenergic, histaminergic, serotonergic, excitatory amino acid and various neuropeptide receptors (Berridge and Irvine 1984; Nahorski et al. 1986; Fisher and Agranoff 1987). Furthermore, the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2) yields at least two important biologically-active intermediates (Hirasawa and Nishizuka 1985; Berridge 1987). These include 1,4,5-inositol trisphosphate (IP_3), which acts to mobilize Ca^{2+} from the endoplasmic reticulum and diacylglycerol, which activates protein kinase C (PKC). These responses are associated with many cellular responses such as stimulus-secretion coupling, stimulus-contraction coupling and cell proliferation. The exact mechanism for receptor-mediated turnover of cell membrane PI is not well understood, but it seems to involve coupling through a G-protein (Cockcroft and Gomperts 1985) and requires extracellular Ca^{2+} to activate phospholipase C (Fisher et al. 1989).

Although the muscarinic receptor-PI link has been known for some time (Hokin and Hokin 1955), recent advances in knowledge of receptor mechanisms and increased interest in the muscarinic receptor have stimulated considerable research in this area. Even though muscarinic agonists can be shown to be weak partial agonists or full agonists for this response (Fisher et al. 1983) and there are brain regional differences in sensitivity (Fisher and Bartus 1985); attempts to show receptor subtype selectivity for stimulation of PI turnover in either heart (Brown et al. 1985) or brain tissue (Fisher and Bartus 1985) have been disappointing. However, recent experiments using cells transfected with genomic clones for the various muscarinic receptors have had more success (Shapiro et al. 1988; Conklin et al. 1988). These studies show that the m_1, m_3 and the m_5 receptor subtypes are linked to PI turnover.

Stimulation of PI turnover by agents such as veratridine, batrachotoxin and ouabain (Gusovsky et al. 1986) show that there are also non-receptor mechanisms that can cause the stimulation of PI turnover.

PROCEDURE

Equipment and Materials

1. McIlwain tissue slicer
2. Disposable columns (Kontes, 200 mm)
3. Column rack (Kontes)
4. Disposable screw-cap tubes (Pyrex, 16 × 100 mm)
5. Disposable culture tubes (Fisher, 16 × 125 mm)

Reagents

1. Modified Krebs bicarbonate buffer

	g/l	mM
NaCl	8.30	142.0
KCl	0.42	5.6
$CaCl_2$	0.24	2.2
$NaHCO_3$	0.30	3.6
$MgCl_2 \cdot 6H_2O$	0.20	1.0
HEPES	7.15	30.0
Adjust pH to 7.4 with NaOH		
d-Glucose[a]	1.01	5.6

[a]Glucose added just before incubation.

2. Concentrated Krebs buffer+LiCl (9-fold concentrated ions, 10-fold concentrated Li^+), stock solution contains no glucose or Ca^{2+}.

	g/100 ml
NaCl	6.88 (amount adjusted to correct for Li^+)
KCl	0.38
$NaHCO_3$	0.27
$MgCl_2 \cdot 6H_2O$	0.18
HEPES	6.44
LiCl	0.42

$CaCl_2$ (11 mg) and d-glucose (45 mg) are added to 5 ml of concentrated buffer before incubation.

3. Dowex AG-1-X8 (100–200 mesh) formate form (Biorad)
4. [^{3}H]Inositol (spec. act. 15 Ci/mmol) is obtained from American Radiolabeled Chemicals, Inc.
5. Myo-inositol (M.Wt. 180.2) is obtained from Sigma Chemical Co. A 5 mM solution is made (0.9 g/l).
6. 1 M Ammonium formate/0.1 M formic acid. Ammonium formate is obtained from Sigma Chemical Co.: 3.85 ml 99% formic acid + 63.1 g ammonium formate to 1 liter in H_2O.
7. $CHCl_3$/methanol (1:2, v/v).

Tissue Preparation

Male Wistar rats, approximately 6/assay.

1. Remove surface blood vessels by rolling brain on filter paper.
2. Remove cerebral cortex and gently scrape myelin layer off.
3. Prepare 350 × 350 micron tissue slices with the McIlwain tissue chopper and place slices in buffer at 37°C.
   Incubate for 10 min.

4. Disperse slices by aspirating into 1-ml pipet (cut off tip).
5. Allow slices to settle, aspirate supernatant, add buffer and repeat until the supernatant is clear.

Assay: Prelabeled Method

1. Add to screw-cap tubes:

   50 µl tissue slices
   350 µl [^{3}H]inositol

2. Incubate for 90 min at 37°C under O_2
3. Add:

   50 µl drug
   H_2O to a final volume of 500 µl

4. Incubate for 30 min at 37°C under O_2.
5. Stop the reaction by the addition of 1.5 ml of $CHCl_3$: MeOH. Place in ice bath.

Assay: Continuous Labeling Method

1. Add to screw-cap tubes:

   50 µl tissue slices
   350 µl [^{3}H]inositol
   50 µl drug
   H_2O to a final volume of 500 µl

2. Incubate for 120 min. at 37°C under O_2.
3. Stop the reaction by the addition of 1.5 ml of $CHCl_3$: MeOH. Place in ice bath.

For antagonist inhibition studies, the antagonist is usually preincubated with the slices before the agonist is added.

Extraction of Total [^{3}H] Inositol Phosphates

1. Add 1 ml of $CHCl_3$ and 0.5 ml of H_2O to each tube. Cap and vortex.
2. Centrifuge at 3000 rpm for 10 min.
3. Aspirate the aqueous phase and place in culture tubes.
4. Add 1.7 ml of H_2O and heat in water bath at 55°C for 20 min.
5. Place samples in cold room overnight.
6. Add 0.5 ml of Dowex 50% slurry to each tube. Vortex 4 times.
7. Centrifuge at 3000 rpm for 10 min.
8. Aspirate.
9. Add 2.5 ml of 5 mM myo-inositol, let the resin settle and aspirate. Repeat 5 times.
10. Centrifuge at 3000 rpm for 10 min.
11. Add 1 ml of ammonium formate/formic acid, pH 4.8.
12. Put 0.7 ml of supernatant into scintillation vial, add 10 ml cocktail and count.

EVALUATION

The stimulation phosphatidylinositol turnover for each test compound is calculated as percent increase in total [^{3}H] inositol phosphates relative to the basal turnover rate of non-treated control brain slices. The EC_{50} values for agonists are determined by log-probit analysis of these data. IC_{50} values for antagonists are determined by log-probit analysis of the percent inhibition of stimulation by a full agonist.

F.2.0.9 [^{3}H]N-Methylcarbamylcholine Binding to Nicotinic Cholinergic Receptors in Rat Frontal Cortex

PURPOSE AND RATIONALE

Nicotinic acetylcholine receptors are a family of ligand-gated ion channels that are classified on the basis of their activation by nicotine, although acetylcholine is the endogenous ligand. These conductance channels for Ca^{2+}, K^+ and Na^+ are pentameric in structure. They are members of a supergene family that also includes glycine, $GABA_A$, and 5-HT3 receptors. α, β, γ, and δ subunits constitute a pentameric neuronal receptor resulting in various receptor subtypes (Alkondon and Albuquerque 1993; Sargent 1993). Ten α (α 1–α10) and four β (β 1–β 4) subunits have been cloned from mammalian and avian sources, each of which has a structural motif of four transmembrane spanning domains M1–M4 of which M2 lines the channel (Gotti et al. 1997; Jensen et al. 2005).

Nicotinic cholinergic receptors are classified as ligand-gated ion channels (Le Novere et al. 2002; Jensen et al. 2005), and are found in skeletal muscle, autonomic ganglia and brain tissue. Nicotine itself has a variety of behavioral effects. Due to its rapid desensitization of the receptor, both stimulatory and depressant effects may result. Also, many of nicotine's effects are thought to be associated with release of neurotransmitter substances (Balfour 1982). Nicotine functions as a nicotinic cholinergic receptor agonist in the CNS and is thought to play a role in learning and memory (Clarke 1987; Levey 1996; Dajas-Bailador and Wonnacott 2004). Reductions in nicotinic binding sites were found in post-mortem tissues from Alzheimer's patients by four separate groups of investigators (Whitehouse et al. 1988; Nordberg and Winblack 1986; Araujo et al. 1988; Shimohama et al. 1986). Neuronal nicotinic acetylcholine receptors play a role in acute and chronic neurodegeneration (O'Neill et al. 2002).

Unconventional ligands and modulation of nicotinic receptors are discussed by Pereira et al. (2002).

The structure and function of the acetylcholine-binding protein (ACHB), a homolog of the ligand-binding domain of the nicotinic acetylcholine receptor, are described by Smit et al. (2003).

Unwin (2003) explored structure and action of the nicotinic acetylcholine receptor by electron microscopy.

Cognitive improvement in Alzheimer patients 30 min after a nicotine infusion was reported (Sunderland et al. 1988). Therefore nicotinic agonists may prove beneficial (Hogg and Bertrand 2004), however, clinical data are still quite limited. N-Methylcarbamylcholine (NMCC) is a nicotinic agonist which binds specifically and with high affinity to central nicotinic receptors and, like nicotine, causes an increase of acetylcholine release from certain cholinergic nerve terminals (Araujo et al. 1988; Lapchak et al. 1989). In addition, chronic nicotine treatment increases [^{3}H] NMCC binding sites in several rat brain regions, as it does with [^{3}H]nicotine and [^{3}H]ACh labeled sites (Lapchak et al. 1989). This is due to the loss of presynaptic nicotinic autoreceptor function (Lapchak et al. 1989). Pharmacological results reveal that along with its specificity and high affinity, [^{3}H]NMCC is selectively displaced by agonists (Araujo et al. 1988; Lapchak et al. 1989), making it a desirable ligand to screen for potential agonistic compounds.

The purpose of the following assay is to determine the binding affinity of potential nicotinic cholinergic agonists in brain, using an agonist ligand.

PROCEDURE

Reagents

1. 0.5 M Tris buffer, pH 7.7
   a) 57.2 g Tris HCl
      16.2 g Tris Base
      q.s. to 1 liter with distilled water
   b) Make a 1:10 dilution in distilled H_20 (0.05 M Tris buffer, pH 7.7 at 25°C)
2. Tris buffer containing physiological ions
   a) Stock buffer
      NaCl 7.014 g

KCl 0.372 g
$CaCl_2$ 0.222 g
$MgCl_2$ 0.204 g q.s. to 100 ml with
0.5 M Tris buffer

b) Dilute 1:10 in distilled H_20
This yields 0.05 M Tris HCl, pH 7.7, containing NaCl (120 mM), KCl (5 mM), $CaCl_2$ (2 mM) and $MgCl_2$ (1 mM).

3. Methylcarbamoylcholine iodide, [N-Methyl-^{3}H]- is obtained from New England Nuclear
For IC_{50} determinations [^{3}H]-NMCC is made up to a concentration of 100 nM in distilled H_2O and 50 µl added to each tube (yields a final concentration of 5 nM in the 1 ml assay).
4. (–)Nicotine ditartrate is obtained from Research Biochemicals Incorporated.
A stock solution of (–)nicotine ditartrate is made up to a concentration of 0.5 mM in distilled H_2O. Twenty µl of stock is added to 3 tubes for the determination of nonspecific binding (yields a final concentration of 10 µM in the assay).
5. Test compounds. For most assays in 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 2×10^{-5} to 2×10^{-8} M. Seven concentrations are used for each assay and higher or lower concentrations may be used depending on the potency of the drug.
6. A 0.5% (w/v) solution of polyethyleneimine is prepared in distilled H_2O. GF/B filters are soaked in this solution for at least four hours at 4°C. This is done to reduce binding of the ligand to the filter strips.

Tissue Preparation

Male Wistar rats are decapitated, their frontal cortices removed, weighed and homogenized in 40 volumes of ice-cold 0.05 M Tris buffer, pH 7.7 (1 b). The homogenate is centrifuged at 48,000 *g* for 10 min. The pellet is rehomogenized in fresh buffer and recentrifuged at 48000*g* for 10 min two more times. The final pellet is resuspended in the original volume of buffer, but with physiological salts (2b). This yields a final tissue concentration of 20 mg/ml in the assay.

Assay

130 µl	0.05 M Tris pH 7.7-physiological salts (2 b).
20 µl	Vehicle (for total binding) or 0.5 mM (–)nicotine ditartrate (for nonspecific binding) or appropriate drug concentration.
50 µl	N-[^{3}H]Methylcarbamylcholine stock solution
800 µl	tissue.

The tubes are incubated at 0°C for 60 min. The assay is stopped by rapid filtration through Whatman GF/B filters which are then washed 4 times with 3 ml of ice-cold 0.05 M Tris buffer, pH 7.7. The filters are then counted in 10 ml of Liquiscint scintillation cocktail.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of the 10 µM (–)nicotine ditartrate. Specific binding is about 1% of the total added ligand and 60–70% of the total bound ligand. IC_{50} calculations are performed using log-probit analysis. The percent inhibition at each drug concentration is the mean of triplicate determinations.

MODIFICATION OF THE METHOD

Pabreza et al. (1991) recommended [^{3}H]cytisine as a useful ligand for studying neuronal nicotinic receptors because of its high affinity and low nonspecific binding.

Badio and Daly (1994) determined [^{3}H]nicotine receptor binding in rat cerebral cortex membrane preparations. The authors concluded that the analgesic activity of epibatidine, an alkaloid originally characterized from frog skin, is due to its activity as nicotinic agonist.

F.2.0.10 Uncompetitive NMDA Receptor Antagonism

PURPOSE AND RATIONALE

The uncompetitive NMDA antagonist memantine with moderate affinity to the (+)MK801-binding site has shown positive effects in the treatment of dementia (Möbius et al. 2004; Sonkusare et al. 2005). Several studies were performed to elucidate the mode of action (Frankiewicz and Parsons 1999; Parsons et al. 1999, 2004; Ikonomidou et al. 2000; Linden et al. 2001; Blanpied et al. 2005; Chen and Lipton 2005; Losi et al. 2006; Volbracht et al. 2006; Zoladz et al. 2006).

Sobolevsky and Koshelev (1998) and Sobolevsky et al. (1998, 1999) studied the blocking effects of memantine in open *N*-methyl-D-aspartate channels.

PROCEDURE

Pyramidal neurons were acutely isolated from the CA-1 region of rat hippocampus using "vibrodissociation techniques" (Vorobjev 1991). The experiments began after 3 h of incubation of the hippocampal slices in a solution containing (in mM): NaCl, 124; KCl, 3; $CaCl_2$, 1.4; $MgCl_2$, 2; glucose, 10; and $NaHCO_3$, 26. The solution was bubbled with carbogen at 32°C. During the whole period of isolation and current recording, nerve cells were washed with a Mg^{2+}-free solution containing 3 µM glycine (in mM: NaCl, 140; KCl, 5; $CaCl_2$, 2; glucose, 15; and HEPES, 10, pH 7.3). Fast replacement of superfusion solutions was achieved by using the concentration jump technique (Benveniste et al. 1990; Vorobjev 1991) with one application tube. This technique allows substitution of the tubular solution for the flowing solution with a time constant <30 ms but backward with the time constant of 30–100 ms (Sobolevsky 1999). Therefore, except where noted, the rate of the solution exchange was fast at the beginning of any application and slightly slower at its termination. The currents were recorded at 18°C in the whole-cell configuration using micropipettes made from Pyrex tubes and filled with an "intracellular" solution (in mM: CsF, 140; NaCl, 4; and HEPES, 10; pH 7.2). Electrical resistance of the filled micropipettes was 3–7 MΩ Analog current signals were digitized at 1 kHz frequency.

EVALUATION

Statistical analysis was performed using the scientific and technical graphics computer program Microcal Origin (version 4.1 for Windows). The data presented are mean ± SE; comparison of the means was done by ANOVA, with $p < 0.05$ taken as significant.

MODIFICATIONS OF THE METHOD

Maskell et al. (2003) reported inhibition of human $\alpha 7$ nicotine acetylcholine receptors by open channel blockers of *N*-methy-D-aspartate receptors. Human $\alpha 7$ nicotine acetylcholine receptors were expressed in *Xenopus* oocytes and the effects of the NMDA receptor open channel blockers memantine and cerestat on this receptor were examined using two-electrode voltage-clamp recordings and the ^{125}I-labeled α-bungarotoxin binding.

Aracava et al. (2005) found that memantine blocks $\alpha 7$* nicotinic acetylcholine receptors more potently than *N*-methyl-D-aspartate receptors in rat hippocampal neurons. Primary hippocampal cultures were from 16- to 29-day-old fetal rats. Electrophysiological recordings were obtained from cultured neurons by means of the whole-cell mode of the patch-clamp technique. Atropine (1 µM) and tetrodotoxin (0.1–0.3 µM) were added to the external solution to block muscarinic receptors and voltage-gated Na^+ channels, respectively. The agonist solutions, with or without memantine, were applied to the neurons through a glass U-tube. Memantine was added at various concentrations to the bathing solution.

F.2.0.11 Secretion of Nerve Growth Factor by Cultured Neurons/Astroglial Cells

PURPOSE AND RATIONALE

Cultured brain cells can be used for many purposes such as investigation of synthesis and secretion of nerve growth factor or for testing neuroprotective drugs (Peruche and Krieglstein 1991). Nerve growth factor is required for the development and maintenance

of peripheral and sensory neurons (Thoenen and Barde 1980). Nerve growth factor (NGF) prevents neuronal death after brain injury (Hefti 1986; Williams et al. 1986; Kromer 1987), especially in basal forebrain nuclei involved in memory processes. Drug induced increase in nerve growth factor secretion may be beneficial in primary degenerative dementia.

NGF belongs to the family of neurotrophins which includes besides of the nerve growth factor, the neurotrophin 3 (NT3), neurotrophin 4/5 (NT 4/5) and brain-derived neurotrophic factor (BDNF). Two types of neurotrophin transmembrane receptors are known: (1) a receptor termed p75, which is common to all neurotrophins and (2) a family of neurotrophin receptor tyrosine kinases trkA, trkB and trkC (Saragovi and Gehring 2000). TrkA is the receptor tyrosine kinase for NGF (Huang and Reichardt 2003).

NGF has a crucial role in the generation of pain and hyperalgesia in several acute and chronic pain states (Hefti et al. 2006).

PROCEDURE

Whole brains of 8-day-old mice (ICR) are dissected out and cut into small pieces. The pieces are washed with calcium- and magnesium-free phosphate-buffered saline, treated with 0.25% trypsin at 37°C for 30 min, and triturated with a Pasteur pipette. The excess trypsin is removed by centrifugation at 200 *g* for 5 min. The cells or cell clumps from one brain are cultured in a culture bottle with Dulbecco's modified Eagle's minimum essential medium (DMEM) containing 10% fetal calf serum (FCS), 50 milliunits/ml penicillin, and 50 mg/ml of streptomycin at 37°C in a humid atmosphere of 5% CO_2 for 1–2 weeks with medium changes every 3 days. After confluence is reached, the cells in each bottle are dissociated by trypsin treatment and recultured in new bottles. This procedure is repeated 3 times. The culture becomes composed of morphologically uniform cells.

Preparation of quiescent cells is performed by inoculating into 96-well plates and culture in FCS-containing DMEM until confluence is reached. Then, the cells are cultured for an additional week in FCS-free DMEM containing 0.5% BSA, with medium changes every 3 days. Because the cells never proliferate in FCS-free medium, most of the cells are arrested in the quiescent phase. Then, the medium is changed to DMEM containing 0.5% BSA with or without drugs, and the cells are cultured for 24 h.

Nerve growth factor (NGF) content in the culture medium is determined by a two-site enzyme immunoassay (Furukawa et al. 1983; Lärkfors and Ebendal 1987). Mouse βNGF isolated from male mouse submaxillary glands is purified by CM-Sephadex C-50 chromatography. Antiserum to this mouse βNGF is produced in New Zealand White rabbits by repeated subcutaneous injections of an emulsion in complete Freund's adjuvant over 18 months. Immunoglobin G is prepared from Anti-mouse βNGF antiserum by Sepharose chromatography. Antibody IgG is incubated with pepsin and chromatographed. Fab' fragments are coupled to β-D-galactosidase. IgG-coated solid phase is prepared in polystyrene tubes. The IgG-coated polystyrene tubes are incubated with 0.25 ml buffer containing various amounts of NGF with gentle shaking. After incubation for 18–24 h at 4°C, each tube is washed twice with 1 ml of buffer and 0.13 milliunits of the Fab'-β-D-galactosidase complex in 0.25 ml buffer is added. After incubation for 18–24 h at 4°C with gentle shaking each tube is washed as described above and β-D-galactosidase activity bound to the tube is assayed. The enzyme reaction is started by addition of 60 mM 4-methylumbelliferyl-β-D-galactoside and 0.1% Triton X-100 in 0.25 ml buffer. After 1-h incubation at room temperature, the enzyme reaction is stopped by the addition of 1.25 ml 0.1 M glycine-NaOH buffer (pH 10.3). The amounts of 4-methylumbelliferone formed are measured by fluorometry (Excitation wavelength 360 nm, emission wavelength 450 nm).

EVALUATION

Time-response curves of release of NGF into the medium are established after addition of drug and compared with controls. Dose-response curves can be prepared after addition of various amounts of test drug.

MODIFICATIONS OF THE METHOD

Cultured neurons from chick embryo hemispheres were used for testing cerebroprotective drug effects *in vitro* and for testing antihypoxic drug effects by Krieglstein et al. (1988), Peruche et al. (1990), Oberpichler-Schwenk and Krieglstein (1994).

Semkowa et al. (1996) found that clenbuterol protects mouse cerebral cortex and rat hippocampus from ischemic damage and attenuates glutamate neurotoxicity in cultured hippocampal neurons by induction of nerve growth factor.

Prehn et al. (1993, 1995) tested the prevention of glutamate neurotoxicity in neocortical cultures from rats. Mixed neuronal/glial primary cultures were derived from the cerebral cortices of neonatal Fischer 344 rats. Excitotoxic injury was induced after 14 days

by L-glutamate following a procedure described by Choi et al. (1988), Koh and Choi (1988).

Kinoshita et al. (1991) used primary cultured neurons from 17-day-old rat fetuses.

Qi et al. (1997), Horton et al. (2001) described a novel catecholaminergic CAD CNS neuronal cell line in which neurotrophin-3 mediates the autocrine survival.

Shinpo et al. (1999) used cultured mesencephalic neurons from embryonic Sprague Dawley rats to study the protective effects of the TNF-ceramide pathway against glutamate neurotoxicity.

Matsumoto et al. (1990) described a method for quantifying the effects of neurotrophic factors on the number of surviving neurons and the total length of neurites in primary cultures from cerebral cortex and hippocampus of the brains from two-week old rats by using digital image processing techniques. Binary images of neuronal neurites were extracted from gray images of cultured neurons stained with Coomassie brilliant blue.

White et al. (1995) measured calcium transients in mouse cerebellar granule cells with the Ca^{2+}-sensitive probe indo-1/AM.

Beresini et al. (1997) developed two types of high throughput assays to identify small molecules that interact with neurotrophin receptors. The first, the receptor binding assay, is a competitive binding assay that uses a recombinant receptor fusion protein and biotinylated neurotrophin. This assay detects compounds that inhibit neurotrophin binding to the receptor; these compounds may be either agonistic or antagonistic. The second assay, the kinase receptor activation ELISA, detects receptor autophosphorylation in response to sample- or neurotrophin-stimulation of receptor transfected cells. Receptor autophosphorylation is evaluated by analyzing lysates of the stimulated cells in a receptor-specific ELISA for phosphotyrosine residues. This assay is bioactivity based, and consequently, has the power of detecting as well as distinguishing receptor agonists and antagonists.

Höglinger et al. (1998) used free-floating roller tube cultures prepared from embryonic-day-14 rat ventral mesencephalon to study the influence of brain-derived neurotrophic factor treatment on dopamine neuron survival and function.

Nerve growth factor is crucial for survival of nociceptive neurons during development. Shu and Mendell (1999) investigated the acute effects of NGF on capsaicin responses of small-diameter dorsal root ganglion cells in culture.

For further studies with brain cell cultures see E.3.1.16.

F.2.0.12 Inhibition of Respiratory Burst in Microglial Cells/Macrophages

PURPOSE AND RATIONALE

Activated phagocytes can produce large amounts of oxygen intermediates that result from a process during which NADPH oxidase reduces O_2 to the superoxide anion (O_2^-), which subsequently dismutates together with H^+ to H_2O_2 and O_2. H_2O_2 is then reduced to hypochlorous acid by myeloperoxidase (Bellavite 1988). The cascade of metabolic steps is known as respiratory bursts. The intracellular formation of reactive oxygen intermediates can be determined by measuring the oxidation of the membrane permeable and non-fluorescent dihydrorhodamine 123 to the cationic and intracellularly trapped, green fluorescent rhodamine 123 in single viable cells. Microglial/brain macrophage-mediated damage in the central nervous system is accompanied by an increased production of free radicals, which also seems important in primary degenerative dementia (Alzheimer's disease) (Banati et al. (1993). Inhibition of this process by drugs may indicate therapeutic value in Alzheimer's disease.

PROCEDURE

Cell Culture

Cultures of new-born rat brain are prepared as described by Guilian and Baker (1986); Frei et al. (1987). Isolated cerebral cortices from new-born albino rats are stripped of the meninges, minced in culture medium and dissociated by trituration for 2 h in 0.25% trypsin solution. Cells are plated in 75 cm^2 plastic culture flasks containing 10 ml medium with 10% fetal bovine serum at a density of 85,000 cells/ml. After 7 days, confluent cultures are vigorously agitated on a rotary shaker at 37°C for 15 h. Glial fibrillary acid protein positive astroglia remain adherent to the flasks. The resulting cell suspension, rich in amoeboid microglia and oligodendroglia, is placed in plastic flasks and allowed to adhere at 37°C. After a 1–3 h adhering interval, loosely adhering and suspended cells (most of which are oligodendroglia) are removed by gently shaking the flasks at room temperature. The strongly adherent microglia cells are then released by vigorous shaking in medium with 0.2% trypsin. Once the majority of microglia is suspended, fetal bovine serum is added (15% final volume), and the cell suspension added to new flasks. After a second 1–3 h interval to allow adhesion, the medium is removed, and adhering microglia are suspended using trypsin. Final prepara-

tion show a nearly homogeneous population of nonspecific esterase positive cells.

Peritoneal macrophages are obtained from 12-week-old male Wistar rats.

For flow cytometric measurement, cells are suspended ($3–4 \times 10^6$ cells/ml) in Hank's buffered saline (HBS; Sigma Chemie, Deisenhofen, Germany) supplemented with N-2-hydroxyethylpiperazine-N′-2-ethane-sulfonic acid (HEPES; 5 mM, pH 7.35; Serva Feinbiochemica, Heidelberg, Germany) (HBS-HEPES) and stored at 4°C for a maximum of 2 h.

Flow Cytometric Measurement of Respiratory Burst

Dihydrorhodamine 123 (DHR) is obtained from Molecular Probes (Eugene, OR, USA) and dissolved to obtain a 1 mM stock solution in N,N-dimethylformamide (DMF; Merck, Darmstadt, Germany).

The cellular suspensions of peritoneal macrophages and microglial cells (10 µl) are each further diluted with 1 ml HBS-HEPES and stained for 5 min at 37°C with 10 µl of a 100 µM DHR solution in HBS (1 mM stock solution in DMF). The DHR-loaded cells are incubated with the test drug at various concentrations for 15, 25, 35, 45, and 60 min with and without Con A (100 µg/ml; Sigma Chemie) stimulation. The DNA of dead cells is counter stained with 10 µl of 3 mM propidium iodide (Serva Feinbiochemica) solution in HBS 3 min before the flow cytometric measurement. To exclude effects from a possible release of endogenous adenosine, control experiments with incubation medium containing adenosine deaminase (200 U/mg, 5 µg/ml Sigma Chemie) are performed.

The forward scatter, side scatter and two fluorescences of at least 10,000 cells/sample are measured simultaneously on a FACScan flow cytometer (Becton Dickinson, San Jose, CA, USA). Rhodamine 123 green fluorescence (515–545 nm) and propidium iodide red fluorescence (> 650 nm) are measured with the light from an argon laser of 488-nm excitation wavelength.

EVALUATION

The differences in respiratory burst activities caused by Con A stimulation and treatment with test drug are tested for significance by unpaired *t*-test. The *t*-test is performed for each time point including the data of at least four independent experiments. Each single fluorescence value of each experiment is based on the measurement of at least 10,000 cells. Before each experiment the flow cytometer is calibrated with standardized yellow-green fluorescent microspheres of 4.3-µm diameter (Polysciences, St. Goar, Germany), thus ensuring the compatibility of the fluorescence values from different experimental series.

F.3 In Vivo Methods

F.3.1 Inhibitory (Passive) Avoidance

One of the most common animal tests in memory research is the inhibition to imitate activities or learned habits. The term "passive avoidance" is usually employed to describe experiments in which the animal learns to avoid a noxious event by suppressing a particular behavior. Netto and Izquierdo (1985) have discussed this term in a brief paper. The term "inhibitory avoidance" is used more often in later publications.

REFERENCES AND FURTHER READING

Netto CA, Izquierdo I (1985) On how passive is inhibitory avoidance. Behav Neural Biol 43:327–330

F.3.1.1 Step-down

PURPOSE AND RATIONALE

An animal (mouse or rat) in an open field spends most of the time close to the walls and in the corners. When placed on an elevated platform in the center of a rectangular compartment, it steps down almost immediately to the floor to explore the enclosure and to approach the wall. The technique is employed in different mod-

ifications, which are described by Jarvik and Essmann (1960), Hudspeht et al. (1964), Chorover and Schiller (1965), Kubanis and Zornetzer (1981), Zornetzer et al. (1982), Abdel-Hafez et al. 1998).

PROCEDURE

Mice or rats of either sex are used. A rectangular box (50 × 50 cm) with electrifiable grid floor and 35 cm fits over the block. The grid floor is connected to a shock device, which delivers scrambled foot shocks. The actual experiments can be performed in different ways. A typical paradigm consists of three phases: (1) Familiarization: The animal is placed on the platform, released after raising the cylinder, and the latency to descend is measured. After 10 s of exploration, it is returned to the home cage. (2) Learning: Immediately after the animal has descended from the platform an unavoidable footshock is applied (Footshock: 50 Hz; 1.5 mA; 1 s) and the animal is returned to the home cage, (3) Retention Test: 24 h after the learning trial the animal is again placed on the platform and the step-down latency is measured. The test is finished when the animal steps down or remains on the platform (cut-off time: 60 s).

EVALUATION

The time of descent during the learning phase and the time during the retention test is measured. A prolongation of the step-down latency is defined as learning.

MODIFICATIONS OF THE TEST

This test procedure is employed in different modifications. One of the most common modifications is to induce amnesia in animals. There are different methods to do so including (i) electroconvulsive shock, (ii) scopolamine, (iii) alcohol, (iv) CO_2.

Ricceri et al. (1996) studied the effect of nerve growth factor on passive avoidance learning and retention in developing mice. At the beginning of each trial 11- or 15-day-old pups were placed on the central platform. Immediately thereafter, the platform began vibrating and a timer was simultaneously activated. A trial was ended when the pup gave a step-down response, or after 120 s without descent from the platform. Each step-down response was followed by a 3-s 0.3-mA foot shock.

CRITICAL ASSESSMENT OF THE METHOD

The variability of this method is relative high; therefore, it is necessary to test large groups of animals (minimum 10 animals per group). There are some critical parts in the experimental procedure: (i) Placing the animal on the platform, since the tendency of the animal to escape the contact with the human hand may shorten the step-down latencies. (ii) Another important point is the timing of the electric shock. It must not be applied at the first contact of the animal with the floor, since the light touch with the forelimbs does not cause the required shock intensity. The duration and intensity of the shock should be constant. (iii) It is also necessary to keep the room sound-proof, and this can be done by using a white noise generator (60–70 dB). Due to all these critical variables the results of different authors are difficult to compare.

F.3.1.2 Step-through

PURPOSE AND RATIONALE

This test uses normal behavior of mice and rats. These animals avoid bright light and prefer dim illumination. When placed into a brightly illuminated space connected to a dark enclosure, they rapidly enter the dark compartment and remain there. The standard technique was developed for mice by Jarvik and Kopp (1967) and modified for rats by King and Glasser (1970). It is widely used in testing the effects of mem-

ory active compounds (Fekete and de Wied 1982; Hock and McGaugh 1985; Hock et al. 1989; Hock 1994).

PROCEDURE

Mice and rats of either sex are used. The test apparatus consists of a small chamber connected to a larger dark chamber via a guillotine door. The small chamber is illuminated with a 7 W/12 V bulb. The test animals are given an acquisition trial followed by a retention trial 24 h later. In the acquisition trial the animal is placed in the illuminated compartment at a maximal distance from the guillotine door, and the latency to enter the dark compartment is measured. Animals that do not step through the door within a cut-off time: 90 s (mice) or 180 s (rats) are not used. Immediately after the animal enters the dark compartment, the door is shut automatically and an unavoidable footshock (Footshock: 1 mA; 1 s – mice; 1.5 mA; 2 s – rat) is delivered. The animal is then quickly removed (within 10 s) from the apparatus and put back into its home cage. The test procedure is repeated with or without drug. The cut-off time on day 2 is 300 s (mice) or 600 s (rats), respectively.

EVALUATION

The time to step-through during the learning phase is measured and the time during the retention test is measured. In this test a prolongation of the step-through latencies is specific to the experimental situation. An increase of the step-through latency is defined as learning.

CRITICAL ASSESSMENT OF THE METHOD

Same as in step-down method

MODIFICATIONS OF THE TEST

This test procedure is employed in different modifications. To test drugs usually several test-groups can be tested. (i) CXC-group: vehicle – without amnesia – vehicle; (ii) DXD-group: drug – without amnesia – drug; (iii) CAC-group: vehicle – amnesia – vehicle; (iv) DAD-group: drug – amnesia – drug; (v) CAD-group: vehicle – amnesia – drug; (vi) DAC-group: drug – amnesia – vehicle. (The first figure means treatment on day 1; the third figure means treatment on day 2). There are different methods to induce amnesia: (i) electroconvulsive shock, (ii) scopolamine, (iii) alcohol, (iv) CO_2 etc.

Step-through experiments were performed after unilateral ibotenic acid lesions in the right nucleus basalis magnacellularis as a rat model of Alzheimer disease by Fine et al. (1985).

Wan et al. (1990) recorded changes in heart rate and body temperature via a telemetry system during step through passive avoidance behavior in rats.

Picciotto et al. (1995) used gene targeting to mutate $\beta 2$, the most widely expressed neuronal nicotinic acetylcholine receptor in the central nervous system for pharmacological and behavioral studies. Retention of the inhibitory avoidance response was better in mutant mice than in their non-mutant siblings.

Galeotti et al. (1997) modified the step-through method. After entry to the dark compartment, mice received a non-painful punishment consisting of a fall into a cold water bath (10°C). For this purpose the dark chamber was constructed with a pitfall floor. The memory degree of received punishment (fall into cold water) was expressed as the increase (in seconds) in the retention latency in comparison with the training latency.

Itokazu et al. (2001) showed that L-DOPA caused memory deficits in mice in a step-through passive avoidance test and recommended this as a model for human dementia.

F.3.1.3 Two Compartment Test

PURPOSE AND RATIONALE

A rodent in an open field tends to enter any recesses in the walls and to hide there. When placed into a large box, connected through a narrow opening with a small dark compartment, the animal rapidly finds the entrance into the small chamber, enters it and spends most of its time there. The times spent in the large and small compartments are measured. The latency of the first entrance into the dark chamber and the number of crossings from one compartment into the other can be used as auxiliary criteria. The technique described was developed by Kurtz and Pearl (1960) and modified by Bures and Buresova (1963).

PROCEDURE

Mice and rats of either sex and a rectangular box with a 50 × 50 cm grid floor and 35 cm high walls are used. In the centre of one wall is a 6 × 6 cm opening connecting the large compartment to a small 15 × 15 cm box with dark walls, electrifiable grid floor and removable ceiling. The connection between the two compartments can be closed with a transparent sliding door. Illumination is provided with a 100 W bulb placed 150 cm above the centre of the large compartment.

EVALUATION

The times the animal spends in the large and the small compartment are measured.

CRITICAL ASSESSMENT OF THE METHOD

Same as in step-down method.

F.3.1.4 Up-Hill Avoidance

PURPOSE AND RATIONALE

Many animal species exhibit a negative geotaxis, i. e. the tendency to orient and move towards the top when placed on a slanted surface. When placed on a tilted platform with head facing down-hill, rats and mice invariably turn around and move rapidly up the incline (Staubli and Huston 1978).

PROCEDURE

Rats of both sex were used and maintained under standard conditions. The experimental apparatus is a 50 × 50 cm box with 35 cm high opaque plastic walls. The box can be inclined at different angles. The floor consists of 10 mm diameter stainless steel grid bars placed 13 mm apart. To deliver the tail-shock, a tail-electrode is constructed, consisting of a wire clip connected to a constant current shock source. The animal is first fitted with the tail-electrode and then placed onto the grid with its nose facing down. During baseline-trials the animal's latency to make a 180° turn and initiate the first climbing response is measured. Thereafter the animal is returned to its home cage. During the experimental trials the latencies are measured and additionally a tail-shock (1.5 or 2 mA) was administered contingent on the first climbing response after the 180° turn. Immediately after the shock the animal is placed in its home cage. Retest is performed 24 h later.

EVALUATION

The latencies are measured.

CRITICAL ASSESSMENT OF THE METHOD

The up-hill avoidance technique promises to provide a useful addition to the existing arsenal of inhibitory (passive) avoidance methods. Its most obvious advantage is that it can be administered to animals debilitated in sensory-motor coordination by pharmacological or surgical treatments that would preclude use of other inhibitory (passive) avoidance tasks.

Staubli U, Huston JP (1978) Up-hill avoidance: A new passive avoidance task. Physiol Behav 21:775–776

F.3.1.5 Trial-to-criteria inhibitory avoidance

PURPOSE AND RATIONALE

As animals experience different sensitivity to the footshock punishment applied in the dark area, immediately after the first trial the animal is returned to the lighted area to evaluate if the task has been acquired. A criteria is established to determine the learning of the test, usually requiring the animal to remain in the lighted area for a period of 30–60 s. (Decker et al. 1990). In this way, all the animals have a similar degree of learning independently of the amount of trials needed to attain it.

PROCEDURE

Mice or rats are generally used. The animals are trained in the same way as in the step-through version. They are placed in the lighted compartment and after they entered with the four paws into the dark area, the door is closed and a mild footshock is delivered. Immediately after the shock they are placed back in the lighted area for another trial. Training would continue this way until the animal remains in the lighted area for a certain period of time (30 or 60 s), a time at which the training is considered to be acquired by all the animals. The number of trials to attain criteria are counted as an indication of the speed of acquisition.

EVALUATION

Retention of the test is measured 24 or 48 Hs later. The animals are placed in the lighted area, the door opened and the latency to step with the four paws into the dark area is recorded. A cut-off latency of 180 or 300 s is usually imposed.

CRITICAL ASSESSMENT OF THE TEST

This modification of the classical inhibitory avoidance procedure is useful to determine the effect of drugs on acquisition as amnesic drugs significantly increase the number of trials to reach the criterion. Saline-treated animals generally need 1–2 trials to reach criterion while animals under diazepam or scopolamine need 3–6 trials. Once the animals have been trained to a predetermined criteria (i. e., 30 s. avoidance) any effect of the drug on the retention trial can be associated to drug effects on consolidation rather on the acquisition process (Brioni 1993; Decker et al. 1990). Alternatively, drugs could be administered before the test session in order to determine the effect of the drug on retrieval processes. Brain lesions differentially affect acquisition or retention (Hepler et al. 1985; Tomaz et al. 1992), and this task has also been used to demonstrate the effect of grafts on recovery of function (Fine et al. 1985).

MODIFICATIONS OF THE TEST

This test can also be performed as a continuous trial-to-criterion. In this procedure the door is not closed after the animal enters the dark area and upon delivery of the shock the animal can escape to the lighted area. The experimenter does not have to touch the animal to placed it in the lighted area for the next trial.

Kameyama et al. (1986) described a similar model for the study of learning and memory in mice using a step-down-type passive avoidance- and escape-learning method.

F.3.1.6 Scopolamine-Induced Amnesia in Mice

PURPOSE AND RATIONALE

The administration of the antimuscarinic agent scopolamine to young human volunteers produces transient memory deficits (Drachman and Leavitt 1974). Analogously, scopolamine has been shown to impair memory retention when given to mice shortly before training in a dark avoidance task (Dilts and Berry 1967; Glick and Zimmerberg 1972; Schindler et al. 1984). The ability of a range of different cholinergic agonist drugs to reverse the amnesic effects of scopolamine is now well documented in animals and human volun-

teers. However, the neuropathology of dementia of the Alzheimer type is not confined to the cholinergic system (Iversen 1998).

PROCEDURE

The scopolamine test is performed in groups of 10 male NMRI mice weighing 26–32 g in a one-trial, passive avoidance paradigm. Five min after i.p. administration of 3 mg/kg scopolamine hydrobromide, each mouse is individually placed in the bright part of a two-chambered apparatus for training. After a brief orientation period, the mouse enters the second, darker chamber. Once inside the second chamber, the door is closed which prevents the mouse from escaping, and a 1 mA, 1-s foot shock is applied through the grid floor. The mouse is then returned to the home cage. Twenty-four hours later, testing is performed by placing the animal again in the bright chamber. The latency in entering the second darker chamber within a 5 min test session is measured electronically. Whereas untreated control animals enter the darker chamber in the second trial with a latency of about 250 s, treatment with scopolamine reduces the latency to 50 s. The test compounds are administered 90 min before training. A prolonged latency indicates that the animal remembers that it has been punished and, therefore, does avoid the darker chamber.

EVALUATION

Using various doses latencies after treatment with test compounds are expressed as percentage of latencies in mice treated with scopolamine only. In some cases, straight dose-response curves can be established whereas with other drugs inverse U-shaped dose-responses are observed (Schindler et al. 1984).

CRITICAL ASSESSMENT OF THE METHOD

In spite of the fact that the pathogenesis of primary degenerative dementia (Alzheimer's disease) in man has been only partially elucidated, the scopolamine-amnesia test is widely used as primary screening test for so-called anti-Alzheimer drugs.

MODIFICATIONS OF THE METHOD

Lenègre et al. (1988) investigated the effects of piracetam on amnesias induced by scopolamine, diazepam and electroconvulsive shock.

Yamaoto et al. (1990) studied the effect of drugs on the impairment of working memory produced by scopolamine, ethylcholine aziridinium (AF64A) or cerebral ischemia using a repeated acquisition procedure in a three-panel runway apparatus.

Hiramatsu and Inoue (2000) demonstrated improvement by low doses of nociceptin on scopolamine-induced impairment of learning and/or memory in mice.

Martin et al. (1995) studied reversal of scopolamine-induced memory impairment by aniracetam in **rats** in an experiment conducted over a 1-year period.

Braida et al. (1998) investigated the short (120 min) and long-lasting (360 min) antagonism of scopolamine-induced amnesia in rats in an eight-arm radial maze by a cholinesterase inhibitor.

Giovannini et al. (1999) investigated the effects of histamine H_3 receptor agonists and antagonists on cognitive performance and scopolamine-induced amnesia.

Several **other drugs** have been shown to induce memory impairment.

Amnesia can also be induced by pretreatment with **benzodiazepines** (Porsolt et al. 1988).

Nabeshima et al. (1986) studied the antagonism against **phencyclidine**-induced retrograde amnesia in mice.

Maurice and Privat (1997) examined learning impairment induced by the non-competitive NMDA receptor agonist **dizocilpine** in mice.

Pitts et al. (2006) showed that **chlordiazepoxide** and **dizocilpine**, but not morphine, selectively impair acquisition under a novel repeated-acquisition and performance task in rats.

Ellison (1995) reported that the ***N*-methyl-D-aspartate antagonists** phencyclidine, ketamine, and dizocilpine provide behavioral and anatomical models of dementia.

Tanaka et al. (1998) studied learning and memory deficits induced by **β-amyloid** protein in rats.

Anandatheerthavarada et al. (2003) reported that mitochondrial targeting and a transmembrane arrest of Alzheimer's **amyloid precursor protein** impairs mitochondrial function in neuronal cells.

Ukai et al. (2001) showed that **endorphins** 1 and 2, endogenous μ-opioid receptor agonists, impair passive avoidance learning in rats.

Patil et al. (2002) used **lipopolysaccharide**-intoxicated mice as a model for Alzheimer's disease.

Yang et al. (2004) induced learning and memory impairment in mice by treatment with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (**MPTP**).

Sparks and Schreurs (2003) reported that trace amounts of **copper** in water induce β-amyloid plaques and learning deficits in a **rabbit model** of Alzheimer's disease using the nictitating membrane response (Buck et al. 2001).

F.3.1.7 Cognitive Deficits on Chronic Low Dose MPTP-Treated Monkeys

PURPOSE AND RATIONALE

Röltgen and Schneider (1994), Schneider et al. (1990, 1993, 1994a, b) described the effect of chronic low-dose 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) exposure on cognitive functions in monkeys. These animals develop cognitive deficits and difficulties in performing previously learned tasks, such as delayed response, delayed matching-to-sample, delayed alternation, visual discrimination reversal, and object retrieval, as well as dopamine depletions in several brain areas without severe Parkinsonian signs as found after high MPZP doses (Burns et al. 1983), see E.7.1.2. In addition, these animals exhibit other behavioral changes such as decreased task persistence, increased restlessness and decreased attention.

PROCEDURE

Adult Macaca monkeys are trained to perform a delayed response task while seated in a restraining chair placed inside a sound attenuating modified Wisconsin General Test apparatus. The monkey sits behind an opaque screen that when raised allows access to a sliding tray that contains recessed food wells with identical sliding white Plexiglas covers that serve as stimulus plaques that can be displaced by the animal to obtain rewards (raisins). Monkeys are trained to retrieve a raisin from one of the food wells after observing the experimenter baits the well. Right and left wells are baited in a randomized, balanced order. Animals are maintained on a restricted diet during the week and tested while food deprived. Training is accomplished with a non-correction procedure with 0 s delay and progressing to 5 s delay. Animals are trained until performance with a 5 s delay is 90% correct or

better for at least 5 consecutive days. Each daily session consists of 25 trials. A response is scored a 'mistake' if the monkey makes its response choice to a well that is not baited with reward. A 'no response' error is scored if the monkey fails to respond to a trail within 30 s.

Once the animals are performing at criterion level, MPTP is administered intravenously in doses ranging from 0.05 mg/kg at the start of the study to 0.20 mg/kg. Animals receive cumulative doses up to 60 mg over periods up to one year.

Pharmacological data are obtained after animals consistently show at least a 15% performance deficit on delayed response. Drugs are administered subcutaneously. Delayed response testing begins 8 min after dug administration. On drug testing days, animals receive drug or saline and are tested for delayed response performance, administered drug (or saline), and retested on the delayed response task.

EVALUATION

Delayed response performance after drug administration is compared with matched control performance obtained on the same day prior to drug administration. The total number of correct responses as well as the number of mistakes and 'no response' errors are tabulated for each session. Date are then expressed as mean (± standard deviation) performance. All animals serve as their own controls. Statistical analysis consists of analysis of variance, repeated measures design, with post hoc comparisons (Bonferroni *t*-test).

F.3.2 Active Avoidance

Active avoidance learning is a fundamental behavioral phenomenon (Herrnstein 1969; Brush 1971; Campbell and Church 1969; D'Amato 1970). As in other instrumental conditioning paradigms the animal learns to control the administration of the unconditioned stimulus by appropriate reactions to the conditioned stimulus preceding the noxious stimulus. The first stage of avoidance learning is usually escape, whereby a reaction terminates the unconditioned stimulus.

F.3.2.1 Runway Avoidance

PURPOSE AND RATIONALE

A straightforward avoidance situation features a fixed aversive gradient which can be traversed by the animal. The shock can be avoided when the safe area is reached within the time allocated (Munn 1950; Capaldi and Capaldi 1972; Hock and McGaugh 1985).

PROCEDURE

Mice or rats of either sex are used and maintained under standard conditions and handled for several days before the experiment. The same box as used in the step-through model can be used in this experiment. The apparatus is uniformly illuminated by an overhead light source. A loudspeaker, mounted 50 cm above the start-box, serves for presenting the acoustic conditioned stimulus (CS; an 80 dB, 2000 Hz tone from an audiogenerator). The footshock is employed by the same source as in the step-through avoidance. The animal is allowed to explore the whole apparatus for 5 min. The guillotine door is then closed and the animal is placed into the light starting area. After 10 s the acoustic CS is applied and the door is simultaneously opened. Shock is turned on after 5 s. The CS continuous until the animal reaches the safe area. It is left there for 50–70 s (intertrial interval, ITI) before returned to the same area again. The procedure starts again. The training is continued until the animal attains the criterion of 9 avoidances in 10 consecutive trials. On the

next day the procedure is repeated until the same learning criterion is reached. The time needed to reach the safe area is measured.

EVALUATION

The time the animal needs to reach the safe area on both days is measured. In addition, the number of errors (not reaching the safe area) is recorded.

MODIFICATIONS OF THE TEST

Several modifications are described in the literature. The CS also can be a light signal. The number of trials and the criterion can be changed.

CRITICAL ASSESSMENT OF THE METHOD

Same as in step-down method.

F.3.2.2 Shuttle Box Avoidance (Two-Way Shuttle Box)

PURPOSE AND RATIONALE

Compared to runway avoidance, shuttle box avoidance (two-way-shuttle-box) is a more difficult task. Since the animal is not handled between trials, the shuttle-box can be easily automated (Capaldi and Capaldi 1972).

PROCEDURE

Rats of both sex are used and maintained under standard conditions. The apparatus used consists of a rectangular box 50 × 15 cm with 40 cm high metal walls, and an electrifiable grid floor. The box is divided by a wall with a manually or solenoid-operated guillotine door (10 × 10 cm). into two 25 × 15 cm compartments. Each compartment can be illuminated by a 20 W bulb mounted in the hinged Plexiglas lids. A fixed resistance shock source with an automatic switch (0.5 s on 1.5 s off) is used. Simple programming equipment provides for automatic delivery of the conditioned stimulus (CS) and the unconditioned stimulus (US). The apparatus is placed in a dimly lit room with a masking noise background (white noise) of 60 dB. The animal is allowed to explore the apparatus for 5 min with the connecting door open and the compartment lights switched off. The guillotine door is then closed. After 20 s the light is switched on in the compartment containing the animal, and the door is opened. A tone (CS) is presented and 5 s later the floor shock is applied in the illuminated compartment and continued until the animal escapes to the dark side of the compartment, the connecting door is closed and the shock discontinued. After a variable intertrial interval (ITI; 30–90 s) the light is switched on in the previous dark compartment, the door is opened and the animal is required to cross to the other side. The training is continued until the animal reaches the criterion of 9 avoidances in 10 consecutive trials. Retention is tested at different intervals after the original training by retraining the animal to the same criterion again.

EVALUATION

The time the animal needs to reach the safe area on both days is measured. In addition, the number of errors (not reaching the safe area) are recorded.

CRITICAL ASSESSMENT OF THE METHOD

The task is rather difficult due to the lack of a permanent safe area, lack of a simple instrumental response, presence of a variable aversive gradient and increased weight of emotional factor.

MODIFICATIONS OF THE METHOD

Salmi et al. (1994) described a computer-assisted two-way avoidance conditioning equipment for rats.

F.3.2.3 Jumping Avoidance (One-Way Shuttle Box)

PURPOSE AND RATIONALE

Since a high degree of automation and minimum handling are additional requirements for this model, the obvious solution is a simplified one-way avoidance, allowing for the spontaneous or forced return of the animal to the start. In order to enhance the start-goal

distinction a vertical gradient is introduced which requires the animal to perform a discrete response of an all-or-none character, such as the jump, which clearly differs from the more continuous translational movements required in the usual avoidance tasks (Tenen 1966; McKean and Pearl 1968).

PROCEDURE

Rats of both sex are used and maintained under standard conditions. The apparatus used consists of a rectangular box 40 × 25 cm with 40 cm high metal walls, an electrifiable grid floor and a Plexiglas ceiling. A 12 × 12 × 25 cm opaque plastic pedestrial, mounted onto one of the narrow walls of the box provides the isolated goal area. Flush with the horizontal surface of the pedestal moves a vertical barrier, which can either be retracted to the rear wall of the apparatus to expose the goal area or pushed forward to block access to the goal completely. The animal is placed into the apparatus for 5 min with the goal area exposed (barrier retracted). The barrier is then moved forwards and the goal is blocked for 2 s. The first trial starts by exposing the goal area and applying an acoustic CS (1000 Hz, 85 dB). Electric shocks – US (1.0 mA; 50 Hz; 0.5 s) – are applied 5 s later (once per 2 s), and continued together with the CS until the animal jumps onto the platform. After 30 s the barrier pushes the animal off the platform onto the grid floor. The sequence is repeated until the criterion of 10 consecutive avoidances is reached. Retention is tested on the next day until the animal reaches criterion.

EVALUATION

The time the animal needs to reach the safe area on both days is measured. In addition, the number of errors (not reaching the safe area) is recorded.

CRITICAL ASSESSMENT OF THE METHOD

In automated procedures extinction is more rapid, especially when short inter test intervals are used.

F.3.3 Discrimination Learning

In the experiments described above the animals have no choice between the conditioned stimuli. They have only one conditioned stimulus. The following examples illustrate the special techniques employed for discrimination among different stimulus modalities. The experiments can be classified either as simultaneous or successive discrimination paradigms. An exhaustive survey of discrimination studies can be found in Gilbert and Sutherland (1969).

F.3.3.1 Spatial Habituation Learning[2]

PURPOSE AND RATIONALE

The open-field test utilizes the natural tendency of rodents to explore novel environments in order to open up new nutrition, reproduction and lodging resources (Birke and Archer 1983; Cerbone and Sadile 1994). The rate of exploratory behaviors exhibited in an unfamiliar environment is limited through the inherent necessity to avoid potential dangers. The observed behavior therefore is always a compromise between these conflicting interests and is regulated in part by the momentary physiological needs (Gerlai 1999; Groves and Thompson 1970). Spatial habituation learning is defined as a decrement in reactivity to a novel environment after repeated exposure to that now familiar environment. This reduction in exploratory behaviors during re-exposures is interpreted in terms of remembering or recognition of the specific physical characteristics of the environment. The test can be used to examine short-term spatial memory (within-trial reductions in exploratory activity) and/or long-term spatial memory (between-trial reductions in exploratory activity after a retention interval of 24, 48 or 96 h after the initial exposure) (Lát 1973).

PROCEDURE

The open-field apparatus is a rectangular chamber (rats: 60 × 60 × 40 cm, mice: 26 × 26 × 40) made of painted wood or grey PVC. A 25 W red or green

[2] Contribution by E. Dere.

light bulb is placed either directly above or beneath the maze to achieve an illumination density at the centre of approximately 0.3 lx. Masking noise is provided by a broad spectrum noise generator (60 dB). Prior to each trial, the apparatus is swept out with water containing 0.1% acetic acid. Housing room and the testing location are separated and animals are transported to the testing room 30 min before testing. The digitized image of the path taken by each animal is stored and analyzed post hoc with a semi-automated analysis system (e. g. Ethovision, Noldus, The Netherlands or Truscan, Coulbourn Instruments, Allentown, PA). In aged or hypoactive rodents testing is performed during the animals dark phase of day. The rodent is placed on the center or in a corner of the open-field for 5–10 minute sessions (mice: up to 20 min, because of the high basal activity level). The animals are re-exposed to the open-field 24 and 96 h after the initial trial (Thiel et al. 1999; Schwarting et al. 1999).

EVALUATION

The exploratory behaviours registered are: (1) Rearings or vertical activity: the number of times an animal was standing on its hind legs with forelegs in the air or against the wall. (2) The duration of single rearings as a measure of non-selective attention (Aspide et al. 2000) (3) Locomotion or horizontal activity: the distance in centimeters an animal moved.

MODIFICATIONS OF THE TEST

In order to assess emotionality parameters either in interaction with spatial novelty (a single exposure) or in interaction with spatial habituation learning (repeated exposures), the aversivity of the open-field can be varied by increasing the size (inducing agoraphobia) and/or the illumination density (inhibits exploration) of the apparatus (File 1980). Rodents exposed to a big sized brightly lit open field tend to spent more time in the corners or close to the wall and avoid the central part of the apparatus. The emotional behaviors registered are: (1) Corner time: the time spent in the 4 corner squares (rats: 15 × 15 cm; mice: 6.5 × 6.5 cm). (2) Wall time: the time an animal spent close to the wall as a measure for thigmotaxis (scanning the walls of the apparatus with the vibrissae). (3) Center time: the time spent in the center of the open field (rats: 20 × 20 cm; mice: 10 × 10 cm). (4) Defecation: number of boli deposited. (5) Freezing: the time the animal stays completely immobile except for movements associated with respiratory activity (Hall 1936; Frisch et al. 2000). To assess habituation learning not only by decrements in exploratory behaviors but also via increments, one can place an object in the center of the open-field. The number of entries into and the time spent in the center increases from exposure one to exposure two without affecting other indices of spatial habituation (Dai et al. 1995).

CRITICAL ASSESSMENT OF THE TEST

The open-field paradigm is a well validated, simple and time economical test, which has been widely used to examine the neurobiological foundations subserving spatial memory, general activity and emotionality in rodents with different approaches including: lesions, drugs, electrophysiology, neuroanatomy, and neurogenetics.

F.3.3.2 Spatial Discrimination

PURPOSE AND RATIONALE

In the simplest case of discrimination learning the animal distinguishes between two symmetric stimulus-response sets, the equal probability of which has been changes by differential reinforcement events. Position of the cues with respect to the animal's body defines the CS^+ and CS^-. Usually left-right discrimination is employed, while axial orientation of the body is ensured by the construction of the apparatus (Siegel 1969).

PROCEDURE

Rats and mice of both sex are used and maintained under standard conditions. The apparatus used is usually a simple T- or Y-maze, with an electrifiable grid floor. The last 10 cm of each arm are separated from the rest of the apparatus by a swing-door which prevent the animal from seeing the food cup or the plastic sheet covering the grid in the goal area. A fixed resistance shock source is connected to an automatically operated switch. In an aversively motivated spatial discrimination learning the animal is trained to escape and/or to avoid foot shocks by always going to the right. Training starts by allowing the animal to explore the apparatus. Then the animal is placed on the start and after 5 s electric shocks (0.5 s, 50 Hz, 1.0 mA) are applied at 3 s intervals. The animals are trained to a criterion. On the following day the animal is retrained to the same criterion. After a 60 min interval the safe goal area is shifted to the other arm of the maze and the discrimination is reversed.

EVALUATION

Errors are scored. An error means that the animal enters the wrong arm with all four legs. During retention the number of trials until the animal makes correct choices are counted.

CRITICAL ASSESSMENT OF THE METHOD

The ecology of rodents makes these animals specially proficient in spatial discrimination learning, which is usually mastered in a few trials. Most of the initial errors are not due to the inability of the animal to remember the correct solution, but rather to its tendency to explore alternative pathways.

MODIFICATIONS OF THE TEST

Barnes (1979) and others introduced the radial maze as a modification of spatial discrimination. This method is now well established and widely used.

Ingram et al. (1994a, b) recommended the Stone 14-unit T-maze to find new pharmacological approaches for cognitive enhancement.

F.3.3.3 Spatial Learning in the Radial Arm Maze

PURPOSE AND RATIONALE

Olton and co-workers have developed a spatial discrimination task for rodents that has been extensively used in learning and memory studies, and that has served as the basic task for one of the most important theories on the role of the hippocampus (Olton et al. 1979; Olton and Samuelson 1976). The rat uses spatial information provided by the distal cues in the room to efficiently locate the baited arms. The radial arm-maze allows the study of spatial reference and working memory processes in the rat. In reference memory procedures, information is useful for many sessions/days and may usually be needed during the entire experiment. On the contrary, working memory procedures have a major temporal component as the information presented in the maze (arms baited) is useful for one session but not for subsequent ones; the rat has to remember the information during a delay interval (min to h). Correct choices in the radial arm-maze are rewarded by food.

PROCEDURE

The apparatus is a wooden elevated eight-arm radial maze with the arms extending from a central platform 26 cm in diameter. Each arm is 56 cm long and 5 cm wide with 2 cm high rails along the length of the arm. The maze is well illuminated and numerous cues are

present. Food pellets (reward) are placed at the end of the arms. During the test, rats are fed once a day and their body weights maintained at 85% of their free-feeding weight to motivate the rat to run the maze. Animals are trained on a daily basis in the maze to collect the food pellets. The session is terminated after 8 choices and the rat has to obtain the maximum number of rewards with a minimum number of errors.

EVALUATION

The number of errors (entries to non-baited arms) are counted during the session.

MODIFICATIONS OF THE TEST

Depending on the hypothesis being tested in the radial arm-maze (1) animals can be trained extensively and then receive specific brain lesions (hippocampus, septum or fimbria-fornix); after recovery from the surgery the rats are re-trained to determine the cognitive ability or the speed of recovery as these lesions severely disrupt processing of spatial information (Olton et al. 1978). (2) In working memory studies animals are forced to obtain reward in specific arms (4 arms), and after a time delay they have to either return to the same arms (win-stay) or to avoid these arms and obtain the food in the rest of the arms (win-shift). (3) Animals are trained to find food in only one arm, and after a delay they are required to return to the same arm. Many versions of the maze exist with differences in the shape, arm-length or the number of arms (12 or 24 arm-mazes), but all of them are appetitively-motivated. An aversively-motivated maze was developed by locating an 8-arm maze in a water tank (Buresova et al. 1985). Extensive modifications on the arm-maze were also developed by Kesner and co-workers and are the basis of the multidimensional attribute theory that characterize mnemonic functions (Kesner 1980, 1986).

CRITICAL ASSESSMENT OF THE TEST

The radial arm-maze has been widely used to determine the neurobiological mechanisms underlying spatial learning in rodents and to evaluate the effect of drugs. The deleterious effects of scopolamine, atropine, ethanol, benzodiazepines, haloperidol, ketamine, PCP, as well as the facilitatory effects of physostigmine, nicotine, pramiracetam, picrotoxin, naloxone have been reported in the literature (Levin 1988). One of the disadvantages of the test is that hypothalamic lesions or the anorectic effect of certain drugs (amphetamine) affect the appetitive nature of the maze and animals do not master the maze for this reason.

F.3.3.4 Visual Discrimination

PURPOSE AND RATIONALE

Vision is better than any other sensory system for the analysis of spatial relationships in the environment of the animal. From the retina to the cerebral cortex, the organization of the visual system ensures processing of visual information according to simple principles, i. e. by fitting the distribution of light over the receptive surface to elementary geometrical concepts and by comparing these patterns with images stored in the memory. Visual pattern recognition is one of the most challenging problems of contemporary neurophysiology and experimental psychology, with significant implications for mathematical and technical modeling of perceptual phenomena (artificial intelligence). For review and details see Grüsser and Klinke (1971) and Sutherland (1969). Experimental studies of pattern discrimination must take into account the visual capability of the given species and present the discriminanda under conditions compatible with light sensitivity and acuity of the eye. The constructions of the apparatus should ensure that the discriminanda are viewed from one optimum distance and for a sufficient period of time. A thorough discussion of the pattern discrimination technique is to be found in Munn (1950).

PROCEDURE

Rats and mice of both sexes are used and maintained under standard conditions. The apparatus consists of a square 10×10 cm start area separated by a Plexi-

glas sliding door from the choice area, which is connected by swing doors to the goal compartment. The grid floor in the starting and the choice areas is electrifiable. The stimulus (mostly plastic cards 8 × 8 cm) can be attached to the swing doors. The patterns are black on a white background and have different forms. The apparatus is illuminated by a dim light. The animal is placed into the apparatus with all doors open and allowed to explore it. Then it is placed in the start and after 5 s released by raising the Plexiglas door. After another 5 s, electric shocks (1 mA, 50 Hz, 0.5 s, 1/3 s) are applied until the animal escapes through either of the open doors to the safe goal compartment where it is left for some seconds. As soon as this preliminary step is mastered, the stimulus cards are inserted, the negative door is locked and the grid section in front of this door is electrified. The animal is trained to a criterion. On the next day the animal is retrained to the same criterion and retention is expressed in savings. Another parameter which can be used to evaluate the savings is the cumulative number of errors until the criterion is reached (Thompson 1969).

EVALUATION

The number of correct answers as well as the number of trials until the criterion is reached are counted.

CRITICAL ASSESSMENT OF THE METHOD

The method is time consuming and only useful to address a specific hypothesis.

MODIFICATIONS OF THE TEST

Steckler et al. (2000) and Van Gaalen et al. (2003) tested mice for their ability to learn and perform a series of simultaneous visual discriminations, which allowed a dissociation between accuracy of discrimination from those of motivation and behavioral disinhibition. Five operant chambers (20 × 15 cm) with curved rear walls (developed with TSE, Bad Homburg, Germany) were used. Set in the curved wall of each box was an array of five circular holes, 2 cm in diameter, 3 cm deep and 1.5 cm above floor level. Each hole was equipped with an infrared photocell beam crossing the entrance vertically, a yellow LED at the rear end of the hole, providing 5 lux illumination at the hole's entrance, and a food pellet dispenser which allowed delivery of a 20-mg dustless food pellet directly into the hole where a correct response has been made. Presentation of the light stimulus, the operandum and the food reward all in the same location was chosen to enhance stimulus–response–reward contiguity. Each hole could be closed separately by a metal sheet to prevent access for the animal, if required. In addition, the chamber could be illuminated by a white house light (30 lux) mounted in the center of the roof. The boxes were housed in dark, sound-attenuating compartments. On-line control of the apparatus and data collection were performed using a special computer system. After habituation and autoshaping, the program was switched to five-choice discrimination and then to two-choice discrimination with increasing and decreasing response requirement.

F.3.3.5 Spatial Learning in the Water Maze

PURPOSE AND RATIONALE

A task was developed where rats learn to swim in a water tank to find an escape platform hidden under the water (Morris 1984). As there are no proximal cues to mark the position of the platform, the ability to locate it efficiently will depend on the use of a configuration of the cues outside the tank. Learning is reflected on the shorter latencies to escape and the decrease on the length of the path to find the platform. Although rodents can find the platform by using non-spatial strategies, the use of a spatial strategy is the most efficient way to escape and young animals develop the spatial strategy after a small number of trials.

PROCEDURE

Different strains of rats are generally used (Long Evans, Wistar, Sprague-Dawley). The apparatus is a circular water tank filled to a depth of 20 cm with 25°C water (Brioni et al. 1990; Morris 1984). Four points equally distributed along the perimeter of the

tank serve as starting locations. The tank is divided in four equal quadrants and a small platform (19 cm height) is located in the centre of one of the quadrants. The platform remains in the same position during the training days (reference memory procedure). The rat is released into the water and allowed 60–90 s. to find the platform. Animals usually receive 2–4 trials per day for 4–5 days until they escape onto the platform. Well-trained rats escape in less than 10 s.

EVALUATION

The latency to reach the escape platform is measured during the training days. A free-swim trial is generally performed after the training days where the escape platform is removed and the animal is allowed to swim for 30 s. With the help of a video system, the latency to reach the previous position of the platform, the number of annulus crossings as well as the time the rat spent in the training quadrant are measured. Well-trained rats show short latencies, a large number of annulus crossings and bias to the quadrant where the escape platform was located during the training sessions.

MODIFICATIONS OF THE TEST

In the "cue" version of the water maze, the platform is clearly visible over the water and allows the evaluation of the motor and motivational aspects of the rat under study, as the animals should easily find the visible platform in 10–15 s. As circling or other non-spatial strategies can be used to find the platform, alternative measures of learning were developed (Gallagher et al. 1993), like the use of brief probe trials during training (rather than at the end), the use of proximity measures (an index of search error or deviations from the optimal path), and the learning index (proximity measures during weighted probe trials). Buresova and co-workers have developed the use of a collapsible platform to improve the accuracy of the water maze (Buresova et al. 1985). To evaluate working memory processes in the water maze, the rat can be trained to find a new platform position and later its performance is tested after a short delay (2–4 h). A spatial discrimination version of the water maze was also developed (Decker et al. 1992; Morris 1984), where the rat has to discriminate between two similar platforms based on spatial differences (one platform provides a mean to escape while the other sinks upon contact).

CRITICAL ASSESSMENT OF THE TEST

This test allows the researcher to study working and reference memory processes, and to dissociate the memory deficits induced by brain lesions or drug injections from the motor, motivational or sensory deficits. This test has been used to study the effect of drugs on memory (Brioni et al. 1991; Brioni et al. 1990. Decker et al. 1992), the participation of the hippocampus, septum, amygdala and nucleus basalis magnocellularis (Morris et al. 1986; Morris 1989), catecholamine depletions, as well as recovery of function (McNamara and Skelton 1993). It has been particularly sensitive to demonstrate that aged rats exhibit deficits in the acquisition of spatial information when compared to young or middle age controls (Rapp et al. 1987). The major advantages of the water maze over the radial arm-maze are: (1) that animals can be trained in a significantly shorter period of time (one week) while the arm-maze studies require several weeks of training; (2) intramaze cues like odor trails are eliminated in the pool; (3) large dose-response studies can be conducted in a week's time; (4) the motor or motivational problems in the rat can be detected in a cue trial; and (5) that the animals are not food-deprived during the test. From a theoretical point of view, the water maze is an aversively-motivated task while the arm-maze is appetitively-motivated.

MODIFICATIONS OF THE METHOD

Nitta et al. (1994, 1996; Nabeshima 1995) found an impairment of the performance of the water maze task in rats treated by infusion into the cerebral ventricle for 14 days with β-amyloid protein which consisted of senile plaques of Alzheimer's disease. The authors recommended that β-amyloid protein-treated rats as an animal model for Alzheimer's disease.

Song et al. (1997) reported that thymectomized rats, 5 weeks after surgery, showed a significant impairment of learning and memory as shown in deficits in passive avoidance and in the Morris water maze test.

Sun and Alkon (2004) found that induced depressive behavior impairs learning and memory in rats using an open space swim test. The model indexes searching activity of the animals, with the induced depressive immobility behavior showing specific sensitivity to three major prototypic classes of antidepressants and a selective serotonin reuptake inhibitor.

Zoladz et al. (2006) reported enhancement of long-term spatial memory in adult rats by the non-competitive NMDA receptor antagonists memantine and neramexane.

F.3.3.6 Active Allothetic Place Avoidance Task

PURPOSE AND RATIONALE

Bures et al. (1997), Fenton et al. (1998), Cimadevilla et al. (2000, 2001a, 2001b), Stuchlik and Bures (2002), Stuchlik et al. (2004), and Stuchlik and Vales (2005) designed a pharmacological mode, which they called the active allothetic place avoidance (AAPA) task, a cognitive task which requires rats to separate two conflicting spatial reference frames (room and arena frames), when only the room frame is relevant for solution of the task. Stuchlik and Vales (2005) showed that systemic administration of MK-801 elicits a behavioral deficit in rats in the AAPA task irrespective of their intact spatial pretraining.

PROCEDURE

Male Long-Evans starin rats weighing 350–450 g were housed under constant temperature at a 12:12 light:dark cycle. Under light ether anesthesia, animals were implanted with a low-impedance connector made from a hypodermic needle, which pierced the rat's skin between the shoulders. The sharp end of the needle was then cut off and bent with tweezers to form a small loop, which prevented the connector from slipping out and provided anchor for an alligator clip, which was connected to a shock-delivering wire.

MK-801 was injected i.p. in doses of 0.15 or 0.2 mg/kg 30 min before each training session.

The AAPA task apparatus consists of a smooth metallic circular arena (80 cm in diameter) enclosed within a 30-cm-high transparent Plexiglas wall and elevated 1 cm above the floor. There were two arenas located in two different rooms. The upstairs room (4 m × 5 m) contained various extramaze landmarks. The downstairs room (5 m × 5 m) contained different visual cues organized in a different layout. At the beginning of each training session, a rat was placed on the rotating arena (1 rpm), where a directly imperceptible 60° to-be-avoided sector (shock sector) was defined by the computer-based tracking system, located in an adjacent room. The location of the shock sector could be determined exclusively by its spatial relation to distal orienting cues in the room. The rat wore an infrared light-emitting diode fixed between the shoulders with a light latex harness, and its position was tracked every 40 ms and recorded onto a computer track file, allowing subsequent reconstruction of the track with an off-line analysis program.

Whenever a rat entered the shock sector for more than 0.5 s, mild electric shocks (50 Hz, 0.5 s) were delivered in intervals of 1.5 s until the rat left the shock sector for at least 0.5 s. The shocks were delivered through a thin low-impedance wire implant on the back of the rat standing on the grounded floor. The appropriate shock current (ranging between 0.2 and 0.7 mA) was individualized for each rat to elicit a rapid

escape reaction but to prevent freezing. Since the arena was rotating, the rat had to move actively away from the shock in the direction opposite to the arena rotation, otherwise it was passively transported to the shock sector. Experimental sessions in AAPA lasted 20 min and each rat had one session every day, carried out during daylight hours.

Initially, non-injected rats were trained for four consecutive daily sessions to avoid a sector located in the north of the upstairs room to learn the task without any drug administration. Subsequently, in session 5 they were injected with either saline or MK-801 and tested for the effect of the drug on the well-pretrained place avoidance (reinforced retention). After a weekend break rats were trained daily under saline or MK-801 in the downstairs arena in order to test reacquisition of AAPA in a new environment, when they were already familiar with the procedural component of the AAPA task (sessions 6–10). The shock sector was defined in the south of the room in the downstairs arena.

Rats were divided in three experimental groups: controls, MK-801 0.15 or 0.2 mg/kg i.p., respectively.

EVALUATION

The following parameters were recorded and analyzed in order to assess rats' behavior in the AAPA: the total distance traveled in a session (DISTANCE) measured in the arena frame (which only takes into account active locomotion) reflected the locomotor activity of the rats, and the number of entrances in the shock sector (ERRORS) reflected the efficiency of spatial performance in the AAPA task. The maximum time a rat spent in the safe part of the arena between two ERRORS in a particular session was also recorded. It reflected the ability to remember the shock sector location and to avoid it. Data from the initial 4 days of intact pretraining in the upstairs room were analyzed using a two-way ANOVA (groups × sessions) with repeated measures on sessions, data from the fifth day (retention session) were compared in a between-group fashion using one-way ANOVA, and data from the reacquisition training in the downstairs room were analyzed with a two-way ANOVA (groups × session) with repeated measures on sessions. Tukey's HSD test was used when appropriate.

CRITICAL ASSESSMENT OF THE METHOD

The AAPA task has been used for various pharmacological studies. In this paper, the authors claim that testing the effect of various substances using the AAPA task may be a promising way to predict their influence on cognitive symptoms.

F.3.3.7 Olfactory Learning

PURPOSE AND RATIONALE

Odors provide rodents with important information on the environment and the learning of successive olfactory discrimination problems in rats is closely related to the acquisition rules of higher primates. Odor-reward associations are learned in few trials as odors exert more discriminative control over other sensory modalities like tones or lights (Nigrosh et al. 1957). Animals have to learn to discriminate an arbitrary designated positive odor (i. e., banana) from a negative one (i. e., orange) to receive a reward.

PROCEDURE

Rats (Sprague-Dawley or Long Evans) are generally used. In procedures described in the literature (Eichenbaum et al. 1992; Roman et al. 1993), animals are deprived of water for 48 h before the training and during the test they receive ad libitum water for only 30 min. The olfactory apparatus is a rectangular box (30 × 30 × 55 cm) with a photosensitive cell mounted

on top of the water spout/odor outlet. Rats are trained to approach the water spout and to brake the light beam. Responses to the positive odor are rewarded with water while responses to the negative odor results in the presentation of a light flash. The intertrial interval before the presentation of a new odor is usually 15 s. and the sessions last 30 min. per day. Sessions are terminated when the rat makes 90% correct choices or after 400 trials.

EVALUATION

The animal is rewarded with 0.05 ml of water when it brakes the beam to the positive odor or when it does not respond to the negative odor. Incorrect responses ("no go" to the positive odor or "go" to the negative odor are followed by a flash and a longer intertrial interval). Results are reported as the % correct responses or as a logit transformation of the % correct/incorrect response ratio.

CRITICAL ASSESSMENT OF THE TEST

The anatomical connections from the olfactory bulbs to cortical as well as subcortical areas are fairly well known, and brain lesions that impair olfactory discrimination learning (Otto et al. 1991; Roman et al. 1993; Stäubli et al. 1984) could be used as models of amnesia. Systemic injections of scopolamine disrupts the performance of rats during long delays with no effect on immediate recall, data that are consistent with the effect of scopolamine in humans (Ravel et al. 1992). Antagonists of the NMDA receptor impair acquisition of odor discriminations and block LTP, an electrophysiological correlate of memory (Lynch and Stäubli 1991). The test can also be used to evaluate the cognitive effects of drugs such as ACTH analogs that facilitate the storage of olfactory information (Roman et al. 1989).

MODIFICATIONS OF THE TEST

A T-maze with controlled access to the reward compartment was developed (Ravel et al. 1992), that allows the test to evaluate working memory processes after time delays (1–3 min.).

Willer et al. (1992) examined the effects of a competitive NMDA agonist on the ability of rats to acquire potentiated aversions to the odor element of a taste-odor compound.

Larson et al. (1995) studied in rats the facilitation of olfactory learning by a modulator of AMPA receptors.

F.3.3.8 Aversive Discrimination in Chickens

PURPOSE AND RATIONALE

One to 2-days old chicks have been extensively used to study learning and memory. The chicks are trained to discriminate between an aversive and a non-aversive stimulus (colored glass beads) in a single 10–15 s learning trial. Following this learning trial, retention is monitored over a comprehensive range of learning-retention intervals to chart the course and to differentiate possible stages of memory formation. Three behaviorally sequentially dependent stages have been identified: a short-term memory stage, lasting approximately 10 min after learning; an intermediate-memory stage, available between 20 and 50 min post-learning, and a long-term memory stage available from 60 min after learning. The three stages are behaviorally separated by transient retention deficits occurring at around 15 and 55 min post-training. Gibbs and Barnett (1976), Gibbs and Ng (1976, 1979), Rickard et al. (1994, 2001), Bennett et al. (1996), Ng et al. (1997) used a three-stage model to test the influence of drugs on memory formation.

PROCEDURE

Day-old, male, White-leghorn black-Australop chickens are housed at an ambient temperature of 28°C. In

a single passive avoidance learning trial, chicks are pre-trained to peck at a 4 mm chromed bead, dipped in water and presented for 10 s. A similar bead, dipped in the chemical aversant methyl anthranilate, is the presented for 10 s. Data from chicks failing to peck the bead on this trial or not showing characteristic disgust responses after pecking are eliminated from subsequent data analysis. Retention is tested by presenting for 10 s a dry bead similar to that used for the pretraining trail.

In a discrimination paradigm, chicks are trained to avoid a red bead and are tested on red and blue beads successively and discrimination ratios registered.

In an additional discrimination paradigm, chicks are given two aversive beads – a chrome and a red bead. They are trained on one of the aversive beads sometime before drug treatment. The other aversive bead is associated with drug treatment and the chicks are subsequently tested with all three beads.

Twenty different chicks are used for each data point. Retention in both paradigms is indexed by the proportion of chicks avoiding the aversive bead, with the proviso that in the discrimination paradigm is indicated by the avoidance of the red bead and pecking on the blue bead. Retention is tested at various times between 5 and 180 min after learning or at 24 h.

Drugs are administered in 0.1 ml volumes subcutaneously into a fold of skin on the ventral side of the rib cage.

EVALUATION

Discrimination ratios of treated animals after various time intervals following administration of drugs are statistically compared with saline treated controls.

CRITICAL ASSESSMENT OF THE METHOD

The test has been used with slight modifications successfully by many authors in several research groups (e. g., Hölscher and Rose 1992; Sandi and Rose 1994; Stephenson and Andrew 1994; Zhao et al. 1994; Deyo and Hittner 1995; Crowe and Shaw 1997; Venero and Sandi 1997; Bennett et al. 1998; Tiunova et al. 1998; Rose and Stewart 1999)

MODIFICATIONS OF THE TEST

Bourne et al. (1991) compared the taste and odor aversant methyl anthranilate with the odorless quinine as averants.

Clements and Bourne (1996) and Stamatakis et al. (1998) injected drugs, e. g., GABA agonists or α_2-noradrenergic agonists and antagonists, directly into the intermediate median hyperstriatum ventrale of day-old chicks, prior to training on a chrome bead dipped in either methyl anthranilate or quinine.

Colombo et al. (1997) injected enkephalins into 2 regions of the 2-day-old chick brain: the intermediate medial hyperstriatum and the lobus parolfactorius.

Tiunova et al. (1996) trained chicks to discriminate between edible chick crumbs and arrays of colored bead glued to the floor of their cage.

Gilbert et al. (1989) reported a simple, one-trial, learning paradigm in young chicks. Chicks were separated from their brood mates and placed in a small isolation chamber. A T-maze connected the isolation chamber to the brood space, allowing the chick to escape isolation stress and rejoin the brood. When the chick successfully negotiated the corridor, the latency to perform this task was recorded. On a subsequent trial, any improvement in the speed of performance was recorded to reflect the chick's memory of the task.

F.3.4
Conditioned Responses

F.3.4.1
Conditioned Nictitating Membrane Response in Rabbits

PURPOSE AND RATIONALE

The rabbit's classically conditioned eyeblink response has become a widely used model system for studying associative learning in mammals (Gormezano et al. 1987) and to find drugs potentially useful in the treatment of age-related memory disorders (Ghoneim et al. 1994; Woodruff-Pak et al. 1994a, b, 1997; Solomon et al. 1988, 1995a, b).

PROCEDURE

Animals

New Zealand white albino rabbits weighing 2.0 kg are housed individually under consistent light with free access to food and water.

Apparatus and General Procedure

A small loop of surgical nylon is sutured into the right nictitating membrane, and the surrounding hair is removed. One day later, the rabbit is placed in a Plexiglas restrainer, and two stainless-steel wound clips are applied to the skin over the parietal region. The rabbit is fit with a headmount that supports a photoresistive assembly for recording the nictitating membrane response by physical coupling with a length of thread to the nylon loop in the nictitating membrane. The transducer assembly converts nictitating membrane movements into electrical signals that are subjected to an analog-to-digital conversion using a 5-ms sampling rate and a resolution of 0.06 mm actual membrane extension. The animal is then positioned in a ventilated, sound-attenuated chamber facing a stimulus panel containing an 11.4-cm speaker and two 6-W, 24-V DC house lights, one mounted at each side of the speaker. During the course of the experiment, two stimuli are employed as conditioned stimulus: a) a 1000-ms, 1-kHz, 84-dB tone; b) a 1000-ms, intermittently presented light produced by interruption of the house lights at 10 Hz to yield a change in illumination, measured at the eye level of the rabbit from 32.11 to 8.01. The unconditioned stimulus is a 100-ms, 3-mA, 60Hz shock delivered to the wound clips by a constant current shock generator.

Drugs

Drug solutions or saline are injected subcutaneously into the cervical area of the rabbit via an infusion pump at a rate of 3 ml/min, 30 min before behavioral testing.

Procedure

Experimentally naive rabbits are randomly assigned in equal numbers to each of the treatments ($n = 10$ per treatment). The experiment consists of two phases: Phase 1 is an adaptation day followed by 9 days of acquisition training. No stimuli are presented during the 60-min adaptation session. Subjects are injected with their assigned treatment 30 min before each acquisition session. Each acquisition session consists of 30 tone-shock and 30 light-shock trials presented in a randomized sequence within 10 trial blocks, with the restriction that no more than three consecutive tone or light trials can occur. On each conditioned stimulus – unconditioned stimulus trial, the offset of the 1000-ms tone or light conditioned stimulus occurs simultaneously with the onset of the 100-ms unconditioned stimulus. The inter-trial interval is about 60 s. A response is defined as at least a 0.5-mm extension of the nictitating membrane. Responses occurring during the tone or light conditioned stimulus, but before the unconditioned stimulus are recorded as conditioned response;

those occurring after the unconditioned stimulus onset are recorded as unconditioned response.

EVALUATION

The data are analyzed by repeated measures analyses of variance and Tukey tests. The significance level is set at $p < 0.05$.

CRITICAL ASSESSMENT OF THE METHOD

The rabbit nictitating membrane response has been used widely to study the effects of drugs on learning (Schindler and Harvey 1990).

MODIFICATIONS OF THE TEST

Several authors used a corneal air puff as unconditioned stimulus (Robinson et al. 1993; Solomon et al. 1995, 1996).

Scavio et al. (1992) studied post-training effects of several drugs, such as amphetamine, chlorpromazine, ketamine, and scopolamine, on the acquisition and extinction of the rabbit's conditioned membrane response.

The effects of modulating tone frequency, intensity, and duration on the classically conditioned rabbit nictitating membrane response were studied by Kehoe et al. (1995).

Solomon et al. (1996) described behavioral paradigms for delay, trace, and long-delay conditioning.

Various drugs influence the nictitating membrane response in rabbits, such as morphine (McEchron and Gormezano 1991), cocaine (Marshall-Goodell and Gormezano 1991), sodium pentobarbital (Chen et al. 1992), haloperidol (Sears and Steinmetz 1990), MDA (3,4-methylenedioyamphetamine) (Kirkpatrick-Steger et al. 1991; Romano and Harvey 1993), harmaline (Harvey and Romano 1993; Du and Harvey 1997), ketamine (Ghoneim et al. (1994), isoflurane (El-Zahaby et al. 1994), L-NAME (nitric oxide synthesis inhibitor, Du and Harvey 1996), serotonin antagonists and agonists (Welsh et al. 1998a, b), calcium antagonists (Woodruff-Pak et al. 1997), nitrous oxide (Ghoneim et al. 1999).

F.3.4.2 Automated Learning and Memory Model in Mice

PURPOSE AND RATIONALE

Vanover and Barrett (1998) developed and validated pharmacologically an automated, relatively rapid, and reproducible behavioral model of learning and memory using an autoshaped procedure in mice. Autoshaping procedures were first described for pigeons by Brown and Jenkins (1968) and have been used subsequently as a means to assess learning and memory in monkeys (Sidman and Fletcher (1968), in rats (Steckler et al. 1993; Oscos et al. 1998), and in mice (O'Connell 1980).

PROCEDURE

Naive male mice weighing 25–35 g are randomly assigned to experimental groups. They are housed at approximately 22°C at a 12:12 light/dark cycle with food and water continuously available. Twenty-four hours before each test, mice are isolated into individual cages and all food is removed. Water remains continuously available. Tests are conducted on two consecutive days. Mice are fed 1.5 g food immediately after the first session (day 1).

For experimental sessions, mice are placed in sound-attenuating enclosures containing specially designed operant chambers ($12.5 \times 11 \times 12.5$ cm) equipped with a recess (dipper well; 2.2 cm diameter, 1.3 cm deep) for dipper accessibility on one wall of the chamber and two additional smaller holes (1.3 cm diameter, 0.9 cm deep) on either side of the dipper well. The dipper can be raised into the dipper well for a sucrose solution (110 g/1.01 water) reinforcer presentation. Each recess has a photocell monitoring nose-poke responses. In addition, a speaker capable of sounding a stimulus tone is located on the wall opposite to the dipper and a house-light is on the ceiling. A computer and associated interface controls stimulus events and records nose-poke responses.

Five to 9 mice per group are tested in a 2-day procedure designed to measure acquisition and retention of nose-poke response under an autoshaping schedule of reinforcement. Experimental sessions are conducted at the same time each day for 2 consecutive days. Both the acquisition session (day 1) and the retention session (day 2) are identical.

During the autoshaping procedure which is used to measure acquisition and retention of the response reinforcement for nose-poking a tone is added. This tone sounds on a variable-interval schedule of presentation (mean of 45 s, range 4–132) and stays for either 6 s or until a nose-poke in the dipper well is made before the end of the 6 s period, at which time the tone is turned off and a dipper with sucrose solution is presented. If a mouse fails to make a dipper well nose-poke during the tone, the dipper is automatically presented at the termination of the tone. A dipper well nose-poke response made during the presence of the tone is counted as reinforced response. Dipper well nose-poke responses made while the tone is off are counted but have no consequence. Each sessions lasts for 2 h or until 20 reinforcers have been earned, whichever comes first. In addition to dipper well nose-poke responses, nose-pokes in the smaller holes to the left and right of the dipper are counted but have no consequence.

Drugs in various doses or vehicle are administered i.p. immediately before the session.

Rates of nose-poke responses made in the small holes on either side of the dipper well serve as a measure of general activity. The computer presents tones on a variable interval with a mean of 45 s and 10 possible intervals (4, 10, 15, 22, 29, 38, 49, 64, 87, 132 s) chosen randomly without replacement until all intervals have been used.

The latency of the response to the 10th reinforcer is considered as a measure of acquisition and retention, because all mice have been exposed to all possible intervals (in random order) by the 10th tone. In order to eliminate the variance due to the variability of the first reinforcer, it is necessary to adjust any measure of acquisition and retention according to the response latency to the first reinforcer. The 10th response latency measure is thus adjusted by subtracting the response latency to the first reinforcer (L-10-1) in order to en-

sure all mice have been exposed to the reinforcement contingency.

An other measure of acquisition and retention consists of the rate of nose-poke responding in the dipper well during the total session.

EVALUATION

The mean and standard error of the mean are calculated for every group. Two-tailed Student *t*-tests are used to compare two independent groups on any one dependent variable. In addition, two-tailed paired *t*-tests are conducted to compare data from day 1 to data from day 2 for any one group. One-way analyses of variance (ANOVA) are conducted across groups for effects of dose on acquisition (day 1 performance). One-way analyses of covariance (ANCOVA) are conducted across groups for effects of dose for retention (day 2 of performance) with the performance on day 1 as the covariate. When an ANOVA or ANCOVA shows statistical significance, post-hoc Duncan's multiple range tests are conducted with every group compared with vehicle. *P* values less or equal to 0.05 are considered statistically significant.

F.3.4.3 Learning Deficits after Postnatal Anoxia in Rats

PURPOSE AND RATIONALE

Oxygen deprivation causes irreversible damage to the adult mammalian brain, but during perinatal development the nervous systems appears to be more tolerant to hypoxic events. Several animal models have been developed to study in detail the pathophysiology of perinatal hypoxia and its behavioral consequences (Speiser et al. 1988; Dell'Anna et al. 1991; Speiser et al. 1991; Raju 1992; Buwalda et al. 1995; Roohey et al. 1997; Lebedev et al. 2003; Zhuravin et al. 2004). Speiser et al. (1998) tested the effect of a monoamine oxidase B inhibitor on cholinergic functions and behavior in rats submitted to postnatal anoxia.

PROCEDURE

Wistar rats were kept at 24 ± 2°C and a 12:12 h light:dark cycle with free access to food and water. For breeding, a male 4- to 8-month-old was kept with a pair of females, 2- to 5-months-old, for 10 days. The male was withdrawn, and the females were kept together for an additional 10-day period, and then housed in individual cages where they had a litter of about 9–12 pups. Mother and five to seven male offspring were kept together until weaning (21 days), then separated and housed five to seven to a cage.

Only male pups were used for anoxia. On the second postnatal day, five to six pups were placed in a glass container equipped with an inlet and outlet for the displacement with 100% nitrogen at near atmospheric pressure. After a stay of 30 min, the pups were removed to room air and resuscitated by soft intermittent massage to the chest, then returned to their mothers.

To avoid handling which could affect behavior, the test drug was administered in drinking water to the nursing mothers starting on the first day of delivery. Controls received tap water. After weaning and to completion of the study, the young rats were given access to drug in drinking water.

For evaluation, motor behavior was recorded at ages of 14, 21, 28, and 35 days. Retention of one-trial step-through passive avoidance was determined at the age of 45 days. Water-maze tests were performed at the age of 50–60 days.

EVALUATION

Data were analyzed by either ANOVA or the unpaired or paired two-tailed Student's *t*-test.

F.3.5 Studies in Monkeys

PURPOSE AND RATIONALE

Nonhuman primates have the closest taxonomic relationship to humans, sharing many morphologic and physiologic similarities in the central nervous system. These similarities increase the likelihood that studies in aged nonhuman primates will provide information about drugs that is relevant to humans. Nonhuman primates offer additional advantages for neurobehavioral animal models of aging in that many of the behavioral processes thought to be affected by aging (e. g. reaction time, attention, learning and memory) can be studied easily in nonhuman primates. Evidence is beginning to accumulate suggesting that certain neurological and behavioral deficits are observed in aged human and in nonhuman primates (Bartus 1979; Struble et al. 1982; Wisniewski et al. 1973).

PROCEDURE

The apparatus developed specifically for the series of studies used to develop the primate model was the Automated General Experimental Device (AGED), the rationale upon which its development was based and its application to geriatric research have been discussed in detail elsewhere (Bartus 1979; Bartus and Dean 1981; Dean et al. 1983). The AGED is a totally automated, computer-controlled testing system, whose prominent feature consists of a 3×3 matrix of stimulus response (SR) panels. Each SR panel is hinge-mounted directly in front of the reinforcement well so that when a panel is pushed, a red switch is magnetically activated and a reinforcement well is exposed. Both colored and patterned stimuli can be projected onto the SR panels. A plastic partition with a stimulus window and armholes separates the monkey from the SR matrix. The stimulus observation window is equipped with a photocell and an infrared light source to detect when the monkey's head is oriented toward the stimuli.

EVALUATION

The monkey must remember the stimulus location to get a reinforcement. Number of correct answers will be counted as well as the time until the monkey answers correctly.

CRITICAL ASSESSMENT OF THE METHOD

This system provides an accurate and objective means of collecting data under a number of behavioral paradigms. Further, this system provides experimental control over a number of variables that might confound behavioral measures (especially in drugged or aged subjects), thus simplifying the interpretation of differences observed and increasing the likelihood that these interpretations are accurate.

MODIFICATIONS OF THE METHOD

Cai and Arnstein (1997) described dose-dependent effects of Dopamine D1 receptor agonists on spatial working memory in aged monkeys.

Gandy and Walker (2004) proposed non-human primates for modeling hemorrhagic and encephalitic complications of Alzheimer amyloid-β vaccination and for assessing the efficacy and safety of immunotherapeutics in Alzheimer's disease.

Taffe et al. (2004) reported the development of a visuo-spatial paired-associate learning task in rhesus monkeys for early detection of symptoms of Alzheimer's type dementia.

F.3.6 Electrophysiological Methods

F.3.6.1 Long-Term Potentiation in Hippocampal Slices

PURPOSE AND RATIONALE

Long-term potentiation (LTP) in the hippocampus is perhaps the most dramatic example of activity-dependent synaptic plasticity that has yet been identified in the mammalian brain (Landfield and Deadwyler 1988; Bashir et al. 1994). A brief tetanus to any one of a number of monosynaptic excitatory pathways in the hippocampus can enhance the amplitude of evoked responses in the tetanized pathway for h or days thereafter. The fact that it occurs in the hippocampus has done much to stimulate interest in LTP as a synaptic model of memory, since the importance of the hippocampus for memory processing has been evident ever since the discovery that its bilateral removal in man causes a profound impairment in the ability to lay down new memories (Scoville and Milner 1957; Milner 1972). The particular popularity of the slice preparation prepared from the rodent hippocampus rests on its lamellar and laminar organization (Teyler 1980).

PROCEDURE

Transverse slices, 400 mm thick, are cut from the hippocampus of male albino guinea pigs weighing 250–300 g and prepared for electrophysiological recordings (Teyler 1980; Tanaka et al. 1989, 1990). Slices are incubated for 90–120 min in the recording chamber to allow equilibration with artificial cerebrospinal fluid. They are submerged, placed on a nylon mesh and perfused at a flow rate of 2–2.5 ml/min with oxygenated (95% O_2/5% CO_2) cerebrospinal fluid having the following composition (in mM): NaCl 124, KCl 3.3, $CaCl_2$ 2.5, KH_2PO_4 1.25, $MgSO_4$ 2, $NaHCO_3$ 25,7, glucose 10. The recording chamber is maintained at 33 ±2°C. The extracellular population spike is obtained using glass microelectrodes filled with 2 M NaCl, which have resistances of 2–5 MΩ. The electrodes are placed into the stratum pyramidale of CA1 or CA3. The signal is amplified and stored on magnetic discs for later analysis. The evoked responses are averaged and analyzed off-line using a personal computer. The magnitude of the population spike is evaluated by taking the voltage difference between the negative peak and the following positive peak. Either mossy fibers in the hilus fasciae or commissural/associational fibers in the stratum radiatum are activated via bipolar, sharpened silver wire electrodes insulated except for the tips. Constant current pulses (100 ms) are delivered with a frequency of 0.2 Hz, only during the test intervals. The stimulation intensity is adjusted to elicit the population spike of about 40% and 80% of its maximal amplitude in CA1 and CA3, respectively. After the baseline is recorded for 10–20 min, LTP is induced by repetitive stimulation of 100 pulses at 20 Hz for 5 s in CA1 and at 50 Hz for 2 s in CA3 at the same strength as for the test pulses. Responses by test pulses are recorded 0, 10, 20 and 30 min after repetitive stimulation. The test drugs are dissolved in the artificial cerebrospinal fluid and applied extracellularly at various concentrations by switching perfusion reservoirs.

EVALUATION

The time course of LTP is registered for CA1 and CA3. The mean percent increase in the amplitude of the population spike from baseline responses after drug application is compared with controls.

MODIFICATIONS OF THE METHOD

Fujii et al. (1997) studied the effects of an adenosine A_1 receptor antagonist, 8-cyclopentyltheophylline, on the reduction of long-term potentiation in CA1 neurons of **guinea pig** hippocampal slices. Reduction of long-term potentiation (depotentiation) was achieved by delivering a train of low-frequency afferent stimuli 20 min after the tetanus.

Behnisch and Reymann (1993) employed slices of hippocampal area CA1 in the **rat** to test the hypothesis that the activation of metabotropic glutamate receptors during tetanization is necessary for the maintenance of long-term potentiation.

Akhondzadeh and Stone (1995) studied the phenomenon of hippocampal long-term depression. Extracellular recordings were made in the CA1 pyramidal cell layer of **rat** hippocampal slices following ortho-

dromic stimulation of Schaffer collateral fibres in stratum radiatum.

Oomura et al. (1996) measured long-term potentiation in hippocampal slice preparations after a brief tetanic stimulation at the Schaffer collateral/-commissural afferents of senescence-accelerated **mice** which were treated from 3 weeks of age up to 10 months either with subcutaneous injections of acidic fibroblast growth factor or saline.

F.3.6.2 Long Term Potentiation in Vivo

PURPOSE AND RATIONALE

Placing recording and bipolar stimulating electrodes in the granule cell layer of the dentate gyrus and angular bundle allows the evaluation of long-term-potentiation *in vivo*, even in freely moving animals, and the comparison with effects on learning.

PROCEDURE

Female Sprague Dawley rats weighing 225–250 g are anesthetized with 1.5 g/kg urethane (i.p.) and placed in a Kopf stereotaxic instrument. The recording and bipolar stimulating electrodes are placed in the granule cell layer of the dentate gyrus and angular bundle, respectively (from bregma and cortical surface: Dentate: A.P. −4.0 mm, M.L. +2.4 mm, D.V. 3.0 mm. Angular bundle: A.P. −7.9 mm, M.L. +4.0 mm, D.V. −3.0 mm, incisor bar −5.0 mm). The recording electrodes are pulled from thin-walled glass capillary tubes, filled with 150 mM NaCl, and adjusted to resistances ranging from 2.0 to 4.0 MΩ. Stimulating electrodes are made from twisted nichrome wire with Teflon insulation, and approximately 0.75 mm separated each tip. The recording electrode is first lowered into area CA1 of the dorsal hippocampus. The stimulating electrode is then placed into the ipsilateral angular bundle. As the recording electrode is lowered further, field potentials are evoked to determine when the recording electrode enters the dentate granule cell layer.

All rats are maintained at 37°C. Responses are evoked using a Grass S-88 stimulator and a Microprobe System M-7070A amplifier, and are recorded on a Nicolet 310 oscilloscope.

Once the electrodes are appropriately placed, field potentials are generated over a range of stimulus intensities to generate an input/output (I/O) curve (pulse duration = 1 ms). The field potentials are quantified in two ways: The population spike (PS) is expressed as the distance from the deepest point (in mV) of negativity to the preceding highest positivity on the left and right side of the response, and then averaged. The slope of the rising phase of the population excitatory postsynaptic potential (pESP) is measured in mV/ms. The amplitude of the test pulse is based is based on the I/O

curve being 25% of the current intensity which evokes the maximal population spike. Long-term-potentiation is induced using three theta-burst stimulus trains, each delivered 1 min apart. Each train consists of five groups of four pulses at 100 Hz, separated by an interval of 150 ms. Each train is delivered at the stimulus intensity which evokes the maximal population spike at the I/O curve.

At the end of the experiment, the electrode placements are verified using standard histological techniques.

EVALUATION

Student's *t*-tests are used to assess the significance of differences between the means of both the population spike amplitudes and the pESP slopes.

CRITICAL ASSESSMENT OF THE METHOD

Hölscher et al. (1997a, 1997b, 2002) argued that high-frequency stimulation-induced long-term potentiation and low-frequency stimulation-induced depotentiation in area CA1 of the hippocampus are not good models for learning.

MODIFICATIONS OF THE METHOD

Errington et al. (1987) perfused a NMDA receptor antagonist through a push-pull cannula into the dentate gyrus of anesthetized **rats** in order to observe its effect on the induction and maintenance of long-term potentiation and on the increase in release of endogenous glutamate associated with long-term potentiation.

Bennett et al. (1992) recommended cytochrome oxidase inhibition as an animal model of Alzheimer's disease. Rats were infused chronically with the selective inhibitor of cytochrome oxidase, sodium azide, delivered via subcutaneously implanted minipumps. The azide treatment impaired both spatial and non-spatial learning. Further, the azide treatment inhibited a low-threshold form of hippocampal long-term potentiation, primed burst potentiation.

Croll et al. (1997) used this model to study time course and corresponding pathology of learning deficits in rats.

Brakebusch et al. (2002) found that mice deficient in brevican (a brain-specific proteoglycan) displayed impaired hippocampal CA1 long-term potentiation but showed no obvious deficits in learning and memory.

Namgung et al. (1995) described the characteristics of long-term potentiation in the intact **mouse**. Perforant path stimulation evoked both a population excitatory postsynaptic potential and a population spike potential from the hippocampal dentate gyrus in urethane anesthetized animals. Long-term potentiation, as measured by increased population-spike amplitude and population excitatory postsynaptic potential slope, was successfully induced and reliably maintained at a stable level for at least 12 h.

Davis et al. (1997) described a simple method for inducing and monitoring long-term potentiation at perforant path-granule cell synapses in the dentate gyrus of freely moving mice using readily available miniaturized components. Tetanic stimulation induced long-term potentiation of the field excitatory postsynaptic potential and the population spike which persisted for more than 24 h but was not present 10 days after the tetanus.

Jibiki et al. (1993) and Kubota et al. (1994) studied the drug-induced blockade of induction of long-term potentiation in perforant path-dentate gyrus pathway in chronically prepared **rabbits**.

Gutnikov and Gaffan (1996) studied the effects of a NMDA receptor antagonist on memory acquisition and retrieval of visual-reward associations in the object-in-place memory task and on NMDA neurotoxicity in **rhesus monkeys**.

F.3.6.3 Long Latency Averaged Potentials

PURPOSE AND RATIONALE

Wirtz-Brugger et al. (1986, 1987) studied long latency averaged evoked potentials (P300) in anesthetized rats as a possible model for detecting memory-enhancing drugs. The P300 waveform is described as a positive long-latency (∼ 300 ms) potential believed to reflect endogenous cognitive processes rather than exogenous physical parameters of the stimulus. Compounds that have been shown clinically to enhance cognitive ability also significantly increase the integrated area under the P300 wave.

PROCEDURE

Male Wistar rats weighing 300–500 g are anesthetized with 120 mg/kg i.p. Inactin. Stainless steel screws serve as recording electrodes located at the surface of the cortex of seven distinct brain areas: posterior: Pz (midline), P3, P4 (lateral); central: Cz (midline); and frontal: Fz (midline, F3, F4 (lateral). A linked reference is provided with platinum needle electrodes behind the ears. All leads are fed into a digital averaging computer. Event-related potentials are elicited in response to an oddball paradigm of two tones (500 Hz frequent and 3 KHz rare) randomly presented with a probability of 10% for the rare tone. The intensity of the tones is 95 bB, pulse duration 100 ms, rise/fall 9.9 ms. The auditory stimuli are delivered bilaterally at a rate of 0.3/s through special Nicolet tubal tip inserts into the ear of each subject. One repetition of the paradigm consists of 300 tones. It is presented twice, before and after drug application. Evaluation of the rare responses consists of defining and comparing the P300 in terms of integrated area before and after drug. P300 area is calculated by integration of area under the curve.

EVALUATION

Values are expressed as means and standard error per group and percent changes from control. Statistical evaluation consists of paired *t*-tests to demonstrate significant differences.

MODIFICATIONS OF THE METHOD

Caudle (1993) demonstrated long latency potentials in the CA1 regions of the rat hippocampal slice suggesting that the *in vitro* P3 is an *in vitro* version of the long latency evoked potential known as the P300 in electroencephalogram studies.

Ikeda et al. (1995) studied the effect on a nootropic compound on event-related potential P300 in rats with lesions of the nucleus basalis magnocellularis.

Antal et al. (1994) studied the influence of cholinergic agents on visual discrimination and P300 in the behaving **monkey**. P300 latency was increased following scopolamine administration. Acetyl-L-carnitine increased P300 amplitude and decreased its latency.

In **squirrel monkeys**, clonidine significantly decreased the area and increased the latency of P300-like potential (Swick et al. 1993).

Kaga et al. (1992) studied P300 and choline acetyltransferase immunohistochemistry in septohippocampal neurons of **cats**.

Wang et al. (1999) reported that P300-like potential depends on muscarinic receptor activation in **rabbits**.

F.3.7
Metabolic Influence

F.3.7.1
Sodium Nitrite Intoxication ($NaNO_2$)

PURPOSE AND RATIONALE

The manipulation of brain metabolism was used to show the beneficial effects of substances which influence learning and memory. Gibson et al. (1976, 1978), during investigations of sodium-nitrite ($NaNO_2$) on brain metabolism, demonstrated a close relationship between oxidative metabolism and cholinergic function. From the results of their studies, the possibility cannot be excluded that an induction of impairment of the cholinergic transmission in addition to a deficiency in brain metabolisms was induced (Schindler et al. 1984).

PROCEDURE

Male or female mice are used and maintained under standard conditions. Chemical hypoxia is induced by the injection of sodium nitrite ($NaNO_2$: 250 mg/kg s.c.), which reduces the oxygen-carrying capacity of the blood by converting hemoglobin to methemoglobin. This lethal dose (lethality 100% of controls) is injected 60 min after drug treatment. Immediately after the $NaNO_2$-injection the animals are placed in small Makrolon cages and the time between injection of $NaNO_2$ and cessation of respiration is recorded (Hock 1993).

EVALUATION

The time between injection of $NaNO_2$ and cessation of respiration is recorded. The prolongation of survival time is expressed in percent.

MODIFICATIONS OF THE METHOD

Using lower doses of $NaNO_2$ mice are submitted to a positive reinforcement paradigm (Schindler et al. 1984). Groups of 10 mice are water deprived for 24 h. The mice are treated with the test compound 45 min before they are placed individually in a large chamber. On one wall of the chamber, there is a small compartment that contains a water bottle. The mouse easily finds the bottle and is allowed to drink for 30 s. Each mouse then receives a subcutaneous injection of 75 mg/kg $NaNO_2$ before being returned to the home cage. Twenty-four hours later, retention testing is performed by placing the mouse in the large chamber, but at this time, the small compartment is kept empty. The duration and frequency of the mouse's exploration of the small compartment while searching for water is evaluated over a period of 3 min. An increase in duration and frequency correlates with improved learning.

The tight rope test (Barclay et al. 1981) was used to test the effect of $NaNO_2$ with and without treatment on performance in mice (Peterson and Gibson 1982; Gibson et al. 1983).

F.4
Animals with Memory Deficits

F.4.1
Memory Deficits After Cerebral Lesions

PURPOSE AND RATIONALE

Cerebral lesions have been used as a method of determining the involvement of a particular brain area in performing a particular function. By training an animal to perform a certain task, then lesioning a specific brain area, one can determine whether that area of the brain

is necessary or sufficient to perform that function; alternatively one can lesion before training and measure the rate of acquisition to determine the involvement of a brain area in learning a particular task.

Memory impairment has been produced by lesions caused by bilateral injections of ibotenic acid into the basal forebrain of rats. Water-maze tasks, habituation tasks, passive avoidance tasks with a light/dark compartment apparatus, and inhibition of the decrease of choline acetyltransferase activity in the cortex can be used to evaluate the effect of drugs (Fuji et al. 1993a).

PROCEDURE

Male Wistar rats weighing 270–310 g are anesthetized with sodium pentobarbital (45 mg/kg i.p.) and placed in a stereotaxic apparatus. Neurotoxic lesions of the basal forebrain are produced by injection of ibotenic acid. An injection needle connected to a 5-µl microsyringe is inserted into the basal forebrain, identified according to the Paxinos and Watson (1986) atlas of rat brain (1.5 mm posterior, 2.8 mm bilateral to the bregma, 7.3 mm below the dura). Ibotenic acid is dissolved in 50 mM Na phosphate buffer at a concentration of 12 µg/ml, and then 0.5 ml (6 µg per side) is infused for 5 min. The injection needle is left in place for an additional 5 min to allow the toxin to diffuse away from the needle tip. One week later, the contralateral side is treated in the same manner. The same procedure is used to administer microinjections of 50 mM Na phosphate buffer into the basal forebrain of sham-operated rats. The lesion sites are mainly distributed in the ventromedial globus pallidus.

Then, 3–5 weeks after the first lesion, the animals are tested on the acquisition of a task in a Morris water maze (Morris 1981), on a habituation task in a novel situation, and on a passive avoidance task with light and dark compartments. The rats are treated once a day during the experiment.

After the behavioral experiments, the animals are sacrificed for determination of choline acetyltransferase activity in the brain according to Fonnum (1975). The tissue is homogenized (4% w/v) in cold 50 mM Na phosphate buffer (pH 7.4), and Triton X-100 (0.55, v/v) is added to homogenates to ensure enzyme release. To 75 µl of enzyme solution, 125 µl of substrate mixture {0.4 mM [^{14}C]acetyl-Co A (50.6 mCi/mmol or 1.87 GBq/mmol), 300 mM NaCl, 50 mM Na phosphate buffer (pH 7.4), 8 mM choline chloride, 20 mM EDTA-2Na, and 0.1 mM physostigmine} is added in a scintillation vial and the mixture is incubated at 37°C for 30 min. After the incubation, 0.8 ml of cold 50 mM phosphate buffer, 0.5 ml of acetonitrile containing 2.5 mg of tetraphenylborate and 2.0 ml toluene are added to the scintillation vial. The vials are shaken lightly and allowed to stand overnight before radioactivity is determined.

EVALUATION

Data are evaluated by usual statistical means. All analyses are followed by a Bonferroni's test.

MODIFICATIONS OF THE METHOD

Although usually permanent, temporary lesions can be made by cooling the tissue of interest or by injecting a local anesthetic. Permanent lesions are of three primary types: **aspirative, electrical, and chemical** (McDonald and Overmier 1998).

Aspirative lesions are made by sucking out the tissue of interest. Lesions of this type are not selective with respect to tissue type. Neurons, support cells, and fibers coursing through the area are all eliminated.

Electrical lesions are also non-selective, i. e., they destroy all tissue types in the lesion area, including cell bodies, support cells, and fibers of passage. Harder et al. (1996) performed bilateral transection of the fornix in young adult **marmosets** producing a specific pattern of cognitive deficits, notably a lack of ability to recall visuospatial tasks learnt preoperatively, and a deficit in acquiring new visuospatial tasks following transection. This impairment could be ameliorated by cholinergic agonists and 5-HT_{1A} antagonists.

Ennaceur (1998) studied the effects of electrolytic lesions of the Medial Septum/Vertical Diagonal Band of Broca, the Globus Pallidus and the Substantia Innominata/Ventral Pallidum on the performance of **rats** in object-recognition memory and radial-maze learning tasks.

Chambers et al. (1996) proposed lesioning of the ventral hypothalamus in neonatal rats as an experimental model of schizophrenia with learning deficits.

Chen et al. (1997) observed a remarkable impairment of passive avoidance response by bilateral dorsal hippocampal lesions in rats.

In several studies **monkeys** were used:

Gaffan (1994) described a model of episodic memory impairment in monkeys with fornix transection.

Alvarez et al. (1994) studied memory functions in monkeys with lesions of the hippocampal formation and adjacent cortex.

Chemical lesions are induced by injecting chemical agents into specific brain sites. Chemical agents induce a more selective lesion, typically destroying cell bodies and dendrites while sparing axons (Coyle et al. 1981; Coyle 1983; Choi 1992).

The most commonly used neurotoxins in memory research are **excitatory amino acid neurotransmitters**, such as glutamate, and glutamate analogs such as ibotenate, NMDA, kainate, quisqualate and AMPA (Dunnet et al. 1989; Connor et al. 1991). These excitotoxins vary in their selectivity for the types of tissue damaged. For example, glutaminergic receptors in the hippocampal CA3 pyramidal cell layer are predominantly of the kainate subtype (Monaghan et al. 1983), and thus kainate administration induces more damage at this site than in areas of the hippocampus, in which kainate receptor density is not as great. In contrast, glutamate receptors in the dentate granule cells are primarily of the quisqualate and NMDA subtypes. As a result, they are relatively insensitive to damage by kainate administration, but highly vulnerable to ibotenate insult (Köhler and Schwarcz 1983).

Ishikawa et al. (1997) reported hippocampal-degeneration-inducing impairment of learning in rats after neonatal administration of monosodium glutamate or oral administration of trimethylin.

Misztal et al. (1996) produced a short-term working memory deficit in rats by intraventricular infusion of quinolinic acid via ALZET osmotic minipumps for 2 weeks.

Zalewska-Wiñska and Wísniewski (2000) tested the influence of (S)-3,5-DHPG, a selective agonist of group 1 metabotropic glutamate receptors, on the activity of the central nervous system in rats.

Zajaczkowski and Danysz (1997) induced deficits of spatial learning in rats by entorhinal cortex lesions with quinolinic acid.

Yamamoto et al. (2003) and Ahmed et al. (2004) infused ibotenic acid into the nucleus basalis magnocellularis of rats in order to establish a model of Alzheimer's disease.

Spowart-Manning and van der Staay (2005) found spatial discrimination deficits in the Morris water escape task in rats after bilateral lesions of the entorhinal cortex by injections of ibotenic acid.

Car and Wiśniewski (1998) evaluated the effect of intracerebroventricular injection of baclofen and AP-7 on behavior in rats.

Two types of chemical lesions are used to examine the role of the cholinergic system in learning and memory. Ethylcholine mustard aziridinium ion, or **AF64A**, is a neurotoxin that is specific to cholinergic cells (Mantione et al. 1981). However, some noncholinergic cells may also be destroyed. A neurotoxin more specific to cholinergic cells in the basal forebrain was described by Wiley et al. (1991). The compound, ^{192}IgG-saporin, is a monoclonal antibody to the low-affinity nerve growth factor receptor (^{192}IgG) conjugated to saporin, a ribosome-inactivating protein. It specifically destroys cholinergic cell bodies in the nucleus basalis Meynert and the medial septal area. Cholinergic cells in the striatum, ventral pallidum, and thalamus are spared, as are non-cholinergic cells.

Fuji et al. (1993b) studied autoradiographically the influence of drugs on alterations in muscarinic cholinergic receptor [^{3}H]QNB binding induced by basal forebrain lesion in rats.

In order to confirm the antisense effects of sigma$_1$ (σ_1) receptor agonists on memory, Maurice et al. (2001) administered a phosphorothioate-modified antisense oligonucleotide and a mismatched analog intracerebroventricularly to mice.

Brandeis et al. (1995) induced deficits in cognitive functioning by stereotaxic application of AF64A (3 nmol/2 µl per side) in both lateral cerebral ventricles in rats.

Carli et al. (1997) caused impairment of spatial learning in rats by intrahippocampal administration of scopolamine or 7-chloro-kynurenic acid.

Abe et al. (1998) investigated the effect of a benzodiazepine receptor partial inverse agonist on the impairment of spatial memory in basal forebrain-lesioned rats.

Stancheva et al. (1993) studied in rats the effect of neonatal 6-hydroxydopamine treatment on learning and retention and on the level of biogenic monoamines in some brain structures as well as the influence of nootropic drugs.

Nitta et al. (1997) reported that the continuous infusion of anti-nerve growth factor monoclonal antibody into the septum of rats produces an impairment of memory.

Inagawa (1994) reported impairment of spatial working memory in rats induced by intracerebroventricular injection of the cholinergic neurotoxin, ethylcholine mustard aziridinium picrylsulfonate.

Bjugstad et al. (1998) gave chronic intraventricular infusions of tumor necrosis factor alpha to rats and found symptoms resembling the AIDS dementia complex in humans, including learning and memory impairment.

Beers et al. (1995) described spatial recognition memory deficits in Lewis rats following encephalitis after intranasal inoculation with herpes simplex virus type 1.

Harkany et al. (1998) showed that bilateral injection of β-amyloid [Phe(SO$_3$H)^{24}]25–35 in rat nucleus basalis magnocellularis induces behavioral dysfunc-

tions, impairs learning and memory, and disrupts cortical cholinergic innervation.

Miguel-Hidalgo et al. (1998) induced specific degeneration of a large part of neurons in the lateral blade of the gyrus dentatus by small intrahippocampal injections of water with or without **β-amyloid 1–28** fragment.

Ogasawara et al. (1999) studied the effects of NS-105, a cognition enhancer, on memory disruption by scopolamine, electrolytic lesion of the nucleus basalis magnocellularis, as well as by AF64A-, baclofen-, cerebral ischemia- and electroconvulsive shock-induced memory disruption in rats.

Baldi et al. (1999) studied the effects of combined medial septal area, fimbria-fornix and entorhinal cortex **tetrodotoxin** inactivations on passive avoidance response consolidation in the rat. Functional inactivation of these brain areas was induced by administration of 5 ng tetrodotoxin dissolved in 0.5 µl saline according to the respective stereotaxic coordinates.

Intracerebroventicular injection of **streptozotocin**, in a subdiabetic dose to rats, causes prolonged impairment of brain glucose and energy metabolism. This is accompanied by impairment in learning and memory (Lannert and Hoyer 1998; Sharma and Gupta 2000, 2002).

Razani et al. (2001) reported that intracerebroventricular infusion of the 5-hydroxytryptamine$_{1A}$ receptor agonist 8-hydroxy-2-(di-*N*-propylamino)tetraline (8-OH-DPAT) in rats induced a deficit in passive avoidance retention, which was attenuated by intraventricular galanin infusion.

Tchekalarova et al. (2003) showed that intracerebroventricular infusion of sarmesin, an angiotensin II analog, decreased seizure susceptibility, memory retention, and nociception in rats.

Rall et al. (2003) demonstrated that infusion of a **cyclooxygenase-2 inhibitor** into the dorsal hippocampus attenuates memory acquisition in rats.

Yu et al. (1997) reported significant impairment of learning and memory ability in **mice** after hippocampal microinfusion with colchicine.

Chapman et al. (1998) observed spatial working memory impairment in apolipoprotein E-deficient mice.

English et al. (1998) showed that infection with the LP-BM5 murine leukemia virus causes an AIDS-like syndrome – murine acquired immunodeficiency syndrome – in C57B1/6 mice and impairs spatial learning without gross motor impairment.

Hiramatsu and Inoue (1999) studied the effects of nocistatin on nociceptin-induced impairment of learning and memory in mice. The drugs were injected into the lateral ventricle of the mouse brain in a volume of 5 µl/mouse under brief ether anesthesia.

Fernandez-Ruiz et al. (1995) studied the long-term cognitive impairment in MPTP-treated **rhesus monkeys**.

Ye et al. (1999) evaluated a reversible acetylcholinesterase inhibitor for its ability to reverse the deficits in spatial memory produced by scopolamine in young adult monkeys and those that are naturally occurring in aged monkeys in a delayed-response task.

Yoneoka et al. (1999) established an adult rat model for the late onset of **radiation-induced cognitive dysfunctio**n in adult rats. Rats were irradiated with a total dose of 40 Gy, given as eight fractions in 24 days. At 12 months after irradiation, the passive avoidance task revealed a deterioration of the cognitive function.

F.4.2
Cognitive Deficits After Cerebral Ischemia

PURPOSE AND RATIONALE

Cerebral vessel occlusion has been used as a model for stroke and multi-infarct cerebral dysfunction (see A.8.1).

Impairment of cerebral metabolism induced by reduced blood supply is known to induce cognitive deficits (Gibson et al. 1981). Because of the absence of posterior communicating arteries in the brain of **Mongolian gerbils**, complete forebrain ischemia can be produced by occluding both common carotid arteries resulting in amnesia (Levine and Sohn 1969; Schindler 1983; Schindler et al. 1984; Chandler et al. 1985; Lundy et al. 1986).

PROCEDURE

Male Mongolian gerbils (strain Hoe:Gerk) weighing 50–70 g are anesthetized by i.p. pentobarbital injection. Both common carotid arteries are exposed through a ventral neck incision and occluded for 5 or 10 min with miniature aneurysm clips. In sham-operated controls, the common carotid arteries are exposed but not occluded. Then, 24 h after occlusion, each animal is placed in the bright part of a light/dark-chambered apparatus for training. After a brief orientation period, the gerbil enters the second, dark chamber. Once inside the second chamber, the door is closed which prevents the animal from escaping, and a 100-V, 2-s foot shock is applied through the grid floor. The gerbil is then returned to the home cage. Testing is repeated 24 h later by placing the animal again in the bright chamber. The latency in entering the second dark chamber within a 5-min test session is measured electronically. The latency compared with sham-operated controls is decreased depending on the duration of ischemia. After drug treatment, an increase of latency before entering the dark compartment indicates good acquisition.

EVALUATION

Using various doses a dose-dependent increase of latency can be found after active drugs, sometimes resulting in inverse U-shaped dose–response curves.

Tamura et al. (2001) described the effect of permanent middle cerebral artery occlusion on cognitive impairments in **rats**.

PROCEDURE

Rats are anesthetized with 2% halothane in a gas mixture of 30% O_2 and 70% N_2O, then maintained with

1% halothane. Under anesthesia, the head is placed in a stereotaxic apparatus and the skin is incised between the external foramen and external canthus. A small hole is bored in the cranial bone under a surgical microscope. The dura is dissected and the middle cerebral artery exposed. The middle cerebral artery is electrically coagulated from its origin using a bipolar forceps. In sham-operated rats, the dura is exposed but the middle cerebral artery is not occluded.

MODIFICATIONS OF THE METHOD

Using a similar method, Yamaguchi et al. (1995) found that a muscarinic agonist improves the impairment of learning behavior in rats. Yonemori et al. (1996) tested spatial memory disturbances after focal cerebral ischemia in rats.

Noda et al. (1995) used a somewhat modified technique of permanent occlusion of the middle cerebral artery. Rats were anesthetized with halothane 2%. After the temporal muscle was retracted via a transretroorbital approach without removal of the temporalis muscle and zygomatic arch, the animals underwent a left subtemporal craniotomy. The stem of the middle cerebral artery was electrocauterized just medial to the olfactory tract and waa cut to ensure the completeness of the vascular occlusion.

Another technique was described by Borlongan et al. (1995). Rats were anesthetized with 60 mg/kg pentobarbital, then shaved on the ventral portion of the neck. A V-shaped incision was made beginning at the caudal end of the sternomastoid and sternothyroid muscles, cutting towards the ears. After dissection, the right common carotid artery was exposed and carefully separated from the vagus nerve. The external carotid artery was then tied off tightly with two 5.0 silk sutures. The internal carotid artery was tied loosely and a small clamp was placed distal to the tie. Upon clamping off the common carotid artery, a small cut was made in the external carotid artery just above the bifurcation. The embolus was then introduced through the external carotid artery and guided into the internal carotid artery until resistance was felt. Mean length of the embolus inserted was 18–22 mm. The embolus, which was made by coating a 30-mm piece of 4.0 silk suture with silicone mixed with hardener, blocked the origin of the right middle cerebral artery. The embolus was left in place for 1 h. After removal of the embolus, the entry point of the embolus was cauterized, and the skin sutured.

Plaschke et al. (1999) used a model of permanent brain vessel occlusion originally described by Pulsinelli and Brierley (1979) to study the interrelation between cerebral energy metabolism and behavior in rats.

Kimura et al. (2000) investigated the pathogenesis of vascular dementia in stroke-prone spontaneously hypertensive rats.

Hattori et al. (2000) tested cognitive deficits after focal cerebral ischemia in **mice**. Adult male C57/BL6 mice were anesthetized with 1%–1.5% halothane in oxygen-enriched air delivered by a face mask, then subjected to 60 or 90 min of intraluminal middle coronary artery occlusion or sham surgery. Unilateral middle coronary artery occlusion was achieved by introducing a 6–0 nylon monofilament into the right internal carotid artery through the external carotid artery, then positioning the filament tip for occlusion at a distance of 6 mm beyond the internal artery-pterygopalatine artery bifurcation. Then, the wound was closed and the animal was allowed to emerge from anesthesia in its home cage. After 60 or 90 min of occlusion, the animals were briefly re-anesthetized with halothane, and the monofilament was removed. Cognitive deficits were evaluated by several behavioral tests and in the elevated plus-maze test.

F.4.3
Strains with Hereditary Memory Deficits

Several animal strains have been recommended to study age-dependent memory deficits, such as the **senescence-accelerated mouse (SAM)** (Takeda et al. 1981, 1994, 1996, 1997; Fujibayashi et al. 1994; Maurice et al. 1996; Nishiyama et al. 1997; Flood and Morley 1998; Markowska et al. 1998). SAM includes accelerated senescence prone SAMP (SAMP1, P2, P3, P6; P7, P8, P9 and P10) and accelerated senescence-resistant mouse SAMR (SAMR1, R2 and R4) (Hosokawa et al. 1984; Yagi et al. 1998). SAMP is associated with signs of advanced senescence, such as reduced activity, hair loss, lack of hair glossiness, skin coarseness, periophthalmic lesions, increased lordokyphosis of the spine, and a shortened life span. In the SAMP series, SAMP8 showed more spontaneous age-related detoriation of memory and learning abilities in passive avoidance response tests (Miyamoto et al. 1986), especially in the acquisition stage (Yagi et al. 1988), than did control SAMR1 mice.

Shimada (1999) reviewed age-dependent cerebral atrophy and cognitive dysfunction in SAMP10 mice.

Banks et al. (2003) found an impairment of efflux of human and mouse amyloid β proteins 1–40 and 1–42 from brain in SAMP8 mice.

Farr et al. (2004) reported that dehydroepiandrosterone sulfate improved learning and memory in aged SAMP8 mice.

Epileptic fowl having a hereditary form of primary generalized epilepsy are characterized by tonic-clonic seizures (Gervais-Fagnou and Tuckek 1996).

F.4.4
Genetically Modified Animals

The use of genetically altered animals in biological research has also affected research in learning

and memory. Genetically engineered strains of mice, modified by transgenesis or gene targeting ("knockout") have been generated and are used as research tools for deciphering the genetic basis of behavior. These animals may be helpful to evaluate the efficacy of new pharmacological treatments (Mayford et al. 1997; Costentin 1998; Anagnostopoulos et al. 2001; Higgins and Jacobsen 2003). Various authors described transgenic mouse models of Alzheimer's disease (van Leuven 2000; Götz 2001; Janus and Westaway 2001).

Several strains were described, such as:

Transgenic mice, which **overexpress S100β**, a calcium binding astrocytic protein influencing hippocampal long-term potentiation (LTP) and depression (LTD) (Roder et al. 1996),

Transgenic **Cu/Zn-SOD mice overexpressing the gene encoding copper/zinc superoxide dismutase** which is also overexpressed in human Down syndrome (Gahtan et al. 1998),

a mutant mice strain exhibiting delayed Wallerian degeneration (Fox and Faden 1998),

Mice with a **modified β-amyloid precursor protein gene** (Tremml et al. 1998; Kim et al. 2004),

Gozes et al. (1993) reported learning impairment and prolonged retardation in memory acquisition in transgenic mice carrying a chimeric gene for the vasoactive intestinal peptide (VIP).

Franowicz et al. (2002) compared mice with a point mutation of the α_{2A}-adrenoceptor, which serves a functional knockout with wild mice. Working memory performance was impaired and the cognitive enhancement by guanfacine was lost.

Silva et al. (1992) studied memory mechanisms in mutant mice that do not express the alpha-calcium-calmodulin kinase II. These mice are deficient to produce hippocampal long-term potentiation and were recommended as a suitable model for studying the relation between long-term potentiation and the learning process.

Moechars et al. (1999) reported early phenotypic changes in transgenic mice cloned by cDNA coding of human wild-type **APP (695 isoform**), the Swedish (K670N,M671L) mutant (770 isoform) and the London (V642I) mutant (695 isoform) in the pTSC vector in the mouse *thy-1* gene (Moechars et al. 1996).

Strazielle et al. (2003) investigated regional brain cytochrome oxidase activity in β-amyloid precursor protein transgenic mice with the Swedish mutation. **APP23 mice** were generated under the control of the murine Thy-1 gene promoter and were backcrossed by several generations to the C57BL6J background (Sturchler Pierrat et al. 1997; Phinney et al. 1999; Boncristiano et al. 2002).

Using this model, Kelley et al. (2003) reported progressive age-related impairment of cognitive behavior in APP23 transgenic mice.

Van Dam et al. (2005) described the symptomatic effects of donepezil, rivastigmine, galantamine and memantine of cognitive deficits in the APP23 model.

Johnson-Wood et al. (1997) studied amyloid precursor protein processing and Aβ_{42} deposition in the PDAPP transgenic mouse model of Alzheimer's disease.

Touma et al. (2004) investigated the TgCRND8 line, a double mutant (Swedish and Indiana) human APP_{695} model of Alzheimer's disease, generated by Chishti et al. (2001).

Steiner et al. (2001) found that **galanin transgenic mice** display cognitive and neurochemical deficits characteristic of Alzheimer's disease. The mouse galanin gene was coupled to the human dopamine β-hydoxylase reporter (Mazarati et al. 2000; Cadd et al. 1992).

Huber et al. (2002) and Qin et al. (2002) described a **fragile X knockout mouse** (*fmr1*KO) mouse, which resembles the fragile X mental retardation syndrome in humans.

Richardson et al. (2003) described a transgenic mouse line overexpressing the 695-amino-acid isoforms of human amyloid precursor protein harboring the Swedish double familial Alzheimer's disease mutation. This line, referred as **TAS10**, exhibits neuropathological features and cognitive deficits that are closely related to the accumulation of Aβ in their brain and that are reminiscent to those observed in Alzheimer's disease.

Oddo et al. (2003) generated a triple transgenic model of Alzheimer's disease harboring three mutant genes: **β-amyloid precursor protein (βAPP_{Swe})**, **presenilin-1 ($PS1_{M146V}$)**, and **tau P_{301L}**. The mice progressively develop Aβ and tau pathology, with a temporal- and regional-specific profile that closely mimics their development in the human Alzheimer's disease brain.

The **Tg2576 transgenic model** of Alzheimer's disease was studied by several authors (Hsiao et al. 1996; Haugabook et al. 2001; King and Arendash 2002; Lehman et al. 2003; Li et al. 2003; Parvathenani et al. 2003; Quinn et al. 2003; Zong et al. 2003; Middei et al. 2004; Rodrigo et al. 2004). Tg2576 transgenic mice overexpressing a mutant gene for β-amyloid precursor protein develop Aβ deposits at the age of 9–11 months. At this time, the animals are impaired in Y-maze spon-

taneous alteration, visible platform recognition, and several sensorimotor tasks. Gong et al. (2004) tested immunization of Alzheimer model (Tg2576) mice with adenovirus vectors encoding amyloid β-protein and granulocyte-macrophage colony-stimulating factor (GM-CSF) and found a reduction of amyloid load in the brain.

Skovronsky et al. (2000) synthesized a fluorescent ligand, [(*trans,trans*)-1-bromo-2,5-bis-(3-hydroxycarbonyl-4-hydroxy)-styrylbenzene (BSB)] which allows *in vivo* detection of amyloid plaques in the Tg2576 transgenic mouse model of Alzheimer's disease.

Tanemura et al. (2001, 2002) and Tatebayashi et al. (2002) generated **Tg mouse lines expressing R406W human tau**.

Reilly et al. (2003) analyzed amyloid deposition in the hippocampus and entorhinal cortex in a transgenic mouse model. Heterozygous **PDAPP transgenic mice** carrying the APPV717F familial AD mutation (Murrell et al. 1991) were bred from the established line PDAPP-109 over several generations on hybrid background representing combinations of C57BL/6. DBNA, and Swiss-Webster strains (Games et al. 1995).

Using these mice strains, Rockenstein et al. (1995) investigated levels and alternative splicing of amyloid β protein precursor (APP) transcripts in brains of APP transgenic mice.

Postina et al. (2004) generated transgenic **mice overexpressing either ADAM10** or a catalytically inactive mutant. ADAM (adisintegrin and metalloprotease) 10 has many properties of a physiologically relevant α-secretase: it cleaves APP-derived peptides at the main α-secretase cleavage site between positions 16 and 17 of the Aβ region and is expressed in mouse and human brain (Hartmann et al. 2002). A disintegrin-metalloproteinase prevents amyloid plaque formation and hippocampal defects in an Alzheimer's disease mouse model.

Apolipoprotein E plays a major role in the amyloid cascade. Xu et al. (1999), Levi et al. (2003), Ophir et al. (2003) and Dolev and Michaelson (2004) used **apoE3- and apoE4-transgenic mice** for their studies.

Oike et al. (1999) generated a mouse model of the **Rubinstein-Taybi syndrome** by an insertional mutation into the cyclic AMP response element-binding protein gene. These mice showed deficiencies in long-term memory and other clinical features of the Rubinstein-Taybi syndrome, such as growth retardation, retarded osseous maturation, hypoplastic maxilla, cardiac anomalies, and skeletal abnormalities.

Impairment of the ubiquitin/proteasome system has been proposed to play a role in neurodegenerative disorders such as Alzheimer's and Parkinson's diseases. Lindsten et al. (2003) developed a model for *in vivo* analysis of the **ubiquitin/proteasome system** by generating mouse strains transgenic for a green fluorescent protein reporter carrying a constitutively active degradation signal.

Higuchi et al. (2005) generated transgenic **mice that overexpress human calplastatin**, a specific and the only natural inhibitor of calpains. Distinct mechanistic roles of calpain and caspase activation in neurodegeneration were revealed in these mice.

Hoyle et al. (2006) reported impaired performance of **alpha7 nicotinic receptor knockout mice** in the five-choice serial reaction time task.

Doubly transgenic mice have been used by several authors to analyze Alzheimer-like pathology (Arendash et al. 2001; Battaglia et al. 2003; Gong et al. 2004; Trinchese et al. 2004).

F.4.5 Studies in Invertebrate Animals

F.4.5.1 Studies in Caenorhabditis Elegans

The worm *Caenorhabditis elegans* has been recommended as a model of human disease (Baumeister 2002). Link (2001, 2005) reviewed invertebrate models of Alzheimer's disease with special emphasis on *Caenorhabditis elegans.*

Link et al. (2001) reported visualization of fibrillar amyloid deposits in living, transgenic *Caenorhabditis elegans* animals using the sensitive amyloid dye X-34.

Drake et al. (2003) found that oxidative stress precedes fibrillar deposition of Alzheimer's disease amyloid β-peptide (1–42) in a transgenic *Caenorhabditis elegans* model.

Link et al. (2003) described gene expression analysis in a transgenic *Caenorhabditis elegans* Alzheimer's disease model. Transgenic *Caenorhabditis elegans* animals were engineered to inducibly express the human beta amyloid peptide.

Strayer et al. (2003) reported that expression of the small heat-shock protein Hsp16–2 in *Caenorhabditis elegans* is suppressed by *Ginkgo biloba* extract EGb 761.

F.4.5.2 Studies in Drosophila

Götz et al. (2004) reviewed transgenic animal models of Alzheimer's disease and related disorders mentioning mice, fish (*Petromyzon marinus*, the sea lamprey), worms (*Caenorhabditis elegans*), and flies (*Drosophila melanogaster*).

Ferber (2001) recommended using the fruit fly to model tau malfunction.

Shulman and Feany (2003) conducted a genetic modifier screen in a *Drosophila* model of taupathy to investigate the molecular mechanisms responsible for Tau-induced neurodegeneration.

Finelli et al. (2004) showed that overexpression of Aβ42 peptides in the nervous system of *Drosophila melanogaster* results in phenotypes associated with neuronal degeneration in a dose- and age-dependent manner.

Crowther et al. (2004) reported that transgenic flies expressing the toxic β-amyloid develop neurodegeneration. The flies exhibit a clear phenotype from a few days of age, including reduced locomotor function, impaired olfactory memory and shortened lifespan. Therapeutic agents that interfere with the generation of toxic aggregates of β-amyloid peptides have been shown to rescue the flies. *Drosophila* is recommended as a model of Alzheimer's disease.

Iijima et al. (2004) used the *Drosophila* model to compare the specific pathological roles of human Aβ40 and Aβ42 in Alzheimer's disease.

Nichols (2006) published a survey on *Drosophila melanogaster* neurobiology, neuropharmacology, and how the fly can inform central nervous system drug discovery.

Chapter G
Effects On Peripheral Nerve Function

G.1 Local Anesthetic Activity

G.1.0.1 General Considerations

One 1′ has to generally distinguish between conduction anesthesia, infiltration anesthesia, and surface anesthesia (Fromherz 1922; Schaumann 1938), and special pharmacological tests have been developed for each of these.

The mode of action of local anesthetics has been reviewed by Ritchie and Greengard (1966), Ritchie (1971), Borchard (1977), Steiner (1978), Butterworth and Strichartz (1990).

G.1.1
Conduction Anesthesia

G.1.1.1
Conduction Anesthesia in the Sciatic Nerve of the Frog

PURPOSE AND RATIONALE

Based on earlier studies by Sollmann (1918), Fromherz (1922), Fußgänger and Schaumann (1931), and Bülbring and Wajda (1945) on plexus anesthesia in frogs, Ther (1953a, b, 1958) described a method for conduction anesthesia of the sciatic nerve in frogs.

PROCEDURE

Frogs (*Rana temporaria*) of either sex are used and are kept at 4°C. The frog is decapitated with a pair of scissors. The skin is incised in the thigh region at both sides and the sciatic nerves are carefully exposed in the thigh, avoiding any stretching and injury of the nerve. The frog is suspended on a vertical board. Small pieces of white cotton are soaked with different concentrations of the test preparations (between 0.05% and 1%) or the standard and placed gently around the sciatic nerve for 1 min. Then the cotton swab is removed and the frog is placed with its extremities into a bath with 0.65% NaCl solution. This allows testing for duration and reversibility of the local anesthetic effect. One side is used for the test preparation and the other for the standard (e. g., 0.25% butanilicaine). Every 3 min the frog is removed from the bath and the toes of the legs or the ankle joint are pinched three times with a small forceps. The reflex contraction is abolished when conduction anesthesia is effective. The stimuli are repeated every 3 min until anesthesia vanishes. Two to 5 frogs are used for each concentration.

EVALUATION

Time of onset and duration of anesthesia are recorded for each concentration. Time-response and dose-response curves can be established.

MODIFICATIONS OF THE METHOD

In the original method by Bülbring and Wajda (1945) the frogs were decapitated and the upper part of the spinal cord was destroyed down to the level of the third vertebra. The viscera are removed exposing the lumbar plexus without damaging it. The frog was pinned to a vertical board and the solution of the local anesthetic dissolved in 0.7% saline is put into the pocket formed by the lower abdomen. Different concentrations of HCl are used as stimuli into which the feet of the frog were immersed every min.

Idänpään-Heikkilä and Guilbaud (1999) used a **rat** model of trigeminal neuropathic pain where the neuropathy is produced by a chronic constriction injury of the infra-orbital branch of the trigeminal nerve, and studied the effects of various drugs on this purely sensory model of neuropathic pain (see H.1.2.11)

For mechanical stimulation, a graded series of ten of von Frey filaments with a bending force between 0.217 and 12.5 g was used. The stimuli were applied within the infra-orbital nerve territory, near the center of the vibrissal pad, on the hairy skin surrounding the mystacial vibrissae. Local injection of an local anesthetic (articaine) into the rostral orbital cavity of the lesioned side, into the close proximity of the ligated infra-orbital nerve increased the mechanical threshold to the upper level. The duration of the effect was dose-dependent.

G.1.1.2 Conduction Anesthesia in the Sciatic Nerve of the Rat

PURPOSE AND RATIONALE

Based on earlier studies (Truant 1958; Truant and Wiedling 1958/59, Åström and Persson 1961) Camougis and Takman (1971) have written a detailed description for testing conduction anesthesia of the sciatic nerve in the rat.

PROCEDURE

Male Wistar or Sprague Dawley rats weighing 125 to 175 g are used. The animal is suspended in a prone position by grasping the base of the tail and thoracic cage. A hind limb is extended to its full length and the depression for needle insertion is located by palpation with the left index finger. The site of injection is the area under the skin at the junction of the biceps femoris and the gluteus maximus muscles. The sciatic nerve is blocked in the midthigh region with 0.2 ml of the drug solution administered by a 24- to 25-gauge needle attached to a 0.25 ml tuberculin syringe. Usually a 1% solution of the test drug in 0.9% NaCl is used as a test solution. The other leg is used for a control drug (e. g., procaine or lidocaine). Immediately after the injection, repeated checks of the digit of the foot and the walking behavior are performed. In the normal foot, the digits are wide apart, while in the blocked leg the digits of the foot are close together. Also the successful block is evidenced by dragging of the leg and an inability of the animal to use the leg in walking up the inclined wire mesh cover of the cage. After the time of block for each leg is noted, each animal is examined every 5 to 10 min in order to note the time of recovery.

EVALUATION

From the data, averages for onset and duration of action are calculated, plus the frequency of blocks are noted. Using various doses of test compound and standard, dose-response curves can be established and potency ratios calculated.

MODIFICATIONS OF THE METHOD

With a similar technique Lembeck (1953) tested the effect of the added vasoconstringent agents adrenaline, noradrenaline and Corbasil to procaine.

Sciatic nerve blockade in the **rat** was used by Feldman and Covino (1988) to study comparative motor-blocking effects of bupivacaine and ropivacaine.

Grant et al. (1992) used a **rat** sciatic nerve model for independent assessment of sensory and motor block induced by local anesthetics. Motor block was assessed by measuring hind paw grip strength with a dynamometer. Sensory block was determined by measuring hind paw withdrawal latency from radiant heat.

Kohane et al. (1998) studied sciatic nerve blockade with ropivacaine and bupivacaine in infant, adolescent, and adult **rats**. Rats were anesthetized briefly with halothane by face mask. The sciatic block was conducted by introducing a 30-gauge needle posteromedially to the greater trochanter, pointing in an anteromedial direction. Once bone was contacted, the needle was withdrawn 1 mm and drug was injected. Nerve blockade was assessed by withdrawal of the hind leg after pinching the lateral aspect of the plantar surface, by a modified hot-plate test, by the positional placing response as a test of proprioception, by extensor postural thrust as a measure of motor strength, and by ability to hop. Thermal latency in the contralateral (uninjected) limb was determined as a measure of systemic toxicity.

Grant et al. (2001) tested perineural antinociceptive effects of opioids in a **rat** model. Analgesia was assessed using the hind paw latency response to radiant heat.

Luduena and Hoppe (1952) used **guinea pigs** to test sciatic nerve block by local anesthetics. The anesthetic solutions were injected close to the sciatic nerve. Sensory paralysis was determined by pricking the posterior site of the thigh with a needle. The effect on motor nerve fibers was determined by observing the abnormal position of the injected leg in locomotion.

Siems and Soehring (1952) described a model in **guinea pigs** resembling peridural and paravertebal anesthesia in man.

Åkerman et al. (1988) used **guinea pigs** to determine brachial plexus block. The syringe was directed towards a line between the head of the humerus and the manubrium of the sternum and the first ribs. The

needle was inserted about 1.5 cm into the pocket felt as a depression by palpation between the head of the humerus and sternum and associated structures. Following retraction of the needle by a few millimeters, 0.2 ml of the solution was injected. The orientation of the needle was changed 3–4 times during the injection to enable all branches of the plexus to be reached. Assessment was made of motor and sensory blockade.

Leszczynska and Kau (1992) used a sciatic nerve blockade method in **mice** to differentiate drug-induced local anesthesia from neuromuscular blockade. The drugs were injected into the popliteal space of the right hind-limb. A positive local anesthetic activity was recorded when a mouse was only able to walk using three limbs on an inverted wire mesh screen and the injected limb was hanging in the air. A positive neuromuscular blockade was recorded when a mouse could walk normally on the top of the wire mesh screen but was unable to stay on the inverted screen.

Thut et al. (1995) used the **rabbit** tooth-pulp assay (see H.1.2.8) to quantify efficacy and duration of antinociception by local anesthetics infiltrated into maxillary tissues.

Rosenberg and Heinonen (1983) found a differential sensitivity of A and C nerve fibers to long-acting local anesthetics.

The Local Anesthetics for Neuralgia Study Group (1994) designed a surgically implantable nerve irrigation system for intermittent delivery of local anesthetics and evaluated long-term performance and histocompatibility in rats.

G.1.1.3 Conduction Anesthesia on the Mouse Tail

PURPOSE AND RATIONALE

The radiant heat method as being used for evaluation of systemic analgesic activity (D'Armour et al. 1941; Ther et al. 1963; Grant et al. 1993) can also be used for determination of conduction anesthesia by injecting the local anesthetic into the root of the tail.

PROCEDURE

Groups of 10 mice (NMRI-strain) of both sexes with a weight between 18 and 22 g are used for each dose. Before administration of the test compound or the standard the normal reaction time is determined. The animal is placed into a small cage with an opening for the tail at the rear wall. The tail is hold gently by the investigator. By opening of a shutter, a light beam exerting radiant heat is directed to the proximal third of the tail. After about 6 s, the reaction of the animal is

observed by the investigator. The mouse tries to pull the tail away and turns the head. The shutter is closed with a switch when the investigator notices this reaction. Mice with a reaction time of more than 6 s are not used in the test.

The test compounds and the standard are injected in a volume of 0.1 ml on both sides in the area of the tail root. The animals are submitted to the radiant heat again after 10 min. The area of heating is about 1.5 cm distal to the injection site. For each individual animal the reaction time is noted.

EVALUATION

There are two possibilities for evaluation:

1. The average values of reaction time after each time interval are calculated and compared with the pretest value by analysis of significance.
2. At each time interval only those animals which show a reaction time twice as high or higher as the pretest value are regarded as positive. Percentages of positive animals are counted for each time interval and each dose and ED_{50} values are calculated according to LITCHFIELD and WILCOXON.

MODIFICATIONS OF THE METHOD

Bianchi (1956) used the tail-clip method of Haffner (1929) as a simple quantitative method for testing local anesthetics. Fully grown albino **mice** of either sex were used. A small artery clip with its blades covered by thin rubber tube was applied to the root of the tail. Those animals that did not show the pain reflex (the mice turn again and again trying to remove the clip) within 30 s were eliminated. The remainder received subcutaneously, about 1 cm from the root of the tail, 0.1 ml of the solution of drug. The pain reflex is tested 15 min after injection, applying the stimulus to the zone where the compound was injected. The proportion of animals that proved to be anesthetized was noted for each dose.

Saxen et al. (1993) and Smith (1997) described the mouse paw withdrawal assay: a method for determining the potency and duration of the effect of local anesthetics in mice. A standard rodent tail-flick apparatus was used to stimulate the dorsal skin of each hind paw in the mouse. The radiant heat intensity of the lamp was adjusted to yield hind paw withdrawal latencies of 6–8 s, with a 20-s cut-off time to prevent tissue damage. Testing was performed by gently restraining the animal in a small towel and passively placing one hind paw on the stage so that the animal was free to withdraw its paw from the stimulus without restriction. Paws were tested in alternative order (right, then left; left, the right, etc.) to minimize procedural bias. The individual left and right paw withdrawal latency times were determined in each mouse and the difference between left and right latencies were calculated. Paw withdrawal time difference was calculated by subtracting the experimentally modified paw withdrawal latency from the control paw latency.

Grant et al. (1993) quantified the duration of the local anesthetic-induced conduction block in the mouse using the tail flick test.

Grant et al. (1994) studied prolonged analgesia with liposomal bupivacaine in mice using the tail flick test.

The tail flick procedure using **rats** as test animals has been proposed by Herr et al. (1953).

Madan et al. (1970) determined conduction anesthesia by a tail-pinch technique in rats. The local anesthetic was injected subcutaneously bilaterally at the root of the tail. The test for local anesthesia was begun 15 min after injection by pinching with a polyethylene sheathed artery forceps and repeated every 15 min. The number of animals failing to remove the forceps by biting was recorded.

Kamerling et al. (1985) described a method for studying cutaneous pain perception and analgesia in **horses**. This method was used by Harkins et al. (1996, 1997) for determination of highest no effect dose (HNED) for local anesthetic responses to procaine, cocaine, bupivacaine, benzocaine and of a plant extract. A heat projection lamp was used as noxious stimulus directed onto the pastern to elicit a flexion-withdrawal reflex. Hoof withdrawal latency was defined as the time between lamp illumination and withdrawal of the hoof. The local anesthetic drugs were injected into the area of the palmar nerve where it passes lateral to the sesamoid bone.

G.1.1.4 Rabbit Tooth Pulp Assay

PURPOSE AND RATIONALE

The rabbit tooth-pulp assay (see H.1.2.8) has been used successfully to evaluate the potency, efficacy, and duration of antinociception of analgesics (Yim et al. 1955; Piercey and Schroeder 1980; Wynn et al. 1984). Thut et al. (1995) described a method for administration of local anesthetic drugs to the maxillary arch of rabbits and subsequent measurement of antinociceptive action.

PROCEDURE

Pulp chambers are exposed close to the facial gingival line of the two central incisors in New Zealand White male rabbits (1.5–2.0 kg) using a high-speed dental drill and 0.5-mm round burr immediately after the i.v. administration of 30 mg/kg ketamine. All experiments are conducted 48 h or more after pulp exposure. A linear ramp function stimulator is used as the direct current voltage source. The rabbit is slightly restrained, and the current is applied to the pulp via fine-wire platinum electrodes held in each of the cavities. Linearly rising voltage is applied at a rate of 0.33 V/s until a patterned lick-chew response occurs. Mean threshold voltages are established for controls using an average of 3 determinations, and then obtained after treatment using a single determination up to a maximum of 10 V. Rabbits having control values greater than 3 V are excluded from the study. The injection site of the test drug is 1.5 cm posterior to the central incisors and 4 mm below the roof of the maxillary buccal vestibule. The buccal vestibule is the area where the cheek and the top of the maxillary tissue join. The tip of a 27-Ga × 1/2″ syringe needle is inserted until it contacts the cancellous bone. The volume of injection is 0.4 ml. Injections are made bilaterally so that the total volume injected is 0.8 ml. The animals can be used chronically, but no rabbit should be exposed to the same drug or the same dose more than once, and non should be injected more frequently than very third day. One animal is used per dosage when analgesia is observed to be either 0% or 100%. Two or 3 animals are used for dosages with effects between 0% and 100%. When more than one animal is used, data are averaged and treated as a single observation. Pulp chambers have to be re-exposed when the drilled openings disappear because of incisor growth (approximately after 3 weeks).

EVALUATION

The percentage of maximum effect (*MPE*) for each observation time is calculated from the following equation:

$$MPE = (TV - CV)/(10V - CV) \times 100$$

TV is the voltage after treatment, *CV* is the control voltage, and *10V* are the maximum volts applied. The voltage that elicits the response is recorded at zero time and 5, 10, 15, 30, 60, 120, and 180 min after injection. The *MPE* is calculated for each observation time. Graphs of the *MPE* values versus time are constructed, and the maximal effect and time of the maximal effect are recorded. Further, the duration of each dosage is defined as the length of time that that dose achieved a *MPE* greater than 25%. Data are regressed between observed time points to provide estimates of the time when 25% *MPE* is first achieved and also the time when 25% *MPE* is no longer observed. A computer program or the standard method of Litchfield and Wilcoxon (1949) can be used to calculate ED_{50}, ED_{90}, and ED_{95} values with 95% confidence limits.

G.1.1.5 Infraorbital Nerve Block in the Rat

PURPOSE AND RATIONALE

Several authors have used the infraorbital nerve block in the rat to study the potency and duration of action of local anesthetics (Fink et al. 1975, 1978; Ready and Fink 1980; Buckley and Fink 1981; Buckley et al. 1985; Renck et al. 1988; Hassan et al. 1989, 1993).

PROCEDURE

Male Sprague-Dawley rats weighing 500–600 g are used. The infraorbital nerve of the rat is 2–3 mm in diameter and supplies the upper lip and whisker area. It is homologous with the infraorbital nerve in humans. Since the rat lacks a closed orbit, the nerve runs forward beneath the eye and emerges from the maxilla through a deep notch rather than a foramen. The animals are lightly anesthetized with intraperitoneal phenobarbitone 25 mg/kg. This degree of sedation abolishes the righting reflex but does not interfere with the generalized aversive response to pinching the upper lip with an artery forceps. Test solution (0.2 ml) is injected unilaterally on the right side. The intact left side serves as control for comparing the responses on the two sides. Only animals whose aversive response is abolished within 60 s of the time of injection are included in the study. The animals are tested at 5-min intervals thereafter until the first sign of return of the aversive response on the injected side. Ten animals are used for each concentration of each test compound.

EVALUATION

The incidence of blocks at each concentration is recorded. The duration of the analgesic block (± SD) is calculated for each concentration and each test compound.

MODIFICATIONS OF THE METHOD

Renck and Hassan (1992) tested analgesia of the upper lip by electrical stimulation using externally applied bipolar stimulatory electrodes (blunted 27-gauge hypodermic needles) connected to a constant current stimulator delivering one impulse per second of 0.24 ms duration.

G.1.1.6 Retrobulbar Block in Dogs

PURPOSE AND RATIONALE

Defalque and Stoelting (1976) published a method to determine latency and duration of action of local anesthetics after retrobulbar injection in dogs.

PROCEDURE

Young female mongrel dogs weighing 13–15 kg are used. Twenty-four h before the test, 0.25% eserine ointment is placed in each conjunctival sac of the dog. Pentobarbital (25 mg/kg) is administered intravenously, then repeated with 10 mg/kg at hourly intervals, thus maintaining the animal in light anesthesia (corneal reflex present). Ten min after induction, the dog is put into 30-degree head-down position, and 20 ml of 0.05% tetracaine is forced into the epidural

space through the interarcuate ligament. Horner's syndrome occurs within 5 min.

A 150-watt surgical lamp is now focused upon the eye from an 1 meter distance. Fifteen min later, a retrobulbar block is performed: The sclera is seized with an ophthalmic forceps and the eyeball is pulled downward and medially; a 23-gauge needle is then introduced through the superior rectus muscle, tangentially to the globe, and is immobilized as soon as a click indicates penetration of the retrobulbar space; correct placement is confirmed by free motion of the needle tip and protrusion-rotation of the eyeball upon injection of 1 ml of air.

After aspiration, 2 ml of the tested anesthetic is then injected at a rate of 0.5 ml per second. The pupil dilates and reaches its maximal diameter (6 mm) within a few minutes. This apparent diameter is estimated with a 2-cm long ruler calibrated in millimeters, whose center is gently applied to the corneal center. The pupil is measured every 15 s for 5 min, then every 5 min until reappearance of maximal miosis (pinpoint and asymmetrical), a precise endpoint which generally coincides with corneal reflex and lacrimation.

EVALUATION

Drug latency (in min) and duration (in 5-min units) are averaged for both eyes of each animal, and the mean and standard deviation then calculated for all test animals. Analysis of variance is performed to find significant differences between various local anesthetics.

G.1.1.7 Isolated Sciatic Nerve Preparation of the Frog

PURPOSE AND RATIONALE

Isolated nerves are immersed between stimulating and recording electrodes in solutions containing local anesthetics which allows electrophysiological measurements (Paterson and Hamilton 1970).

PROCEDURE

A large frog is sacrificed by decapitation with a pair of scissors, and the spinal cord severed. The skin around the entire body in the region immediately posterior to the forelimbs is cut, and the abdomen and hind legs are skinned by peeling the skin in a posterior direction. The fat, muscles, and other tissues are cut at the posterior end of the body so as to expose the nerves extending posteriorly from the cord. The muscles of the thigh are cut and retracted so as to expose the sciatic nerve. Finally, the gastrocnemius muscle is removed and the peroneus muscle is extended laterally from the tibiofibula. The entire sciatic nerve with branches should now be exposed. A thread with a loop next to the nerve is tied around the nerve in the region of the sacral vertebra. The nerve is then cut anterior to the thread. During the isolation procedure the nerve is kept moist with frog Ringer solution. The connective tissue and the nerve branches are cut carefully. The nerve is finally cut near the distal end of the tibiofibula and extended on a filter paper previously soaked with Ringer solution. With the nerve anchored by the thread, the remaining connective tissue is peeled back toward the distal end of the nerve. Any remaining branches are cut at the point of their bifurcation. The distal end of the nerve is tied with a length of thread. The sciatic-peroneal nerve preparation is mounted in a nerve chamber for recording.

Electrodes for stimulation are placed on the proximal end of the nerve while recording electrodes are placed at the distal end. The nerve is immersed in a trough containing frog Ringer solution as bathing fluid. The stimuli are applied with a commercial stimulator (e. g., Grass Model S4) with a duration of 5 ms, a frequency between 30/s, and 1.5 to 15 mV. The recording electrodes are connected with an amplification and display system. Stimulation of the nerve produces a display on the oscilloscope. Adjusting the voltage setting on the stimulator will cause the action potential to increase and decrease correspondingly on the scope. After pinching the nerve between the last two recording sites, the action potential should be monophasic and appear entirely above the base line. The spike is observed periodically for several min to ascertain its stability.

The bathing trough is changed to a trough containing the local anesthetic dissolved in Ringer solution. At one or 2 min intervals the amplitude of the spike is read and recorded on a polygraph. After 5 min treatment, the drug trough is removed and the nerve is immersed in the Ringer solution of the bathing trough. Amplitudes are measured in periodic intervals and thus the recovery process is recorded.

EVALUATION

Block and recovery curves are achieved with various concentrations of the test compound and the standard. Dose-response curves can be obtained.

MODIFICATIONS OF THE METHOD

Specialized techniques with isolated nerves (desheathed nerves, equilibrium blocks, single nerve fibers) have been described by Camougis and Takman (1971).

Den Hertog (1974) used the **desheathed cervical vagus of the rabbit** mounted in a single sucrose gap apparatus and measured changes in the membrane potential and compound action potential. The ratio of the distance between stimulation and recording electrode (15 mm) and the time between stimulation of the nerve and the top of the action potential was taken as an index for the mean conduction velocity.

Salako et al. (1976) tested a new anti-arrhythmic drug as a local anesthetic on desheathed **frog** nerve.

Lee-Son et al. (1992) used the sucrose-gap method on desheathed isolated frog peripheral nerves to study the stereoselective inhibition of neuronal sodium channels by local anesthetics.

Lambert et al. (1994) studied the reversibility of conduction blockade in desheathed bullfrog sciatic nerves, using the sucrose gap method for recording compound action potentials, before and during exposure to local anesthetics and during drug washout.

Isolated nerves from other species have been used for the study of local anesthetics, such as those from rabbits by Ritchie et al. (1965a, b), or from rats by Condouris and Lagomarsino (1966), Štolc and Mai (1993).

Gissen et al. (1980) observed differential sensitivities of mammalian nerve fibers to local anesthetic agents in rabbits. A fibers were blocked at the lowest drug concentrations, the intermediate B fibers were blocked at a higher drug concentration, and the smallest, slowest-conducting C fibers required the highest drug concentration for conduction blockade.

Fink and Cairns (1984) showed differential slowing and block of conduction by lidocaine in individual afferent myelinated and unmyelinated axons in rabbits.

Åkerman et al. (1988) studied the block of evoked action potential in the isolated sheathed sciatic nerve of the frog for primary evaluation of a local anesthetic compound.

G.1.1.8 Isolated Mammalian Sciatic Nerve Preparation

PURPOSE AND RATIONALE

Karlsson et al. (1994) tested the local anesthetic-like effects of an NK_1 receptor antagonist in a mammalian sciatic nerve preparation using guinea pigs.

PROCEDURE

Male guinea pigs weighing 250–400 are sacrificed and the sciatic-tibial nerves immediately excised and cleaned in buffer equilibrated with 95% O_2 + 5% CO_2 under a dissecting microscope. The nerve is mounted in a Plexiglas chamber consisting of three connecting wells. The central well is perfused with buffer at a rate of 5 ml/min and contained the grounding electrode (Ag/AgCl), the in- and outlet of the peristaltic pump driven perfusion system and a thermistor probe. The two lateral wells (one for stimulating, the other for recording) are filled with mineral oil. Stimulating and recording electrodes are made from bare platinum-iridium wire. The passages between the central and lateral wells are sealed with petroleum jelly. The length of the nerve exposed to the drug in the central well is 8 mm. The nerve chamber is kept at a temperature of 27.0 ± 0.5°C.

A constant current supramaximal stimulus of 50 µs duration is used throughout the experiment. The intensity of the stimulus is ten times greater than the threshold intensity required to elicit a compound action potential. Throughout the experiment the nerve is stimulated at the low frequency of 1/min to determine basal compound action potential amplitude. Once the response has stabilized, a single burst of pulses (pulse train duration 250 ms, at 40 Hz) is applied approximately 5 min before drug application (control train) and again after drug application to determine the extent of frequency dependent block. The compound action potentials are digitized with a computer interface and a software program and recorded on a PC. A two channel storage oscilloscope is used to follow the experiment and to automatically sample and calculate the amplitudes of the compound action potentials.

The drugs are dissolved in buffer and applied approximately 5 min after the control train. The development of basal block following drug application is followed with 0.0167 Hz stimulation. In the case of lidocaine, the maximal inhibition is reached 20–30 min after application. The basal block is allowed to reach equilibrium, which is defined as the condition in which the difference in amplitude between the first and the last of five consecutive responses is less than 1% of the control compound action potential amplitude obtained prior to drug application. To assess frequency dependent block, a second stimulus is given after equilibrium is reached. Once basal and frequency dependent block has been determined, the nerves are washed with fresh buffer.

EVALUATION

The magnitude of the basal block (%) is calculated by comparing the average peak amplitude of the last three compound action potentials with the average peak amplitude of the last three compound action potentials prior to drug application. Similarly, frequency dependent block is expressed in percent of the control train, and is effectively the basal block plus the additional decrease in compound action potential amplitude. Dose-response curves for the standard and the test drugs are constructed by plotting basal block and frequency dependent block against drug concentration. The pIC_{50} values (the negative logarithm of the molar concentration of the drug producing 50% inhibition of the compound action potential amplitude) are estimated by linear regression analysis of the results in the 10–90% interval of the dose-response curves.

The dose-response data obtained with the standard and the test drugs and the effect of a single concentration (0.5 mM) of all compounds on basal block and frequency dependent block are analyzed by ANOVA. The values of latency to the peak of compound action potential are analyzed by paired *t*-test.

MODIFICATIONS OF THE METHOD

Fink and Cairns (1984) studied differential slowing and block of conduction by lidocaine in individual afferent myelinated and unmyelinated axons.

G.1.1.9 Effect of Local Anesthetics on Different Nerve Fibers

PURPOSE AND RATIONALE

Wildsmith et al. (1989) examined the *in vitro* sensitivities of different types of fibers in rabbit vagus nerves to

local anesthetic block with a range of local anesthetic drugs at high and low frequency stimulation. Rapidly conducting, myelinated (A) fibers are more sensitive than more slowly conducting, unmyelinated (C) fibers.

PROCEDURE

The cervical portions of the vagus nerves of rabbits weighing 2.5 kg are removed, desheathed and mounted in an airtight chamber which is maintained at 37°C by a water jacket. A central 1-cm section of the nerve chamber is perfused at 0.5 ml/min with carbonated Liley solution (pH 7.4 ± 0.02 after equilibration with 5% carbon dioxide in oxygen). A tap system allows the perfusate to be changed to test solution without admission of air.

A square wave generator is used to apply supramaximal electrical stimuli (10–15 V for 1 ms) at a rate of 0.0167 Hz during a 30-min period of stabilization. Two trains of stimuli (duration 0.25 s) are applied, one at 20 Hz and the other at 40 Hz. The preparation is considered valid only if there is less than 5% decrement in height of the action potential during stimulation at 40 Hz. The signals from the nerve are amplified, digitized (Unilab 532.001 interface sampling at 40 µs intervals for 8 ms, then at 200 µs intervals for 50 ms) and recorded with a microcomputer based system. The numeric derivative of the signal can be printed out immediately or stored on disc for subsequent processing. Signals are monitored also on a storage oscilloscope.

A submaximal blocking concentration of the hydrochloride salt of a test drug dissolved in carbonated Liley solution is applied. Only one concentration of one drug is applied to each nerve. The stimulation rate remains at 0.0167 Hz until any changes in the compound action potential are complete (minimum period 30 min), when the trains of high frequency stimulation are repeated. Drug effect is measured as the percent decreases in the height of the three components (A, B and C fibers) of the compound action at each frequency of stimulation. At 20 and 40 Hz, the last signal produced by each train of stimulation is used for analysis. An experiment is considered valid only if the action potentials recover to more than 90% of control height on washing the drug from the nerve.

EVALUATION

From the data obtained, the ED_{50} (and its SE) for the effect of each drug on each fiber type at each rate of stimulation is determined by log-probit analysis. Plots of the development of block while the nerves are being stimulated at 0.0167 Hz are also made. From these an index of the rate of development of A and C fiber block is derived ($T_{1/2B}$). This is defined as the time taken to develop 50% of the eventual maximum degree of block for the particular fiber type in each experiment.

MODIFICATIONS OF THE METHOD

Scurlock et al. (1975) examined the relative sensitivity of sympathetic preganglionic and postganglionic axons, B and C fibers, respectively, to structurally dissimilar local anesthetics. Cervical sympathetic trunks from adult rabbits were submerged in Krebs-Henseleit solution except during the brief recording periods, when they were stimulated electrically with twice maximal square-wave pulses of 0.15 ms (B fibers) or 0.5 ms (C fibers) duration. After control records, the bath chambers were filled with various concentrations of local anesthetics and the action potentials recorded at 5-min intervals. The decrease of action potentials of the B- and C-fibers was recorded separately.

G.1.1.10 Measurement of Sodium and Potassium Conductance in Voltage Clamp Experiments

PURPOSE AND RATIONALE

Voltage clamp experiments on single nodes of Ranvier can be performed with single myelinated nerve fibers from the sciatic nerve of the frog (Stämpfli 1954, 1968; Nonner 1969; Nonner et al. 1975; Stämpfli and Hille 1976; Borchard and Drouin 1978). Sodium, potassium and leakage currents (I_{Na}, I_K, I_L) can be measured.

Descriptions of structure and function of voltage-gated sodium channels were given by Catterall (1988, 1992), Stühmer (1991), Narahashi and Herman (1992), Cohen and Barchi (1993).

PROCEDURE

Single myelinated nerve fibers are dissected from the sciatic nerve of the frog (*Rana esculenta*). The fibers

are bathed in a Ringer solution containing 110 mM NaCl, 2.5 mM KCl, 1.8 mM $CaCl_2$, 5.0 mM Tris, pH 7.3, at 15°C. For measurement of sodium, potassium and leakage currents (I_{Na}, I_K, I_L), the nodal membrane is clamped to a holding potential of –30 mV (relative to the resting potential of –70 mV). Hyperpolarizing prepulses (–40 mV, 50 ms) followed by 2 ms test pulses (60 mV) are applied every 5 s to record peak sodium currents, I_{Na}, and to avoid the influence of accumulation of frequency-dependent block. Every second pulse is followed by an afterpulse (120 mV, 20 ms) to measure steady state I_K. The leakage current, I_L, is measured at the end of the hyperpolarizing prepulse and recorded every 10 s.

After superfusion of the nodal membrane with a local anesthetic, a quick and then a slow decrease of the peak sodium current (I_{Na}) occurs. When the application of the local anesthetic is stopped, I_{Na} increases quickly and then slowly within min indicating a reversible action of the local anesthetic on the nerve fiber. With local anesthetics, the potassium current (I_K) behaves similarly, whereas the leakage current (I_L) remains unchanged.

Dose Dependent Action of Local Anesthetics on I_{Na}-V Relations

The holding potential is set at –30 mV. A hyperpolarizing prepulse (–40 mV, 50 ms) is followed by a depolarizing test pulse (30 ms) with varying amplitudes. Local anesthetics induce a dose-dependent reduction of sodium-inward and -outward currents over the whole range of voltage clamp steps. The measurements are performed at extracellular pH 7.3.

Dose Dependent Action of Local Anesthetics on I_K-V Relations

Potassium currents, I_K, are measured at the end of depolarizing test pulses of 30 ms duration. Local anesthetics induce a dose-dependent decrease of potassium currents at extracellular pH 7.3.

EVALUATION

The effects on sodium, potassium and leakage currents (I_{Na}, I_K, I_L), the dose dependence of action on I_{Na}-V relations, and the dose dependence of action on I_K-V relations of various local anesthetics are compared.

MODIFICATIONS OF THE METHOD

Bräu et al. (1998) determined half-maximal blocking concentrations of local anesthetics for tonic block of Na^+ and K^+ channels by using the axonal patch clamp method (Vogel and Schwarz 1995) to study potencies of clinically used local anesthetics in suppressing Na^+ and delayed rectifier K^+ channels of peripheral nerve.

Sciatic nerves of the clawed **toad** *Xenopus laevis* were enzymatically prepared (Jonas et al. 1989). The nerves were dissected, desheathed, and treated with collagenase and protease to obtain single, partially demyelinated fibers. For recording axonal ionic currents, the outside-out configuration of the patch clamp method (Hamill et al. 1981) was applied to partially demyelinated axons. Patch pipettes were pulled from borosilicate glass (Clark Electromedical Instruments, Pangbourne, UK) and coated with Sylgard 184 (Dow Corning, Seneffe, Belgium) and were fire-polished at the tip before use. The resistance of the pipettes after filling with internal solution was 15–25 MΩ. The bath solution contained (in mM): NaCl 115; KCl 2.5; $CaCl_2$ 2, HEPES 10; adjusted to pH 7.4 with TRIS. For Na^+ current recording, 10 mM tetraethylammoniumchloride was added to suppress K^+ currents; for K^+ recording, 100 nM tetrodotoxin was added to suppress Na^+ currents. The pipette solution for Na^+ current recording contained (in mM): CsCl 110; NaCl 13; EGTA 2; HEPES 10, pH adjusted to 7.2 with TRIS. For the investigation of K^+ channels, CsCl was replaced by KCl.

Different concentrations of local anesthetics were applied to the patches using a multi-barrel perfusion system that allowed solution changes within 1 s.

After forming an outside-out patch from the nodal membrane, the holding potential was adjusted to –90 mV in the voltage clamp mode using an EPC7 patch clamp amplifier (List, Darmstadt, Germany). The pulse protocol used to elicit Na^+ currents comprised a 50-ms prepulse to –130 mV to remove fast inactivation, followed by a 50-ms test pulse to –40 mV to activate Na^+ currents. Steady-state K^+ currents were activated by a 50-ms potential step to 60 mV and were measured as the mean current during the last 20 ms of the pulse. For analysis, currents were filtered with a four-pole Bessel filter, digitized with a Labmaster TM-40 AD/DA board (Scientific Solutions, Solon, Ohio, USA), and stored in the hard disk of a computer. To reduce the noise of single current traces that originated from individual channel openings, 20 successive traces, elicited every 5 s, were averaged to measure the peak Na^+ current or steady-state K^+ current. Blocking potencies of the local anesthetics were determined by analyzing concentration–inhibition curves, which were constructed by measuring the inhibition of the peak Na^+ current or steady-state K^+ current amplitude at different concentrations normalized to control.

Half-maximal inhibiting concentrations (IC_{50}) were obtained from non-linear least-square fits of the function $F_1 = b_{max}/(1+[IC_{50}/c]^p)$ to the data points. As first-order binding kinetics of the drug with the channel were assumed, the Hill coefficient (p) was set to 1 during fitting; b_{max} is the maximal achievable block. Data acquisition and evaluation were performed with pClamp 5.5.1 (Axon Instruments, Burlingame, Calif., USA); Fig.P 5.0 software (Biosoft, Cambridge, UK) was used for fitting procedures.

Olschewski et al. (1998) applied the patch clamp technique to intact lateral horn neurons from laminae I-III identified in 200-µm slices of spinal cord from newborn rats. Under voltage clamp conditions, the whole-cell Na^+ and K^+ currents activated by depolarization were recorded in the presence of different concentrations of anesthetics.

Olschewski et al. (2002) combined the patch clamp recordings in spinal cord slices of the rat with the "entire soma isolation" method, as described by Safronov et al. (1997) and Safronov (1999). In the whole-cell recording mode, the entire soma of the neuron was isolated from the slice by slow withdrawal of the recording pipette, leaving all or nearly all of its processes in the slice. The isolated structure was classified as *soma* if it had lost all its processes during isolation and preserved only 10%–20% of the original Na^+ current recorded from the neuron in the slice before its isolation. The isolated structure was considered as *soma + axon* complex if it contained one 10- to 100-µm process and preserved > 85% of the original Na^+ current recorded from the neuron in the slice before isolation. The structure was considered as *axon + dendrite* if it preserved one adjacent process but the amplitude of the Na^+ current was in the range of those typically seen in isolated *somata*. A successful isolation was usually accompanied by a considerable decrease in membrane leakage currents due probably to the loss of the large area of the dendritic membrane. The good physiological state of the isolated structures was confirmed by a considerable increase in their output resistances (reflecting a decrease in membrane leakage conductance), and by stable and even improved membrane resting potentials. Three types of tetrodotoxin-sensitive voltage-gated Na^+ channels on soma and processes of dorsal horn neurons of rat spinal cord were identified. Bupivacaine, lidocaine and mepivacaine at low concentrations (1–100 µM) enhanced delayed-rectifier potassium current in intact neurons within the spinal cord slice, while exhibiting a partial blocking effect at higher concentrations (> 100 µM).

G.1.1.11 Inhibition of Fast Axonal Transport

PURPOSE AND RATIONALE

Local anesthetics block not only nerve conduction but also fast axonal transport (Aasheim et al. 1974; Lavoie 1983; Lavoie et al. 1989). This mechanism may also be the way in which local anesthetics cause injury to nerve and spinal cord (Kalichman 1993).

PROCEDURE

The biological material consists of the eighth and ninth dorsal root ganglia of the bullfrog (*Rana catesbeiana*) and their respective spinal nerves. Each side of the animal provides one such set of ganglia and associated structures. The dissection is performed at room temperature with the preparation in an oxygenated medium with a pH of 7.1 and of the following composition (in mM): NaCl, 114; KCl, 2.0; $CaCl_2$, 1.8; dextrose; 5.5; HEPES 20. Once the dissection is completed, each spinal nerve is ligated at approximately 24 mm from the ganglion.

The ganglia are pulse-labeled with [^{3}H]leucine for 1 h. After the pulse-labeling, the preparations are incubated for 16–17 h at 18°C in medium free of radioactivity; the two ganglia and spinal nerves from one side of the animal serve as control preparations and those from the other side as experimental preparations. The preparations are placed in a Lucite incubation chamber. The ganglion and the first 10 mm of the nerve trunk occupy one compartment, the next 3 mm is in the groove between two communicating compartments, and the rest of the nerve trunk (including the point of ligature) is placed in the second compartment. The two communicating compartments are then sealed from one another by filling the rest of each groove with silicone grease. The compartment containing the control ganglia and that containing the experimental ganglia are filled with medium for all experiments. A local anesthetic agent is added to the medium bathing the distal half of the experimental nerve trunks whereas the same area of the control nerve trunks is in the corresponding medium without local anesthetic.

At the end of the incubation, the nerves are cut into 2-mm segments, and the protein-bound radioactivity of each ganglion and nerve segment is determined by liquid scintillation counting (Lavoie 1981). For each preparation, the total quantity of transported radioactivity is calculated by summing up the radioactivity present in the individual segments of the nerve starting at 6 mm from the ganglion and extending up to the point of ligature. The total quantity of [^{3}H]leucine incorporated into protein is calculated for each preparation as the sum of transported radioactivity and radioactivity remaining in the ganglion.

EVALUATION

Mean values ± SEM for the ratio of radioactivity in the experimental preparation to radioactivity in the control preparation are computed in each pair of preparations for the total incorporated radioactivity, the total transported radioactivity, and the radioactivity at the ligature. The difference in the absolute amount of radioactivity at the ligature, the difference in total transported radioactivity, and the difference in total incorporated radioactivity are calculated for each pair of preparations. A Student's *t*-test for paired samples is performed on the mean differences between control and experimental preparations. Using the individual ratios of radioactivity in experimental preparation to control preparation, an analysis of variance on parallel groups is done to compare the drugs; pairwise comparisons are obtained using Scheffé's critical *F* value.

MODIFICATIONS OF THE METHOD

Anderson and Edström (1973) and Lavoie (1982) used frog sciatic nerves *in vitro* to study the effect of local anesthetics on fast axonal transport of proteins. Rabbit vagus nerves were used by Fink et al. (1972) and Aasheim et al. (1974).

Factors, such as kinesin and dynein, influencing fast axonal transport have been identified (Shea and Flanagan 2001).

G.1.2 Infiltration Anesthesia

G.1.2.1 Infiltration Anesthesia in Guinea Pig's Wheals

PURPOSE AND RATIONALE

Based on earlier work by McIntyre and Sievers (1937) and Sievers and McIntyre AR (1938), the use of intracutaneous wheals in guinea pigs was recommended by Bülbring and Wajda (1945). This method has become a standard operating procedure for testing local anesthetics.

PROCEDURE

Adult guinea pigs of either sex weighing 250–300 g are chosen. On the day preceding the experiment the hair on the back is clipped and two areas of 4–5 cm diameter are shaved. This produces a certain amount of irritation which disappears overnight. The sensitivity of the skin is greatest in the midline and slightly more so in the front than in the back area. For this reason each concentration of a local anesthetic must be tested in both areas. Six tests using three guinea pigs can be performed simultaneously. The doses of local anesthetics are always injected intracutaneously in 0.1 ml saline. Three guinea pigs receive one dose in the front area and another dose in the back area; the size of the wheal is marked with ink. One side is used for the test preparation, the other side for the standard (e. g., 1% butanilicaine). The reaction to pin prick is tested 5 min after injection in the following way. After observing the animal's normal reaction to a prick applied outside the wheal, six pricks are applied inside the wheal and the number of pricks is counted to which the guinea pig fails to react. The pricks are applied at intervals of about 3–5 s. Six pricks are applied every 5 min for 30 min. Having completed the test on 3 guinea pigs, the same solutions are injected into 3 other guinea pigs, but the solution which was used for the front is now used for the back area and vice versa.

EVALUATION

The number of times the prick fails to elicit a response during the 30 min period is added up, and the sum, out of possible 36, gives an indication of the degree of anesthesia. Using various doses, dose-response curves can be established. For time-response curves, the prick tests are repeated every 10 min. Half-life times are calculated as the time, when after complete anesthesia 3 out of 6 pricks elicit again a response (Ther 1953a, b).

MODIFICATIONS OF THE METHOD

The test can also be used to study the influence of vasoconstrictors, such as adrenaline.

G.1.2.2 Infiltration Anesthesia in Mice

PURPOSE AND RATIONALE

Grant et al. (2000) described a mouse model for evaluation of skin anesthesia after infiltration of local anesthetics.

PROCEDURE

Male Swiss Webster mice weighing 23±3 g are used. On the day preceding the experiment, the abdominal hair is shaved using electric clippers. On the day of the experiment, on either side of the abdomen (∼0.5 cm lateral to the midline and ∼1.0 cm below the thoracic cage) circular areas of ∼0.7 cm diameter are marked with indelible ink for subcutaneous injections. For the generation of nociceptive electrical stimuli, a square wave general purpose generator (model S48, Grass Instruments) coupled to an isolator unit (Model PSIU6 F, Grass Instruments) is used. The stimuli are delivered to the skin via blunt electrodes fashioned from 25-gauge needles. A thin layer of electrically conductive gel is applied to the area to be tested with a cotton-tipped applicator.

Mice are screened to determine their vocalization threshold, the current required to produce a vocalization (squeak).While nociceptive stimulus is applied, animals are restrained gently in the experimenter's palm by grasping the nape of their neck and their tail. The output of the stimulator is initially set at 5 mA, and is progressively increased in steps of 1 mA. Mice are screened once, and those animals that vocalized at ≤8 mA are included in the study.

The local anesthetics are injected in various concentration subcutaneously in a volume of 0.15 ml in the marked area of one side. After fixed time intervals (5, 10, 20, 30, 40, 50, 60, and 70 min) the skin overlying the injection sire and the corresponding "control" side are stimulated using the threshold stimulus. If the animal does not vocalize after the threshold stimulus was applied to the test site, the intensity of the stimulus is increased twice in 1-mA increments, to deliver a "maximal" stimulus 2 mA above the threshold. This is done to ensure lack of vocalization response.

To assess the duration analgesia is tested at 15-min intervals.

EVALUATION

The all-or-none response data are subjected to statistical analysis using the survival curves procedure. The curves are generated using the method of Kaplan and Meier, and the 95% confidence interval for fractional survival at any particular time is calculated using the Prism program (GraphPad Software). The curves are compared using the log rank test. In this method of statistical analysis, the term "survival" refers to any well-defined end-point and in the present study it is lack of analgesia. The two-tailed p value of $< 0{,}05$ is considered significant.

G.1.3 Surface Anesthesia

G.1.3.1 Surface Anesthesia on the Cornea of Rabbits

PURPOSE AND RATIONALE

Following the pioneering work of Sollmann (1918), block of the rabbit corneal reflex as described by Régnier (1923) has become a standard test method for evaluating local anesthetics (Quevauviller 1971).

PROCEDURE

Albino rabbits of either sex weighing 2.5–3 kg are placed into rabbit holding cages. The upper and lower eyelashes are carefully clipped. The conjunctival sac of one eye is held open, thus forming a pocket. From a 1 ml syringe with a 22-gauge needle, 0.5 ml of a solution of the anesthetic is applied into the conjunctival sac for 30 s. Then the procedure is repeated, so that 1.0 ml is applied within 1 min. One ml of the standard (0.1% solution of tetracaine hydrochloride) is applied to the other eye. Effective local anesthetics extinguish the corneal reflex (blinking) elicited by any touch of the cornea. For quantitative purposes, the irritation with a bristle according to von Frey (1894, 1896, 1922) has been recommended. An equine hair bending at a load of 230 mg is attached perpendicularly to a glass rod. Within 25 s, the cornea is touched 100 times. The summation of many stimuli applied this way gives better results than a single touch with a glass rod (Ther and Mügge 1953). The test is started 5 min after application of the drug and repeated every 5 min until anesthesia vanishes and blinking occurs again. The time between disappearance and reappearance of the corneal reflex is registered.

EVALUATION

Using the time of loss of the corneal reflex as parameter after application of different doses, dose-response curves can be established and potency ratios versus the standard calculated.

MODIFICATIONS OF THE METHOD

Chance and Lobstein (1944) used **guinea pigs** for testing surface anesthesia by the corneal reflex.

Bartsch and Knopf (1970) described an electrically operated stimulator with a bristle allowing variable frequencies to evaluate surface anesthesia on rabbit cornea.

Hotovy (1956) investigated the synergism between the local anesthetic compound dibucaine hydrochloride applied to the conjunctival sac of rabbits and intravenously administered analgesics using Régnier's method

G.1.3.2 Suppression of Sneezing Reflex in Rabbits

PURPOSE AND RATIONALE

Nieschultz et al. (1958), Åström und Persson (1960) used the sneezing reflex in rabbits to test local anesthetic activity.

PROCEDURE

Groups of male rabbits weighing 3 kg are used. Using a cotton tampon, the test solution is applied to the mucous membrane of one nostril. The solution of a standard local anesthetic is administered to the nasal mucosa of the other nostril. After 2 min the mucous membrane is stimulated by a fine pencil. Loss of the sneezing reflex is regarded as sign of complete anesthesia. The stimulation is repeated after 3, 6, 10 and 15 min and continued every 5 min until the sneezing reflex reappears. Various concentrations of test compound and standard are applied.

EVALUATION

Using the loss of the sneezing reflex as parameter after application of different doses, dose-response curves can be established and potency ratios versus the standard calculated. Furthermore, the duration of activity can be evaluated.

G.1.4 Epidural Anesthesia

G.1.4.1 Epidural Anesthesia in Various Species

PURPOSE AND RATIONALE

Activity and tolerability of new local anesthetics after epidural injection have to be studied in various animal species in order to predict both parameters in patients.

PROCEDURE

Studies in Rats

Blomberg and Rickstein (1988) described a simple technique for cannulation of the thoracic epidural space in conscious and anesthetized rats. Male Wistar rats weighing 300–400 g were anesthetized with methohexital sodium 100 mg/kg intraperitoneally for insertion of PE-50 catheters into the tail artery and right jugular vein. Supplementary doses of methohexital were given during the cannulation of the epidural space. The catheters were exteriorized in the neck and the animals were placed in a lucite restraining cylinder where they were left to recover for 1–2 h from methohexital anesthesia and cannulation procedures. Arterial pressure, heart rate, and body temperature were recorded. A PE-50 catheter was inserted into the right common carotid artery for measurement of cardiac output with the cardiogreen dye-dilution technique and measurement of left ventricular end-diastolic pressure.

For cannulation of the thoracic epidural space, the skin of the upper part of the back of the animal was shaved and a 3-mm-long midline incision was made over the spinous process from a point between the two scapulae. The fascia covering the superficial muscles of the back was opened and the muscles were dissected from the thoracic vertebrae and retracted laterally. The thick and protruding spinous process of the second thoracic vertebra was localized. The identification of the spinous process of Th3 to Th7 was easily made by the nail of the index finger. The interspinal muscles and ligaments between the spinous processes of Th6 to Th7 were cut and the spinous process of Th7 was removed. The distance between Th6 and Th7 was then maximized by a rostral traction of Th6 with a forceps attached to spinous process of Th6. The yellow ligament between Th6 and Th7 was identified by a dissecting microscope at ×16 magnification and cut open to visualize the dura and the spinal cord. A PE-10 catheter, filled with the local anesthetic, was introduced cranially to a length of 1 cm. The area between Th6 and Th7 was covered and the catheter was firmly attached with cyanoacrylate, which completely prevented extradural leakage of the local anesthetic. The catheter tip was now located at the Th4–5 level. The superficial muscles were then sutured and the catheter was brought through the closed skin incisions. Incremental doses of 10 µl of bupivacaine were administered epidurally and the amount of the anesthetic bupivacaine (5 mg/ml) that caused no further heart rate decrease was assessed. The spread of the analgesia was assessed by a modified pin-prick technique. All hemodynamic measurements were made before, and then 10–15 min and 45–55 min after the induction of thoracic epidural anesthesia.

Studies in Guinea Pigs

A method to test epidural anesthesia in guinea pigs was described by Åkerman et al. (1988).

Male guinea pigs weighing 300–500 g are anesthetized by means of an intraperitoneal injection of an aqueous solution of chloral hydrate 42.5 g/l; ethanol 90 g/l; propylene glycol 428 g/l; sodium pentobarbitone 9.75 g/l; and magnesium chloride 21 g/l. A skin incision is made from the level of the lumbosacral fossa and approximately 1.5 cm down in order to expose the sacral area in the mid-line. With the vertebral column flexed, the lumbosacral intervertebral ligament is carefully incised. Through this small opening a polyethylene catheter (PE 10) is inserted maximally 1.5 cm along the roof of the vertebral canal to the L4–L5 region. The catheter is sutured to the overlying lumbar fascia which is then closed. The catheter is tunneled under the skin and exteriorized through an incision in the neck region. After fixation of the catheter to the fascia of the neck muscles and suturations of the incisions, the catheter is filled with saline and sealed.

After a recovery period of at least 1 day, 0.1 ml of 2.0% lidocaine is injected over a period of 1 min, and the motor and sensory blocks are assessed. The injection of lidocaine which results in a bilateral, reversible blockade indicates a successful preparation. A minimum of 8 animals are used in the further experiments for each test solution.

Mean time to onset of block and mean duration of block are calculated from number of legs blocked.

Siems and Soehring (1952) described a model in **guinea pigs** resembling peridural and paravertebal anesthesia in man.

Studies in Rabbits

Chernyakova et al. (1994) studied the effects of azacaine during epidural anesthesia in **rabbits**.

Hughes et al. (1993) described a rabbit model for the evaluation of epidurally administered local anesthetics. A "loss of resistance technique" similar to that employed in caudal epidural injection in humans was used. The rabbit was carefully restrained by an assistant. The readily palpable cranial dorso-iliac spines, lying on either side of the prominent spinous process of the seventh lumbar vertebra, served as landmarks.

The thumb and the middle finger of the left hand were placed on the two crests and the left index finger used to palpate the midline, L7 spine and the depression over the lumbosacral fossa. With the index finger in position on the L7 spine to serve as a guide, a short bevel 1.5 cm 20 gauge spinal needle was introduced a right angles to the skin in the midline with the bevel aligned longitudinally. After passage through the skin, only minor resistance was felt until the ligamentum flavum was reached. When passing through the ligament, a definite "pop" was felt and resistance to advancement of the needle was lost. When correctly placed, the needle was at a depth of approximately 0.75 to 1.0 cm and firmly held by the ligament. The stylet was then withdrawn and the hub inspected for the presence of blood or cerebrospinal fluid. If absent, the needle was rotated through 90° to direct the bevel caudally, a 1.0 ml syringe was attached and 0.1 ml of air injected. Accurate placement was indicated by the absence of resistance to injection and lack of subcutaneous crepitus. A syringe containing the desired dose of the local anesthetic was attached and the solution injected over a 5–10 s period. The pharmacodynamic responses were assessed by (1) sensory loss, (2) loss of weight-bearing ability, and (3) flaccid paresis.

Studies in Dogs

Kief and Bähr (1970) studied the epidural tolerance of artecaine with and without addition of Suprarenin in Beagle dogs weighing 9–12 kg. For pre-operative sedation, the dogs received 0.03 ml/kg Combelen (= propionylpromazine) intravenously. The fur of the lumbosacral area was shaved and the skin disinfected. A single dose of 5 ml of a 2% articaine solution was administered epidurally under sterile conditions. All dogs showed the typical symptoms of spinal anesthesia, which subsided after a few hours. The dogs were sacrificed after 1 or 3 days. The portion of the vertebral column with the site of injection in the middle was removed and placed in 8% buffered formalin. When semifixed, the vertebral arches were opened and the spinal cord as well as the roots of the spinal nerves with the adipose tissue of the epidural space were removed. After embedding in gelatin and Paraplast, the serial sections from the area of injection were stained with fast red 7B, hematoxylin-eosin and myelin sheath staining after Olivecrona was performed. Furthermore, the PAS and iron reaction were performed on one section. The presence or absence of nerve damage and of inflammation was noted.

A technique for epidural administration in the **dog** was described by Feldman and Covino (1988).

Defalque and Stoelting (1966) used a standard veterinary epidural technique to study latency and duration of action of some local anesthetic mixtures in **dogs**. The animals, prone and with their spread-out extremities attached to the table, were placed in 40-degree Trendelenburg position. Under sterile conditions, the epidural space was penetrated through the interarcual ligament with a short-beveled No. 22 spinal needle. After identification of the epidural space (aspiration, air injection), 4 ml of the investigated solution were injected with a constant injection rate of 2 ml per sec. Absence to skin-twitch response to pinching with an Allis clamp was considered analgesia. This was tested on both flanks, along a line 2 cm off the spine. Disappearance of contraction of the anal sphincter in response to stroking all quadrants of the anal margin closely correspond to complete analgesia at the level of the interarcual ligament; since this was an easily measurable parameter, disappearance and recurrence of this reflex was chosen as endpoint of latency and duration of action, respectively.

Raner et al. (1994) performed thoracic epidural anesthesia in **dogs** after general anesthesia with thiopental/chloralose and under artificial respiration. A thoracic epidural catheter (18G, Braun-Melsungen, Germany) was inserted percutaneously via the Th7–8 or Th8–9 interspace. Thoracic epidural anesthesia was established with a bolus injection of 10 mg/kg mepivacaine followed by a continuous infusion of 5 mg/kg per hour.

Kamibayachi et al. (1995) studied the halothane-induced myocardial sensitization to the dysrhythmogenic effect of epinephrine after thoracic epidural anesthesia in **dogs**. An epidural catheter was inserted under halothane anesthesia. The vertebral arches of T8 and T9 were surgically exposed and the catheter was introduced, via the T8–9 interspace, to the epidural space, which was identified by the loss-of-resistance technique. The catheter was advanced 5 cm in the cephalad direction and secured to the back. After the experiment, the position of the catheter was confirmed radiographically by injection of iopamidol (0.2 ml/kg).

Studies in Other Species

Ide et al. (2001) studied the effect of epidural anesthesia on respiratory distress induced by airway occlusion in isoflurane-anesthetized **cats**. The authors developed an animal model for the study of airway occlusion and proposed new concepts of minimum alveolar anesthetic concentration for airway occlusion, and the duration from the start of airway occlusion to the onset of the positive motor response. Adult cats were anesthetized with isoflurane and an epidural catheter was placed after L5 laminectomy.

Richer et al. (1998) described sacrococcygeal and trans-sacral epidural aesthesia in the laboratory **pig**. The aim of the study was to assess epidural accessibility in 30- to 50-kg piglets, not in adult hogs. Each animal received general anesthesia combined with epidural anesthesia. The level of catheter insertion was the sacrococcygeal interspinous space or the adjacent space (S4-S5). Localization of the injection site was simple. The sacrococcygeal junction corresponds to the junction between the fixed portion (sacrum) and the mobile portion (coccyx) of the animal's tail. The catheter was inserted along the median line at this level or the level above. The bony structures were palpable beneath the superficial planes. The animals were placed on their sides under general anesthesia and disinfected under surgical conditions. Epidural space injection was performed using a 16-gauge needle, traversing the sacrococcygeal or trans-sacral interspinous space. Entry to the epidural space was detected by a loss of resistance to puncture with absence of blood or cerebrospinal fluid on aspiration and by the ease of cephalic catheter progression within this space. A first injection of local anesthetic was performed 10 min prior to laparotomy. Epidural analgesia was maintained after this first injection by continuous administration of the same agent with a syringe. It was discontinued on awaking for a brief period in order to confirm functional recovery of the lower limbs.

Lebeaux (1975) recommended the **sheep** as a model for testing spinal and epidural anesthetic agents. To ensure accurate and reproducible administration of drugs into these restricted anatomical regions, a wooden stock was built to restrain the sheep without stress but allow arching of the lumbosacral spine in order to open the inter vertebral space. The stock consisted of a table with holes for the front feet, hinged at one end to a fixed stanchion. The hinges permitted tilt of the table. The sheep was placed prone on the table, the head secured in the stanchion and the front feet passed through the holes and tied. The lumbosacral interspace used for both spinal and epidural tap was separated by positioning and tying the rear limbs cephalad beside the abdomen, thereby extending the knee and flexing the hip. The wool was clipped from the sheep's back, the skin of the lumbosacacral area was washed and swabbed with iodine, and the vertebral spines and interspaces identified by palpation, marked, and numbered with a felt pen.

Epidural block was performed with a 19-gauge Crawford-point needle, using the loss-of-resistance method, with a syringe containing saline to identify the epidural space. After withdrawal of the stylet, a Luer-Lok syringe containing 10 ml of sterile saline solution with a final concentration of 1:200,000 epinephrine and 25.0 mg (0.25%) bupivacaine was attached to the needle. After careful aspiration of blood or spinal fluid, the local anesthetic solution was injected within 30 s. The needle was withdrawn and the table kept horizontal.

Immediately after injection, the rear feet were untied and allowed to hang free on either side of the table for evaluation of sensation and/or reflexes in the rear limbs. Then, 20 min after injection the sheep was removed from the table and positioned in a sling fashioned from a heavy duty 50-gallon plastic barrel split in half longitudinally and mounted on a metal support. Holes cut in the barrel allowed the feet to drop through so that comfortable sternal recumbency was maintained while permitting anesthetic evaluation to continue. When complete sensation returned in the skin of the dorsum, the sheep was removed from the sling and placed on a straw-bedded floor so that weight support and full recovery could be assessed.

Feldman et al. (1997) compared anesthetic efficacy and pharmacokinetics of epidurally administered ropivacaine and bupivacaine in the **sheep**.

G.1.5 Intrathecal (Spinal) Anesthesia

G.1.5.1 Spinal Anesthesia in Various Species

PURPOSE AND RATIONALE

Transient neurological symptoms have been observed in patients after spinal anesthesia (Hampl et al. 1995). Myers and Sommer (1993) published a survey on methodology for spinal neurotoxicity studies.

Activity and tolerability of new local anesthetics after intrathecal injection were studied in various animal species in order to predict both parameters for spinal (subarachnoid) anesthesia in patients.

PROCEDURE

Studies in Rats

Intrathecal injections to **rats** are performed according to the method of Hylden and Wilcox (1980) or Åkerman (1985) as being used by Ossipov et al. (1988). Male Sprague-Dawley rats weighing 50–75 g are used. The rat is held firmly by the pelvic girdle. A 30-gauge needle is attached to a 25-µl Hamilton syringe is inserted into the tissue on one side of the L5 or L6 spinous process at an angle of about 20°. The needle is advanced to the groove between the spinous and transverse processes and then moved forward the intervertebral space at an angle of about 10°. About 0.5 cm of the needle is then in the vertebral column. Correct placement of the needle is indicated by an arching of the tail. Drugs are dissolved in saline or water and administered in a volume of 5 µl. Antinociception is determined in a modification of tail flick assay in rats by placing the tail of the rat under a focused radiant heat source. The degree of antinociception is defined as the percentage of maximum possible effect. This percentage is determined for each dose at each time measured allowing to calculate ED_{50}values.

Omote et al. (1995) studied the effects of verapamil on spinal anesthesia induced by local anesthetics administered via a chronic intrathecal polyethylene catheter in **rats**. The catheter was inserted 15 mm cephalad into the lumbar subarachnoid space at the L4–5 vertebrae with the tip located near the lumbar enlargement of the spinal cord. The catheter was tunneled subcutaneously and externalized through the skin in the neck region. At least 6 days of postsurgical recovery was allowed before animals were used in experiments. The tail-flick and the mechanical paw pressure tests were used to assess thermal and mechanical nociceptive thresholds.

Mestre et al. (1994) described a method for performing direct intrathecal injections in **rats** without introducing a spinal catheter.

Wang et al. (1991) described lumbar subarachnoid catheterization in rats. Male Wistar rats weighing 500–600 g were anesthetized with intraperitoneal ketamine 75–100 mg/kg. Following a midline skin incision, the paravertebral muscles were detached from the spinous processes and retracted laterally. The intervertebral ligament between Th13 and L1 or between L1 and L2 was removed. After dissection, the inferior border of T13 or L1 was retracted cephalad, facilitating the application of rongeurs for partial laminectomy at the cephalic border of L1 or L2. This exposed the dura and the underlying spinal cord, which was easily identified by a mid-line blood vessel. Lidocaine (1.5%) was applied topically to the dura to prevent movement of the animal when the dura was picked up with fine forceps. The dura was perforated with a short-bevel No. 20-gauge needle, resulting in some leakage of cerebrospinal fluid. Under magnification, a PE10 catheter was immediately inserted tangentially through the dural opening. It was directed caudally and maintained dorsal to the spinal cord. The catheter, 10 cm in length and containing a volume of 0.02 ml was advanced

slowly in the subarachnoid space to a mark 1.5 cm from the tip, while 0.01–0.02 ml of normal saline was simultaneously injected to open the way. Leakage of fluid through the dural opening during injection confirmed the patency of the catheter and also indicated that the catheter was properly placed in the subarachnoid space.

For fixation of the catheter, the spinous process rostral to the laminectomy was denuded and perforated with a No. 18-gauge needle. The free end of the catheter was threaded through this lumen. On retraction of the needle, the PE10 catheter was left in the perforation of the spinous process, and anchored with cyanoacrylate glue. A connector was attached to the free end of the catheter for injection.

The wound was irrigated with saline and closed in layers leaving the catheter buried in the subcutaneous tissue. The hub of the connector was sutured to the skin with fine stainless steel wire. The injection port, covered by a removable metal cap, was brought out of the skin via a separate small opening lateral to the main skin incision.

One week after surgery, 0.03–0.05 ml of 1.5% lidocaine was injected through the subarachnoid catheter. Correct positioning of the catheter was evidenced by prompt sensory and motor block of the hind limbs, developing in 1–5 min, and exhibiting motor blockade for 20–30 min.

Dirksen et al. (1992) studied the dose–response and time–effect relationships of intrathecal bupivacaine in rats. The effect was a quantified drug-induced and graded reduction in the magnitude of the withdrawal reflexes elicited by transcutaneous stimulation.

Sakura et al. (1996) described an improved technique for morphological analysis of drug-induced injury after intrathecal catheterization in the rat. Male Sprague Dawley rats weighing 200–300 g were anesthetized by intraperitoneal injection of methohexital (40–60 mg/kg). Catheters were composed of 28-gauge polyurethane, 32-gauge polyimide, 32-gauge polyurethane, PE10 polyethylene, or PE-10 polyethylene that has been stretched to twice its original length. They were passed through a slit in the atlanto-occipital membrane and advanced 11 cm, to lie with the tip caudal to the conus medullaris. Animals were allowed to recover for 24 h before the study was started. The animals were placed in a horizontal acrylic restraint, and baseline tail-flick latency was assessed immediately before infusion. Infusions were administered via a mechanical infusion pump at a rate of 1 µl/min for 4 h. Animals were evaluated for alteration in tail-flick latency 7 days after infusion.

Animals were sacrificed by injecting an overdose of pentobarbital 7 days after infusion. They were perfused intracardially with a phosphate-buffered glutaraldehyde-paraformaldehyde fixative. The spinal cord and nerve roots were dissected out, immersed in the same glutaraldehyde solution for infusion fixation and embedded in glycol methacrylate. The embedded tissue was sectioned at the conus medullaris, 6 mm rostral, and 6 and 12 mm caudal, using a Sorvall JB-4 microtome. The tissue was stained with hematoxylin-eosin or was treated with 4% osmium tetroxide and stained with toluidine blue. Histologic evaluation was performed with light microscopy. Specimens obtained 12 mm caudal to the conus were used for quantitative comparison of catheter-induced damage. This region was chosen because cross sections obtained below the conus have a greater number of fascicles. Each fascicle present in the cross-section was assigned to injury scores of 1 to 3, where 0 = normal, 1 = mild, 2 = moderate, and 3 = severe injury. The injury score of each cross-section was then calculated as the average score of all fascicles present in the cross-section. The data were compared using the Kruskal-Wallis test and Dunnett's test. For all comparisons, $P < 0.05$ was considered significant.

Grouls et al. (1997) compared the effects of *n*-butyl-*p*-aminobenzoate and bupivacaine after epidural and intrathecal solution in the **rat**. Anesthesia was measured by the latency of tail withdrawal from warm water (55°C).

Kirihara et al. (2003) compared the **neurotoxicity** of intrathecal and epidural lidocaine in **rats**. Male Sprague Dawley rats were anesthetized with sodium pentobarbital (30 mg/kg i.p.) and 1.5% halothane. A catheter of stretched polyethylene tubing PE10 was introduced into the subarachnoid or epidural space using an aseptic technique. Catheters were passed via the L4–L5 intervertebral space and advanced 1.3 cm in the caudal direction. Rats were allowed 4 days to rest for recovery from the operation.

To measure the response to noxious heat stimulus, a tail-flick test was performed. A 100-W projector lamp was focused on the distal segment of the tail approximately 5 cm from the tip. The time at which rats withdrew the tail was defined as the tail-flick latency. A cutoff time of 10 s was used to avoid damaging the tail.

To measure the response of legs to a noxious mechanical stimulus, a paw pressure test was applied to the dorsal surface of both hind paws using a device capable of progressively increasing the pressure at a rate of 15 g/s. The pressure at which the rat withdrew the

paw from the device was defined as the paw pressure threshold, and the mean for both paws was used for analysis. A cutoff pressure of 400 g was used to prevent damage to the paws.

Motor function in the lower limbs was assessed by grading: 0 = none, 1 = partially blocked, and 2 = completely blocked.

Various concentrations of local anesthetic or saline were injected intrathecally in a volume of 20 µl or epidurally in a volume of 100 µl followed by 10 µl saline to flush the catheter. Tail-flick test, paw pressure test and motor function assessment were performed 10, 20. 30. 60. 120, 180, and 240 min after injection and continued daily for 4 days.

After the last experiments, the rats were euthanized by injection of an overdose of pentobarbital and then perfused intracardially with a phosphate-buffered 2.0% paraformadehyde/2.5% glutaraldehyde fixative. Methyl green solution was injected to confirm the location of the catheter after the perfusion. The spinal cord and nerve roots were dissected out and immersed in the same fixative for 4 h. Two specimens (10 mm rostral and caudal to the conus medullaris from each rat) were postfixed with cacodylate-buffered 1% osmium tetroxide, dehydrated in a series of graded alcohol solutions, and embedded in epoxy resin. From the embedded tissue, 1- µm transverse sections were obtained and stained with toluidine blue dyes. Sections obtained from 10 mm rostral to the conus (caudal spinal cord) were used for qualitative evaluation. Quantitative analysis of nerve injury was performed using the sections obtained from 10 mm caudal to the conus. Each fascicle present in the cross-section was assigned an injury score of 0 to 3. The injury score for each cross-section was then calculated as the average score of all fascicles present in the cross-section.

Data are presented as mean ± SEM. Tail-flick latencies and paw pressure thresholds were converted to the percentage of the maximal possible effect. The area under the time–effect curve was calculated by accumulating the effect measured at discrete time intervals using the trapezoidal integration method. The results were analyzed by ANOVA with repeated measures followed by Scheffe and Dunnett tests. The injury score for each technique and each solution was compared using two-way ANOVA followed by the Scheffe test. The frequency (i. e., the number of rats with lesions) in each group was analyzed by the chi-square test.

De la Calle and Paíno (2002) described a procedure for direct **lumbar puncture in rats**. Female Sprague Dawley rats weighing 180–250 g were used. The rats were placed in a transparent plastic box and anesthetized with a mixture of 4% isoflurane in O_2:N_2O (30:70 v:v). Then, a mask was placed over the rat's nose and mouth, and the isoflurane concentration was lowered to 1.5%–2% for the remainder of the procedure. The lower half of the animal's back was shaved and scrubbed with povidone-iodine. The animals were then placed in a prone position on a Styrofoam board (25 cm ×13 cm ×6 cm), with the mask opening fixed 12 cm from the end of the board. The rat's forelimbs were extended to the front and fixed to the board with tape, taking care not to force the neck. The hind limbs were left to hang off the board, lying on the table. In that way, the animal's vertebral column was flexed around the L3–L5 level, widening these intervertebral spaces. Using the anterior part of the iliac crest as a tactile landmark for the L5–L6 intervertebral level, a 2-cm longitudinal incision was made with a scalpel rostral to this point. The fascia of the paravertebral muscles was excised and withdrawn to the sides with the help of sterile cotton plugs. A neonatal lumbar puncture needle (25 G × 1 TW) was introduced perpendicular to the surface through the widest intervertebral space and lowered until it came into contact with the vertebral body. Occasionally, a short flicking of the tail or of a limb was observed. The moment of penetration into the intrathecal space could be detected by a change of resistance to the introduction of the needle. Normally, the bevel of the needle was oriented rostrally although, if the puncture was not initially successful, the needle was tentatively rotated. A few seconds after withdrawal of the inner needle filament, the cerebrospinal fluid (CSF) could be observed to spontaneously flow into the needle cup. Triggering or accelerating liquid flow could be achieved by: (1) pressing the neck of the animal with a finger (thereby increasing the intrathecal pressure), (2) holding the head of the rat secure with one hand and pulling its tail with the other (the mechanical traction accommodates the needle tip in the intrathecal space), and (3) changing the inclination of the board to about 45° (also increases intrathecal pressure).

The procedure can also be used for the delivery of chemical products or cell suspensions to the intrathecal space. After collecting 20–50 µl CSF, 50 µl of 2% mepivacaine was injected. Hind limb paresis and anesthesia were produced that lasted for 30 min.

Bahar et al. (1984a) described chronic cannulation of the intradural and extradural space in the **rat**. Under anesthesia a hole was drilled in the penultimate lumbar vertebra of male rats and the appropriate space can-

nulated. The catheter was tunneled subcutaneously to emerge at the neck.

Using this technique, Chanimov et al. (1997) studied neurotoxicity after spinal anesthesia induced by serial intrathecal injections of magnesium sulfate. Male Wistar rats were given intrathecal injections of 0.02 ml of 6.3% or 12.6% magnesium sulfate or 2% lignocaine or 0.9% sodium chloride as a series of 15 injections on alternate days for a period of 1 month.

Yaksh and Rudy (1976) described a procedure of chronic catheterization of the spinal subarachnoid space in **rats** and **rabbits**. A polyethylene catheter (PE-10) was inserted through a puncture of the atlanto-occipital membrane into the spinal channel in anesthesia and secured to the skull. In this way, drugs could be administrated into the spinal subarachnoidal space of unanesthetized animals.

Cole et al. (1990) used this model to determine the influence of spinal tetracaine on central nervous system metabolism during nociceptive stimulation in **rats**.

Studies in Mice

Åkerman et al. (1988a, b) used **mice** to study spinal morphine antinociception potentiation by local anesthetics.

A simple technique for intrathecal injections by lumbar puncture in unanesthetized **mice** was described by Hylden and Wilcox (1980).

This model has been used by Langerman et al. (1994) to evaluate the potency of various local anesthetics. Adult Swiss Webster male mice were slightly anesthetized with halothane and the skin overlying the dorsal lumbar spine was opened using a transverse incision 8–10 mm. Animals were allowed to recover for 1 h before the evaluation of the baseline nociceptive response latency. Thirty min after baseline testing, intrathecal local injections were performed with an automatic syringe fitted with a 30-gauge needle. Fourth spinal space was identified and the needle was inserted between the two spinal processes in a cephalad direction at a 20° angle. Resistance encountered at approximately 5–6 mm from the skin indicated proper location of the needle in the spinal canal. A fixed 10 µl volume of injectate was used. Analgesia was measured using the tail-flick test based on tail withdrawal in response to heat generated by a light beam focused on the ventral tail surface.

Using this model, Åkerman (1985) obtained dose–response curves for lignocaine, mepivacaine, bupivacaine, amethocaine and cinchocaine after a single intrathecal injection in **mice**.

Studies in Rabbits

Bieter et al. (1936a) described a method of inducing spinal anesthesia in the **rabbit** and determined threshold anesthetic and lethal concentrations. Injections were performed at the lumbo-sacral union between the spinous process of the last lumbar vertebra and the first sacral spinous process. A dose of 0.02 ml per centimeter of spinal length was chosen as standard volume for determining minimal anesthetic and minimal lethal doses. These authors (Bieter et al. 1936b) determined the duration of spinal anesthesia in the rabbit after applying an electrical stimulus to the skin of the animal and observing the changes in respiration.

This method was also used by Luduena et al. (1960).

Langerman et al. (1991) studied the duration of anesthesia after a single subarachnoid injection of a local anesthetic in **rabbits**. Tetracaine 1% 0.5 mg/kg was administered in 10% glucose or in lipid solution via catheters chronically implanted in the subarachnoid space. The pharmacologic effect was assessed by evaluating the intensity and duration of motor blockade according to a three-stage scale.

Wakamatsu et al. (1999), Ohtake et al. (2000), and Oka et al. (2001) studied the effects of intrathecally administered local anesthetics on glutamate release and neuronal injury in **rabbits**. New Zealand white rabbits were anesthetized with isoflurane. With the rabbits in prone position, midline skin and subcutaneous fascia were incised between the third lumbar and the first sacral spinous process after infiltration with 0.25% bupivacaine. Muscles were dissected; the third to seventh processes, ligamentum flavum and epidural fat were sequentially removed; and the underlying dura was exposed. Using an operating microscope, a small slit was made in the dura and arachnoid membrane at the L3–L4 interlaminar space. A loop-type dialysis probe was then implanted. A PE10 catheter for the administration of saline or the local anesthetic to be tested was implanted intrathecally through the slit made at the L6–7 interlaminar space so that the tip of the catheter was located at the level of the cauda equina. The implanted dialysis probe was perfused with artificial cerebrospinal fluid bubbled with 95% oxygen and 5% CO_2 at pH 7.2. Samples were collected before and after administration of test substance and analyzed for glutamate.

After collecting the last sample (90 min after intrathecal administration of test substance) the catheters were removed, and all incisions were sutured. Isoflurane was discontinued, and the lungs were ventilated with 100% oxygen. Extubation of the trachea was

performed when adequate spontaneous ventilation occurred. The animals were allowed to recover with infusion of Ringer's solution and antibiotic treatment.

The animals were neurologically assessed daily until 1 week after test drug administration by an observer unaware of the treatment group. Sensory function was evaluated by seeking an aversive response to pinprick stimulation with a 23-gauge needle, progressing from sacral to thoracic dermatomes. The score of the sensory function was assessed by a three-point grading scale. The hind limb motor function was assessed by a five-point grading scale.

After completion of the neurologic function scoring at 1 week, the animals were re-anesthetized, and transcardiac perfusion and fixation were performed. The spinal cord was removed and refrigerated in phosphate-buffered formalin 10% for 48 h. After dehydration in graded concentrations of ethanol and butanol, the spinal cord was embedded in paraffin. The coronal sections of the spinal cord at L3, L4, and L5 levels were cut at a thickness of 8 μm and stained with hematoxylin and eosin. The degree of spinal cord damage was assessed in terms of vacuolation of the dorsal funiculus with a four-point grading scale and chromatolytic changes in the motor neuron. The neurons with chromatolytic appearance were identified by round-shaped cytoplasm with the loss of Nissl substance from the central part of the cell and eccentric nuclei. The number of motor neurons with a chromatolytic appearance was counted in two sections for each animal and averaged.

Parametric data were presented as mean ± SD. To determine differences in glutamate concentrations, a repeated-measures analysis of variance was performed. The cutaneous sensation, hind limb motor function, and morphological changes of the spinal cord were analyzed with a non-parametric method (Kruskal-Wallis test) followed by the Mann–Whitney *U*-test

Studies in Dogs

Wagner et al. (1940) performed spinal anesthesia in anesthetized **dogs** by puncture at the fourth lumbar interspace and measured the duration of anesthesia after the application of various local anesthetics.

Muschaweck et al. (1971) performed comparative intrathecal tolerance studies in dogs. **Beagle dogs** weighing 8–12 kg were anesthetized with 30 mg/kg sodium pentobarbital intravenously. The animals were intubated and submitted to artificial respiration. The fur on the neck was shaved and the skin disinfected. All further procedures were carried out under sterile conditions. The spinal canal was punctured through the foramen magnum at the atlanto-occipital joint. Successful entry of the spinal cervical canal was checked by withdrawal of cerebrospinal fluid. Then 5 ml of cerebrospinal fluid was withdrawn and used as the solvent for the tested local anesthetics. The same volume was injected intrathecally either as a solution of local anesthetics in concentrations used in therapy or as control (saline solution). Artificial respiration was continued until spontaneous breathing resumed. Motor performance was checked for 24 h. Two days later, the animals were sacrificed under anesthesia. Dissection included the cerebellum, medulla oblongata, and sections from the cervical, thoracic and lumbar cord, carefully observing that the same segments were always taken, including the injection site. Segments were semi-fixed in 8% buffered formaldehyde for 2 days. When semi-fixed, the vertebral arches were opened, and the spinal cord as well as the roots of the spinal nerves were removed and completely fixed. After embedding in gelatin and Paraplast, a fast red 7B and myelin sheath staining according to Olivecrona were performed on serial sections from the site of injection as well as from cervical, thoracic and lumbar marrow. Hematoxylin–eosin staining as well as periodic acid-Schiff (PAS) staining and the iron reaction were all performed in one section. The presence or absence of nerve damage and of inflammation was noted.

A chronic model for investigation of experimental spinal anesthesia in the **dog** was described by Feldman and Covino (1981).

Dohi et al. (1987) inserted a polyethylene catheter into the lumbar subarachnoid space in **dogs** through a small hole in the dura for administration of drugs. The tip of the catheter was placed approximately 2–3 cm cephalad to the lumbar electrode introduced for recording of hydrogen clearance to measure spinal cord blood flow.

Kozody et al. (1985) measured spinal cord and spinal dural blood flow in the cervical, thoracic and lumbosacral regions in **dogs** using the microsphere technique. Measurements were taken 20 and 40 min after lumbar subarachnoidal injection through the L5-L6 or L6-L7 interspace.

Yaksh et al. (1995) studied the safety of chronically administered neostigmine methylsulfate in rats and **dogs**. Adult beagle dogs weighing 13–17 kg were adapted for 5 days to experimental protocols and placement of a nylon vest. For placement of the spinal catheter, the dogs were sedated (atropine 0.04 mg/kg and xylazine-Rompun 1–2 mg/kg i.m.) given an i.m. injection of penicillin G and procaine. Anesthesia

was induced by mask administration of halothane (3%–5%) and then the trachea was intubated. The dog was maintained under spontaneous ventilation with 1%–2% halothane and 50% N_2/50%O_2. Surgical areas on the back of the neck and head were shaved and prepared with alcohol and a povidone-iodine scrub, and the dog was placed in a stereotaxic head holder. After draping and using sterile technique, the cisterna magna was exposed, and a small incision (1–2 mm) was made. The intrathecal catheter (polyethylene rubbing PE-50 stretched by 30%, making the nominal diameter 0.6 mm) was inserted and passed caudally at a distance of 40 cm, to a level corresponding approximately to the L3–L4 segment. The presence of the catheter in the intrathecal space was confirmed by free withdrawal of cerebrospinal fluid. A small stainless steel screw was placed in the skull and the catheter fixed to the screw. The catheter was tunneled subcutaneously and caudally to exit on the upper left back at the level of the scapula. The incision was closed by sutures, the halothane turned off and the animal allowed to recover. An analgesic was administered for postoperative pain medication. At this time, the catheter was connected to the infusion pump placed into a vest side pocket, and an infusion of sterile saline (2 ml/day) was started.

For a 28-day infusion study, dogs were randomly assigned to receive saline or neostigmine (4 mg/4 ml). After 28 days of infusion, the dogs were sacrificed. After induction of deep anesthesia, the animal was manually ventilated to maintain adequate oxygenation. A percutaneous puncture of the cisterna magna was performed and cerebrospinal fluid withdrawn for analysis. The chest was opened and a large-bore cannula placed in the aortic arch through which was perfused saline followed by 10% formalin. After fixation, the dura was exposed by an extensive laminectomy of the spinal canal and the lower brainstem, being careful to leave the catheter and the dura undisturbed. Dye was injected through the catheter to determine its integrity, visualize the position of the intrathecal catheter, and determine the spread of dye around the catheter. The spinal cord was removed in four blocks (cervical, thoracic, caudal, and rostral from the catheter tip), taking care to keep the dura intact, and placed in formalin. After fixation, tissue blocks were embedded in paraffin and then decalcified overnight, embedded in paraffin, sectioned at a thickness of 6–7 µm and stained with hematoxylin and eosin. Particular attention was given to the presence or absence of fibrosis and other reactions around the catheter, dural thickening or other reaction, such as inflammation in the epidural space, leptomeninges/subarachnoid space, or spinal cord parenchyma, microglial nodules, demyelinization, or gliosis. The degree of chronic and/or acute inflammation was graded as normal, mild, moderate or severe.

Studies in Other Species

Bahar et al. (1984b) performed chronic implantations of nylon catheters into the subarachnoid space of Wistar **rats** and **marmosets** and tested the effects of local anesthetics.

The technique of evaluation of spinal anesthesia by a local anesthetic in the **Rhesus monkey** was described by Denson et al. (1981).

Lebeaux (1975) recommended the **sheep** as a model for testing spinal and epidural anesthetic agents. To ensure accurate and reproducible administration of drugs into these restricted anatomical regions, a wooden stock was built to restrain the sheep without stress but to allow arching of the lumbosacral spine in order to open the inter vertebral space. The stock consisted of a table with holes for the front feet, hinged at one end to a fixed stanchion. The hinges permitted tilt of the table. The sheep was placed prone on the table, the head secured in the stanchion and the front feet passed through the holes and tied. The lumbosacral interspace used for both spinal and epidural tap was separated by positioning and tying the rear limbs cephalad beside the abdomen, thereby extending the knee and flexing the hip. The wool was clipped from the sheep's back, the skin of the lumbosacacral area was washed and swabbed with iodine, and the vertebral spines and interspaces identified by palpation, marked, and numbered with a felt pen.

Spinal block was performed using either the midline or lateral approach for tapping the subarachnoid space. A 22-gauge disposable spinal needle was inserted subarachnoidally, and proper position was verified by spontaneous flow of cerebrospinal fluid upon removal of the stylet. With the table top and sheep parallel to the floor, the Luer-Lok syringe holding 1 ml of sterile 5.0% dextrose solution containing 2.5 mg (0.25%) tetracaine was attached to the needle. After aspiration of spinal fluid, the solution was injected within 5 s. At completion of the injection, spinal fluid was again aspirated to confirm injection into the subarachnoid space. The needle was withdrawn and the table tilted 10° caudally to restrict the spread of the hyperbaric solution to the lumbosacral area. The sheep was held in this position for 20 min.

Immediately after injection, the rear feet were untied and allowed to hang free on either side of the table

for evaluation of sensation and/or reflexes in the rear limbs. Then, 20 min after injection the sheep was removed from the table and positioned in a sling fashioned from a heavy duty 50-gallon plastic barrel split in half longitudinally and mounted on a metal support. Holes cut in the barrel allowed the feet to drop through so that comfortable sternal recumbency was maintained while permitting anesthetic evaluation to continue. When complete sensation returned in the skin of the dorsum, the sheep was removed from the sling and placed on a straw-bedded floor so that weight support and full recovery could be assessed.

Kyles et al. (1992) described a simple and noninvasive method for the chronic implantation of intrathecal catheters in the **sheep**.

G.1.5.2 Blockade of Urethral Reflex in Rabbits

PURPOSE AND RATIONALE

For evaluation of spinal anesthetics the test substance has to be injected into the spine. For the study of local anesthetics for which conduction anesthesia has been verified, intraspinal injection provides more complete information. Spinal anesthesia has been studied in rabbits (Bieter et al. 1936a, 1936b; Luduena and Hoppe 1951; Luduena 1957; Gonzalez and Luduena 1961; Turner RA 1965), cats (Sechzer 1965), and dogs (Dvorak and Manson 1930). If the solution of test substance is injected intrathecally to male rabbits, the presence of anesthesia may be determined by the urethral reflex (Luduena 1957).

PROCEDURE

Male Chinchilla rabbits weighing 3.0–3.5 kg are used. The volume administered intrathecally is 0.02 ml per centimeter of spinal length. It is injected at a rate of 1 ml per min with a 22-gauge needle that is 3.8 cm long. The needle is introduced between the sixth and seventh lumbar vertebrae, and not through the lumbosacral space. The needle, held as lightly as possible between the thumb and forefinger, is introduced slowly until a typical sharp and sudden twitch occurs. This indicates penetration into the subarachnoidal space. A one ml tuberculin syringe is then attached to the needle. It is not possible to aspirate fluid after insertion of the needle. However, it is possible to aspirate a portion of the injected solution. Very little pressure is required for injection of 0.4 to 0.6 ml of anesthetic solution while the animal is restrained in a canvas hammock. A catheter is inserted into the urethra, where it is kept without digital pressure. At 15- or 20-s intervals, 2 to 3 ml of water, at room temperature, are injected rapidly into the catheter. This causes the "urethral reflex", consisting of retraction of the penis and contraction of the anal sphincter. The water runs out of the urethra around the catheter. Without medium or high concentrations of the anesthetics the reflex is absent on the first reading. After loss of the urethral reflex, the test is repeated every minute or two for 15 min, and thereafter at longer intervals. The duration of urethral areflexia is taken as the time of the first positive reading (reflex absent) to the middle of the interval between the last positive and the first negative reading. This duration varies linearly with the logarithm of concentration.

EVALUATION

The threshold anesthetic concentration in grams per 100 ml for abolition of the urethral reflex for 5 min, the TAC_5, is a standard for comparison. There is a correlation between activity and systemic toxicity. The ratio of the activity to the irritancy is the most important parameter.

MODIFICATIONS OF THE METHOD

Burdyga and Magura (1986) studied the effects of local anesthetics on the electrical and mechanical activity of the guinea-pig ureter.

G.1.6 Endoanesthetic Effect

PURPOSE AND RATIONALE

Endoanesthesia has been described as the effect of local anesthetics on viscero-afferent receptors, located predominantly in the lung as distension receptors (Meier and Bein 1950; Zipf 1953, 1957, 1959, 1966.

1968; Zipf et al. 1955; Zipf and Oehler 1955; Reichertz et al. 1957; Zipf and Reichertz 1957; Zipf et al. 1963; Wellhöner and Conrad 1965; Siemoneit et al. 1966; Dittmann and Zipf 1973; Borchard 1979). The endoanesthetic effect has been claimed to be the basis of an antitussive action of local anesthetics (Bucher 1956; Bein and Bucher 1957; Kraushaar et al. 1964).

PROCEDURE

Male guinea pigs weighing 300–400 g are anesthetized by intraperitoneal injection of 1.25 g/kg urethane. The studies are carried out on spontaneously breathing or artificially respirated monovagotomized or bivagotomized animals. Intravenous injections are given via a catheter into the jugular vein. The flow rate of the respiratory air is measured with a Fleisch tube connected to a pneumotachograph. In experiments with positive pressure respiration, the open end of the Fleisch tube is attached to a respiratory pump (40 strokes per min). A cannula is inserted into the carotid artery and connected to a pressure transducer.

The left nervus vagus is exposed from the thorax aperture until his entry into the foramen jugulare and cut in the middle of the distance. Both ends are placed over 3 wires of Ag/AgCl 6-way electrodes. The edges of the skin wound are pulled upwards with clamps and the space around the trachea is filled with paraffin to prevent the nerve from drying out. The afferent and efferent vagus potentials and also their integration curve (Zipf and Reichertz 1957) are recorded on a direct recorder. In addition, the ECG in the second lead is recorded continuously. The animal is shielded electrically with the aid of a Faraday cage.

The nervus vagus conducts not only afferences from the lung but also from other organs to the brain. The base points of the integral curve, which correspond to the vagus action potentials being synchronous with inspiration and issued by the pulmonary distension receptors, therefore lie above the baseline of the recorder tracing. The vagus afferences which remain after subtraction of the vagus activity synchronous with respiration ("inspiratorial activity") are called "residual activity". The level of inspiratorial activity depends both on the bronchial width (degree of inflation of the lungs) and on the functional state of the pulmonary receptors and of the afferent pathway. The occurrence of a bronchospasm is detectable from the decrease in the pneumotachogram, if the respiratory rate is not reduced at the same time.

EVALUATION

The following parameters are evaluated:

Afferent and efferent inspiratorial vagal activity, maximum flow rate of the respiratory air during inspiration and expiration, tidal volume, duration of the respiratory phases (inspiration = t_i, expiration = t_e, respiratory pause = t_p), heart rate and blood pressure.

The decrease of electrical activity after various doses of standard and test drugs is calculated at different time intervals after drug administration. Maximum of activity and decay with time are registered.

Statistical analysis is performed using the paired and non-paired *t*-test, after the applicability has been first checked with the F-test.

CRITICAL ASSESSMENT OF THE METHOD

The correlation between antitussive and local anesthetic activity has been challenged by Sell et al. (1958) and by Ther and Lindner(1961).

MODIFICATIONS OF THE METHOD

Bein and Bucher (1967), Wellhöner and Conrad (1955) tested various compounds for their anesthetic effect on pulmonary stretch receptors of **rabbits**.

G.1.7 Effect on Electroretinogram

PURPOSE AND RATIONALE

The retina, which belongs in ontogenesis to the central nervous system, can be prepared without damaging the parenchyma. The transretinal potential which can be induced by a light flash can be used as an objective criterion for the functional state (Sickel et al. 1960). The multi-phase potential path of the electroretinogram consists of an initial a-wave, a subsequent b-wave and an e-wave which starts with a delay after the end of the stimulus. While the amplitudes of the a- and e-wave are in the order of 50 µV, the amplitude of the b-wave (Φ_b) is 500–1000 µV. The electroretinogram can be used for various purposes, such as the evaluation of local anesthetics (Borchard 1979).

PROCEDURE

Frogs (*Rana esculenta*) are kept in dark for 1 h before beginning of the preparation. The frog is sacrificed by decapitation, the eyeball excised in dim red light and cut into two halves with the aid of a rotating blade. The retina together with the pigmented epithelium and choroid is removed from the rear half of the eye and transferred to a dish with Tyrode solution. The retina is then detached from the pigmented epithelium by careful shaking and spread out on a Monodur net. The net is fixed to a round carrier with a narrow ring and the chamber is transferred to a flow-through apparatus. An electrical pump is used for superfusion of the retina with Tyrode solution.

In order to apply the local anesthetic only to the receptor or vitreous body side of the retina, an apparatus is used in which the tissue on a silk net is stretched as the partition between two chamber halves which can perfused separately (Borchard and Erasmi 1974).

The electroretinogram is recorded with Ag/AgCl electrodes. After amplification, the signal is registered on a recorder or an oscillograph. Light stimuli of 10 ms are generated. The light from a low-voltage light source is focused on a electromagnetic shutter with a stimulus frequency of 0.1 Hz. Light stimuli of 1 s duration are used at intervals of 3 min to measure the influence of the local anesthetics on the electroretinogram as a function of light intensity.

All experiments are performed after adaptation to darkness and at room temperature. The amplitude of the b-waves (Φ_b) which is measured from the lowest point of the a-wave to the maximum of the b-wave is used for evaluation. In order to obtain stationary test conditions, the experiment is started after a 45 min adaptation period. The stimulus signal is recorded by means of a photocell inserted in the light path.

Various concentrations of the local anesthetics are applied and various light intensities are used. The decrease of the b-wave starts immediately and then progresses slowly and continuously. After changing over to Tyrode solution, the decrease in the exposure potential is completely reversible.

EVALUATION

After various doses, time-response curves can be drawn and for a given time interval ED_{50} values can be calculated. Moreover, the influence of local anesthetics on the b-wave at various light intensities can be estimated.

MODIFICATIONS OF THE METHOD

Isolated retina for electroretinogram has been used not only from **frogs** but also from **rats** (Huang et al. 1991; Doly et al. 1993), **rabbits** (Mochizuki et al. 1992; Maynard et al. 1998) and from **beef** (Gosbell et al. 1996; Walter et al. 1999).

Moreover, the electroretinogram has been used as parameter for many *in vivo* studies with different purposes, e. g., on the effect of drugs after retinal ischemia, in various animal species, such as **rats** (Sugimoto et al. 1994; Hotta et al. 1997; Biró et al. 1998; Block and Schwarz 1998; Estrade et al. 1998; Ettaiche et al. 1999; Li et al. 1999), **rabbits** (Takei et al. 1993; Zemel et al. 1995; Horiguchi et al. 1998; Jarkman et al. 1998; Liang et al. 1998), **cats** (Imai et al. 1991; Ostwald et al. 1997; Kim et al. 1998), **dogs** (Jones et al. 1995; Yanase and Ogawa 1997) or **monkeys** (Tagliati et al. 1994).

G.2 Neuromuscular Blocking Activity

G.2.0.1 General Considerations

Neuromuscular transmission is mediated by mediated by nicotinic acetylcholine receptors for which various

subtypes are described (Sargent 1993; McGehee and Role 1995; Karlin and Akabas 1995; Alexander et al. 2001).

Neuromuscular blocking agents are distinguished by whether or not they cause depolarization of the motor end plate. They are classified either as competitive (stabilizing) agents, of which d-tubocurarine is the classical example, or as depolarizing, desensitizing agents such as succinylcholine.

The **rabbit head-drop method** was described by Varney et al. (1948, 1949), Burn et al. (1952), Levis et al. (1953). Rabbits were given an interrupted intravenous injection at a rate of 0.1 ml every 15 s until the muscles supporting the head become sufficiently relaxed to prevent the head to be raised when the back is stimulated. This method has been replaced by the rabbit sciatic nerve-gastrocnemius muscle preparation, the isolated phrenic nerve diaphragm preparation of the rat, and the chick sciatic nerve-tibialis anticus muscle preparation.

The method described by Allmark and Bachinski (1949) used an inclined screen for testing curare-like activity in **rats**.

Skinner and Young (1947) placed **mice** weighing 15–17 g in sloping rotating cylinders. Mice falling away during 20 min after subcutaneous injection were considered as reactors. Dose response-curves and potency ratios could be calculated from the logarithmic dose-response curves using different doses of test compound and the standard tubocurarine chloride.

Collier et al. (1949) used a rotating drum to assess the activities of paralysant, convulsant and anesthetic drugs in mice.

Fatt and Katz (1951) performed an extensive study on neuromuscular junction by recording end-plate potentials from curarized frog sartorius motor end-plates, using a KCl-filled microelectrode inserted into the muscle fiber in the region of the motor end-plate.

Electrophysiological analysis of transmission at the skeletal neuromuscular junction was reviewed by Prior et al. (1993).

A review on new neuromuscular blocking drugs was given by Hunter (1995).

Savarese et al. (1975) discussed the potential uses of short-acting non-depolarizing neuromuscular-blocking agents as predicted from animal experiments.

G.2.0.2 Isolated Phrenic Nerve Diaphragm Preparation of the Rat

PURPOSE AND RATIONALE

The isolated phrenic nerve diaphragm preparation of the rat was originally described by Bülbring (1946) to study the influence of adrenaline on tissue functions normally elicited by acetylcholine. The method has been modified and is widely used by many investigators for studying drugs affecting the neuromuscular transmission.

PROCEDURE

Adult male Wistar rats are used. The animal is sacrificed and the blood is drained. The skin is removed from the middle of the chest. The thorax is opened and the front part of the left thoracic wall is removed.

The phrenic nerve can bee seen quite distinctly. The nerve is cut just below the thymus and a thread is attached to the cut end. The nerve is than freed carefully from the attached tissue. However, no attempt is made to clean the nerve completely from all attached tissue. An incision is made in the left abdominal wall just below the diaphragm. Two converging cuts are made through the diaphragm and the ribs towards the tendinous part of the diaphragm with the phrenic nerve attached to the center of the diaphragm. The fan-like preparation is about 3 mm wide at the tendinous end and is about 15 mm wide at the costal margin. A thread is attached to the tendinous part of the diaphragm.

The preparation is fixed by a stainless steel rod with a pair of pins hooked to the rib. It is lowered into an organ bath and the thread from the muscle is attached to a force transducer. The nerve is stimulated with a pair of electrodes with a hole about 1 mm wide. The right phrenic nerve-diaphragm preparation is isolated in the same manner. The organ bath containing Tyrode solution with 2.0 g/l glucose is oxygenated at 37°C with 95% O_2 and 5% CO_2. The nerve is stimulated 12 times per min by rectangular-wave pulses of 0.5 ms duration at 3–5 V. Contractions are isometrically recorded through a transducer on a polygraph. The test drugs are left in the organ bath either for short periods of time (3–8 min) or for as long as the maximum effect can be observed. After a wash-out period of 3–5 min, the next dose can be added.

EVALUATION

The force of contractions after addition of various doses of the test drug is compared with the effect seen prior to drug application. Dose-response curves can be established.

CRITICAL ASSESSMENT OF THE METHOD

The isolated phrenic nerve diaphragm preparation of the rat is an excellent method for determining the potency of a drug to block or facilitate neuromuscular transmission. However, it is not a good preparation for differentiating between depolarizing and non-depolarizing neuromuscular blocking agents because, in many cases, depolarizing blocking agents fail to demonstrate initial facilitation and fail to reverse the effect of non-depolarizing blocking agents. For differentiating between depolarizing and non-depolarizing blocking agents the chick sciatic nerve-tibialis anticus muscle preparation is preferred. In this preparation, the curare-like drugs produce a neuromuscular blockade whereas the decamethonium-like drugs induce a contracture of the slow fiber when the neuromuscular transmission is blocked.

MODIFICATIONS OF THE METHOD

Colbert et al. (1990) studied the effects of temperature on the experimental reliability of the isolated rat phrenic nerve/diaphragm preparation.

Vizi et al. (2003) used *in vitro* isolated phrenic nerve-hemidiaphragm preparations of mice, rats and guinea pigs and *in vivo* sciatic nerve-anterior tibialis muscle preparations from anesthetized rats, guinea pigs and cats to characterize a new short-acting non-depolarizing muscle relaxant.

Van Riezen (1968a, b) described the sciatic nerve-tibialis anticus muscle preparation in **chicks**. Three to 8 day old chicks are decapitated and the skin of the legs is rapidly removed. The leg is separated from the body by cutting through the hip joint. The muscles of the thigh are dissected and the sciatic nerve with the superficial peroneal branch is freed from the upper leg tissue. The fascia is removed from the lower leg and the tibialis anticus tendon identified. A thread is attached to the tendon of the muscle and the tibialis anticus muscle is freed towards but not up to the knee joint attachment where the nerve enters into this region. The upper and lower leg bones are then cut off leaving the muscle with its nerve attached to the knee joint. The tendon is fasted by a hook to a ring in the bottom of the organ bath. A thin steel rod is attached to the knee joint. The contractions of the muscle are recorded isometrically. The nerve is passed through an electrode similar to that used in the rat phrenic nerve-diaphragm method. The nerve is stimulated six times per min for 0.5 ms duration at supramaximal voltage.

Jenden et al. (1954) described the isolated lumbrical muscle of the **rabbit** as a preparation which is sensitive to competitive (*d*-tubocurarine-like) and depolarizing (decamethonium-like) blocking agents. This muscle is cylindrical in shape, about 18 mm long and 1 mm in diameter and has a wet weight of about 15 mg.

Jenden (1955) used the isolated diaphragm of **guinea pigs** to study the effect of drugs upon neuromuscular transmission.

Hoppe (1955) reviewed the potency of neuromuscular blocking agents in various species.

Birmingham and Hussain (1980) used the phrenic nerve-diaphragm and the hypogastric nerve-vas deferens preparation of the guinea pig for comparison of the skeletal neuromuscular and autonomic ganglion-blocking potencies of non-depolarizing relaxants.

Wessler and Kilbinger (1986), Wessler and Steinlein (1987), Wessler et al. (1992) described a modi-

fied **rat** phrenic nerve-hemidiaphragm preparation whereby most of the muscle was cut off (end-plate preparation).

Muir et al. (1989) used biventer cervicis nerve-muscle preparations from **young chickens** and phrenic nerve-hemidiaphragm preparations from **rats** to evaluate neuromuscular blocking agents. Microelectrode recordings were obtained from the nerve-hemidiaphragm preparation of the rat and from the costocutaneous nerve-muscle preparation of the North American **garter snake** (*Thamnophis sirtalis*). The later preparation is particularly suitable for voltage clamp recording from the neuromuscular junction because it possesses large diameter fibers which aid visualization and penetration of endplates. This, coupled with compact endplates, allows good control of membrane voltage over the entire endplate region when using the two-microelectrode voltage clamp technique.

In order to record evoked endplate currents without accompanying muscle contraction, cut fiber preparations were used. Dissection and cutting of muscle fibers was performed at low K^+ (2 mmol/L) physiological solution perfused for approximately 30 min. Snake nerve-muscle preparations were mounted in a physiological salt solution of pH 7.1–7.2 containing (mmol/l) NaCl 159, KCl 4.2, $CaCl_2$ 1.5, $MgCl_2$ 4.2, HEPES 10. Rat nerve-muscle preparations were mounted in Krebs solution of the same composition as that used for tension experiments. The muscles were mounted in a Sylgard-coated Perspex dish and endplates were voltage clamped using glass capillary microelectrodes (resistance 2–10 MΩ). Voltage recording electrodes were filled with potassium chloride 3 mol/l and current passing electrodes were filled with potassium sulfate 0.6 mol/l.

The nerves were stimulated through platinum electrodes at a frequency of 0.5 Hz with rectangular pulses of 0.05 ms duration and of strength sufficient to produce evoked endplate currents. The evoked endplate currents were filtered by a 5-kHz low pass filter and recorded on magnetic tape. The currents were amplified and digitized by a laboratory interface connected to a computer at a digitization rate of 25 kHz. Ten to 20 evoked endplate currents were collected and averaged after alignment at the middle of their rising phase. Evoked endplate currents decayed as a single exponential function according to the following relationship:

$$I(t) = I(0)\exp^{-t/\tau}$$

where I(t) is the current amplitude at time t after the peak, $I(0)$ is the peak current amplitude and τ is the decay constant.

Experiments were carried out at room temperature. Drug solutions were perfused through the tissue bath for 10 min by peristaltic pump, ensuring a complete exchange of solution.

G.2.0.3 Sciatic Nerve-Gastrocnemius Muscle Preparation in the Rabbit

PURPOSE AND RATIONALE

Levis et al. (1953), Long and coworkers (1959, 1967, 1969) described the sciatic nerve-gastrocnemius muscle preparation in the rabbit as an *in vivo* model for testing neuromuscular blocking agents.

PROCEDURE

Dutch rabbits, weighing 1–2 kg, are anesthetized with 200 mg/kg of phenobarbital administered slowly into the marginal ear vein. The sciatic nerve is ligated and cut, and a shielded electrode is placed on the peripheral portion of the nerve. The gastrocnemius muscle is freed as completely as possible from surrounding muscles and a thread is attached to the tendon of the muscle. The twitches of the muscle are elicited by supramaximal stimulation and are recorded through a force transducer. The parameters for interrupted tetanic stimulation are 250 c.p.s. with pulse durations of 1 ms at 15 V applied for 0.2 s every 10 s. The test drugs are administered intravenously into the marginal ear vein.

EVALUATION

The force of contraction after injection of various doses of the test drug is compared to the values obtained prior drug administration.

CRITICAL ASSESSMENT OF THE METHOD

The preparation has the advantage of studying the drug effects under conditions similar to clinical use.

MODIFICATIONS OF THE METHOD

There are two other preparations, the **cat soleus muscle** preparation and the **cat tibialis anticus muscle** preparation that very useful. They can be prepared in a method similar to that described for gastrocnemius muscle except that close arterial injection can be made using the tibialis anticus preparation. Also, soleus muscle consists primarily of slow muscle, whereas tibialis anticus is fast muscle. The experimental procedures for these two preparations are described in detail by Brown (1938), Bowman et al. (1962), Salafsky (1968).

G.2.0.4 Evaluation of Neuromuscular Blockade in Cats, Pigs, Dogs and Monkeys

PURPOSE AND RATIONALE

Neuromuscular blocking drugs have been evaluated in various animal species. Muir et al. (1991) studied the effects of an analog of vecuronium in anesthetized cats, pigs, dogs and monkeys.

PROCEDURE

Anesthetized Cats

Experiments were carried out on cats of either sex anesthetized with a mixture of α-chloralose (80 mg/kg) and pentobarbitone (5 mg/kg) injected intraperitoneally. Animals were ventilated with air at a rate of 26 breaths per minute using a tidal volume of 13 ml/kg. The right hind limb was immobilized and the contractile responses of the tibialis anterior and soleus muscles to single shock stimulation of the sciatic nerve were recorded. The sciatic nerve was stimulated at a rate of 0.1 Hz using rectangular pulses of 0.2 ms duration and of a strength greater than that required to produce a maximal twitch. Contractions of the nictitating membrane were evoked in response to preganglionic stimulation of the cervical sympathetic nerve with 10-s-duration trains at a frequency of 5 Hz and a strength sufficient to produce maximal contractions of the nictitating membrane. Arterial blood pressure was recorded from the carotid artery using a Statham PC45 pressure transducer. The blood pressure pulse triggered a cardiotachograph to display the heart rate. Both vagus nerves were ligated and, at 100-s intervals, the right vagus nerve was stimulated with 10-s-duration trains at a frequency of 2–5 Hz and with pulses of 0.5 ms duration and strength greater than that required to produce a maximal reduction of heart rate. Contractile responses of muscles were recorded using Grass FTO3C and FT10C force displacement transducers. All responses were displayed on a Grass model 5 ink writing oscillograph.

Savarese (1979) determined not only the potencies of metocurine and d-tubocurarine but also the autonomic margins of safety in anesthetized cats.

PROCEDURE

Adult cats of either sex are anesthetized with α-chloralose, 80 mg/kg, and pentobarbital 7 mg/kg, given intraperitoneally. Cannulas were placed in the left femoral vein and artery for drug injection and recording blood pressure and heart rate. The lungs were mechanically ventilated through a tracheostomy and a small animal ventilator set to deliver 15 ml/kg tidal volume and 20 breaths/min.

The right vagus nerve and the right sympathetic trunk were exposed and divided in the neck. The distal ends were placed on the same shielded platinum wire electrode to permit preganglionic stimulation of both nerve trunks. The left sympathetic trunk was also dissected along its postganglionic portion at the base of the skull, and cut distal to the superior cervical ganglion to permit postganglionic stimulation through another electrode. Trains of square wave pulses (20 Hz for 10 s) were delivered at supramaximal voltage every 4 min simultaneously to all three autonomic nerve trunks. The resulting bradycardia and hypotension (the vagal response) were measured. Contractions of both nictitating membranes, one (the right) elicited preganglionically and the other (the left) elicited postganglionically, were recorded. The maximal vagal response (i. e., cardiac arrest for 10 s) was achieved by stimulation of the right vagus nerve or of both vagus nerves.

Twitches of the right tibialis anterior muscle were elicited at 0.15 Hz via the peroneal branch of the right sciatic nerve, to which square-wave shocks of 0.2 ms were applied at supramaximal voltage. Twitch recording was done via a transducer. All nerves and tendons were kept moist in small pools of mineral oil or in cotton pledges soaked in mineral oil. Tibialis anterior and esophageal muscle temperatures were monitored and kept between 35°C and 38°C by heat lamps.

Simultaneous recordings of heart rate, arterial pressure, pre- and postganglionic elicited contractions of the nictitating membrane, and twitches of the tibialis anterior muscle were made on a polygraph. Cumulative dose–response curves for inhibition of neuromuscular, vagal (parasympathetic) and sympathetic functions were determined simultaneously for each animal. The mechanism of vagal inhibition was localized at parasympathetic ganglia or cardiac muscarinic receptors by determining whether the bradycardic response to methacholine (20 µg/kg) was blocked as well as the neurally elicited bradycardia.

A single-bolus dose of the neuromuscular relaxants producing the delayed depressor response plus tachycardia (Paton 1957) was determined in each animal. This response, being pathognomonic for histamine release, is defined as sudden hypotension to less than 80% of the control arterial pressure within 2 min of relaxant injection and with tachycardia to more than 25% above the baseline value.

Test drugs were given intravenously.

EVALUATION

Data analysis was done by the method of Litchfield and Wilcoxon. Mean dose–response curves were plotted on log-probit paper. Best fit to straight lines on these scales was determined by computerized regression. The cumulative ED_{50} values for vagal and sympathetic inhibition and the cumulative ED_{95} values for neuromuscular blockade were determined from the lines and 95% confidence limits were calculated. Dif-

ferences in potency were considered significant when $P < 0.05$.

The occurrence of histamine release was also treated as an all-or-none response to permit log-probit plotting. The delayed depressor response plus tachycardia was judged to have or have not occurred after each single bolus injection of the drugs. The percentage of animals responding at each dose level was then determined and the data handled by the Litchfield–Wilcoxon method.

The autonomic margins of safety of the test drugs were calculated as the ratios of cumulative doses producing 50% block (ED_{50}) of vagal (parasympathetic) and sympathetic transmission and the ED_{50} for histamine release, each divided by the ED_{50} of neuromuscular blockade.

Anesthetized Dogs

Anesthesia was induced in beagle dogs using intravenous pentobarbitone sodium (3 mg/kg). Animals were intubated, without the use of a muscle relaxant, and artificially ventilated. Anesthesia was maintained with halothane (1.2% inspired concentration) and oxygen. The electrocardiogram was recorded continuously and the signal used to integrate heart rate throughout the experiment. Catheters were inserted percutaneously into the right femoral artery and vein for the recording of arterial blood pressure and the injection of drugs respectively.

A "boomerang" type transducer, originally constructed for recording adductor human pollicis tension (Walts 1973), was fitted to the lower left leg for recording muscle contractions. Submaximal rectangular pulses of 0.1 ms duration at a frequency of 0.1 Hz were delivered to the sciatic nerve through electrodes inserted percutaneously, and the resultant twitches of the foot recorded.

Clutton et al. (1992) studied the autonomic and cardiovascular effects of neuromuscular blockade antagonism in the **dog**. Neuromuscular blockade was antagonized with various anticholinesterase-antimuscarinic drug combinations including atropine, neostigmine, and glycopyrrolate.

Anesthetized Pigs

Domestic pigs of either sex (10–15 kg) were administered a tranquillizing dose (approximately 2 mg/kg) of azaperone about 20 min before induction of anesthesia with 3%–4% halothane in oxygen. Following induction, anesthesia was maintained with α-chloralose (200 mg/kg) dissolved in polyethylene glycol 300 given slowly into a jugular vein. Approximately 1 h later, anesthesia was supplemented with additional chloralose given by slow intravenous infusion which was continued throughout the investigation. The lungs were mechanically ventilated with room air via a tracheal cannula at a rate of 28 breaths per minute and a tidal volume of 12–14 ml/kg. Arterial pressure was recorded through a polyethylene catheter placed in the right carotid artery and connected to a Gould-Statham pressure transducer. Heart rate was monitored continuously by using the arterial pulse pressure to trigger a Grass 7P4F cardiotachometer. Drugs were administered through a catheter in the contralateral vein. Contractions of the tibialis anterior and soleus muscle were recorded by force displacement transducers. A resting tension of 30 g was applied to each muscle. Twitches were evoked every 10 s by stimulation the two branches of the sciatic nerve supplying the lower leg, immediately distal to the point where the nerve divides, using square wave pulses of 0.25 ms duration and at twice the voltage required to produce maximum contraction.

Anesthetized Rhesus Monkeys

Rhesus monkeys were anesthetized with intramuscular ketamine (10 mg/kg). Endotracheal intubation was performed without the use of muscle relaxants. Anesthesia was maintained using a single bolus of pentobarbitone sodium (4 mg/kg) given intravenously followed by infusion, which was adjusted to maintain a steady state of anesthesia. Heart rate was measured continuously by integration of the electrocardiogram. Atropine sulfate (0.25–0.5 mg) was administered i.m. to prevent excessive salivation. Artificial ventilation was supplied and blood pressure recorded continuously. The ulnar nerve was stimulated with rectangular electrical pulses via bipolar subcutaneous needle electrodes. The twitch response of the adductor pollicis muscle were recorded via a Statham transducer attached by a wire to a small U-clamp, which was fixed firmly to the basal phalanx of the thumb.

EVALUATION

Experiments were performed in the various animal species by injecting different doses at hourly intervals to obtain a range of neuromuscular paralysis, i. e., between 10 and 95% inhibition of single-twitch tension. From the data, dose-inhibition lines were constructed using the Levenberg-Marquardt non-linear interactive curve-fitting routine (Brown and Dennis 1972). From these data, doses producing 50% inhibition of induced contractions of the tibialis anterior muscle (cat and pig), hind limb (dog) and adductor pollicis muscle

(monkey) were calculated. Time course measurements were made with doses which produced between 85% and 95% neuromuscular block. Onset time was measured as the time from injection to the first maximally depressed contraction. The recovery time was the time from 75% block to 25% block and the duration of action was the time elapsing from injection to 90% spontaneous recovery compared to pre-drug control twitch tension.

MODIFICATIONS OF THE METHOD

Bowman et al. (1988) investigated structure:action relationships among some desacetoxy analogues of pancuronium and vecuronium in the anesthetized **cat**. Blockade of sciatic nerve-induced contraction of the tibialis and soleus muscles, as well as the effects on vagal-induced bradycardia and on sympathetically induced contractions of the nictitating membrane, were studied.

Khuenl-Brady et al. (1990) used anesthetized **cats** to study the effects of two new nondepolarizing neuromuscular blocking drugs. The indirectly evoked twitch tension of the anterior tibialis muscle elicited by supramaximal square-wave stimuli applied to the peroneal nerve was continuously quantitated by means of a force-displacement transducer and recorded. Onset time (from injection of muscle relaxant to maximum depression of twitch tension), duration of action and recovery index were determined.

Muir et al. (1989) used tibialis anterior and soleus muscle/sciatic nerve preparations in anesthetized **cats** and **pigs** to evaluate neuromuscular blocking agents.

Hoppe (1950) used a nerve-muscle preparation in **dogs** to evaluate curarimimetic drugs. Diaphragmatic respiration was recorded directly by means of a light thread from a suture imbedded in the peritoneal aspect of the right hemi-diaphragm. Stimulation of the peripheral end of the sectioned tibial nerve was accomplished by an induced current once every ten seconds. Muscle contraction was recorded from the Achilles tendon being severed just proximal to the calcaneus.

Hughes and Chapple (1976a, b, 1981; Hughes 1984) used nerve-muscle preparations of **cats**, **dogs** and **rhesus monkeys**.

Ono et al. (1990) recorded the twitch tension of the gastrocnemius-soleus muscle in **rats** after stimulation of the distal stump of the tibial nerve under the influence of a centrally acting muscle relaxant.

Cullen et al. (1980) described two mechanical techniques to measure neuromuscular activity in the intact, anesthetized **dog**. Simultaneous stimulation of the dorsal buccal branch of the facial nerve and ulnar nerve was performed and the evoked mechanical muscle responses measured.

Keesey (1988) discussed the use of single-fiber electromyography (SFEMG) by the AAEE minimonograph 33 as an electrodiagnostic approach to defects of neuromuscular transmission.

Marshall et al. (1994) gave an overview of the pharmacology of rocuronmium bromide in experimental animals.

G.2.0.5 Evaluation of Neuromuscular Blockade in Anesthetized Mice

PURPOSE AND RATIONALE

Electromyographic investigations of the neuromuscular junction are relatively easy to perform in large animal species such as the dog (Cullen et al. 1980). A simple *in vivo* method for the quantitative evaluation of neuromuscular blockade in anesthetized mice has been described by Lefebvre et al. (1992).

PROCEDURE

Female BALB/c mice, 7–9 weeks old, are anesthetized by intraperitoneal administration of 50 mg/kg etomidate or 250 mg/kg mephenesin. Hair is removed from the sciatic area and hind leg by application of a depilatory cream. A lamp is placed 30 cm above the anesthetized animal to maintain a constant body temperature. Two monopolar needle-stimulating electrodes are subcutaneously inserted into the sciatic notch area and two monopolar recording electrodes subcutaneously over the gastrocnemicus belly and in the vicinity of the tendo calcaneus communis, respectively. A ground electrode is inserted under the skin between recording and stimulating electrodes. Stimulation is carried out using a square signal of 0.2-ms duration. The supramaximal stimulation of the sciatic nerve consists of a train of 10 stimuli, lasting 3.3 s with a frequency of 3 Hz. Stimulation intensity is fixed to a value 50% higher than that required to attain the maximal evoked potential response. Two control trains of stimulation are applied before test-drugs administration and then repeated at 1-min intervals until the end of anesthesia which is assessed by reflex movement after pinching the toes or the tail.

Muscle action potentials are recorded using an electromyograph. The low and high cut-off frequencies are set to 16 Hz and 10 kHz, respectively. The electromyogram signal is amplified and plotted on an oscilloscope screen and printed. Evoked active potentials are analyzed using an 8 bits digitizer and the area under the response wave is evaluated for each stimulus (S).

The neuromuscular blocking agents are administered by intraperitoneal route.

EVALUATION

The effects of the test drugs are quantified by measuring the ratio of the fifth response (S5) to the first one (S1) in a given train (S5/S1 response) according to Keesey (1989). These values are almost not influenced by etomidate anesthesia. Neuroblocking agents of competitive type, such as alcuronium, or depolarizing type, such as suxamethonium, decrease this ratio significantly. These effects can be blocked by neostigmine, but not the effect of the snake venom alpha-bungarotoxin.

H.1 Central Analgesic Activity

H.1.0.1 General Considerations

Pain is a symptom of many diseases requiring treatment with analgesics. Severe pain due to cancer metastases needs the use of strong analgesics, that means opioid drugs. The addiction liability of opioids led to intensive research for compounds without this side effect. Many approaches have been used to differentiate the various actions of strong analgesics by developing animal models not only for analgesic activity but also

for addiction liability. Several types of opioid receptors have been identified in the brain allowing *in vitro* binding tests. However, the *in vitro* tests can only partially substitute for animal experiments involving pain. Pain is a common phenomenon in all animals, at least in vertebral animals, similar to that felt by man. Analgesic effects in animals are comparable with the therapeutic effects in man. Needless to say, that in every instance painful stimuli to animals must be restricted as much as possible. Painful stimuli can consist of direct stimulation of the efferent sensory nerves or stimulation of pain receptors by various means such as heat or pressure. The role of endogenous peptides such as enkephalins and endorphins gives more insight into brain processes and the action of central analgesics.

Pain can also be elicited by inflammation. Progress has been made in elucidating the role of various endogenous substances such as prostaglandins and peptides in the inflammatory process. Most of the so called non-steroidal anti-inflammatory agents have also analgesic activity. Lim and Guzman (1968) differentiated between antipyretic analgesics causing analgesia by blocking impulse generation at pain receptors in the periphery while the narcotic analgesics block synaptic transmission of impulses signaling pain in the central nervous system. An old but excellent survey on methods being used to test compounds for analgesic activity has been provided by Collier (1964). Today, the classification into central and peripheral analgesics is definitively too simplified (Bannwarth et al. 1993) but provides a guide for differentiation by pharmacological methods.

H.1.1 In Vitro Methods for Central Analgesic Activity

H.1.1.1 Survey

In 1973, high-affinity stereospecific binding of radiolabeled opiate compounds by CNS membrane preparations was reported (Pert and Snyder 1973; Simon et al. 1973; Terenius 1973). The *in vivo* pharmacological potency of opiate agonists and antagonists parallels the *in vitro* displacement of ^{3}H-naloxone, a potent narcotic antagonist. Based on these findings, the ^{3}H-naloxone binding assay was introduced for evaluation of potential analgesics with opiate-like properties. According to different pharmacological profiles of opiates, several receptor types have been identified designated as μ, κ, δ, and σ receptor (μ for morphine = MOP receptor, κ for ketocyclazocine = KOP receptor, δ for deferens because it was first identified in mouse vas deferens = DOP receptor). The σ receptor (σ for SKF10047) was only initially classified as an opioid receptor (see below). Several reviews on opioid receptors have been published: Knappe et al. (1995), Mansour et al. (1995), Satoh and Minami (1995), Dhawan et al. (1996), Singh et al. (1997), Standifer and Pasternak (1997), Law et al. (2000), Snyder and Pasternak (2003), Janecka et al. (2004), Eguchi (2004), and Waldhoer et al. (2004).

The opioid receptors were reclassified according to recommendations of the International Union of Physiological Sciences, the International Union of Pharmacology (IUPHAR; Dhawan et al. 1996, 1998; Alexander and Peters 2000). This nomenclature applies an abbreviation of the generic term for the family (OP for opioid) and a subscript number. **OP_1 stands for δ, OP_2 for κ**, and **OP_3 for μ receptor.**

For the **μ receptor, subtypes named μ_1 and μ_2** have been described (Fowler and Fraser 1994; Traynor 1994; Pasternak 2001). Analgesia is thought to involve activation of μ receptors (largely at supraspinal sites) and κ receptors (principally within the spinal cord); δ receptors may also be involved at the spinal and supraspinal level. Other consequences of μ activation include respiratory depression, miosis, reduced gastrointestinal motility, and euphoria. The μ_1 receptors are postulated to mediate the supraspinal analgesic action and the μ_2 receptors to mediate respiratory depression and suppression of gastrointestinal motility. Moreover, different effects on heart rate were described (Paakkari et al. 1992). Two endogenous peptides were described, named **endomorphins**, as agonists with high specific affinity for the μ-receptor (Hackler et al. 1997; Zadina et al. 1997, 1999; Horvath 2000).

Several studies provide evidence for the existence of **δ-opioid receptor subtypes** (Sofuoglu et al. 1991; Porreca et al. 1992; Horan et al. 1993; Miyamoto et al. 1993; Tiseo and Yaksh 1993; Burkey et al. 1998).

Binding studies with δ opioid receptors have been performed by Mosberg et al. (1983). Simonin et al. (1994) reported the genomic organization, cDNA cloning, the functional expression in COS cells, and the distribution in human brain of the human δ-opioid receptor.

Endogenous ligands for δ receptors are **enkephalins**.

A rat **κ opioid receptor** has been cloned (Meng et al. 1993). Evidence for different subtypes of the κ-opioid receptor is available (Zukin et al. 1988; Clark et al. 1989; Rothman et al. 1989, 1992, 1993; Wollemann et al. 1993). Simonin et al. (1995) described cDNA and genomic cloning, chromosomal assignment, functional expression, pharmacology, and expression pattern in the central nervous system of the δ-opioid receptor in humans.

Salvinorin A – derived from *Salvia divinorum*, a hallucinogenic plant used by Mazatec Indians of Mexico for traditional spiritual ceremonies – is a highly selective κ-opioid receptor agonist with antinociceptive effects (Yan and Roth 2004; John et al. 2006; Rothman et al. 2006; Stewart et al. 2006; Vortherms and Roth 2006).

Endogenous ligands for κ receptors are **dynorphins**.

With the development of highly selective ligands it has become possible to label selectively each of the μ-, δ-, and κ-opioid binding sites.

The **μ-binding sites** are labeled with [^{3}H]-[Tyr-D-Ala^2,MePhe^4,Gly-ol^5]enkephalin (Kosterlitz and Paterson 1981), ^{125}I-FK 33–824 (Moyse et al. 1986), [^{3}H]-Tyr-Pro-MePhe-D-Pro-NH_2 (PL O17; Hawkins et al. 1987), or [^{3}H]-[H-D-Phe-Cys-Tyr-D-Trp-Orn-Thr-Pen-Thr-NH_2] (CTOP); Hawkins et al. 1989), the **δ-binding sites** with [^{3}H]-[D-Pen^2,D-Pen^5]enkephalin (Akiyama et al. 1985; Cotton et al. 1985; Mosberg et al. 1987); [^{3}H]-D-Ser^2 (O-*tert*-butyl),Leu^5]enkephalyl-Thr^6 (Delay-Goyet et al. 1988) or [^{3}H]-[D-Pen^2-pClPhe^4,D-Pen^5]enkephalin (Vaughan et al. 1989); [^{3}H]TIPP (Nevin et al. 1993), and the **κ-sites** with [^{3}H]-U-69593 (Lahti et al. 1985; Maguire et al. 1992), [^{3}H]-PD117302 (Clark et al. 1988), or [^{3}H]-CI-977 (Boyle et al. 1990) or [^{3}H]norBNI (Marki et al. 1995).

Cloning and molecular biology of opioid receptors has been reviewed (Reisine and Bell 1993).

Advances in research on non-peptide opioid receptor ligands were published by Kaczor and Matusiuk (2002).

Exploring the opioid system by gene knockout was described by Kieffer and Gaveriaux-Ruff (2002).

Oligomerization of opioid receptors and the generation of novel signaling units was discussed by Levac et al. (2003).

OTHER RECEPTORS

There is some evidence that other opioid receptors may exist, such as a β-endorphin-sensitive **ε receptor** (Wüster et al. 1981). The **ζ receptor** (Zagon et al. 1991) and a high affinity binding site referred to as the **λ site** (Grevel et al. 1985) may also be part of the opioid receptor system.

The existence of a **σ receptor** was first postulated by Martin et al. (1976) to account for the psychotomimetic effects of N-allylnormetazocine (SKF 10,047) in the chronic spinal dog. σ Binding sites were proposed to be identical to phencyclidine binding sites based on the finding that phencyclidine generalized to (+)-SKF 10,047 in drug discrimination tests. Further work led to the application of the **term σ to an unique class of non-opiate, non-phencyclidine sites** that may serve as receptors for an as yet unidentified neuromodulator or neurotransmitter (Monnet et al. 1994). At least two subtypes of binding sites, σ_1 and σ_2, are proposed (Bowen et al. 1989; Itzhak and Stein 1991; Karbon et al. 1991; Knight et al. 1991; Connick et al. 1992; Quirion et al. 1992; Leitner et al. 1994). Radioligands for σ receptors (Weber et al. 1986; de Costa et al. 1989) and for subtype σ_1 (Matsuno et al. 1996) and subtype σ_2 (Mach et al. 1999) were described. Pharmacological studies indicate a role of σ receptors not only in analgesia (Mach et al. 1999), but also in motor function (Walker et al. 1993), schizophrenia (Debonnel and de Montigny 1996; Guitard et al. 1998; Takahashi et al. 1999) and learning and memory (Maurice et al. 1999).

The heterogeneity of opioid receptors has been studied in **isolated tissue preparations** in which neurotransmission is sensitive to inhibition by opioids. The relative potencies of opioid agonists are assessed by their ability to inhibit the electrically evoked contractions of isolated tissue preparations from five different species: the contractions of the mouse **vas deferens** are inhibited by μ-, δ-, and κ-agonists (Maguire et al. 1992), those of **the guinea-pig myenteric plexus-longitudinal muscle** preparation by μ- and κ-agonists (Berzetei-Gurske 1992), those of the **rabbit vas deferens** by κ-agonists, and those of the **hamster vas deferens** by δ-agonists (Sheehan et al. 1986). The contractions of the **rat vas deferens** are inhibited mainly, but not exclusively, by δ-agonists. The actions of β-endorphin in the rat vas deferens are mediated by a further type of opioid receptors, termed **ε-receptor**

(Wüster et al. 1981; Corbett et al. 1992; Smith and Leslie 1992).

H.1.1.2 ^{3}H-Naloxone Binding Assay

PURPOSE AND RATIONALE

A good correlation between the *in vivo* pharmacological potency of opiate agonists and antagonists with their ability to displace radiolabeled naloxone has been reported. The later discovery that Na^+ (100 mM) enhances the binding of antagonists and reduces the binding of agonists has led to the development of an assay which is used to classify compounds as opiate agonists, mixed agonist-antagonists and antagonists by determining the IC_{50} values for ^{3}H-Naloxone in the presence or absence of Na^+.

PROCEDURE

Reagents

[N-allyl-2,3-^{3}H] Naloxone (38–58 Ci/mmol) is obtained from New England Nuclear.

For IC_{50} determinations ^{3}H-naloxone is made up to a concentration of 100 nM and 50 µl is added to each tube yielding a final concentration 5 nM in the assay.

Levorphanol tartrate is obtained from Hoffmann LaRoche. A stock solution of 1 mM levorphanol is made up in distilled water. This stock is diluted 1:200 in distilled water and 20 µl is added to 3 tubes to determine stereospecific binding yielding a final concentration of 0.1 µM in the assay.

Dextrorphan tartrate is obtained from Hoffmann LaRoche. A stock solution of 1 mM dextrophan is made up in distilled water. This stock is diluted 1:200 in distilled water and 20 µl is added to the tubes containing the various concentrations of test drug and the tubes for total binding.

Test compounds: For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay

ranges from 10^{-5} to 10^{-8} M. At least 7 concentrations are used for each assay. Higher or lower concentrations may be used, depending on the potency of the drug.

Tissue Preparation

Male Wistar rats are decapitated and their brains rapidly removed. Whole brains minus cerebella are weighed and homogenized in 50 volumes of ice-cold 0.05 M Tris buffer with a Tekmar tissue homogenizer. The homogenate is centrifuged at 40,000 *g* for 15 min, the supernatant is decanted and the pellet resuspended in fresh buffer and recentrifuged at 40,000 *g*. The final pellet is resuspended in the original volume of fresh 0.05 M Tris buffer. This yields a tissue concentration in the assay of 10 mg/ml.

Assay

310 µl	H_2O
20 µl	5 µM dextrorphan (total binding) or
	5 µM levorphanol (non-specific binding)
50 µl	2 M NaCl or H_2O
50 µl	0.5 M Tris buffer, pH 7.7
20 µl	drug or vehicle
50 µl	^{3}H-naloxone
500 µl	tissue suspension.

The tubes are incubated for 30 min at 37°C. The assay is stopped by vacuum filtration through Whatman GF/B filters which are then washed 3 times with ice-cold 0.05 M Tris buffer, pH 7,7. The filters are then counted in 10 ml of Liquiscint liquid scintillation cocktail. Stereospecific binding is defined as the difference between binding in the presence of 0.1 µM dextrorphan and 0.1 µM levorphanol. Specific binding is roughly 1% of the total added ligand and 50% of the total bound in the absence of Na^+ and 2% of the total added ligand and 65% of the total bound ligand in the presence of Na^+ (100 mM). The increase in binding is due to an increase in specific binding.

EVALUATION

Data are converted into % stereospecific ^{3}H-naloxone binding displaced by the test drug. IC_{50} values are determined from computer-derived log-probit analysis. The sodium shift is calculated from IC_{50} values with and without NaCl. High sodium shifts are found with agonists, low values with antagonists and medium values with mixed agonists-antagonists.

Data can be analyzed using a computer program as described by McPherson (1985).

H.1.1.3 ^{3}H-Dihydromorphine Binding to μ Opiate Receptors in Rat Brain

PURPOSE AND RATIONALE

μ Receptors are considered to mediate the supraspinal activity of opioids. ^{3}H-Dihydromorphine (^{3}H-DHM) exhibits some selectivity for the μ receptor, a high affinity opiate binding site. The test is used to detect compounds that inhibit binding of ^{3}H-DHM in a synaptic membrane preparation obtained from rat brain.

PROCEDURE

Reagents

[1,7,8-^{3}H]Dihydromorphine (^{3}H-DHM) (specific activity 69 Ci/mmol) is obtained from Amersham.

For IC_{50} determinations a 20 nM stock solution is made up. Fifty µl are added to each test tube to yield a final concentration of 0.5 nM in the 2 ml assay.

Levallorphan tartrate is used for the determination of nonspecific binding. A 0.1 mM stock solution is prepared in deionized water. Twenty µl added to each of 3 tubes yields a final concentration of 0.1 µM in the 2 ml assay.

A 1 mM stock solution is made up of the test compounds in a suitable solvent and serially diluted, such that the final concentrations in the assay range from 10^{-6} to 10^{-9} M. At least 7 concentrations are used for each assay.

Tissue Preparation

Male Wistar rats are sacrificed by decapitation. Whole brains minus cerebella are removed, weighed and homogenized in 30 volumes of ice-cold 0.05 M Tris buffer, pH 7.7. The homogenate is centrifuged at 48,000 *g* for 15 min, the supernatant is decanted and the pellet resuspended in the same volume of buffer. This homogenate is then incubated for 30 min at 37°C to remove the endogenous opiate peptides and centrifuged again as before. The final pellet is resuspended in 50 volumes of 0.05 M Tris buffer, pH 7.7.

Assay

1850 µl	tissue suspension
80 µl	distilled water
20 µl	vehicle, or levallorphan, or appropriate concentration of drug
50 µl	[^{3}H]DHM.

Tubes are incubated for 30 min at 25°C. The assay is stopped by vacuum filtration through Whatman GF/B filters which are washed twice with 5 ml of 0.05 M Tris buffer. The filters are then placed into scintillation vials with 10 ml Liquiscint scintillation cocktail and counted.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of 0.1 mM levallorphan. IC_{50} values are calculated from the percent specific binding at each drug concentration.

The K_D value for [^{3}H]DHM binding was found to be 0.38 nM by Scatchard analysis of a receptor saturation experiment. The K_i value may be calculated from the IC_{50} by the Cheng–Prusoff equation:

$$K_i = IC_{50}/1 + L/K_D\,.$$

H.1.1.4 ^{3}H-Bremazocine Binding to κ Opiate Receptors in Guinea Pig Cerebellum

PURPOSE AND RATIONALE

κ Receptors are thought to be involved in the analgesic activity of opiates mainly within the spinal cord, whereas μ receptors are predominately located at supraspinal sites. The pharmacological effects of κ agonists differ from the μ agonists in various analgesic tests, effects on diuresis, sensitivity to naloxone and propensity to cause respiratory depression. κ Agonists may induce water diuresis (Salas et al. 1992). The receptor subtype selectivity can be determined by testing the affinity of new compounds for the κ opiate receptor and comparing these results with the data from the μ receptor assay.

Although the benzomorphanes, such as ethylketocyclazocine and bremazocine, are potent κ agonists, they are not selective for this receptor subtype. To demonstrate specific binding of these ligands to κ receptors, the assay must be done in a tissue where the κ subtype predominates, such as the guinea pig cerebellum. Moreover, binding to μ and δ receptors is prevented by inclusion of the peptide DAGO (Tyr-D-Ala-Gly-N-Me-Phe-Gly-ol) to mask the μ receptor and of

[D-Pen^{2,5}]-enkephalin (Tyr-D-Pen-Gly-Phe-D-Pen) to mask the δ receptor.

PROCEDURE

Reagents

Bremazocine(–)-[9-^{3}H] (specific activity 21–28 Ci/mmol), is obtained from, New England Nuclear. For IC_{50} determinations a 24 nM stock solution is made up. Fifty µl are added to each tube to yield a final concentration of 0.6 nM in the 2 ml assay.

U50,488H is made up to a 500 µM stock solution in deionized water. Twenty ml are added to each of the 3 tubes for determination of unspecific binding yielding a final concentration of 5.0 µM in the 2 ml assay.

Opiate peptides of the μ- and δ-type are included in the assay to prevent binding of the radioligand and the test drug to these receptors. DAGO and [D-Pen^{2,5}]-enkephalin are obtained from Penninsula Laboratories. Concentrated stock solutions of 10^{-3} M are made up in deionized water and further diluted to 10^{-5} M. Twenty µl of this solution are added to each tube to result in a final concentration of 100 nM of each in the 2 ml assay.

For the assays a 1 mM stock solution of test compounds is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. At least 7 concentrations are used for each assay.

Tissue Preparation

Male guinea pigs are sacrificed and cerebella are removed, weighed and homogenized in 10 volumes of ice-cold 0.05 M Tris-buffer, pH 7.4. The homogenate is centrifuged at 48,000 *g* for 10 min, the supernatant decanted and the pellet resuspended in 20 volumes of buffer. This homogenate is then incubated for 45 min at 37°C to remove endogenous opiate peptides and centrifuged again as before. This pellet is resuspended in 200 volumes of 0.05 M Tris buffer, pH 7.4.

Assay

1850 µl	tissue suspension
60 µl	distilled water
20 µl	peptide solution
20 µl	vehicle, or U50,488H, or test drug
50 µl	[^{3}H]bremazocine

Tubes are incubated for 40 min at 25°C. The assay is stopped by vacuum filtration through Whatman GF/B filters which are then washed 3 times with 5 ml of 0.05 M Tris buffer. The filters are then placed in scintillation vials with 10 ml Liquiscint scintillation cocktail and counted.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of 5.0 µM U50,488H. IC_{50} values are calculated from the percent specific binding at each drug concentration.

The K_D value for [^{3}H]bremazocine binding was found to be 0.14 nM by Scatchard analysis of a receptor saturation experiment. The K_i value may be calculated from IC_{50} by the Cheng–Prusoff equation:

$$K_i = IC_{50}/1 + L/K_D\,.$$

H.1.1.5 Inhibition of Enkephalinase

PURPOSE AND RATIONALE

Since the discovery of brain peptides with pharmacological properties similar to morphine (Hughes 1975), the metabolic breakdown of enkephalins has been studied (Malfroy et al. 1978; Llorens and Schwartz 1981; Mumford et al. 1981; Malfroy and Schwartz 1982; Roques 1982; Schwartz 1983). Roques BP et al. (1980), Costentin et al. (1986) found that the enkephalinase inhibitor thiorphan shows antinociceptive activity in mice. A highly sensitive fluorometric assay for "enkephalinase", a neutral metalloendopeptidase that releases tyrosine-glycine-glycine from enkephalins has been developed by Florentin et al. (1984). A fluorogenic peptide, dansyl-D-Ala-Gly-Phe(pNO$_2$)-Gly (DAGNPG) was synthesized as a selective substrate for the neutral metalloendopeptidase involved in enkephalin metabolism. This enzyme, designated "enkephalinase" cleaves the Gly-Phe(pNO$_2$) peptide bond of DAGNPG leading to a fluorescence increase related to the disappearance of intramolecular quenching of the dansyl fluorescence by the nitrophenyl residue.

Enkephalinase induces inactivation of atrial natriuretic factor (ANF). The protection of endogenous ANF against inactivation may result in therapeutic applications (Schwartz et al. 1990).

PROCEDURE

Fresh rat kidney is homogenized in 10 vol of cold 0.05 M Tris-HCl buffer, pH 7.4, using a Polytron homogenizer. The homogenate is centrifuged for 5 min at 1000 g. The pellet is discarded and the supernatant centrifuged at 60,000 g for 60 min. The resulting pellet is resuspended in 50 mM Tris-HCl buffer, pH 7.4, and used as the enzyme source.

Standard assays for "enkephalinase" activity using DAGNPG are carried out at 37°C in hemolysis tubes. A 0.1-ml amount of 50 mM Tris-HCl buffer, pH 7.4, containing 50 µM DAGNPG is preincubated 15 min at 37°C. The reaction is initiated by addition of 50 µl of the enzyme preparation together with 0.5 µM Captopril. The tubes are incubated for 30 min in a water bath with constant shaking. The enzymatic reaction is stopped by boiling at 100°C for 5 min. The samples are then diluted with 1.35 ml of Tris HCl buffer and centrifuged at 500 g for 30 min. An aliquot of 1 ml of the supernatant is transferred to thermostated cells of a spectrofluorometer. Readings are performed at 562 nm with an excitation wavelength of 342 nm. A calibration curve is prepared by adding increasing concentrations of DNS-D-Ala-Gly and decreasing concentrations of the substrate in Tris-HCl buffer containing the denaturated enzymatic preparation. For the assay of "enkephalinase" inhibition, the test compound or the standard thiorphan = [(R-,S-)-3-mercapto-2-benzylpropanoyl]glycine is added in various concentrations.

EVALUATION

The inhibitory potencies of test compounds are compared with the standard.

MODIFICATIONS OF THE METHOD

Ksander et al. (1989) incubated synaptic membranes from rat striatum with ^{3}H-Tyr-Leu-enkephalin for 15 min at 30°C, pH 6.5, in the presence of 10^{-6} M bestatin. The reaction was stopped by the addition of 30% acetic acid and the reaction product ^{3}H-Tyr-Gly-Gly was separated from unreacted ^{3}H-Tyr-Leu-enkephalin on a Porapak Q column followed by a Cu^{2+} chelex column. The ^{3}H-Tyr-Gly-Gly was counted by liquid scintillation.

The antinociceptive effects of intrathecally administered SCH32615, an enkephalinase inhibitor were studied in the rat by Oshita et al. (1990).

H.1.1.6 Nociceptin

H.1.1.6.1 General Considerations on Nociceptin

PURPOSE AND RATIONALE

A heptadekapeptide (nociceptin or orphanin FQ) has been isolated as endogenous agonist of the **opioid receptor-like ORL_1 receptor** (Reinscheid et al. 1995; Meunier et al. 1995; Barlocco et al. 2000; Mollereau and Mouledous 2000; Mogil and Pasternak 2001; Witta et al. 2004) which shows high structural homology with opioid peptides, especially dynorphin A (Calò et al. 2000). Nociceptin activates a specific receptor, which has been cloned in man and animals and has been shown to be structurally similar to opioid receptors (Mollereau et al. 1994; Calò et al. 2000; Hawkinson et al. 2000). At the cellular level, the nociceptin receptor has been shown to act through the same mechanisms as classical opioid receptors, namely the inhibition of adenylyl cyclase, the activation of potassium channels and inhibition of calcium channels (Connor et al. 1996a, b). *In vitro* and *in vivo* studies have demonstrated that nociceptin mediates a variety of biological actions (Civelli et al. 1998; Darland et al. 1998). Nociceptin induces analgesia when administered intrathecally (Stanfa et al. 1996; Xu et al. 1996), while it causes hyperalgesia and reversal of opioid induced analgesia when given intracerebroventricularly; nociceptin stimulates food intake (Polidori et al. 2000) and produces anxiolysis. Depending on the dose, nociceptin stimulates or inhibits locomotor activity. Nociceptin inhibits long-term potentiation, memory processes, induces bradycardia, hypotension and diuresis. In addition, nociceptin inhibits neurotransmitter release both at central and peripheral sites. Intracavernosal injection of nociceptin induces a potent and relatively long-lasting erectile response in the cat (Champion et al. 1997, 1998). Intrathecal injection of nociceptin elicits scratching, licking and biting in mice (Sakurada et al. 1999, 2000). Synthetic agonists and antagonists of the nociceptin receptor have been reported (Guerrini et al. 1998; Salvadori et al. 1999; Calò et al. 2000; Hashimoto et al. 2000; Meunier 2000; Ozaki et al. 2000).

H.1.1.6.2 Receptor Binding of Nociceptin

PURPOSE AND RATIONALE

The nociceptin receptor has been termed by different groups of investigators as ORL1, LC132, ROR (see Meunier 1997). Based on the structural and transductional similarities between receptors for nociceptin and those for opioids, Hamon (1998) proposed to include the nociceptin receptor in the opioid receptor family with the name OP_4.

Varani et al. (1999) tested synthetic nociceptin analogs for their displacement at the nociceptin- and at classical opioid receptors. The displacement of [^{3}H]$NCNH_2$ ([^{3}H]nociceptin amide, ORL1 site), and of the selective opioid receptor ligands [^{3}H]DAMGO (μ site), [^{3}H]deltorphin II (δ site), and [^{3}H]U69593 (κ site) was studied.

Wisner et al. (2006) described human opiorphin, a natural antinociceptive modulator of opioid-dependent pathways inhibiting enkephalin-inactivating zinc ectopeptidases.

PROCEDURE

Membrane Preparation

Guinea pigs are decapitated and the whole brain (without cerebellum) rapidly removed. The tissue is disrupted in a Polytron homogenizer (setting 5) in 50 mM Tris HCl, pH 7.4, to prepare membranes for the classic opioid receptor studies. The homogenate is centrifuged at 4000 *g* for 10 min and the pellet is resuspended with a Polytron PTA 10 probe (setting 5) in the same ice-cold buffer. To study the binding to ORL1 receptor, the tissue is homogenized in 50 mM Tris HCl, 2 mM EDTA and 100 µM phenylmethylsulphonylfluoride HCl (PMSF) at pH 7.4. The suspension is centrifuged at 40,000 *g* for 10 min and the pellet is resuspended in the same buffer. After 30 min of incubation at 37°C the membranes are centrifuged at 40,000 *g* for 10 min and the pellets are stored at –70°C. The protein concentration is determined with bovine albumin as standard.

Binding Assays

Classic opioid receptors, μ, δ and κ, are studied according to Bhargava and Zhao (1996). Saturation binding experiment are carried out using 8–10 different concentrations of [^{3}H]DAMGO ranging from 0.15 nM to 15 nM, [^{3}H]deltorphin II from 0.1 nM to 10 nM, and [^{3}H]U69593 from 0.15 nM to 15 nM, respectively. Inhibition experiments are carried out in duplicate in a final volume of 250 µl in test tubes containing ei-

ther 1.5 nM [^{3}H]DAMGO or 1.0 nM [^{3}H]deltorphin II or 1.5 nM [^{3}H]U69593, 50 mM Tris HCl at pH 7.4, guinea pig brain membranes (150–200 µg of protein/assay) and at least 8–10 different concentrations of the ligands under study. Binding assays to the ORL1 receptor are carried out according to Varani et al. (1998). In saturation studies, membranes are incubated with 8–10 different concentrations of [^{3}H]$NCNH_2$ ([^{3}H]nociceptin amide) ranging from 0.1 mM to 10 mM. Inhibition experiments are carried out in duplicate in a final volume of 250 µl in test tubes containing 1 mM [^{3}H]$NCNH_2$, 50 mM Tris HCl, 2 mM EDTA, 100 µM phenylmethylsulphonylfluoride HCl (PMSF) at pH 7.4, guinea pig membranes, and at least 8–10 different concentration of the compound under examination. The incubation time is 1 h for [^{3}H]DAMGO and [^{3}H]U69593 and 2 h for [^{3}H]deltorphin II and [^{3}H]$NCNH_2$. Nonspecific binding is defined as the binding measured in the presence of 100 µM bremazocine for classic opioid receptors and 10 µM $NCNH_2$ for ORL1 receptors.

Bound and free radioactivity are separated by filtering the assay mixture through Whatman GF/B glass-fibre filters, previously treated with PEI 0.1%; the incubation mixture is diluted with 3 ml of ice-cold incubation buffer, rapidly filtered by vacuum, and the filter washed three times with 3 ml of incubation buffer. The filter-bound radioactivity is measured in a Beckman LS-1800 Spectrometer.

EVALUATION

The inhibitory binding constant (K_i) values are calculated from the IC_{50} values according to the Cheng and Prusoff equation. The weighted non-linear last-squares curved fitting program LIGAND (Munson and Rodbard 1980) is used for computer analysis of saturation and inhibition experiments.

MODIFICATIONS OF THE METHOD

Ardati et al. (1997) developed two radioligands for the orphanin FQ receptor: a tritiated OFQ peptide ([^{3}H]orphanin FQ) and radioiodinated form in which Leu^{14} is substituted by tyrosine (^{125}I-Tyr^{14}-orphanin FQ). Both exhibit virtually identical characteristics.

Seki et al. (1999) analyzed the pharmacological properties of κ-opioid receptor-selective agonist TRK-820 using Chinese hamster ovary cells expressing cloned rat μ-, δ- and κ-opioid receptors and human nociceptin receptor.

Mouledous et al. (2000) reported a site-directed mutagenesis study of the ORL1 receptor transmembrane-binding domain.

H.1.1.6.3 Bioassays for Nociceptin

PURPOSE AND RATIONALE

Nociceptin receptors in the periphery can be characterized by studies in isolated organs (Guerrini et al. 1998; Bigoni et al. 1999): the guinea pig ileum according to Paton (1957) (see J.4.3.1), the mouse vas deferens according to Hughes et al. (1975), the rabbit vas deferens according to Oka et al. (1980) (see A.1.2.3), the guinea pig renal pelvis (Giuliani and Maggi 1996) (see C.4.2.1).

PROCEDURE

Tissues are taken from male Swiss mice (25–30 g), guinea pigs (300–350 g) Sprague Dawley rats (300–350 g) and New Zealand albino rabbits (1.5–1.8 kg). They are suspended in 10 ml organ baths containing Krebs solution oxygenated with 95% O_2 and 5% CO_2. The temperature is set at 33°C for the mouse vas deferens and at 37°C for the other tissues. A resting tension of 0.3 g is applied to the mouse deferens, 1 g to the guinea pig ileum, rats vas deferens, and rabbit vas deferens and 0.15 g to the guinea pig renal pelvis. For experiments at the mouse vas deferens a Mg^{2+}-free Krebs solution is used and for rat vas deferens experiments a Krebs solution containing 1.8 mM $CaCl_2$. Guinea pig renal pelvis experiments are performed in the presence of indomethacin (3 μM).

The mouse vas deferens, guinea pig ileum, rat vas deferens, and rabbit vas deferens are continuously stimulated through two platinum ring electrodes with supramaximal voltage rectangular pulses of 1 ms duration and 0.1 Hz frequency. The electrically evoked contractions are measured isotonically with a strain gauge transducer and recorded on a multichannel chart recorder. After an equilibration period of about 60 min the contractions induced by electrical field stimulation are stable; at this time, cumulative concentration response curves to nociceptin or opioid peptides are performed (0.5 log unit steps).

The guinea pig renal pelvis is stimulated through two platinum ring electrodes with 100 V square wave pulses of 1 ms duration at a frequency of 5 Hz for 10 s. The spontaneous activity and the positive inotropic responses to electrical field stimulation are measured by an isotonic transducer and recorded by a two channel recorder. The experiments are started following a 60 min equilibration period. Four electrical field stimulation are performed with each tissue at 30 min intervals. Agonists are added to the bath 5 min, and antagonists 15 min before the next stimulus. The contractile responses to electrical field stimulation are expressed as % increment the spontaneous activity of the tissue; the biological effects of the application of agonists or antagonists are expressed as % inhibition of electrical filed stimulation-induced contraction.

EVALUATION

Data are expressed as means ±SEM of *n* experiments and statistically analyzed with Student two-tailed *t*-test of one way ANOVA plus Dunnett test. The agonist potencies are given as pE_{50}, which is the negative logarithm to base 10 of the agonist molar concentration that produces 50% of the maximal possible effect of that agonist. The E_{max} is the maximal effect that an agonist can elicit in a given preparation. Antagonist potencies are expressed in terms of pA_2, which is the negative logarithm to base 10 of the antagonist molar concentration that makes it necessary to double the agonist concentration to elicit the original submaximal response.

MODIFICATIONS OF THE METHOD

Rizzi et al. (1999) studied nociceptin and nociceptin analogs in the isolated mouse colon.

Bigoni et al. (1999) used nociceptin, a series of nociceptin fragments, naloxone as well as [$Phe^1\Psi$ (CH_2-NH)Gly^2]nociceptin(1–13)NH_2 and [$Nphe^1$]nociceptin(1–13)NH_2 to characterize nociceptin receptors in peripheral organs, such as mouse and rat vas deferens (noradrenergic nerve terminals), in the guinea pig ileum (cholinergic nerves) and renal pelvis (sensory nerves) and *in vivo* by measuring the blood pressure and heart rate in anesthetized rats.

Menzies et al. (1999) described the agonist effects of nociceptin and [$Phe^1\Psi$ (CH_2-NH)Gly^2] nociceptin(1–13)NH_2 in the mouse and rat colon and in the mouse vas deferens.

Kolesnikov and Pasternak (1999) found an ED_{50} of 16.3 μg after peripheral administration of nociceptin in the tail flick test in mice.

Bertorelli et al. (1999) found anti-opioid effects of nociceptin and the ORL1 ligand [$Phe^1\Psi$ (CH_2-NH)Gly^2]nociceptin(1–13)NH_2 in the Freund's adjuvant-induced arthritic rat model of chronic pain.

Yamamoto and Sakashita (1999) studied the effect of nocistatin, a 17 amino acid peptide which is processed from prepronociceptin and its interaction with nociceptin in the rat formalin test.

Hashiba et al. (2003) measured the effects of nociceptin/orphanin FQ receptor ligands on blood pressure, heart rate, and plasma catecholamine concentrations in guinea pigs.

Using the forced swimming test and the tail suspension test in rats and mice, Gavioli et al. (2004) demonstrated antidepressant-like effects of the nociceptin/orphanin FQ receptor antagonist UFP-101.

Varty et al. (2005) characterized a nociceptin receptor (ORL-1) agonist in tests of anxiety across three species: rat, guinea pig, and mouse.

H.1.1.7 Vasoactive Intestinal Polypeptide (VIP) and Pituitary Adenylate Cyclase-Activating Peptide (PACAP)

PURPOSE AND RATIONALE

Several peptides are considered to play a role in the altered transmission of sensory information in neuropathic conditions, such as neuropathic pain arising from trauma or compression injury of peripheral nerves (Zhang et al. 1998).

Vasoactive intestinal polypeptide (VIP), isolated by Nakajima et (1970), is a neuropeptide of 28 amino acids with widespread distribution in both the central and peripheral nervous system (Fahrenkrug 1979; Gafvelin 1990).

Together with the structurally related pituitary adenylate cyclase-activating peptide (PACAP) this peptide is considered to play an important role in the somatosensory processing of pain (Dickinson and Fleetwood-Walker 1999). PACAP-38 (a 38 amino-acid polypeptide) and the C-terminally truncated form PACAP-37 share 68% amino acid homology at their N-terminal domain with VIP. A shorter peptide with 27 amino acids, named as PACAP27 was described by Miyata et al. (1990). These peptides are members of a superfamily of hormones that includes glucagon, glucagon-like peptide, secretin and growth hormone releasing factor.

Three G-protein-coupled receptors are described: the $VPAC_1$ receptor, originally described as the VIP receptor and subsequently designated as VIP_1 receptor; the $VPAC_2$ receptor, previously designated VIP_2; and the PAC_1 receptor, previously known as PACAP type I receptor (Buscail et al. 1990; Guijarro et al. 1991; Felley et al. 1992; Calvo et al. 1994; Van Rampelbergh et al. 1996; Harmar et al. 1998; Robberecht et al. 1999).

Many peripheral activities of VIP/PACAP are described, such as stimulation of pancreatic secretion (Onaga et al. 1997; Ito et al. 1998; Soo Tek Lee et al. 1998); stimulation of duodenal bicarbonate secretion (Takeuchi et al. 1998); relaxation of smooth muscle cells in the intestinal tract, e. g., gall bladder (Pang and Kline 1998), cecal circular smooth muscle (Motomura et al. 1998), internal anal sphincter (Rattan and Chakder 1997); on duodenal motility (Onaga et al. 1998); enhancement of insulin secretion (Yada et al. 1997; Filipsson et al. 1998); bronchodilation (Linden et al. 1998; Shigyo et al. 1998; Okazawa et al. 1998). Centrally administered PACAP showed an anorectic effect (Mizuno et al. 1998).

Agonists (Gourlet et al. 1997a, b) and antagonists (Gozes et al. 1991; Gourlet et al. 1997c) for VIP were described. Further studies are aimed to development of drugs for neuropathic analgesia, ultimately of non-peptide nature, using $VPAC_1$, $VPAC_2$, and PAC_1, receptors as drug targets (Dickinson and Fleetwood-Walker 1999).

PROCEDURE

CHO cell lines expressing the rat VIP_1 receptor (Ciccarelli et al. 1994), the human VIP_2 receptor (Sreedharan et al. 1993), the rat PACAP I receptor (Ciccarelli et al. 1995), and the rat secretin receptor (Ishihara et al. 1991) are used.

Transfected CHO cells are harvested with a rubber policeman and pelleted by low speed centrifugation. The supernatant is discarded and the cell lysed in mM $NaHCO_3$ solution and immediate freezing in liquid nitrogen. After thawing, the lysate is first centrifuged at 4°C for 10 min at 400 *g* and the supernatant is further centrifuged at 20,000 *g* for 10 min. The pellet, resuspended in 1 mM $NaHCO_3$ is used immediately as a crude membrane fraction.

Binding is performed using [^{125}I]VIP (specific radioactivity of 0.5 Ci/nmol), [^{125}I]Tyr^{25} secretin (specific radioactivity of 1.0 Ci/nmol) and [^{125}I-Ac-His^{1}]PACAP-27 (specific radioactivity of 0.7 Ci/nmol) as tracers. In all cases, non-specific binding is defined as the residual binding in the presence of 1 μM of the unlabeled peptide corresponding to the tracer. Binding is performed at 37°C in a 20 mM Tris-maleate, 2 mM $MgCl_2$, 0.1 mg/ml bacitracin, 1% bovine serum albumin (pH 7.4) buffer. Bound radioactivity is separated from free by filtration through glass-fibre GF/C filters presoaked for 24 h in 0.1% polyethyleneimine and rinsed three times with a 20 mM (pH 7.4) sodium phosphate buffer containing 1% bovine serum albumin.

EVALUATION

The IC_{50} values (in mM) for each peptide on each receptor are calculated from complete dose-effect curves performed on three different membrane preparations using the LIGAND program.

MODIFICATIONS OF THE METHOD

Schmidt et al. (1993) studied the binding of PAPAC, VIP and analogues of VIP and PAPAC in rat AR 4–2J pancreatic carcinoma cells and isolated pancreatic acini to the PAPAC-1 receptor, abundantly expressed in AR 4–2J pancreatic carcinoma cells, and to the VIP/PAPAC-2 receptor. Simultaneously, biological effects (lipase secretion and cAMP production) in pancreatic acini were determined. PAPAC was regarded as a potent ligand for both receptor types and as a potent VIP-like secretagogue.

H.1.1.8 Cannabinoid Activity

H.1.1.8.1 General Considerations on Cannabinoids

In the centuries since hashish and marijuana (*Cannabis sativa*) were used as psychoactive drugs the most significant discoveries in regard to the mechanism of action were made with the isolation of (–)-trans-Δ^9-tetrahydrocannabinol (Δ^9-THC) as the principal active ingredient (Mechoulam et al. 1970), the characterization and localization of the cannabinoid receptor in the brain (Devane et al. 1988), the cloning of its gene (Matsuda et al. 1990), and the identification of an endogenous ligand (Devane et al. 1992). Most cannabinoid effects occur receptor mediated in the CNS (Martin 1986; Herkenham et al. 1990; Porter and Felder 2001; Howlett et al. 2002). The recognized CNS responses to cannabinoids include alterations in cognition and memory, euphoria and sedation (Howlett 1995). Ranganathan and D'Souza (2006) reviewed the acute effects of cannabinoids on memory in humans.

Cannabinoids have been shown to produce analgesia without the respiratory problems associated with opioid analgesics (Buxbaum 1972; Martin 1985; Dewey 1986; Razdan 1986; Compton et al. 1992; Meng et al. 1998; Strangman et al. 1998) which may be of value for therapeutic applications (Hollister 1986; Izzo et al. 2000a; Pertwee 2000). Simultaneous administration of cannabinoid receptor agonists and μ- or κ-receptor agonists indicate a cannabinoid-opioid interaction in anti-nociception (Manzanares et al. 2000). Baker et al. (1990, 2000) described experimental allergic encephalomyelitis with relapsing-remitting episodes, spasticity and tremor similar to multiple scle-

rosis in human beings in Biozzi AB/H mice. These symptoms could be antagonized by cannabinoids.

A multiple-evaluation paradigm of *in vivo* mouse assays is employed to test for cannabimimetic effects. This paradigm includes assays for reduction in spontaneous activity, and the production of hypothermia, catalepsy, and antinociception measured by tail-flick assay (Compton et al. 1992; Welch et al. 1998). The behavioral effects of Δ^9-THC and related cannabinoids in mice have been termed the "popcorn" effect. That is, groups of mice are in a sedated state with little or no movement until a stimulus causes one mouse to jump (hyper-reflexia). This animal falls on another mouse which in turn jumps so that this repeated hyper-reflexic jumping looks like corn popping in a machine. Subsequently, all mice will be sedated until another stimulus reinitiates the process (Dewey 1986). Like the opioids, cannabinoids inhibit electrically evoked contractions of the mouse vas deferens and the guinea pig ileum, but unlike the opioids, these effects are not antagonized by naloxone (Pertwee et al. 1992; Hillard et al. 1999).

In addition to the effects in the CNS (Chaperon and Thiebot 1999), peripheral effects of cannabinoids are known (Lynn and Herkenham 1994) including actions on the **endocrine system** (Patra and Wadsworth 1990, (Block et al. 1991; Wenger et al. 2000), on the **digestive tract** (Rosell and Agurell 1975; Izzo et al. 1990a, b, 2000; Coutts et al. 2000; Massa et al. 2005), on **ingestive behavior** (Giuliani et al. 2000), on the **pulmonary and cardiovascular system** (Stengel et al. 1998; White and Hiley 1998; Niederhoffer and Szabo 1999; Liu et al. 2000; Niederhoffer et al. 2003), and on **immune modulation** (Kaminski et al. 1992; Lynn and Herkenham 1994; Achiron et al. 2000).

An endogenous cannabinoid was isolated from porcine brain by Devane et al. (1992) and found to be an unsaturated fatty acid ethanolamide, arachidonylethanolamide, also called **anandamide**, which activates CB1 receptors (Devane et al. 1992; Hillard and Jarrahian 2005) and produces similar effects as Δ^9-tetrahydrocannabinol including anti-nociception, hypothermia, hypomotility and catalepsy in mice (Smith et al. 1994). The brain enzyme hydrolyzing and synthesizing anandamide has been characterized by Ueda et al. (1995). The human brain fatty-acid amide hydrolase was characterized by Maccarrone et al. (1998) as a single protein, which hydrolyses anandamide to arachidonate and ethanolamine.

Similar effects are produced by other polyunsaturated N-acetylethanolamines, such as N-palmitoylethanolamine, which activates the CB-2-like receptor subtype (Hanu et al. 1993; Facci et al. 1995). Both endogenous cannabinoids (called endocannabinoids) derive from cleavage of a precursor phospholipid, N-acylphosphatidylethanolamine, catalyzed by Ca^{2+}-activated D-type phosphodiesterase activity (Cadas et al. 1996). 2-Arachidonylglycerol was described as a further endogenous ligand for cannabinoid receptors (Ameri and Simmet 2000; Sigiura et al. 2000)

Numerous synthetic analogs and cannabimimetic compounds have been evaluated as agonists and antagonists by *in vitro* and *in vivo* pharmacological methods (Martin et al. 1991; D'Ambra et al. 1992; Melvin et al. 1993; Barth and Rinaldi-Carmona 1999; Hillard et al. 1999; Palmer et al. 2000; Piomelli et al. 2000; De Petrocellis et al. 2004; Costa et al. 2005; Griebel et al. 2005; Lange et al. 2005; Makriyannis et al. 2005; Pertwee 2006).

Costa et al. (2004) described oral anti-inflammatory activity of cannabidiol, a non-psychoactive constituent of cannabis, in acute carrageenan-induced inflammation in the rat paw.

For studies on the effects of cannabinoids and cannabinoid antagonists on digestive system and obesity see L.3.1.3.

H.1.1.8.2 Receptor Binding of Cannabinoids

PURPOSE AND RATIONALE

After the discovery of cannabinoid receptors in brain (Howlett et al. 1988; Devane et al. 1988; Pertwee 1993), two cannabinoid receptor subtypes were identified: CB1 and CB2. Cannabinoid receptors and were reviewed by Felder and Glass (1998), Pertwee (1999, 2001).

CB1 has an amino acid sequence consistent with a tertiary structure typical of the seven transmembrane-spanning proteins that are coupled to G proteins (Gerard et al. 1990, 1991; Howlett et al. 1990; Matsuda et al. 1990). The CNS responses to cannabinoid compounds are apparently mediated exclusively by CB1, since CB2 transcripts could not be found in brain tissue. CB1 transduces signals in response to CNS active constituents of *Cannabis sativa*, as well as synthetic bicyclic and tricyclic analogs, aminoalkylindole, and eicosanoid cannabi-mimetic compounds. CB1 is coupled to G_1 to inhibit adenylate cyclase activity and to a pertussis-sensitive G protein to regulate Ca^{2+} currents. Zimmer et al. (1999) produced a mouse strain with a disrupted CB1 gene. These CB1 knockout mice had a significantly increased mortality rat and displayed reduced locomotor activity, increased ring catalepsy, and hypoalgesia in hot plate and formalin tests.

CB2, the second cannabinoid-binding seven-transmembrane spanning receptor, exhibits 68% identity to CB1 within the helical regions, and 44% identity throughout the total protein. The CB2 clone was derived from a human promyelocytic leukemia cell lin HL60 cDNA library (Munro et al. 1993), also expressed in human leukocytes (Bouaboula et al. 1993). The gene for the rat CB2 receptor was cloned,

expressed, and its properties compared with those of mouse and human CB2 receptors (Griffin et al. 2000).

Receptor binding of cannabinoids in correlation to *in vivo* activities was described by Compton et al. (1993).

PROCEDURE

Membrane Preparation

Male Sprague Dawley rats weighing 150–200 g are decapitated and the brain rapidly removed. The cortex is dissected free using visual landmarks following reflection of cortical material from the midline and immersed in 30 ml of ice-cold centrifugation solution (320 mM sucrose, 2 mM Tris-EDTA, 5 mM $MgCl_2$). The process is repeated until the cortices of five rats are combined. The cortical material is homogenized with a Potter-Elvehjem glass-Teflon grinding system. The homogenate is centrifuged at 1600 *g* for 15 min, the supernatant saved and combined with the two subsequent supernatants obtained from washing and 1600 *g* centrifugation of the P_1 pellet. The combined supernatant fractions are centrifuged at 39,000 *g* for 15 min. The P_2 pellet is resuspended in 50 ml buffer (50 mM Tris-HCl, 2 mM Tris EDTA, 5 mM $MgCl_2$, pH 7.0), incubated for 10 min at 37°C, then centrifuged at 23,000 *g* for 10 min. The P_2 membrane is resuspended in 50 ml of buffer A, incubated again except at 30°C for 40 min, then centrifuged at 11,000 *g* for 15 min. The final wash-treated P_2 pellet is resuspended in assay buffer B (50 mM Tris-HCl, 1 mM Tris EDTA, 3 mM $MgCl_2$, pH 7.4) to a protein concentration of approximately 2 mg/ml. The membrane preparation is divided into 4 aliquots and quickly frozen in a bath solution of dry ice and 2-methylbutane and then stored at −80°C.

Binding Assay

Binding is initiated by the addition of 150 mg of P_2 membrane to test tubes containing [^{3}H]CP-55,940 (79 Ci/mmol), a cannabinoid analog, (for displacement studies) and a sufficient quantity of buffer C (50 mM Tris-HCl, 1 mM Tris EDTA, 3 mM $MgCl_2$, 5 mg/ml BSA) to bring the total incubation volume to 1 ml. The concentration of [^{3}H]CP-55,940 in displacement studies is 400 pM, whereas that in saturation studies varies from 25 to 2500 pM. Nonspecific binding is determined by the addition of 1 mM unlabeled CP-55,940. The standard CP-55,940 and other cannabinoid analogs are prepared in suspension buffer C from a 1 mg/ml ethanolic stock without evaporation of the alcohol.

After incubation at 30°C for 1 h, binding is terminated by addition of 2 ml ice-cold buffer D (50 mM Tris-HCl, 1 mg/ml BSA) and vacuum filtration through pretreated filters in a 12-well sampling manifold. Reaction vessels are washed once with 2 ml of ice-cold buffer D, and the filters washed twice with 4 ml of ice-cold buffer D. Filters are placed into 20-ml plastic scintillation vials with 1 ml of distilled water and 10 ml of Budget-Solve (RPI Corp., Mount Prospect, IL). After shaking for 1 h, the radioactivity present is determined by liquid scintillation photometry.

EVALUATION

The B_{max} and K_d values obtained from Scatchard analysis are determined via a suitable computer program. Displacement IC_{50} values are determined by unweighted least squares linear regression of log concentration-percent displacement data and then converted to K_I values.

MODIFICATIONS OF THE METHOD

To further characterize neuronal cannabinoid receptors, Thomas et al. (1998) compared the ability of cannabinoid analogs to compete for receptor sites labeled either with [^{3}H]SR141716A or[^{3}H]CP-55940.

Herkenham et al. (1991) characterized and localized cannabinoid receptors in rat brain by a quantitative autoradiographic study.

Felder et al. (1995) compared the pharmacology and signal transduction of the human cannabinoid CB1 and CB2 receptors.

Ross et al. (1998) compared cannabinoid binding sites in guinea pig forebrain and small intestine.

Rinaldi-Camora et al. (1998) tested the affinity of an antagonist of the CB2 cannabinoid receptor for rat spleen and cloned human CB2 receptors.

Bilkei-Gorzo et al. (2005) described early age-related cognitive impairment in mice lacking cannabinoid CB1 receptors.

H.1.1.9 Vanilloid (Capsaicin) Activity

H.1.1.9.1 General Considerations on Vanilloids

PURPOSE AND RATIONALE

Several authors reviewed the recent development of capsaicin and vanilloid receptors (Holzer P 1991; Bíró et al. 1997; Sterner and Szallasi 1999; Szallasi and Blumberg 1999; Caterina and Julius 2001; Piomelli 2001; Gunthorpe et al. 2002). Capsaicin was isolated by Thresh (1846). The chemical structure was determined by Nelson (1919). The analgesic use of capsaicin was reviewed by Lembeck (1987). Capsaicin excites a subset of primary sensory neurons with somata in the dorsal root ganglion or trigeminal ganglion. As a general rule, these vanilloid-sensitive neurons are peptidergic, small diameter (50 µm) neurons, giving rise to thin, unmyelinated C fibers. Among sensory neuropeptides, the tachykinin Substance P shows the best correlation with vanilloid sensitivity. Vanilloid-sensitive neurons transmit noxious information (usually perceived as itching or pain) to the CNS, whereas peripheral terminals rare sites of release of a variety of pro-inflammatory neuropeptides. Among irritant compounds acting on primary sensory neurons, capsaicin and related vanilloids are unique in that the initial stimulation by vanilloids is followed by a long lasting refractory state. Neurotoxicity has been observed when capsaicin as given to newborn rats (Jancsó et al. 1977; Nagy and van der Kooy 1983).

Besides capsaicin, several natural vanilloid agonists were described (Jonassohn and Sterner 1997; Liu et al. 1997; Sterner and Szallasi 1999; Mendes et al. 2000). The irritant principle from *Euphorbia resinifera*, named resiniferatoxin, was isolated by Hergenhahn et al. (1975). In several assays, resiniferatoxin and its derivatives are several thousand-fold more potent than capsaicin (Szolcsanyi et al. 1990; Ács et al. 1995), which is explained by specific receptor binding (Szallasi and Blumberg 1990; Ács et al. 1994). Lee et al. (2001) described simplified resiniferatoxin derivatives as potent vanilloid receptor agonists with potent analgesic activity and reduced pungency.

The high affinity of vanilloid receptors argues for the existence of endogenous vanilloids. Hwang et al. (2000), Piomelli (2001) reported a direct activation of capsaicin receptors by products of lipogenases. Pain-inducing substances, such as bradykinin, may activate phospholipase-linked receptors in sensory neurons, mobilizing arachidonic acid from phospholipids and generating 12-HPETE. This lipid second messenger interacts in turn with a cytosolic domain of the VR1 receptor channel, increasing its opening probability and causing the sensory neuron to become depolarized.

The endogenous ligand of CB_1 cannabinoid receptors, anandamide, is also a full agonist at vanilloid VR1 receptors (Zygmunt et al. 1999; Maccarrone et al. 2000; Smart et al. 2000; DePetrocellis et al. 2001).

Premkumar and Ahern (2000) showed that activation of protein kinase C activates VR1 channel activity.

The first capsaicin or vanilloid receptor, termed VR1, was cloned by Caterina et al. (1997). Hayes et al. (2000) reported the cloning and functional expression of a human orthologue of rat vanilloid receptor 1. Pharmacological differences between the human and rat vanilloid receptor 1 were observed (McIntyre et al. 2001). VR1 functions as a molecular integrator of painful chemical and physical stimuli including capsaicin, noxious heat and low pH (Tominaga et al. 1998; Michael and Priestley 1999; Davis et al. 2000; Welch et al. 2000). In mice lacking the capsaicin receptor impaired nociception and pain sensation was observed (Caterina et al. 2000).

Vanilloid receptors are differently distributed in the central and peripheral nervous system (Szallasi 1995; Szallasi et al. 1995; Mezey et al. 2000; Ichikawa and Sugimoto 2001). Bíró et al. (1998) reported characterization of functional vanilloid receptors expressed by mast cells. Biological and electrophysiological data indicate heterogeneity within the vanilloid receptors. Caterina et al. (1999) described a capsaicin-receptor homologue, named vanilloid-receptor-like protein (VRL-1) with a high threshold for noxious heat. A novel human vanilloid receptor-like protein, named VRL-2 was identified and characterized by Delany et al. (2001).

Price et al. (2004) repoted modulation of trigeminal sensory neuron activity by the dual cannabinoid-vanilloid agonists anandamide, *N*-arachidonoyl-dopamine and arachidonyl-2-chloroethylamide.

Several vanilloid antagonists were described, such as capsazepine (Bevan et al. 1992; Walpole et al. 1994) or iodo-resiniferatoxin (Wahl et al. 2001).

H.1.1.9.2 Vanilloid Receptor Binding

PURPOSE AND RATIONALE

Ács et al. (1994) described [^{3}H]resiniferatoxin binding by the human vanilloid (capsaicin) receptor. Receptor types and species differences of the vanilloid receptor were described by Szallasi et al. (1994, 1996). The rat vanilloid receptor (rVR1) was cloned and stably expressed in HEK293 cells by Jerman et al. (2000). A detailed pharmacological characterization was conducted using the Ca^{2+}-sensitive dye, Fluo3AM in a fluorimetric imaging plate reader (FLIPR). Ross et al. (2001) studied structure-activity relationship for the endogenous cannabinoid, anadamide, and certain of its analogues at vanilloid receptors in transfected CHO cells.

PROCEDURE

Cell Culture

Rat vanilloid receptor (rVR1) transfected CHO cells are maintained in MEM Alpha minus media containing 2 mM L-glutamine supplemented with 10% hyclone fetal bovine serum, 350 µg/ml G418 (Sigma-Aldrich), 100 units/ml penicillin and 100 µg/ml streptomycin. Cells are maintained in 5% CO_2 at 37°C and passed twice a week using non-enzymatic cell dissociation solution. For the radioligand binding assay, cells are removed from flasks by scraping and then frozen as a pellet at –20°C for up to one month.

Radioligand Binding Experiments

Assays are performed in DMEM containing HEPES (25 mM) and BSA (0.25 mg/ml). Total assay volume is 500 µl containing 20 µg of cell membranes. Binding is initiated by addition of [^{3}H]resiniferatoxin ([^{3}H]-RTX). Assays are carried out at 37°C for 1 h, before termination by addition of ice-cold wash buffer (50 mM Tris-buffer, 1 mg/ml BSA, pH 7.4) and vacuum filtration using a 12-well sampling manifold (Brandell cell harvester) and Whatman GF/B filters that have been soaked in wash buffer at 4°C for at least 24 h. Each reaction is washed 9 times with a 1.5 ml aliquot of wash buffer. The filters are oven-dried and then placed in 5 ml scintillation fluid. Radioactivity is quantified by liquid scintillation spectrometry. Specific binding is determined in the presence of 1 µM unlabelled RTX. Protein assays are performed using a Bio-Rad De Kit. Unlabelled compounds are added in a volume of 50 µl after serial dilution using assay buffer from a 10 mM stock in ethanol or DMSO. [^{3}H]-RTX is also added in a 50 µl volume following dilution in assay buffer.

EVALUATION

The K_D value and B_{max} for [^{3}H]-RTX and the concentration of competing ligands to produce 50% displacement of the radioligand (IC_{50}) from specific binding sites are calculated using GraphPad Prism (GraphPad Software, San Diego). Dissociation constant (K_i) values are calculated using the Cheng and Prussoff equation.

MODIFICATIONS OF THE METHOD

Wardle et al. (1997) used a 96-well plate assay system to characterize pharmacologically the vanilloid receptor in the dorsal spinal cord of the rat.

Hayes et al. (2000) described the cloning and functional expression of a human orthologue of rat vanilloid receptor-1.

H.1.1.9.3 Evaluation of Vanilloid Receptor Antagonists

PURPOSE AND RATIONALE

Several vanilloid receptor antagonists were described, such as capsazepine (Bevan et al. 1992; Walpole et al. 1994) or iodo-resiniferatoxin (Wahl et al. 2001). Kirschstein et al. (1999) described the inhibition of rapid heat responses in nociceptive primary sensory neurons of rats by vanilloid receptor antagonists.

PROCEDURE

Adult Sprague Dawley rats of both sexes are deeply anesthetized with diethyl ether and rapidly decapitated. The spine is chilled at 4°C in F12 Dulbecco's modified Eagle's medium saturated with carbogen gas and additionally containing 30 mM $NaHCO_3$, 100,000 units/l penicillin and 100 mg/l streptomycin. Thoracic and lumbar dorsal root ganglions are quickly dissected and freed from connective tissue. Neurons are dissociated in an incubation chamber enriched with carbogen gas at 37°C using collagenase CLS II (5–10 mg/ml, 10–12 min) and trypsin (0.2–1 mg/ml, 10–12 min) dissolved in F12 medium. After trituration (4–6 times with a Pasteur pipette) neurons are plated in 35-mm culture dishes, which also serve as recording chambers, and stored at 37°C in a humidified 5% CO_2 atmosphere before used for electrophysiological recordings.

Only round or oval-shaped neurons without any processes are included in the study. The average of the major and the minor diameter is used to measure the size of oval shaped neurons. Whole cell patch-clamp experiments are performed in carbogen gas saturated F12 medium (pH 7.4) at room temperature using an Axo-patch 200A amplifier (Axon Instruments) in voltage-clamp mode at a holding potential of –80 mV controlled by pCLAMP6 software. Data are also registered on a chart recorder. Patch pipettes are fabricated from borosilicate glass using a horizontal micropipette puller and filled with a solution contain-

ing (in mM) 160 KCl, 8.13 EGTA, 10 HEPES (pH 7.2, $R_{Tip} = 5.3 \pm 0.2$ MΩ, mean ±SE). Cell diameter, cross sectional area, and membrane capacitance are measured, and excitability is tested by depolarizing voltage steps for each neuron. Cells lacking a fast inward current with a reversal potential close to the equilibrium potential of sodium followed by a prolonged outward current are excluded from further investigation. Experiments in current-clamp mode are performed to measure the resting membrane potential of each neuron and to investigate single action potentials elicited by short (3 ms) depolarizing current pulses in neurons that are hyperpolarized by constant current injection resulting in membrane potentials between –70 and –80 mV. Inflections in the repolarizing phase are qualitatively detected as second negative peak in the first derivative (dV/dt) of each action potential; the duration of repolarization is quantitatively assessed by the 10–90% decay time.

Applications of ~50 µl of heated extracellular solution through a puffing system fixed on a micromanipulator is used to elicit heat-evoked currents. Control measurements with a fast temperature sensor (BAT-12, Physitemp; $\tau = 5$ ms) in place of the neurons are made revealing an effective temperature of ~53°C, a rise time of ~250 ms, and a decay with a time constant of ~20 s. Effects are compared with those of application of the same amount of medium at room temperature. Heat stimuli with or without vanilloid receptor antagonists and control applications at room temperature are repeated 2–10 times, and the elicited currents are averaged. A neuron is considered as heat sensitive when the heat-evoked inward current is significantly greater than any fluctuations caused by superfusion of solution at room temperature. Heating the buffered solution may change its pH, and acid solution of pH 6.2 are known to activate nociceptive dorsal root ganglion neurons (Bevan and Yeats 1991). The pH of a HEPES-buffered solution decreases while heating (e. g., pH 7.1 at 50°C). In contrast, higher temperatures increase the pH of a $NaHCO_3/CO_2$ buffer, because the solubility of CO_2 is reduced and thus reverses the HEPES effect. The pH of the F12 medium maximally changes in a range of 7.28–7.52 while heating to 50°C and cooling down to room temperature. The membrane conductance is measured in voltage-clamp mode by hyperpolarizing pulses (5 mV, 10 ms, 50 s^{-1}), and conductance changes are determined at the maximum amplitude of heat evoked currents.

Reversal potentials of heat- and capsaicin-induced currents are measured as described by Liu et al. (1997) using fast depolarizing ramps (–80 to +30 mV in 22 ms every 550 ms). Patch pipettes are filled with a potassium-free solution containing (in mM) 140 CsCl, 10 HEPES, 10 EGTA, and 4 $MgCl_2$ (adjusted to pH 7.2). Tetrodotoxin (100 µM) and nifedipine (1 µM) are added to the extracellular solution to block voltage gated Na^+ and Ca^{2+} channels. Capsaicin is dissolved in ethanol, diluted to its final concentration with F12 medium, and applied through the puffing system. Capsazepine (dissolved in DMSO) and ruthenium red are prepared as concentrated stock solutions, diluted to final concentration in F12 medium, and applied either at room temperature or at ~53°C. Reversibility of antagonist action is tested by reapplication of heated extracellular solution without any agents.

EVALUATION

Off-line measurements and statistical analysis is done using pCLAMP6 (Axon Instruments) and EXCEL 5.0 (Microsoft). Data are presented as means ± SE. Treatment effects are statistically analyzed by Student's t-test for paired data and χ^2 test for analysis of incidences.

MODIFICATIONS OF THE METHOD

Nagy et al. (1983) described dose-dependent effects of capsaicin on primary sensory neurons in the neonatal rat.

Lopshire and Nicol (1998) performed whole-cell and single-channel studies in rat sensory neurons and found a prostaglandin E_2 induced enhancement of the capsaicin elicited current.

Jung et al. (1999) performed patch-clamp experiments in dorsal root ganglion neurons of neonatal rats and concluded that capsaicin binds to the intracellular domain of the capsaicin-activated ion channel.

Nagy and Humphrey (1999) compared the membrane responses of rat sensory neurons to noxious heat and capsaicin, using electrophysiological and ion flux measurements.

Baumann and Martenson (2000) found that extracellular protons both increase the activity and reduce the conductance of capsaicin-gated channels.

Liu et al. (2001) investigated mechanisms underlying capsaicin-mediated inhibition of action potentials and modulation of voltage-gated sodium channels in cultured trigeminal ganglion neurons.

Gunthorpe et al. (2004) identified and characterized a potent and selective vanilloid receptor antagonist isolated via high-throughput screening of a large chemical library in an FLPR-based C^{2+} assay.

For further information on the vanilloid receptor see A.1.1.32.5.

H.1.2 In Vivo Methods for Testing Central Analgesic Activity

H.1.2.1 General Considerations

Although the *in vivo* methods have been used more extensively in the past, they are still necessary in present research analgesic tests in animals before a compound can be given to man. Mostly, rodents, such as mice or rats, are used for analgesic tests, but in some instances experiments in higher animals such as monkeys are necessary.

Several methods are available for testing central analgesic activity, such as

- Haffner's tail clip method in mice,
- tail flick or other radiant heat methods,
- tail immersion tests,
- hot plate methods in mice or rats,
- electrical stimulation (grid shock, stimulation of tooth pulp or tail),
- monkey shock titration,
- formalin test in rats.

H.1.2.2 Haffner's Tail Clip Method

PURPOSE AND RATIONALE

The method was described as early as 1929 by Haffner who observed the raised tail (Straub phenomenon) in mice treated with morphine or similar opioid drugs and found the tail after drug treatment to be less sensitive to noxious stimuli. He already described the high sensitivity of this method to morphine. Since then, the method has been used and modified by many authors.

PROCEDURE

An artery clip is applied to the root of the tail of mice and the reaction time is noted. Male mice (Charles River strain or other strains) with a weight between 18 and 25 g are used. The control group consists of 10 mice. The test compounds are administered subcutaneously to fed mice or orally to fasted animals. The test groups and the control group consist of 7–10 mice. The drug is administered 15, 30 or 60 min prior testing. An artery clip is applied to the root of the tail (approximately 1 cm from the body) to induce pain. The animal quickly responds to this noxious stimuli by biting the clip or the tail near the location of the clip. The time between stimulation onset and response is measured by a stopwatch in 1/10 seconds increments.

EVALUATION

A cut-off time is determined by taking the average reaction time plus 3 times the standard deviation of

the combined latencies of the control mice at all time periods. Any reaction time of the test animals which is greater than the cut-off time is called a positive response indicative of analgesic activity. The length of time until response indicates the period of greatest activity after dosing. An ED_{50} value is calculated at the peak time of drug activity. ED_{50} values found by this method were 1.5 mg/kg s.c. for morphine and 7,5 mg/kg for codeine s.c.

CRITICAL ASSESSMENT OF THE TEST

The test does not need any sophisticated equipment but a skilled, preferably "blind", observer. Peripheral analgesics of the salicylate type are not detected by this test.

MODIFICATIONS OF THE METHOD

Bartoszyk and Wild (1989) described a modification of the original Haffner clip test using pressure on the tail of rats instead of mice. Additionally hyperalgesia was induced by injection of carrageenan suspension into the tail. In this case not only an effect of a nonsteroidal anti-inflammatory agent but also a potentiation by B-vitamins could be shown.

Takagi et al. (1966) published a modification of HAFFNER's method for testing analgesics.

Ossipov et al. (1988) used the Haffner test to compare the antinociceptive effects of intrathecally administered opiates, α_2-adrenergic agonists, and local anesthetics.

Yanagisawa et al. (1984) described a tail pinch method *in vitro* for testing antinociceptive drugs consisting of an isolated spinal cord, spinal nerve roots and the functionally connected tail of a new-born rat. Changes of electric potential in the ventral root are induced by noxious pressure on the tail. In addition, responses after electric stimulation of the dorsal root were recorded. The authors recommend the method for studying actions of analgesic drugs.

Pinch of the toes of guinea pigs was recommended as a test for opioid analgesics by Collier (1965).

Tail-pinch feeding in rats after intracerebroventricular injection of various opioid antagonists has been used to differentiate opioid receptor subtypes (Koch and Bodnar 1993).

Person et al. (1985) used three different techniques of mechanical tail stimulation (reaction threshold determined with an Analgesymeter at two different cut-off values and HAFFNER's tail clip) to study morphine-caffeine analgesic interaction in rats.

Arndt et al. (1984) studied pain responses (increase of heart rate and arterial pressure, respiratory effects) to tail clamping in trained unanesthetized spontaneously breathing dogs after administration of fentanyl.

H.1.2.3 Radiant Heat Method

PURPOSE AND RATIONALE

Originally, the method was developed by Schumacher et al. (1940), Wolff et al. (1940) for quantitative measurements of pain threshold in man against thermal radiation and for evaluation of analgesic activity of opiates. Later on, the procedure has been used by many authors to evaluate analgesic activity in animal experiments by measuring drug-induced changes in the sensitivity of mice or rats to heat stress applied to their tails. The test is very useful for discriminating between centrally acting morphine-like analgesics and non-opiate analgesics.

Mice are placed into cages leaving the tail exposed. A light beam is focused to the proximal third of the tail.

Within a few seconds the animal flicks the tail aside or tries to escape. The time until this reaction occurs is measured.

PROCEDURE

The method was described by Ther, Lindner and Vogel (1963) as a modification of earlier publications (D'Armour and Smith 1941). Groups of 10 mice (NMRI-strain) of both sexes with a weight between 18 and 22 g are used for each dose. Before administration of the test compound or the standard the normal reaction time is determined. The animal is put into a small cage with an opening for the tail at the rear wall. The tail is held gently by the investigator. By opening of a shutter, a light beam exerting radiant heat is directed to the proximal third of the tail. For about 6 s the reaction of the animal is observed by the investigator. The mouse tries to pull the tail away and turns the head. With a switch the shutter is closed as soon as the investigator notices this reaction. Mice with a reaction time of more than 6 s are not used in the test. The escape reaction which is the endpoint of this test can be regarded as a complex phenomenon mediated by the brain. In contrast, the simple tail flick as an endpoint of this test may be mediated as a spinal reflex. Therefore the observation of the escape reaction can be regarded as a true assessment of the influence of the drug on the brain.

The test compounds and the standard are administered either orally or subcutaneously. The animals are submitted to the same testing procedure after 30, 60 and eventually 120 min. For each individual animal the reaction time is noted. Other time intervals can be used according to the question to be investigated.

EVALUATION

There are two possibilities for evaluation:

- The average values of reaction time after each time interval are calculated and compared with the pretest value by analysis of significance.
- At each time interval only those animals which show a reaction time twice as high or higher as the pretest value are regarded as positive. Percentages of positive animals are counted for each time interval and each dose and ED_{50} values are calculated according to LITCHFIELD and WILCOXON.

As standards codeine, pethidine and morphine can be used. The ED_{50} values of these drugs are:

- Codeine 12 mg/kg s.c.
- Pethidine 12 mg/kg s.c.
- Morphine 2 mg/kg s.c.

CRITICAL ASSESSMENT OF THE TEST

The radiant heat test on the tail of mice is very effective to estimate the efficacy and potency of central acting analgesic drugs. With pyrazolones ED_{50} values still can be calculated but these are achieved only with relatively high doses. Compounds like acetylsalicylic acid and phenyl-acetic acids show only slight effects making it impossible to calculate ED_{50} values.

MODIFICATIONS OF THE METHOD

Originally, the method has been described for testing analgesic properties in the rat (D'Armour and Smith 1941, Winter et al. 1954, Harris and Pierson 1964). Goldstein and Malseed (1979) adapted the procedure for utilization in **cats**. The effect of morphine could be antagonized by naloxone in this test. No response to sodium salicylate or pentobarbital was observed. Lutz et al. (1994) used a modification of the rat tail withdrawal test to investigate the structure-activity profile of a series of opioid analgesics. One day before testing, polyethylene tubings were implanted in the femoral vein and externalized behind the neck for intravenous application of test substances.

Various instruments have been described for measuring tail flick latencies by several authors, e. g., Davies et al. 1946; Owen et al. (1981), Isabel et al. (1981), Walker and Dixon (1983), Yoburn et al. (1984), Harris et al. (1988).

Tail flick analgesy meters are commercially available (e. g., IITC Life Science, Woodland Hills, CA, USA).

Green and Young (1951) compared the heat and pressure analgesiometric methods in rats. Mohrland et al. (1983) described an ultrasound-induced tail-flick procedure.

Hargreaves et al. (1988), Costello and Hargreaves (1989), Hylden et al. (1991) exposed the plantar surface of hindpaws of unrestrained rats to a beam of radiant heat applied through the glass floor of a testing chamber. Paw withdrawal latency was automatically recorded by a photocell.

This method was also used by Schuligoi et al. (1994).

Taylor et al. (1997) used this method to investigate the brief (phase 1) and persistent (phase 2) nociceptive responses of rats after injection of dilute formalin into the hindpaw.

Carmon and Frostig (1981) used brief laser induced heat applied to the rat ear for pharmacological testing of analgesics.

Perkins et al. (1993), Perkins and Kelly (1993) used ultra-violet-induced hyperalgesia in rat paw. Female

Sprague-Dawley rats weighing about 100 g were exposed on the plantar surface of one hind paw to UV light (intensity maximum 365 nm, 69 mW/cm^2) for 90 s and this was repeated 18 h later. On the following days, each group of rats was placed in a transparent Perspex box and the withdrawal threshold to a focused beam of radiant heat applied to the underside of each hind paw was measured.

McCallister et al. (1986) directed radiant heat to the **ears of rabbits** and measured ear-withdrawal time.

H.1.2.4 Hot Plate Method

PURPOSE AND RATIONALE

The paws of mice and rats are very sensitive to heat at temperatures which are not damaging the skin. The responses are jumping, withdrawal of the paws and licking of the paws. The time until these responses occur is prolonged after administration of centrally acting analgesics, whereas peripheral analgesics of the acetylsalicylic acid or phenyl-acetic acid type do not generally affect these responses.

PROCEDURE

The method originally described by Woolfe and Mac Donald (1944) has been modified by several investigators. The following modification has been proven to be suitable:

Groups of 10 mice of either sex with an initial weight of 18 to 22 g are used for each dose. The hot plate, which is commercially available, consists of a electrically heated surface. The temperature is controlled for 55° to 56°C. This can be a copper plate or a heated glass surface. The animals are placed on the hot plate and the time until either licking or jumping occurs is recorded by a stop-watch. The latency is recorded before and after 20, 60 and 90 min following oral or subcutaneous administration of the standard or the test compound.

EVALUATION

The prolongation of the latency times comparing the values before and after administration of the test compounds or the values of the control with the experimental groups can be used for statistical comparison using the *t*-test. Alternatively, the values which exceed the value before administration for 50% or 100% can be regarded as positive and ED_{50} values can be calculated.

Doses of 7.5 mg/kg s.c. morphine hydrochloride, 30 mg/kg s.c. codeine hydrochloride, 30 mg/kg s.c. pethidine hydrochloride and 400 mg/kg s.c. phenazone were found to be effective, whereas aspirin showed no effect even at high doses.

CRITICAL ASSESSMENT OF THE TEST

The hot plate test has been used by many investigators and has been found to be suitable for evaluation of centrally but not of peripherally acting analgesics. Mice as well as rats have been used. The method has the drawback that sedatives and muscle relaxants (Woolfe and MacDonald 1944) or psychotomimetics (Knoll 1967) cause false positives, while mixed opiate agonists-antagonists provide unreliable results. The validity of the test has been shown even in the presence of substantial impairment of motor performance (Plummer et al. 1991). Mixed opiate agonists-antagonists can be evaluated if the temperature of the hot plate is lowered to 49.5°C (O'Callaghan and Holtzman 1975; Zimer et al. 1986).

MODIFICATIONS OF THE METHOD

O'Neill et al. (1983) described an automated, high-capacity method for measuring jump latencies on a hot plate. A hot-plate test with increasing temperature was recommended by Tjølsen et al. (1991).

Hot plate analgesy meters are commercially available (e. g., IITC Life Science, Woodland Hills, CA, USA).

H.1.2.5 Tail Immersion Test

PURPOSE AND RATIONALE

The method has been developed to be selective for morphine-like compounds. The procedure is based on the observation that morphine-like drugs are selectively capable of prolonging the reaction time of the typical tail-withdrawal reflex in rats induced by immersing the end of the tail in warm water of 55°C.

PROCEDURE

Young female Wistar rats (170–210 g body weight) are used. They are placed into individual restraining cages

leaving the tail hanging out freely. The animals are allowed to adapt to the cages for 30 min before testing. The lower 5 cm portion of the tail is marked. This part of the tail is immersed in a cup of freshly filled water of exactly 55°C. Within a few seconds the rat reacts by withdrawing the tail. The reaction time is recorded in 0.5 s units by a stopwatch. After each determination the tail is carefully dried. The reaction time is determined before and periodically after either oral or subcutaneous administration of the test substance, e. g., after 0.5, 1, 2, 3, 4 and 6 h. The cut off time of the immersion is 15 s. The withdrawal time of untreated animals is between 1 and 5.5 s. A withdrawal time of more than 6 s therefore is regarded as a positive response.

EVALUATION

ED_{50} values can be calculated for each compound and time response curves (onset, peak and duration of the effect) be measured. All the morphine-like analgesics have been shown to be active at doses which do not produce gross behavioral changes. For example, an ED_{50} of 3.5 mg/kg s.c. for morphine and an ED_{50} of 1.7 mg/kg s.c. methadone was found. Acetylsalicylic acid at a dose of 640 mg/kg p.o., phenylbutazone at a dose of 160 mg/kg s.c. as well as nalorphine at a dose of 40 mg/kg s.c. were inactive.

CRITICAL ASSESSMENT OF THE TEST

The test is useful to differentiate central opioid like analgesics from peripheral analgesics.

MODIFICATIONS OF THE METHOD

Ben-Bassat et al. (1959) described the receptacle method in mice. Each mouse was inserted in a conoid paper receptacle with its tail protruding, the cone being closed by a stapler. The protruding tail was entirely immersed in a water bath (58°C) and the time until withdrawal of the tail was measured by a stop watch.

Pizziketti et al. (1985) modified the tail immersion test in rats in this way that they used a 1:1 mixture of ethylene-glycol and water **cooled** to a temperature of minus 10°C as noxious stimulus. Linear dose-response curves were found with levo-methadone and morphine. Low ceiling effects or curvilinear dose-response curves were obtained with narcotic agonist-antagonist analgesics such as pentazocine. Diazepam and aspirin were inactive.

Tiseo et al. (1988) could show that the endogenous kappa agonist dynorphin A was inactive in the rat tail immersion test at 55°C, but gave dose-response curves in the cold water version of the test.

Abbott and Melzack (1982) examined the effects of brainstem lesions on morphine analgesia using the formalin test which produced moderate pain that lasted about 2 h, and the tail-flick hot water-immersion test which measured brief threshold-level pain.

Abbott and Franklin (1986) used two forms of the rat tail flick test: In the restrained form of the test rats were placed in wire restraining tubes from 10 min before drug injection till the end of the test. In the unrestrained form of the test rats were left free in their home cages and handheld during each test for approximately 30 s. Responses to the thermal pain stimulus were assessed by the latency with which the rat removed its tail from 55°C water. Two types of morphine analgesia have been postulated in animals: One type, exemplified in rats that are restrained during tail flick testing, is sensitive to an interaction between morphine and brain 5-HT, the level of which is elevated by restrained stress (Kelly and Franklin 1984).

Luttinger (1985) determined the antinociceptive activity of drugs using different water temperatures in a tail-immersion test in mice. The results roughly paralleled the differences in the severity of pain for which various analgesics are effective.

Dykstra et al. (1986, 1987) described a tail withdrawal procedure for assessing analgesic activity in **Rhesus monkeys** by immersion of the tail into water of 55°C. This procedure was used by Rothman et al. (1989) to determine the pharmacological activities of optically pure enantiomers of the κ opioid agonist, U50,488, and its cis diastereomer.

Using this method, Ko et al. (1999) found that activation of peripheral κ opioid receptors inhibits capsaicin-induced nociception in Rhesus monkeys.

H.1.2.6 Electrical Stimulation of the Tail

PURPOSE AND RATIONALE

Since the tail of mice is known to be sensitive to any stimulus, a method of electrical stimulation has been described as early as 1950 by Burn et al. The stimulus can be varied either by the duration of the electric shock or by an increase in the electric current.

PROCEDURE

As described by Kakunaga et al. (1966), male mice with a weight of 20 g are placed into special cages. A pair of alligator clips is attached to the tail whereby the positive electrode is placed at the proximal end of the tail. Rectangular wave pulses from a constant voltage stimulator at an intensity of 40–50 V are applied. The frequency of the stimulation is 1 shock/s, and the pulse duration 2.5 ms. The normal response time range of the stimuli is 3–4 s. Following administration of the drug, the response time is registered at 15 min intervals until the reaction time returns to control levels.

EVALUATION

The data for each animal are plotted with reaction times on the ordinate and time intervals following administration on the abscissa. The area under the time response curve is calculated. In control animals the reaction time remains fairly constant and the area under the curve is approximately zero. Effects of morphine at 5 mg/kg s.c. and meperidine 30 mg/kg s.c. could easily be demonstrated.

CRITICAL ASSESSMENT OF THE TEST

The effect of central analgesics can be clearly demonstrated, however also the activity of peripheral analgesics given at higher doses can be detected.

MODIFICATIONS OF THE METHOD

Vidal et al. (1982) measured the thresholds of 3 nociceptive reactions (tail withdrawal, vocalization, vocalization afterdischarge) following electrical stimulation of the tail.

A variation of the test has been introduced by Yanaura et al. (1976), using ultrasonic stimulation instead of electric stimulation. The method is considered to be fast, simple, and precise. The stimulus can be applied repeatedly without causing injury to the tissue. A vocalization test in rats with electrical stimulation of the tail has been described by Hoffmeister (1968).

Ludbrook et al. (1995) described a method for frequent measurement of sedation and analgesia in sheep using the response to a ramped electrical stimulus. Sheep were placed in a canvas sling in their metabolic crates to allow their limbs to partially bear weight in order to minimize spontaneous limb movements. Two needles were placed subcutaneously 0.5 cm apart in the anterior aspect of the lower third of the sheep's hind and connected to the nerve stimulator. The current ramp rate was set at one mA per sec. As soon as limb withdrawal was observed, the stimulus was switched off and the highest current and ramp duration were recorded.

H.1.2.7 Grid Shock Test

PURPOSE AND RATIONALE

The electric grid shock test in mice has been described by Blake et al. (1963) as a modification of an earlier approach (Evans 1962) to measure the analgesic properties by the "Flinch-jump" procedure in rats.

PROCEDURE

Male mice with a weight between 18 and 20 g are individually placed into clear plastic chambers. The floor of the box is wired with tightly strung stainless steel wire, spaced about 1 mm apart. The stimulus is given in the form of square wave pulses, 30 cycles per second with a duration of 2 ms per pulse. The output of the stimulator has to be connected to alternate wires of the grid. A fixed resistance is placed in series with the grid and in parallel to an oscilloscope to allow calibration in milliamperes. With increasing shock intensities the mice flinch, exhibit a startling reaction, increase locomotion or attempt to jump. The behavior is accurately reflected on the oscilloscope by marked fluctuations of the displayed pulse and defined as pain threshold response. Pain thresholds are determined in each individual mouse twice before administration of the test drug and 15, 30, 60, 90 and 120 min after dosing. Groups of 10 animals are used for control and for the test drugs.

EVALUATION

The current as measured in milliamperes is recorded for each animal before and after administration of the drug. The average values for each group at each time interval are calculated and statistically compared with the control values. Placebo treated controls show a slight increase of threshold over time. Morphine sulfate in a dose of 10 mg/kg p.o. but also acetylsalicylic acid in a dose of 200 mg/kg p.o. definitely increase the threshold.

CRITICAL EVALUATION OF THE METHOD

The modification of the method as described by Blake et al. (1963) showed an effect not only of morphine but also of acetylsalicylic acid which is not easily picked up by other tests based on stimulation by physical means.

MODIFICATIONS OF THE TEST

Weiss and Laties (1961) in a "fractional escape" procedure trained animals to press a lever to reduce the intensity of shock delivered continuously through the floor grids of the experimental chamber. Each time, the rat depresses the lever, it reduces the intensity of the shock. An external timer is programmed to increase the intensity of the shock every few seconds. If the animal fails to press the lever, the shock continues to increase in intensity until lever-pressing behavior drives it down. Thus, the level of shock fluctuates depending on the rat's lever pressing. The action of an analgesic in altering the level of shock which the rat will "tolerate" can than be measured by comparing the average level at which the rat maintains the shock under control conditions with the average level at which the rat maintains the shock during treatment.

Painful stimulation of the paws of mice placed into cages equipped with metal bands for electrical stimulation was described by Charlier et al. (1961) as "pododolorimetry".

A modification of the jump-flinch technique for measuring pain sensitivity in rats based on four categories of responses was described by Bonnet and Peterson (1975).

Eschalier et al. (1988) described an automated method to analyze vocalization of unrestrained rats submitted to noxious stimuli.

H.1.2.8 Tooth Pulp Stimulation

PURPOSE AND RATIONALE

The method has been first described by Kohl and Reffert (1938) and by Ruckstuhl and Gordanoff (1939) for testing central analgesic activity in rabbits and has since applied by several authors to various animal species. Stimulation of the tooth pulp induces characteristic reactions, such as licking, biting, chewing and head flick which can be observed easily.

PROCEDURE

Rabbits of either sex with an weight between 2 and 3 kg are anaesthetized with 15 mg/kg thiopental or 0.2 mg/kg fentanyl-citrate intravenously. Pulp chambers are exposed close to the gingival line in the lateral margins of the two front upper incisors with a high-speed dental drill. On the day of the experiment, clamping electrodes are placed into the drilled holes. After an accommodation period of 30 min stimulation is started to determine the threshold value. The stimulus is applied by rectangular current with a frequency of 50 Hz and a duration of the stimulus of 1 s. The electrical current is started with 0.2 mA and increased until the phenomenon of licking occurs. In some cases, the current has to be increased and than to be decreased again in order to find the appropriate threshold. For assessing the basic value, the threshold is determined 3 times in each animal. Each animal serves as its own control. For testing analgesic activity of a new drug and determination of an ED_{50} 8 to 10 animals are used for each dose of the analgesic. The test substance is either injected intravenously or given orally by gavage. The threshold as the indicator of the antinociceptive effect is determined again after 15, 30, 60 and 120 min. The animals serve as their own controls. Threshold current is determined again 5, 15, 30, 45 and 60 min after intravenous application and 15, 30, 60 and 120 min after oral application.

EVALUATION

For screening procedures the increase of threshold, expressed in mV, is the indicator of intensity and duration of the analgesic effect. For determination of the ED_{50}, 8 to 10 rabbits are used for each dose, using 3 doses, which provided effects between 10 and 90%. An antinociceptive effect is defined as an increase of the threshold versus the initial control by a factor of 2 or more.

CRITICAL ASSESSMENT OF THE METHOD

Central analgesics, especially opioid agonists, have been found to be very active in this test. Compared with other tests for central analgesic activity, like the hot plate test in mice, the tests result in lower ED_{50}-values indicating a high sensitivity of the method. In addition, non-opiate analgesics like ketamine and peripheral analgesics like pyrazolone derivatives gave a positive response.

MODIFICATIONS OF THE METHOD

The method has been performed primarily in rabbits (Hertle et al. 1957; Hoffmeister 1962, 1968; Piercey and Schröder 1980), but also **dogs** (Koll and Fleischmann 1941; Skinkle and Tyers 1979) and **cats** (Mitchell 1964) have been used.

Among several methods in different species, Fleisch and Dolivo (1953) found the electrical stimulation of the tooth pulp in the rabbit as the only satisfactory method to test the efficacy of different analgesic drugs.

The effects of tooth pulp stimulation in the thalamus and hypothalamus of the **rat** have been investigated by Shigena et al. (1973).

The method has been adapted for freely moving rats (Steinfels and Cook 1986). Medium effective doses could be determined for ì and ê agonists. Non-steroidal

anti-inflammatory drugs were also effective in this test procedure, but the slopes of the dose-response curves for these compounds were lower than for the opioid analgesics. Microinfusion of bradykinin solution onto the tooth pulp of unrestrained rats was described by Foong et al. (1982) as a reliable method for evaluating analgesic potencies of drugs on trigeminal pain.

Kidder and Wynn (1983) described an automatic electronic apparatus for generating and recording a ramp stimulus for analgesia testing.

Thut et al. (1995) used the rabbit tooth-pulp assay to quantify efficacy and duration of antinociception by local anesthetics infiltrated into maxillary tissues.

Shyu et al. (1984) studied the role of central serotoninergic neurons in the development of dental pain in the **monkey**.

H.1.2.9 Monkey Shock Titration Test

PURPOSE AND RATIONALE

Generally, analgesic tests in rats and mice result in correlation with the analgesic activity of a drug in man. To clarify the mode of action in more detail and to find a suitable dose for therapy in man, experiments in monkeys may be necessary.

PROCEDURE

This test has been recommended by Weiss and Laties (1958) and later developed further by several authors. The monkeys are seated in restraining chairs. Electrical current is delivered by a Coulbourn Instrument Programmable Shocker through electrodes coupled to two test tube clamps which are attached to a shaved portion of the tail. The current ranges from 0 to 4 mA through 29 progressive steps. The monkey presses a bar to interrupt the shock. A stable baseline shock level is established for each monkey on the day prior to drug administration. After drug administration shock titration activity is rated according to the change in maximum level of median shock intensity attained for drug as compared to control levels. Doses of 3.0 mg/kg i.m.

morphine, 1.7 mg/kg i.m. methadone and 10 mg/kg i.m. pentazocine were found to be effective.

CRITICAL ASSESSMENT

The monkey shock titration test may be used for final evaluation of a new compound before administration to man. For screening activities the procedure can not be recommended since the test is too time consuming and the apparatus too complicated. Furthermore, higher animals such as monkeys should only be used if absolutely necessary.

H.1.2.10 Formalin Test in Rats

PURPOSE AND RATIONALE

The formalin test in rats has been proposed as a chronic pain model which is sensitive to centrally active analgesic agents by Dubuisson and Dennis (1977).

PROCEDURE

Male Wistar rats weighing 180–300 g are administered 0.05 ml of 10% formalin into the dorsal portion of the front paw. The test drug is administered simultaneously either sc. or orally. Each individual rat is placed into a clear plastic cage for observation. Readings are taken at 30 and 60 min and scored according to a pain scale. Pain responses are indicated by elevation or favoring of the paw or excessive licking and biting of the paw. Analgesic response or protection is indicated if both paws are resting on the floor with no obvious favoring of the injected paw.

EVALUATION

Using various doses, ED_{50} values for protection can be calculated. Doses of 1.7 mg/kg morphine s.c. and 15 mg/kg s.c. pethidine were found to be effective.

CRITICAL ASSESSMENT

The formalin test identifies mainly centrally active drugs, whereas peripherally acting analgesics are almost ineffective. Therefore, the formalin test may allow a dissociation between inflammatory and non-inflammatory pain, a rough classification of analgesics according to their site and their mechanism of action (Chau 1989). Cowan (1990) underlined the aspect that the formalin-test is a model of chronic pain whereas most other methods measure only the effect on acute pain.

MODIFICATIONS OF THE METHOD

Murray et al. (1988) used **mice** instead of rats. They injected 0.020 ml of 5% formalin solution into the subplantar region of the hind paw. Morphine at a dose of 2.1 mg/kg s.c. and pentazocine at a dose of 23.8 mg/kg s.c. were active whereas the cyclooxygenase inhibitor zomepirac was inactive even at a dose of 100 mg/kg s.c.

Hunskaar et al. (1986), Hunskaar and Hole (1987) injected a small amount of formalin (20 µl of 1% solution) under the skin of the dorsal surface of the right hind paw of mice. A biphasisic response with an early (0–5 min) and a late (20–30 min) phase with high licking activity was observed. Central acting analgesics were active in both phases, whereas non-steroidal anti-inflammatory drugs and corticosteroids inhibited only the late phase. Acetylsalicylic acid and paracetamol were antinociceptive in both phases.

Shibata et al. (1989) again used lower concentrations of formalin (0.025 ml of 0.5% formalin solution) and also mice instead of rats. They found a characteristic biphasic pain response. Centrally acting drugs such as morphine inhibited both phases, whereas according to their data peripherally acting drugs such as acetylsalicylic acid, oxyphenylbutazone and corticosteroids inhibited only the second phase.

Abbott et al. (1995) used the formalin test for scoring properties of the first and second phases of the pain response in rats.

Abbadie et al. (1997) determined the pattern of c-fos expression in the rat spinal cord to study the two phases of the formalin test.

Clavelou et al. (1989), Dallel et al. (1995). Gilbert et al. (2001) used a modification of the formalin test for assessing pain and analgesia in the **orofacial region of the rat**. After injection into the upper lip, pain intensity was evaluated by the animal's behavior of rubbing of the injected area. A subcutaneous injection of 0.05 ml of 0.92% formaldehyde solution was made into the upper lip, just lateral to the nose. Following injection, the rat was immediately brought back in a test box equipped with a videocamera for a 45 min observation period. The recording time was divided into 15 blocks of 5 min and a pain score was determined for each block, by measuring the number of seconds that the animals spent rubbing the injected area with the ipsilateral fore- or hindpaw. The animals were sacrificed after the end of the experiment to avoid unnecessary suffering.

Tjølsen et al. (1992) attributed the early phase to C-fibre activation, whereas the late phase appeared to be dependent on the combination of an inflammatory reaction in the peripheral tissue and functional changes in the dorsal horn of the spinal cord.

Alreja et al. (1984) used the formalin test for assessing pain in **monkeys** after volunteering of one of the authors to carry out the same procedure on himself.

Corrêa and Calixto (1993) studied the participation of B_1 and B_2 kinin receptors in the formalin-induced nociceptive response in the **mouse**. Pain response was increased after ACE-inhibition and decreased by bradykinin receptor antagonists.

Herman and Felinska (1979) proposed a rapid test for screening of narcotic analgesics in mice by evaluation of behavioral symptoms after subcutaneous injection of EDTA.

Legat et al. (1994), Dumas et al. (1997) induced hyperalgesia in rats by subplantar injection of collagenase (100 µg in 100 µl saline) and rated the behavioral reactions after treatment with analgesics according to a modified formalin-test.

H.1.2.11 Neuropathic Pain

H.1.2.11.1 General Considerations

Partial injury to somatosensory nerves sometimes causes causalgia in humans. Causalgia is characterized by spontaneous burning pain combined with hyperalgesia and allodynia and usually follows an incomplete peripheral nerve injury. Allodynia, a pain sensation due to normally innocuous stimulation, is a particularly troublesome symptom in patients. Neuropathic pains are classified according to either the etiological diagnosis of the neuropathy (e. g., painful diabetic neuropathy, post-herpetic neuralgia, post-traumatic neuralgia, etc.), or the anatomical lesion (e. g., central pain, peripheral neuralgia). See Hansson and Dickenson (2005). Various animal models are described to study neuropathic pain. See below.

REFERENCES AND FURTHER READING

H.1.2.11.2 Chronic Nerve Constriction Injury

PURPOSE AND RATIONALE

Bennet and Xie (1988) described a peripheral neuropathy due to nerve constriction in the rat that produces disorders of pain sensation like those seen in man. This method with slight modifications was used by Davar et al. (1991), Mao et al. (1992), Munger et al. (1992), Yamamoto and Yaksh (1992), Tal and Bennet (1993) and reviewed by Bennett (1993).

PROCEDURE

Anesthesia is induced in male Sprague-Dawley rats by inhalation with halothane 4% and maintained at a concentration of 2–3% as needed. After a local incision, the biceps femoralis of each leg is bluntly dissected at midtigh to expose the sciatic nerve. Each nerve is then mobilized with care taken to avoid undue stretching. Four 4–0 chromic gut sutures are each tied loosely with a square knot around the right sciatic nerve. The left sciatic nerve is only mobilized. Both incisions are closed layer to layer with silk sutures and the rats allowed to recover. During the next days, the animals show a mild eversion of the affected paw and a mild-to-moderate degree of foot drop.

The thermal nociceptive threshold is measured according to the method of Hargreaves et al. (1988), (see H.1.2.3). The rats are placed beneath a clear plastic cage ($10 \times 20 \times 24$ cm) upon an elevated floor of clear glass. A radiant heat source (halogen projector lamp) is placed beneath the glass floor on a movable holder and positioned such that is focuses at the plantar area of one hind paw. The time interval between the application of the light beam and the brisk hind paw withdrawal response is measured to the nearest 01. sec.

The maximum hyperesthesia occurs between 7 and 14 days after nerve ligation. Before intrathecal injection of the drug or vehicle, the hind paws are tested 3 times alternatively with 5-min intervals as the baseline data. The left and right test sequence is carried out at 5, 15, 30, 60 and 90 min after injection.

EVALUATION

The mean ±SEM of the paw withdrawal latency (PWL) is plotted. To analyze the magnitude of hyperesthesia, the difference score (DS) is calculated by subtraction the maximum PWL of the control side (left side) from the maximum PWL of the affected side (right side). Maximum PWL is defined as the PWL that was the maximum during the first 30 min after injection. To analyze the drug effects in hyperesthetic rats, the dose is plotted against the change in DS (post-drug difference score minus pre-drug difference score).

MODIFICATIONS OF THE METHOD

The chronic constriction injury (CCI) model according to Bennett and Xie (1988) has been used by several authors: Sotgiu and Biella (1998), Toda et al. (1998), Blackburn-Munro and Jensen (2003), Keay et al. (2004), Bingham et al. (2005), Bomholt et al. (2005), Costa et al. (2005), and Howard et al. (2005).

Sotgiu et al. (1996) performed laminectomy from L1 to S2 in anesthetized rats with sciatic chronic constriction injury. For extracellular recording, two tungsten microelectrodes were positioned under a dissecting microscope on the surface of the spinal cord at L2 and L5–L6 level ipsilaterally to the injured nerve, and were advanced at steps of 2 μm. Neuronal activity was conventionally recorded and then digitized; frequency histograms were constructed by computer programs. The search stimulus for dorsal horn neurons at L2 and L5–L6 segments was the electrical stimulation of saphenous and sciatic nerve peripheral territories. Nat-

ural stimuli (brushing of the skin) and noxious stimuli (calibrated pinching) were defined. After the responses to saphenous stimuli in the neurons were recorded, a small pad of gel-foam soaked with 0.5 ml lidocaine was placed around the intact epineurium proximally to the ligatures on the sciatic nerve. The saphenous stimulation was repeated during the block and after complete recovery of the preblock baseline activity. In this way, the effect of the local anesthetic on the spontaneous activity and on the response to a noxious stimulus could be evaluated.

The first animal model of painful neuropathy was reported by Wall et al. (1979a, b). The sciatic nerve of rats or mice was sectioned and either tied or implanted in a polyethylene tube sealed at its far end. Moreover, in one modification also the saphenous nerve was cut, such that the hind paw was completely denervated. This procedure, which is known as the neuroma model, is believed to replicate the human syndromes seen after amputation (phantom pain) or after nerve transection in an intact limb (anesthesia dolorosa). Within several days, the animals begin to self-mutilate the hindpaw on the side of the nerve transection: a behavior named 'autotomy'.

Seltzer et al. (1990) ligated only one-half of the sciatic nerve in rats unilaterally. The withdrawal thresholds to repetitive von Frey hair stimulation at the plantar side were decreased bilaterally as were the withdrawal thresholds to CO_2 laser heat pulses. The contralateral phenomena resemble the "mirror image" pains in humans with causalgia.

This "partial sciatic nerve injury model" has been used by several authors (Malmberg and Basbaum 1998; Lindenlaub and Sommer 2000; Bingham et al. 2005). Patel et al. (2001) studied the effects of $GABA_B$ agonists and gabapentin on mechanical hyperalgesia in models of neuropathic (partial sciatic ligation) and inflammatory (Freund's complete adjuvant) pain in the rat and the inhibitory action on spinal transmission *in vitro*.

Hofmann et al. (2003) described the tibial nerve injury model in rats as a surgically uncomplicated model of neuropathic pain based on unilateral transection (neurotomy) of the tibial branch of the sciatic nerve.

Walczak et al. (2005) characterized the saphenous nerve partial ligation in rats as a model of neuropathic pain.

Kim and Chung (1992) described an experimental model for peripheral neuropathy produced by segmental spinal nerve ligation in the rat. Either both the L_5 and L_6 spinal nerves or the L_5 spinal nerve alone on one side of the rat were tightly ligated. A modified version of this technique was used by LaBuda and Little (2005) and by Bertorelli et al. (2005).

DeLeo et al. (1994) performed cryoneurolysis of the sciatic nerve in the rat using a cryoprobe cooled to –60°C in a 30/5/30 s freeze-thaw-freeze sequence. Autotomy was observed after 4–14 days.

Coderre et al. (2004) produced a neuropathic-like pain syndrome in rats following prolonged hind paw ischemia and reperfusion, creating an animal model of complex regional pain syndrome-type I (CRPS-I; reflex sympathetic dystrophy), called **chronic post-ischemia pain**. A tourniquet ring was placed on one hindlimb of an anesthetized rat just proximal to the ankle joint for 3 h, which was removed prior to termination of anesthesia to allow reperfusion. Rats exhibited hyperemia and edema/plasma extravasation of the ischemic hind paw for a period of 2–4 h after reperfusion. Hyperalgesia to noxious mechanical stimulation (pin prick) and cold (acetone exposure), as well as mechanical allodynia to innocuous mechanical stimulation (von Frey hairs) are evident in the affected hindpaw as early as 8 h after reperfusion, and extend for at least 4 weeks.

Mice that lack protein kinase C gamma (PKCγ) displayed normal response to acute pain stimuli, but they almost completely failed to develop a neuropathic pain syndrome after partial sciatic nerve section, and the neurochemical changes that occurred in the spinal cord after nerve injury were blunted (Malmberg et al. 1997).

Shimoyama et al. (2002) developed a **mouse model of neuropathic cancer pain** by inoculating Meth A sarcoma cells in the immediate proximity of the sciatic nerve in BALB/c mice. The tumor grows predictably with time and gradually compresses the nerve, thereby causing nerve injury. Time courses of thermal hypersensitivity and mechanical sensitivity to von Frey hairs were determined and signs of spontaneous pain were evaluated. The authors compared this model with the chronic constriction model.

Panesar et al. (1997) and Campbell et al. (1998) studied mechanical hyperalgesia associated with partial peripheral ligation in the **guinea pig**.

H.1.2.11.3 Peripheral Nerve Injury Model

PURPOSE AND RATIONALE

In addition to chronic ligation techniques, nerve dissection and nerve crush models have been used to study neuropathic pain. Nerve crush injury was described by Decosterd et al. (2002).

PROCEDURE

Male Sprague Dawley rats weighing 200–250 g were anesthetized with halothane (1.5%–3%). The left sciatic nerve was exposed at the mid-thigh level and crushed by a pair of hemostat forceps with smooth protective pads that were placed perpendicularly to the

sciatic trunk for 30 s (Bester et al. 2000). Muscle and skin were closed in two layers.

Animals were habituated to the tester, the environment and the handling procedures prior to commencement of the testing. A calibrated von Frey monofilament was applied five times until it bent on the lateral dorsal side of the hindpaw that is in crushed nerve territory or the intact sural nerve, ipsilateral to the nerve lesion. A series of monofilaments (1.0–200.0 g) were applied and the test started with the lowest force filament. The mechanical withdrawal threshold corresponds to the minimum force required to elicit a reproducible flexor withdrawal movement after application of the von Frey hairs. Once baseline threshold was determined, eight light strokes were applied manually at 1 Hz to the dorsum of the paw at 5-min intervals, for 2 h. The mechanical withdrawal threshold was recorded immediately after the application of the light touch, at the same interval of 5 min during the whole test period.

EVALUATION

Data are expressed as mean ±SEM of the recorded mechanical withdrawal threshold in grams, or as a percentage of the baseline value. The differences between groups were analyzed with analysis of variance (ANOVA) two-way repeated measures.

MODIFICATIONS OF THE METHOD

Vogelaar et al. (2004) described sciatic nerve regeneration in mice and rats. Under anesthesia, the sciatic nerve was carefully exposed. At a point immediately distal from the gluteus maximus muscle, the nerve was crushed for 30 s using a hemostatic forceps. The animals were followed for 70 (rats) and 32 (mice) days and functional recovery of sciatic nerve function was monitored by the foot reflex withdrawal test, locomotor pattern, and mechanical withdrawal thresholds.

Rodrigues-Filho et al. (2003, 2004) published the technique of avulsion injury of the rat brachial plexus that triggers hyperalgesia and allodynia in the hindpaws. Male Wistar rats weighing 250–300 g were anesthetized by chloralose i.p. The brachial plexus was approached through a horizontal incision parallel to the clavicle, running from the sternum to the axillary region. The pectoralis major muscle was displaced, leaving the cephalic vein intact. The subclavian vessels were located and the lower trunk dissected and crushed three times for 5 s using microsurgical forceps. At the end of this procedure, the nerve was completely flattened and transparent. The tissue layers were then brought together and the skin closed with silk sutures.

For assessment of mechanical hyperalgesia, mechanical thresholds were measured in the hindpaws with an analgesymeter (Ugo Basile, Italy) according to the method of Randall and Sellitto (1957). Furthermore, thermal hyperalgesia, mechanical allodynia, and cold allodynia were measured in the hindpaws, as well as grasping force in the forepaws.

Sweitzer et al. (2001) studied prevention of allodynia induced by transection of the L5 spinal nerve in rats.

Devor et al. (2005) studied heritability of symptoms in the neuroma model of neuropathic pain.

H.1.2.11.4 Spared Nerve Injury Model

PURPOSE AND RATIONALE

In addition to the above-described models of peripheral neuropathic pain [chronic constriction injury model according to Bennett and Xie (1988), partial ligation according to Seltzer et al. (1990), segmental spinal nerve ligation according to Kim and Chung (1992)], Decosterd and Woolf (2000) described **spared nerve injury** as an animal model of persistent peripheral neuropathic pain.

PROCEDURE

Adult male Sprague Dawley rats were used. Under halothane (2%) anesthesia the skin on the lateral surface of the thigh was incised and a section made directly through the biceps femoris muscle exposing the sciatic nerve and its three terminal branches: the sural, common peroneal and tibial nerves. The procedure comprises an axotomy and ligation of the tibial and common peroneal nerves leaving the sural nerve intact. The common peroneal and the tibial nerves were tightly ligated with 5.0 silk and sectioned distal to the ligation, removing 2–4 mm of the distal nerve stump. Care was taken to avoid any contact with or stretching of the intact sural nerve. Muscle and skin were closed in two layers. Behavior testing was performed only after a period of at least 1 week.

For testing mechanical allodynia, animals were placed on an elevated wire grid and the plantar surface of the paw stimulated with a series of ascending force von Frey filaments. The threshold was taken as the lowest force that evoked a brisk withdrawal response to one of five repetitive stimuli. The lateral and medial plantar surface of the paw as well as its dorsal surface were tested.

For testing mechanical hyperalgesia, a pin prick test was performed using a safety pin. The lateral part of the plantar surface of the paw was briefly stimulated at an intensity to indent but not penetrate the skin. The duration of paw withdrawal was recorded.

For testing cold allodynia, a drop of acetone solution was delicately dropped onto the lateral plantar surface of the paw, using a blunt needle connected to a syringe without touching the skin. The duration of the withdrawal response was recorded.

The lateral plantar surface was exposed to a beam of radiant heat through a transparent Perspex surface (Hargreaves et al. 1988). The withdrawal latency and duration were recorded. The heat stimulation was repeated 3 times at an interval of 5–10 min for each paw and the mean calculated.

EVALUATION

Results were presented as mean ±SEM. The data were analyzed by one-way ANOVA and the non-parametric Wilcoxon matched-pairs signed-rank tests.

MODIFICATIONS OF THE METHOD

The rat spared nerve injury model has been used by several authors: Blackburn-Munro and Jensen (2003), Rode et al. (2005), and Howard et al. (2005).

H.1.2.11.5 Spinal Cord Injury

PURPOSE AND RATIONALE

Spinal cord injuries result in a devastating loss of function. Chronic central pain syndromes frequently develop in the majority of affected patients. Several attempts have been made to find animal models of this situation. Xu et al. (1992), Hao and Xu (1996), Hao et al. (1998a, 1998b, 2000), Wu et al. (2003), and Colpaert et al. (2004) performed studies in rats after ischemic spinal cord injury photochemically induced by laser irradiation.

PROCEDURE

Female Sprague Dawley rats were anesthetized with 300 mg/kg chloral hydrate i.p. and one jugular vein was cannulated. Vertebrae T11–L2 were exposed after a midline incision of the skin on the back. The animals were positioned beneath a tuneable argon ion laser (Innova, Model 70, Coherent Laser Production Division) and irradiated with a knife edge beam, which was used to cover the single T13 vertebra with an average power of 0.16 W for 10 min. No laminectomy was performed. Immediately before the irradiation, erythrosine B (Red No. 3, Aldrich-Chemie) was injected intravenously in 0.9% saline at a dose of 32.5 mg/kg. Since erythrosine B is rapidly metabolized, the injection at this dose was repeated at 5-min intervals during the irradiation in order to maintain an adequate blood concentration.

Erythrosine B has an optimal absorption wavelength similar to that of the laser light. When it receives this light, a photochemical reaction occurs inside the spinal cord blood vessel where the laser is aimed. One of the reaction products accumulates in the vessel, injuring the endothelial layer and causing platelet release and coagulation and, thus, ischemia. After irradiation the incision was closed and the animals were kept warm for 2 h. The bladders were emptied manually 2–3 times a day until normal function was regained.

A set of calibrated von Frey hairs was used to test the vocalization threshold in response to graded mechanical pressure ranging from 0.021 to 410.0 g. During the test the rats were gently restrained in a standing position by the experimenter and the von Frey hair was pushed onto the skin until the filament became bent. The frequency of the stimulation was about every 3–4 s per stimulus and at each intensity. The stimuli were applied 5–10 times. The pressure which induced consistent vocalization (>75% response rate) over a relatively large skin area was considered to be the pain threshold.

EVALUATION

Rats were randomized for different treatment groups. The data are expressed as medians and variability as mean ±SEM. Data were analyzed with Kruskal-Wallis one-way ANOVA followed by Wilcoxon signed ranks test or by Mann-Whitney *U*-test.

MODIFICATIONS OF THE METHOD

Christensen et al. (1996), Christensen and Hulsebosch (1997a, 1007b), and Bennett et al. (2000a, 2000b) used a rodent spinal hemisection model of spinal cord injury in which mechanical and thermal allodynia develop by 24 days after injury.

Male Sprague Dawley rats (175–200 g) were deeply anesthetized by i.p. injection of 75 mg/kg ketamine and 15 mg/kg xylazine. The spinal cord was hemidissected at T13 on the left side by the following procedure: after palpation of the dorsal surface to locate the cranial borders of the sacrum and the dorsal spinous processes of the lower thoracic and lumbar vertebrae, the T11, T12, and T13 laminae were determined by locating the last rib, which attaches the cranial end of the T13 vertebrae. The surgical field was shaved and prepared with povidone-iodine, and a longitudinal incision was made exposing several segments. A laminectomy was performed at vertebral level T11, the lumbar spinal cord was identified with the accompanying dorsal vessel, and the spinal cord was hemisected at T13, cranial to the L1 dorsal root entry zone, with a scalpel blade without damage to the major dorsal vessel or vascular branches. The musculature and the fascia were then sutured and the skin was apposed by autoclips.

Siddall et al. (1995) and Drew et al. (2004) described mechanical allodynia following contusion injury of the rat spinal cord. Contusive spinal cord injury was produced in anesthetized Wistar rats weighing 200–300 g. Laminectomy was performed at the vertebral thoracic T10 level to expose a 3-mm window over the dorsal spinal cord and adjacent rostral and caudal spinous processes were clamped to stabilize the spine. A brass guide tube 15 cm in length was positioned perpendicularly above the exposed cord and a cylindrical 10 g steel weight (2 mm in diameter) with a rounded tip was suspended within the tube 2 cm above the cord surface. The weight was held within the tube by a metal pin. Removing the pin and allowing the weight to drop onto the exposed cord produced spinal cord injury at the T12–T13 segmental level. The wound was closed in layers and antibiotics were administered.

Abraham et al. (2001) and Caudle et al. (2003) described excitotoxic spinal cord injury induced by intraspinal injection of quisqualic acid.

Zochodne et al. (1994) induced a segmental chronic pain syndrome by lumbar intrathecal NMDA infusion.

Malmberg and Yaksh (1992) reported that hyperalgesia mediated by spinal glutamate or substance P receptor is blocked by spinal cyclooxygenase inhibition.

H.1.2.11.6 Chemotherapy-Induced Pain

PURPOSE AND RATIONALE

Within the numerous adverse effects associated with antineoplastic drugs, painful peripheral neuropathy is frequent. Vincristine, an antineoplastic agent widely used in cancer therapy, was found to be neurotoxic for all treated patients and can induce peripheral neuropathy (Windebank 1999). Aley et al. (1996), Authier et al. (1999, 2003) and Marchand et al. (2003) developed an animal model of nociceptive neuropathy using repeated injections of vincristine.

PROCEDURE

Male Sprague Dawley rats weighing 180–200 g received five intravenous injections of 150 µg/kg vincristine every 2 days until a cumulative dose of 750 µg/kg was reached. Thresholds to paw pressure were determined before and 14 days after vincristine treatment. Test drug was then applied and the vocalization thresholds were determined 15, 30, 45, 60, 90, and 120 min after this injection.

The C-fiber-evoked flexor reflex elicited in the right hind limb (Falinower et al. 1994; Mestre et al. 1997) was recorded from halothane-anesthetized rats. Rectangular electric pulses of 6–7 mA strength and 2 ms duration were applied every 10 s to the sural nerve receptive field by means of two stainless steel needles inserted into the skin of toes 4 and 5. The C-fiber-evoked reflex response (electromyographic responses) was recorded from the ipsilateral biceps muscle by utilizing another pair of stainless steel needles. Once a stable threshold C reflex response was obtained, the stimulus strength was increased by a factor of threefold. Test drug was then injected in various doses and the mean C-fiber reflex (mean of the 12 C-fiber reflexes recorded during the 2-min period) was calculated every 2 min between 25 and 35 min.

EVALUATION

The data analysis was performed by a two-way analysis of variance (ANOVA) followed by a Student-Newman-Keuls test for the time course of the effect of drug on mechanical nociceptive thresholds. For the C reflex, results were expressed as mean percentage inhibition of the integrated C reflex responses obtained between 25 and 35 min after drug injection and plotted against log dose, allowing ED_{50} calculation.

MODIFICATIONS OF THE METHOD

Lynch et al. (2005) tested the effect of a nicotinic acetylcholine agonist against allodynia in rats in the vincristine-induced pain model.

Polomano et al. (2001) described painful peripheral neuropathy in the rat produced by the chemotherapeutic drug, paclitaxel.

Dalziel et al. (2004) described allodynia in rats infected with varicella zoster virus as an animal model for **post-herpetic neuralgia**.

H.1.2.11.7 Trigeminal Neuropathic Pain Model

PURPOSE AND RATIONALE

Trigeminal neuralgia is an extreme form of neuropathic pain. Although the pathophysiology of the disorder is uncertain, vascular compression of the trigeminal root resulting in damage to primary afferent neurons is thought to play a major role in the generation of pain. Idänpään-Heikkilä and Guilbaud (1999) used a rat model of **trigeminal neuropathic pain**, developed by Gregg (1973), Jacquin and Zeigler (1983), Vos and Maciewicz (1991), Vos et al. (1994), and Vos and Strassman (1995), where the neuropathy is produced by a chronic constriction injury of the infra-orbital branch of the trigeminal nerve, and studied the effects of various drugs on this purely sensory model of neuropathic pain.

PROCEDURE

Male Sprague Dawley rats weighing 175–200 g were used. The head of the rat, which was anesthetized with sodium pentobarbital 50 mg/kg i.p. and treated with 0.4 mg/kg atropine i.p., was fixed in a stereotaxic frame. A mid-line scalp incision was made exposing skull and nasal bone. To expose the intra-orbital part of the left infra-orbital nerve, the edge of the orbit, formed by the maxillary, frontal, lacrimal and zygomatic bones, was dissected free. To give access to the infra-orbital nerve, the orbital contents were gently deflected with a cotton-tipped wooden rod. The infra-orbital nerve was dissected free at its most rostral extent of the orbital cavity, just caudal to the infra-orbital foramen. Two chromic catgut (5–0) ligatures (2 mm apart) were loosely tied around the infra-orbital nerve. The ligatures reduced the diameter of the nerve by just a noticeable amount and retarded, but did not interrupt, the epineural circulation. The scalp incision was closed with silk sutures.

Before the first actual stimulation session, the rats were allowed to adapt to the observation cage and to the testing environment. During this period, the experimenter reached slowly into the cage to touch the walls with a plastic rod, similar to the ones on which the von Frey filaments were mounted.

For mechanical stimulation, a graded series of ten von Frey filaments with a bending force of between 0.217 and 12.5 g was used. The stimuli were applied within the infra-orbital nerve territory, near the center of the vibrissal pad, on the hairy skin surrounding the mystacial vibrissae. The complete series of von Frey hair intensities was presented in an ascending series and either a brisk withdrawal of the head or an attack/escape reaction was considered as the mechanical threshold. Local injection of a local anesthetic (articaine) into the rostral orbital cavity of the lesioned side, in close proximity to the ligated infra-orbital nerve, increased the mechanical threshold to the upper level. The duration of the effect was dose-dependent.

EVALUATION

Data are expressed as means ±SEM. The non-parametric Kruskal–Wallis one-way ANOVA was used and comparisons between the groups were performed using the Mann-Whitney *U*-test.

MODIFICATIONS OF THE METHOD

Christensen et al. (2001) studied the effect of gabapentin and lamotrigine on mechanical allodynia-like behavior in the rat model of trigeminal neuropathic pain.

Deseure et al. (2002) studied the effects of acute i.p. injections of 5-HT_{1A} receptor agonists on mechanical allodynia in a rat model of trigeminal pain.

Cutrer and Moskowitz (1996) studied the actions of valproate and neurosteroids in a **guinea pig model** of trigeminal pain. Hartley guinea pigs were pretreated with valproate or allopregnanolone 30 min prior to activation of trigeminal afferent fibers via intracisternal

injection of capsaicin. The effects were examined on c-fos expression within the trigeminal nucleus caudalis.

H.1.2.11.8 Migraine Model in Cats

PURPOSE AND RATIONALE

In order to simulate pain experienced by humans in migraine attacks, Storer and Goadsby (1997) developed a model of **craniovascular pain in cats** by stimulating the superior sagittal sinus and monitoring trigeminal neuronal activity using electrophysiological techniques.

PROCEDURE

Adult cats were anesthetized with α-chloralose (60 mg/kg i.p.), paralyzed (gallamine 6 mg/kg i.v.) and ventilated. The superior sagittal sinus was accessed and isolated for electrical stimulation by a mid-line circular craniotomy. The region of the dorsal surface of C_2 spinal cord was exposed by a laminectomy and an electrode placed for recording evoked activity by sinus stimulation and spontaneous activity of the same cells. Signals were amplified and monitored on-line. Cells were recorded that were activated by stimulation of the sinus and were also spontaneously activated. Cells fired with latencies consistent with Aδ and C fibers, generally firing three or four times per stimulus (0.3 Hz, 250 µs duration, 100 V) delivered to the sinus. Both evoked and spontaneous firing could be inhibited by iontophoretic application of serotonin (5-$HT)_{1B/1D}$ agonists.

EVALUATION

The suppression or activation of cell firing was determined from both peri-stimulus and post-stimulus histograms using the criteria of a shift of >30% from baseline. Drug comparisons were made using the Kruskal-Wallis one-way analysis of variance assessing significance at the $P < 0.05$ level.

MODIFICATIONS OF THE METHOD

Using the same method, Goadsby et al. (2002) studied the inhibition of trigeminovascular nociceptive transmission by adenosine A_1 receptor agonists.

H.1.3 Side Effects of Central Analgesic Drugs

See Chap. I.J.

H.2 Peripheral Analgesic Activity

H.2.0.1 General Considerations

The differentiation between central and peripheral analgesic drugs is nowadays of more or less historical value. Most of the so called peripheral analgesics possess anti-inflammatory properties and in some cases also antipyretic activity besides analgesia. For many of them the mode of action has been elucidated as an inhibition of cyclooxygenase in the prostaglandin pathway. Nevertheless, new peripheral analgesics have to be tested not only for their *in vitro* activity on cyclooxygenase but also for their *in vivo* activity.

The most commonly used methods for measuring peripheral analgesic activity are the writhing tests

in mice (various modifications) and the RANDALL-SELITTO-test in rats.

H.2.0.2 Writhing Tests

PURPOSE AND RATIONALE

Pain is induced by injection of irritants into the peritoneal cavity of mice. The animals react with a characteristic stretching behavior which is called writhing. The test is suitable to detect analgesic activity although some psychoactive agents also show activity. An irritating agent such as phenylquinone or acetic acid is injected intraperitoneally to mice and the stretching reaction is evaluated. The reaction is not specific for the irritant.

PROCEDURE

Mice of either sex with a weight between 20 and 25 g are used. Phenylquinone in a concentration of 0.02% is suspended in a 1% suspension of carboxymethylcellulose. An aliquot of 0.25 ml of this suspension is injected intraperitoneally. Groups of 6 animals are used for controls and treated mice. Preferably, two groups of 6 mice are used as controls. Test animals are administered the drug or the standard at various pretreatment times prior to phenylquinone administration. The mice are placed individually into glass beakers and five min are allowed to elapse. The mice are then observed for a period of ten min and the number of writhes is recorded for each animal. For scoring purposes, a writhe is indicated by stretching of the abdomen with simultaneous stretching of at least one hind limb. The formula for computing percent inhibition is: average writhes in the control group minus writhes in the drug group divided by writhes in the control group times 100%. The time period with the greatest percent of inhibition is considered the peak time. A dose range is reserved for interesting compounds or those which inhibit writhing more than 70%. Compounds with less than 70% inhibition are considered to have minimal activity.

EVALUATION

A dose range is run in the same fashion as the time response except 8 animals/ group are tested at the peak time of drug activity. Four drug groups and a vehicle control group are employed. Animals are dosed and tested in a randomized manner. An estimated ED_{50} is calculated. Doses of 1.0 mg/kg p.o. indomethacin, 30 mg/kg p.o. acetylsalicylic acid, 40 mg/kg p.o. amidopyrine and 80 mg/kg p.o. phenacetin have been found to be ED_{50} values.

CRITICAL ASSESSMENT OF THE TEST

In this test both central and peripheral analgesics are detected. The test, therefore, has been used by many investigators and can be recommended as a simple screening method. However, it has to be mentioned that other drugs such as clonidine and haloperidol also show a pronounced activity in this test. Because of the lack of specificity, caution is required in interpreting the results, until other tests have been performed. Nevertheless, a good relationship exists between the potencies of analgesics in writhing assays and their clinical potencies.

MODIFICATIONS OF THE METHOD

Instead of a phenylquinone suspension, 0.1 ml of a 0.6% solution of acetic acid is injected intraperitoneally to mice with an weight between 18 and 25 g (Koster et al. 1959; Taber et al. 1969). The response is similar to that after phenylquinone. Some authors have used this method together with observation of changes in capillary permeability in order to distinguish between narcotic and non-narcotic analgesics (Whittle 1964).

Eckhardt et al. (1958), Collier et al. (1968), Loux et al. (1978) showed that several substances are able to elicit the writhing response. For example, Amanuma et al. (1984) as well as Nolan et al. (1990) used as irritant intraperitoneal injections of acetylcholine.

Emele and Shanaman (1963), Burns et al. (1968) proposed bradykinin being a endogenous transmitter of pain as irritant.

Sancillo et al. (1987) induced abdominal constriction in mice by intraperitoneal injection of 31.6 µg/kg of prostaglandin E_1.

Bhalla and Bhargava (1980) described a method for assessing aspirin-like activity using aconitine to induce writhing.

Adachi (1994) described a device for automatic measurement of writhing in mice.

Analgesic effects of non-acidic non-steroidal anti-inflammatory drugs in the acetic acid writhing test after intracisternal administration have been found by Nakamura et al. (1986).

The writhing phenomenon can also be observed in **rats** (Fukawa et al. 1980). The writhing responses were induced by intraperitoneal injection of 4% sodium chloride solution. Narcotic and non-narcotic analgesics, antipyretic and nonsteroidal anti-inflammatory drugs were effectively evaluated at relatively low doses. Methamphetamine also showed an analgesic action. VonVoigtlander and Lewis (1982, 1983) induced writhing in rats by injection of

7 ml air or 6% aqueous saline into the peritoneal cavity.

Ethacrinic acid-induced writhing response in rats was used by Björkman et al. (1992).

Schweizer et al. (1988) described a photoelectronic motility monitoring apparatus to measure automatically the writhing movements. A good correlation was found between ED_{50} values after oral administration in mice and the clinically effective oral doses in man.

Heapy et al. (1993) induced the abdominal constriction response in mice by intraperitoneally injecting 0.4 ml of either 0.25% acetic acid, 7.5 mg/ml kaolin suspension, 2.4 mg/ml zymosan solution, or 25 µg/ml bradykinin solution.

H.2.0.3 Pain in Inflamed Tissue (RANDALL-SELITTO-Test)

PURPOSE AND RATIONALE

This method for measuring analgesic activity is based on the principle that inflammation increases the sensitivity to pain and that this sensitivity is susceptible to modification by analgesics. Inflammation decreases the pain reaction threshold and this low pain reaction threshold is readily elevated by non-narcotic analgesics of the salicylate-amidopyrine type as well as by the narcotic analgesics. Brewers yeast has been used as an inducer for inflammation which increases pain after pressure.

PROCEDURE

Groups of male Wistar rats (130 to 175 g) are used. Only for oral testing the animals are starved 18 to 24 h prior to administration. Otherwise, the route of administration can be intraperitoneal or subcutaneous. To induce inflammation, 0.1 ml of a 20% suspension of Brewer's yeast in distilled water is injected subcutaneously into the plantar surface of the left hind paw of the rat. Three hours later, pressure is applied through a tip to the plantar surface of the rat's foot at a constant rate by a special apparatus to the point at which the animal struggles, squeals or attempts to bite. The apparatus being used has been modified by various authors such as using the Analgy Meter (Ugo Basile, Apparatus for Biological Research, Milan, Italy). Each animal is tested for its control pain threshold. Any animal with a control pain threshold greater than 80 g is eliminated and replaced.

For a time response, groups of at least 7 animals are used, four groups for the agent to be tested and one for the vehicle control. The tests are done at 15 min intervals after subcutaneous administration and at 30 min intervals after oral administration for any change in pain threshold. The interval of time which indicates the greatest increase in pain threshold is regarded as the peak time.

A dose range is obtained in the same manner as the time response. The drug to be tested is administered in a randomized manner. The pain threshold is recorded at time zero and again at the determined peak time.

EVALUATION

The mean applied force is determined for each time interval tested. The percentage increase in pain threshold is calculated by subtracting the applied force of the vehicle control from the applied force of the drug group which is divided by the applied force of the vehicle control in order to give the percentage of increase in pain threshold of the drug group. Doses of 50 mg/kg s.c. Na salicylate, 50 mg/kg amidopyrine, 3 mg/ kg s.c. morphine, 12.5 mg/kg s.c. codeine or pethidine have been found to be effective.

CRITICAL ASSESSMENT OF THE METHOD

The method originally described by RANDALL and SELITTO has been used by many investigators and has been proven to detect central analgesics as well as peripheral analgesics. Peripherally acting analgesics such as the nonsteroidal anti-inflammatory drugs increase only the threshold of the inflamed paw, whereas opiate analgesics increase also the threshold of the intact paw (Dubinsky et al. 1987). In most modifications, the assay has a shallow dose-response curve. Nevertheless, the ED_{50} values of nonsteroidal anti-inflammatory drugs in this test showed a good correlation with human doses (Romer 1980).

MODIFICATIONS OF THE METHOD

The test has been modified by various authors. In some instances the pressure on the inflamed paw has been omitted. Instead the animals were allowed to walk on a metal grid. The gait of the animals is assessed by an observer using a scoring system:

- 0 = three-legged gait
- 0.5 = marked limping
- 1 = normal gait.

The scores are transformed into percent analgesia.

Other noxious stimuli were used to induce inflammation and hyperalgesia, such as carrageenin (Winter et al. 1962), Freund's adjuvant or prostaglandin E_2 (Ferreira et al. 1978a).

Vinegar et al. (1990) injected 0.1 ml of 0.25% solution of trypsin into the subplantar region and applied the load force 60 min later. They found a biphasic hyperalgesia and relatively low ED_{50} values for central and peripheral analgesics.

Technically, the method has been improved by several authors, such as Takesue et al. (1969).

Chipkin et al. (1983) modified the test by decreasing the rate of acceleration of the noxious stimulus (mechanical pressure) on the inflamed paw from 20 to 12.5 mm Hg/s and an extension of the cut-off time from 15 to 60 s. This modification is claimed to discriminate analgesics active against mild to severe clinical pain (narcotic-like) from those only useful against mild to moderate pain (non-narcotic-like).

Randall-Selitto analgesy meters are commercially available (e. g., IITC Life Science, Woodland Hills, CA, USA).

Central and peripheral analgesic action of aspirin-like drugs has been studied with a modification of the Randall-Selitto method applying constant pressure to the rat's paw by Ferreira et al. (1978b).

A modification of an analgesia meter for paw pressure antinociceptive testing in neonatal rats was described by Kitchen (1984).

Learning and retention has been tested in rats by Greindl and Preat (1976) inducing pain by a light quantifiable pressure applied to the normal hind paw.

Hargreaves et al. (1988) described a sensitive method for measuring thermal nociception in cutaneous hyperalgesia in rats. One paw was injected with

0.1 ml carrageenan solution, the other paw with saline. The rats were placed in chambers with glass floor and radiant heat was directed to the paws. A photoelectric cell detected the light reflected from the paw and turned off the radiant heat when paw movement interrupted the reflected light.

Perkins et al. (1993) described hyperalgesia after injection of 100 µl of Freund's adjuvant into the knee of anesthetized rats. After 64–70 h the animal was placed with each hind paw on a pressure transducer and a downward force was exerted until the uninjected leg was bearing 100 g. At this point animals were less tolerant to a load on the injected leg, indicating a hyperalgesic response.

Davis et al. (1996) induced mechanical hyperalgesia by injection of substance P and capsaicin in the rat knee joint and measured the download force tolerated by the injected leg.

Ferreira et al. (1993a, b) induced hyperalgesia by intraplantar injection in the hindpaw of rats of various agents, e. g., bradykinin, carrageenin, LPS, PGE_2, dopamine, TNFα, IL-1β, IL-6 and IL-8. A constant pressure of 20 mm Hg was applied to the hind paws and discontinued when the rats presented a typical freezing reaction.

Subplantar injection of 0.1 µg of serotonin in the rat results in a brief period (up to 20 min) of increased pain sensitivity to an applied force (hyperalgesia) which precedes a longer period of decreased pain sensitivity (hypoalgesia). Vinegar et al. (1989) used this phenomenon for pharmacologic characterization of the algesic response.

Similarly, a biphasic algesic behavior after subplantar injection of 250 µg of trypsin was described by Vinegar et al. (1990)

Courteix et al. (1994) proposed the Randall-Selitto paw pressure test in rats with streptozocin-induced diabetes as a model of chronic pain with signs of hyperalgesia and allodynia that may reflect signs observed in diabetic humans.

Amann et al. (1955, 1996) evaluated local edema and effects on thermal nociceptive threshold after intraplantar injection of nerve growth factor into the rat hind paw and studied the effect of a 5-lipoxygenase inhibitor in this test.

Zhou et al. (1996) tested the effects of peripheral administration of NMDA, AMPA or KA on pain behavior in rats. A 28-gauge needle was inserted in the skin of rats proximal to the footpads and advanced about 1 cm so that the tip reached the base of the third toe. A bolus of 20 µl containing concentrations between 1 and 10,000 µM of KA, NMDA or AMPA. For behavioral testing, each animal was placed in a Plexiglas box on a wire mesh screen. Mechanical stimuli were applied using four von Frey filaments with different bending forces. Each von Frey filament was applied 10 times to the skin on the base of the third toe. The paw withdrawal was rated as scores allowing dose-response curves for the hyperalgesic effects of excitatory amino acids. Furthermore, using the highest concentration of the stimulant, effects of antagonists were tested.

H.2.0.4 Mechanical Visceral Pain Model in the Rat

PURPOSE AND RATIONALE

Animal models designed to test the effectiveness of analgesic agents against visceral pain typically rely on noxious chemical irritation of the peritoneum, e. g., acetic acid and phenylquinone induced writhing tests based on acute inflammation. Ethical constraints prevent repeated assessments in a single animal, thereby compounding the difficulty of assessing development of tolerance to analgesic agents. To overcome these constraints, a model for mechanical visceral pain was developed based on repeatable and reversible distension of duodenum in the rat (Coburn et al. 1989; deLeo et al. 1989).

PROCEDURE

A one-piece balloon catheter is prepared composed of PE 50 tubing with a terminal latex rubber balloon which is 7.5 mm long and distensable to hold more than 1.5 ml fluid. Male Sprague Dawley rats weighing 175–200 g are anesthetized with N_2O and halothane. The abdomen is shaved and an 2.5 cm incision is made transversely just below the left costal margin. On the greater curvature of the stomach an incision is made 10 to 20 mm above the pylorus and a purse string is accomplished with 4–0 silk prior to gastrostomy. Through a 2 mm gastrostomy the catheter is introduced and advanced through the pylorus to the first portion of the duodenum (approximately 15–20 mm from the pylorus). The purse string is tied snugly closing the gastrostomy around the catheter. The catheter is tunneled to the base of the scull, externalized and anchored to the dermis with a silicon sleeve and suture. The animals recover from anesthesia within 5 min. Following a 4–5 days recovery period, the duodenal distension volume is determined by the mean threshold that produces writhing (usually 0.5 to 0.7 ml). For the test, the animals are randomized and administered either saline, the standard (0.1, 0.25, 1, and 10 mg/kg indomethacin i.p.) or the test drug in various doses prior to challenging. The animals are placed in a polypropylene box and challenged by inflating the balloon with saline, using a 1 ml calibrated syringe, pulsed 5 times over 30 s and then distended for 1 min. Behavioral responses are scored:

- 0 = Normal behavior defined as exploration, escape attempts and resting
- 1 = Slightly modified behavior defined as cessation of exploration, focusing, wet-dog shake, excessive facial grooming, teeth chattering and deep breathing
- 2 = Mildly to moderately modified behavior defined as retching-like activity, hunching, abdominal grooming or nipping and immobility of the hind limbs (disappears with removal of the stimulus).
- 3 = Severely modified behavior defined as stretch ing of the hindlimbs, arching and dorsoflection of the hind paws.
- 4 = Intensive visceromotor activity defined as repetitive stretching of the body, extension of the hind limbs, and pelvis, frequent rotating sideward, i. e., writhing.

EVALUATION

The average scores of the groups are plotted on semi log paper and ED_{50} values are determined by best line fit.

CRITICAL ASSESSMENT OF THE METHOD

In the mechanical visceral pain model in the rat, morphine and indomethacin have been found to be active but not other agents involved in prostaglandin inhibition, like acetylsalicylic acid and mefenamic acid. Other mechanisms besides those involving the arachidonic acid cascade have to be investigated.

MODIFICATIONS OF THE METHOD

Ness and Gebhart (1988) used colorectal distension as a noxious visceral stimulus in awake, unanesthetized, unrestrained rats. A 7–8 cm flexible latex balloon was inserted intra-anally under ether anesthesia and kept in position by taping to the base of the tail. Opening a solenoid gate to a constant pressure air reservoir initiated a 20 s, constant pressure stimulus in the descending colon and rectum. Femoral arterial and venous catheters were tunneled subcutaneously and exteriorized at the back of the neck. Teflon-coated stain-less steel wire electrodes were stitched into the external oblique musculature immediately superior to the inguinal ligament for electromyographic recordings. Blood pressure and heart frequency increase were proportional to the degree of colorectal distension. These effects could be dose-dependently antagonized by morphine and clonidine.

Renal pelvis distension with a pressure of 80 cm H_2O causes a decline in mean arterial blood pressure in pentobarbital-anesthetized rats. Brasch and Zetler (1982) used this blood pressure response, which disappears rapidly after cessation of the distension, to study the effects of analgesic drugs known to be effective in renal colic pain in man.

Moss and Sanger (1990) measured falls in diastolic blood pressure and intragastric pressure after distension of the duodenum by rapid application of intraluminal pressure (10–75 cm H_2O) in anesthetized rats. The distension-induced responses were blocked by pretreatment with morphine, an action reversible by injection of naloxone. Bilateral cervical vagotomy reduced the distension-evoked fall in intragastric pressure but had no effect on the corresponding fall in blood pressure.

H.2.0.5 Antagonism Against Local Effects of Bradykinin

PURPOSE AND RATIONALE

Guzman et al. (1962) and Lim et al. (1964) described the responses (vocalization, respiratory and blood pressure changes) to intra-arterial injection of bradykinin and other algesic agents in cats and dogs. Deffenu et al. (1966) and Blane (1968) used the bradykinin-induced effects after intra-arterial injection in rats as an assay for analgesic drugs. Paravascular sensory nerves which accompany blood vessels throughout the body to end in unmyelinated free-branching terminals close to the capillaries and venules most likely carry the chemoreceptors of pain (Lim 1970). Due to rapid enzymatic degradation, bradykinin is ineffective as noxious stimulus after intravenous or oral administration.

PROCEDURE

Male Wistar rats weighing 280–320 g are lightly anesthetized with ether. A polyethylene catheter with an internal diameter of 0.5 mm is inserted centripetally into the right carotid artery. The catheter is passed through the subcutaneous tissues to protrude from the back of the animal. One hour after recovery from anesthesia, the first dose of bradykinin is injected into the catheter producing dextro-rotation of the head, flexing of the forelimb and occasionally squeaking. For each rat the minimum dose of bradykinin is determined necessary to provoke these effects. The test compounds are applied subcutaneously or intraperitoneally 15 min prior to injection of the threshold dose of bradykinin. The bradykinin injections are repeated in 5 min intervals until the bradykinin effect reappears. Each rat receives one drug at one dose level.

EVALUATION

The criterion for protection is the disappearance of the bradykinin effect after at least 2 consecutive doses of bradykinin. Using groups of 10 rats for various dose levels, ED_{50} values are calculated.

CRITICAL ASSESSMENT OF THE METHOD

Not only narcotic analgesics, but also pyrazolones and phenacetin or acetylsalicylic acid are active in this test. In some animals, the bradykinin-induced response can be diminished after repeated injections, classified as the noxious-adaptable group (Satoh et al. 1979).

MODIFICATIONS OF THE METHOD

Haubrich et al. (1990) tested analgesic activity by the intracarotid bradykinin-induced head/forepaw flexion in the rat. Male Charles River rats (280–320 g) fasted overnight were prepared surgically under light ether anesthesia by insertion of a capped polyethylene cannula (PE-60) centripetally into the right carotid artery and then exteriorizing the cannula to a harness on the back, to permit repeated i.a. injections. The rats were allowed to recover at least 2 h from the surgery, and then given single i.a. injections of bradykinin (triacetate salt in 0.2 ml 0.9% NaCl per injection) at 10-min intervals to determine the threshold dose which produced marked dextrorotation of the head and flexion of the right forepaw of each rat. This response was elicited by threshold doses of bradykinin ranging from 0.1 to 0.5 µg/injection. After administration of the test drugs, the response of the threshold dose of bradykinin was determined at 10-min intervals for 1 h and then at 20-min intervals during the second hour. ED_{50} values were determined by probit analysis of the maximum percentage of rats that failed to respond to bradykinin at each dose of test drug any time within the 2-h test period.

Collier and Lee (1963) described nociceptive responses of **guinea pigs** to intradermal injections of bradykinin and kallidin-10.

Vargaftig (1966) measured the effect of nonnarcotic analgesics on the hypotension induced by intra-arterial injection of bradykinin in **rabbits**.

Adachi and Ishii (1979) used the response to injection of bradykinin into the femoral artery of guinea pigs for quantitative assessment of analgesic agents.

Griesbacher and Lembeck (1987) and Lembeck et al. (1991) used the reflex hypotensive response as an indicator of nociception after injection of bradykinin into the ear artery of anesthetized rabbits. Rabbits were anesthetized and the blood pressure was recorded from the carotid artery. The central artery of one ear was cannulated and the ear was separated from the head with the exception of the auricular nerve, which remained connected to the head. The ear was perfused with Tyrode solution to which acetylcholine and bradykinin were added. The reflex fall in blood pressure induced by bradykinin and acetylcholine were monitored. The effect could be inhibited by bradykinin antagonists.

Heapy et al. (1993) tested the effects of the bradykinin antagonist HOE140 on the abdominal constriction response after intraperitoneal injection of bradykinin to **mice**.

Further Methods Used to Study the Role of Bradykinin and Bradykinin Antagonists in Inflammation and Algesia

Teixeira et al. (1993) investigated the mechanisms of inflammatory response induced by extracts of *Schistosoma mansoni* larvae in guinea pig skin. *Biomphalaria glabrata* snails with patent *Schistosoma mansoni* infections were induced to shed cercariae by exposure to light and water with a temperature of 31°C. The cercariae were concentrated, homogenized and extracts prepared. Purified eosinophils or neutrophils obtained from peritoneal exudates were radiolabeled by incubation with ^{111}In chelated to 2-mercaptopyridine-*N*-oxide. Radiolabeled leukocyte infiltration and edema formation were measured simultaneously at injected skin sites. [^{125}I]Human serum albumin was added to the labeled leukocytes and these were injected i.v. into anesthetized guinea pigs. After 15 min the extracts of cercariae were locally injected with/or without the inhibitors. After 2 h, the animals were sacrificed and the injected sites were punched out with a 17-mm punch. Serum exudation and leukocyte infiltration were measured by counting the two isotopes. The bradykinin antagonist HOE 140 reduced substantially the extract-induced inflammation.

Ahluwalia et al. (1994) induced plasma protein extravasation in the rat urinary bladder by i.p. injection of cyclophosphamide mediated by capsaicin-sensitive primary afferent neurons which could be significantly inhibited by the bradykinin B_2 receptor antagonist HOE140 and the tachykinin NK_1 receptor antagonist RP67,580.

Davis and Perkins (1994a, b) described a model of persistent inflammatory mechanical hyperalgesia using intra-articular injections of bradykinin or cytokines into the knee joint of rats.

Lecci et al. (1995) analyzed the local and reflex responses to bradykinin on rat urinary bladder motility *in vivo*.

H.2.0.6 Effect of Analgesics on Spinal Neurons

PURPOSE AND RATIONALE

The mode of action of peripheral analgesics is still a matter of debate. Besides inhibition of the arachidonic acid derived pathway, activities on the spinal and central level have been discussed. Schaible and Schmidt (1983a, b, 1985, 1987, 1988) performed electrophysiological experiments in anesthetized cats and rats after local mechanical stimulation and after induction of acute arthritis of the knee joint. With this method Xe et al. (1990a, b), Neugebauer et al. (1994) found evidence for a spinal antinociceptive action of antipyretic analgesics, such as dipyrone.

PROCEDURE

In cats weighing 2.0–4.0 kg anesthesia is induced by i.m. injection of 15–30 mg/kg ketamine hydrochloride followed by i.v. injection of 60 mg/kg α-chloralose. After immobilization with i.v. pancuronium bromide the cats are artificially ventilated. The skin of the right thigh is incised from rostral of the inguinal fossa to a point below the medial condyle of the tibia. The tendon of the sartorius muscle is cut close to its insertion at the capsule of the knee joint. The muscle is removed to expose the medial aspects of the joint and the medial articular nerve (MAN). The thigh is rigidly fixed to the mounting table by a threaded bolt fitted through the femur so that the lower leg can be flexed and extended in the horizontal plane. The saphenous nerve is cut in the inguinal fossa for recording. Bipolar electrodes are inserted at the MAN near the knee for en passent stimulation of articular afferents. **Extracellular recordings from single MAN units** in the saphenous nerve are performed using platinum wire electrodes. According to their conduction velocities units are classed as group IV afferents (<2.5 m/s, unmyelinated axons) or group III afferents (2.5–20 m/s, thinly myelinated axons).

For **recordings from spinal cord neurons** the spinal segments T12–L7 are exposed by laminectomy. The spinal cord is transected at the lower thoracic region after injection of 0.1 ml of 1% procaine hydrochloride solution to prevent mechanical activation of axons in the long spinal tracts. The animals are fixed to a rigid frame with spinal and pelvic clamps. A pool is formed by skin flaps and filled with warm paraffin oil. The upper lumbar spinal cord is mounted on a pair of platinum wire stimulating electrodes surrounding the whole cord. Ascending tract neurons are identified by electrical stimulation (Neugebauer and Schaible 1990). Single spinal neurons that can be excited by mechanical stimulation of the knee joint tissue are recorded extracellularly using glass-insulated carbon filament electrodes. The neurons are either nociceptive specific neurons responding only to noxious mechanical stimuli or wide dynamic range neurons re-

sponding to innocuous stimuli but showing strongest responses to stimuli of noxious intensity.

Acute arthritis in the right knee joint is induced several hours before recordings are started by injecting 0.3–0.5 ml of 4% kaolin suspension and 15–20 min later 0.3 ml of 2% carrageenan solution. Acute arthritis develops within 1–3 h.

Action potentials are displayed on a storage oscilloscope, amplified, filtered, fed to a window discriminator and processed using an interface and a personal computer for construction of peristimulus time histograms. After a control period of at least 40 min during which a stable discharge rate of the afferent or spinal cord unit is obtained, the test substances are administered i.v. in various doses. Effects of the test substance on ongoing and mechanically evoked activity (by movements, pressure stimuli) are determined.

EVALUATION

Ongoing activity is counted every min. The means and standard deviations in 10 min periods are calculated before and after drug application. The values after drug injection are calculated as percentage of control values. To calculate the net effects of the different mechanical stimuli, the number of impulses in the preceding 30 s is subtracted from the total discharges during the stimulus. The responses to at least 4 stimuli before drug application are averaged and set to 100%. The responses to the different mechanical stimuli after drug administration are expressed as a percentage of the controls. Statistical significance is evaluated using the *t*-test for unpaired samples.

MODIFICATIONS OF THE METHOD

Using the model of kaolin-induced arthritis in the knee of rats, Han and Neugebauer (2005) and Han et al. (2005) developed a computerized analysis of audible and ultrasonic vocalizations of rats as a standardized measure of pain-related behavior.

Several other electrophysiological methods have been applied to elucidate the mode of action of non-opioid analgesic agents. Carlsson et al. (1986, 1988), Jurna and Brune (1990) recorded the activity from single neurons in the dorsomedial part of the ventral nucleus of the thalamus in rats. Activity was elicited by supramaximal stimulation of nociceptive afferents in the sural nerve. In addition, activity was recorded in ascending axons of the spinal cord.

Chapman and Dickenson (1992) studied the spinal and peripheral roles of bradykinin and prostaglandins in nociceptive processing in the rat by recording C-fibre activity in the dorsal spinal horn after injection of formalin into the center of the respective field of the toe of the hind paw.

Dray et al. (1992) described a preparation of the neonatal rat spinal cord with functionally connected tail maintained *in vitro*. The preparation was placed in a chamber and the spinal-cord and tail were separately superfused with a physiological salt solution. Peripheral nociceptive fibers were activated by superfusion of the tail with bradykinin, capsaicin or by a superfusate heated to 48–50°C (noxious heat). The activation of peripheral fibres was assessed by measuring the depolarization produced in a spinal ventral root.

Malmberg and Yaksh (1992) described a direct analgesic action of NSAIDs through spinal cyclooxygenase inhibition by blocking the thermal hyperalgesia in rats induced after intrathecal administration of excitatory amino acids or substance P.

A simple technique for intrathecal injections by lumbar puncture in unanesthetized mice was described by Hylden and Wilcox (1980).

Mestre et al. (1994) described a method for performing direct intrathecal injections in rats without introducing a spinal catheter.

Bahar et al. (1984) performed chronic implantations of nylon catheters into the subarachnoid space of Wistar rats and marmosets and tested the effects of local anesthetics.

McQueen et al. (1991) investigated the effects of paracetamol and lysine acetylsalicylate on high-threshold mechano-nociceptors by recording neural activity from the inflamed ankle joint in anesthetized rats with mild adjuvant-induced mono-arthritis.

Yamamoto and Yaksh (1992) studied the effects of excitatory amino acid antagonists administered through chronically implanted lumbar intrathecal catheters on the thermal hyperesthetic state induced by unilateral partial ligation of the sciatic nerve in rats.

Hashimoto and Fukuda (1990) described a spinal cord injury model produced by spinal cord compression in the rat.

Aanonsen and Wilcox (1987) tested effects of spinally administered opioids, phencyclidine and sigma agonists on the action of intrathecally administered NMDA in the tail-flick, hot-plate and biting and scratching nociceptive tests in **mice**.

Brambilla et al. (1996) demonstrated that intrathecal administration of AMPA produced a dose-dependent behavioral syndrome in mice characterized by caudally directed biting, which could be antagonized by peripheral administration of AMPA-receptor and NMDA-receptor antagonists.

Aanonsen et al. (1990) tested the effect of iontophoretically applied excitatory amino acid agonists, such as NMDA, AMPA, quisqualate and kainate, on the firing rate of rat spinal neurons after peripheral noxious stimulation.

Cumberbatch et al. (1994) studied the roles of receptors for AMPA in spinal nociceptive and non-nociceptive transmission on dorsal horn wide dynamic range neurones in anesthetized spinalized rats. The effects of systemically administered competitive and non-competitive AMPA antagonists were examined on responses to peripheral noxious heat and non-noxious tap stimuli as well as to iontophoretic AMPA and NMDA.

With this technique, Chizh et al. (1994) studied the effects of intravenous administration of AMPA antagonists to iontophoretically applied excitatory amino acids.

Watkins et al. (1994) induced hyperalgesia in rats by intraperitoneally administered lipopolysaccharides as measured by radiation heat tail flick in rats. Intrathecal catheters were implanted into the subdural space surrounding the spinal cord to test the involvement of excitatory amino acids, substance P, CCK and opioids assessing the effects of antagonists.

Mjellem et al. (1993) produced a behavioural syndrome of caudally directed biting in mice by intrathecal injection of either NMDA or AMPA.

H.2.0.7
Antagonism to Nerve Growth Factor

H.2.0.7.1
General Considerations on Nerve Growth Factor

Nerve growth factor (NGF) is a member of the neurotrophin family of structurally related secreted proteins that includes brain-derived neurotrophic factor (BDNF), neurotrophin 3 (NT-3) and NT-4. Mature neurotrophins are homodimers that are derived by proteolytic cleavage from precursor proteins encoded by separate genes. They bind to two types of receptor: a common receptor, $p75^{NTR}$, which binds all neurotrophins with a similar affinity; and members of the trk family of receptor tyrosine kinases, trkA, trkB and trkC, which bind different neurotrophins.

NGF and BDNF have a crucial role in the generation of pain and hyperalgesia in several acute and chronic pain states (Woolf et al. 1994; McMahon 1996; Mannion et al. 1999; Thompson et al. 1999; Pezet et al. 2002; Allen and Dawbarn 2006). The expression of NGF is high in injured and inflamed tissues, and activation of the receptor tyrosine kinase trkA in nociceptive neurons triggers and potentiates pain signaling by multiple mechanisms (McMahon et al. 1995; Huang and Reichardt 2003; Hefti et al. 2006) (see also F.2.0.10).

An effective pain therapeutic needs to prevent the activation of trkA by NGF. This may be achieved by agents that remove free NGF, by molecules that prevent binding to trkA, and by molecules that prevent activation of trkA.

H.2.0.7.2
In Vitro Assays of Nerve Growth Factor

PURPOSE AND RATIONALE

The neurotrophin nerve growth factor (NGF) binds to two receptor types: the tyrosine kinase receptor TrkA and the common neurotrophin receptor $p75^{NTR}$. Although many of the biological effects of NGF (such as neuronal growth and survival) are associated with TrkA activation, $p75^{NTR}$ also contributes to these activities by enhancing the action of TrkA when receptors are coexpressed (Verdi et al. 1994; Kaplan and Miller 1997). Colquhoun et al. (2004) studied the NGF antagonist PD90780 (Spiegel et al. 1995), which interacts with NGF, preventing its binding to $p75^{NTR}$. In this study, the actions of this compound were further explored, and it was found that PD90780 is not able to inhibit the binding of either brain-derived neurotrophic factor or neurotrophin-3 to $p75^{NTR}$, consistent with the direct interactions of the antagonist with NGF. In addition, it was demonstrated that the ability of PD90780 to inhibit NGF-$p75^{NTR}$ interactions is lower when receptors are coexpressed, compared with when $p75^{NTR}$ is the only neurotrophin receptor expressed.

PROCEDURE

Radiolabeled Neurotrophin and Receptor Preparation

The iodination of NGF (mouse 2.5s; Cedarlane Labs, Toronto, ON) and rhBDNF (Alomone Labs, Jerusalem, Israel) was performed as described by Sutter et al. (1979) with modification (Ross et al. 1997). The ability of PD90780 to block neurotrophin binding to the $p75^{NTR}$ receptor was evaluated under various receptor conditions. This was accomplished with

the use of PC12 cells (TrkA and $p75^{NTR}$), $PC12^{nnr5}$ cells ($p75^{NTR}$ only), and truncated $p75^{NTR}$. The two cell types were cultured in RPMI 1640 medium with 10% fetal calf serum. Recovery of the cells was permitted with the replacement of the medium with calcium/magnesium-free balanced salt solution followed by a 15-min incubation at 37°C. Cells were centrifuged, and pellets were suspended in HKR buffer (10 mM HEPES, pH 7.35 containing 125 mM NaCl, 4.8 mM KCl, 1.3 mM $CaCl_2$, 1.2 mM $MgSO_4$, 1.2 mM KH_2PO_4, 1 g/l glucose, and 1 g/l bovine serum albumin). In the case of truncated $p75^{NTR}$, the culture medium used to grow PC12 cells was removed and centrifuged to ensure it was free of cells. This medium contained $p75^{NTR}$ extracellular domains previously sloughed by the cells (molecular weight approximately 50 kDa) (DiStefano and Johnson 1988).

Chemical Cross-Linking of ^{125}I-NGF to TrkA and/or $p75^{NTR}$ in the Presence of Antagonists and Immunoprecipitation

^{125}I-NGF (0.1 nM) alone or in combination with NGF (100 nM), BDNF (10 nM), or PD90780 (100 μM) was incubated with PC12 cells at a concentration of 10^6 cells/ml in HKR buffer in a volume of 1 ml for 2 h at 4°C with rocking. After binding, 20 μl of the cross-linker bis-(sulfosuccinimidyl)suberate (BS^3) was added (final concentration of 0.4 mM) to each sample and incubated at room temperature for 30 min. The cells were washed three times with TBS, after which reducing SDS sample buffer was added to the pelleted cells to dissolve the proteins, or in the case of immunoprecipitations prepared as described below. Cell samples undergoing immunoprecipitations for TrkA or $p75^{NTR}$ were solubilized in lysis buffer (TBS containing 10% glycerol, 1% Triton X-100, 1 mM phenylmethylsulfonyl fluoride, 10 μg/ml aprotinin, and 1 μg/ml leupeptin) and incubated for 40 min at 4°C. After centrifugation, the lysates were removed to a new tube, and either rabbit polyclonal anti-Trk cytoplasmic domain antibody or rabbit polyclonal anti-$p75^{NTR}$ antibody (9992) (antisera against glutathione *S*-transferase-fusion protein containing the cytoplasmic domain of $p75^{NTR}$) was added to the soluble proteins to isolate the respective receptors. The samples were left to incubate at 4°C overnight. Antibody complexes were removed through application and incubation with 70 μl of a 50% slurry of immobilized Protein G (Pierce Chemical, Rockford, Ill., USA) for 2 h at 4°C. The solid phase was washed with lysis buffer three times, with distilled water once, and then the proteins were dissolved in SDS sample buffer. Proteins from cross-linking and immunoprecipitation experiments were separated via 6% SDS-polyacrylamide gel electrophoresis (PAGE).

Chemical Cross-Linking of ^{125}I-NGF to $p75^{NTR}$ and Concentration Effect Assays

^{125}I-NGF was incubated at 4°C for 2 h with or without PD90780. PC12 or $PC12^{nnr5}$ cells were added at 10^6 cells/ml, and samples were incubated at 4°C for 2 h with rocking. Bound ^{125}I-NGF and $p75^{NTR}$ proteins were cross-linked with final concentrations of 5 mM 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) and 2 mM sulfo-*N*-hydroxy-sulfosuccinimide (SNHS) (20 μl of each) and incubated with rocking at room temperature for 30 min. Samples were washed with TBS [10 mM Tris(hydroxymethyl)-aminomethane, pH 8.0, and 150 mM NaCl] three times before the addition of reducing SDS sample buffer to dissolve the proteins. The proteins were then separated on a 6% SDS-PAGE gel. In the experiments involving truncated $p75^{NTR}$, ^{125}I-NGF or ^{125}I-BDNF was exposed to the same concentrations of PD90780 and incubated with medium containing truncated $p75^{NTR}$ before cross-linking with EDC/SNHS. The reaction was quenched by adding 15 μl of 1 M glycine followed by 10 min of mixing. The samples were then immunoprecipitated using 192 IgG, which recognizes the extracellular domain of $p75^{NTR}$ (Calbiochem, San Diego, Calif., USA).

Neurotrophin Receptor Binding

Neurotrophins NGF, BDNF, and NT-3 were iodinated, and PC12 and $PC12^{nnr5}$ cells were cultivated and recovered as previously described. Tubes were set up containing single data points that held iodinated neurotrophin (0.5 nM), PD90780 (10 μM), a final concentration of 10^6 cells/ml and NGF (at 50 nM for nonspecific binding) as required, and were then incubated at 4°C for 2 h. Aliquots (100 μl) were layered on top of 200 μl of 10% glycerol in HKR buffer in 0.4-ml tubes. Samples were then centrifuged at 5000 rpm for 2 min, after which the tip containing the cell pellet was cut off and radioactivity present was determined.

TrkA Phosphorylation Assay

Modification of the methods described permitted determination of TrkA phosphorylation (Ross et al. 1998). NGF (40 pM) was incubated with varying concentrations of PD90780 (3, 30, or 300 μM) for 2 h in HKR buffer. PC12 cells used at 10^6 cells/ml were incubated with NGF and PD90780 solutions for 15 min at 37°C. Samples were washed once with cold PBS and once with cold TBS and then lysed with solutions

containing 500 μM orthovanadate and immunoprecipitated with anti-Trk antibody as previously described. An SDS-PAGE run on 6% gel followed by Western blot analysis performed with antiphosphotyrosine antibody (4G10; UBI, Lake Placid, N.Y., USA) and visualized with ECL (Amersham) permitted the resolution of isolated phosphoproteins. The resulting bands were quantified via densitometry analysis.

NGF Protomer Cross-Linking

^{125}I-NGF (0.1 nM) was incubated for 2 h at 4°C with $ZnCl_2$ (100 μM), PD90780 (30 μM), or $ZnCl_2$ and PD90780 (100 and 30 μ M, respectively), along with HKR buffer, for a total volume of 0.1 ml. After incubation, BS^3 was added (final concentration of 0.4 mM) in 5 μl volume and set at room temperature for 30 min. Proteins were dissolved with the addition of 50 μl of SDS sample buffer and heating to 95°C for 10 min. Separation of ^{125}I-NGF dimers and ^{125}I-NGF monomers was completed using a 15% acrylamide gel SDS-PAGE.

EVALUATION

Following SDS-PAGE, gels were fixed and dried, and the radio-iodinated ligands cross-linked to receptors were detected via autoradiography. Receptor ligand bands within SDS-PAGE gels were excised, and radioactivity within each band was detected with a Beckman gamma counter. The concentration–effect curves, SEM, IC_{50} values, and 95% confidence intervals (CIs) described in the concentration–effect studies were determined by non-linear regression analyses and carried out by the program GraphPad Prism, version 3.00 (GraphPad Software, San Diego, Calif., USA).

MODIFICATIONS OF THE METHOD

Debeir et al. (1999) described a nerve growth factor mimetic TrkA antagonist that causes withdrawal of cortical cholinergic boutons in the adult rat. A small peptide, C(92–96), which blocks NGF–TrkA interactions, was delivered stereotactically into the rat cortex over a 2-week period, and its effect and potency were compared with those of an anti-NGF monoclonal antibody (mAb NGF30). Two presynaptic antigenic sites were studied by immunoreactivity, and the number of presynaptic sites was counted by using an image analysis system. Synaptophysin was used as a marker for overall cortical synapses, and the vesicular acetylcholine transporter was used as a marker for cortical cholinergic presynaptic sites.

Owolabi et al. (1999) characterized the antiallodynic actions of ALE-0540, a novel nerve growth factor receptor antagonist that inhibits the binding of NGF to tyrosine kinase (Trk) A or both p75 and TrkA (IC_{50} 5.88± 1.87 μM, 3.72±1.3 μM, respectively), as well as signal transduction and the biological responses mediated by TrkA receptors.

H.2.0.7.3 In Vivo Assays of Nerve Growth Factor Antagonism

PURPOSE AND RATIONALE

Many studies indicate the role of NGF in pain perception.

Herzberg et al. (1997) reported NGF involvement in pain induced by chronic constriction injury of the rat sciatic nerve.

Ma and Woolf (1997) reported that the progressive tactile hyperalgesia induced by peripheral inflammation is nerve growth factor dependent. An i.p. injection

of anti-NGF antiserum (5 µl/g) 1 h before induction of inflammation by intraplantar complete Freund's adjuvant (CFA) injection and 24 h after reduced the basal inflammatory hypersensitivity and significantly attenuated the progressive increase of spontaneous activity, touch-, pinch- and Aβ-afferent-evoked responses, as well as the progressive reduction of the mechanical threshold of biceps femoris/semitendinosus alpha motoneurons normally evoked by repeated (every 5 min) tactile stimulation of the inflamed hindpaw, in decerebrate-spinal rats.

Ro et al. (1999) described the effect of NGF and anti-NGF on neuropathic pain in rats following chronic constriction injury of the sciatic nerve.

Theodosiou et al. (1999) studied the role of nerve growth factor in hyperalgesia due to nerve damage.

Gwak et al. (2003) found attenuation of mechanical hyperalgesia following spinal cord injury by administration of antibodies to nerve growth factor in the rat.

PROCEDURE

Adult Sprague Dawley rats (200–250 g) were spinally hemisected at T13 (Christensen et al. 1996). Under enflurane anesthesia (induction 3% and maintenance 2%) the T11–12 laminae were determined by counting the dorsal spinous processes from the sacrum. The surgical field was then shaved, a longitudinal incision made exposing several segments, and a laminectomy performed at two vertebral segments, T11–T12. The spinal cord was hemisected just cranial to the L1 dorsal root entry zone with a micro-dissecting knife without damaging the major dorsal vessel or vascular branches. An insulin syringe with a 28-gauge needle was placed dorsal-ventrally at the midline of the cord, and pulled laterally to ensure the completeness of the hemisection. The incised skin was sutured, and postoperative care was done. After the hemisection, animals were either treated once a day for 10 days with anti-NGF (anti-nerve growth factor-2.5S, Sigma, i.p., 2 µg, 0.2 ml), or with saline (0.2 ml), or were untreated.

In the behavioral experiments, rats were housed in clear plastic boxes ($8 \times 8 \times 24$ cm) above a metal mesh (0.5×0.5 cm) and acclimatized for 30 min to avoid the stress associated with environmental change. Mechanical paw withdrawal threshold to the application of a von Frey filament was measured by using the up-down testing paradigm (Ro et al. 1999). An ascending series of von Frey filaments of incremental force (0.35, 0.53, 0.78, 2.5, 3.7, 5.2, 6.0, and 12.5 g) was applied for 3 s to the middle of the plantar surface of the hind paw, starting with the 2.5 g stimulus (Chaplan et al. 1994).

For electrophysiology experiments, rats were anesthetized with sodium pentobarbital (40–50 mg/kg), with supplementary pancuronium bromide (2–4 mg/kg per h), and artificially ventilated. Extracellular recordings of neuronal activity were made from the dorsal horn neurons in the lumbar spinal cord (L4–L5), using a recording glass microelectrode with a carbon filament (3–5 MΩ) while mechanical stimuli were applied onto the receptive fields. The single unit responses of the dorsal horn neurons, characterized as wide dynamic range (WDR) neurons by their graded responses to increased intensities of mechanical stimuli, were amplified, filtered, and displayed on an oscilloscope. The output signals were also fed into a data acquisition system (CED 1401 plus) via a window discriminator for the construction of real-time recordings of peristimulus time histograms, which were displayed as the number of spikes per second.

The mechanical stimuli were applied for 10 s and included: (1) brushing the skin with a camel hair brush in a stereotypic manner (brush); (2) sustained application of a large clamp that produced a sense of firm pressure when placed on human skin (pressure); and (3) sustained application of a small clamp that produced a distinctly painful sensation (pinch).

EVALUATION

Statistical analysis was performed using Mann–Whitney's unmatched pairs rank-sum test to evaluate the differences between the scores in two groups. All data are displayed as means ±standard error.

MODIFICATIONS OF THE METHOD

Spinal cord injury often leads to central pain syndrome including hyperalgesia to mechanical stimulation. Several authors studied the influence of nerve growth factor in **models of neuropathic pain** (Ramer and Bisby 1999; Li et al. 2002, 2003; Cahill et al. 2003; Ruiz et al. 2004).

Nerve Ligation Injury

Nerve ligation injury was performed according to the method described previously (Kim and Chung 1992). This technique produces signs of tactile allodynia and thermal hyperalgesia. Rats were anesthetized with halothane and the L5 and L6 spinal nerves were exposed, carefully isolated, and tightly ligated with 4–0 silk suture distal to the dorsal root ganglion (DRG). After ensuring homeostatic stability, the wounds were sutured, and the animals were allowed to recover in individual cages. Sham-operated

rats were prepared in an identical fashion except that the L5 and L6 spinal nerves were not ligated.

Intrathecal Catheter Placement

Two routes of administration, a systemic i.p. and a spinal intrathecal (i.th.) route, were used explore the activity of compounds. For the spinal route, test compounds were injected through indwelling i.th. catheters in the manner described by Yaksh and Rudy (1976). While under anesthesia, polyethylene tubing 10 tubing (8 cm) was inserted through an incision made in the atlanto-occipital membrane to the level of the lumbar enlargement of the rat and secured. Drug injections were made in a volume of 5 µl followed by a 9-µl saline flush.

Thermal Sensitization

Rats were lightly anesthetized with ether. The left hindpaw was placed in a water bath maintained at 50°C for 1 min. Inflammation suggested by rubor of the paw developed immediately. The rats were allowed to recover from anesthesia and tactile testing was begun 2 h after thermal sensitization. This procedure has produced signs of thermal hyperalgesia and tactile allodynia that persisted for over 12 h.

Evaluation of Tactile Allodynia

Mechanical allodynia was determined in the manner described previously (Chaplan et al. 1994). The paw withdrawal threshold was determined in response to probing with calibrated von Frey filaments. The rats were kept in suspended cages with wire mesh floors and the von Frey filaments were applied perpendicularly to the planar surface of the paw of the rat until it bent slightly, and was held for 3–6 s, or until the paw was withdrawn. A positive response was indicated by a sharp withdrawal of the paw. The 50% paw withdrawal threshold was determined by the nonparametric method (Dixon 1980).

Shelton et al. (2005) found that nerve growth factor mediates **hyperalgesia and cachexia in autoimmune arthritis**. Function-blocking antibodies to NGF completely reverse established pain in rats with fully developed arthritis despite continuing joint destruction and inflammation. Likewise, these antibodies reverse weight loss while not having any effect on levels of the pro-cachectic agent tumor necrosis factor (TNF).

Banik et al. (2005) reported that increased nerve growth factor after rat plantar incision contributes to **guarding behavior and heat hyperalgesia**. The therapeutic effect of a monoclonal antibody against endogenous NGF was evaluated by intraperitoneal administration of a single preoperative dose of anti-NGF.

Adult male, 225–275 g, Sprague-Dawley rats were used in a plantar incision animal model. The animals were anesthetized with 1.5%–2% halothane and the surgical field was prepared in a sterile manner. A 1-cm longitudinal incision was made in the plantar aspect of the hind paw beginning 0.5 cm from the end of heel; skin, fascia and muscle were incised and the skin was closed with 5–0 nylon suture. Topical antibiotics were administered. On the second postoperative day, sutures were removed under brief anesthesia.

For measuring guarding behaviors, unrestrained rats were placed on a small plastic mesh floor (grid 8 × 8 mm). Using an angled magnifying mirror, the incised and non-incised paws were viewed. Both paws of each animal were closely observed over a 1-min period repeated every 5 min for 1 h. Depending on the position in which each paw was found during the majority of the 1-min scoring period, a 0, 1 or 2 was given. A score of 0 was given for full weight bearing with the area of the wound blanched or distorted by the mesh; 1 for the wound area just touching the mesh without blanching or distortion; and 2 for the wound area completely off the mesh. The sum of the 12 scores (0–24) obtained during 1-h session for each paw was obtained.

For measuring heat sensitivity rats were placed individually on a glass floor covered with a clear plastic cage and allowed to acclimate. Withdrawal latencies to radiant heat were assessed by applying a focused radiant heat source underneath a glass floor on the middle of the incision. The latency time to evoke a withdrawal was determined with a cut-off value of 30 s. The intensity of the heat was adjusted to produce a withdrawal latency in normal rats of 25–30 s. Each rat was tested at least three times, at an interval of 10 min. The average of at least three trials was used to obtain paw withdrawal latency.

For measuring mechanosensitivity, rats were placed individually on a plastic mesh floor covered with a clear plastic cage and allowed to acclimate. The withdrawal response to punctate mechanical stimulation was determined using calibrated von Frey hairs applied underneath the cage to an area adjacent to the incision. Each filament was applied once starting with 10 mN and continuing until a withdrawal response occurred or 250 mN was reached. If a rat did not respond to the 250-mN filaments (522 mN), the next filament was recorded. This was repeated a total of three times with at least a 5- to 10-min test-free period between withdrawal responses. The lowest force from the three

tests producing a response was considered the withdrawal threshold.

Zahn et al. (2004) described the effect of blockade of nerve growth factor and tumor necrosis factor on pain behaviors after plantar incision.

Obata et al. (2002) described the expression of neurotrophic factors in the dorsal root ganglion in a **rat model of lumbar disc herniation**. The left L4/5 nerve roots were exposed after hemilaminectomies and autologous intervertebral discs, which were obtained from coccygeal intervertebral discs, were implanted on each of the exposed nerve roots without mechanical compression.

Lamb et al. (2003) studied nerve growth factor (NGF) and **gastric hyperalgesia** in the rat. Male Sprague Dawley rats (300–400 g) were anesthetized and the stomach exposed and placed in a circular clamp. Acetic acid (60%) or saline was injected into this area and aspirated 45 s later, resulting in kissing ulcers. A balloon was surgically placed into the stomach and electromyographic responses to gastric distension recorded from the acromiotrapezius muscle. Animals received a daily injection of neutralizing NGF antibody or control serum for 5 days; NGF in the stomach was measured with an ELISA. The severity of gastric injury was assessed microscopically and by determination of myeloperoxidase activity.

Winston et al. (2003) investigated molecular and behavioral changes in nociception in a novel **rat model of chronic pancreatitis** induced by pancreatic infusion of trinitrobenzene sulfonic acid as a model of painful pancreatitis. Nociception was assessed by measuring mechanical sensitivity of the abdomen and by recording the number of nocifensive behaviors in response to electrical stimulation of the pancreas. Expression of neuropeptides calcitonin gene-related peptide (CGRP) and substance P (SP) in the thoracic dorsal root ganglia receiving input from the pancreas and nerve growth factor in the pancreas were measured.

Guerios et al. (2006) reported that nerve growth factor (NGF) mediates peripheral mechanical hypersensitivity that accompanies **experimental cystitis in mice**. Cystitis was induced by intraperitoneal injection of cyclophosphamide (CYP) in female mice. Sensitivity of hind paws to mechanical stimuli was determined prior to and 4, 9, and 24 h after CYP, and the sensitivity of the tail to thermal stimuli was determined prior to, and 4 and 24 h after CYP treatment. To investigate the role of NGF in these processes, other groups of mice received NGF antiserum or normal serum intravenously 30 min after CYP administration. CYP induced bladder inflammation that was not ablated by treatment with NGF antiserum. Sensitivity to mechanical stimuli was increased 4 and 9 h after CYP administration. This was reversed by NGF antiserum but not by normal serum.

Cyclophosphamide-induced cystitis was also used as a model for visceral pain by Lanteri-Minet et al. (1995), Boucher et al. (2000), and Bon et al. (2003).

Jaggar et al. (1999) studied hyperalgesia to thermal stimulation of the hind limb of rats after inflammation of the urinary bladder by instillation of 0.5 ml of 50% turpentine in olive oil.

Dmitrieva and McMahon (1996) and Dmitrieva et al. (1997) reported sensitization of visceral afferents by NGF in the adult rat.

Delafoy et al. (2003) studied the role of NGF in **trinitrobenzene sulfonic acid-induced colonic hypersensitivity**. The function of NGF as a mediator of persistent pain states was tested in a model of colonic hypersensitivity measured by isobaric distension in conscious rats. The effects of exogenous NGF on colonic pain threshold, the involvement of NGF in trinitrobenzene sulfonic acid-induced colonic hypersensitivity, and the involvement of sensory nerves in the effects of NGF and trinitrobenzene sulfonic acid using rats treated neonatally with capsaicin were studied.

Sevcik et al. (2005) found that anti-NGF therapy profoundly reduced **bone cancer pain** and the accompanying increase of markers of peripheral and central sensitization. Osteolytic murine sarcoma cells were injected into the intramedullary space of the mouse femur. Administrations of a NGF-sequestering antibody produced a profound reduction in cancer pain-related behavior that was greater than that achieved with administration of morphine.

H.3 Anti-Inflammatory Activity

H.3.0.1 General Considerations

Inflammation was characterized two thousand years ago by Celsus by the four Latin words: Rubor, calor, tumor and dolor. Inflammation has different phases: the first phase is caused by an increase of vascular permeability resulting in exudation of fluid from the blood into the interstitial space, the second one by infiltration of leukocytes from the blood into the tissues and the third one by granuloma formation. Accordingly, anti-inflammatory tests have to be divided into those measuring acute inflammation, subacute inflammation and chronic repair processes. In some cases, the screening is directed to test compounds for local application. Predominantly, however, these studies are aimed to find new drugs against polyarthritis and other rheumatic diseases. Since the etiology of polyarthritis is considered to be largely immunologically, special tests have been developed to investigate various immunological and allergic factors (see Chapter I).

H.3.1 In Vitro Methods for Anti-Inflammatory Activity

H.3.1.1 General Considerations

An array of physiological substances, sometimes called autacoids, are involved in the process of inflammation and repair. These include histamine, serotonin,

bradykinin, substance P, and the group of eicosanoids (prostaglandins, thromboxanes and leucotrienes), the platelet-activating factor (PAF) as well as cytokines and lymphokines. Their discovery makes the use of *in vitro* studies possible. The influence of non-steroidal anti-inflammatory agents on the eicosanoid pathway gave rise to numerous studies.

H.3.1.2 ^{3}H-Bradykinin Receptor Binding

PURPOSE AND RATIONALE

Tissue injury or trauma initiates a cascade of reactions which results in the proteolytic generation of bradykinin and kallidin from high-molecular-weight precursors, kininogens, found in blood and tissue. The rapid enzymatic cleavage of kininogens is accomplished by the kallikreins, a group of proteolytic enzymes which are present in most tissues and body fluids. Bradykinin produces pain by stimulating A and C fibers in the peripheral nerves, participates in the inflammatory reaction and lowers blood pressure by vasodilatation. Since its breakdown occurs via the same enzyme responsible for converting angiotensin I into angiotensin II some of the effects of converting enzyme inhibitors may be due to presence of bradykinin. The ^{3}H-bradykinin receptor binding is used to detect compounds that inhibit binding of ^{3}H-bradykinin in membrane preparations obtained from guinea-pig ileum. Two types of bradykinin receptors (B_1 and B_2 receptors) are known (Feres et al. 1992; Bascands et al. 1993; Tropea et al. 1994; Marceau et al. 1998; Calixto et al. 2004; Leeb-Lundberg et al. 2005). The existence of a pulmonary BK_3 receptor has been proposed by Farmer et al. (1989) and Meini et al. (2004). Evidence was obtained for the existence of three subtypes of B_2 receptors, B_{2a}, B_{2b}, and B_{2c} (Seguin et al. 1992; Seguin and Widdowson 1993).

PROCEDURE

Ileum from guinea pigs is cleaned from its content and cut into pieces of 2 cm length. They are homogenized for 30 s in ice-cold TES buffer, pH 6.8, containing 1 mM 1,10-phenanthroline, in a Potter homogenizer. The homogenates are filtered through 3 layers of gauze and centrifuged twice at 50,000 *g* for 10 min with an intermediate rehomogenization in buffer.

For routine studies the final pellets are resuspended in 40 vol of incubation buffer (25 mM TES buffer, pH 6.8, containing 1 mM 1,10-phenanthroline, 0.1% bovine serum albumin, 140 µg/ml bacitracin, 1 mM dithiothreitol, 0.1 µM captopril). In the competition experiment, 50 µl ^{3}H-bradykinin (one constant concentration of $0.5–2 \times 10^{-9}$ M), 50 µl test compound (6 concentrations, $10^{-5}–10^{-10}$ M) and 150 µl membrane suspension from guinea pig ileum (approx. 6.6 mg wet weight/ml) per sample are incubated in a shaker bath at 25°C for 90 min.

Saturation experiments are performed with 12 concentrations of ^{3}H-bradykinin ($14.2–0.007 \times 10^{-9}$ M). Total binding is determined in the presence of incubation buffer, non-specific binding is determined in the presence of non-labeled bradykinin (10^{-6} M).

The reaction is stopped by rapid vacuum filtration through glass fibre filters. Thereby the membrane-bound radioactivity is separated from the free one. The retained membrane-bound radioactivity on the filter is measured after addition of 3 ml liquid scintillation cocktail per sample in a liquid scintillation counter.

EVALUATION

The following parameters are calculated:

- total binding of ^{3}H-bradykinin
- non-specific binding in the presence of 10 µM bradykinin
- specific binding = total binding–non-specific binding
- % inhibition: 100–specific binding as percentage of control value

Compounds are first tested at a single high concentration (10,000 nM) in triplicate. For those showing more than 50% inhibition a displacement curve is constructed using 7 different concentrations of test compound. Binding potency of compounds is expressed either as a relative binding affinity (*RBA*) with respect to the standard compound (bradykinin) which is tested in parallel or as an IC_{50}.

$$RBA = \frac{IC_{50}\ \text{standard compound}}{IC_{50}\ \text{compound}} \times 100\%$$

The dissociation constant (K_i) and the IC_{50} value of the test drug are determined from the competition experiment of ^{3}H-bradykinin versus non-labeled drug by a computer-supported analysis of the binding data (McPherson 1985).

Tests for Bradykinin Receptor Types and Subtypes

Prado et al. (2002) described mechanisms regulating the expression, self-maintenance, and signaling function of the bradykinin B_2 and B_1 receptors.

Cloning and pharmacological characterization of a human bradykinin (BK-2) receptor was reported by Hess et al. (1992).

Menke et al. (1994) reported the expression cloning of a human bradykinin B_1 receptor.

Bradykinin B_1 receptors have been studied in the isolated rabbit aorta (Bouthillier et al. 1987), in the isolated rabbit carotid artery (Pruneau and Bélichard 1993) and in the rabbit urinary bladder (Butt et al. 1955).

A potent bradykinin B_1 receptor antagonist has been described by Wirth et al. (1991).

Heterogeneity of B_1 receptors has been suggested by Wirth et al. (1992).

Heitsch (2002) reviewed non-peptide antagonists and agonists of the bradykinin B_2 receptor.

Bradykinin receptor ligands were described by Marceau and Regoli (2004) and Fortin and Marceau (2006).

Drummond and Cocks (1995) used rings of bovine left anterior descending coronary artery to study endothelium-dependent relaxations mediated by inducible B_1 and constitutive B_2 kinin receptors.

The production of cyclic GMP via activation of B_1 and B_2 kinin receptors in cultured bovine aortic endothelial cells was described by Wiemer and Wirth (1992).

Pharmacological characterization of bradykinin receptors in canine cultured tracheal smooth muscle cells has been reported by Yang et al. (1995).

Bradykinin B_2 receptors and their antagonists have been studied in human fibroblasts by Alla et al. (1993), with the high affinity radioligand [^{125}I]PIP HOE 140 by Brenner et al. (1993), in guinea pig gall bladder by Falcone et al. (1993), in the smooth muscle of guinea-pig taenia caeci by Field et al. (1994), in guinea pig ileum membranes by Graneß and Liebmann (1994), Liebmann et al. (1994a), in isolated blood vessels from different species by Félétou et al. (1994), in endothelial cells by Wirth et al. (1994).

Hallé et al. (2000) described *in vitro* and *in vivo* effects of kinin B_1 and B_2 receptor agonists and antagonists in inbred control and cardiomyopathic hamsters.

The role of B_1 and B_2 receptors and of nitric oxide in bradykinin-induced relaxation and contraction of isolated rat duodenum was studied by Rhaleb and Carretero (1994).

Campos et al. (1996) investigated the effect of pretreatment with bacterial endotoxin on the bradykinin B_1 and B_2 receptor-induced edema in the rat paw and the interaction of B_1-mediated responses with other inflammatory mediators.

Characterization of kinin receptors by bioassays was described by Gobeil and Regoli (1994). Molecular cloning, functional expression and pharmacological characterization of a human bradykinin B_2 receptor gene was performed by Eggerickx et al. (1992).

Simpson et al. (2000) characterized bradykinin analogues on recombinant human bradykinin B_1 and B_2 receptors using a high throughput functional assay which measures intracellular Ca^{2+} responses.

Bradykinin B_2 receptor subtypes were discussed by Liebmann et al. (1994b) and Regoli et al. (1994).

Evidence for a pulmonary B_3 bradykinin receptor has been given by Farmer et al., (1989) and Meini et al. (2004).

Bradykinin B_3 receptors have been described by Field et al. (1992) in the smooth muscle of the guinea-pig *taenia caeci* and trachea.

H.3.1.3 Substance P and the Tachykinin Family

H.3.1.3.1 General Considerations

Substance P belongs to the tachykinin family of peptides that share a common carboxy-terminal sequence (Phe-X-Gly-Leu-Met-NH_2). It was first described by von Euler and Gaddum (1931) as a brain and gut extract that stimulates smooth muscle contraction. Bioassay extracts from spinal dorsal roots implicated substance P as a pain neurotransmitter (Lembeck 1953; Lembeck and Holzer 1979). After determination of the amino acid sequence (Chang et al. 1971) the distribution of substance P in the CNS could be studied (Hökfelt et al. 1975). Neurokinins belong like substance P to a group of neuropeptides named tachykinins. Following the discovery of neurokinin A and neurokinin B, three distinct G protein-coupled receptors, NK_1, NK_2 and NK_3, were described (Maggi et al. 1993; Mussap et al. 1993; Patacchini and Maggi 1995). Neurokinin A and substance P are preferred agonists of the tachykinin NK_1 and NK_2 receptors, whereas neurokinin B preferentially interacts with the tachykinin NK_3 receptor. The receptor sensitivity of these peptides is relatively poor, and it is possible that their actions could be mediated by interactions with their less preferred receptors.

Nomenclature of tachykinins and tachykinin receptors has been discussed repeatedly (Henry 1987; Maggi 2000).

Tachykinin NK_1 antagonists are potent antiemetics, however other possible therapeutic uses, including rheumatoid arthritis, asthma, migraine, pain and psychiatric disorders, were suggested (Longmore et al. 1995). The P-preferring NK_1 receptor has attracted most interest as a CNS target because it is the predominant tachykinin receptor expressed in the human brain, while NK_2 and NK_3 receptor expression is in extremely low abundance or absent. Several NK_1 receptor agonists antagonists were synthesized and evaluated (Snider et al. 1991; Emonds-Alt et al. 1993; Cascieri et al. 1992; Sakurada et al. 1993; Bristow and Young 1994; Jung et al. 1994; Rupniak and Williams 1994; Smith et al. 1994; Vassout et al. 1994; Patacchini and Maggi 1995; Bonnet et al. 1996; Chapman et al. 1996; Herbert and Bernat 1996; Palframan et al. 1996; Ren et al. 1996). Moreover, agonists and antagonists at the NK_2 receptor (Hagan et al. 1991, 1993; Beresford et al. 1995; Robineau et al. 1995; Kudlacz et al. 1997; Lecci et al. 1997) and at the NK_3 receptor (Guard et al. 1990; Edmonds-Alt et al. 1995; Patacchini et al. 1995; Nguyen-Le et al. 1996; Beaujouan et al. 1997; Sarau et al. 1997) were reported (Longmore et al. 1995; Rupniak 1999).

Understanding the role of substance P in the brain has been complicated by marked species differences in the distribution of the tachykinin receptor types. There appears to be a relative increase in NK_1 receptor density during evolution, such that NK_3 receptors ara abundant in lower vertebrates and mammals but, like NK_2 receptors, are apparently absent in human brain. Preclinical studies with substance P receptor antagonists have been hindered not only by phylogenetic differences in tachykinin receptor expression, but also by pharmacological heterogeneity of the NK_1 receptor and the NK_2 receptor. An other confounding feature of neurokinin receptor antagonist is the blockade of Na^+ and Ca^{2+} channels at high doses which produces effects in various assays that are independent of receptor antagonism (Patacchini and Maggi 1995; Rupniak 1999). Most developments were guided by the effects of substance P as a pain neurotransmitter. Surprisingly, most clinical studies of analgesic activity of NK_1 receptor antagonists were negative (Rupniak and Kramer 1999). However, clinical findings indicated that substance P receptor antagonists ara able to alleviate depression and anxiety in patients suffering from major depressive disorder (Kramer et al. 1998).

H.3.1.3.2 ^{3}H-Substance P Receptor Binding

PURPOSE AND RATIONALE

Substance P is an undekapeptide which is widely distributed in the central and peripheral nervous systems and functions as a neurotransmitter/neuromodulator in a variety of physiological processes. Substance P is released from neurons in the midbrain in response to stress where it facilitates dopaminergic neurotransmission and from sensory neurons in the spinal cord in the response to noxious stimuli, where it excites dorsal neurons. In the periphery, release of substance P from sensory neurons causes vasodilatation and plasma extravasation, suggesting a role in neurogenic inflammation. Selective antagonists to substance P found in receptor binding studies may elucidate the physiological role of substance P and may be candidates for anti-inflammatory and analgesic drugs.

PROCEDURE

Fresh porcine brains are obtained from the slaughterhouse. Striata are dissected and homogenized (Ultraturrax) in 50 mM ice-cold Tris-HCl buffer, pH 7.4) containing 150 mM NaCl, 150 mM KCl, 12 mM EDTA, 200 µM phenylmethylsulfonylfluoride, 40 µg/ml bacitracin, 4 µ g/ml leupeptin, and 2 µg/ml chymostatin. These homogenates are then incubated for 30 min at 4°C before being centrifuged at 30,000 *g* for 20 min at 4°C and washed twice with 50 mM Tris-HCl (pH 7.4) buffer. Pellets are resuspended in 0.32 M sucrose containing 200 µM phenylmethyl sulfonylfluoride and 40 µg/ml bacitracin before storage at –80°C until use.

Sixty-minute incubations are carried out at room temperature in 50 mM Tris-HCl buffer, pH 7.4, containing various concentrations of [^{3}H]substance P ([^{3}H]SP) (0.05–20 nM), 5 mM $MgSO_4$, 40 mg/ml bacitracin, 4 mg/ml leupeptin, and 2 mg/ml chymostatin in the presence of 0.8–1 mg of membrane protein in a final volume of 1 ml. Total binding and nonspecific binding are determined in triplicate in the absence or presence of 1 mM unlabeled substance P. Incubations are terminated by adding 4 ml of ice-cold Tris-HCl buffer (pH 7.4) and membranes are filtered on Whatman glass fiber filters that are presoaked in 0.5% polyethylenimine for a minimum of 3 h to reduce absorption. Filters are then washed three times (5 ml each) using ice-cold Tris-HCl buffer (pH 7.4). Bound radioactivities are determined using a liquid scintillation counter.

EVALUATION

Saturation and competition data are analyzed using a computer program as described by McPherson (1985).

H.3.1.3.3 Neurokinin Receptor Binding

PURPOSE AND RATIONALE

The actions of tachykinins are mediated through three subtypes of neurokinin receptors belonging to the G protein-linked receptor family, namely, NK_1, NK_2 and NK_3. Substance P displays highest affinity to NK_1

receptors, whereas neurokinin A and neurokinin B preferably bind to NK_2 and NK_3 receptors, respectively. NK_1 receptors are expressed in a wide variety of peripheral tissues and in the CNS. NK_2 receptors are expressed primarily in the periphery, while NK_3 receptors are primarily expressed in the CNS.

PROCEDURE

Tachykinin NK_1 receptor binding assay is performed in intact Chinese hamster ovary (CHO) cells expressing the human tachykinin NK_1 receptor (Cascieri et al. 1992). The receptor is expressed at a level of 3×10^5 receptors per cell. Cells are grown in a monolayer culture, detached from the plate with enzyme-free cell dissociation solution (Specialty Media), and washed prior to use in the assay. ^{125}I[Tyr^8]substance P (0.1 nM, 2000 Ci/mmol; New England Nuclear) is incubated in the presence or absence of test compounds (dissolved on 5 µl DMSO) with 5×10^4 CHO cells. Ligand binding is performed in 0.25 ml of 50 mM Tris-HCl, pH 7.5, containing 5 mM $MnCl_2$, 150 mM NaCl, 0.02% bovine serum albumin, 40 µg/ml bacitracin, 0.01 mM phosphoramidon and 4 µg/ml leupeptin. The incubation proceeds at room temperature until equilibrium is achieved (>40 min) and the receptor ligand complex is harvested by filtration over GF/C filters presoaked in 0.1% polyethylenimine using a Tomtek 96-well harvester. Nonspecific binding is determined using excess substance P (1 µM) representing <10% of total binding.

For **NK_2 receptor binding assays** membranes of CHO cells transfected with human ileum NK_2 receptor are used (Hagan et al. 1993; Beresford et al. 1995). The membrane suspensions (5 µg protein) in assay buffer (Tris base (50 mM), $MnCl_2$ (3 mM), bovine serum albumin (0.05%), chymostatin (2 µg/ml) and leupeptin 4 µg/ml, pH 7.4) are incubated for 90 min at room temperature with wash buffer (Tris base (50 mM), $MnCl_2$ (3 mM), lauryl sulphate (0.01%), pH 7.4) or test compound, and [^{3}H]-GR100679 (0.5 nM final concentration). Non-specific binding is defined by use of GR159897 (1 µM).

For **NK_3 receptor binding assays** guinea pig cortical membranes (Guard et al. 1990) are incubated at room temperature for 60 min with HEPES wash buffer or test compound and [^{3}H]-senktide (final concentration 0.8–1.0 nM). Non-specific binding is defined by addition of eledoisin (10 µM).

EVALUATION

Inhibition curves are analyzed and pIC_{50} values calculated by use of a curve fitting program. pIC_{50} values are converted to inhibition constants (pK_i values) using the Cheng Prussoff equation

$$K_i = IC_{50}/(1 + L/K_D)$$

where L is the ligand concentration and K_D is the dissociation constant. The K_D and B_{max} (maximum number of binding site per mg of tissue) are determined from saturation curves and analyzed by a curve fitting program. Values are expressed as means ±SEM.

MODIFICATIONS OF THE METHOD

Watson et al. (1955) performed substance P binding assays in **ferret brain membranes** and assessed neurokinin NK_1 receptor binding using human lymphoblasts (IM-9 cells).

Rupniak et al. (1997) studied displacement of ^{125}I-[Tyr^8]substance P binding to cloned human tachykinin NK_1 receptors and to ferret brain membranes *in vitro*.

Beattie et al. (1995) used U373 MG cell membranes and cerebral cortical membranes from rat, ferret and gerbil and [^{3}H]substance P for NK_1 receptor binding assays.

Bonnet et al. (1996), McLean et al. (1996) used the IM9 lymphoblastoma cell line expressing the human NK_1 receptor.

Emonds-Alt et al. (1995) studied binding of [^{125}I] Bolton-Hunter labelled substance P to **NK_1 receptors** of rat brain cortex, human lymphoblast cells (IM9), and human astrocytoma cells (U373MG, STTG1), binding of [^{125}I]iodohistidyl-NKA (or [^{125}I]neuropeptide γ) to **NK_2 receptors** of rat or hamster urinary bladder or guinea pig ileum, binding of [^{125}I]iodohistidyl-[Me-Phe^7]NKB (or [^{125}I]Eledoisin) to tachykinin **NK_3 receptors** of rat, guinea pig and gerbil brain cortex., and of [^{125}I]iodohistidyl-[Me-Phe^7]NKB to the human NK_3 receptor, cloned and expressed in CHO cells (Buell et al. 1992).

Cascieri et al. (1992) described the binding of a potent, selective, radioiodinated antagonist to the human neurokinin-1 receptor.

A radioligand of the tachykinin NK_2 receptor was described by Renzetti et al. (1998).

Jordan et al. (1998) evaluated the Cytosensor microphysiometer, a system that measures the extracellular acidification rate as an index of the integrated functional response to receptor activation, as a method to study NK_3 receptor pharmacology and used this system to assess the functional activity of novel compounds at this receptor.

Appell et al. (1998) reported biological characterization of neurokinin antagonists discovered through

screening of a combinatorial library. Using stably transfected CHO-K1 cell lines expressing human NK-1, NK-2 and NK-3 receptor subtypes and europium time-resolved fluorescence, primary receptor binding assays were designed to define active compounds. In addition, a secondary, functional assay measuring intracellular calcium flux with the calcium-sensitive fluorophore, fluo-3, in CHO cells transfected with the human NK-1 or NK-2 receptor was used to determine agonist or antagonist activities.

H.3.1.3.4 Characterization of Neurokinin Agonists and Antagonists by Biological Assays

PURPOSE AND RATIONALE

Several biological assays have been used to characterize neurokinin agonists and antagonists on their receptors (Review by Regoli et al. 1994).

The following functional assays are recommended for evaluation of antagonists:

For NK_1 Receptors

- Inhibition of [Sar^9,$Met(O_2)^{11}$]substance P-induced endothelium-dependent **relaxation of rabbit pulmonary artery**, previously contracted with 0.1 µM noradrenaline (D'Orléans-Juste et al. 1986; Rubino et al. 1992; Emonds-Alt et al. 1993),
- inhibition of [Sar^9,$Met(O_2)^{11}$]substance P or [Sar^9]substance P sulfone-induced contractions of **guinea pig ileum** in the presence of 3 µM atropine and 3 µM mepyramine and indomethacin (Dion et al. 1987; Emonds-Alt et al. 1993; Patacchini et al. 1995; Hosoki et al. 1998; Walpole et al. 1998),
- **rabbit vena cava** stimulated by substance P or [Sar^9,$Met(O_2)^{11}$]substance P (Nantel et al. 1991; Regoli et al. 1994; Gitter et al. 1995; Robineau et al. 1995; Bonnet et al. 1996; Nguyen-Le et al. 1996),
- inhibition of substance P-induced **relaxation of the isolated dog carotid artery** previously contracted with norepinephrine (Snider et al. 1991),
- **rat urinary bladder**, stimulated by the selective agonist [Sar^9,$Met(O_2)^{11}$]substance P and treated with SR 48986 (1.7×10^{-7} mol/l) to eliminate NK-2 functional sites (Rouissi et al. 1993; Nguyen-Le et al. 1996),
- Ca^{2+} mobilization in **rat vas deferens** (Nagata et al. 1991),
- inhibition of **substance P-induced plasma extravasation in the bladder and bronchi** of the guinea pig (Bonnet et al. 1996),
- inhibition of **substance P-induced vasodilation in the nasal mucosa of pigs** using an acoustic rhinometer (Rinder and Lundberg 1996),
- inhibition of **[Sar^9,$Met(O_2)^{11}$]substance P-induced plasma extravasation in guinea-pig bronchi** (Cirillo et al. 1998),
- inhibition of **methacholine-induced contractions of isolated rat tracheal strips** (Tian et al. 1997),
- inhibition of **cyclophosphamide- and radiation-induced damage in the rat and ferret organs** (Alfieri and Gardner 1997, 1998),
- inhibition of **edema formation induced by substance P and antigen in rat skin** (Herbert and Bernat 1996),
- inhibition of **reciprocal hindlimb scratching after intracerebroventricular injection of substance P, [Sar^9, $Met(O_2)^{11}$]substance P or septide in mice (Jung et al. 1994) or gerbils** (Smith et al. 1994),
- inhibition of **turning behavior after intracerebroventricular injection of substance P, [Sar^9,$Met(O_2)^{11}$] substance P or septide in mice** (Jung et al. 1994),
- inhibition of **hind paw tapping and chromodacryorrhea after intracerebroventricular injection of tachykinin agonists in gerbils** (Graham et al. 1993; Bristow and Young 1994; Rupniak and Williams 1994; Rupniak et al. 1995, 1997; Vassout et al. 1994),
- inhibition of **cis-platin-induced emesis in ferrets** (Rupniak et al. 1997; Singh et al. 1997; Minami et al. 1998).

For NK_2 Receptors

- Inhibition of neurokinin A-induced contraction of **isolated rabbit aorta** (Snider et al. 1991),
- inhibition of neurokinin A-induced contraction of **isolated endothelium-deprived rabbit pulmonary artery or hamster trachea** (D'Orléans-Juste et al. 1986; Emonds-Alt et al. 1993; Patacchini et al. 1995),
- the **hamster urinary bladder** (Dion et al. 1987; Maggi et al. 1990; Regoli et al. 1994; Emonds-Alt et al. 1997; Tramontana et al. 1998),
- inhibition of **motor responses induced by intravesival administration of capsaicin** in rats *in vivo* (Lecci et al. 1997),
- **rat esophageal tunica muscularis** (Croci et al. 1995),
- inhibition of **turning behavior induced by intrastriatal injection of Nle^{10}-neurokinin A in mice** (Emonds-Alt et al. 1997).

For NK_3 Receptors

- Inhibition of **senktide- or neurokinin B-induced contractions of the rat portal vein** (Mastrangelo et al. 1987; Snider et al. 1991; Emonds-Alt et al. 1993; Patacchini et al. 1995),
- antagonism against **senktide-induced contractions in the isolated rabbit iris sphincter muscle** (Medhurst et al. 1997; Sarau et al. 1997),
- inhibition of**colonic propulsion in rats** (Broccardo et al. 1999)
- inhibition of **turning behavior induced by intrastriatal injection of senktide in gerbils** (Emonds-Alt et al. 1994),
- inhibition of **citric acid-induced cough in guinea pigs** (Daoui et al. 1998).
- The failure of NK_1 receptor antagonists in most clinical tests for analgesia in spite of clear preclinical data is a matter of discussion (Hill R 2000a, b; Urban and Fox 2000).

H.3.1.4 Assay of Polymorphonuclear Leukocyte Chemotaxis In Vitro

PURPOSE AND RATIONALE

Leukocyte accumulation is an important aspect of host defense mechanisms. Chemotactic factors attract leukocytes to an infected or inflamed site. The method of Boyden (1962) has been widely employed to measure the chemotactic effects on polymorphonuclear leukocytes. Watanabe et al. (1989) described a rapid assay of polymorphonuclear leukocyte chemotaxis *in vitro*.

PROCEDURE

Two 96-well tissue-culture plates are utilized as one set of multiple Boyden chambers. One plate as multiple lower compartments and the other plate upside down as multiple upper compartments can be tightly sandwiched with the aid of 12 sets of bolts. The holes, into which bolts are set and polymorphonuclear leukocytes (PMN) suspensions are introduced, are opened by a heated stick. Eight sets of 6 holes are made on the bottom of the upper plate to serve as multiple upper compartments for introducing PMN suspensions. Eight sets of polycarbonate filter (approximately 3.2 × 2.2 cm), cut from a round filter (Nuclepore Co.) with pores of 2 μm in diameter, are sandwiched between the upper and lower plates. One sheet of the filter can separate six sets of the upper compartments from the lower ones. Silicon grease is spread on all the plate surfaces that attach to the filters. The lower compartments are filled with a chemoattractant (400 μ l/well) diluted in RPMI-1640 medium. The eight sheets of filter paper are carefully placed on each set of the lower compartments to avoid air bubbles. The upper plate is positioned over the lower plate and fastened with bolts. The upper compartments are filled with 0.3 ml of PMN suspension (at 10^7 cells/ml). The assembly is incubated at 37°C for 60 min in a humidified atmosphere containing 5% CO_2. Then the fluid in the upper compartment is decanted and the upper compartments are completely washed with a jet of water. The lower plate is centrifuged at 2400 rpm for 5 min at room temperature and the supernatant in the well is decanted. The pellet of PMNs is dispersed in 200 μl of phosphate buffered saline containing 0.1% EDTA. Absorbance at 660 nm of each well containing PMN suspension is determined with a 96-well microplate reader. The number of PMNs in the lower compartments is further determined by a Coulter counter.

EVALUATION

The migration rate is calculated as percentage from the number of PMNs in the lower compartment/number of PMNs applied in the upper compartment. The migration rate is dependent on the concentration of the chemoattractant (e. g., zymosan-activated serum). Moreover, a dose dependent decrease of migration rate is achieved by chemotaxis inhibitors.

MODIFICATIONS OF THE METHOD

Nelson et al. (1975) described chemotaxis under agarose as a simple method for measuring chemotaxis and spontaneous migration of human polymorphonuclear leukocytes and monocytes.

Migration of PMNs in agarose gel was measured after fixation with glutaraldehyde and staining with Giemsa by Shalaby et al. (1987).

Optimal conditions for simultaneous purification of mononuclear and polymorphonuclear leukocytes from human blood were described by Ferrante and Thong (1980).

PMN chemotaxis was measured in multiwell microchemotaxis chambers separated by 5-µm pore size polyvinylpyrrolidone-free polycarbonate membranes by Harvath et al. (1980), Figari et al. (1987).

H.3.1.5 Polymorphonuclear Leukocytes Aggregation Induced by FMLP

PURPOSE AND RATIONALE

Aggregation of polymorphonuclear leukocytes (PMNs) can be induced by FMLP (formyl-L-methionyl-L-leucyl-L-phenylalanine). The aggregation can be inhibited by xanthine derivatives.

PROCEDURE

PMNs cell suspensions are prepared from peritoneal exudates obtained 17 h after intraperitoneal injection of 10 ml 6% sodium caseinate into Sprague Dawley rats. The cells are washed twice in Geys-balanced-salt-solution (Gibco GBSS) and resuspended to a final concentration of 15×10^6 cells/ml. The test compounds and the standard (pentoxiphylline) are dissolved in GBSS. FMLP (formyl-L-methionyl-L-leucyl-L-phenylalanine) is dissolved in DMSO. The further dilutions are made up to a final concentration of 10^{-7} mol FMLP in GBSS. Before addition of FMLP, the cell suspensions are pre-incubated for 10 min with the drugs. PMNs aggregation is carried out in a Born aggregometer.

EVALUATION

The results are expressed as change in transmittance, measured in mm on the recorder. The mean peak of the untreated cells is set 100%.

MODIFICATIONS OF THE METHOD

Moqbel et al. (1986) measured the activation of human leukocytes after FMLP in a rosette assay by the change in the expression of complement (C3b) and IgG (Fc)

receptors and in a cytotoxic assay by the *in vitro* capacity to adhere to and kill the complement-coated larvae (schistosomula) of Schistosoma mansoni.

Bradford and Rubin (1986) determined the effect of various drugs on IP_3 accumulation evoked by FMLP in neutrophils from New Zealand white rabbits.

Bourgoin et al. (1991) studied the influence of granulocyte-macrophage colony-stimulating factor (GM-CSF) on phosphatidylcholine breakdown by phospholipase D in human neutrophils.

H.3.1.6 Constitutive and Inducible Cellular Arachidonic Acid Metabolism In Vitro

PURPOSE AND RATIONALE

The various metabolites of arachidonic acid are involved in many inflammatory processes. Arachidonic acid is released from the cellular phospholipid fraction by the action of phospholipase A_2, and subsequently metabolized via two major routes: the cyclooxygenase pathway yielding the primary prostaglandins and thromboxane, and the 5-lipoxygenase pathway yielding the leukotrienes. Thromboxanes, prostaglandins, and leukotrienes play a pathophysiological role in many diseases. Receptor assays for these autocoids were developed (Haluska et al. 1989). Murata et al. (1997) produced mice lacking the prostaglandin receptor which showed increased susceptibility to thrombosis and altered pain reception and inflammatory response.

The therapeutic mode of action of the classical non-steroidal anti-inflammatory drugs (NSAID), such as aspirin or indomethacin, is primarily explained by their inhibitory effect on cyclooxygenase, the key enzyme of the prostaglandin pathway. Inhibitors of the 5-lipoxygenase pathway have attracted considerable attention as potential anti-inflammatories with high potency. Appropriate assay systems for the determination of the different eicosanoids allow to study the influence of drugs towards the specific pathways of the arachidonic acid cascade in various cellular systems (Samuelsson 1986; Vane and Botting 1987).

According to recent discoveries there are two forms of cyclooxygenase (Xie et al. 1992; Lee et al. 1992; Gierse et al. 1996). Cyclooxygenase-1 (COX-1) is found as a constitutive enzyme in most tissues including blood platelets. Prostaglandins generated by constitutive pathways may exert cytoprotective effects, and are involved in maintaining vital functions in vascular hemostasis, gastric mucosa and kidney.

Chandrasekharan et al. (2002) described the cloning, structure and expression COX-3, a cyclooxygenase-1 variant, which is selectively inhibited by analgesic/antipyretic drugs, such as acetaminophen, phenacetin, antipyrine, and dipyrone.

The inhibition of these prostaglandins by the classical cyclooxygenase inhibitors is now generally accepted as an explanation of their adverse side effects.

COX-2 which shares about 62% amino acid homology with COX-1, is only expressed after cell activation, especially by mitogenic or inflammatory stimuli (Herrmann et al. 1990; Funk et al. 1991; Crofford 1997). Thus, specific suppression of the COX-2-pathway may represent a superior target for the evaluation of new antiinflammatory drugs. Drugs which have a high potency on COX-2 and a favorable COX-2/COX-1 ratio have potent anti-inflammatory activity with fewer side effects (Riendeau et al. 1997; Vane 1998; Hawkey 1999; Song et al. 1999; Chan et al. 1999). Shigeta et al. (1998) described the role of cyclooxygenase-2 (COX-2) in the healing of gastric ulcers in rats. Hull et al. (2005) investigated the expression of cyclooxygenase-1 and -2 by human gastric endothelial cells.

The cardiovascular value of selective COX-2 inhibitors has been questioned because they selectively reduce prostacyclin production, thus disrupting the hormonal balance and promoting a prothrombotic state (Hankey and Eikelboom 2003).

These theoretical concerns were supported by the results of clinical trials demonstrating an increased risk of myocardial infarction with COX-2 inhibitors compared with conventional non-steroidal anti-inflammatory drugs (NSAIDs) (Bombadier et al. 2000). The debate on benefit-risk assessment of COX-2 inhibitors is ongoing (Bing 2003; Schmidt et al. 2004).

H.3.1.6.1 Formation of Leukotriene B_4 in Human White Blood Cells In Vitro

PROCEDURE

Human white blood cells are prepared according to the standard procedure published by Salari et al. (1984): 40 ml freshly drawn citrated blood are admixed with 8 ml of PM16-buffer, containing 6% (v/v) dextran (MW = 480,000), and incubated at room temperature for one hour. The supernatant containing the white blood cell fraction is removed, diluted 1:1 (v/v) with PM16 and centrifuged for 15 min at 300 *g*. The precipitate is resuspended in PM16 and adjusted to 10^{10} cells/l (Counter HT, Coulter Electronics, Krefeld, FRG).

The metabolism of endogenously bound arachidonic acid to LTB_4 is measured in a total volume of 0.3 ml of the cell suspension at 37°C. The reaction tube contains 2 mmol/l $CaCl_2$, 0.5 mmol/l $MgCl_2$ and the investigational drug. After 15 min pre-incubation the reaction is started by addition of 12.5 µg of the Ca-ionophore A 23187 and 2 µg glutathione. After 5 min the reaction is stopped with 30 µl 0.1 M HCl at 0°C. After centrifugation for 2 min at 0°C, aliquots of the supernatant are subjected to HPLC, similarly as described by Veenstra et al. (1988), using a C-18 Nucleosil column (5 µm, 100 × 3 mm, Chrompack GmbH, Frankfurt, FRG) and, at a flow rate of 0.7 ml/min, a solvent mixture consisting of 725 ml methanol, 275 ml water and 0.1 ml acetic acid. Authentic standard drugs are used to identify cis-, trans- and epi-LTB_4. The separation of the three isomers can be followed photometrically at the UV-maximum of 278 nm.

EVALUATION

The peak areas of cis-, trans- and epi-LTB_4 are measured as a function of drug concentration, and related to a control experiment without drug.

CRITICAL ASSESSMENT

The tested pathway involves the enzymatic steps of phospholipase A_2 and the 5-lipoxygenase. Thus inhibitors of these enzymes are to decrease formation of the three isomers of LTB_4. The step of phospholipase A_2 can be circumvented by the addition of exogenous arachidonic acid (1 µmol/l).

Inhibitors of LTA_4-hydrolase which catalyzes the intermediary conversion of LTA_4 to the biologically active cis-LTB_4, can also be identified by this assay. Such drugs are to exhibit an increased formation of the non-enzymatic hydrolysis products trans- and epi-LTB_4 at the expense of decreased cis-LTB_4.

MODIFICATIONS OF THE METHOD

Winkler et al. (1988) used differentiated U-937 cells expressing LTB_4 receptors to study Ca^{2+} mobilization in response to LTB_4.

Jones et al. (1995) tested inhibition of [^{3}H]leukotriene D_4 specific binding in guinea pig lung, sheep lung, and dimethylsulfoxide-differentiated U837 cell plasma membrane preparations.

H.3.1.6.2 Formation of Lipoxygenase Products from ^{14}C-Arachidonic Acid in Human Polymorphonuclear Neutrophils (PMN) In Vitro

PROCEDURE

PMN are prepared by the standard procedure of Böyum (1976). The first steps are carried out at room temperature: 50 ml citrated human blood are centrifuged at 130 *g* for 15 min. The pellet is resuspended in 20 ml Dulbecco's minimal essential medium, and subsequently underlayered with 15 ml lymphoprep. After centrifugation at 400 *g* for 25 min the pellet is resuspended in 28 ml Dulbecco's HBSS containing 3% dextran. After incubation at 0°C for 120 min the decanted supernatant is centrifuged at 400 *g* for 15 min. The pellet is resuspended in 1 ml Dulbecco's PBS, containing 11 µmol/l glucose, to a leukocyte count of 2×10^{10}/l.

The method of HPLC determination of cellular metabolites of exogenous 1-C-14-arachidonic acid, as published by Borgeat and Samuelsson (1979), is modified as briefly described:

0.1 ml of the leukocyte suspension are incubated in Dulbecco's phosphate buffered saline (DPBS) at 37°C with the test drugs for 15 min. The incubation is then interrupted by cooling in an ice bath. Calcium ionophore A 23187 (final concentration 7×10^{-5} mol/l) and 1-C-14-arachidonic acid (final concentration 8.4×10^{-5} mol/l, 0.5 µCi) are added, and, after a second incubation period of 15 min at 37°C, terminated by the addition of 0.4 ml methanol. The assay mixture is then extracted with chloroform. The chloroform is evaporated, and, after redissolving the residue in a minor amount of methanol/water, analyzed by HPLC and radiomonitoring for the C-14-eicosanoids.

HPLC-conditions are as follows: Column: Nucleosil C-18, 5 µm; organic phase: 700 ml methanol, 300 ml water, 0.1 ml acetic acid; after 35 min change to pure methanol. Flow: 1 ml/min, 2000 psi. Radiomonitor: LB 507 (Berthold, Wildbad, FRG).

A viability assay (trypan blue exclusion) ascertains that cells remain intact during incubation periods.

EVALUATION

The radioactivity of the separated 5-HETE and LTB_4 is measured as a function of drug concentration, and related to a control experiment without drug. Two further lipoxygenase products, 12-HETE and 15-HETE, which are additionally generated under the test conditions, can be quantified in a similar way.

CRITICAL ASSESSMENT

The measured reaction sequence starts with arachidonic acid, and involves its transformation to 5-HETE by 5-lipoxygenase, as well as the subsequent enzymatic hydrolysis to LTB_4. Inhibitors of 5-lipoxygenase exhibit a decreased formation of 5-HETE and LTB_4. Effects of drugs on the side products 12-HETE and 15-HETE can also be studied in this test system.

H.3.1.6.3 Formation of Eicosanoids from ^{14}C-Arachidonic Acid in Human Platelets In Vitro

PROCEDURE

Blood is drawn from the vena brachialis of healthy volunteers and collected into plastic tubes containing sodium citrate (0.38% final concentration (w/v)). After centrifugation at 100 *g* for 15 min the platelet rich plasma (PRP) containing about $2{,}5 \times 10^{11}$ platelets/l (Counter HT, Coulter Electronics, Krefeld, FRG) is saved, and kept at 20°C no longer than one hour until the experiment is started. Metabolism of ^{14}C-arachidonic acid is followed by the HPLC procedures published by Weithmann et al. (1994), modifying the method of Powell (1985). PRP is mixed with the same volume of a citrate/D-glucose solution (27.35 g trisodium citrate· $2H_2O$, 1.47 g citric acid and 27.74 g D(+)-glucose· H_2O ad 1 l water) and centrifuged at 1000 *g* for 20 min (4°C). The saved precipitate is resuspended in Dulbecco's solution (DPBS, Serva, Heidelberg, FRG) in the original volume. 0.495 ml of this platelet suspension is incubated at 37°C for 15 min with the test compound. Subsequently eicosanoid formation is started by the addition of 5 µl of 1-^{14}C-arachidonic acid solution (50 Ci/mol, 9×10^{-4} Ci/l, NEN, Dreieich, FRG). After 5 min (37°C) the reaction is stopped by adding 0.5 ml of chilled acetone/0.1 ml 1n HCl, cooled to 0°C, and extracted two times with 3 ml ethylacetate. The combined organic extracts are evaporated and the residue redissolved in 0.2 ml methanol. Aliquots are separated by HPLC at a flow rate of 1.5 ml/min, using a C-18 Nucleosil column (5 µm, 125 × 4.6 mm, Bischoff, Leongang, FRG) connected with a pre-column C-18 Nucleosil (5 µm, 20 × 4.6 mm) of the same type. The formed ^{14}C-eicosanoids are analyzed using a liquid scintillation flow detector LB 507 (Berthold, Wildbad, FRG). The radiochromatogram is analyzed by comparison with tritiated authentic eicosanoids (NEN, Dreieich, FRG). The elution system consists of the following solvent mixtures (elution time in parenthesis): I 725 ml water/275 ml acetonitrile/1 ml acetic acid (40 min), II 700 ml methanol/300 ml H_2O/1 ml acetic acid (40 min), III pure methanol (20 min).

EVALUATION

The radioactivity of the separated TXB_2 and PGE_2 is measured as a function of drug concentration, and related to a control experiment without drug addition.

A further lipoxygenase product, 12-HETE, which is additionally generated under the test conditions, can be quantified in a similar way.

Lasché and Larson determined PGI_2 by a bioassay based on its generation by aortic rings and assay by its ability to inhibit platelet aggregation.

CRITICAL ASSESSMENT

The measured reaction sequence starts with arachidonic acid, and involves its transformation to prostaglandin endoperoxides, which is catalyzed by cyclooxygenase. The unstable and short-living endoperoxides transform immediately into thromboxane A_2 by the action of thromboxane isomerase. TXA_2 is unstable, too, and yields the stable non-enzymatic hydrolysis product TXB_2.

Inhibitors of cyclooxygenase exhibit a decreased formation of TXB_2. Specific inhibition of the thromboxane isomerase step results in an accumulation of the mentioned endoperoxide intermediates, which due to their chemical instability are non-enzymatically transformed to the primary PGE_2. Thus, inhibitors of the TXA_2-isomerase lead to a significant increase of the PGE_2-peak at the expense of the TXB_2-peak. Effects of drugs on the side product 12-HETE can also be studied in this test system.

H.3.1.6.4 Stimulation of Inducible Prostaglandin Pathway in Human PMNL

PROCEDURE

The procedure of Herrmann et al. (1990) with the modification of Weithmann et al. (1994), is used to stimu-

late cyclohexamide-inhibitable generation of PGE_2 in human PMNL by LPS.

H.2.5×10^9 PMNL/l culture medium (RPMI 1640, completed with 1 mmol/l sodium pyruvate, 5% FCS (w/v), 2 mmol/l glutamine and each 100 U/ml penicillin/streptomycin) are incubated with 100 µmol/l acetylsalicylic acid for 60 min (37°C, 5% CO_2), and the latter subsequently removed by four times washing with medium. 0.25 ml-aliquots (containing 2.5×10^9 PMNL/l medium) are incubated with 0.1 mg/ml LPS (lipopolysaccharide from Salmonella abortus equii, Sigma GmbH, Deisenhofen, FRG) along with the test compound for 18 h (96-well plates, 37°C, 5% CO_2). The generation of eicosanoids is induced by the administration of 7×10^{-5} mol/l of the calcium ionophore A 23187. After incubation for 30 min at 37°C the plates are centrifuged at 400 *g* for 15 min. PGE_2 is determined in the supernatant, using an ELISA-kit commercially available from several distributors. Alternatively the test compound is added along with the calcium ionophore. At least 90% of the cells remain intact during incubation times (trypan blue exclusion assay).

EVALUATION

The PGE_2-concentration in the sample is determined from appropriate calibration curves. The PGE_2-concentration is measured as a function of drug concentration, and related to a control experiment without drug.

CRITICAL ASSESSMENT

Long term activation with LPS or other inflammatory effectors leads in human polymorphonuclear neutrophils to the stimulation of a prostaglandin synthesizing capacity, which under normal conditions is not present in this system. The described assay system detects compounds which interfere with this activation process.

Incubation of drugs with already activated cells allows to search for drugs that directly influence the enzyme activity.

H.3.1.6.5 COX-1 and COX-2 Inhibition

PURPOSE AND RATIONALE

Several assays were described to characterize COX-1 and COX-2-inhibitors, such as *in vitro* COX enzyme assay (Seibert et al. 1994), COX-2 protein extraction and analysis (Anderson et al. 1996), a human whole blood assay using LPS-induced PGE_2 production as an index for cellular COX-2 activity (Riendeau et al. 1997) or whole-cell assays with transfected Chinese hamster ovary cells expressing COX-1 and COX-2 or COX-2 specific (osteosarcoma cells) and COX-1 specific (U937 cells) making use of PGE_2 production after arachidonic challenge as an index of cellular potency and selectivity of cyclooxygenase inhibitors (Chan et al. 1999; FitzGerald and Loll 2001; Rao et al. 2003).

PROCEDURE

In Vitro Cyclooxygenase Inhibition

The ability of test compounds to inhibit COX-1 and COX-2 (IC_{50} values, µM) is determined using an enzyme immunoassay kit (Cyman Chemical, Ann Arbor, Mich., USA, no. 560101) (Uddin et al. 2004). This COX (ovine) inhibitor screening assay directly measures the amount of the prostaglandin $PGF_{2\alpha}$ produced in the cyclooxygenase reaction. The prostanoid product is quantified via enzyme immunoassay (EIA) using a broadly specific antibody that binds to all the major prostaglandin compounds. Thus, this COX assay is more accurate and reliable than an assay based on peroxidase inhibition. The COX (ovine) inhibitor screening assay includes both ovine COX-1 and COX-2 enzymes in order to screen isozyme-specific inhibitors. This assay is an excellent tool, which can be used for general inhibitor screening, or to eliminate false-positive leads generated by less specific methods.

Cyclooxygenase catalyzes the first step in the biosynthesis of arachidonic acid to PGH_2. $PGF_{2\alpha}$ produced from PGH_2 by reduction with stannous chloride is measured by enzyme immunoassay. This assay is based on the competition between PGs and a PG-acetylcholinesterase conjugate (PG tracer) for a limited amount of PG antiserum. The amount of PG tracer that is able to bind to the PG antiserum is inversely proportional to the concentration of PGs in the wells since the concentration of PG tracer is held constant while the concentration of PGs varies. This antibody–PG complex binds to a mouse anti-rabbit monoclonal antibody that was previously attached to the well. The plate is washed to remove any unbound reagents and then Ellman's reagent, which contains the substrate for acetylcholinesterase, is added to the well. The product of this enzymatic reaction produces a distinct yellow color that absorbs at 405 nm. The intensity of this color, determined spectrophotometrically, is proportional to the tracer bound to the well, which is inversely proportional to the amount of PGs present in the well during the incubation. Percent inhibition is calculated by the comparison of compound treated to various control incubations. The concentration of the

test compound causing 50% inhibition (IC_{50}, μM) is calculated from the concentration–inhibition response curve.

Inhibition Studies with Recombinant Human COX-1 and COX-2

Microsomal preparations of recombinant human COX-1 and COX-2 are prepared from a vaccine virus-COS-7 cell expression system (O'Neill et al. 1994). Recombinant human COX-1 and COX-2 are expressed in baculovirus-Sf9 cells, and enzymes are purified (Ouellet and Percival 1995; Cromlish and Kennedy 1996). Enzymatic activity is monitored continuously by either a fluorescence assay measuring the appearance of the oxidized form of the reducing agent cosubstrate homovanillic acid or by oxygen consumption (Ouellet and Percival 1995).

Classical non-steroidal anti-inflammatory drugs (NSAIDs) and COX-2 inhibitors are time-dependent, irreversible inhibitors of hCOX-2, which is consistent with a two-step process involving an initial rapid equilibrium binding of enzyme and inhibitor, followed by the slow formation of a tightly bound enzyme–inhibitor complex. COX-2 inhibitors show a time-independent inhibition of hCOX-1, consistent with the formation of a reversible enzyme–inhibitor complex (Ouellet and Percival 1995; Riendeau et al. 2001).

HPLC Assay for Oxygenation of Radiolabeled Arachidonic Acid by COX-1

Purified recombinant human COX-1 (50 μl of 1 μg/ml in 100 mM Tris-HCl, pH 8.0, 5 mM EDTA, 1 mM phenol, 1 μM hematin) is preincubated with 2 μl of the inhibitor solution (50 fold concentrated stock in DMSO, 0–2.5 mM) for 15 min. The reaction is then initiated by the addition of 5 μl of 1 μM [^{14}C]-arachidonic acid (0.005 μCi) to obtain a final concentration of 0.1 μM. After 7 min incubation at room temperature, the reaction is stopped by the addition of 5 μl 1 M HCl and 50 μl acetonitrile. Aliquots of 50 μl of each reaction mixture are analyzed for substrate conversion by reverse phase HPLC onto a C-18 Nova-Pak column (3.9 × 150 mm) which is developed with acetonitrile/water/acetic acid (85:15:0.1) at 2 ml/min. Arachidonic acid metabolites and arachidonic acid eluted at 0.6–1 min and 2.2–2.5 min, respectively, are quantitated by a Packard radiochromatography detector. Percentages of inhibition are calculated from the difference in conversion of arachidonic acid to prostaglandin metabolites between inhibitor-treated samples and controls exposed to DMSO vehicle.

Determination of the Stoichiometry of Inhibitor Binding

Aliquots of purified COX-2 (0.25 mg/ml, concentration of subunit of 3.4 mM) are incubated in buffer (100 mM Tris-HCl, pH 8.0, 5 mM EDTA, 1 mM phenol) in the presence of various inhibitors (0–8 μM) for 15 or 30 min. An aliquot (20 μl) is then removed for determination of the cyclo-oxygenase activity which is monitored continuously by oxygen consumption by a Clark-type polarographic oxygen probe. The oxygen chamber is filled with 0.6 ml of reaction buffer (100 mM Tris-HCl, pH 8.0, 5 mM EDTA, 1 μM hematin,1 mM phenol, 100 μM arachidonic acid at 30° or 37°C) and the reaction is initiated by the addition of 20 μl of a solution of 4 mM hydrogen peroxide and 0.5 mM N,N,N′,N′-tetramethyl-p-phenylenediamine (TMPD) in assay buffer. Enzyme concentration is determined by amino acid concentration following acid hydrolysis.

Determination of the Dissociation Rate Constant of the Enzyme-Inhibitor Complex

Purified COX-2 (2.0 nmol, 2 ml) in 20 mM Tris-HCl, pH 8.0, 0.1 mM EDTA, 2 μM hematin, 0.1% β-octylglucoside is treated with 2.0 nmol [^{14}C]-DFU (18 Ci/mol) and incubated at 20°C for 3 h. A control (0.7 ml) is removed and 13 nmol unlabelled DFU is added to the remaining 1.3 ml of the mixture containing COX-2 and [^{14}C]-DFU. At timed intervals, 0.1 ml (in duplicate) is transferred to a Microcon-30 micro concentration device (Amicon) and the free inhibitor is separated from enzyme-bound inhibitor by centrifugation at 14,000 *g* for 6 min at 4°C. Buffer (0.1 ml) is added to the retentate and the centrifugation repeated. The filtrate and retentate are then removed and mixed with 10 ml scintillation fluid and counted in a liquid scintillation counter.

An aliquot of purified COX-2 (1.0 nmol) is treated with 1.25 mol equivalents of inhibitor or with DMSO vehicle control and incubated at 20°C for 1 h. The enzyme-inhibitor mixture is then transferred to a Pierce Microdialyzer 100 apparatus and dialyzed continuously against 2 l of buffer (20 mM Tris-HCl, pH 8.0, 0.1 mM EDTA, 0.1 mM phenol, 0.1% octylglucoside) for 5 h at 22°C during which aliquots are moved and frozen at –70°C until assayed for cyclyo-oxygenase activity by oxygen uptake as described above.

Recovery of Inhibitor from the COX-2-Inhibitor Complex

Purified COX-2 (0.79 nmol) is treated with 1.0 mol equivalent of inhibitor and the mixture is incubated for 60 min at room temperature. The remaining activity at this time is 4% that of a vehicle-treated con-

trol. The sample is then divided in two and the protein denaturated by treatment with four volumes of ethyl acetate/methanol/1 M citric acid (30:4:1). After extraction and centrifugation (10,000 *g* for 5 min), the organic layer is removed and the extraction repeated. The two organic layers are combined and dried under N_2. The extract is dissolved in 10 µl of HPLC solvent mixture consisting of water/acetonitrile/acetic acid (50:41:0.1) and 50 µl are injected onto a Novapak C-18 column (3.9 × 150 mm) and developed at 1 ml/min. The inhibitor is detected by absorption at 260 nm and eluted with a retention time of 6.6 min in this system. Control experiments for inhibitor recovery are performed with incubation of the inhibitor in the absence of enzyme and processing of the samples in an identical fashion before quantitation by HPLC.

Spectrophotometric Assay of Recombinant Human COX-2

Enzymatic activity of the purified COX-2 is measured using a chromogenic assay based on the oxidation of N,N,N′,N′-tetramethyl-p-phenylenediamine (TMPD) during the reduction of PGG_2 to PGH_2 (Copeland et al. 1994). The assay mixture (180 µl) contains 100 mM sodium phosphate, pH 6.5, 1 µM hematin, 1 mg/ml gelatin, 2 to 5 µg/ml of purified COX-2, and 4 µl of the test compound in DMSO. The assay is also performed in the presence of the detergent Genapol X-100 at a final concentration of 2 mM. The mixture is preincubated at room temperature (22°C) for 15 min before the initiation of the enzymatic reaction by the addition of 20 µl of a solution of 1 mM arachidonic acid and 1 mM TMPD in assay buffer (without enzyme or hematin). For assays in the presence of Genapol, the arachidonic acid and TMPD solution is prepared in 50% aqueous ethanol. The enzyme activity is measured by estimation of the initial velocity of TMPD oxidation over the first 36 s of the reaction as followed from the increase in absorbancy at 610 nm. A low rate of non-enzymatic oxidation is observed in the absence of COX-2 and is subtracted before the calculation of the percentage of inhibition.

Whole-Cell Assays with Transfected Chinese Hamster (CHO) Cells Expressing COX-1 and COX-2

Stably transfected CHO cells expressing human COX-1 and COX-2 are cultured and assayed for the production of PGE2 after stimulation with arachidonic acid (Kargman et al. 1996). Cells (0.3×10^6 cells in 200 µ l) are pre-incubated in HBSS containing 15 mM HEPES, pH 7.4, with 3 µl of the test drug or DMSO vehicle for 15 min at 37°C before challenge with arachidonic acid. Cells are challenged for 15 min with an arachidonic acid solution (10% ethanol in HBSS) to yield final concentrations of 10 µM arachidonic acid in the CHO[COX-2] assay and 0.5 µM arachidonic acid in the CHO[COX-1] assay. In the absence of addition of exogenous arachidonic acid, levels of PGE_2 in samples from CHO[COX-1] are <30 pg $PGE_2/10^6$ cells. In the presence of 0.5 µM exogenous arachidonic acid, levels of PGE_2 in samples from CHO[COX-1] cells increase to 260 to 1500 pg $PGE_2/10^6$ cells. After stimulation with 10 µM exogenous arachidonic acid, levels of PGE_2 in samples from CHO[COX-2] cells increase from <120 to 700 to 1600 pg $PGE_2/10^6$ cells. Compounds are tested in eight concentrations in duplicate using 3-fold serial dilutions in DMSO. COX activity in the absence of test compounds is determined as the difference in PGE_2 levels of cells challenged with arachidonic acid versus PGE_2 levels in cells mock-challenged with ethanol vehicle.

Arachidonic acid-dependent production of PGE_2 is measured in both cell lines after addition of test drugs. Indomethacin shows similar IC_{50} values in both CHO[COX-1] and CHO[COX-2] cells, whereas specific COX-2 inhibitors show a 1,000-fold specificity.

Assays with Murine Macrophages

Mitchell et al. (1994), Hu et al. (2003), and Joo et al. (2004) used mouse peritoneal macrophages for evaluation of COX-2 inhibitors.

Adherent peritoneal macrophages were harvested from the peritoneal cells of male C5BL-6J mice after intraperitoneal injection of brewer thioglycollate medium (5 ml/100 g body weight) for 3 days. The peritoneal cells obtained from three to four mice were mixed and seeded in 48-well culture cluster at a cell density of 1 × 109 cell/l in RPMI-1640 supplemented with 5% newborn calf serum, penicillin, and streptomycin. After settlement for 2–3 h, non-adherent cells were washed by D-Hanks' balanced salt solution. Then macrophages were cultured in RPMI-1640 without serum. Almost all of the adherent cells were macrophages as assessed by Giemsa staining. Cell viability was examined by trypan blue dye exclusion. All incubation procedures were performed with 5% CO_2 in humidified air at 37°C.

COX-1 Assay

Macrophages were incubated with test compound at different concentrations or solvent (Me_2SO) for 1 h and were stimulated with calcimycin 1 µmol/l for 1 h. The amount of 6-keto-$PGF_{1\alpha}$ (a stable metabolite of PGI_2) in supernatants was measured by RIA according to manufacturer's guide. The inhibitory ratio was

calculated as

$$IR = \frac{(C_s - C_t)}{(C_s - C_c)}.$$

C_s, C_t, C_c refer to 6-keto-PGFα concentration in supernatants of calcimycin, test compound, and control groups, respectively.

COX-2 Assay

Macrophages were incubated with test compound at different concentrations or solvent (Me_2SO) for 1 h and were stimulated with lipopolysaccharide (LPS) 1 mg/l for 9 h. The amount of PGE_2 in supernatants was measured by RIA. The inhibitory ratio was calculated using the same formula as in COX-1 assay section. C_s, C_t, C_c refer to PGE_2 concentration in supernatants of LPS, test compound, and control groups, respectively.

Statistical analysis data were expressed as the mean ±SD of more than three independent experiments. Dose–inhibitory effect curves were fit through "uphill dose–response curves, variable slope" using Prism, GraphPad version3.00:

$$Y = \frac{1}{1 + 10^{[(\log IC_{50} - X) \times \text{Hillslope}]}}.$$

Whole-Cell Assays with Osteosarcoma Cells (COX-2) and U937 Cells (COX-1)

The human osteosarcoma cell line has been shown to selectively express COX-2 by reverse transcription-polymerase chain reaction and immunoblot analysis, whereas undifferentiated human lymphoma U937 cells selectively express COX-1. The production of PGE_2 by these cells after arachidonic acid challenge is used as an index of cellular COX-2 and COX-1 activity, respectively. Test substances are preincubated for 5 to 15 min with the cells under serum-free conditions (HBSS) before a 10-min stimulation with 10 µM arachidonic acid and measurement of PGE_2 production (Wong et al. 1997). COX activity in each cell line is defined as the difference in PGE_2 concentrations in samples incubated in the presence or absence of arachidonic acid.

Human Whole Blood Assay

For the COX-2 assay, fresh heparinized human whole blood is incubated with lipopolysaccharide from *E. coli* at 100 µg/ml and with 2 µl of vehicle or a test compound for 24 h at 37°C (Brideau et al. 1996). PGE_2 levels in the plasma are measured using radioimmunoassay after deproteination. For the COX-1 assay, an aliquot of fresh blood is mixed with either DMSO or test compound and is allowed to clot for 1 h at 37°C. TBX_2 levels in the serum are measured using an enzyme immunoassay after deproteination.

MODIFICATIONS OF THE METHOD

Young et al. (1996) and Khanapure et al. (2003) used a similar assay to determine COX-1 and COX-2 enzyme activity in human whole blood. Human blood from non-fasted donors, who had not taken any aspirin or NSAIDs for 14 days, was collected in sodium heparin and distributed in 1-ml aliquots per well in a 24-well tissue culture plate. The plate was placed on a gently rotating platform shaker in a 5% CO_2 incubator at 37°C for 15 min. Test compounds were dissolved and diluted in dimethylsulfoxide (DMSO) and 1 µl of each dilution of test compound was added per well in duplicate wells. To induce COX-2, lipopolysaccharide (LPS) from *E. coli* was added at 10 µg/ml to appropriate wells 15 min after addition of the test compounds. For the stimulation of COX-1, the calcium ionophore A23187 was added to a final concentration of 25 µM to separate wells 4.5 h after the addition of the test compounds. At 30 min after addition of A23187 or 5 h after LPS addition, all incubations were terminated by cooling on ice and adding EGTA to a final concentration of 2 mM. The blood samples were then transferred to 15 ml polypropylene centrifuge tubes and centrifuged at 1200 *g* for 10 min at 4°C. Then, 100 µl of plasma was removed from each blood sample and added to 1 ml of methanol in a 15 ml polypropylene centrifuge tube, mixed vigorously, and stored overnight at –20°C. The next day, the samples were centrifuged at 2000 *g* for 10 min at 4°C, and the supernatants were transferred to glass tubes and evaporated to dryness. After reconstitution with EIA buffer, and appropriate dilution (2000-fold for COX-1 and 500-fold for COX-2), the samples were assayed for thromboxane B2 using EIA kits (Cayman, Ann Arbor, Mich., USA) in duplicate wells.

Kalajdzic et al. (2002) showed that a preferential COX-2 inhibitor suppresses peroxisome proliferator-activated receptor induction of COX-2 gene expression in human synovial fibroblasts.

Berg et al. (1997) developed a cell assay system using the human erythroleukemic cell line HEL as a source for COX-1 and the human monocytic cell line Mono Mac 6 as a source for COX-2.

Kalgutkar et al. (2000) exploited biochemical differences between the COX isoforms to improve upon the selectivity of carboxylate-containing NSAIDs as COX-2 inhibitors.

Faust et al. (2003) recommended human peritoneal macrophages in culture as a model for studying inflammatory disorders *in vitro*.

Krause et al. (2003) reported that the NSAIDs indomethacin and diclofenac and a selective COX-2 inhibitor uncouple mitochondria in intact cells. To analyze the effects on energy metabolism of rat thymocytes, top-down elasticity analysis (Brand 1996, 1998; Ainscow and Brand 1999) was applied. Energy metabolism was conceptually divided into three blocks of reactions that generated and consumed the central intermediate mitochondrial membrane potential (ψ_m). The substrate oxidation subsystem encompassed all cellular catabolic reactions that provide the respiratory chain with its substrates NADH and succinate (e. g., glucose, fatty acid, and amino acid metabolism) and the electron transport chain itself, which together generate ψ_m. The ψ_m -consuming reactions were further divided into the subsystems proton leak and ATP turnover. The ATP turnover subsystem encompassed ATP synthesis by ATP synthase and subsequent ATP consumption by cellular pathways (e. g., ion pumps or protein synthesis). Manipulation of the biochemical properties of one block of reactions prompted a change of the intermediate ψ_m. The whole system evolved into a new steady state, which was determined by the kinetic responses of the other blocks to changes of ψ_m. Successive inhibition of one block of reactions permitted determination of these kinetic responses of the other blocks to changes of ψ_m. A comparison of the kinetic responses in the presence and absence of effectors (e. g., drugs) allowed for the identification of sites of actions.

H.3.1.7 Influence of Cytokines

H.3.1.7.1 Induced Release of Cytokines (Interleukin-1α, IL-1β, IL-6, IL-8 and TNFα) from Human White Blood Cells In Vitro

PURPOSE AND RATIONALE

Cytokines represent a class of different, biologically highly potent peptides, that are endogenously syn-

thesized upon stimulation. They are involved in numerous cellular processes, such as inflammation, immunological responses and many others. Their broad pleiotrophic biological activities are best characterized by their former classification as

- B-cell activating and differentiating factor, endogenous pyrogen, osteoclast activating factor, thymocyte proliferation factor, monocyte cell factor, leukocyte endogenous factor (IL-1);
- hepatocyte stimulatory factor, hybridoma growth factor, haematopoietic cell stimulatory factor (IL-6);
- neutrophil chemotactic factor and adhesion inhibitor (IL-8);
- tumor necrosis factor (TNFalpha).

There are presently 18 cytokines with the name interleukin (IL) (Dinarello 2000). The concept of proinflammatory cytokines and antiinflammatory cytokines (IL-4, IL-10, IL-13) is fundamental to cytokine biology and novel drug discovery strategies.

Blocking IL-1 or TNF has been highly successful in patients with rheumatoid arthritis, inflammatory bowel disease, or graft-vs.-host disease.

The following procedure is used to detect compounds that interact with the lipopolysaccharide in ced cytokine release from human mononuclear blood cells. The cytokines measured are interleukines 1alpha, 1beta, 6 and 8, as well as TNFalpha.

PROCEDURE

According to Böyum (1976)10 ml of freshly prepared human citrated blood is diluted 1:1 with PM 16-buffer (Serva, Heidelberg, FRG), and underlayered with 15 ml Lymphoprep (Molter GmbH, Heidelberg, FRG), and subsequently centrifuged at 20°C with 400 *g* (Minifuge, Heraeus, Hanau, FRG) for 30 min. The cell fraction appearing as a white ring between the two phases is carefully removed by means of a syringe, diluted 1:1 (v/v) with PM 16 and again centrifuged for 15 min. The pellet is washed with 10 ml of RPMI 1640 (Gibco, Berlin, FRG), containing in addition 300 mg/l L-glutamine. The washed cell fraction is taken up in 1 ml RPMI 1640, containing in addition 300 mg/l L-glutamine, 25 mmol/l HEPES, 5% FCS and 100 IU/ml penicillin/streptomycin (Gibco). Using a cell counter (type IT, Coulter Diagnostics, Krefeld, FRG) the cell suspension which consists of about 90% lymphocytes and 10% monocytes is adjusted to approx. 5×10^9 cells/ml.

Synthesis and release of cytokines according to Tiku et al. (1986) is performed in 96 wells microtiter plates. To 0.23 ml of the cell fraction 500 ng LPS (lipopolysaccharide from Salmonella abortus equii, Sigma GmbH, Deisenhofen, FRG), dissolved in 0.01 ml dimethylsulfoxide/water (1:10, v/v), and the investigational drug, dissolved in 0.01 ml, are added. The cell suspension is now kept at 37°C/5% CO_2 in a common incubator. Incubation time is usually 20 h (for Il-6 and Il-8 only four or one hour, respectively). The reaction is stopped by placing the microtiter plate into an ice bath. The plate is then centrifuged at 2000 rpm for 2 min. The cytokine levels are determined in various aliquots of the supernatant using the appropriate ELISA-kit, which is commercially available from several distributors.

EVALUATION

The cytokine-concentration in the sample is determined from appropriate calibration curves. The cytokine-concentration is measured as a function of drug concentration, and related to a control experiment without drug. In general, Hostacortin (10 to 0,1 µmol/l) is used as the standard compound.

CRITICAL ASSESSMENT

Drugs interfering with LPS-activation, biosynthesis and cellular release of cytokines are to exhibit activity in these assay systems. Usually cell viability is not altered, as assessed by the lactate-dehydrogenase test.

MODIFICATIONS OF THE METHOD

Van der Pouw-Kraan et al. (1992) examined the regulation of interleukin (IL)-4 production by human peripheral blood T cells. Production of IL-4 as measured by ELISA was shown to be regulated differently from IL-2 and INF-γ (also measured by ELISA).

A proinflammatory role for interleukin-18 (IL-18) in rheumatoid arthritis was attributed by Gracie et al. (1999).

The role of the interleukin-6 family of cytokines in inflammatory arthritis and bone turnover was reviewed by Wong et al. (2003).

Kim et al. (2005) reported an inhibitory effect of luteolin, a flavonoid from *Lonicera japonica*, on tumor-necrosis-factor-α-induced IL-8 production in human colon epithelia cells.

H.3.1.7.2 Flow Cytometric Analysis of Intracellular Cytokines

PURPOSE AND RATIONALE

Flow cytometry is a powerful analytical technique in which individual cells can be simultaneously analyzed for several parameters, including size an granularity, as well as the expression of surface and intracellular markers defined by fluorescent antibodies. Fluorescent anti-cytokine and anti-chemokine monoclonal antibodies are very useful for the intracellular staining and multiparameter flow cytometric analysis of individual cytokine-producing cells within mixed populations. Multicolor immunofluorescent staining with antibodies against intracellular cytokines and cell surface markers provides a high resolution method to identify the nature and frequency of cells which express particular cytokines (Sander et al. 1991, 1993; Jung 1993).

PROCEDURE

Cells and Cell Culture

Peripheral blood is obtained from healthy human volunteers. Mononuclear cells are isolated by Ficoll gradient centrifugation. For purification of T cells or further cell sorting, mononuclear cells are incubated with neuraminidase treated sheep red blood cells and centrifuged over Ficoll. Erythrocytes are eliminated by ammonium chloride lysis. For isolation of memory cells or naive cells, T cells are incubated with a cocktail of antibodies containing anti-CD16, anti-CD56, anti-CD20, anti-CD14, (anti-CD8), and anti-CD45RA or anti-CD45R0. Cell sorting is done with the magnetic cell sorter (MACS) according to Abts et al. (1989), Miltenyi et al. (1990) using rat anti-mouse IgG1 or Ig2a antibodies labeled with superparamagnetic beads (Miltenyi, Bergisch Gladbach, Germany). Depleted cells are highly enriched with $CD4^+(CD3^+)CD45R0^+$ or $CD4^+(CD3^+)CD45R0^-CD45RA^+$ cells (>95%) and are referred to as memory cells and naive cells ($CD4^+CD45R0^-CD45RA^+$) respectively. Only depleted cells are used for experiments.

Cells (2×10^5/100 ml) are cultured in 96 well flat bottom plates for various periods of time at 37°C and 8% CO_2 in RPMI 1640 supplemented with 2 mM glutamine, 1 mM sodium pyruvate, 100 IU/ml penicillin, 100 µg/ml streptomycin, 2×10^{-5} M mercaptoethanol and 10% AB serum. Cells are stimulated with phorbol 12-myristate 13-acetate 1–10 ng/ml+1 µM ionomycin, phytohemagglutinin 2.4 µg/ml or phytohemagglutinin 2.4 µg/ml+phorbol 12-myristate 13-acetate 1 ng/ml in the presence or absence of 3 µM monensin (Sigma).

Staining

Cultured cells are washed twice in Hanks' balanced solution (HBSS) and then fixed in ice-cold HBSS containing 4% paraformaldehyde for 10 min. After two further washes in HBSS the cells are resuspended to 2×10^5 in 300 µl HBSS containing 0.1% saponin, 10% AB serum, 100 µ g/ml goat IgG and 0.01 M HEPES buffer. After 10 min, the cells are spun

down and cytokine specific antibodies diluted in HBSS with 0.1% saponin and 0.1 M HEPES buffer (saponin buffer) are added at a concentration of 1 µg/ml for 30 min at room temperature. Cells are washed twice in saponin buffer and subsequently incubated with isotype-specific second step antibodies in a concentration ranging from 0.5 to 5 µg/ml for 20 min in the dark. Cells are washed in saponin buffer and stained with streptavidin conjugates or in the case of surface staining incubated with 200 µg/ml mouse IgG diluted in saponin buffer for 15 min. After subsequent washing in saponin buffer cells are washed twice in HBSS and stained for 20 min with different antibodies in order to determine their surface phenotype. As a last step, cells are washed in HBSS.

Flow Cytometry

A FACScan flow cytometer (Becton Dickinson, Mountain View, USA) equipped with a 15 mW argon ion laser and filter settings for fluorescein-isothiocyanate (530 nm), phycoerythrin (585 nm) and TRI-Color (Medac, Hamburg, Germany) or PerCP (Becton Dickinson, USA) emitting in the deep red (>650 nm) is used.

EVALUATION

5000–10000 cells are computed in list mode and analyzed using the FACScan research software (Becton Dickinson)

MODIFICATIONS OF THE METHOD

Slauson et al. (1999) combined the analytical power of flow cytometry with mitogen-driven, whole blood lymphocyte activation and proliferation assays to investigate the *in vitro* mechanism of action of malononitrilamides.

Protocols for immunofluorescent staining of intracellular cytokines for flow cytometric analysis are provided by BD Phar Mingen, Life Science Research Europe, Heidelberg, Germany.

Ashcroft and Lopez (2000) highlighted the opportunities in high throughput flow cytometry (HTFC) which are opened by commercial high speed machines. The specifications of these machines are cell analysis rates over 100,000 cells/s and cell sorting rates of 55,000 cells/s with high purity.

H.3.1.7.3 Screening for Interleukin-1 Antagonists

PURPOSE AND RATIONALE

Interleukin-1α and -1β are potent regulators of inflammatory processes. The naturally occurring IL-1 receptor antagonist (IL-1ra) is effective *in vitro* and *in vivo* in modulating biological responses to IL-1 (Carter et al. 1990; Hannum et al. 1990; Schreuder et al. 1995). Using a combination of anion exchange, gel filtration, and reverse-phase HPLC, three species of native IL-1ra were identified. An unglycosylated, intracellular isoform is designated as icIL-1ra (Lennard 1995; Arend et al. 1991, 1998).

A cell-free, non-isotopic assay has been developed to discover molecules that compete with the natural ligands for binding to the active sites of the type-I IL-1 receptor. The key reagents are the IL-1 receptor antagonist, a recombinant soluble form of the receptor (sIL-1R), and a specific anti-sIL-1R non-neutralizing monoclonal antibody (Sarrubi et al. 1996).

PROCEDURE

Proteins

The extracellular portion of the type-I IL-1 receptor (sIL-1R) is expressed on the membrane of Chinese hamster ovary cells using a phosphatidinyl-inositol-glycan linkage (PIG-tail). Its expression, cleavage with phosphoinositol-specific phospholipase C, and purification are performed according to Whitehorn et al. (1995).

The three IL-1 ligands are expressed in *Escherichia coli* using synthetic genes (Dower et al. 1989; Yanofsky and Zurawski 1990). The purification of IL-1ra

and IL-β is accomplished according to Schreuder et al. (1995) and Yem et al. (1988).

IL-1α is purified as follows: *E. coli* cell sonicates are precipitated with 2 M ammonium sulfate, and the pellet is resuspended in TE (25 mM Tris/HCl, pH 8.9, 1 mM EDTA), dialyzed against the same buffer and loaded on a DEAE-Sepharose column equilibrated with TE. The protein is eluted with a linear NaCl gradient to 300 mM. Ammonium sulfate to 0.8 M is added to the IL-1α-containing fractions which are loaded onto a phenyl-Sepharose column equilibrated with TE containing 0.8 M ammonium sulfate. The elution is performed with a linear gradient to TE with no salt. IL-1α-containing fractions are concentrated and chromatographed on a Sephacryl S-200 column in PBS (phosphate-buffered saline: 20 mM sodium phosphate, pH 7.3, 150 mM sodium chloride).

Fluorescein-labeled IL-1α is obtained by incubating 1 mg/ml IL-1α with 1 mg/ml fluorescein isothiocyanate in PBS for 2 h at room temperature in the dark. The reaction solution is passed directly over a G-25 column (Pharmacia) equilibrated with PBS to remove unreacted fluorescein isothiocyanate.

The monoclonal antibody Mab79 is used as direct dilutions ($1{:}10^5$–10^6) of ascitic fluid in PBSA (PBS containing 0.3% bovine serum albumin). Horseradish-peroxidase-linked anti-mouse IgG polyclonal antibody is used.

Protein concentrations are determined using the Bio-Rad protein assay kit, based on the dye-binding procedure according to Bradford (1976). BSA is used as reference protein.

Immobilized-Ligand IL-1 Receptor Binding Assay

Essentially the same procedure can be used for both manual and automated versions of the assay, with all steps and incubations performed at room temperature. In the automated assay a Beckman Biomek 1000 Work-Station was used for all steps, from coating to spectrophotometric measurements.

Ligand immobilization is obtained by incubation of 3.6 µg/ml IL-1ra in 50 µl PBS in flat-bottomed culture-treated microplate wells, equivalent to 10 pmol/well of IL-1ra. After overnight incubation microplates are emptied and 250 µl/well of 3% BSA in PBS is added to block unreacted sites. After 2 h of incubation and three washes with an excess of PBS, the ligand-coated microplates are ready for the receptor binding reaction.

In separate microplates with U-shaped wells, 12 µl of samples (containing up to 50% DMSO or DMF) or controls (the same solution without compound) is mixed with 48 µl of 150 pM sIL-1R in PBSA. Then 50 µl of these mixtures is transferred to the IL-1ra-coated plates (equivalent to 6 fmol/well of sIL-1R) and incubated for 2 h. Microplates are then washed twice with PBS and 50 µl of 1:500,000 dilution of Mab79 ascitic fluid in PBSA is added to each well. After 1 h of incubation, 25 µl of 1:100 dilution of HRP-labeled anti-mouse IgG in PBSA is added and the incubation prolonged for an additional hour. Plates are finally washed four times with PBS and bound peroxidase activity is measured spectrophotometrically, using either *o*-phenylenediamine (OPD) or tetramethylbenzidine (TMB) as substrate. In the first case, 150 µl of 1 mg/ml OPD in 0.1 M citric acid, pH 5.0, containing 0.03% of a 35% solution of hydroperoxide is added and, after color development, the reaction is stopped with 50 µl of 4.5 M sulfuric acid. Alternatively, 100 µl of 0.1 mg/ml TMB in 25 mM citric acid and 50 mM sodium phosphate, containing 0.02% hydrogen peroxide (35% solution), is added and the reaction is stopped with 50 ml of 2.5 M sulfuric acid.

EVALUATION

Absorbance (at 492 nm for OPD and 450 nm for TMB) is measured using either a Titertek microplate reader (for the manual procedure) or directly by the Biomek 1000 WorkStation (in the automated version). IC_{50} values can be calculated from dose–response curves.

CRITICAL ASSESSMENT OF THE METHOD

Since no cells or cell membranes are used, the assay is very robust, with no interference from membrane-perturbing agents, and has high resistance to the organic solvent normally used to resuspend compounds of chemical libraries.

MODIFICATIONS OF THE METHOD

High-affinity type I interleukin-1 receptor antagonists were discovered by screening recombinant peptide libraries (Yanosfky et al. 1996).

Akeson et al. (1996a) developed an *ex vivo* method for studying inflammation in cynomolgus monkeys using whole blood for analysis of IL-1 antagonists administered *in vivo*. Animals were given an i.v. infusion of IL-1ra, and blood samples were taken pre-infusion and during the infusion. The samples were incubated with or without IL-1β and the subsequent *ex vivo* induction of IL-6 determined. This allows the analysis of the *in vivo* efficacy of antagonists without exposing the animals to IL-1.

A novel low-molecular-weight antagonist, selectively binding the type I IL-1 receptor and blocking the *in vivo* responses to IL-1 was described by Akeson et al. (1996b).

Evaluation of the IL-1 receptor antagonist IL-1ra in a rodent abscess model of host resistance was published by Colagiovanni and Shopp (1996).

Blocking monoclonal antibodies (mAbs) specific to mouse IL-1 receptor antagonist (IL-1ra) were prepared by immunizing Armenian hamsters with recombinant mouse IL-1ra by Fujioka et al. (1995). A sensitive and specific ELISA against mouse IL-1ra was established.

Miesel et al. (1995) tested the anti-arthritic reactivity of the IL-1 receptor antagonist IL-1ra in male DBA/1xB10A(4R) mice with arthritis induced by intraplantar injection of potassium peroxochromate. Then 3 µ mol/kg K_3CrO_8 was administered topically into the left hind paws and 1 h after the induction of arthritis, 2 mg/kg IL-1ra was administered intraperitoneally, which was repeated on day 2. An arthritis index was determined daily.

Nakae et al. (2003) found that IL-17 production from activated T cells is required for the spontaneous development of destructive arthritis in mice deficient in IL-1 receptor antagonist.

Redlich et al. (2003) reviewed rheumatoid arthritis therapy after tumor necrosis factor and interleukin-1 blockade.

H.3.1.7.4 Inhibition of Interleukin-1β Converting Enzyme (ICE)

PURPOSE AND RATIONALE

Programmed cell death (apoptosis) is effected through a cascade of intracellular proteases known as caspases (Alnemri et al. 1996). The interleukin-1β-converting enzyme (ICE), alternatively known as capsase-1, was

the first such protein identified on the basis of its sequence homology to the pro-apoptotic *Caenorhabditis elegans* gene product, ced-3 (Yuan et al. 1993). The caspase family includes 10 reported human homologs of ICE. By sequence homology comparisons between three caspase subfamilies have been identified. The ICE subfamily includes three caspases: ICE, TX (caspase-4), and TY (caspase-5). The CPP32 subfamily includes CPP32 (caspase-3), CMH-1 (caspase-7), and MCH-2 (caspase-6). A third caspase subfamily includes ICH-1 (caspase-2), FLICE (caspase-8) and caspases-9 and -10.

ICE processes pro-IL-1β to yield active IL-1β, which plays a pivotal role in inflammatory cell activation (Dinarello 1996) and is known to inhibit the expression of apoptosis (Tatsuda et al. 1996). Inhibition of IL-1β formation is an approach for the treatment of inflammatory disorders such as rheumatoid arthritis. Livingstone (1997) presented a review on *in vitro* and *in vivo* studies of peptidyl ICE inhibitors.

PROCEDURE

Neutrophil Isolation

Neutrophils are isolated from healthy volunteers by dextran sedimentation and centrifugation through a discontinuous Ficoll gradient (Lee et al. 1993). Isolated neutrophils are resupended in polypropylene tubes at a concentration of 1×10^6 cells/ml in DMEM supplemented with 10% FCS, 1% glutamine, and 1% penicillin/streptomycin solution. Neutrophil purity is assessed by size and granularity on flow cytometry.

Quantification of Apoptosis

Neutrophil apoptosis is quantified by flow cytometry as the percentage of cells with hypodiploid DNA (Nicoletti et al. 1991). Cells are centrifuged at 200 *g* for 10 min, gently resuspended in 500 µl of hypotonic fluorochrome solution (50 µg/ml propidium iodide, 3.4 mM sodium citrate, 1 mM Tris, 0.1 mM EDTA, and 0.1% Triton X-100) and stored in the dark at 4°C for 3–4 h before analysis using a Coulter Epics XL-MCL cytofluorometer. A minimum of 5000 events are collected and analyzed. Apoptotic nuclei are distinguished from normal neutrophil nuclei by their hypodiploid DNA; neutrophil debris is excluded from analysis by raising the forward threshold. Apoptotic nuclei appear as a broad hypodiploid DNA peak which is easily discernible from the narrow peak of cells with normal diploid DNA content. Apoptosis is assessed at 24 h after treatment.

Assay of Caspase-1 Activity

Cell lysates are prepared from the membrane fraction of 20×10^6 neutrophils following experimental manipulation. Aliquots of the lysates (10 µl) are diluted in assay buffer 100 mM HEPES (pH 7.4), 10% sucrose, and 0.1% 3-([[3-cholamidopropyl]dimethylammonio]-1-propanesulfonate) containing 20 µM Ac-Tyr-Val-Ala-Asp-7-amino-4-methylcoumarin (Calbiochem) and then incubated for 45 min at room temperature. The release of 7-amino-4-methylcoumarin is detected by continuous measurement using a Perkin-Elmer LS50 luminescence spectrometer with an excitation of 380 nm and an emission slit at 460 nm. Specific ICE (caspase-1) activity is measured as pmol/s per milligram of protein.

EVALUATION

Individual experiments are repeated a minimum of four times; results are expressed as the mean ±SD. Analysis is performed using the Student's *t*-test or ANOVA with Scheffè's correction.

MODIFICATIONS OF THE METHOD

Norman et al. (1997) found that the severity and mortality of experimental pancreatitis are dependent on interleukin-1 converting enzyme.

H.3.1.7.5
Nuclear Factor-κB

H.3.1.7.5.1
General Considerations

Nuclear factor kappa B (NF-κB) is an inducible transcription factor of the Rel family, sequestered in the cytoplasm by the IκB family of proteins. NF-κB exists in several dimeric forms, but the p50/p65 heterodimer is the predominant one. Activation of NF-κB by a range of physical, chemical, and biological stimuli leads to phosphorylation and proteasome dependent degradation of IκB, leading to the release of free NF-κB. This free NF-κB then binds to its target site (κB sites in the DNA), to initiate transcription. This transcription is involved in a number of diseases including cancer, AIDS, autoimmune diseases, and inflammatory disorders. The nuclear factor κB is essential for the transcriptional regulation of the proinflammatory cytokines IL-1, IL-6, IL-8 and tumor necrosis factor α. NF-κ B is also the target for glucocorticoid–mediated IL-8 repression. Reduction-oxidation (redox) regulation is implicated in the activation of NF-κB. (Mukaida et al. 1994, Aupperle et al. 1999, Christman et al. 2000a, 2000b, Nichols et al. 2001, D'Acquisto et al. 2002, Nishi et al. 2002, Palanki 2002, Tian et al. 2002, Heynink et al. 2003, Aggarwal et al. 2004, Pande and Ramos 2003, 2005, Kaltschmidt et al. 2005). The IKK complex, as a critical activator of NF-κB function, consists of a core of three subunits, two of which, namely IKKα and IKKβ contain functional kinase domains and are capable of phosphorylating IκB at specific N-terminal residues to initiate its ubiquitination. In contrast, the third core subunit of the IKK complex, called NEMO (also known as IKKγ or IKKAP) is a non-catalytic component that functions as a key regulator of IKK activity (Gosh and Karin 2002, Karin et al. 2004).

Studying joint erosion in rheumatoid arthritis O'Gradaigh et al. (2003) found that interactions between tumor necrosis factor α, interleukin, and receptor activator of nuclear factor κB ligand (RANKL) regulate osteoclasts

H.3.1.7.5.2
Inhibition of Nuclear Factor-κB

PURPOSE AND RATIONALE

Several authors studied the inhibition of NF-κB by compounds.

Staal et al. (1990) found that intracelluar thiols regulate activation of nuclear factor κB and transcription of human immunodeficiency virus. Schrenk et al. (1992) reported dithiocarbamates as potent inhibitors of nuclear factor κB activation in intact cells. Natara-

jan et al. (1996) described caffeic acid phenyl ester as a potent and specific inhibitor of activation of nuclear transcription factor NF-κB. Geng et al. (1997) reported that S-allyl cysteine inhibits activation of nuclear factor κB in human T cells. Hiramoto et al. (1998) described nuclear-targeted suppression of NF-κB by a quinone derivative. Ichiyama et al. (1999) found inhibition of peripheral NF-κB activation by a central action of α-melanocyte-stimulating hormone. Castrillo et al. (2001) described inhibition of the nuclear factor κ B pathway by tetracyclic kaurene diterpenes in macrophages with specific effects on NF-κB-inducing kinase activity and on the coordinated activation of ERK and p38 MAPK. Kang et al. (2001) reported that genistein prevents nuclear factor kappa B activation and acute lung injury induced by intratracheal treatment of rats with lipopolysaccaride. Lee et al. (2002) found that kamebakaurin, a kaurane diterpene, inhibits NF-κB by directly targeting the DNA-binding activity of p50 and blocks the expression of antiapoptotic NF-κB target genes. Palanki et al. (2002) reported structure–activity relationship studies of ethyl 2-[3-methyl-2,5-dioxo(3-pyrrolinyl) amino]-4-(trifluoromethyl)pyrimidine-5-carboxylate, an inhibitor or AP-1 and NF-κB mediated gene expression. Kim et al. (2004) found that tripolide, a natural compound extracted from the Chinese herb *Tripterygium wilfordii*, inhibits murine-inducible nitric synthase expression by down-regulating lipopolysaccharide-induced activity of nuclear factor κB and c-Jun NH_2-terminal kinase. Jancso et al. (2005) studied the effect of acetylsalicylic acid on nuclear factor-κB activation and on late preconditioning against infarction of the myocardium. Kunsch et al. (2005) described redox-sensitive inflammatory gene expression of AGIX-4207, an antioxidant and anti-inflammatory compound.

Tse et al. (2005) found that honokiol, a small m olecular weight lignan isolated from *Magnolia officinalis*, inhibits tumor-necrosis-factor-α-stimulated NF-κB activation and NF-κB-regulated gene expression through suppression of inhibitor κB kinase (IKK) activation.

PROCEDURE

Honokiol was dissolved in DMSO as a 100 mM stock solution and stored at -20°C.

Cell Culture

The cell lines used in this experiment were obtained from American Type Culture Collection (Manassas, Va., USA). U937 and HL-60 cells were grown in RPMI-1640 medium containing 10% fetal bovine serum, 100 U/ml penicillin, and 100 µg/ml streptomycin (Gibco, NY, USA) at 37°C in humidified 5% CO_2 atmosphere. MCF-7 and HeLa cells were cultured in Eagles' minimum essential medium containing 10% fetal bovine serum under the same condition.

Electrophoretic Mobility Shift Assay (EMSA)

For the electrophoretic mobility shift assay according to Chaturvedi et al. (2000), equal quantities of nuclear protein (5 µg) from each sample was incubated with radiolabeled gel shift oligonucleotides for 15 min at 37°C and then resolved on a non-denaturing 5% (w/v) polyacrylamide gel. The gel was dried onto 3 MM blotting paper and used to expose X-ray film for overnight at −70°C. For supershift assays, 1 µl of antiserum recognizing each of the NF-κB subunits was added to the EMSA reaction 30 min before electrophoresis.

Western Blot Analysis

To obtain the whole-cell lysates, samples containing 1×10^7 cells were pelleted, washed twice with ice-cold PBS, then lysed in 150 µ l of modified RIPA buffer [50 mM Tris–Cl, 1% (v/v) NP-40, 0.35% (w/v) sodium-deoxycholate, 150 mM NaCl, 1 mM EDTA, 1 mM EGTA, pH 7.4] supplemented with 1 mM phenylmethylsulfonyl fluoride (PMSF), 1 mM NaF, 1 mM Na_3VO_4, 10 µg/ml each of aprotinin, leupeptin and pepstatin A for 20 min at 4°C. Supernatants after centrifugation at 14,000 *g* for 15 min at 4°C were collected. Alternatively, cytoplasmic extracts were prepared. Samples containing 30–50 µg of protein were separated on SDS-polyacrylamide gel and then transferred onto nitrocellulose membrane (0.45 µm, Bio-Rad). Membranes were immunoblotted with primary antibodies and followed by horseradish-peroxidase-conjugated secondary antibodies (1:5000) and visualized by ECL (Amersham Biosciences) according to manufacturer's instructions.

IKK Assay

Whole-cell lysates (500 mg) were collected in modified RIPA buffer without sodium deoxycholate, and cellular debris was removed by high-speed centrifugation. Lysates were pre-cleared by incubation with 0.25 µg of the appropriate control IgG together with 20 µl of protein A/G plus (25%, v/v) agarose conjugate for 30 min at 4°C, followed by centrifugation. Supernatants were then incubated with 1 µg of anti-IKKα/β for 2 h at 4°C, and then 20 µl of protein A/G plus agarose was added and incubated at 4°C on a rocker platform

overnight. After several washes with IP buffer and PBS, beads containing IKKα/β were incubated with 0.5 µg GST- Iκ *B*α substrate, 200 µM ATP in 20 µl kinase buffer (50 mM Tris–Cl pH 7.4, 20 mM $MgCl_2$, 20 mM β-glycerophosphate, 1 mM NaF, 1 mM Na_3VO_4, 1 mM PMSF, 0.5 mM DTT, 1 mM benzamidine, 10 µg/ml aprotinin and 1 µg/ml leupeptin) at 30°C for 30 min. Kinase reactions were stopped by the addition of 5 µl 5 × Laemmli's loading buffer and heated at 100°C for 5 min. The samples were resolved by 8% SDS-PAGE, electro-transferred to nitrocellulose membrane and probed with anti-phosphor-Iκ *B*α (Ser^{32}) antibody (1:1000). Membranes were re-probed with anti-IKK to ensure equal loading and the presence of total IKK protein.

Plasmids, Transfection and NF-κB-Dependent-Luciferase Reporter Assay

To measure the effect of honokiol on TNF-α-induced NF-κ B-dependent gene reporter transcription, HeLa cells were seeded into 24-well plates at a density 1.6×10^5 cells/well for 24 h. Subsequently, cells were transiently transfected with p3EnhConA-Luc or pControl-Luc (0.75 µg) using LipofectAMINE 2000 (Invitrogen). To normalize the transfection efficiency, cells were co-transfected with 0.25 µg of β-galactosidase control vector. After overnight incubation, cells were pre-treated with honokiol for 12 h following by 5 ng/ml TNF-α for 15 h and then harvested with 1 × reporter lysis buffer (Promega, Madison, Wis., USA). Relative luciferase activity was measured with a Bright-GLO luciferase assay system using POLARStar OPTIMA luminometer (BMG Labtechnologies). Luciferase activity was normalized with β-galactosidase activity, as measured by the Beta-GLO luciferase assay system according to the manufacturer's instructions.

To measure the effect of honokiol on NF-κB-dependent gene reporter transcription induced by various kinases, HeLa cells were transfected with p3EnhConA-Luc and β-galactosidase control vector together with 0.2 µg of expression vectors. After 5 h of incubation, cells were treated with honokiol for 24 h and then harvested and assayed as described above.

EVALUATION

Statistical analyses were performed using an unpaired two-tailed Student's *t*-test. Two compounds (A and B) were considered enhancing each other's actions if the effect of combined treatment (AB) was larger then the sum of their individual effects (AB > A + B) after subtraction of the respective background control values.

MODIFICATIONS OF THE METHOD

Mortellaro et al. (1999) reported that the immunosuppressive drug PNU156804 blocks IL-2-dependent proliferation and NF-κB and AP-1 activation in human primary T lymphocytes.

Spencer et al. (1999) found in murine NIH3T3 fibroblasts and primate COS-7 cells that taxol selectively blocks microtubule-dependent NF-κB activation by phorbol ester via inhibition of Iκ *B*α phosphorylation and degradation.

Yan and Polk (1999) reported that aminosalicylic acid inhibits IκB kinase α phosphorylation of Iκ *B*α in mouse intestinal epithelial cells.

Acarin et al. (2000) found that oral administration of the anti-inflammatory substance triflusal results in the downregulation of constitutive transcription factor NF-κB in the postnatal rat brain.

Eberhardt et al. (2002) studied involvement of nuclear factor κB and Ets transcription factors in glucocorticoid-mediated suppression of cytokine-induced matrix metalloprotease-9 expression in rat mesangial cells.

Kang et al. (2002) showed that inhaled nitric oxide attenuated acute lipopolysaccharide-induced lung injury in rabbits via inhibition of nuclear factor-κB.

Macotela et al. (2002) found on rat pulmonary fibroblasts that 16K prolactin induces NF-κB activation.

Roshak et al. (2002) reported small-molecule inhibitors of NF-κB for the treatment of inflammatory joint disease.

Burke et al. (2003) found that BMS-345541 is a highly selective inhibitor of IκB kinase that binds at an allosteric site of the enzyme and blocks NF-κB–dependent transcription in mice.

Castro et al. (2003) described β-carbolines as inhibitors of the NF-κB kinase.

Clarke et al. (2003) reported that two distinct phases of virus-induced nuclear factor κB regulation enhance tumor necrosis factor-related apoptosis-inducing ligand-mediated apoptosis in virus-infected cells.

Murata et al. (2003) described discovery of selective IKK-β serine-threonin protein kinase inhibitors.

Yadav et al. (2003) reported that a diarylheptanoid from lesser galangal (*Alpinia officinarum*) inhibits proinflammatory mediators via inhibition of mitogen-activated protein kinase, P44/42, and transcription factor nuclear factor-κB.

HMG-CoA reductase inhibitors (statins) inhibited the binding of nuclear proteins to both NF-κB and AP-1 DNA consensus oligonucleotides in human endothelial and vascular smooth muscle cells as assed by EMSA (Dichtl et al. 2003).

Gupta et al. (2004) discussed the essential role of caspases in epigallocatechin-3-gallate-mediated inhibition of nuclear factor *kappa*B and induction of apoptosis.

Mühlbauer et al. (2004) studied differential effects of deoxycholic acid and taurodeoxycholic acid on NF-κB signal transduction and IL-8 gene expression in human colonic epithelial cells.

Syrovets et al. (2005) found that acetyl-boswellic acids inhibit lipopolysaccaride-mediated TNF-α induction by direct interaction with IκB kinases.

Eberhardt et al. (2005) found that dissociated glucocorticoids equipotently inhibit cytokine- and cAMP-induced matrix degrading proteases in rat mesangial cells.

Matsubara et al. (2005) found that a histamine H1 receptor antagonist blocks histamine-induced proinflammatory cytokine production through inhibition of Ca^{2+}-dependent protein kinase C, Raf/MEK/ERK and IKK/ Iκ B/NF-κB signal cascades.

Mendoza-Milla et al. (2005) reported that NF-κB activation but not PIK/Akt is required for dexamethasone-dependent protection against TNF-α cytotoxicity in L929 cells.

APPENDIX

Electrophoretic Mobility Shift Assay (EMSA)

Most papers mentioned above used the electrophoretic mobility shift assay (EMSA) for determination of nuclear factor κB. This method is one of the most sensitive ones for studying the DNA-binding properties of a protein. It can be used to deduce the binding parameters and relative affinities of a protein for one or more DNA sites or for comparing the affinities of different proteins to the same sites (Fried 1989). It is also useful for studying higher-order complexes containing several proteins, observed as a "supershift assay." EMSA can also be used to study protein- or sequence-dependent DNA bending (Crothers et al. 1991).

In an EMSA, or simple "gel shift," a ^{32}P-labeled DNA fragment containing a specific DNA site is incubated with a candidate DNA-binding protein. The protein–DNA complexes are separated from free (unbound) DNA by electrophoresis through a nondenaturing polyacrylamide gel. The protein retards the mobility of the DNA fragments to which it binds; thus, the free DNA migrates faster through the gel than does the DNA–protein complex. An image of the gel reveals the positions of the free and bound ^{32}P-labeled DNA.

A protocol of the detailed procedure was described by Carey and Smale (2000).

PROCEDURE

1. Prepare a 40-ml 4.5% native acrylamide gel (using 1- to 1.5-mm spacers)

Acrylamide mix (30%:29:1 acrylamide:bisacrylamide)	6 ml
5 × Tris-borate/EDTA (TBE) buffer	4 ml
Glycerol (20% vol/vol)	2 ml
Water	28 ml
Ammonium persulfate (10% solution in water)	300 µl
N,N,N,N-tetramethylenediamine (add just before pouring the gel)	30 µl

Pre-run the gel for 2 h at 10 mA.

2. Set up binding reactions in 0.5-ml siliconized microcentrifuge tubse

Recombinant protein (0.5–100 ng)	1.00 µl
^{32}P-labeled DNA template (ideally 1 fmol)	1.00 µl
Poly(dl:dC) (1 µg/µl)	0.20 µl
Dimethylsulfoxide (0.1 M)	0.10 µl
$MgCl_2$ (0.1 M)	0.75 µl
Buffer D	6.70 µl
Water	to 10 µl

Buffer D is 20 mM HEPES-KOH (pH 7.9), 20% glycerol (vol/vol), 0.2 mM EDTA, 0.1 M KCl, 0.5 mM phenylmethylsulfonyl fluoride (PMSF), 1 mM DTT. Add PMSF and DTT just before use.

3. Incubate the reaction at 30°C (incubate at 15°C–25°C or on ice for crude extracts) for 1 h.
4. Load the samples directly (with no dye) onto gel. Carefully layer the mix onto the bottom of the well and observe the schlieren line form at the glycerol–buffer interface.
5. Rune the gel for desired time at 10 mA; for a 30-bp fragment, allow the bromophenol blue dye to migrate about two-thirds of the way down the gel.
6. When the electrophoresis run is complete, carefully pour out the buffer into the sink and remove the gel from the apparatus. Remove the comb and split the plates, leaving the gel attached to one plate.
7. (Optional) Fix the gel in gel fixing solution (200 ml methanol, 100 ml acetic acid, 700 ml water) at 15°C–25°C for 15 min.
8. Place the gel on two sheets of Whatman 3MM paper. Cover the other side of the gel with Saran Wrap and dry on a gel dryer at 70°C for 1 h.
9. Expose the gel to autoradiography film or to phosphorimager screen overnight.

H.3.1.8 TNF-α Antagonism

H.3.1.8.1 General Considerations

TNF-α has been cloned and identified by Beutler et al. (1985). It is primarily produced in macrophages, lymphocytes, neutrophils, endothelial cells, keratinocytes and fibroblasts during acute inflammatory reactions. TNF-α is a member of a large family of proteins and receptors that are involved in immune regulation such as kinases, including nuclear factor kappa B (NF-κ B), p38 MAP kinase, JUN kinases and others. Therefore, it is a therapeutic target for immune-mediated inflammatory diseases (Pfizenmaier et al. 1996; Van Deventer 1997; Rath and Aggarwal 1999; Feldmann et al. 2001; Furst et al. 2001; Taylor 2001; Doggrell 2002; Braun et al. 2003; Sharma and Anker 2003; Louie et al. 2003; Nanes 2003; Peng et al. 2003; Chen et al. 2003; Taylor et al. 2004; Gupta et al. 2005; Pfeifer et al. 2006; Reber et al. 2006; Wagner and Laufer 2006). This may be achieved by small molecular anti-cytokine agents inhibiting cytokine production, which target p38 mitogen activated protein (MAP) kinase, TNF-α converting enzyme (TACE), or IL-1β converting enzyme (ICE).

Several so-called "biologicals" are in clinical use:

Etanercept (Enbrel), a fully human soluble TNF receptor fusion protein consisting of the extracellular ligand-binding domain of the 75-kDa receptor for human tumor necrosis factor-α and and the constant portion of human IgG1 (Jarvis and Faulds 1999; Pugsley 2001; Scallon et al. 2002; Agnholt et al. 2003; Cole and Rabasseda 2004; Goffe 2004; Moe et al. 2004; Vallejo et al. 2005). The compound has been approved for treatment of psoriasis, psoriatic arthritis, ankylosing spondylitis and rheumatoid arthritis.

Infliximab (Remicade), a chimeric anti human TNF-α monoclonal antibody (Scallon et al. 2002; Agnholt et al. 2003; Di Sabatino et al. 2004; Wagner et al. 2004; Panaccione et al. 2005; Shen et al. 2005; Pfeifer et al. 2006). The compound is used for treatment of rheumatoid arthritis and Crohn's disease.

Adalimumab (HUMIRA), a recombinant human anti-human TNF-α monoclonal antibody (Gordon et al. 2005; Aggarwal et al. 2006; Scheinfeld 2006; Shen et al. 2006). The compound is used for treatment of rheumatoid arthritis and psoriatic arthritis.

Imatinib mesylate (STI571, Gleevec), a kinase inhibitor of TNF-α production (Kilic et al. 2000; Traxler et al. 2001; Dietz et al. 2004; Kaelin 2004; Lassila et al. 2005; Wolf et al. 2005; Adcock et al. 2006). The compound has been found to be active in the treatment of chronic myelogenous leukemia, gastrointestinal stromal tumors, eosinophilic disorders, and systemic mast cell disease.

Omalizumab (Xolair), a recombinant humanized monoclonal antibody which specifically binds the Cε3 domain of IgE, the site of high-affinity IgE receptor binding (Easthope and Jarvis 2001; Anonymous 2002; Johansson et al. 2002; Davis 2004; Richards et al. 2004; Belliveau 2005; D'Amato 2006). The compound is used for treatment of bronchial asthma and allergic rhinitis.

Anakinra (Kineret) is a specific recombinant human interleukim-1 receptor antagonist that differs from naturally occurring IL-1 receptor antagonist by the presence of a methionine group (Cvetkovic and Keating 2002; Fleischmann et al. 2004; Le and Abbenante 2005; Waugh and Perry 2005). The compound is effective in patients with active rheumatoid

arthritis, either when given alone or in combination with methotrexate.

H.3.1.8.2 Inhibition of TNF-α Release

PURPOSE AND RATIONALE

There are two distinct types of tumor necrosis factors, TNF-alpha (cachectin) and TNF-beta (lymphotoxin), with biological activities going beyond the necrosis of tumor cells. Some of the known activities include the induction of interleukin 1, activation of PMNs, modulation of endothelial cell functions, and augmentation of specific immune functions. The complex sequence of hemodynamic and metabolic collapse, which leads to shock and death during lethal endotoxinemia, appear to represent the response of the infected host to the acute, systemic release of TNF-alpha. Thus, drugs that antagonize the activity of this mediator could be of clinical value in combating its fatal effects.

PROCEDURE

Twenty hours before the initiation of the experiments, L 929 cells are harvested from stock cultures and are plated in 96 well culture plates (2×10^4 cells/well) and incubated at 37°C and 5% CO_2 in air. For each group 6 wells are set up. The cells are then preincubated for 30 min with test substances or solvent before TNF-alpha is added (between 1 and 10 IU/well). After an additional incubation time of 20 h, the culture plates are flicked out and the remaining living cells are lysed by the addition of bidistilled water (100 µl). After 30 min incubation at room temperature, 100 µl of LDH reagent are given to each culture well. After 15 min, the enzyme activity is determined photometrically at 490 nm.

EVALUATION

The percent inhibition is calculated according to the formula:

$$\% \text{ inhibition} = 100\% - \frac{\text{ext. test group} - \text{ext. spontaneous lysis}}{\text{ext.positive control} - \text{ext. spontaneous lysis}} .$$

The positive control is the group which receives vehicle and TNF-alpha. The spontaneous lysis is based on cultures which receive vehicle without TNF-alpha.

MODIFICATIONS OF THE METHOD

Maloff and Delmendo (1991) measured the binding of tumor necrosis factor (TNF-α) to the human TNF receptor. Membranes were prepared from HeLa S3 human cervical epithelioid carcinoma cells. An aliquot of 0.2 mg of membrane preparation was incubated with 62 pM [^{125}I]TNF-α for 3 h at 4°C. Nonspecific binding was measured in the presence of 50 nM TNF-α. Membranes were filtered and washed 3 times and the filters were counted to determine the bound [^{125}I]TNF-α.

Golebiowski et al. (2005) tested pyrazolone-based cytokine synthesis inhibitors for the inhibition of TNF-α production using lipopolysaccharide-stimulated monocytic cells. Duplicate cultures of human monocytic cells (2.0×10^6/well) were incubated for 15 min in the presence or absence of various concentrations of inhibitor before the stimulation of cytokine release by the addition of lipopolysaccharide (1 µg/ml). The amount of TNF-α released was measured 4 h later using an ELISA system.

Kumar et al. (1997) described homologs of CSBP/p38 MAP kinase, their activation, as well as substrate specificity and sensitivity to inhibition by pyridyl imidazoles.

McLay et al. (2001) reported the discovery of a p38 MAP kinase inhibitor displaying a good oral anti-arthritic efficacy.

Ignar et al. (2003) described the regulation of TNF-α secretion by a specific melanocortin-1 receptor peptide agonist.

Kinases Assay

The p38 enzyme assay is carried out at room temperature for 1 h, using 40 ng/well of the mouse enzyme. The substrate, 50 µg/ml ATF-2 transformation factor, is coated onto 96-well plates, and the assay is carried out in 25 mM Hepes buffer, pH 7.7 containing 25 mM magnesium chloride, 2 mM dithiothreitol, 1 mM sodium orthovanadate and 100 µM ATP. Phosphorylated ATF-2 is quantitated using a phospho-specific ATF-2 primary antibody (rabbit anti-human) followed by a europium-labeled secondary antibody (sheep anti-rabbit IgG) with addition of the DELFIA enhancement solution resulting in fluorescence. ERK was measured using a [^{33}P]ATP filtration assay format using for substrates myelin basic protein. ZAP-70, Syk and Lck kinase activities were measured using the homogeneous time-resolved fluorescence methodology (HTRF) with the catalytic domains of each of the tyrosine kinases, biotinylated, specific peptide substrates, streptavidin-linked APC and europium cryptate-conjugated anti-phosphotyrosine antibody.

Monocyte TNF-α Release Assay

Adherent human monocytes (100,000 cells/well) were incubated with LPS (10 ng/ml) in the absence and presence of compound for 18 h. Individual experiments were carried out in quadruplicate samples. TNF-α was measured by sandwich ELISA and IC_{50} values calculated for the activity of individual compounds. IC_{50} values shown from repeat experiments are means ±SEM.

Mouse TNF-α Release Assay

Compound was administered orally to BALB/c mice 30 min prior to LPS (0.1 mg/kg i.p.) challenge. Serum TNF-α levels were determined 90 min after LPS insult. Results represent means ±SEM.

H.3.1.8.3 Effect of TNF-α Binding

PURPOSE AND RATIONALE

Several authors compared the effects of the prototypes of the tumor necrosis factor (TNF) antagonists infliximab or adalimumab and etanercept (Vuolteenaho et al. 2002; Kirchner et al. 2004; Shen et al. 2005).

Scallon et al. (2002) compared the binding and functional properties of the two prototypes of the TNF antagonists infliximab and etanercept-

Although both infliximab and etanercept are potent neutralizers of TNF bioactivity, there are fundamental differences in their molecular structures, their binding specificities, and the manner in which they neutralize TNF. Infliximab is a chimeric monoclonal antibody (mAb) with murine variable regions and human IgG1 and κ constant regions (Knight et al. 1993). The size (149 kDa) and structure of infliximab are therefore similar to those of naturally occurring antibodies. Etanercept is a fusion protein made up of the extracellular domain of the p75 TNF receptor (CD120b) and the hinge and Fc domains of human IgG1 (Mohler et al. 1993), a structure distinct from any known naturally occurring molecule. Importantly, infliximab is not known to bind to any antigen other than TNF, whereas etanercept binds equally well to both TNF and lymphotoxin α (LT α), consistent with observations reported for the cellular p75 TNF receptor (Schall et al. 1990; Smith et al. 1990). Each infliximab molecule is capable of binding to two TNF molecules, and up to three infliximab molecules can bind to each TNF ho-

motrimer, thereby blocking all receptor binding sites on TNF. In contrast, it is believed that the bivalent etanercept molecule forms a 1:1 complex with the TNF trimer in which two of the three receptor binding sites on TNF are occupied by etanercept, and the third receptor binding site is open. In addition, the p75 TNF receptor is known to have fast rates of association and dissociation with TNF (Evans et al. 1994), which suggests that etanercept may only transiently neutralize the activity of an individual TNF molecule.

PROCEDURE

Cell Culture

KYM-1D4 cells that endogenously express TNF receptors (Butler et al. 1994) were maintained in RPMI-1640 medium supplemented with 2 mM L-glutamine and 10% FBS. Human umbilical vein endothelial (HUVE) cells from Cell Systems (Seattle, Wash., USA) were maintained in HUVE cell medium supplied by Cell Systems. K2 cells were maintained in Iscove's modified Dulbecco's medium (IMDM) supplemented with 5% FBS, 2 mM L-glutamine, 0.5 µg/ml mycophenolic acid, 2.5 µg/ml hypoxanthine, and 50 µg/ml xanthine. All cells were cultured in a humidified incubator maintained at 37°C and 5% CO_2.

Binding to Monomer Subunits of TNF

Dimethylsulfoxide (DMSO) was added to ^{125}I-TNF (40–60 µCi/µ g; 1.48–2.2 MBq/µg) to a final concentration of 10% DMSO and incubated at 20°C for 30 min to allow dissociation of TNF trimers. The mixture was passed over a 10 × 300-mm Superose 12 column equilibrated with PBS, and ^{125}I-TNF trimer and monomer were collected separately. Polystyrene 96-well microtiter plates were coated by incubating 50 µl of 1 µg/ml of infliximab, etanercept, or an isotype-matched, negative control antibody (cM-T412) in the wells overnight at 4°C. After washing with PBS-0.05% Tween 20 (PBS-T), all wells were blocked for 1 h at 37°C with PBS-1% bovine serum albumin and washed three times with PBS-T. Triplicate wells were then incubated with ^{125}I-TNF trimer [0.4 µCi (14.8 kBq), 10 ng/ml] or ^{125}I-TNF monomer [0.1 µCi (3.7 kBq), 2.5 ng/ml] alone or with 5 µg/ml unlabeled TNF. After 1 h at 37°C, the wells were washed with PBS-T and counted for ^{125}I.

Binding Assay to Measure Stability of Complexes with Soluble TNF

Each well of a 96-well enzyme immunoassay plate was incubated overnight at 4°C with 100 µl of 0.1 M carbonate, pH 9.6, containing 10 µ g/ml goat anti-human γ Fc antibody. Plates were washed three times with PBS-T and then incubated for 1 h at 37°C in blocking buffer (10 mM HEPES, pH 7.5, containing 0.1% porcine gelatin, 150 µl/well). Wells were incubated for 1 h at 37°C with 100 µl/well of blocking buffer containing 1 µg/ml infliximab or etanercept. Plates were washed three times with PBS-T, and then all TNF binding sites were saturated by incubating the wells for 1 h at 37°C in 100 µl/well of blocking buffer containing 10 ng/ml ^{125}I-TNF (40–60 µCi/µg). Wells were washed three times with PBS-T and then filled with 100 µl/well of blocking buffer alone or containing an excess of soluble, unlabeled competitor such as infliximab, etanercept, or human TNF, and subsequently incubated at 37°C. At the indicated time points, triplicate wells were washed three times with PBS-T to remove free ^{125}I-labeled TNF. The last wash was aspirated and replaced with 50 µl of scintillation fluid and the entire plate counted in a Packard TopCount gamma counter.

Assay for Bioactivity of Dissociated Soluble TNF

Microtiter plates were coated with goat anti-human γ Fc antibody and used to capture etanercept as described above. Wells were washed three times with PBS-T and incubated with 100 µl of 10 ng/ml unlabeled human TNF in 100 µl/well of blocking buffer for 1 h at 37°C. Wells were washed three times with KYM media, filled with 100 µl of KYM media, and 500 ng/ml mouse TNF was added to each well as a competitor. After a 1-h incubation at 37°C, the soluble fraction was removed and pre-incubated for 1 h in fresh wells with either no mAb, 10 µg/ml anti-human TNF mAb (infliximab), 85 µg/ml anti-mouse TNF mAb (cV1q huG3), or a combination of 10 µg/ml anti-human TNF and 85 µg/ml anti-mouse TNF mAb. After the pre-incubation, the soluble fractions were added to cultures of KYM-1D4 cells (50,000 cells/well in a 96-well plate) and the cells incubated for 16 h at 37°C in the presence of 0.5 µg/ml actinomycin D. To quantitate cell viability, MTT dye was added to a final concentration 0.5 mg/ml and the cells incubated at 37°C for 4 h. The medium was aspirated and 100 µl of 100% DMSO was added to the cells. The difference between the absorbance at 550 and 650 nm was then determined.

HUVE Cell Assay to Measure Stability of Complexes with Soluble TNF

Infliximab or etanercept was mixed with 1 µg/ml human TNF at 10:1 or 30:1 M ratios in HUVE cell medium and incubated for 30 min at 37°C. Serial di-

lutions of the preformed complexes were then added to confluent HUVE cells cultured in 96-well plates. Cells were incubated with the preformed complexes in 100 µl of HUVE cell medium for 4 h at 37°C and then washed three times with HBSS. The cells were then incubated for 1 h at 37°C in HBSS containing 1 µg/ml ^{125}I-labeled anti-E-selectin (20 µCi/µg). Cells were washed three times with HBSS, the last wash was aspirated and replaced with 30 µl of scintillation fluid, and the entire plate was counted in a Packard TopCount gamma counter.

Binding Assay to Measure Stability of Complexes with Transmembrane TNF

K2 cells, which stably express an uncleavable and thus permanently transmembrane (tm) form of TNF, were seeded at a density of 5×10^4 cells/well in a 96-well round-bottom plate in 100 µl of IMDM, 5% FBS. Subsequently, ^{125}I-labeled infliximab or ^{125}I-labeled etanercept (both at 8.5 µCi/µg) was added to a final concentration of 0.5 µg/ml (enough to saturate all TNF binding sites on the cells). After a 1-h incubation at 25°C, unbound infliximab and etanercept were removed by washing three times with IMDM medium. Fresh IMDM, 5% FBS medium (100 µl) alone, or containing 50 µg/ml of an unlabeled soluble competitor, was added to the cells. Soluble competitors were either infliximab or etanercept for samples treated with radiolabeled infliximab and one of infliximab, etanercept, or human LTα for samples treated with radiolabeled etanercept. The cells were then incubated at 37°C in 5% CO_2. At different time points, cells in selected wells were washed with PBS, and the number of counts bound to the cells determined using a gamma counter (PerkinElmer Wallac, Wellesley, Mass., USA).

Characterization of Infliximab and Etanercept Binding to tmTNF

K2 cells or TNF-negative Sp2/0 control cells were seeded in 96-well round-bottom plates at a density of 5×10^4 cells/well in IMDM, 5% FBS. Varying amounts of ^{125}I-labeled infliximab (23.4 µ Ci/µg) or ^{125}I-labeled etanercept (22.4 µCi/µg) were added to the cells. After a 16-h incubation at 4°C, cells were washed four times with culture medium (IMDM, 5% FBS), the last wash was aspirated, and 50 µl of culture medium was added to each well. The cells were then removed with cotton swabs and the number of counts per well was determined using a gamma counter (PerkinElmer Wallac). The resulting binding data were analyzed by non-linear regression using Prism software (GraphPad Software, San Diego, Calif., USA).

HUVE Cell Assay to Compare Ability to Inhibit tmTNF Bioactivity

K2 cells or Sp2/0 control cells were seeded in 96-well round-bottom plates at a density of 1×10^5 cells/well in IMDM, 5% FBS. Varying amounts of infliximab or etanercept in IMDM, 5% FBS were added and the mixture incubated for 1 h at 37°C. This mixture was then added to confluent cultures of HUVE cells in 96-well plates. The resulting cell-cell mixture was incubated for an additional 4 h at 37°C in a 5% CO_2 incubator. Cells were then washed three times with HBSS and incubated for 1 h with 1 µg/ml ^{125}I-anti-E-selectin (20 µCi/µg). Cells were washed three times with HBSS, the last wash was aspirated and replaced with 30 µl of scintillation fluid, and the plate counted in a Packard TopCount gamma counter.

EVALUATION

Data were analyzed using a paired Student's *t*-test to determine whether there was a statistically significant difference between the capacities of infliximab and etanercept to block the bioactivity of tmTNF.

MODIFICATIONS OF THE METHOD

Maloff and Delmendo (1991) developed high-throughput radioligand binding assays for interleukin 1-α (IL-1-α) and tumor necrosis factor (TNF-α) in isolated membrane preparations.

Zhang et al. (2002) described identification and characterization of a dual tumor necrosis factor converting enzyme/matrix metalloprotease inhibitor for the treatment of rheumatoid arthritis.

Transgenic mice expressing human tumor necrosis factor develop severe polyarthritis (Keffer et al. 1991; Kollias et al. 1999; Kontoyiannis et al. 1999; Mijatovic et al. 2000; Akassoglou et al. 2003; Li and Schwarz 2003). A targeting vector containing a genomic fragment encoding the entire TNF-α with the ARE-containing 3′ UTR was replaced with the 3′ UTR from the β-globin gene. This mutation increases the stability and translational efficiency of TNF-α mRNA and thus results in chronic TNF-α over-expression that leads to severe erosive polyarthritis. Administration of anti- TNF-α antibodies completely prevents the disease.

H.3.1.9 Binding to Interferon Receptors

PURPOSE AND RATIONALE

The interferons (IFNs) were discovered in 1957 as biological agents interfering with virus replication. They are a family of secreted proteins occurring in vertebrates and can be classified as cytokines. The IFNs are multifunctional and are components of the host defense against viral and parasitic infections and certain tumors. They affect the functioning of the immune system in various ways and also affect cell proliferation and differentiation.

IFNs were initially classified by their sources as leukocyte, fibroblast, and immune IFNs. Leukocyte and fibroblast IFNs, together, were also designated as Type 1 IFNs and immune IFN as Type 2 IFN. The recent nomenclature designates leukocyte IFNs as IFN-α and IFN-ω (earlier α-1 and α-2, respectively) fibroblast IFN as IFN-β, and immune IFN as IFN-γ.

Interferons bind to receptors on the cell surface and induce the synthesis of specific proteins. Littman et al. (1985) found that recombinant IFN-γ produced in bacteria, which is not glycosylated, binds to cellular receptors with an affinity similar to that of natural IFN-γ.

PROCEDURE

Human lymphoblastoid cells (Daudi, MOLT-4 and Raji) are grown in stationary cultures in Dulbecco's medium with 10% heat-inactivated horse serum. HeLa cells are grown in Eagle's medium with 7% horse serum.

The following interferons are used: Purified recombinant interferon-γ (rIFN-γ) (Genentech, antiviral activity 1.2×10^7 units/mg); natural human INF-β (Interferon Working Group of the NCI, antiviral activity 2×10^5 roentgen units/mg); rIFN-2α (Schering, antiviral activity 2×10^8 reference units/mg); rIFN-β (Cetus Corp., antiviral activity 2.6×10^8 reference units/mg).

Fifty micrograms of rIFN-γ are reacted for 2 h at 0°C with 1 mCi of ^{125}I-Bolton-Hunter reagent

(2000 Ci/mmol) in 0.25 ml of sodium borate buffer, pH 8.0. The reaction is stopped by the addition of glycine to a final concentration of 0.2 M and applied to a 26×0.7 cm column of Sephadex G-75 equilibrated with phosphate-buffered saline, pH 7.4, containing 0.25% gelatin. The reaction vial is washed with 20-µl aliquots of this buffer containing 40% ethylene glycol and then with buffer alone. The washes are added to the column and 0.32 ml fractions are collected. The fractions containing ^{125}I-rIFN-γ are pooled and diluted with 1/10 volume of 10-fold concentrated Eagle's medium containing 10 mg/ml bovine serum albumin and 0.1 mM dithiothreitol.

Cells harvested from exponentially growing cultures are centrifuged and resuspended at 8×10^6/ml in their own medium supplemented with 10 mM HEPES buffer, pH 7.4. Standard binding assays contain 3 to 5×10^6 cells and 0.46 nM ^{125}I-rIFN-γ. At the end of the reaction, the cells are centrifuged through 10% sucrose at 10,000 rpm in Microfuge tubes and the cell pellet is counted. A blank value is determined by incubating and processing in the same way an equal amount of ^{125}I-rIFN-γ in the absence of cells; this blank is subtracted from the cpm bound.

EVALUATION

The binding data are analyzed using the LIGAND program developed by Munson and Rodbard (1980).

MODIFICATIONS OF THE METHOD

Blatt et al. (1996) described the biological activity of consensus interferon, a wholly synthetic type I interferon, developed by scanning several interferon-alpha nonallelic subtypes and assigning the most frequently observed amino acid in each position.

IFN-τ, a new class of type I interferon was described by Pontzer et al. (1994), Alexenko et al. (1997, 1999), Martal et al. (1998), Swann et al. (1999).

Thiam et al. (1998) reported the agonist activities of a lipopeptide derived from INF-γ on murine and human cells by analysis and quantification of cell surface markers using flow cytometry and cell-ELISA.

Bosio et al. (1999) reported efficacy of type I interferon in cytomegalovirus infections *in vivo*. Oral administration of type I interferons (murine INF-α and INF-β) reduced early replication of murine cytomegalovirus in both the spleen and liver of infected BLB/c mice.

Tovey and Maury (1999) found a marked antiviral activity of murine interferon-α/β or individual recombinant species of murine INF-α, INF-β, or INF-γ or recombinant human INF-α1–8 in mice challenged systemically with a lethal dose of encephalomyocarditis virus, vesicular stomatitis virus, or varicella zoster virus. Oromucosal administration of INF-α also exerted a marked antitumor activity in mice injected i.v. with highly malignant Friend erythroleukemia cells or other transplantable tumors, such as L1210 leukemia, the EL4 tumor, or the highly metastatic B16 melanoma.

To gain more insight into similarities of different INF-α species, Viscomi et al. (1999) evaluated neutralization and immunoactivity of a variety of INF preparations with various monoclonal antibodies obtained through immunization with recombinant, lymphoblastoid, and leukocyte INF-α.

Reporter transgenic mice expressing the luciferase gene under the control of separate TCR-response elements from the INF-γ promoter or expressing the green fluorescent protein gene under the control of an INF-γ minigene were employed by Zhang et al. (1999) to explore the basis for IL-12 regulation of INF-γ gene transcription.

Poynter and Daynes (1999) studied the influence of constitutively expressed INF-γ on age-associated alterations in inducible nitric oxide synthase regulation using cell cultures from mouse spleen for nitrite and cytokine analysis.

H.3.1.10 Chemokine Antagonism

PURPOSE AND RATIONALE

The human chemokine system comprises about 50 distinct chemokines and 20 G-protein-coupled chemokine receptors (Rossi and Zlotnik 2000; Sallusto et al. 2000; Zlotnik and Yoshie 2000; Fernandez and Lolis 2002; D'Ambrosio et al. 2003; Houshmand and Zlotnik 2003; Ono et al. 2003; Proudfoot et al. 2003; Chen et al. 2004; Haringman and Tak 2004; Cunha et al. 2005). The biological activities of chemokines range from the control of leukocyte trafficking in basal and inflammatory conditions to regulation of hematopoiesis, angiogenesis, tissue architecture and organogenesis. Grainger and Reckless (2005) studied the anti-inflammatory effects of broad-spectrum chemokine inhibitors. Several groups described CC chemokine receptor-1 antagonists (Liang et al. 2000a, 2000b; Naya et al. 2001; Eltayeb et al. 2003; Gladue et al. 2006). CC chemokine receptor-3 (CCR3) antagonists were reported by De Lucca et al. (2005) and Fryer et al. (2006). CC chemokine receptor-5 (CCR5) antagonists were described by Rosi et al. (2005) and Saita et al. (2005).

De Lucca et al. (2005) described the discovery of CC chemokine receptor-3 (CCR3) antagonists with picomolar potency.

PROCEDURE

Biological Assays

CCR3-Receptor Binding

Millipore filter plates (no. MABVN1250) are treated with 5 µg/ml protamine in phosphate-buffered saline, pH 7.2, for 10 min at room temperature. Plates are washed three times with phosphate-buffered saline and incubated with phosphate-buffered saline for 30 min at room temperature. For binding, 50 µl of binding buffer (0.5% bovine serum albumen, 20 mM HEPES buffer, and 5 mM magnesium chloride in RPMI 1640 media) with or without a test concentration of a compound present at a known concentration is combined with 50 µl of ^{125}I-labeled human eotaxin (to give a final concentration of 150 pM radioligand) and 50 µl of cell suspension in binding buffer containing 5×10^5 total cells. Cells used for the binding assay are CHO cell lines transfected with a gene expressing human CCR3 (Daugherty et al. 1996). The mixture of compound, cells, and radioligand is incubated at room temperature for 30 min. Plates are placed onto a vacuum manifold, vacuum is applied, and the plates are washed three times with binding buffer with 0.5 M NaCl added. The plastic skirt is removed from the plate, and the plate is allowed to air-dry; the wells are punched out, and the radioactivity counted (cpm).

EVALUATION

The percent inhibition of binding is calculated using the total count obtained in the absence of any competing compound or chemokine ligand and the background binding determined by addition of 100 nM eotaxin in place of the test compound.

Human Eosinophil Chemotaxis Assay

Neuroprobe MBA96 96-well chemotaxis chambers with Neuroprobe poly(vinylpyrrolidone)-free polycarbonate PFD5 5-µm filters in place are warmed in a 37°C incubator prior to the assay. Freshly isolated human eosinophils are suspended in RPMI 1640 with 0.1% bovine serum albumin at 1×10^6 cells/ml and warmed in a 37°C incubator prior to the assay. A 20 nM solution of human eotaxin in RPMI 1640 with 0.1% bovine serum albumin is warmed in a 37°C incubator prior to the assay. The eosinophil suspension and the 20 nM eotaxin solution are each mixed 1:1 with prewarmed RPMI 1640 with 0.1% bovine serum albumin with or without a dilution of a test compound that is at twofold the desired final concentration. The filter is separated, and the eotaxin/compound mixture is

placed into the bottom part of the chemotaxis chamber. The filter and upper chamber are assembled, and 200 µL of the cell suspension/compound mixture is added to the appropriate wells of the upper chamber. The upper chamber is covered with a plate sealer, and the assembled unit is placed in a 37°C incubator for 45 min. After incubation, the plate sealer is removed and all remaining cell suspension is aspirated off. The chamber is disassembled, and unmigrated cells are washed away with phosphate-buffered saline and then the filter is wiped with a rubber-tipped squeegee. The filter is allowed to completely dry and stained with Wright Giemsa. Migrated cells are enumerated by microscopy.

Calcium Mobilization Assay

Intracellular calcium flux was measured as the increase in fluorescence emitted by the calcium-binding fluorophore, fluo-3, when preloaded cells were stimulated with CCR3 ligand. Freshly isolated eosinophils were loaded with fluorophore by resuspending them in a HEPES-buffered PBS solution containing 5 µM fluo-3 and incubating for 60 min at 37°C. After being washed twice to remove excess fluorophore, cells were resuspended in binding buffer (without phenol red) and plated into 96-well plates at 2×10^5/well. Plates were placed individually in a FLIPR-1 (Molecular Devices) that uses an argon-ion laser to excite the cells and robotically adds reagents while monitoring changes in fluorescence in all wells simultaneously. To determine the IC_{50}, compound or buffer alone was added and cells were incubated for 5 min; eotaxin was then added to a final concentration of 10 nM. The fluorescence shift was monitored, and the base-to-peak excursion was computed automatically. All conditions were tested in duplicate, and the mean shift per condition was determined. The inhibition achieved by graded concentrations of compound was calculated as a percentage of the compound-free eotaxin control.

MODIFICATIONS OF THE METHOD

Chen et al. (1998) reported *in vivo* inhibition of CC and CX_3C chemokine-induced leukocyte infiltration and attenuation of glomerulonephritis in Wistar–Kyoto (WKY) rats by the viral protein vMIP-II.

Ruth et al. (2001) investigated fractalkine, a chemokine, in rheumatoid arthritis and in rat adjuvant-induced arthritis. Fractaline in vascular biology was discussed by Umehara et al. (2004).

Laudanna and Constanin (2003) described new models of intravital microscopy for analysis of chemokine receptor-mediated leukocyte vascular recognition.

H.3.1.11 Influence of Peroxisome Proliferator-Activated Receptors (PPARs) on Inflammation

PURPOSE AND RATIONALE

Peroxisome proliferator-activated receptors (PPARs) play an important role not only in lipid metabolism and diabetes but also in the inflammation process (Devchand et al. 1996; Delerive et al. 2001; Cabrero et al. 2002; Clark 2002; Blanquart et al. 2003; Moller and Berger 2003; Nencioni et al. 2003; Tai et al. 2003; Woerly et al. 2003; Diep et al. 2004).

Jiang et al. (1998) reported that PPAR-γ antagonists inhibit production of monocyte inflammatory cytokines.

PROCEDURE

Monocyte Preparation

Human monocytes are isolated from freshly collected buffy-coat preparations of whole human blood. The mononuclear cell fraction is prepared by dilution with an equal volume of phosphate-buffered saline (PBS) at room temperature and layered over a solution containing 3 ml Ficoll-Hypaque per 10 ml blood and PBS and centrifuged for 10 min at 900 *g*. The mononuclear cell layer is transferred to a fresh tube, mixed with 3 vols of PBS, and centrifuged for 10 min at 400 g. The supernatant is removed and the dilution and centrifugation are repeated three times. Mononuclear cells are resuspended in RPMI medium 1640, counted and diluted to 5×10^6 cell per ml, after which 1 ml is transferred to each well of a 24-well tissue culture plate and incubated for 37°C in a 5% CO_2 humidified incubator. The non-adherent cells are removed and the monocytes washed once with PBS before adding 1 ml of fresh RPMI medium 1640 with 10% fetal bovine serum. Experiments are initiated on the day blood is collected, and all manipulations are carried out under endotoxin-free conditions.

Cytokine Assay

Monocytes in fresh medium are treated with inducers and candidate induction inhibitors at the time of culture initiation. Medium is collected from triplicate wells 18–20 h after the test compounds are added. Supernatant concentrations of TNF-α, IL-6 and IL-1β are measured by ELISA.

RNA Blot

Total RNA of human monocyte cultures is isolated 15 h after stimulation with 25 nM PMA in the absence or presence of PPARγ agonists. RNA blot analyses are performed with standard procedures and labeled probes prepared from human TNF-α and GAPDH cDNA with the Megaprime DNA labeling Kit (Amersham Life Science).

Luciferase Assay

U937 cells (2×10^7) are transfected with 10–20 µg luciferase reporter DNA by electrophoresis at 875 V cm^{-1}, 960 µF (Bio-Rad Laboratories). Transfected cells are allowed to recover for 1 h and triplicate samples are either untreated or treated with 25 nM PMA in the absence or presence of indicated drugs. Luciferase activity is measured 18–36 h later using the Dual-luciferase reporter assay system (Promega) with the pRL-TK vector as an internal reporter control.

EVALUATION

To obtain IC_{50} values, data are fitted to a four-parameter exponential and the derived parameters used to calculate the concentration at which 50% of the maximal activity is observed.

MODIFICATIONS OF THE METHOD

Kojo et al. (2003) evaluated human PPAR subtype selectivity of a variety of anti-inflammatory drugs based on a novel assay for PPARδ (β).

PROCEDURE

Plasmids

The cDNAs for human PPAR α, δ, and γ were synthesized using the polymerase chain reaction (PCR) with human liver cDNA for human PPARα, human heart cDNA for human PPARδ (β), and human fat cell cDNA for human PPARγ 1 as templates. Retinoid X receptor (RXR)α expression plasmids were constructed by inserting a coding sequence of RXRα into the expression vector pcDNA3.1(+) (Invitrogen, Carlsbad, Calif., USA). The cDNA for human RXRα was synthesized with human kidney cDNA as a template. The template cDNAs used were purchased from Clontech Laboratories (Palo Alto, Calif., USA). The amplified cDNA fragments were cloned into pCRII (Invitrogen) and the nucleotide sequences of the cDNAs were determined by the dideoxy chain termination method using an automated laser fluorescent DNA sequencer. Multiple clones of each cDNA were sequenced and artifacts generated by the *Taq* polymerase used in the PCR were revised by replacement of the specified region among the clones. The PPAR and RXRα expression plasmids were constructed by inserting each full-length cDNA at a multiple cloning site of the mammalian expression vector pCDM8, pcDNAI, or pcDNA3.1 (+) (Invitrogen). Coactivator expression plasmids pcDNA3.1-CBP and pcDNA3.1-SRC-1 were provided by Fujimura and Aramori of the Pharmacological Research Laboratories of Fujisawa Pharm. The human RXRγ expression plasmid was purchased from Invitrogen.

The reporter gene plasmid pGVPPREluc-1 was constructed as follows. Three copies of a 33-bp PPRE identical to that of acyl CoA oxidase were first cloned at the *Sal*I site of pBLCAT-2 to generate pBLPPRECAT-1. The luciferase reporter plasmid pGVPPRELuc was constructed by inserting the PPRE-containing fragment of pBLPPRECAT-1 at a multiple cloning site of PGV-P2 (Wako Pure Chemical, Osaka).

Gal4-PPARδ (β) fusion expression plasmid for one-hybrid assay was constructed as follows: full-length PPARδ (β) cDNA and PPARδ (β)-LBD cDNA were prepared by PCR amplification using pCDM8-hPPARδ as a template, and the amplified cDNA was cloned into a multiple cloning site of the pBIND vector (Promega, Madison, Wis., USA). The nucleotide sequence of each fusion expression plasmid was checked with an automated DNA sequencer. Reporter plasmid pG5luc for the one-hybrid assay was purchased from Promega.

Transient Transfection Assay

The African green monkey fibroblast cell line CV-1 was obtained from ATCC (Manassas, Va., USA) and maintained in Dulbecco's modified Eagle's medium (DMEM) (Gibco-BRL, Gaithersburg, Md., USA) supplemented with penicillin, streptomycin, and 10% heat-inactivated fetal calf serum. Cells were seeded at 2×10^5 per well of 6-well culture dishes and after overnight culture transiently transfected with 1 µg each of pGVPPRELuc luciferase reporter plasmid, PPAR expression plasmid, and RXRα expression plasmid together with the control *Renilla* luciferase expression plasmid RL-TK (Promega) using Lipofectamine 2000 (Gibco-BRL). Coactivator expression plasmid was also included when a transfection was performed for the PPARδ assay. For the one-hybrid assay, cells were transfected with 1 µg each of pG5luc reporter plasmid and Gal4-PPARδ fusion expression plasmid with RL-TK control plasmid. Cells were harvested 4 h after transfection and plated again at 1.6×10^4 per well onto 96-well plates. The drugs dissolved in dimethyl sulfoxide were added to the culture and the cells were incubated at 37°C for 24 h. After being washed with PBS(-), cells were lysed with PLB (passive lysis buffer) (Promega) and the lysates were used for reporter assays. Expression of the reporter was measured by the activity of firefly luciferase using the dual luciferase reporter assay system (Promega) and ARVO HTS 1420 multilabel counter (Amersham Biosciences) as a luminometer. Firefly luciferase activity was corrected for transfection efficiency based on the activity of internal control *Renilla* luciferase.

Bishop-Bailey and Warner (2003) found that PPARγ ligands induce prostaglandin production in vascular smooth muscle cells and concluded that indomethacin acts as a peroxisome proliferator-activated receptor-γ antagonist.

Fahmi et al. (2001) reported that peroxisome proliferator-activated receptor γ activators, such as 15-deoxy-$\Delta^{12,14}$-PGJ_2, inhibit interleukin-1β-induced nitric oxide and metalloproteinase 13 production in human chondrocytes.

Cheng et al. (2004) found that peroxisome proliferator-activated receptor γ, which is activated by ligands such as troglitazone or 15-deoxy-$\Delta^{12,14}$-PGJ_2, inhibits interleukin-1β-induced membrane-associated prostaglandin E_2 synthase-1 expression in human synovial fibroblasts by interfering with the early growth response protein Egr-1.

H.3.1.12 Binding to Histamine H_4 Receptor

PURPOSE AND RATIONALE

Histamine receptors have been classified on the basis of pharmacological analysis (Hill et al. 1997). Histamine exerts its action via at least four receptor subtypes. The H_1 receptor couples mainly to $G_{q/11}$, thereby stimulating phospholipase C, whereas the H_2 receptor interacts with G_s to activate adenylyl cyclase. The histamine H_3 and H_4 receptors couple to G_i proteins to inhibit adenylyl cyclase, and to stimulate MAPK (Hough 2001).

The H_4 receptor is highly expressed in peripheral leukocytes and intestinal tissue, making this receptor an interesting target in inflammatory diseases (Fung-Leung et al. 2004; De Esch et al. 2005; Lim et al. 2006; Zhang et al. 2006). The new receptor was cloned and characterized by Oda et al. (2000). Liu et al. (2001b) reported comparison of histamine H_4 receptors in several species. Gbahou et al. (2006) compared the pharmacology of human histamine H_3 and H_4 receptors and described structure–activity relationships of histamine derivatives. Thurmond et al. (2004) described a potent and selective histamine H_4 antagonist with anti-inflammatory properties. Lim et al. (2005) evaluated histamine H_1-, H_2-, and H_3-receptor ligands at the human H_4 receptor and identified 4-methylhistamine as the first potent and selective H_4 receptor agonist.

PROCEDURE

Cell Culture

SK-N-MC cell lines, which stably express either the human H_3R (SK-N-MC/hH_3) or H_4R (SK-N-MC/hH_4) as well as a cAMP-responsive-element-(CRE-) driven β-galactosidase reporter gene SK-N-MC/hH_3 or SK-N-MC/hH_4 cells (Lovenberg et al. 1999; Liu et al. 2001a), were cultured in Eagle's minimum essential medium supplemented with 5% fetal calf serum, 0.1 mg/ml streptomycin, 100 U/ml penicillin, and 600 µg/ml G418 at 37°C in 5% CO_2 and 95% humidity.

Radioligand Binding Assays

The SK-N-MC/hH_3 cell homogenates were incubated for 40 min at 25°C with approximately 1 nM [^{3}H]*N*-methylhistamine in 25 mM KPO_4 buffer and 140 mM NaCl (pH 7.4 at 25°C), with or without competing ligands, whereas the SK-N-MC/hH_4 cell homogenates were incubated 1 h at 37°C in 10 nM [^{3}H]histamine and 50 mM Tris-HCl (pH 7.4 at 37°C), with or without competing ligands. Bound radioligands were col-

lected on 0.3% polyethyleneimine-pretreated Whatman GF/C, and washed three times with 3 ml of ice-cold washing buffer (4°C) containing 25 mM Tris-HCl and 140 mM NaCl (pH 7.4 at 4°C) for the hH_3R and 50 mM Tris-HCl (pH 7.4 at 4°C) for the hH_4R).

EVALUATION

Binding analysis of 10 nM [^{3}H]JNJ 7777120 (test compound) and 0.1 nM [^{125}I]iodophenpropit to the hH_4R was performed with the same conditions as described for [^{3}H]histamine. In saturation binding analysis, the non-specific binding of [^{3}H]histamine or [^{3}H]JNJ 7777120 was determined with 1 μM clobenpropit. The binding analysis of [^{3}H]mepyramine and [^{125}I]iodoaminopotentidine binding to human H_1R and human H_2R, respectively, was performed according to Bakker et al. (2004). The binding data were analyzed with Prism 4.0 (GraphPad Software, San Diego, Calif., USA), and data are presented as mean ±SEM. Mouse and rat H_4R radioligand binding assays were performed according to Liu et al. (2001b).

H.3.2 In Vivo Methods for Anti-inflammatory Activity

H.3.2.1 General considerations

The inflammatory process involves a series of events that can be elicited by numerous stimuli, e. g., infectious agents, ischemia, antigen-antibody interactions, chemical, thermal or mechanical injury. The response is accompanied by the clinical signs of erythema, edema, hyperalgesia and pain. Inflammatory responses occur in three distinct phases, each apparently mediated by different mechanisms:

- an acute, transient phase, characterized by local vasodilatation and increased capillary permeability,
- a subacute phase, characterized by infiltration of leukocytes and phagocytic cells,
- and a chronic proliferative phase, in which tissue degeneration and fibrosis occur.

According to these phases, pharmacological methods have been developed.

Methods for testing acute and subacute inflammation are:

- UV-erythema in guinea pigs
- Vascular permeability
- Oxazolone-induced ear edema in mice
- Croton-oil ear edema in rats and mice
- Paw edema in rats (various modifications and various irritants)
- Pleurisy tests
- Granuloma pouch technique (various modifications and various irritants)

The proliferative phase is measured by methods for testing granuloma formation, such as:

- Cotton wool granuloma
- Glass rod granuloma
- PVC sponge granuloma.

Furthermore, methods for testing immunological factors have been developed, such as:

- Adjuvant arthritis in rats (various modifications)
- Experimental allergic encephalomyelitis
- Schultz-Dale-reaction
- Passive cutaneous anaphylaxis
- Arthus type immediate hypersensitivity
- Delayed type hypersensitivity

(see Chapter I).

H.3.2.2 Methods for Testing Acute and Subacute Inflammation

H.3.2.2.1 Ultraviolet Erythema in Guinea Pigs

PURPOSE AND RATIONALE

The test was first described by Wilhelmi (1949) who was able to delay the development of ultraviolet erythema on albino guinea pig skin by systemic pretreatment with clinically equivalent doses of phenylbutazone and other nonsteroidal anti-inflammatory agents. The test procedure was further developed by Winder et al. (1958) and since that time modified by various investigators.

PROCEDURE

Albino guinea pigs (Pirbright white strain) of both sexes with an average weight of 350 g are used. Eighteen h prior testing, the animals are shaved on both flanks and on the back. Then they are chemically depilated by a commercial depilation product or by a suspension of barium sulfide. Twenty minutes later, the depilation paste and the fur are rinsed off in running warm water. On the next day, the test compound is dissolved (or suspended) in the vehicle and half the dose of the test compound is administered by gavage (at 10 ml/kg) 30 min before ultraviolet exposure. Control animals are treated with the vehicle alone. Four animals are used for each treatment group and control. The guinea pigs are placed in a leather cuff with a hole of 1.5 × 2.5 cm size punched in it, allowing the ultraviolet radiation to reach only this area. An original Hanau ultraviolet burner Q 600 is warmed up for about 30 min prior to use and placed at a constant distance (20 cm) above the animal. Following a 2 min ultraviolet exposure, the remaining half of the test compound is administered. The investigator has to protect himself/herself by gloves and ultraviolet glasses. The erythema is scored 2 and 4 h after exposure.

EVALUATION

The degree of erythema is evaluated visually by 2 different investigators in a double-blinded manner. The followings scores are given:

- 0 = no erythema,
- 1 = weak erythema,
- 2 = strong erythema,
- 4 = very strong erythema.

Animals with a score of 0 or 1 are considered to be protected. The scoring after 2 and after 4 h gives some indication of the duration of the effect. ED_{50} values can be calculated. Doses of 1.5 mg/kg indomethacin p.o., 4 mg/kg phenylbutazone p.o. and 60 mg/kg acetylsalicylic acid p.o. have been found to be effective.

CRITICAL ASSESSMENT

The test has the advantage of simplicity but needs training of the investigators. Attempts to use reflection photometers in order to eliminate subjective scoring were unsuccessful. Corticosteroids after systemic application are rather ineffective in this test, however, can be evaluated after topical administration. The test is not particularly useful to study the duration of the anti-inflammatory effect.

MODIFICATIONS OF THE TEST

Yawalkar et al. (1991) tested several steroids after local application in the ultraviolet-induced dermatitis inhibition in guinea pigs. Clobetasol propionate was more effective than hydrocortisone, halobetasol propionate was superior to both corticosteroids.

Woodward and Owen (1979) used the albino guinea-pig ear as the site of inflammation produced by UV radiation. Ear temperature, water content of the ear and vascular permeability were measured. Indomethacin, phenylbutazone and aspirin given subcutaneously were active but paracetamol was not.

Warren et al. (1993) studied the role of nitric oxide synthase and cyclo-oxygenase in the skin blood flow to UVB irradiation in the shaved dorsal skin of anesthetized male **Sprague Dawley rats** with a laser Doppler flow probe. Topical application of clobetasol-

17-propionate immediately after irradiation inhibited the 18 h UVB response in a dose-dependent manner.

Gloxhuber (1976) measured skin thickness using calipers in **hairless mice** after UV-irradiation of the back and treatment with anti-inflammatory drugs.

Woodbury et al. (1994), Kligman (1994) described a rapid assay of the anti-inflammatory activity of topical corticosteroids by inhibition of a UVA-induced neutrophil infiltration in hairless mouse skin. Skh-hairless mice were irradiated with UVA light on an area of 2 × 2 cm square on the dorsal trunk fore 200 min in anesthesia. Steroid treatment was once daily for 7 days. Irradiation was on the 8th day. Neutrophils were counted microscopically in punch biopsies.

H.3.2.2.2 Vascular Permeability

PURPOSE AND RATIONALE

The test is used to evaluate the inhibitory activity of drugs against increased vascular permeability which is induced by a phlogistic substance (Miles and Miles 1992). Mediators of inflammation, such as histamine, prostaglandins and leucotrienes are released following stimulation e. g. of mast cells. This leads to a dilation of arterioles and venules and to an increased vascular permeability. As a consequence, fluid and plasma proteins are extravasated and edemas are formed. These effects are counteracted by H_1-antihistaminics, inhibitors of arachidonic acid metabolism and by leucotriene receptor antagonists. In addition, membrane-stabilizing drugs are able to reduce capillary permeability. Vascular permeability is increased by intracutaneous injection of the mast cell-degranulating compound 48/80. The increase of permeability can be recognized by the infiltration of the injected sites of the skin with the vital dye Evan's blue.

PROCEDURE

Male Sprague-Dawley rats with a body weight between 160 and 200 g are used. The ventral sides of the animal are shaved. Five ml/kg of an 1% solution of Evan's blue are injected intravenously. One hour later the animals are dosed with the test compound orally or intraperitoneally or with the vehicle. Ten animals are used for each test group and the control. Thirty minutes later, the animals are briefly anaesthetized with ether and 0.05 ml of an 0.01% solution of compound 48/80 are injected intracutaneously at 3 sites both at the left and ventral side. Ninety minutes after the injection of compound 48/80 the animals are sacrificed by ether anesthesia. The abdominal skin is removed and the dye-infiltrated areas of the skin are measured.

EVALUATION

The diameter of the dye-infiltrated areas is measured in millimeters in two perpendicular directions and the mean values of all injection sites in one animal are calculated. The percent inhibition in the treated animals as compared to the control group is calculated. A treated animal which shows values less than 50% of controls can be considered as positive. ED_{50} values can be calculated in this way. Phenylephrine at a dose of 15 mg/kg has been found to be effective.

CRITICAL ASSESSMENT OF THE METHOD

The test for vascular permeability is useful for characterization of a new anti-inflammatory compound.

Since compounds with sympathomimetic activity have a pronounced effect this test cannot be regarded as a primary screening test for anti-inflammatory products. Together with an observation of writhing or

"squirming" of mice, Whittle (1964) has proposed to be able to distinguish between narcotic and non narcotic analgesics.

MODIFICATIONS OF THE METHOD

Shionoya and Ohtake (1975) described a simple method for extraction of extravasated dye (Evan's blue) in the skin.

Frimmer and Müller (1962) presented a critical survey on the use of dye methods for quantitative determination of increased capillary permeability following intracutaneous injection of active substances.

McClure et al. (1992) used the Olympus CUE-2 Image Analyzer to quantify vascular permeability in the Miles assay in guinea pigs.

Zentel and Töpert (1994) used oxazolone-induced Evans blue extravasation for preclinical evaluation of topical corticosteroids. Female**NMRI-mice** were sensitized by topical application of 50 µl of 40% oxazolone in ethanol to 4 cm^2 of the left flank. After 13 days the animals were injected intravenously with 0.2 ml of 0.5% Evan's blue in water and 20 µl of 4% oxazolone in ethanol were topically applied to 6 cm^2 of the right flank immediately after injection. Three h later the challenged skin was treated with various corticosteroids in ointment. The animals were sacrificed 24 h after treatment and the challenged skin removed. Evans blue extravasation was measured spectrophotometrically at 623 nm.

Teixeira et al. (1993) studied acute inflammatory reactions in **guinea pig skin** measuring infiltration of ^{111}In-labelled eosinophils and neutrophils and edema formation by extravasation of ^{125}I-human serum albumin.

Fujii et al. (1996) quantified vascular permeability by the extravasation of pontamine sky blue in the skin of male ddY mice after subcutaneous injection of lipopolysaccharides.

Blackham and Woods (1986) measured extravasation of pontamine sky blue in the **mouse** peritoneal cavity.

Cambridge et al. (1996) investigated 6-hydroxydopamine-induced plasma extravasation in **rat skin** after intravenous injection of ^{125}I-human serum albumin and Evan's blue.

Rouleau et al. (1997) measured the inhibition of capsaicin-induced plasma extravasation by a histamine H_3 receptor agonist prodrug by analysis of extravasated Evan's blue in skin, eye conjunctiva, nasal mucosa, trachea, main bronchi, esophagus and urinary bladder of rats.

Watanabe et al. (1984) used fluorescein isothiocyanate-labeled bovine serum albumin as tracer to measure vascular permeability in the **carrageenin air pouch of rats**.

Collins et al. (1993) studied the pro-inflammatory properties of the human recombinant vascular permeability factor containing 165 amino acids in **rabbits**.

Urinary bladder cystitis induced by cyclophosphamide was used as model of intestinal inflammation and pain by several authors (Ahluwahlia et al. 1994; Bon et al. 1996; Boucher et al. 1997; Alfieri and Gardner 1997). Male Wistar rats weighing 300–400 g were treated first with test drug or saline subcutaneously or intraperitoneally and then injected 5 min later with 150 mg/kg i.p. cyclophosphamide. One h later, anaesthesia was induced by 40 mg/kg i.p. pentobarbitone and 50 mg/kg Evans blue were injected into the jugular vein. Fifteen min later, the rat was exsanguinated by infusion of 50 ml saline into the left cardiac ventricle. The urinary bladder, the left kidney, the superior lobe of the left lung and approximately 1-cm portions of the duodenum and jejunum were removed and blotted before dry weighing. The content of Evens blue dye was determined by spectrophotometry at 620 nm after extraction in known volumes of formamide at 60°C for 60 h.

Ferrets were treated in the same way, but the dose of cyclophosphamide was 125 mg/kg and the volume of exsanguination was 300 ml.

Hirota et al. (1995) induced **chemical peritonitis in rats** by applying 0.02 M HCl on the surface of the cecum or appendix and quantified the inflammation by measuring the extravasation of intravenously injected Evan's blue bound to albumin extracted from those tissues.

H.3.2.2.3 Inhibition of Leukocyte Adhesion to Rat Mesenteric Venules In Vivo

PURPOSE AND RATIONALE

Reversible adherence of leukocytes to endothelium, basement membranes and other surfaces is an essential event in the establishment of inflammation. Their entry into tissues is controlled by the dynamic interaction between adhesion molecules expressed by these cells and the endothelium. White cells circulating in the blood have the tendency to adhere to the walls of blood vessels and this tendency is greatly increased in states of inflammation. Normally, when leukocytes collide with the vessel wall, the collision behaves elastically and the cells bounce off and back into the lumen. However, biochemical changes in inflamed tissues results in inelastic collisions of cells and an increase in their adhesion, thus initiating rolling of leukocytes along the endothelial surface. As adhesion further increases, rolling is slowed and may be followed by the cells coming to a complete stop and their migration out of the vessel. This can be observed by preparing a mesenteric venule of an anesthetized rat and following the flow and rolling of leukocytes by means of a microscope, thus allowing in-vivo studies. In this test procedure, adhesion of leukocytes, to the vessel wall, is artificially induced by the application of the formyl-methionyl peptide fMet-Leu-Phe (FMLP). Formyl peptides are released from bacteria and mitochondria of damaged tissue, so these peptides provide a specific signal marking the presence of invading bacteria or tissue damage. The density of FMLP receptors ranges from 10^4 to 10^5 per cell, depending on the cell type. Activation of leukocytes through this receptor results in rapid expression of preformed L-selectin (LECAM-1) on the cell surface which causes the cells to roll along the endothelial surface. LECAM-1 are very rapidly shed from the surface of leukocytes, however, and integrins take over to maintain further adhesion and migration into the tissue.

PROCEDURE

Sprague-Dawley rats are anesthetized by administration of Nembutal. The trachea, jugular vein and carotid artery are prepared free, the abdominal cavity is opened and a section of ileum is pulled out and draped over a heated microscope table. Prior to test compound administration, the number of spontaneous adhering leukocytes is counted, every 5 min, in a defined section of a venule (covered with paraffin oil) during a 30-min period (control). Blood pressure, body

temperature and velocity of blood flow are also registered. The test compound is administered via continuous infusion during the entire test procedure beginning at $t = -30$ min. Following the determination of control values for spontaneous adhesion, FMLP (f-Met-Leu-Phe, 10^{-4} M) is dripped twice ($t = -30$ min and $t = 0$ min) on the preparation and the number of adhering leukocytes is determined every 5 min over a 90 min period, beginning with the second application of FMLP ($t = 0$ min). Each test group consists of at least 10 animals. The mean leukocyte count of every rat prior to FMLP and/or test substance application is taken as the 100% value to obtain the baseline for further comparisons. The test compounds are dissolved in 0.9% NaCl shortly before application.

EVALUATION

Following the second topical application of FMLP (10^{-4} M), the number of adhering leukocytes in the mesenteric venule section is counted 30 min after the stimulus is given, and again at the end of the observation period of 2 h. The influence of a continuous i.v. infusion of the test drug is compared with the positive control group (FMLP stimulation, without drug).

MODIFICATIONS OF THE METHOD

A simple, rapid, *in vitro* assay for granulocyte adherence was developed by MacGregor et al. (1974). Heparinized whole blood is filtered through nylon fibers packed in Pasteur pipettes, and the percentage of granulocytes adhering was calculated.

Neutrophil adherence was tested *in vitro* by Burch et al. (1992). Human umbilical vein endothelial cells were plated at 5×10^4 cells/well into collagen coated culture plates and grown to confluence. Neutrophils were labeled with ^{51}Cr. Experimental agents were added to the neutrophils before their activation with FMLP. After 15 min incubation at 37°C, the non-adherent leukocytes were removed by gentle aspiration followed by a wash with saline. The adherent neutrophils were lysed by 1 N NaOH and the radioactivity was quantitated.

H.3.2.2.4 Oxazolone-Induced Ear Edema in Mice

PURPOSE AND RATIONALE

The oxazolone-induced ear edema model as first described by Evans (1971) in mice is a model of delayed contact hypersensitivity that permits the quantitative evaluation of the topical and systemic anti-inflammatory activity of a compound following topical administration.

PROCEDURE

Mice of either sex with a weight of 25 g are used. Before each use a fresh 2% solution of oxazolone (4-ethoxymethylene-2-phenyl-2-oxazolin-5-one) in acetone is prepared. The mice are sensitized by application of 0.1 ml on the shaved abdominal skin or 0.01 ml on the inside of both ears under halothane anesthesia. The mice are challenged 8 days later again under anesthesia by applying 0.01 ml 2% oxazolone solution to the inside of the right ear (control) or 0.01 ml of oxazolone solution, in which the test compound or the standard is solved. Special pipettes of 0.1 ml or 0.01 ml are used. Groups of 10 to 15 animals are treated with the irritant alone or with the solution of the test compound. The left ear remains untreated. The maximum of inflammation occurs 24 h later. At this time the animals are sacrificed under anesthesia and a disc of 8 mm diameter is punched from both sides. The discs are immediately weighed on a balance. The weight difference is an indicator of the inflammatory edema.

EVALUATION

Average values of the increase of weight are calculated for each treated group and compared statistically with the control group. A 0.003% solution of hydrocortisone and a 1% solution of indomethacin were found to be active.

CRITICAL ASSESSMENT OF THE METHOD

The method is suitable for both steroidal and non-steroidal compounds as well as for the evaluation of various topical formulations.

MODIFICATIONS OF THE METHOD

Griswold et al. (1974) applied a 3% solution of oxazolone to the left paw of mice. The edema was assessed plethysmographically.

Various cutaneous models of inflammation for the evaluation of topical and systemic pharmacological agents have been discussed by Young and Young (1989).

Bailey et al. (1995) described a contact hypersensitivity model in mice for rank-ordering formulated corticosteroids. Male Swiss Webster mice were sensitized with 20 µl of 2% oxazolone on the inner and outer aspects of each ear (10 µl each side). Mice were challenged 7 days later with 2% oxazolone in acetone:olive oil (4:1) on both sides of the right ear. Animals were topically treated with corticosteroids or non-steroidal antiinflammatory drugs or 20 mg formulated corticosteroids immediately after challenge. The mice were sacrificed after 24 h and edema and myeloperoxidase activity were determined. Edema was measured by taking the weight of 6 mm trephine punch biopsies of the right and left ears. Inhibition was calculated from change in ear weight of control or drug treated ears versus placebo treated ears. Myeloperoxidase activity was assessed spectrophotometrically (Williams et al. 1983) on tissue homogenates. In a delayed-type hypersensitivity model animals were treated as in the contact hypersensitivity model, except the mice were sensitized with 40 µl of 2% oxazolone in acetone:olive oil (4:1) on the unshaved inguinal areas.

Meingassner et al. (1997) studied anti-inflammatory activity using allergic contact dermatitis im **mice, rats** and **pigs**. Mice were sensitized on the shaved abdomen with 50 µl of 2% oxazolone solution in acetone. After 7 days, they were challenged with 10 µl of 2% (for topical testing) or 0.5% (for systemic testing) oxazolone on the inner surface of the right ears. Pinnal weight was taken as a measure of inflammatory edema 24 h after challenge. Female Sprague Dawley *rats* were sensitized by application of 80 µl of 2,4-dinitrofluorobenzene solution applied in 20 µl volumes to the inner surface of both ear lobes and to both shaved inguinal regions on day 1. Allergic contact dermatitis was elicited with 30 µl of 0.5% 2,4-dinitrofluorobenzene applied to the test sites of ≈15 mm in diameter on both shaved flanks on day 12. Animals were treated by gavage 2 h before and immediately after challenge. Dermatitis was evaluated by measuring the thickness of the lifted skin fold at the test sites with a spring-loaded micrometer. Domestic **pigs** were sensitized wit 400 µl of 10% 2,4-dinitrofluorobenzene applied to four areas on both ears and groins. Challenge reactions were elicited 12 days later with 15 µl of 2,4-dinitrofluorobenzene (1%) applied topically to test sites arranged in four craniocaudal lines on the dorsolateral shaved back (24 or 32 per pig). Test sites were treated twice either with 20 µl solution of test compound or with ≈50 mg of a cream formulation applied topically 30 min and 6 h after challenge. One day after challenge the test sites were visually evaluated for intensity and extent of erythema and induration.

H.3.2.2.5 Croton-oil Ear Edema in Rats and Mice

PURPOSE AND RATIONALE

The method has been developed primarily as a bioassay for the concomitant assessment of the antiphlogistic and thymolytic activities of topically applied steroids by Tonelli et al. (1965)

PROCEDURE

For tests in mice the irritant is composed as follows (v/v): 1 part Croton oil, 10 parts ethanol, 20 parts pyridine, 69 parts ethyl ether. For tests in rats the following mixture is prepared (v/v): 4 parts Croton oil, 10 parts ethanol, 20 parts pyridine, 66 parts ethyl ether. The standards and the test compounds are dissolved in this solution. For tests in mice male NMRI-mice with an weight of 22 g, for tests in rats male

Sprague-Dawley rats with a weight of 70 g are used. Ten animals are used for controls and each test group. The test compounds are dissolved in a concentration of 0.03 mg/ml to 1 mg/ml for mice and in a 3 to 10 times higher concentration for rats in the irritant solution. On both sides of the right ear 0.01 ml in mice or 0.02 ml in rats are applied. Controls receive only the irritant solvent. The left ear remains untreated. The irritant is applied under ether anesthesia. Four hours after application the animals are sacrificed under anesthesia. Both ears are removed and discs of 8 mm diameter are punched. The discs are weighed immediately and the weight difference between the treated and untreated ear is recorded indicating the degree of inflammatory edema. In the originally described method the ears are removed by sharp, straight scissors 6 h after application and weighed as total. The animals were sacrificed 48 h after topical administration and the thymus glands were removed, weighed and expressed as mg thymus/100 g body weight.

EVALUATION

The antiphlogistic effect can be determined by expressing the increase in weight of the treated ear as percentage of the weight of the contralateral control ear. The difference of both weights is divided by the weight of the contralateral ear times 100. Otherwise, the difference between both ears or excised discs is calculated as the average values for treated and control groups and the effect is evaluated by statistical methods. Concentration of 0.5 to 1 mg/ml hydrocortisone have been proven to be effective.

CRITICAL ASSESSMENT OF THE METHOD

The method is useful for evaluation of anti-inflammatory topical steroids especially in the modification when thymus weight is determined simultaneously. The method also can be used for topically applied nonsteroidal antiphlogistics.

MODIFICATIONS OF THE METHOD

Wilhelmi and Domenjoz (1951) tested various drugs using Croton oil induced ear edema in mice and rabbits.

Tubaro et al. (1985) tested various anti-inflammatory drugs in the Croton oil test in mice. Granulocyte infiltration in plugs taken from the inflamed ears was assessed by measuring peroxidase activity.

Zentel and Töpert (1994) used Croton oil-induced ear edema in rats to evaluate topical corticosteroids. A plastic collar was fixed around the neck of Wistar rats of either sex (160–200 g body weight) to exclude oral uptake of the compounds. Fifty µl of 5% Croton oil in ethanol or ethanol alone were topically applied to both ears. In the treatment groups drugs were coapplied with Croton oil. Five h after treatment the animals were sacrificed by CO_2 gas and the ears removed. Edema formation was measured by the increase in wet weight.

Iwasaki et al. (1995) measured the inhibition of Croton oil-induced ear edema in Wistar rats by locally applied clobetasol-17-propionate, a synthetic glucocorticoid, and the influence of simultaneously applied RU 486.

Weirich et al. (1977) measured skin temperature, ear thickness and weight of excised punches after Croton oil induced edema in the ears of **white rabbits** and calculated phlogostasis values as the products of the percent reduction in skin temperature, auricular thickness and tissue weight in relation to controls. The authors recommended this model for the primary evaluation of topical anti-inflammatory agents.

Colorado et al. (1991) described an apparatus to measure Croton oil induced ear edema in mice using precisely reproducible pressure on the ear. The device allows to follow the time course of inflammation by repeated measurements.

Akiyama et al. (1994) studied staphylococcus aureus infection on experimental Croton oil-inflamed skin in mice. Staphylococcus aureus cells were inoculated on the surface of skin inflamed by application of Croton oil in cyclophosphamide-treated mice. Skin specimens were taken at 1, 3, 6, 12, and 24 h after inoculation and examined by microscopy. The staphylococcus aureus cells which attached to the surface of the skin immediately after inoculation had invaded the horny layer within 1 h. The cells gradually penetrated deeper into the epidermis. Application of corticosteroid ointments decreased the number of staphylococcus aureus cells in the lesions.

Anderson and Groth (1984) induced **toxic contact reactions** to Croton oil or dinitrochlorobenzene (DNCB), or **allergic contact reactions** to DNCB or oxazolone in guinea pig skin and tested the effect of various locally applied corticosteroids by macroscopic assessment and microscopic evaluation of cellular infiltrates.

Tarayre et al. (1984) used a 0.25% solution of **cantharidin** in acetone and applied 0.025 ml to one mouse ear. Two phases of inflammation were observed. After local application nonsteroidal drugs showed effects in the first phase only, whereas steroids influenced both phases.

De Young et al. (1987) induced ear inflammation in rats by intradermal injection of 10 ng **recombinant human interleukin-1β** in 10 µl of saline.

Maloff et al. (1989) injected 20 µl of interleukin-1 solution into the left ear of mice and found a dose-dependent increase of ear thickness and myeloperoxidase activity which reached the maximum after 24 h. These effects were reduced by high doses of glucocorticoids but not by nonsteroidal anti-inflammatory drugs.

Chang et al. (1987) applied 4 µg **tetradecanoyl phorbol acetate** and test drugs dissolved in acetone to the right ear of mice. Ear edema was calculated by subtracting the thickness of the left ear (vehicle control) from the right ear (treated ear).

De Young et al. (1989) examined the temporal patterns of edema and accumulation of the polymorphic nuclear cell marker enzyme myeloperoxidase following application of tetradecanoyl phorbol acetate to mouse ears. Topical and oral corticosteroids inhibited both edema and myeloperoxidase accumulation, whereby clobetasol propionate was more effective than fluocinolone and dexamethasone. Cyclo-oxygenase and lipoxygenase inhibitors were very effective against myeloperoxidase accumulation but were inactive or moderately active vs. edema.

Murakawa et al. (2006) studied the involvement of tumor necrosis factor-α in phorbol ester 12-*O*-tetradecynoylphorbol-13-acetate- (TPA-) induced skin edema in mice.

Topical application of arachidonic acid to mouse ear has become a widely used test (Young et al. 1983, 1984; Opas et al. 1985; Crummey et al. 1987; Hensby et al. 1987; Tomchek et al. 1991) One mg arachidonic acid is applied to the right ear of mice and vehicle to the left ear of each animal. Drugs are topically applied in acetone to the ear 30 min prior to the arachidonic acid application. Ear swelling was measured using a caliper one hour after arachidonic acid.

Griswold et al. (1995) induced inflammation in mice by local application of arachidonic acid or phorbol ester. Besides ear thickness, myeloperoxidase and DNA content was measured.

H.3.2.2.6 Paw Edema

PURPOSE AND RATIONALE

Among the many methods used for screening of anti-inflammatory drugs, one of the most commonly employed techniques is based upon the ability of such agents to inhibit the edema produced in the hind paw of the rat after injection of a phlogistic agent. Many phlogistic agents (irritants) have been used, such as brewer's yeast, formaldehyde, dextran, egg albumin, kaolin, Aerosil, sulfated polysaccharides like carrageenin or naphthoylheparamine. The effect can be measured in several ways. The hind limb can be dissected at the talocrural joint and weighed. Usually, the volume of the injected paw is measured before and after application of the irritant and the paw volume of the treated animals is compared to the controls. Many methods have been described how to measure the paw volume by simple and less accurate and by more sophisticated electronically devised methods. The value of the assessment is less dependent on the apparatus but much more on the irritant being chosen. Some irritants induce only a short lasting inflammation whereas other irritants cause the paw edema to continue over more than 24 h.

PROCEDURE

Male or female Sprague-Dawley rats with a body weight between 100 and 150 g are used. The animals are starved overnight. To insure uniform hydration, the rats receive 5 ml of water by stomach tube (controls) or the test drug dissolved or suspended in the same volume. Thirty minutes later, the rats are challenged by a subcutaneous injection of 0.05 ml of 1% solution of carrageenan into the plantar side of the left hind paw. The paw is marked with ink at the level of the lateral malleolus and immersed in mercury up to this mark. The paw volume is measured plethysmographically immediately after injection, again 3 and 6 h, and eventually 24 h after challenge.

Apparatus

Various devices have been developed for plethysmography of the paw. Winter et al. (1963) used mercury for immersion of the paw. A more sophisticated apparatus has been described by Hofrichter et al. (1969). Alpermann and Magerkurth (1972) described an apparatus based on the principle of transforming the volume being increased by immersion of the paw into a proportional voltage using a pressure transducer. Webb and Griswold (1984) reported a sensitive method of measuring mouse paw volume by interfacing a Mettler DeltaRange top-loading balance with a microcomputer. Several authors used a commercially available plethysmometer from Ugo Basile, Varese, Italy (Damas and Remacle-Volon 1992; Braga da Motta et al. 1994; Legat et al. 1994; Griesbacher et al. 1994).

EVALUATION

The increase of paw volume after 3 or 6 h is calculated as percentage compared with the volume measured immediately after injection of the irritant for each animal. Effectively treated animals show much less edema. The difference of average values between treated animals and control groups is calculated for each time interval and statistically evaluated. The difference at the various time intervals give some hints for the duration of the anti-inflammatory effect. A dose-response curve is run for active drugs and ED_{50} values can be determined.

MODIFICATIONS

Many agents can be used as irritants to induce paw edema in rats or mice. These are:

- 0.05 ml undiluted fresh egg white (Randall and Baruth 1976)
- 0.1 ml of 1% ovalbumin solution (Turner 1965)
- 0.1 ml of 1% formalin (Turner 1965)
- 0.1 ml of 0.2% carrageenan solution (Schönhöfer 1967) Introduction
- 0.1 ml of 1% carrageenan solution plus 100 ng PGE_2 or PGI_2 (Higgs et al. 1978; Portanova et al. 1996)
- 0.1 ml of 1 to 3% dextran solution (Turner 1965)
- 0.1 ml of 2.5% brewer's yeast powder suspension (Tsumuri et al. 1986)
- 0.1 ml of 0.5% β-naphthoylheparamine solution (Peterfalvi et al. 1966)
- 0.1 ml of 0.1% trypsin solution (Kalbhen and Smalla 1977)

0.1 ml of 0.1% collagenase solution (Souza Pinto et al. 1995)

0.1 ml of 0.1% solution of collagenase from *Clostridium histolyticum* (Legat et al. 1994)

0.1 ml of solution of 100 IU hyaluronidase (Dewes 1955, Kalbhen and Smalla 1977)

0.1 ml of complete Freund's adjuvant

0.05 ml of 0.02% serotonin solution (Kalbhen and Smalla 1977)

0.1 ml of 0.005% bradykinin solution (Damas and Remacle-Volon 1992)

0.1 ml of 0.1 mg/ml prostaglandin E2 (Nikolov et al. 1978)

0.1 ml of 2.0 µg/ml prostaglandin E2 (repeated injections, Willis and Cornelsen 1973)

0.1 ml of 1% concanavalin A solution (Lewis et al. 1976)

0.1 ml of 2.5% suspension of Aerosil

0.1 ml of 5% suspension of kaolin (Lorenz 1961; Wagner-Jauregg et al. 1962)

0.05 ml of bentonite gel (Marek 1980)

0.1 ml of nystatin 15000 units (Schiatti et al. 1970, Arrigoni-Martelli et al. 1971)

0.1 ml of 1% phytohaemagglutinin-P solution (Lewis et al. 1976)

0.01 ml of 0.5% adriamycin (mouse paw) (Siegel et al. 1980)

0.1 ml of 0.001–0.1% solutions of various phospholipases A2 (Cirino et al. 1989)

0.1 ml of 0.1% Zymosan solution (Gemmell et al. 1979)

0.1 ml of 0.05% anti^{-}IgG solution (Gemmell et al. 1979)

0.1 ml of 2.5% mustard powder suspension (Tsumuri et al. 1986)

0.1 ml of solution containing 1 unit of cobra venom factor(Leyck and Parnham 1990)

0.05 ml of 0.02–0.2% sonic extract from *Porphyromonas gingivalis* (Griesbacher et al. 1994)

0.1 ml of 0.25% suspension of papaya latex (Gupta et al. 1994)

The edema induced by the various irritants lasts for different times such as a few hours after serotonin and up to 2 days after Aerosil or after kaolin. These irritants therefore are suitable to study not only the degree but also the duration of the anti-inflammatory action.

Standards

Depending on the irritant steroidal and nonsteroidal anti-inflammatory drugs have a pronounced effect in the paw edema test. With carrageenan as irritant doses of 50 to 100 mg/kg phenylbutazone p.o. have been found to be effective.

CRITICAL ASSESSMENT OF THE METHOD

The paw edema method has been used by many investigators and has been proven to be suitable for screening purposes as well as for more in depth evaluations. Dependent on the irritant steroidal and nonsteroidal anti-inflammatory drugs, antihistaminics and also, to a lesser degree, serotonin antagonists are active in the paw edema tests. Since so many different irritants have been used by the various investigators the results are often difficult to compare.

FURTHER MODIFICATIONS OF THE METHOD

Besides paw volume Shirota et al. (1984) determined the surface temperature of the inflamed paw in rats using a special cage with rolling rods.

Kunz et al. (2004) assessed protein patterns in lumbar cord during a zymosan-induced paw inflammation in rats employing a two-dimensional gel electrophoresis revealing a time-dependent breakdown of scaffolding proteins such as neurofilament light chain protein. A calpain inhibitor prevented inflammation-induced neurofilament light chain breakdown in the spinal cord and reduced hyperalgesia.

Brooks et al. (1991) used anesthetized **dogs** and demonstrated that a significant inflammatory response can be elicited in the dog paw by subcutaneous injection of carrageenan. The increase in paw volume can be quantitatively measured as a pressure change recorded via a water-filled balloon fixed against the paw with nonexpandable tape. Effective doses of nonsteroidal antiinflammatory drugs were closer to human therapeutic doses in dogs than in rats.

Oyanagui and Sato (1991) described an **ischemic paw assay in mice**. A commercial rubber ring (1×1 mm, $d = 42$ mm) was bound 14 times to the right hind leg of mice just above the articulation. After 20 min of ischemia, the rubber was cut off with scissors. Paw swelling was measured after an other 20 min of natural blood recirculation.

Wirth et al. (1992) described a **thermic edema** which was induced in anesthetized Sprague-Dawley rats by immersing paws of the right and left hindlimb into water of 55°C. Immediately thereafter, the rats received the test drug (the bradykinin antag-

onist Hoe 140) intravenously. Paw volume was measured at regular intervals by plethysmography.

Braga da Motta et al. (1994) described drug modulation of **antigen-induced paw edema in guinea-pigs**. Male short-haired guinea pigs weighing 250–350 g received on day 0 a single dorsal s.c. injection of 1 ml of phosphate buffered saline containing 20 µg of ovalbumin, dispersed in 1 mg $Al(OH)_3$. The animals were boosted with a similar injection of antigen on days 14, 21, and 28. Thirty five days after the first injection of antigen or $Al(OH)_3$, the animals received an intraplantar injection of 0.5, 5, 50, or 200 µg ovalbumin, diluted in 100 µl of phosphate buffered saline. Edema was measured 2, 4, 6, 8, 24, and 48 h after the challenge.

H.3.2.2.7 Pleurisy Test

PURPOSE AND RATIONALE

Pleurisy is a well known phenomenon of exudative inflammation in man. In experimental animals pleurisy can be induced by several irritants, such as histamine, bradykinin, prostaglandins, mast cell degranulators, dextran, enzymes, antigens, microbes, and nonspecific irritants, like turpentine and carrageenan (Survey by DeBrito 1989). Carrageenan-induced pleurisy in rats is considered to be an excellent acute inflammatory model in which fluid extravasation, leukocyte migration and the various biochemical parameters involved in the inflammatory response can be measured easily in the exudate.

PROCEDURE

Male Sprague-Dawley rats weighing 220–260 g are used. The animal is lightly anaesthetized with ether, placed on its back and the hair from skin over the ribs of the right side is removed using animal clippers. The region is swabbed with alcohol. A small incision is made into the skin under the right arm between the seventh and eighth rib. The wound is opened and a further shallow incision is made into the exposed intercostal muscle. 0.1 ml of 2% carrageenin solution is injected into the pleural cavity through this incision. The injection needs to be made swiftly to avoid the risk of injuring the lung. The wound is closed with a Michel clip.

One hour before carrageenan injection and 24 and 48 h thereafter, groups of 10 rats are treated with the standard or the test compound subcutaneously or orally. A control group receives only the vehicle of medication. The animals are sacrificed 72 h after carrageenin injection by ether inhalation. The animal is pinned on a dissection board with the forelimbs fully extended. An incision in the skin over the xiphosternal cartilage is made to free the cartilage from overlying connective tissue. The cartilage is lifted with a forceps and a small cut is made with scissors in the body wall below to gain access into the pleural cavity. One ml of heparinized Hank's solution is injected into the pleural cavity through this cut. The cavity is gently massaged to mix its contents. The fluid is aspirated out of the cavity using a pipette. This is made easier if the dissection board is raised to an angle of 45–60°; the contents then pool in the corners of the cavity. The aspirated exudate is collected in a graduated plastic tube.

EVALUATION

One ml (the added Hank's solution) is subtracted from the measured volume. The values of each experimental group are averaged and compared with the control group. ED_{50} values can be calculated using various doses. Several other parameters can be used:

- Measuring the white blood cell number in the exudate using a Coulter counter or a hematocytometer,
- Determination of lysosomal enzyme activities,
- Determination of fibronectin,
- Determination of PgE_2.

CRITICAL ASSESSMENT OF THE METHOD

The pleurisy model has been accepted as a reliable method to study acute and subacute inflammation allowing the determination of several parameters simultaneously or successively. The activity of steroids as well as of non-steroidal drugs can be measured (Tomlinson et al. 1994; Harada et al. 1996).

MODIFICATIONS OF THE METHOD

The Evans blue-carrageenan-induced pleural effusion model has been proposed by Sancilio (1969, 1973) for screening of compounds with anti-inflammatory activity.

Meyers et al. (1993) tested the effect of treatment with interleukin-1 receptor antagonist on the development of carrageenan-induced pleurisy in intact and adrenalectomized rats.

Fröde et al. (2001, 2002) tested the effects of TNF-α and IL-1β, IL-6, and IL-10 and their specific antibodies in the acute inflammatory response induced by carrageenan in a **mouse** model of pleurisy. Adult Swiss mice received a single intrapleural injection of 0.1 ml of sterile saline containing 1% carrageenan. As the inflammatory response caused by carrageenan in the pleural space of the mice exhibits a biphasic response, peaking at 4 h, characterized primarily by neutrophils, and at 48 h due mainly to mononuclear cells, both interval points were studied. On the day of the experiment, different doses of TNF-α, IL-1β, IL-6 or IL-10 and their antibodies were injected into the pleural cavity of anesthetized mice. After 4 h or 48 h, the animals were sacrificed, the thorax was opened and the pleural cavity was washed with 1 ml of sterile PBS containing 20 IU/ml heparin. All animals had been injected 60 min previously with a solution of Evans blue dye (25 mg/kg, 0.2 ml, i.v.) in order to evaluate the degree of exudation into the pleural space. Leukocytes were counted and evaluated microscopically. The amount of dye was estimated by colorimetry.

H.3.2.2.8 Granuloma Pouch Technique

PURPOSE AND RATIONALE

The method originally invented by Selye has been developed for screening by Robert and Nezamis (1957) using croton oil as irritant. An aseptic inflammation resulting in large volumes of hemorrhage exudate is elicited which resembles the subacute type of inflammation. Instead of croton oil carrageenan can be used as irritant.

PROCEDURE

Male or female Sprague-Dawley rats with a body weight between 150 and 200 g are used. Ten animals are taken for controls and for test groups. The back of the animals is shaved and disinfected. With a very thin needle a pneumoderma is made in the middle of the dorsal skin by injection of 20 ml of air under ether anesthesia. Into the resulting oval airpouch 0.5 ml of a 1% solution of Croton oil in sesame oil is injected avoiding any leakage of air. Forty-eight hours later the air is withdrawn from the pouch and 72 h later any resulting adhesions are broken. Instead of croton oil 1 ml of a 20% suspension of carrageenan in sesame oil can be used as irritant. Starting with the formation of the pouch, the animals are treated every day either orally or subcutaneously with the test compound or the standard. For testing local activity, the test compound is injected directly into the air sac at the same time as the

irritant. On the 4th or the 5th day the animals are sacrificed under anesthesia. The pouch is opened and the exudate is collected in glass cylinders. Controls have an exudate volume between 6 and 12 ml, which is reduced dose dependent in the treated animals.

EVALUATION

The average value of the exudate of the controls and the test groups is calculated. Comparison is made by statistical means. A clear dose response curve could be found by s.c. injection of 0.5, 1.0 and 2.0 mg hydrocortisone acetate/rat. Also doses of 1.5 mg/kg indomethacin were found to be active.

CRITICAL ASSESSMENT OF THE METHOD

The method has been very useful to estimate the potency of anti-inflammatory corticosteroids both after local and after systemic application. By injection of a depot-preparation and induction of the granuloma pouch after various time intervals up to 4 weeks the duration of action can also be determined (Vogel 1963, 1965).

MODIFICATIONS OF THE METHOD

Carrageenin was used to induce exudate formation (Boris and Stevenson 1965).

Bobalik and Bastian (1967) developed a modified granuloma pouch technique in which *Mycobacterium butyricum* (adjuvant) was used as phlogistic agent.

Moreno (1993) sensitized rats by subcutaneous injection of methylated bovine serum albumin emulsified in complete Freund's adjuvant one week prior to the preparation of air pouches which were reinflated 4 days later. Seven days after formation of the air pouches inflammation was induced in the pouches by injection of 1 mg methylated bovine serum albumin.

Martin et al. (1994) described an air pouch model in the 6-day-old rat by injection of carrageenan. Besides the usual parameters, leukocyte influx and the level of prostaglandin E_2 in the pouch exudate were measured.

In order to measure the effects of different classes of proteinase inhibitors, Karran and Harper (1995) studied collagen degradation in subcutaneous air pouches in rats. The air pouches were formed in the dorsal region and were inflamed 6 to 8 days later by injecting λ-type carrageenan. Degradation of ^{14}C-collagen was followed in the inflammatory exudate fluid of the air pouches.

Sugio and Tsurufuji S (1981) re-evaluated the vascular constriction hypothesis as the mechanism of anti-inflammatory action of glucocorticoids. Rats were injected with 8 ml of air subcutaneously on the dorsal surface under light ether anesthesia to make an oval air sac. After 24 h, 4.0 ml of 2% heat-sterilized solution of carrageenin in 0.9% NaCl solution was injected into the air sac (day 0). Drug effects were tested on day 7. Vascular permeability in the granuloma pouch was measured using ^{125}I-HSA and ^{131}I-HSA. About 1 μCi of purified ^{125}I-HSA in 0.2 ml saline was injected into the femoral vein. After 30 min, 1.0 ml of the pouch fluid was withdrawn to measure the leakage of ^{125}I-HSA into the pouch fluid. After administration of the drug, about 1 μCi of purified ^{131}I-HSA was injected into the femoral vein. After 30 min, 1.0 ml of the pouch fluid was again withdrawn to measure the concentration of ^{131}I-HSA. The ratio of ^{125}I-HSA/^{131}I-HSA was taken as an index of vascular permeability change induced by drug treatment.

Atkinson et al. (1962) implanted compressed pellets of carrageenin subcutaneously to rats and measured the effects of some anti-inflammatory substances on wet weight of the pellets.

Bowers et al. (1985) described a method to induced a **granuloma in the rat lung** by instillation of a 2% carrageenan solution into one lower lobe of the lung via the trachea. No respiratory impairment was noticed during this procedure.

Further phlogistic agents inducing specific inflammatory cascades such as zymosan (complement activation) or lipopolysaccharide (cytokine release) have been used for pharmacological evaluation of anti-inflammatory agents (Erdö 1994; Miller 1997).

H.3.2.2.9 Urate-Induced Synovitis

PURPOSE AND RATIONALE

The importance of urate in gout and the deposition of sodium urate in gouty tophi is well known. Faires and McCarty (1962) reported that they themselves were the subjects for a study injecting 20 mg sodium urate crystal suspension in their own knee-joint. They experienced severe pain and prostration which resembled an acute gouty attack. Based on this experience they developed an experimental model in dogs for testing anti-inflammatory compounds (McCarty et al. 1963, 1966).

PROCEDURE

Preparation of Sodium Urate Crystals

0.4 g (0.01 Mol) sodium hydroxide pellets are dissolved in 400 ml distilled water in a glass beaker; 1.68 g (0.01 Mol) uric acid is added. The resultant opaque preparation is allowed to remain overnight at room temperature. The next morning, the crystals are harvested by decanting the supernatant solution and are then washed 3 times in cold saline, resuspended in saline and sterilized in an autoclave. Suspensions for injections are kept in rubber-stoppered, multi-dose vials containing 15 to 24 mg of urate per ml.

Unanesthetized healthy dogs weighing between 18 and 25 kg are used. They are trained to lie quietly on their backs in a dog cradle under light restraint. The skin above one knee is shaved, disinfected and a sterile 21-gauge needle inserted into the joint. Slight aspiration produces a small amount of clear, viscous synovial fluid, indicating entry into the joint. The needle is left in place, a syringe containing the urate suspension is attached and volumes from 0.1 to 0.5 ml are injected into the joint (approximately 2–10 mg urate).

One hour before the injection of urate crystals the animals are treated with the test compound or the standard. Experiments are designed so that a pair of dogs is tested on each of 2 days. On the first day, only one dog receives the drug. One week later the opposite knee of each dog is injected, but the other dog is treated.

EVALUATION

A scoring system is adopted in which inflammatory symptoms ranging from tenderness, limping, occasional 3-legged gait to complete 3-legged gait are scored from 1+ to 4+.

CRITICAL ASSESSMENT OF THE METHOD

In spite of the fact that the experiment originally has been performed in human volunteers and that the method closely resembles pathological conditions in man, due to animal protection law conditions the method can be recommended only for special investigations.

MODIFICATIONS OF THE METHOD

Carlson et al. (1986) developed an automated microcomputer-based system for determining canine paw pressure quantitatively in the dog synovitis model.

According to Phelps et al. (1967) dogs are anesthetized and placed on their sides with the hind leg firmly fixed with tape so that the femur and tibia form a 90-degree angle. The knee is punctured with a needle. When a few drops of synovial fluid can be withdrawn indicating a correct puncture of the joint, 6–10 ml of saline are injected to distend the joint and a polyethylene catheter is inserted through the needle, which is then withdrawn. 0.5 ml of a 0.02% sodium urate suspension are injected into the joint. The catheter is attached to a pressure transducer. Constant pressure recordings can be taken during the acute phase of inflammation. Pressure changes are plotted against time, whereby each dog is compared with his own control. Treatment with nonsteroidal anti-inflammatory drugs, such as indomethacin, show a considerable reduction of intraarticular pressure.

Fujihira et al. (1971) injected the urate suspension into the knee joint of a hind leg of well trained Beagle dogs. They were placed on three weighing ma-

chines whereby both forelegs rested on one balance, and the hindlegs individually on other balances. In this way, the relative change of weight on each hindleg after intra-articular injection of urate suspension can be measured, indicating a decrease of weight in the injected leg, counterbalanced to the other leg. Time response curves could be found after non-steroidal anti-inflammatory drugs.

Rosenthale et al. (1972) found a long-lasting inflammatory effect of prostaglandins PGE_1 and PGE_2 after injection in the knee joint of dogs.

Schaible and Schmidt (1985) induced an acute experimental arthritis in the knee joint of anesthetized **cats** by intraarticular injection of a 4% kaolin suspension and recorded the activity of single fine afferent units from filaments of the saphenous nerve.

Perkins and Campell (1992) injected either sodium urate crystals or Freund's complete adjuvant into one knee of **rats**. The maximum tolerated pressure was determined with or without treatment by analgesic drugs after 18–24 h (urate injections) or 64–70 h (Freund's complete adjuvant).

Daniel and Jouvin (1984) induced inflammation of the **guinea pig palatal mucosa** by injection of a microcrystalline suspension of monosodium urate.

Botrel et al. (1994) induced chronic inflammation in the knee joint of Beagle dogs by intra-articular injection of Freund's complete adjuvant. Besides body temperature, differences in skin temperature, difference in stifle diameter, the vertical force exerted by the arthritic hind limb measured by a force plate was chosen as parameter.

Schött et al. (1994) induced monoarthritis in rats by injection of 300 µg carrageenan in 50 µl saline into the right tibio-tarsal joint. Weight bearing was found to be an objective measure of arthritic pain.

Carleson et al. (1996) induced acute inflammation in the temporomandibular joint of rats by intraarticular injection of substance P and measured neurokinin A, calcitonin gene-related peptide and neuropeptide Y in the perfusate.

H.3.2.3 Methods for Testing the Proliferative Phase (Granuloma Formation)

H.3.2.3.1 Cotton Wool Granuloma

PURPOSE AND RATIONALE

The method has been described first by Meier et al. (1950) who showed that foreign body granulomas

were provoked in rats by subcutaneous implantation of pellets of compressed cotton. After several days, histologically giant cells and undifferentiated connective tissue can be observed besides the fluid infiltration. The amount of newly formed connective tissue can be measured by weighing the dried pellets after removal. More intensive granuloma formation has been observed if the cotton pellets have been impregnated with carrageenin.

PROCEDURE

Male Wistar rats with an average weight of 200 g are anaesthetized with ether. The back skin is shaved and disinfected with 70% ethanol. An incision is made in the lumbar region. By a blunted forceps subcutaneous tunnels are formed and a sterilized cotton pellet is placed on both sides in the scapular region. The pellets are either standardized for use in dentistry weighing 20 mg or pellets formed from raw cotton which produce a more pronounced inflammation than bleached cotton. The animals are treated for 7 days subcutaneously or orally. Than, the animals are sacrificed, the pellets prepared and dried until the weight remains constant. The net dry weight, i. e. after subtracting the weight of the cotton pellet is determined.

EVALUATION

The average weight of the pellets of the control group as well as of the test group is calculated. The percent change of granuloma weight relative to vehicle control group is determined.

CRITICAL ASSESSMENT OF THE METHOD

The method has been useful for evaluation of steroidal and nonsteroidal anti-inflammatory drugs. For testing corticosteroids, the test can be performed in adrenalectomized rats.

MODIFICATIONS OF THE METHOD

Bush and Alexander (1960) produced granulomata in rats by means of cotton-wool pellets which have been impregnated with carrageenin.

Tanaka et al. (1960) implanted filter paper pellets soaked with 7% formalin solution in rats.

Hicks (1969) implanted pellets impregnated with irritant substances, such as capsicum oleoresin.

Instead of cotton pellets, paper disks have been implanted (Tsurumi et al. 1986).

Roszkowski et al. (1971) immersed the cotton pellets in a 1% carrageenan solution, dried overnight and soaked in a 0.25 oxytetracycline solution before implantation.

D'Arcy and Howard (1967) induced a localized inflammatory reaction in the chorio-allantoic membrane of the chick embryo by the implantation of a sterile filter paper disc, followed by re-incubation *in situ* for 4 days.

Rudas (1960) described a method for quantitative evaluation of the granulation tissue formed in experimental wounds. Plastic rings were incorporated into the wounds on the back of rats inhibiting contraction of the wound edges and epithelialization of the wound. The growth of granulation tissue inside the rings was measured.

H.3.2.3.2 Sponge Implantation Technique

PURPOSE AND RATIONALE

The sponge implantation technique was described first by Saxena (1960) for short term experiments but was used subsequently to study the formation of granulomata using long-term implantation.

PROCEDURE

Sponges used for implantation are prepared from polyvinyl foam sheets (thickness 5 mm). Discs are punched out to a standard size and weight (10.0 ±

0.02 mg) using a 13 mm cork borer. The sponges are then soaked in 70% v/v ethanol for 30 min, rinsed four times with distilled water and heated at 80°C for 2 h. Prior to implantation in the animal, the sponges are soaked in sterile 0.9% saline in which either drugs, antigens or irritants have been suspended. Typical examples include 1% carrageenan, 1% yeast, 1% Zymosan A, 6% dextran, heat killed *Bordetella pertussis* (4×10^9 to 5×10^{10} organisms/ml) or 0.5% heat killed mycobacterium tuberculosis.

Sponges are implanted in female Wistar rats weighing 150–200 g under ether anesthesia. A 20 mm dorsal incision is made and the dermis separated from the underlying muscle layer by insertion of blunt forceps to form separate cavities into which sponges are inserted. Up to 8 sponges may be implanted per rat. The dorsal incision is closed with Michel clips and the animals are maintained at a constant temperature of 24°C.

For short term experiments, the animals are treated with test drug or standard once before implantation orally or subcutaneously. For long term experiments, the rats are treated daily up to 3 weeks.

EVALUATION

For estimation of the fluid phase of sponge exudates, e. g. protein content, enzyme levels and biological mediators such as prostaglandins as well as for leukocyte migration, the sponges are removed already after 9 h.

For studying the chronic phase of inflammation besides dry weight DNA, indicating cell content, hexosamine, indicating glycosaminoglycane content, and hydroxyproline, indicating collagen content, can be determined.

CRITICAL ASSESSMENT OF THE METHOD

The sponge implantation technique has been proven to be a versatile method which was used and modified by many investigators.

MODIFICATIONS OF THE METHOD

Boucek and Noble (1955) implanted polyvinyl sponges in rats, hamsters, rabbits and humans.

Holm-Pedersen and Zederfeldt (1971) implanted 2 cubes $10 \times 10 \times 10$ mm of cellulose sponge connected with a silk suture. After various implantation periods, the sponges were dissected free and the strength of the connection between the two parts of the sponge was determined after removal of the connecting suture.

Paulini et al. (1974, 1976) implanted polyester-polyurethane sponges which were inserted at both ends of a 15 mm long PVC tube separated by a cotton wool plug.

Bonta et al. (1979) used polyether sponges measuring $4 \times 1.5 \times 0.5$ cm. A thin polyethylene cannula is inserted into a hole of the sponge and fixed with two stitches. After implantation of the sponge the cannula is pulled through a subdermal tunnel to a neck incision where about 1.5 cm is exteriorized and closed with a tube sealer. One ml of a 2% carrageenin solution is injected into the sponge via the cannula. To study the local effect of drugs, the test compounds can be injected together with the carrageenin. The drugs can be administered repeatedly at any time.

The cannulated sponge method was further modified by Bragt et al. (1980) using a subdermally implanted Teflon cylinder. This cylinder is provided with holes to ensure contact and exchange between the inner chamber and the surrounding tissue and with two cannulae allowing injection of material and withdrawal of exudate at any given stage of granuloma development.

Damas and Remacle-Volon (1992) implanted in rats sterilized polyester sponges which were removed after 4 h and weighed.

H.3.2.3.3 Glass Rod Granuloma

PURPOSE AND RATIONALE

The glass rod granuloma as first described by Vogel (1970) reflects the chronic proliferative inflammation. Of the newly formed connective tissue not only wet and dry weight, but also chemical composition and mechanical properties can be measured.

PROCEDURE

Glass rods with a diameter of 6 mm are cut to a length of 40 mm and the ends rounded off by flame melting. They are sterilized before implantation by boiling in water. Male Sprague-Dawley rats with an initial weight of 130 g are anaesthetized with ether, the back skin shaved and disinfected. From an incision in the caudal region a subcutaneous tunnel is formed in cranial direction with a closed blunted forceps. One glass rod is introduced into this tunnel finally lying on the back of the animal. The incision wound is closed by sutures. The animals are kept in separate cages. The rods remain *in situ* for 20 or 40 days. Treatment with drugs is either during the whole period or only during the last 10 or 2 days. At the end the animals are sacrificed under CO_2 anesthesia. The glass rods are prepared together with the surrounding connective tissue which forms a tube around the glass rod. By incision at one end the glass rod is extracted and the granuloma sac inverted forming a plain piece of pure connective tissue. Wet weight of the granuloma tissue is recorded. The specimens are kept in a humid chamber until further analysis. For measurement of the mechanical properties the specimens are fixed into the clamps of the Instron$^{(R)}$ instrument allowing a gauge length of 30 mm. The load until break is recorded with a crosshead speed of 50 mm/min. In order to calculate tensile strength (N/mm^2), the value of load at rupture (N) is divided by cross sectional area (measured as volume = wet weight divided by length). Finally, the granuloma tissue is dried and the dry weight is recorded. In addition, biochemical analyses, such as determination of collagen and glycosaminoglycans, can be performed.

EVALUATION

Several parameters can be determined by this method. Granuloma weight was reduced by corticosteroids depending on dose and time of administration and was also diminished after treatment with nonsteroidal anti-inflammatory agents and lathyrogenic compounds. Furthermore, antiproliferative terpenoids reduced the granuloma weight. The mechanical parameters showed different results after these drugs indicating a different mode of action. Treatment with corticosteroids increased tensile strength. Only after long term treatment with toxic doses a decrease was found. Anti-inflammatory compounds, such as acetylsalicylic acid or indomethacin and antiproliferative terpenoids showed an increase of strength at medium and high doses.

CRITICAL ASSESSMENT OF THE METHOD

In contrast to most other granuloma methods, the glass rod granuloma measures the late proliferative phase of inflammation. Since the newly formed connective tissue is not contaminated with the irritant biochemical analyses can be performed. The peculiar feature is the possibility to study the mechanical properties of newly formed proliferative connective tissue.

H.4 Antipyretic Activity

H.4.0.1 General Considerations

Treatment with antipyretics has been very important in the pre-antibiotic era. Nevertheless, for treatment of acute viral diseases and for treatment of protozoal infections like malaria reduction of elevated body temperature by antipyretics is still necessary. For anti-

inflammatory compounds, an antipyretic activity is regarded as a positive side effect. To evaluate these properties, fever is induced in rabbits or rats by injection of lipopolysaccharides or Brewer's yeast.

H.4.0.2 Antipyretic Testing in Rats

PURPOSE AND RATIONALE

The subcutaneous injection of Brewer's yeast suspension is known to produce fever in rats. A decrease in temperature can be achieved by administration of compounds with antipyretic activity.

PROCEDURE

A 15% suspension of Brewer's yeast in 0.9% saline is prepared. Groups of 6 male or female Wistar rats with a body weight of 150 g are used. By insertion of a thermocouple to a depth of 2 cm into the rectum the initial rectal temperatures are recorded. The animals are fevered by injection of 10 ml/kg of Brewer's yeast suspension subcutaneously in the back below the nape of the neck. The site of injection is massaged in order to spread the suspension beneath the skin. The room temperature is kept at 22–24°C. Immediately after yeast administration, food is withdrawn. 18 h post challenge, the rise in rectal temperature is recorded. The measurement is repeated after 30 min. Only animals with a body temperature of at least 38°C are taken into the test. The animals receive the test compound or the standard drug by oral administration. Rectal temperatures are recorded again 30, 60, 120 and 180 min post dosing.

EVALUATION

The differences between the actual values and the starting values are registered for each time interval. The maximum reduction in rectal temperature in comparison to the control group is calculated. The results are compared with the effect of standard drugs, e. g. aminophenazone 100 mg/kg p.o. or phenacetin 100 mg/kg p.o.

CRITICAL ASSESSMENT OF THE METHOD

The antipyresis test in rats in can be regarded as a classical method in pharmacology.

MODIFICATIONS OF THE METHOD

Stitt and Shimada (1991), Shimada et al. (1994) induced fever in rats by microinjecting 20 ng PGE_1 directly into one of the brain's circumventricular organs of the rat known as the organum vasculosum laminae terminalis.

Luheshi et al. (1996) induced fever by intraperitoneal injection of 100 µ g/kg lipopolysaccharide into rats and measured the inhibition of fever by interleukin-1 receptor antagonist.

Telemetry has been used to record body temperature in animals (Riley et al. 1978; Gallaher et al. 1985; Clement et al. 1989; Guillet et al. 1990; Kluger et al. 1990; Bejanian 1991; Watkinson et al. 1996; Miller et al. 1997).

H.4.0.3 Antipyretic Testing in Rabbits

PURPOSE AND RATIONALE

Lipopolysaccharides from Gram-negative bacteria, e. g. *E. coli*, induce fever in rabbits after intravenous injection. Only lipopolysaccharide fractions are suitable, which cause after 60 min an increase of body temperature of 1°C or more at a dose between 0.1 and 0.2 µg/kg. In the rabbit, two maxima of temperature increases are observed. The first maximum occurs after 70 min, the second after 3 h.

PROCEDURE

Rabbits of both sexes and of various strains with a body weight between 3 and 5 kg can be used. The animals are placed into suitable cages and thermocouples connected with an automatic recorder are introduced into the rectum. The animals are allowed to adapt to the cages for 60 min. Then 0.2 ml/kg containing 0.2 µg lipopolysaccharide are injected intravenously into the rabbit ear. Sixty min later the test compound is administered either subcutaneously or orally. Body temperature is monitored for at least 3 h.

EVALUATION

A decrease of body temperature for at least 0.5°C for more than 30 min as compared with the temperature value before administration of the test compound is regarded as positive effect. This result has been found after 45 mg/kg phenylbutazone s.c. or 2.5 mg/kg indomethacin s.c.

CRITICAL ASSESSMENT OF THE METHOD

Measurement of body temperature in rabbits with polysaccharide induced fever is a more sensitive test than the yeast fever in rats. Furthermore, the method is used as a decisive test for the absence of pyrogens in parenteral drugs by several pharmacopoeias such as USP 23 (1955).

MODIFICATIONS OF THE METHOD

Cashin and Heading (1968) described a simple and reliable assay for antipyretic drugs in **mice**, using intracerebral injection of pyrogens.

Davidson et al. (1991) tested the effect of human recombinant lipocortin on the pyrogenic action of the synthetic polyribonucleotide polyinosini:polycytidylic acid in rabbits.

Yeast-induced pyrexia in **rats** has been used for antipyretic efficacy testing by Loux et al. (1982) and Cashin et al. (1977).

van Miert et al. (1977) studied the effects of antipyretic agents on fever and ruminal stasis induced by endotoxins in **conscious goats**.

Petrova et al. (1978) used turpentine-induced fever in rabbits to study antipyretic effects of dipyrone and acetylsalicylic acid.

Lee et al. (1985) studied the antipyretic effect of dipyrone on endotoxin fever of **macaque monkeys**.

Loza Garcia et al. (1993) studied the potentiation of chlorpromazine-induced hypothermia by the antipyretic drug dipyrone in anesthetized rats.

Shimada et al. (1994) studied the mechanism of action of the mild analgesic dipyrone preventing fever induced by injection of prostaglandin E_1 or interleukin-1β into the organum vasculosum terminalis of rat brain.

Chapter I
Antiarthrotic and Immunomodulatory Activity[1]

[1] With contributions to this and former editions by A. Huwiler, R.X. Raiss, R.R. Bartlett, and R. Schleyerbach.

I.1 Anti-Arthrotic Activity

I.1.0.1 General Considerations

Multifactorial causes can lead to osteoarthritis (OA), and its pathogenesis is not clearly understood as yet. The main characteristics of OA are the slowly progressing deterioration of the articular cartilage, accompanied by intermitted painful inflammatory episodes, and a continuous subchondral bone remodeling, often resulting in osteophyte formation in non-weight-bearing joint areas. Because of the lack of innervation and vascularization of cartilage, the destruction of this specific tissue remains unnoticed until other joint compartments are involved such as synovial membranes, answering with reactive synovitis to cartilage debris, or mechanoreception changes in the underlying bone, or until the diminution of articular cartilage results in a radiographically detectable joint space narrowing.

Therefore, analgesic and anti-inflammatory therapy has been the major treatment for OA in the past, and NSAIDs still constitute 92% of the drugs used against OA. Intraarticular injections of corticosteroids are also applied, although with geographically variable emphasis. Nevertheless they are still considered a useful tool in severe cases. Both classes of drugs are now reviewed more carefully with regard to their potentially harmful effects on cartilage maintenance and chondrocyte function – which leads to a more critical approach in drug selection. So-called 'chondroprotective' drugs, mainly sulfated polysaccharides, played a certain role in the pharmacotherapy of OA in Central Europe and some Eastern countries, but failed to demonstrate clinical efficacy, and now have lost significance.

Anti-oxidative enzymes or drugs such as superoxide dismutase or diacerein are also considered to influence osteoarthritic conditions. Recently, matrix metalloprotease-inhibitors (MMP-I), originally designed to inhibit tumor cell invasion, have shown promising results in counteracting the progressive enzymatic cartilage degradation, and some compounds are being developed for this indication. A further treatment gaining interest are derivatives of hyaluronic acid, which are applied intra-articularly in a series of injections. Their mechanism, however, is not clear yet, and most preparations have been filed as 'devices' rather than 'drugs', claiming a viscosupplementation with anti-inflammatory, analgesic, and chondroprotective properties.

I.1.1 In Vitro Methods for Anti-Osteoarthritic Activity

I.1.1.1 General Considerations

Since most of the drugs in use for OA were originally selected for other (e. g. arthritic) indications and only subsequently claimed to be effective in OA, they have not been primarily selected and optimized by *in vitro* assays specific for this condition. Thus, the indication lacks commonly agreed upon *in vitro* assays as well as clearly defined standard drugs to evaluate such models. Correspondingly, the variety of assay systems used to test compounds for their effect on cartilage maintenance and/or degradation is large, and the list below reflects this multitude.

The *in vitro* systems applied to assess drug effects upon chondrocytes range from homogenates of cartilage (Yu et al. 1991; Vignon et al. 1991; Zafarullah et al. 1992) over chondrocyte monolayers at different culture conditions and passages, suspensions of aggregated chondrocytes or clusters, cells cultured in or over an artificial matrix like agarose to cartilage explants and even organ cultures (Korver et al. 1989) like mouse patellas (Verschure et al. 1994). The species used in these studies vary over an equally wide range from mouse (Mohamed-Ali 1992), rat (Ismaiel et al. 1991; Seed et al. 1993; Seong et al. 1994; Srinivas et al. 1994), rabbit (Akatsuka et al. 1993; Collier, Ghosh 1991; Shimazu et al. 1993), dog (Venn et al. 1990), cattle, to human tissues (Bulstra et al. 1992; Green et al. 1995) derived from normal as well as osteoarthritic conditions. The chondrocyte and cartilage explant culture systems used for several years are described in more detail below with special emphasis on comparability and standardization.

PURPOSE AND RATIONALE

Articular chondrocytes not only control the regular balance of matrix synthesis and degradation in healthy cartilage turnover, but are also regarded as key players in the enhanced degradation and finally reduced synthesis of matrix components in pathological conditions like OA. The two main cartilage constituents are col-

lagen type II fibrillar network, and proteoglycans attached to hyaluronic acid filaments, also termed aggrecans. The latter are the more sensitive and the first ones to change in cartilage degradation. Therefore, the *in vitro* assays are performed mainly with chondrocytes, and the parameters measured focus on proteogly can synthesis and/or degradation.

The exact mechanisms of cartilage pathophysiology are not yet elucidated, but enzymatic degradation involving metallo-proteinases are considered the main events. *In vitro*, interleukin-1 and retinoic acid induce enhanced matrix degradation as well as reduced matrix synthesis, as observed in OA. Their role in the actual disease process *in vivo*, however, remains obscure. They therefore are used rather as tools to induce a disease-relevant condition *in vitro* than being subject of direct pharmacological intervention. Thus, the *in vitro* assays described here are suitable to compare and select a variety of drugs for their effect upon the main biological activity of articular chondrocytes. To address the respective mechanisms of drug action, more specific follow-up assays like enzyme inhibition or cytokine release or inhibition tests should be applied.

I.1.1.2 Modulation of Cellular Proteoglycan Metabolism

PURPOSE AND RATIONALE

In primary cultures, articular chondrocytes grown in an artificial matrix after digestion of the original bone, maintain their characteristic synthesis and turnover rate of cartilage matrix macromolecules for a long time. These metabolic processes can be influenced pharmacologically. In the following assay, compounds are tested for their effect upon the normal turnover of cartilage matrix by chondrocytes. The test is used to detect stimulation of matrix formation, but also to check for potential impairment of cartilage function. Specific matrix staining reveals the amount of newly formed matrix remaining around the cells at the end of treatment. Alternatively, incorporation of radiolabeled sulfate into the newly formed proteoglycans allows to quantitate the anabolic activity at the end of the experiment.

PROCEDURE

Reagents

A 1% (w/v) solution of Pronase from Boehringer in Ham's F12 is prepared, filtered under sterile conditions, and supplemented with 10% FCS.

A 0.025% (w/v) solution of Collagenase type II, activity 242 U/mg, from Worthington, corresponding to an activity of 6 U/ml in Ham's F12 is prepared, filtered under sterile conditions, and supplemented with 10% FCS.

Hank's balanced salt solution (HBSS) is obtained from Biochrome.

Ham's F12 is supplemented with 50 µg/ml gentamycine and 2.5 µg/ml amphotericin B.

A sterile stock solution of 5 mg/ml ascorbic acid in Ham's F12 is prepared, and aliquots are stored at –20°C.

A 2% solution of low melting agarose from Seaplaque in 0.9% NaCl is prepared by heating in a microwave, and stored in a water bath at about 50°C.

A buffer of 25 mM sodium-acetate (2.051 g/l) with 0.4 M magnesium-chloride 6-hydrate (81.32 g/l) is prepared, and adjusted with acetic acid to pH 5.6.

A staining solution is prepared with 0.1 g of alcian-blue, obtained from Sigma, in 67.5 ml buffer, filtered, and supplemented with 10 ml of a 25% solution of glutaraldehyde.

An 8 M guanidinium-hydrochloride solution is prepared.

Tissue and Cell Preparation

Fetlocks of freshly slaughtered steers (age 18 to 20 months) are skinned and the metacarpo-phalangeal joint opened under semi-sterile conditions. With a sterile scalpel, articular cartilage is then carefully removed from the underlying bone from all accessible cartilaginous regions and transferred into a sterile Ham's F12 solution at +4°C. The tissue is washed with Ham's F12 to remove adherent synovial fluid. The pieces are then transferred into a 150 ml trypsinizing flask, containing the pronase solution including the added serum, and incubated with gentle stirring for 1 h at 37°C and 95% humidity. The fluid is then removed, and the collagenase solution including the added serum is incubated with gentle stirring overnight. The resulting cell suspension is first filtered through a 90 µm and then a 50 µm Nylon filter and then centrifuged at 800 rpm for 10 min. Resuspension and washing is performed with HBSS and cells are counted and checked for vitality under the microscope using the Eosin staining. The vitality level should reach at least 95%. A cell suspension is prepared of 4×10^6 cells/ml Ham's F12 supplemented with 20% FCS.

To prepare the agarose cell cultures, 24 well plates are coated with 0.2 ml/well of a 1:1 mixture of the 2% agarose solution with preheated Ham's F12 and left at room temperature to gel. Then 0.1 ml/well (0.2 ml/well for radiolabeling) of a 1:1 mixture of the above described cell suspension with the 2% agarose solution is added. Care has to be taken to maintain an even cell suspension, and not to overheat the cells during this procedure. After gel formation at room temperature, the multiwell plates are placed in the incubator, and 0.5 ml/well medium is added either 4 h later or the following day. The medium consists of Ham's F12 supplemented with 5% FCS and 25 µg/ml ascorbic acid, and is changed every second day.

Assay

The assay starts 5 days after cell preparation. Compounds are added to the medium in a final concentration of 10 µM with 6 to 8 replicae per compound, and added anew with each change of medium over a total period of 8 days. The concentration can be varied according to the expected potency of the drug studied. An untreated control group as well as standard compound groups are always included. As standard compound, pentosane polysulfate to check for matrix increase, or retinoic acid to cause matrix decrease, can be applied.

At the end of treatment, the medium is removed, the wells washed 3× with 500 µl of medium without supplements, and 1 ml/well of the staining solution is added for 48 h. After removal of the supernatant, the following washing steps are performed for 10 min each:

- 3 × 500 µl/well 3% acetic acid,
- 1 × 500 µl/well 3% acetic acid in 25% ethanol,
- 2 × 500 µl/well 50% ethanol,
- 1 × 500 µl/well 70% ethanol.

With 500 µl/well of 8 M guanidinium hydrochloride solution, the bound stain is then extracted for 24 h at +4°C. After shaking the plates gently for 10 min, 100 µl/well of each supernatant is then transferred to round-bottom microtiter-plates, and the extinction photometrically assessed in the plate-reader at a wavelength of 610 nm.

EVALUATION

The extinction is expressed in percentage as staining density with the control values defined as 100%. Values $\geqslant 110\%$ are interpreted as stimulation of matrix formation, values lower than 80% as inhibition of matrix formation. Experiments with 8 wells/treatment usually exhibit a standard deviation below 7%.

CRITICAL ASSESSMENT OF THE TEST

The described method is suitable to compare up to 50 drugs in one experiment. The price for this is the limited quantification, as the staining is not strictly stoichiometric, and does not allow the distinction between matrix synthesis and degradation. For more detailed assessment, radiolabeling is the better choice. The limitation of these primary culture assays lies in the elaborate preparation and isolation of the chondrocytes. Several attempts to immortalize this differentiated mesenchymal cell type have resulted in the loss of cartilage-specific properties. A new cell line developed by MB Goldring (Green et al. 1995) might overcome this difficulty, but has not yet been reported to be modified pharmacologically.

MODIFICATIONS OF THE TEST

The agarose culture system for chondrocytes, originally described by Benya and Schaffer (1982), has been well characterized by Aydelotte et al. (1988, 1992), and the effects of different agarose densities have been studied by Verbruggen et al. (1990).

Instead of agarose gel cultures, some authors use 3D chondrocyte clusters in suspension (Bassleer et al. 1990, 1992; Henrotin et al. 1992), or suspensions over agarose (Archer et al. 1990), or embedded in collagen gels (Malemud et al. 1994).

Alternatively, encapsulation in alginate beads, either directly after isolation (Guo et al. 1989), even as primary culture for several months (Häuselmann et al. 1994), or after expansion in monolayers (Bonaventure et al. 1994), offers the opportunity to recover the chondrocytes later by depolymerization of the alginate.

Monolayers of articular chondrocytes can be used as well, but preferentially short-term (up to three days of culture), as under this culture condition chondrocytes tend to dedifferentiate to a fibroblast-like appearance and metabolic program. Authors using this modification are e. g. Kolibas, Goldberg (1989), Lane et al. (1992), and McCollum et al. (1991). The importance of culture conditions is addressed in the study by Seid et al. (1993), and that of culture duration in the paper by van der Kraan et al. (1992).

A dot blot assay by cuprolinic blue precipitation has been described by Jortikka et al. (1993), which is restricted to serum free conditions. Instead of matrix staining, radiolabeling can be applied as described in the next assay. In this case, the amount of cells should be doubled per well to assure sufficient label incorporation.

I.1.1.3 Cellular Chondrocytic Chondrolysis

PURPOSE AND RATIONALE

In this assay a disease-relevant situation is achieved by adding interleukin-1 (IL-1) to articular chondrocytes grown in agarose gel. IL-1 suppresses proteoglycan (PG) synthesis as well as increases their degradation, and thus results in a process which is also observed in degradative joint diseases *in vivo*. This process is termed chondrocytic chondrolysis. The test is used to detect the potential interference of a drug with this pathological process. Effect upon PG synthesis is studied by radiolabeling at the end of the experiment, and measuring the amount of incorporated sulfate. The effect upon PG degradation, and its release from the cellular environment, can be examined by prelabeling with $Na_2{}^{35}SO_4$, and following the amount of released incorporated sulfate over time from the supernatant with each or every second medium change.

PROCEDURE

Reagents

A 1% (w/v) solution of Pronase from Boehringer in Ham's F12 is prepared, filtered under sterile conditions, and supplemented with 10% FCS.

A 0.025% (w/v) solution of Collagenase type II, activity 242U/mg, from Worthington, corresponding to an activity of 6 U/ml in Ham's F12 is prepared, filtered under sterile conditions, and supplemented with 10% FCS.

Hank's balanced salt solution (HBSS) is obtained from Biochrome.

Ham's F12 is supplemented with 50 µg/ml gentamycin and 2.5 µg/ml amphotericin B.

A sterile stock solution of 5 mg/ml ascorbic acid in Ham's F12 is prepared, and aliquots are stored at –20°C.

A 2% solution of low melting Agarose from Seaplaque in 0.9% NaCl is prepared under heating and microwave application, and stored in a water bath at about 50°C.

Human recombinant interleukin-1 (IL-1)α or β from Genzyme is stored in aliquots at –20°C.

For radiolabeling, $Na_2{}^{35}SO_4$is purchased from Amersham.

A 4 M and 8 M guanidinium-hydrochloride (GuHCl) solution is prepared.

Tissue and Cell Preparation

Tissue and cell preparations are performed as for the previous assay, except the initial number of cells/well should be 400000, corresponding to a cell-containing gel volume of 0.2 ml/well, and the medium added is supplemented with 10% FCS and 25 µg/ml ascorbic acid. It is changed every second day.

Assay

The assay starts 6 days after cell preparation. Except for a control group, interleukin-1α is added in a concentration of 3 U/well, and added anew with each consecutive medium change. Except for the IL-1-control group, compounds are added to the medium in a final concentration of 10 µM with 4 replicae per compound, and with the subsequent medium changes. The concentration can be varied according to the expected potency of the drug studied. At the end of an 8 day treatment, the medium is replaced by medium containing 1 µCi $Na_2{}^{35}SO_4$/well and incubated for 24 h. The supernatant is then removed, mixed 1:1 with 8 M GuHCl, and separated with a PD10-Sephadex column into free versus incorporated sulfate. The multiwell plates with the remaining gels are deep frozen for at least 24 h to facilitate solubilization, thawed and then extracted with 500 µl/well 8 M GuHCl supplemented with inhibitors. The content of each well is then centrifuged at 13,000 rpm for 30 min. After this step, the supernatant contains the matrix trapped around the cells. This is equally separated by a PD10 Sephadex column into free versus incorporated radiolabel. The probes containing the incorporated sulfate and derived from both fractions (medium and gel) are then mixed with scintillating fluid and assessed in a β-scintillation counter.

EVALUATION

Counts per minute (cpm) from medium and gel fraction are calculated and related to the total well content. They are added if total incorporation is measured, or left separately, in case the ratio between released versus retained label is of interest. The data are converted into percent incorporation, with the values of the untreated control group or those of the IL-1 control group serving as 100%.

CRITICAL ASSESSMENT OF THE TEST

This is a sensitive test, in which an adequate labeling protocol can provide detailed information. The time- and material-consuming separation of free from incorporated radiolabel at the end, however, limits the size of the experiments and number of compounds to be studied.

In both cellular tests drug effects should be checked for (anti)proliferative activity in a separate proliferation test.

MODIFICATIONS OF THE TEST

If the catabolic response to a drug is of more interest than the anabolic one, the radiolabeling can be shifted to a time point prior to treatment, and the release of incorporated sulfate into the supernatant will allow to follow the time course and amount of PG degradation. This prelabeling should not start earlier than 4 days after plating to assure a comparable matrix synthesis rate. Because IL-1 suppresses PG synthesis at a lower concentration than it stimulates its degradation, a double to triple amount of IL-1 should be used in this modification.

Instead of bovine, human chondrocytes can be used (Raiss et al. 1992). One should allow 4 days of adjustment in the agarose system before starting treatment with human cells. If available, human serum gives a higher PG synthesis rate than fetal calf serum (Oestensen et al. 1991). The heterogeneity of responses depends on the individual source and should be considered (Verbruggen et al. 1989).

When using human instead of bovine cells, the stimulation of degradation and inhibition of synthesis is more effective with IL-1β than IL-1α: a concentration of 0.1 U/ml results in a reduction of PG synthesis of ca 50% (Raiss et al. 1995). When incubating with radiolabeled sulfate, the exposure time should be doubled to 48 h to yield sufficient incorporation.

To exclude direct interference of a drug with interleukin-1, all-trans retinoic acid can be used instead of this cytokine.

I.1.1.4 Cartilage Explant Chondrolysis

PURPOSE AND RATIONALE

Chondrocytes vary in their metabolic activity and cytokine response depends on the relative location within the joint (surfacial vs deep, weight-bearing vs non-weight-bearing, etc). Therefore, the cellular assays are a homogeneous mixture of an otherwise heterogeneous cell population. Two reasons suggest a verification of the cellular results obtained in tissue culture assays: First, chondrocytes are more reactive after isolation compared to those in tissue culture, which may lead to false positive results. Second, intact cartilage matrix acts as barrier for certain compounds of high molecular size and fixed charge, so that they may not reach their target cells. Therefore, explant assays are recommended as a follow-up to the cellular tests.

PROCEDURE

Reagents

Ham's F12 medium is supplemented with 50 µg/ml gentamycin and 2.5 μ g/ml amphotericin B.

A sterile stock solution of 5 mg/ml ascorbic acid in Ham's F12 is prepared, and aliquots are stored at –20°C.

Human recombinant interleukin-1 (IL-1)α or β from Genzyme is stored in aliquots at –20°C.

For radiolabeling, $Na_2{}^{35}SO_4$ is purchased from Amersham.

A 4 M and 8 M guanidinium-hydrochloride (GuHCl) solution is prepared.

Tissue Preparation

Fetlocks of freshly slaughtered steers (age 18 to 20 months) are skinned and the metacarpo-phalangeal joint opened under semi-sterile conditions. With a sterile punch (as used for obtaining skin biopsies) full thickness disks of cartilage are obtained from all accessible cartilaginous areas and their wet weight is assessed. In each well, 1 ml of medium is added, consisting of Ham's F12 supplemented with 10% FCS and 25 µg/ml ascorbic acid, and approximately 30 mg wet

weight of cartilage are transferred corresponding to 3 discs of 4 mm diameter.

Assay

The assay is started 1 to 2 days after tissue preparation. Except for a control group, interleukin-1α is added in a concentration of 8 U/well, and with each of the following medium changes (every second day). Except for an IL-1-control group, compounds are added to the medium in a final concentration of 10 µM with 6 to 8 replicae per compound, which are also added with each medium change. The concentration can be varied according to the expected potency of the drug studied. At the end of an 8 day treatment, the medium is replaced by a medium containing 15 µCi $Na_2{}^{35}SO_4$/well and incubated for 24 h. The supernatant is removed, mixed 1:1 with 8 M GuHCl, and separated with a PD10-Sephadex column into free versus incorporated sulfate. The explants are washed three times with Ham's F12 at +4°C, and extracted with 1 ml/well 4 M GuHCl supplemented with inhibitors for 48 h, and then a second time with 0.5 ml/well for 24 h. Both fractions are mixed, and separated with a PD10 Sephadex column into free versus incorporated sulfate. The samples containing the incorporated sulfate derived from medium as well as explant extraction are then mixed with scintillating fluid and assessed in a β-scintillation counter.

EVALUATION

Counts per minute (cpm) from medium and explant fractions are calculated related to mg wet weight of cartilage of the respective wells. They are either added if total incorporation is measured, or left separately, in case the ratio between released versus retained matrix is of interest. The data are converted into percent incorporation in comparison with the values of the untreated control or of the IL-1 control group serving as 100%.

CRITICAL ASSESSMENT OF THE TEST

Punched discs of similar size standardize the surface/volume ratio, and give more reproducible results than chips of cartilage obtained by scalpel dissection. A disadvantage is the greater amount of cartilage needed, which makes it unsuitable for human tissue obtained from joint replacement surgery. When using human tissue, interpretation and comparison of results should be restricted to the same source: striking differences occur between specimens from surgery or postmortem, between different joints (hip vs knee), and different ages of the donor (young or adolescent vs 35 years and older), as well as different stages of severity and the duration of degenerative joint diseases in cases of surgical specimens.

MODIFICATIONS OF THE TEST

The effect of serum concentrations on proteoglycan synthesis has been studied by McQuillen et al. (1986), and the effect of different concentrations of DMSO and glycerol, of importance for cryopreservation, has been examined on human fetal hip cartilage by Yang and Zhang (1991).

Some authors (Nixon et al. 1991) use bovine nasal septum as cartilage source, but the convenient homogeneity and mass of this tissue is outweighed by a matrix composition and biomechanical properties clearly distinct from articular cartilage.

Several authors use human cartilage from joint replacement surgery (e. g. Pelletier et al. 1989; Pelletier, Martel-Pelletier 1989), and some compare drug effects upon visually normal cartilage to those with fibrillated or osteoarthritic cartilage (Lafeber et al. 1992, 1993; Verbruggen et al. 1989, 1990).

A step towards organ culture represents the culture of full thickness cartilage with subchondral bone, cultured for 24 h on moist lens tissue (Chayen et al. 1994).

Bordji et al. (2000) published evidence for the presence of peroxisome proliferator-activated receptor (PPAR) α and γ and retinoid Z receptor in cartilage.

Bondeson et al. (2006) established a model of cultures of synovial cells from digested osteoarthritis synovium derived from patients undergoing knee or hip arthroplasties.

I.1.1.5 Influence on Matrix Metalloproteases

PURPOSE AND RATIONALE

Matrix metalloproteases (MMPs) form a multigene family of more than 20 secreted and membrane-tethered zinc-dependent endopeptidases, which are classified according to their structures and substrate specificities (Nicholson et al. 2005). Members of the family include: collagenases (MMP-1, -8, -13), gelatinases (MMP-2, -9), stromelysins (MMP-3, -7, -10, -11, -12) and membrane-type matrix metalloproteases (MT1-MMP to MT6-MMP). They are regulated by natural inhibitors, such as α_2-macroglobulin and the tissue inhibitors of metalloproteases (TIMPs). The catalytic domains of the MMPs have an ellipsoid shape with a small active cleft. This cleft contains the catalytic zinc ion, which is essential for catalysis. MMPs can degrade all components of the extracellular matrix and have been implicated in a number of pathological conditions. They are produced in response to the pro-inflammatory cytokines tumor necrosis factor (TNF) and interleukin-1 (IL-1) and are found in excess in the arthritic joint (Borkakoti 1998, 2004; Close 2001; Rosenblum et al. 2003; Mott and Werb 2004). MMPs belong to the metzincin superfamily of metalloproteinases, which also includes astacins, ADAMs (proteins with a disintegrin and metalloprotease domain) and ADAM-TS (an ADAM with a thrombospondin-like motif). Several trials are ongoing to find inhibitors of MMPs for treatment of rheumatism and osteoarthritis (Levin et al. 1998; Bigg and Rowan 2001; Martel-Pelletier et al. 2001; Matter et al. 2002; Nelson et al. 2002; Aranapakam et al. 2003; Skotnicki et al. 2003; Zask et al. 2003; Matter and Schudok 2004; Skiles et al. 2004). Besides these indications, metalloprotease inhibitors may be useful in treatment of other diseases, such as chronic obstructive bronchitis, atherosclerosis, inflammatory bowel disease, and cancer (Chang and Werb 2001; Whelan 2004).

Cauchard et al. (2004) tested the activation of latent transforming growth factor 1 and inhibition of matrix metalloproteinase activity by a thrombospondin-like tripeptide linked to elaidic acid.

PROCEDURE

In Vitro Assays

The influence of test substances on recombinant MMP-2, MMP-3, and MMP-9 activity was determined using the fluorescent quenched substrate Mca-Pro-Leu-Gly-LeuDpa-Leu-Ala-Arg [where Mca = (7-methoxy-coumarin-4-yl) acetyl and Dpa = 3-(2′,4′-dinitrophenyl)-L-2,3-diaminopropionyl].

Each enzyme was active site-titrated using a standard preparation of human recombinant TIMP-1 for MMP-1, and TIMP-2 for MMP-2 and TIMP-9 for MMP-9. Then, 200 pM MMP-2 or MMP-9, 400 pM of MMP-3 or 3 nM of MMP-1 was mixed with increasing concentrations of test substances in a 50 mM HEPES buffer, pH 7.6, containing 150 mM NaCl and 5 mM $CaCl_2$ and the assay was initiated by adding 2 µM of substrate. The rate of substrate hydrolysis was linear up to 30 min at 22°C. The reaction was stopped by adding 10 mM EDTA. The rate of the reaction was measured in triplicate for each test drug concentration examined using Perkin-Elmer LS50B spectrofluorometer with excitation and emission wavelength of 325 and 375 nm, respectively. Less than 5% of the substrate was hydrolyzed during the rate measurements.

EVALUATION

IC50 (µM) values were determined by plotting V_i/V_0, where V_i is the rate of substrate hydrolysis in the presence of inhibitor, V_0 is the rate in its absence, as a function of test drug concentrations and non-linear regression analysis.

MODIFICATIONS OF THE METHOD

Similar procedures were used in the following studies:

Lewis et al. (1997) to study an orally active collagenase inhibitor;

Billinghorst et al. (2000) and Dahlberg et al. (2000) to compare the degradation of type II collagen and proteoglycan in nasal and articular cartilages induced by interleukin-1;

Berton et al. (2001) to study the inhibition of matrix metalloproteinase activities by long-chain fatty acids; and

Matter et al. (2002) to investigate structure–activity relationship of tetrahydroisoquinoline-3-carboxylate-based matrix-metalloprotease inhibitors.

Bottomley et al. (1997) studied the inhibition of bovine nasal cartilage degradation by selective matrix metalloprotease inhibitors.

The potency of the inhibitors against human collagenase 1 (MMP-1), stromelysin (MMP-3), gelatinase B (MMP-9), and aggrecan metabolism was tested. Medium from human dermal fibroblasts (CCD45) cultured in the presence of recombinant human IL-1α (25 ng/ml) was used as source of collagenase. Collagenase activity was determined by measuring the degradation of ^{14}C-labeled collagen fibrils. Human prostromelysin-1 was antibody-affinity purified from conditioned human fibroblast culture medium. Progelatinase B was purified by gelatin-agarose affinity chromatography from human neutrophils. Both prostromelysin and procollagenase B were activated by treatment with trypsin. Stromelysin and gelatinase B activities were determined by measuring the cleavage of the fluorogenic substrate Mca-Pro-Lys-Pro-Leu-Gly-Leu-Dpa-NH_2; assays were performed using 50 mM borate buffer/1 mM $CaCl_2$ containing 0.05% Brij-35, at a substrate concentration of 2 µM. Assays were started by the addition of enzyme to a mixture of substrate and an inhibitor, and incubated for 4 h at 37°C; the assay was stopped by addition of acetic acid to a final concentration of 0.17 mM. The fluorescence of the product Mca-Pro-Lys-Pro-Leu-Gly (λ_{ex} 325 nm; λ_{em} 395 nm) was measured with a Hitatchi F-4500 fluorescence spectrophotometer.

A similar method was used by Reichelt et al. (2002) for design, synthesis, and evaluation of matrix metalloprotease inhibitors bearing cyclopentane-derived peptidomimetics as P1′ and P2′ replacements.

Perlman et al. (2003) found that IL-6 and matrix metalloproteinase-1 are regulated by the cyclin-dependent kinase inhibitor p21 in human synovial fibroblasts.

A fluorescent screening assay for collagenase using collagen labeled with 2-methoxy-2,4-diphenyl-3(2*H*)-furanone was recommended by O'Grady et al. (1984).

Zhang et al. (2004) identified and characterized a dual tumor necrosis factor-α-converting enzyme (**TACE**)/matrix metalloprotease inhibitor for the treatment of rheumatoid arthritis.

Assay of TNF-α Converting Enzyme (TACE)

A synthetic peptide of pro-TNF-α containing the minimal TACE cleavage sequence, Abz-LAQAVRSSSR-Dpa, was used as substrate. A segment of the extracellular portion of the human TACE that comprises the catalytic domain, the disintegin domain, the epidermal growth factor-like domain, and the Crambin-like domain was used. The protein was expressed in Chinese hamster ovary (CHO) cells and purified by nickel-nitrilotriacetic acid and preparative size exclusion chromatography to near homogeneity. Compounds were tested for their ability to inhibit the cleavage of the substrate by the purified enzyme in a fluorescence-based fluorescence resonance energy transfer (FRTE) assay. The human TACE protein (1 µg/ml) was pretreated with the inhibitors at various concentrations for 10 min at room temperature. The reaction was initiated by the addition of pro-TNF-α peptide to the TACE protein, and the increase in fluorescence was monitored at an excitation wavelength of 320 nm and emission wavelength of 420 nm over a period of 10 min (Jin et al. 2002).

MMP Enzymatic Assays

A continuous assay was used in which the substrate is a synthetic peptide containing a fluorescent group (7-methoxycoumarin), which is quenched by energy transfer to a 2,4-dinitrophenyl group. When the peptide was cleaved by MMPs, an increase in fluorescence was observed. The substrate used was 7-methoxycoumarine-PQGL-(3-[2,4-dinitrophenyl]-L-2,3-diaminopropionyl)-AR-OH. The assays were carried out at room temperature in a buffer containing 50 mM HEPES, pH 7.4; 100 mM NaCl, 5 mM $CaCl_2$, and 0.005% Brij-35 (Knight et al. 1992). The enzyme reaction was initiated by adding the substrate to a final concentration of 20 µM. The initial rate of the cleavage reaction was determined immediately after substrate addition.

Sadowski and Steinmeyer (2001) studied the effects of non-steroidal anti-inflammatory drugs and dexamethasone on the activity and expression of MMP-1, MMP-3 and tissue inhibitor of metalloproteinases-1. Bovine chondrocytes were cultured in alginate gel beads. Cells were treated with IL-interleukin 1α in the presence of vehicle or drugs at various concentrations. After 48 h mRNA expression of MMP-1, MMP-3, and the tissue inhibitor of metalloproteinases (TIMP-1) was analyzed by RT-PCR-ELISA. The protein synthe-

sis of TIMP-1 and MMP-3 was determined by immunoprecipitation. The activity of enzymes and inhibitors was measured by functional assays (Yoshioka et al. 1987; Steinmeyer et al. 1998).

The synthesis and biological activity of **TACE-inhibitors** are described by Beck et al. (2002), by Letavic et al. (2002, 2003) and by Tsukida et al. (2004).

Downs et al. (2001) used an **ELISA** for analysis of collagenase-cleavage of type II collagen to the C-terminal neoepitope. Valleala et al. (2003) described an ELISA assay for MMP-9 (gelatinase B).

Microtiter plates were coated with 100 µl of 5 µg/ml MMP-9-specific monoclonal antibody (TNO-S22.2) in PBS overnight at 4°C. After three washes in PBS containing 0.05% Tween 20 (PBS-T), 100 µl of purified MMP-9 or cell supernatant was added. After overnight incubation at 4°C, the plates were washed and incubated for 1 h at 37°C with 100 µl of biotin-labeled anti-MMP-9 polyclonal antibody (TNO-B21) diluted in PBS-T/EDTA + 0.1% casein (PBS-T/DTA/C) (0.8 µg/ml). After washing, bound polyclonal antibody was assessed by incubation with 100 μl of avidin/HRP at 1:10,000 in PBS-T/EDTA/C. Non-bound conjugate was washed away after 1 h at 37°C, and the chromogene 3,3′ 5,5′-tetramethyl benzidine in the presence of H_2O_2 was added. The reaction was stopped after 20 min with 2M H_2SO_4 and the absorption was measured at 450 nm in a Titertek Multiscan spectrophotometer.

Peppard et al. (2003) developed an assay suitable for high-throughput screening to measure matrix metalloprotease activity.

Sabatini et al. (2005) studied the effect of inhibition of matrix metalloproteinases on cartilage loss *in vitro* and in a guinea pig model of osteoarthritis.

Zymography was used by several authors to measure the activity of metalloproteases (Maquoi et al. 1998, 2002; Hattori et al. 2002; Sartor et al. 2002; Sato et al. 2002; Kaji et al. 2003; Kerkvliet et al. 2003; Kim and Kim 2004; Liu et al. 2004; Martin-Chouly et al. 2004; Naqvi et al. 2005).

Samples were subjected to electrophoresis on a 4.5% acrylamide stacking gel/7% acrylamide separating gel containing 1 mg/ml gelatin, in the presence of sodium dodecyl sulfate, under non-reducing conditions. After electrophoresis, gels were washed twice with 2.5% Triton X-100, rinsed with water, and incubated at 37°C overnight in 50 mM Tris, 5 mM $CaCl_2$, 2 mM $ZnCl_2$, pH 8.0. The gels were stained with Coomassie brilliant blue and destained in a solution of 25% ethanol and 10% acetic acid. Gelatinase activities appeared as clear bands against a blue background. To determine the inhibition profile of the enzyme activities, gels were incubated in the presence of one of the following inhibitors in the activation buffer: 10 mM EDTA as an inhibitor of MMPs, or 10 mM PMSF (phenylmethylsulfonyl fluoride) as an inhibitor of serine proteases. The molecular weight of gelatinolytic bands was estimated using recombinant protein molecular weight markers. Images of zymograms were acquired with the Gel Doc 1000 Gel Documentation System. The amount of enzyme was quantified by measuring the intensity of the negative bands using a densitometer analyzer with Quantity one software. Results were expressed as arbitrary units of relative intensity.

J Pharmacol Exp Ther 309:348–355

I.1.1.6 Aggrecanase Inhibition

PURPOSE AND RATIONALE

Degenerative joint diseases are characterized by cartilage extracellular matrix degeneration, where loss of aggrecan, an aggregating proteoglycan, is an early event in the destruction of articular cartilage. Aggrecan, a multidomain proteoglycan, is a major component of cartilage and provides compressive resistance to articular cartilage. During the early stages of osteoarthritis, and then throughout the disease, there is increased loss of glycosaminoglycan-rich aggrecan fragments via proteolysis attributable to "aggrecanase" activity.

Aggrecanase-1 and -2 are members of the ADAMTS (a disintegrin and metalloprotease possessing thrombospondin domain) family of zinc-containing metalloproteases, responsible for the cleavage of the aggrecan interglobular domain (IGD) at the Glu^{373}-Ala^{374} peptide bond, a unique site untouched by any previously identified enzyme (Arner et al. 1998; Abbaszade et al. 1999; Arner et al. 2002; Little et al. 1999; Tortorella et al. 1999, 2001; Arner 2002; Patwari et al. 2005; Stanton et al. 2005; Wight 2005; Song et al. 2007).

Inhibition of aggrecanase may impart overall cartilage protection and offer a potential therapy to alter the progression of osteoarthritis. Besides of endogenous inhibitors of aggrecanase (Bonassar et al. 1997; Sandy et al. 1998; Hashimoto et al. 2001, 2004; Little et al. 2002a; Malfait et al. 2002; Munteanu et al. 2002; Gendron et al. 2003; Pratta et al. 2003; Tortorella et al. 2004); also synthetic inhibitors are described (Bottomley et al. 1997; Munteanu et al. 2000; Little et al. 2002b; Sabatini et al. 2002, 2005; Sawa et al. 2002; Wada et al. 2002; Cherney et al. 2003; Vankemmelbeke et al. 2003; Noe et al. 2004; Liacini et al. 2005).

Xiang et al. (2006) described the synthesis and biological evaluation of biphenylsulfonamide carboxylate aggrecanase-1 inhibitors.

PROCEDURE

Bovine carpal joints were obtained from young (1- to 2-week-old) animals. Full-depth articular cartilage plugs were harvested using a cork borer and then sliced on a custom dice to generate individual disks 6 mm wide, 1 mm thick, and 30 mg in weight.

Cartilage explants were cultured at 37°C for 5 days in a humidified atmosphere of 5% CO_2 in air in cartilage explant media (CEM) consisting of Dulbecco's modified Eagle's medium containing 1% an-

timycotic/antibiotic, 2 mM glutamine, 10 mM HEPES, and 50 µg/ml of ascorbate (all from Sigma, St. Louis, Mo., USA). The explants were washed with CEM and one weighed disk per well was placed in a 96-well culture dish with 0.2 ml medium and six to eight replicates per treatment and cultured for 3 days in the presence or absence of recombinant human IL-1α (rhIL-1, 5 ng/ml, Sigma) and the presence or absence of small molecule compound. Media were replaced every day. The proteoglycan content in the medium was measured as sulfated glycosaminoglycan (GAG) by a colorimetric assay (Farndale et al. 1982) using dimethylmethylene blue (DMMB) and chondroitin sulfate C from shark cartilage (Sigma) as a standard. Treatment of cartilage with IL-1 results in the induction of catabolic enzymes including aggrecanases that degrade cartilage matrix proteoglycan. The cleaved proteoglycan is released from the matrix into the media. Addition of the compound together with IL-1 to the cartilage results in a decrease of proteoglycan release, indicating the inhibition of proteoglycan degradation. During this early phase of proteoglycan degradation, aggrecanases are the predominant catabolic enzymes that cleave aggrecan with no significant role of other MMPs (Pratta et al. 2003).

EVALUATION

Measured proteoglycan was expressed per weight of cartilage. IC_{50} values were calculated.

MODIFICATIONS OF THE METHOD

Miller et al. (2003) reported a microplate assay specific for the enzyme aggrecanase. Peppard et al. (2003) developed a high-throughput screening assay for inhibitors of aggrecan cleavage using luminescent oxygen channeling (AlphaScreen).

A simplified assay was reported by Kashiwagi et al. (2001).

Activities of ADAM-TS4 and ADAM-TS5 were measured by incubating enzyme with purified bovine aggrecan (500 nM) in 100 µl of 50 mM Tris-HCl buffer, pH 7.5, containing 0.1 M NaCl and 10 mM $CaCl_2$, for 2 h at 37 °C and terminating the reaction with 10 mM EDTA. The digestion products were then deglycosylated with chondroitinase ABC (0.1 units/10 µg aggrecan) and then with keratinase (0.1 units/10 µg aggrecan) and keratinase II (0.002 units/10 µg aggrecan) for 2 h at 37 °C in 0.1 M Tris-HCl, pH 6.5, containing 50 mM sodium acetate. The enzymatically treated products were analyzed by Western blotting using BC-3 antibody or an antibody against the GELE^{1480} neoepitope (Tortorella et al. 2000). To determine apparent inhibition constant $K_{i(app)}$ values for inhibitors against the aggrecanases, ADAM-TS4 or ADAM-TS5 (at a final concentration of 50 pM) was incubated with various concentrations of the inhibitor in 44 µl of the above buffer at room temperature for 30 min and then a solution of bovine aggrecan (5.5 µl) was added. The reaction products were detected with anti-GELE^{1480} antibody. The concentrations of ADAM-TS4 and ADAM-TS5 were confirmed by titration with recombinant N-TIMP-3.

I.1.2
In Vivo Methods for Anti-Osteoarthritic Activity

I.1.2.1
General Considerations

The current availability of animal models of osteoarthritis (OA) for pharmacological assessment is impeded in several aspects: Firstly, the difficulty to address a generally slow progression of cartilage destruc-

tion and deterioration of joint function as encountered in human OA with an animal model achieving sufficient similarity to human pathology in an acceptable time frame. Secondly, the discrepancy between the need of mild, reversible pathological changes, which can be modified therapeutically, and the paucity of reliable parameters with which to determine normal versus disease stages with a gradable range large enough to assess drug effects. This includes also the lack of validation (clinically as well as in animal models) of noninvasive methods to assess disease progression. Thirdly, the lack of a true disease-modifying standard drug with which to validate the pharmacological effects in respect to the predicted clinical outcome.

This results in a situation that animal models closer to human pathology like the spontaneous OA in the Hartley strain of guinea pigs or the surgically inflicted joint instability in the Pond-Nuki dog model are too elaborate to be used routinely for drug selection. On the other hand, models like the chymopapain-induced cartilage degradation in rabbits, are suitable to study drugs, but are limited in their predictive value.

Some progress can be expected from the use of genetically modified animals (Rintala et al. 1997; Serra et al. 1997; Ameye and Young 2002; Han et al. 2002; van Lent et al. 2002; Johnson and Terkeltaub 2003; Scharstuhl et al. 2003; Glasson et al. 2004, 2005; Ueblacker et al. 2004; Ford-Hutchinson et al. 2005; Wadhwa et al. 2005; Xu et al. 2005; Zaka and Williams 2005; Zhang et al. 2005).

It should be noted that differences exist in the pathomechanisms of cartilage destruction between rheumatoid arthritis (RA) and OA. The destruction occurring in RA is closely linked to the inflammatory process, synovial tissue proliferation and transgression across the cartilage surface, degrading cartilage proteoglycans and collagens simultaneously. In OA inflammation is only an intermitted event, not instrumental in the degenerative cartilage destruction, in which proteoglycan degradation is the early event, and collagen loss occurs at a distinctly later stage. Therefore, animal models with a predominant inflammatory component as the air pouch model or other arthritis models, even those focusing on cartilage destruction, are not discussed in this chapter (see Sect. H.3). They are described in detail by Greenwald and Diamond (1988) and recently reviewed by Greenwald (1991, 1993).

PURPOSE AND RATIONALE

As a multitude of different events can lead to OA, equally different techniques have been used to initiate osteoarthritic conditions in animal models: Surgical methods are used to either stiffen the joint in a defined position (Palmoski, Brandt 1982; Konttinen et al. 1990; Meyer-Carrive and Ghosh 1992; Torelli et al. 2005) or inflict joint instability by partial meniscectomy or anterior crucial ligament (ACL) dissection. They are performed mainly in dogs, rabbits (Colombo et al. 1983; Moskowitz et al. 1973, 1979), and guinea pigs (Schwartz 1985; Meacock et al. 1990). Chemical modifications like intraarticular injections of iodoacetate, cytokines like IL-1, or enzymes like chymopapain or stromelysin, are carried out mainly in rabbits (Williams et al. 1992; Reglin et al. 1989), in chicken (Kalbhen 1983, 1987), and in rats (Combe et al. 2004). Mechanical forces are applied on bent or opened joints like impulse loading on sheep (Lindenhayn et al. 1984) or rabbit (Farkas et al. 1987; Mazière et al. 1984) knees, resulting in trauma models of OA. Spontaneously occurring OA is described in horses (Todhunter and Lust 1992; Haakenstad 1969), some breeds of dogs (Lust et al. 1985), rhesus macaques (Pritzker et al. 1989), guinea pigs (Bendele, Hulman 1988) and several strains of mice. For pharmacological purposes only guinea pigs and STR/1N (Walton 1965; Raiss et al. 1992), STR/ORT (Dunham et al. 1989), and C57 black (Pataki et al. 1990) mice have been adapted. In all models mentioned (except horses), the relevant joint is the knee.

Since there exist recent extensive and critical reviews of OA models (Burton-Wurster et al. 1993; Pritzker 1994; Moskowitz 1990, 1992; Adams and Billingham 1982; Oegema et al. 1999; Bendele 2001, 2002; Bonnet and Walsh 2005), also with respect to reversibility (Pita et al. 1986), with special emphasis on drug testing (Hess & Herman 1986; Hinz and Brune 2004; Wieland et al. 2005), and in perspective to cartilage research and markers (Malemud 1993; Carney 1991), only some representative models of each category are described here.

I.1.2.2 Canine Anterior Cruciate Ligament (ACL) Transection Model

PURPOSE AND RATIONALE

Similar to human ACL ruptures, ACL transection in the dog knee and the subsequent joint instability results in progressive cartilage erosion, fibrillation, and formation of osteophytes. This elaborate model is well characterized, and regarded of high predictive value. It is mostly known as the "Pond-Nuki dog model". These authors achieved the ACL transection originally through a lateral stab incision, whereas others also performed the ligament transection after opening the joint. Both versions lead to similar morphological and biochemical changes, and are described and illustrated in detail by Adams and Pelletier (1988).

PROCEDURE

Animals

Mongrels, beagles, greyhounds, and foxhounds are reported to be suitable, provided purebred strains are used. In general, younger animals display more repair phenomena, whereas older ones seem to show more rapid degeneration. As the epiphyses fuse at the age of 13 months, and as pronounced changes require up to 4 months to fully develop, careful planning ahead is essential.

Operation

The dogs are initially anesthetized with 30 mg/kg sodium pentobarbital i.v., followed by a continuous inhalation of 1% halothane with 1 l/min N_2O and 2 l/min O_2. After shaving and sterilizing the knee joint externally, it is fixed in a bent position at 90°, and a scalpel blade is inserted medially deep into the joint space diagonally posterior to the ACL, and parallel to the lateral border of the patellar ligament. By rotation of the blade, the ACL is then dissected, the blade withdrawn, and the wound closed. In the contralateral knee, a sham operation is performed to inflict similar disturbance to the joint tissue, but without harming the ACL. The ACL dissection results after 8 to 12 weeks, in contrast to the sham-operated contralateral knee, in fibrillation and erosion of the cartilage, more pronounced on the tibial plateau than on the femoral condyles. Also observed histologically is a loss of metachromatic staining, and a fissured surface with cell clones appears. A marked osteophytosis and subchondral sclerosis has also developed at that time. Proteoglycan content and overall cartilage thickness, however, seems to remain stable (Pelletier and Martel-Pelletier 1985) or even increase not only for several months (McDevitt et al. 1977; Vignon et al. 1983; Brandt and Adams 1989), but for up to 3 years after transection, as Brandt, Myers et al. (1991) could show. At later stages, however, severe cartilage thinning and loss is recorded (Brandt, Braunstein et al. 1991).

EVALUATION

Macroscopic inspection of cartilage and osteophytes are recorded. Histological grading based on the Mankin score has been reported to be modified by drug

treatment over 7 weeks (Abatangelo et al. 1989; Schiavinato et al. 1989). As levels and activity of neutral matrix metalloproteases are elevated in cartilage and synovium (Pelletier, Martel-Pelletier 1985), they might be additional parameters of interest to profile the test compounds.

CRITICAL ASSESSMENT OF THE TEST

In this instability model, a polysulfated glycosaminoglycan preparation (Arteparon), as well as intra-articular injections of a hyaluronic acid preparation induced some morphological and biochemical changes, whereas low-dose prednisone had no effect. As there seems to prevail an anabolic response to the instability in the articular cartilage for quite a long time, the selected time points and parameters to assess disease progression and therapeutic success require careful consideration.

MODIFICATIONS OF THE TEST

Caron et al. (1996) and Pelletier et al. (1997) investigated the *in vivo* effect of the recombinant human interleukin-1 receptor antagonist on the development of lesions in the anterior cruciate ligament transection model in dogs.

Wenz et al. (1998) used the Pond-Nuki model in dogs to evaluate the effectiveness of intra-articular application of hyaluronic acid on early forms of femoropatellar arthrosis. Transection of the anterior cruciate ligament in dogs was also used in studies by Myers et al. (1999), Boileau et al. (2002, 2005), Smith et al. (1999, 2002), Behets et al. (2004), and Matyas et al. (2004).

Pelletier et al. (2005) studied the effects of licofelone, a 5-lipoxygenase/cycloogygenase inhibitor, in the experimental anterior cruciate ligament dog model of osteoarthritis.

ACL transection can be performed also in an arthrotomy operation as described by Adams and Pelletier (1988), and an instability can be achieved equally by meniscectomy (Hannan et al. 1987).

The **rabbit** is the main other species used for instability models, as described in detail for partial medial meniscectomy by DiPasquale et al. (1988), and for partial lateral meniscectomy in connection with ligament transection by Colombo (1988).

Obara et al. (1993) induced osteoarthritis by surgical dissection of the anterior cruciate ligament in rabbits and investigated fluorescence distribution after intra-articular administration of fluorescein-labeled sodium hyaluronate.

Anterior cruciate ligament transection in rabbits was used in several studies (Amiel et al. 2003; Kawano et al. 2003; Doschak et al. 2004; Zhang et al. 2004; Diaz-Gallego et al. 2005; Tiraloche et al. 2005).

Kobayashi et al. (2005) studied a vitamin B1 derivate, and its ability to enhance the chondroprotective effects of glucosamine hydrochloride and chondroitin sulfate in osteoarthritis created by partial medial meniscectomy of the knee joint in rabbits.

A partial medial meniscectomy with ligament transection is described for the **guinea pig** by Bendele (1987) and Schwartz (1988). This method has been used by Bendele et al. (1999) and by Sabatini et al. (2005).

Layton et al. (1987) produced biomechanical stress-induced hip osteoarthritis in guinea pigs by extra-articular myectomy and tendotomy.

The Hartley guinea pig strain spontaneously develops knee osteoarthritis whose manifestations are markedly similar to those of spontaneous knee osteoarthritis in humans (Bendele et al. 1989; Kraus et al. 2004).

Janusz et al. (2002) described a model of osteoarthritis in **rats** induced by surgically transecting the medial collateral ligament and meniscus and evaluated the effectiveness of a matrix metalloproteinase inhibitor in this model. Using this model, Moore et al. (2005) found that fibroblast growth factor-18 stimulates chondrogenesis and cartilage repair.

Machner et al. (1999) investigated the influence of an altered sensible joint innervation on the development of knee osteoarthritis in Wistar rats. Partial sensible joint denervation was performed by injection of 100 µg capsaicin into a sponge placed on the sensible nerve trunk. Half of the rats underwent strenuous running exercises (20 km in a running wheel by intracranial self-stimulation). Under these conditions, severe osteoarthritis changes were observed, which were only mild without exercise.

Hayamai et al. (2004) studied cartilage degeneration and osteophyte formation in the anterior cruciate ligament transection model in rats**.**

Wancket et al. (2005) used the medial meniscotomy model in Lewis rats to study the anatomical localization of cartilage degradation markers.

Ghosh et al. (1993), Appleyard et al. (1999), and Burkhart et al. (2001) used an osteoarthritis model induced by lateral meniscectomy in **sheep**.

I.1.2.3 Chymopapain-Induced Cartilage Degeneration in the Rabbit

PURPOSE AND RATIONALE

Intraarticular injection of chymopapain into the rabbit knee joint results in cartilage degradation with rapid loss of proteoglycans. A transient inflammation shortly after injection normally subsides after 1–2 days. Severity and reversibility of the cartilage damage can be altered using different protocols (Williams et al. 1992).

PROCEDURE

Most authors use New Zealand White rabbits at the age of 2 to 4 months. Male Chinchilla and Chinchilla Bastard rabbits are preferred, as they display a thicker cartilage than the New Zealand strain. The animals with an initial body weight of ca 2.5 kg are anesthetized with a continuous inhalation of 4% halothane – 3 l/min N_2O – 1.8 l/min O_2. Both knee joints are carefully shaved and moisturized with 70% alcohol. With a sterile syringe a volume of 0.1 ml of the following solution is injected laterally into the joint space: eighteen mg chymopapain (Sigma) are dissolved in 1 ml 0.9% NaCl, and 50 mg l-cysteine-HCl is added for activation. The preparation is then passed under sterile conditions through a 0.22 µm Millipore filter, and tested for activity prior to each operation. (Potential direct interference of the therapeutic agent to be tested with the chymopapain can also be addressed at that point). One injection of 1.8 mg chymopapain in 0.1 ml per joint usually results in a proteoglycan loss/cartilage

dry weight of ca 40% after 10 to 12 days. Two to 4 animals per experiment receive chymopapain in 0.9% NaCl in one joint, and 0.9% NaCl into the contralateral knee to assess the proteoglycan loss caused by the enzyme. Care is taken with all injections to apply the same volume to both joints, as the contralateral serves as internal control. If the drug is given orally, only one knee receives chymopapain treatment, whereas if the drug is applied intraarticularly into one knee (1 to 5 injections of 0.1 ml volume each, vehicle into contralateral joint, in a period of 5 to 10 days), both knees are treated with chymopapain. The animals are sacrificed after 10 to 14 days, and from defined regions of weight-bearing areas in the joint full thickness samples are obtained for histology and assessment of proteoglycan content.

Histology is performed on full thickness sections of the articular cartilage, fixed with 3% formalin, embedded in paraffin, and stained routinely with safranin-O/fast green, or with toluidin-blue (Romeis 1989).

The proteoglycan content is determined with the dimethyl-methylen blue (DMB) method modified after Farndale et al. (1986) and Chandrasekhar et al. (1987). The wet weight of the cartilage samples is determined immediately after preparation, and their dry weight is recorded after 3 day drying at 60°C. Samples are then soaked overnight in 1 ml buffer (containing 20 mM disodiumhydrogenphosphate, 1 mM EDTA, and 2 mM dithiothreitol in 500 ml aqua bidest at pH 6.8). Ten µl of papain, suspended in 0.05 M sodiumacetate (Sigma 9001–73-4), are then added, and incubated at 60°C for 6 h. Ten µl of standard (shark chondroitinsulfate C (Sigma C4384) in a concentration range from 10–200 µg/ml buffer) and of each probe are then transferred into a 96 well microtiter-plate. Two hundred µl of DMB is added, and, after 1 min, the extinction recorded photometrically at 690/540 nm. The DMB solution is prepared by dissolving 16 mg DMB (Serva 20335) in 2 ml methanol, adding 400 ml aqua bidest, 9.6 ml 1N HCl-solution, 3.04 g glycine, and 2.36 g NaCl, stirred and warmed until dissolved, and then diluted to a final volume of 1000 ml with aqua dest (pH 3.0). The results are recorded as µg chondroitinsulfate equivalents/mg cartilage dry weight.

EVALUATION

The histological appearance of the articular cartilage is assessed with a modified Mankin score, emphasizing more earlier changes, and separating degradative aspects, (e. g. loss of safranin staining), from repair aspects, (e. g. the occurrence of pericellular staining). The proteoglycan content is expressed as % change to the contralateral knee, or, comparing groups, to chymopapain-treated or. untreated control groups. To relate the proteoglycan content to cartilage dry weight has been found to be more reliable than choosing wet weight as baseline, as the cartilage water content is known to change in this model according to matrix composition.

CRITICAL ASSESSMENT OF THE TEST

In this model, hyaluronic acid preparations and some MMP inhibitors can be detected, NSAIDs do not change the parameters tested. The protocol can be modified to emphasize repair phenomena, or to assure a more severe course of cartilage loss (Williams et al. 1993).

MODIFICATIONS OF THE MODEL

Muehleman et al. (2002) investigated bone remodeling inhibition by a biphosphonate in the rabbit model of cartilage matrix damage by chymopapain injection.

To avoid interaction of a drug with the enzymatic nature of the chymopapain, other degradation mediators can be applied instead, as e. g. fibronectin fragments (Williams et al. 1988).

To ensure continuous synovial levels of a given drug, an osmotic minipump containing the drug can be implanted into the femoral muscles with a prolonged fine tube to insert into the patellar groove (Karbowski et al. in prep). This is an elaborate procedure in which a Ketavet/Rampun anesthesia is needed, and postoperative plastic collars to prevent the rabbits to interfere with the operated region for the first three days. This results in highly consistent data compared to repeated injections.

Kikuchi et al. (1998) induced experimental osteoarthritis in mature rabbits by intra-articular injection of collagenase.

Pomonis et al. (2005) developed a **rat model of osteoarthritis pain.** Male Sprague Dawley rats were anesthetized with isoflurane and received a single injection of iodoacetate (0.3, 1, or 3 mg), papain (0.5, 1, 2, or 3%) or saline in a 50 µl volume into the left knee joint using a 27-gauge needle inserted through the patella tendon. Assessment of pain-related behaviors was performed using a hind limb weight-bearing apparatus (Linton Incapacitance Tester Stoelting, Wood Dale, Ill., USA). Animals treated with intra-articular iodoacetate were evaluated for alterations in weight bearing after the acute and chronic administration of various drugs.

Osteoarthritic lesions in the knee joints of male C57bl10 mice were induced by a single intra-articular

injection of bacterial collagenase (Van der Kraan et al. 1990; Van den Berg et al. 1993).

Van der Kraan et al. (1989) and Scharstuhl et al. (2002) induced arthritis in mice by a single intra-articular injection of papain in their knee joints.

Van Osch et al. (1995) developed a device to measure laxity of knee joints in mice. Reproducible, non-linear S-shaped load displacement curves were determined from knee joints of normal mice. Parameters of anterior-posterior translation, varus-valgus rotation, and compliance were calculated from the curves. Laxity was marked increased in animals with osteoarthritis induced by intra-articular injection of collagenase.

Saez-Llorens et al. (1991) and Cohen et al. (2004) described a model of **septic arthrosis** in rabbits.

Four-month-old female New Zealand rabbits were anesthetized with an intramuscular injection of 60 mg/kg ketamine and 6 mg/kg xylazine. The skin overlying the knees was shaved and cleansed with povidone-iodine and 70% ethanol. The right knee was injected with 10^5–10^6 colony forming units of *Staphylococcus aureus*, while the left knees were injected with sterile saline. Following injection, all rabbits were allowed normal cage activity. The rabbits were left either untreated, or were treated with antibiotic (40 mg/kg ceftriaxone) alone or additionally with different doses of test drug. Animals were anesthetized at 1, 4, and 7 days following initiation of treatment. Prior to aspiration of synovial fluid, the knee joint was inspected for evidence of effusion and range of motion testing. Following an arthrotomy, the gross appearance of the joint was examined for joint degradation and the fluid grossly inspected for purulence. Prior to sacrifice, an arterial blood sample was plated on agar plates, incubated for 48 h at 37°C, and analyzed for colony growth. In the synovial fluid the number of white blood cells was determined and bacterial growth examined in serial dilutions. Histology was performed in synovial tissue from the pre-patellar fat pad and the medial femoral condyle.

I.1.2.4 Spontaneous OA Model in STR/1N Mice

PURPOSE AND RATIONALE

This spontaneous model has the advantage of a gradually developing OA starting with cartilage surface ero-

sion and fibrillation to osteophyte formation, subchondral bone remodeling, and finally eburnation, in a moderate time frame. All these steps, with only intermittent inflammatory flares, are similar to human pathology, and develop without any interference. The disadvantages are, however, the restriction to systemic drug application, due to the relative small animal size, and the variance in onset and severity of the disease among the animals.

PROCEDURE

The STR/1N mouse strain, characterized extensively by Walton (1977–1979) can be obtained from the National Institute of Health, Bethesda MA, USA. It is not identical to the STR/ORT strain as described by Benjamin et al. (1995), since it displays, in contrast to the ORT, no calcification in ligaments or tendons. Male mice develop OA earlier and more consistently than females, and, without dietary restriction, develop additionally obesity.

Beginning at the age of 10 weeks, male mice are trained to walk on a slowly rotating cylinder (or treadmill, manufactured by Ugo Basili, Italy) recording the mean walking time of each mouse. Mice with a moderate activity (neither dropping off too soon, nor staying on for hours) are then selected to enter the experiment. In groups of 8 to 10 animals, the drug is applied systemically for 8 weeks, and the mobility of each animal is recorded once or twice a week on the rotating cylinder. The body weight is recorded regularly as well. At the end of the experiment, the animals are sacrificed, both knee joints dissected, fixed, decalcified, and embedded in defined orientation for histology.

EVALUATION

The mean walking time decreases with age and disease progression, and is recorded in a time-dependent graph over the treatment period. The medial tibial plateau of the knee joints exhibits the most pronounced cartilage fibrillation and loss, and is, therefore, selected for histological evaluation, based on a modified Mankin grade.

CRITICAL ASSESSMENT OF THE TEST

Since this model is best suitable for oral drug application, experience with disease-modifying drugs for osteoarthritis is limited. Drugs with anti-inflammatory properties increase walking time, but do not alter the morphological aspects of cartilage degradation in the joint. Analgesic drugs have no effect on either.

MODIFICATIONS OF THE TEST

Rudolphi et al. (2003) studied an inhibitor of interleukin-1β converting enzyme in STR/1N mice and in a collagenase-induced osteoarthritis model in Balb/c mice. Weakening of knee joint ligaments was achieved by intra-articular injection of highly purified bacterial collagenase leading to increased joint laxity which resulted in osteoarthritic lesions preferentially in the medial compartments of the injected knee joint (Van der Kraan et al. 1990).

Several authors (Nakamura 1990; Pataki and Witzemann 1990; Wilhelmi and Meyer 1983) have used the C57black mouse which, however, is reported to vary considerably in the incidence and severity of the disease, and also to develop the osteoarthritis only at older ages.

The STR/ORT strain differs in its calcification of fibrous cartilage (Benjamin et al. 1995), and seems to change the orientation of the proteoglycans in the hyaline cartilage (Dunham et al. 1989).

Gaffen et al. (1997) found elevated aggrecan mRNA in STR/ort mice. Brewster et al. (1998) tested an orally active collagenase inhibitor in STR/ORT mice. Microfocal X-ray-generated images of the hind limbs as well as histologic sections of the knees were scored for degradative changes and drug effects. Chambers et al. (2001) reported that matrix metalloproteinases and aggrecanases cleave aggrecan in different zones of normal cartilage but co-localize in the development of osteoarthritis lesions on STR/ort mice. Mason et al. (2001) reviewed the use of the STR/ort mouse as a model of osteoarthritis. Flannelly et al. (2002) studied the temporal expression of matrix metalloproteinases and tissue inhibitors in the murine STR/ort model of osteoarthritis. Price et al. (2002) compared collagenase-cleaved articular cartilage collagen in mice in the naturally occurring STR/ort model of osteoarthritis and in collagen-induced arthritis.

Glant et al. (1998) reported progressive polyarthritis induced in BALB/c mice by aggrecan from normal and osteoarthritic human cartilage.

I.1.2.5 Transgenic Mice as Models of Osteoarthritis

PURPOSE AND RATIONALE

Osteoarthritis comprises a group of diseases characterized by gradual degeneration of articular cartilage and a number of associated processes within the joint. Consequently, no single animal model based on one genetic alteration is likely to fulfill all the criteria of human osteoarthritis (Helminen et al. 2002; Säämänen and Vuorio 2004). Transgenic mice with **collagen mutations** include different types of collagen.

Several lines of transgenic mice have been produced harboring mutations in the type II collagen gene. These include a line expressing a human *COL2A1* transgene with a large internal deletion (Vandenberg et al. 1991), and another expressing a murine *Col2a1* transgene with a Gly58Cys substitution in the helical domain (Garofalo et al. 1991). An osteoarthritis phenotype can also be produced by increasing the expression rate of the normal *Col2a1* gene, which leads to disruption of the regulation of type II collagen fibril assembly (Garofalo et al. 1993). The transgenic mouse line Del1 harbors six copies of a *Col2a1* transgene with a 150-bp deletion of exon 7 and introns 7, removing sequences coding for the 15 amino acids at the amino-terminal end of the triple helical domain (Metsäranta et al. 1992). Homozygous Del1 mice die at birth due to respiratory distress. Heterozygous Del1 mice develop early-onset human osteoarthritis-like lesions, usually confined to the knee joint (Säämänen et al. 2000).

Mice transgenic for type IX collagen mutations carrying a central in-frame deletion mutation that codes for truncated α1(IX) chains develop mild chondrodysplasia and progressive osteoarthritis with ocular involvement (Nakata et al. 1993). Fässler et al. (1994) reported non-inflammatory degenerative joint disease in mice lacking α1(IX) collagen.

Xu et al. (2003) demonstrated osteoarthritis-like changes and decreased mechanical function of articular cartilage in the joints of mice with the chondrodysplasia gene (*cho*). A mutation in the gene encoding the α1 chain of type XI collagen (*Col11a1)* was identified as the genetic cause of chondrodysplasia in mice.

Several transgenic models of osteoarthritis with mutations in non-collagenous molecules were described. Ameye et al. (2002) reported that abnormal collagen fibrils in tendons of biglycan/fibromodulin-deficient mice lead to gait impairment, ectopic ossification, and osteoarthritis. Ameye and Young (2002) recommended mice deficient in small leucine-rich proteoglycans as novel *in vivo* models of osteoporosis, osteoarthritis, Ehlers-Danlos syndrome, muscular dystrophy, and corneal diseases.

Zemmyo et al. (2003) described accelerated, aging-dependent development of osteoarthritis in $\alpha 1$ integrin-deficient mice. Morko et al. (2004) reported upregulation of cathepsin K expression in articular chondrocytes in a transgenic mouse model of osteoarthritis.

Involvement of **matrix metalloproteinases** has been demonstrated in the degradation of cartilage and the development of human osteoarthritis lesions. Holmbeck et al. (1999) reported that MT1-MMP-deficient mice develop dwarfism, osteopenia, arthritis, and connective tissue disease due to inadequate collagen turnover. Neuhold et al. (2001) found that postnatal expression in hyaline cartilage of constitutively active human collagenase-3 (MMP-13) induces osteoarthritis in mice. These mice develop cartilage lesions with histological similarities to human osteoarthritis. Salminen et al. (2002) reported differential expression patterns of matrix metalloproteinases and their inhibitors during development of osteoarthritis in the transgenic Del1 mouse model. Glasson et al. (2005) reported that deletion of active ADAMTS5 prevents cartilage degradation in a murine model of osteoarthritis.

I.2
Methods for Testing Immunological Factors

I.2.1
In Vitro Methods

I.2.1.1
Inhibition Of Histamine Release from Mast Cells

PURPOSE AND RATIONALE

Hypersensitivity reactions can be elicited by various factors: either immunologically induced, i. e. allergic reactions to natural or synthetic compounds mediated by IgE, or non-immunologically induced, i. e. activation of mediator release from cells through direct contact, without the induction of, or the mediation through immune responses. Mediators responsible for hypersensitivity reactions are released from mast cells. An important preformed mediator of allergic reactions found in these cells is histamine. Specific allergens or the calcium ionophore 48/80 induce release of histamine from mast cells. The histamine concentration can be determined with the *o*-phthalaldehyde reaction.

PROCEDURE

Preparation of Mast Cell Suspension

Wistar rats are decapitated and exsanguinated. Fifty ml of Hank's balanced salt solution (HBSS) are injected into the peritoneal cavity and following massage of the body, the abdominal wall is opened. The fluid containing peritoneal cells is collected in a centrifuge tube and centrifuged at 2000 rpm. The cells are resuspended in HBSS. Then the cell suspension is brought to a final concentration of 10^5 mast cells/100 µl.

Test Compound Administration and Induction of Histamine Release

1 ml test drug (concentration range between 10^{-4} and 10^{-8} Mol) is added to the mast cell suspension (10^5 cells/100 ml) and the mixture is incubated at 37°C for 15 min. The cells are made up to a volume of 3 ml with HBSS, an equal volume of calcium-ionophore (10^{-6} g/ml), compound 48/80 or specific allergen is added. The suspension is incubated at 37°C for 30 min followed by centrifugation at 2500 rpm.

The Following Control Solutions are Needed

- *Spontaneous histamine release:* contains only mast cells and solutions used to determine baseline.
- *Histamine release:* contains mast cells and solutions and calcium-ionophore (10^{-6} g/ml).
- *Test compound control:* contains solutions and test compound to test the compound for native fluorescence.
- *Solution control:* contains only solutions used in the test to determine baseline.

Extraction of Histamine

One ml of the top layer is transferred to a tube containing 300 mg NaCl and 1.25 ml butanol. The sample is alkalized to extract the histamine into butanol by adding 1 ml 3 N NaOH. Following mechanical shaking, the sample is centrifuged for 5 min. One ml of the top layer (butanol) is pipetted into a 5 ml tube containing 2 ml of n-heptane and 0.4 ml of 0.12 N HCl. The tube is mixed by inverting it several times. Following separation into aqueous and organic phases, 0.5 ml of the aqueous phase is transferred to another tube.

Induction of o-Phthaladehyde Complexing Reaction

To each sample 100 µl 1 N NaOH is added under constant stirring immediately followed by administration of 100 µl 0.2% *o*-phthalaldehyde solution. After 2 min, the *o*-phthalaldehyde complexing reaction is stopped by addition of 50 µl 3 N HCl.

Determination of Histamine Release

The total sample is transferred to an autosampler vial and the histamine concentration is determined by a fluorescence detector (using excitation and emission wave lengths of 350 and 450 nm respectively).

EVALUATION

Percent histamine release (hist. rel.) can be expressed by the following formula:

$$\frac{\text{sample hist. rel.} - \text{spontaneous hist. rel.}}{100\%\ \text{hist. rel.} - \text{spontaneous hist. rel.}} \times 100$$

The statistical evaluation is carried out using the Student's *t*-test (comparison of 100% control to experimental group)

CRITICAL ASSESSMENT OF THE METHOD

Disodium cromoglycate has been reported to inhibit the release of histamine and the degranulation of rat mast cells (Orr and Cox 1969; Orr et al. 1971; Johnson and Bach 1975; Church and Young 1983). However, this effect of disodium cromoglycate and its analogues does not parallel the clinical efficacy (Kay et al. 1987).

MODIFICATIONS OF THE METHOD

Johnston et al. (1978) studied the increased superoxide anion production by immunologically activated and chemically elicited macrophages.

Flint et al. (1985) found a significant inhibition of histamine release by disodium cromoglycate in human mast cells recovered by bronchoalveolar lavage.

Ali et al. (1985) investigated the histamine release from rat peritoneal mast cells, human basophil and neutrophil leukocytes, mast cells from mesentery lung and heart of rats and guinea pigs by the skin irritating constituents thapsigargin and thapsigargicin from the resin of the umbelliferous plant *Thapsia gargania.*

Eady (1986) studied the reactivity of mast cells in bronchoalveolar lavage fluid of macaques repeatedly infected with *Ascaris suum*.

Wells et al. (1986) compared release of histamine, LTC_4, and PGD_2 from primate bronchoalveolar mast cells with that of rat peritoneal mast cells.

The release of β-hexosaminidase from mouse or rat bone marrow derived mast cells and from rat peritoneal mast cells was studied by Broide et al. (1986).

Peretti et al. (1990) recommended flow cytometry to investigate mast cell degranulation. Peptides, including substance P and bradykinin analogs release histamine from human skin mast cells (Lawrence et al. 1989).

Williams et al. (1991) studied the vancomycin-induced release of histamine from rat peritoneal mast cells and a rat basophil cell line (RBL-1).

A sensitive colorimetric assay for the release of tryptase from human lung mast cells *in vitro* has been described by Lavens et al. (1993).

I.2.1.2 Mitogen Induced Lymphocyte Proliferation

PURPOSE AND RATIONALE

Cultured lymphocytes can be stimulated to a proliferative response and to DNA synthesis by various mitogens. Measurement of DNA synthesis can be accomplished by pulse-labeling the culture with tritiated thymidine (^{3}H-thymidine), a nucleoside which is incorporated into the newly synthesized DNA. Immunmodulating properties can be detected either by pre-

treatment of the animals *in vivo* or by adding the test drug to the cultured lymphocytes.

PROCEDURE

Mice of NMRI strain weighing 18–20 g or rats of Lewis strain weighing 180–200 g are used.

Materials

Sheep red blood cell (SRBC) specific antigen and/or the following mitogens:

- Lipopolysaccharide 10–0.1 µg/ml
- Dextran sulfate 30–7.5 µg/ml
- Phytohaemagglutinin 0.5–0.12 % stock solution
- Concanavallin A 0.5–0.12 µg/ml
- As standards levamisole, cyclosporine A, prednisolone or leflunomide are used.

Ex Vivo

Animals receive the test compound once a day for 5 days. Thereafter, they are sacrificed, spleens are removed and a single cell suspension of 5×10^6 cells/ml is prepared. Mitogens are titrated (4 replicates/group) in 0.1 ml/well and 0.1 ml of the cell suspension is added. Plates are incubated at 37°C in 5% CO_2 in air for 48–60 h and for another 8 h after addition of 0.25 µC ^{3}H-thymidine per well. Cells are harvested on glass fiber filters and after drying the degree of radioactivity is determined using a β-counter.

In Vitro

Animals are sacrificed and their spleens removed. A single cell suspension of 10^7 cells/ ml is prepared and 0.05 ml placed in each microtiter well (4 replicates/group). Then the test compound (4 times concentrated) is added in 0.05 ml. At last 0.1 ml of the double concentrated mitogen is added. Plates are incubated and processed as described above.

EVALUATION

Stimulation index = proliferation ratio according to positive control, either with or without mean spleen weight. Statistical evaluation is carried out using the Student's *t*-test (comparison of positive and/or negative control to experimental group).

I.2.1.3 Inhibition of T Cell Proliferation

PURPOSE AND RATIONALE

Activation and/or proliferation of clonal populations of T cells are critical for the initiation of an antigen-specific immune response. Thus, inhibition of T cell activation provides a potent means for suppressing specific immune response. A number of immunosuppressive agents exhibit the ability to suppress T cell activation.

PROCEDURE

Purification of Peripheral Blood Leukocytes and T Cells

Peripheral blood leukocytes from normal donors are separated on Ficoll-Hypaque (Pharmacia, Piscataway, NJ). Leukocyte suspensions are washed in HBSS and are resuspended in RPMI 1664 medium (Gibco, Grand Island, NY) containing 10% heat-inactivated fetal bovine serum and 100 U/ml penicillin/streptomycin. Leukocyte suspensions are resuspended in RPMI 1664 containing 10% heat-inactivated pooled human serum. Highly enriched T cells are obtained by passing leukocytes through a nylon wool column to remove macrophages and B cells and then depleted of NK and monocytes with anti-Leu 11 b (Becton Dickinson, Mountain View, CA) plus complement (Pel-Freeze, Brown Deer, WI). These highly enriched T cells are approximately 95% CD3+ cells, the remaining cells being B lymphocytes.

Mixed Lymphocyte Reaction

Peripheral blood leukocytes are incubated at 2×10^5/well with equal numbers of gamma-irradiated (3000 rads) allogenic peripheral blood leukocytes and various concentrations of test compounds. Assays are performed in triplicate in 96-well, U-bottom plates. After 6 days of coculture, the cells are pulsed for 6 h with 1 µC of [^{3}H]thymidine per well. [^{3}H]Thymidine incorporation is then measured by scintillation

counting. Data are presented as:

$$\% \text{ inhibition} = \frac{CPM_{expt} - CPM_{bckgrd}}{CPM_{ctrl} - CPM_{bckgrd}} \times 100$$

where CPM_{expt} is mean counts per min of experimental cultures, CPM_{bckgrd} is mean counts per min of background well, unstimulated cultures, and CPM_{ctrl} is mean counts per min of uninhibited, stimulated cultures.

Lymphocyte Stimulation and Proliferation

Peripheral blood leukocytes and isolated T cells are cultured with anti-CD3 (5 ng/ml) plus PMA (5 ng/ml), anti-CD28 (1:5000 dilution) plus PMA (5 ng/ml), or 100 U/ml rhuIL-2 in RPMI 1644 containing 10% fetal bovine serum. Peripheral blood leukocytes or T cells are cultured at 2×10^5 cell per well in a total volume of 200 µl/well. Assays are performed in quadruplicate in 96-well, U-bottom plates. [^{3}H]Thymidine (1 µC) is added to each well after 48 h of coculture and after a 20 h pulse of [^{3}H]thymidine, the cells are harvested and the amount of [^{3}H]thymidine uptake is quantitated on a scintillation counter.

ELISA Assays

Supernatants/well (100 ml) are harvested 24 h after initiation of cultures of peripheral blood leukocytes or T cells stimulated with anti-CD3 or anti-CD28 plus PMA. IL-2 in the coculture supernatant is quantitated using a commercially available IL-2 ELISA kit. All experiments are performed in duplicate.

IL-2R Assays

The expression of IL-2R on T cells stimulated for 48 h with anti-CD3 or anti-CD28 plus PMA is determined using FITC-conjugated anti-CD25 mABs (Becton Dickinson, Mountain View, CA). T cells are washed in HBSS and then stained with phycoerythrin-conjugated anti-CD3 mAB and fluorescein-conjugated antiCD25 mAB. The percent of cells coexpressing CD3+ and CD25+ are determined from 2000 cells using an EPICS C flow cytometer (Coulter, Hialeah, FL).

EVALUATION

Dose response curves of inhibition of one-way mixed lymphocyte reaction and of IL-2 in the supernatant after stimulation with antiCD3 or anti-CD28 are established.

MODIFICATIONS OF THE METHOD

Zielinski et al. (1993, 1994) studied the influence of leflunomide on expression of lymphocyte activation expression markers (IL-2 and transferrin receptors) as well as on cell cycle and on IL-2 receptor gene expression.

Calcineurin was found to be a key signaling enzyme in T lymphocyte activation and the target of immunosuppressive drugs (Clipstone and Crabtree 1993).

I.2.1.4 Chemiluminescence in Macrophages

PURPOSE AND RATIONALE

The stimulation of macrophages by antigen, complement, phorbol-esters, ect. leads to elaboration of O_2^- and other oxygen metabolites. Superoxide ion (O_2^-) and other highly reactive oxygen metabolites (radicals) form the basis for an efficient microbicidal system *in vivo*. Yet, when these radicals are released in response to self-antigens, tissue damage is often the result. Inhibition of this process can be regarded as a measure for immun-modulating effects of compounds. The oxygen metabolites can produce light-emitting reactions (chemiluminescence), which is measurable if amplified with suitable agents, such as the cyclic hydrazide luminol.

PROCEDURE

NMRI mice weighing 30 g or Sprague-Dawley rats weighing 250–300 g of either sex are used.

Positive Control

1. Sensitized mice, receiving vehicle
2. Mice, developing an autoimmune disease, receiving vehicle
3. Rats, developing adjuvant arthritis, receiving vehicle

Negative Control

1. Mice not sensitized, receiving vehicle
2. Mice, not developing an autoimmune disease, receiving vehicle
3. Rats without adjuvant arthritis.

Materials

- 5×10^8 SRBC (sheep red blood cells)/0.5 ml 0.9% NaCl solution (for sensitization)
- *Phorbolester:* Stock solution of 1 mg/ml phorbolmyristenacetate. This stock solution is diluted with Hank's balanced salt solution to a final concentration of 3.5 µM (working solution). For the induction of chemiluminescence, the working solution is diluted in the test tube 1:4, resulting in a final phorbolester concentration of 0.875 µM.
- Luminol (5-amino-2,3-dihydro-1,4-phthalazinedione, Sigma) final concentration 25 µg /ml

Ex Vivo Experiment

Groups of 6 animals are treated for 6 days orally or subcutaneously with test compound or the standard (prednisolone acetate or leflunomide). They are decapitated and exsanguinated. Macrophages are obtained by flushing the peritoneal cavity with 10 ml saline, containing 250 IU heparin. The cells are pooled, washed several times and suspended again at a final concentration of 2×10^6/200 µl.

For measurement in the luminometer the following mixture is prepared:

200 µl macrophages (2×10^6)
100 µl luminol solution (100 µg/ml)
100 µl phorbolmyristenacetate solution (3.5 µM)

Each sample is mixed thoroughly without the phorbolmyristenacetate solution, put into the luminometer and counted at 2 min intervals for 10 s. The addition of the phorbolester induces the reaction.

In Vitro Experiment

To 100 µl of macrophage suspension (2×10^6 cells) are 100 µl of the solution of the test compound added and incubated for 15 min at 37°C.

Then, 100 µl of luminol solution (100 µg/ml) and 100 µl of the 3.5 µM phorbolester solution are added and the luminescence measured in the luminometer.

EVALUATION

The time of maximal counts for the positive control is recorded. For all groups the ratio of counts per 10 s is determined at that time, compared to the positive control counts per 10 s and the percent change is calculated. For statistical evaluation the experimental group is compared with the positive control group using Student's *t*-test.

MODIFICATIONS OF THE METHOD

Bird and Giroud (1985) described a technique of polymorphonuclear leukocyte chemiluminescence as a means to detect compounds with anti-inflammatory activity. Inflammatory polymorphonuclear leukocytes were obtained by injecting rats intrapleurally with 1 ml of a 1% solution of calcium pyrophosphate and collection of the pleural exudate 4 h later. Chemoluminescence responses were measured using a Packard Picolite chemoluminometer and opsonized zymosan as the stimulus.

Seeds et al. (1985) found an independent stimulation of membrane potential changes and the oxidative metabolic burst in polymorphonuclear leukocytes.

A microtechnique for studying chemiluminescence response of phagocytes using whole blood was described by Selvaraj et al. (1982).

I.2.1.5 PFC (Plaque Forming Colony) Test In Vitro

PURPOSE AND RATIONALE

Identification of antibody producing cells is based on the ability of the secreted IgM antibody to fix complement and thereby lyse the indicator erythrocytes. Spleen cells or peripheral blood lymphocytes, previously incubated with antigen, are mixed with sheep red blood cells (SRBC). After addition of compliment and incubation, plaques (clear areas) caused by the lysis of SRBC appear in the otherwise cloudy layer. Antibody forming cells can be detected by the appearance of plaques. The number of plaques obtained is proportional to the number of antibody producing lymphocytes in the cell population.

PROCEDURE

NMRI mice weighing 16–18 g or Lewis rats weighing 180–200 g of either sex are used.

Materials

- absorbed guinea pig complement
- SRBC stored in Alsever's solution

Positive Control

Spleen cells incubated with antigen and medium

Negative Control

Spleen cells incubated with medium alone. The animals are decapitated and the spleens are removed from the peritoneal cavity. A single cell suspension of 15×10^6 cells/ml is prepared. For the induction of PFC, a 0.5 ml splenocyte suspension is added to 0.5 ml of a suspension of SRBC, previously washed in medium and diluted to 8×10^6 cells/ml. Thereafter, 1 ml of the solution of the test compound is added and the limbrowells are incubated at 37°C in a CO_2 incubator for 5 days. Per group 3 limbrowells are set up. On day 5, the 3 wells of each group are pooled, washed in medium and the number of cells is determined. For each cell pellet, 875 µl of washed SRBC and 125 µl absorbed guinea pig compliment are added. The suspension is mixed thoroughly and filled in chambers constructed of microslides. The chambers are placed in the incubator at 37°C for 90–120 min. The plaque forming colonies are counted immediately after incubation.

EVALUATION

The activity of test compounds can be determined using the following formula:

1. 1. PFC/3 wells:

$$x = \frac{\text{plaques} \times 100}{\mu\text{l}}$$

2. % change in the number of plaques:

$$x = \frac{\text{plaques} \times 100}{\text{plaquespos. control}}$$

$$d\% = x - 100$$

3. % change in number of cells:

$$x = \frac{\text{number of cells} \times 100}{\text{number of cells pos. control}}$$

$$d\% = x - 100$$

I.2.1.6 Inhibition of Dihydro-Orotate Dehydrogenase

PURPOSE AND RATIONALE

Dihydro-orotate dehydrogenase catalyzes the fourth committed step in the de novo biosynthesis of pyrimidines. As rapidly proliferating human T cells have an exceptional requirement for de novo pyrimidine biosynthesis, small molecule dihydro-orotate dehydrogenase inhibitors constitute an attractive therapeutic approach to autoimmune diseases, immunosuppression, and cancer. The main mode of action of the immuno-suppressive compound leflunomide and its active metabolites is considered to be the inhibition of the enzyme dihydro-orotate dihydrogenase (Bruneau et al. 1998; Graul and Castañer 1998; Knecht and Löffler 1998; Rückemann et al. 1998; Schorlemmer et al. 1998; Herrmann et al. 2000; Liu et al. 2000).

PROCEDURE

A fragment of human dihydro-orotate dehydrogenase is expressed by means of the baculovirus expression vector system and purified to a specific activity greater than 50 U/mg (Knecht et al. 1996, 1997). Enzyme assays are performed with purified recombinant dihydro-orotate dehydrogenase at 30°C. The oxidation of the substrate dihydro-orotate and the reduction of the co-substrate quinone is coupled to the reduction of the chromogen 2,6-dichlorophenolindophenol (DCIP). The reaction mixture contains 0.1 mM Q_D or 0.1 M Q_{10}, 1 mM L-dihydro-orotate, 0.06 mM DCIP, 0.1% Triton X-100 in 50 mM Tris-HCl buffer, 150 mM KCl, pH 8.0. The reaction is started by addition of the enzyme. The loss of absorbance of the blue DCIP is monitored at 600 nm; $\in = 18.800\,l\,mol^{-1}cm^{-1}$. The enzyme activity in control assays without Q_D or Q_{10} which is approximately 1% of maximum enzyme activity is subtracted from the activity values measured. Stock solutions of the test compounds are prepared in dimethylsulfoxide with further dilutions in the buffer taken for the assays.

EVALUATION

To determine the inhibitory potency of the agents, the initial velocity of dihydro-orotate dehydrogenase reaction is measured at saturating substrate concentrations, 1 mM dihydro-orotate and 100 µM Q_D and varying concentrations of the drugs (1 nM through 100 µM). The equation is fitted to the initial velocities:

$$v = V/\{1 + [I]/IC_{50}\}$$

([I] is the inhibitor concentration) in order to find the concentration causing 50% inhibition of the enzyme activity (IC_{50}).

I.2.1.7 Sphingosine 1-Phosphate

I.2.1.7.1 General Considerations

Sphingolipids have emerged as molecules whose metabolism is regulated to generation of bioactive products including ceramide, sphingosine, and sphingosine-1-phosphate. The balance between cellular levels of these bioactive products is recognized to be critical to cell regulation and may be a promising approach to tumor therapy (Huwiler and Pfeilschifter 2006); whereby ceramide and sphingosine cause apoptosis and growth arrest phenotypes, and sphingosine-1-phosphate mediates proliferative and angiogenic responses. Sphingosine kinase is a key enzyme in modulating the levels of these lipids (Hannun and Obeid 1995; Hofmann and Dixit 1998; Mathias et al. 1998; Prieschl et al. 1999; Pyne and Pyne 2000; Cummings et al. 2002; MacKinnon et al. 2002; Rosen and Liao 2003; Chen et al. 2004; Deguchi et al. 2004; Lee et al. 2004; Peng et al. 2004; Cyster 2005; Kee et al. 2005; Watterson et al. 2005; Gardell et al. 2006; Taha et al. 2006). Ceramide formation and degradation are influenced by nitric oxide (NO) (Huwiler et al. 1999a, 1999b; Franzen et al. 2002a, 2002b).

I.2.1.7.2 Binding to Sphingosine 1-Phosphate Receptors

PURPOSE AND RATIONALE

At least five subtypes of the sphingosine 1-phosphate receptor with tissue specificity are known (Meyer zu Heringdorf et al. 1998; Kon et al. 1999; Im et al. 2000, 2001; Forrest et al. 2004; Hale et al. 2004a; Sanna et al. 2004; Zhou and Murthy 2004; Xin et al. 2004; Lepley et al. 2005; Kimura et al. 2006; Kitano et al. 2006).

The immunomodulator FTY720 is an agonist to sphingosine 1-phosphate receptors (Brinkmann et al. 2002; Gräler and Goetzl 2004; Kunzendorf et al. 2004; Xin et al. 2004; Albert et al. 2005; Bandhuvula et al. 2005; Chiba 2005; Sawicka et al. 2003, 2005; Habicht et al. 2005; Xin et al. 2006; Zhou et al. 2006). FTY720 is derived from ISP-1 (myriomycin), a fungal metabolite that is an eternal youth nostrum in traditional Chinese herbal medicine (Fujita et al. 1994). The compound {2-amino-2-[2-(4-octophenyl)ethyl]propane-1,3-diol} is a highly potent immune modulating agent.

Further derivates such as sphingosine 1-phosphate receptor agonists (Hale et al. 2004b, 2004c; Clemens et al. 2005; Foss et al. 2005; Kiuchi et al. 2005; Jo et al. 2005; Li et al. 2005; Colandrea et al. 2006) and antagonists (Davis et al. 2005) have been described. Brinkmann et al. (2002) used the [γ-^{35}S]GTPS binding assay to study the binding of the immune modulator FTY720 to sphingosine 1-phosphate receptors.

Forrest et al. (2004) studied the binding of sphingosine 1-phosphate agonists on distinct receptor subtypes.

PROCEDURE

Receptors and Cell Lines

CHO cells stably expressing human $S1P_{1,2,3,4,5}$ were used (Mandala et al. 2002). cDNA sequences encoding rodent S1P receptors were cloned from genomic DNA by polymerase chain reaction using the following primers for each respective receptor:
5′-GAACCCGGGTGTCCACTAGCATCCCGG and 5′CCCGAATTCTTAGGAAGAAGAATTGACGTTTCC (mouse $S1P_1$), 5′-GAACCCGGGCGGCTTATACTCAGAGTACC and 5′-GGCGAATTCTCAGACCACTGTGTTACCCTC (mouse $S1P_2$), 5′-GAACCCGGGCAACCACGCATGCGCAGG and 5′-GTCGAATTCTCACTTGCAGAGGACCCCG (mouse $S1P_3$), 5′-GA

ACCCGGGAACATCAGTACCTGGTCCACGC and GCGGAATTCTAGGTGCTGCGGACGCTGG (mouse $S1P_4$), 5′-GAACCCGGGCTGCTGCGGCC GG and 5′-CGCGAATTCAGTCTGTAGCAGTAGG CACC (mouse $S1P_5$), 5′-GTAGGATCCGTGTCCTC CACCAGCATC and 5′GGCCGAATTCTTAAGAAG AAGAATTGACGTTTC (rat $S1P_1$), 5′-GAACCCGG GCATCCACGCATGCGCAG and 5′-GCCGAATTC TCACTTGCAGAGGACCCCATTCTG (rat $S1P_3$).

The polymerase chain reaction products were inserted in-frame after a FLAG tag using vector pCMV-Tag2 (Stratagene, La Jolla, Calif., USA). Stable lines were established by transfecting plasmids into CHO cells using lipofectamine reagent, selecting for neomycin resistance, and screening single cell cultures for increased [^{33}P]S1P-specific binding. Membranes were prepared from positive clones and confirmed in [^{33}P]S1P and [^{35}S]GTPγS binding assays.

S1P Receptor Assays

Binding assays were conducted as described by Mandala et al. (2002). [^{33}P]S1P was sonicated with fatty-acid-free bovine serum albumin, added to test compounds diluted in dimethylsulfoxide (DMSO), and mixed with membranes in 200 µl in 96-well plates with assay concentrations of 0.1 nM [^{33}P]S1P (22,000 dpm), 0.5% bovine serum albumin, 50 mM HEPES-Na (pH 7.5), 5 mM $MgCl_2$, 1 mM $CaCl_2$, and 0.3 to 0.7 µg of membrane protein. Binding was performed for 60 min at room temperature and terminated by collecting the membranes onto GF/B filter plates with a Packard Filtermate Universal Harvester. Filter bound radionuclide was measured on a Perkin Elmer 1450 MicroBeta. Specific binding was calculated by subtracting radioactivity that remained in the presence of 1000-fold excess of unlabeled S1P.

To measure functional activation of the S1P receptors, [^{35}S]GTPγS binding was measured. Membranes (1–4 µg of protein) were incubated in 96-well plates with test compounds diluted in DMSO in 100 µl of buffer containing 20 mM HEPES (pH 7.4), 100 mM NaCl, 10 mM $MgCl_2$, and 2–10 µM GDP, depending on the expressed receptor. The assay was initiated with the addition of 100 µl of [^{35}S]GTPγS (1200 Ci/mmol or 44,400 BGq/mmol; Perkin Elmer Life and Analytical Sciences, Boston, Mass., USA) for an assay concentration of 125 pM. After 60 min of incubation at room temperature, membranes were harvested onto GF/B filter plates and bound radionuclides were measured.

MODIFICATIONS OF THE METHOD

Murata et al. (2000) described a radioreceptor-binding assay for quantitative measurement of sphingosine 1-phosphate.

I.2.1.7.3 Sphingosine Kinase Activation Assay

PURPOSE AND RATIONALE

Sphingosine 1-phosphate produced by two sphingosine kinase isoenzymes, denoted SphK1 and SphK2, is the ligand for a family of specific G-protein-coupled receptors that regulate cytoskeletal re-arrangements and cell motility. Unlike the proliferative action of SphK1, the isoenzyme SphK2 has been shown to possess anti-proliferative and pro-apoptotic action. Both kinases have been cloned and functionally characterized (Kohama et al. 1998; Liu et al. 2000, 2003; Nava et al. 2000; Olivera 2000; Igarashi et al. 2003; Paugh et

al. 2003; Sanchez et al. 2003; Billich et al. 2005; Döll et al. 2005; Hait et al. 2005; Kharel et al. 2005; Okada et al. 2005; De Palma et al. 2006; Zemann et al. 2006).

Sphingosine kinase activity assays were performed in a similar way by Paugh et al. (2003) and by Huwiler et al. (2006).

PROCEDURE

Sphingosine Kinase Activity Assay

In vitro kinase reactions were performed according to Olivera et al. (2000). In brief, 30 µg of protein lysates was incubated with 50 µmol/l of sphingosine (dissolved as 1 mmol/l stock solution in 4 mg/ml of BSA in PBS) and 10 µCi (370 kBq) of [γ-^{32}P]ATP for 15 min at 37°C. For SK-2 activity assay, the same buffer including 1 M KCl was used to inhibit SK-1 activity (Liu et al. 2000). Reactions were terminated by addition of 20 µl of 1N HCl followed by 800 µl of chloroform/methanol/HCl (100:200:1, v/v), 240 µl of chloroform and 240 µl of 2 mol/l KCl. After vigorous vortexing and phase separation, 50 µl of the lower organic phase was loaded onto TLC plates and run in 1-butanol/ethanol/acetic acid/water (80:20:10:20, v/v).

EVALUATION

Spots corresponding to S1P were analyzed and quantified using an Imaging System (Fuji).

I.2.1.7.4 Lymphocyte Trafficking After Sphingosine 1-Phosphate Receptor Agonists

PURPOSE AND RATIONALE

Adaptive immunity depends on T-cell exit from the thymus and T and B cells traveling between secondary lymphoid organs to survey for antigen. After activation in lymphoid organs, T cells must again return to circulation to reach sites of infection. The immunomodulatory drug FTY720 induces sequestration of circulating mature lymphocytes by acceleration of lymphocyte homing via the S1P receptor 1 (Chiba et al. 1998; Yanagawa et al. 1998a, 1998b; Henning et al. 2001; Forrest et al. 2004; Matloubian et al. 2004; Hait et al. 2005; Kharel et al. 2005; Huwiler et al. 2006). Mandala et al. (2000) described alteration of lymphocyte

trafficking by sphingosine 1-phosphate receptor agonists.

PROCEDURE

Induction of Lymphopenia and Reduction of Thoracic Duct (TD) Lymphocytes by S1P and Analogs in Rats

Blood or thoracic duct lymph lymphocyte counts were determined by autoanalyzer (H2000, CARESIDE, Culver City, Calif., USA) and normalized to counts in vehicle controls after administration of FTY720 (2.5 mg/kg p.o.), or test compound. S1P was administered by continuous infusion beginning at 8 mg/kg per hour for 20 min followed by 2 mg/kg per hour for a further 220 min. The measured physiological S1P concentration in rat plasma by LC-MS was 0.5 µg/ml. This rose to a C_{max} of 2.5 µg/ml at 30 min and was maintained at 1.5 µg/ml for the remainder of the experiment. Studies on the effect on lymphocyte numbers in thoracic-duct-cannulated rats were performed after administration of FTY720 or test compound. Lymph flow remained constant for the duration of the experiment and numbers are shown as the average cell concentration maintained over the preceding 30 min.

FACS Measurement of Peripheral Blood Lymphocyte Depletion in Cannulated Rats:

Percentage depletion by FTY720 compared to vehicle control was measured. Similar nadir lymphopenia was produced by FTY720 or non-metabolizable phosphonates. Peripheral blood samples were diluted 1:1 with phosphate-buffered saline (PBS), layered on the same volume of Lymphocyte Separation Medium (ICN Biomedicals, Aurora, Ohio, USA) and centrifuged at 400 *g* for 30 min. Peripheral blood mononuclear cells (PBMC) were resuspended in PBS and counted using a hemocytometer. PBMC were then stained with FITC-labeled anti-CD8, PE-labeled anti-CD45RA, and Cy-Chrome-labeled anti-CD4 antibodies. Numbers of CD4-, CD8- and CD45RA-positive cells were calculated by multiplying total PBMC count with the percentages of $CD4^+$, $CD8^+$ and $CD45RA^+$ generated from flow cytometry.

Quantitation of Lymph Node Cells

Single-cell suspensions were prepared by passage of tissues through a 40-µm sieve. Peripheral blood lymphocytes were further isolated from spleens by ammonium chloride lysis of red blood cells. Cells were subsequently washed in UltraCULTURE medium (Biowhittaker, Walkersville, Md., USA) and all samples were adjusted to the same volume with PBS. An equal volume of 4% paraformaldehyde was added while gently vortexing the samples. The total number of viable, unstained lymphocytes per sample was determined by flow cytometry (FACScan; Becton Dickinson) using CELLquest software (Becton Dickinson), based upon forward and side scatter characteristics. Beads (Sigma; P7458) were used as an internal standard.

EVALUATION

Data were calculated as cell number per node by dividing the total number of lymphocytes quantitated by the number of nodes harvested per site (i. e., the number of Peyer's patches, mesenteric or peripheral lymph nodes collected).

MODIFICATIONS OF THE METHOD

Kawa et al. (1997) reported inhibition of chemotactic motility and trans-endothelial migration of human neutrophils by sphingosine 1-phosphate.

Fueller et al. (2003) described activation of human monocytic cells by lysophosphatidic acid and sphingosine-1-phosphate.

Roviezzo et al. (2004) studied human eosinophil chemotaxis and selective *in vivo* recruitment by sphingosine 1-phosphate.

I.2.2 In Vivo Methods for Testing Immunological Factors

I.2.2.1 Spontaneous Autoimmune Diseases in Animals

Several spontaneous autoimmune diseases have been reported in several inbred animal strains:

New Zealand black mouse (NZB mouse) (Bielschowski et al. 1959; Howie and Helyer 1968; Barthold et al. 1974; Blanchard and Bach 1980). The NZB mouse develops a spontaneous autoimmune disease with autoimmune hemolytic anemia, splenomegaly, glomerulonephritis, lymphoproliferative disorders and peptic ulcerations.

New Zealand black/white F1 (B/W) mouse (Helyer and Howie 1963; Kessler 1968): These animals develop nephritis similar to that in human systemic lupus erythematosus and show mononuclear cell infiltration in salivary and lachrymal glands such as in human Sjögren's syndrome.

A substrain of the autoimmune-prone mouse, NZB/kl, was found to show spontaneous elevation of the auditory brainstem response threshold with age (Sone et al. 1995).

Immunodeficient alymphoplasia mice were recommended as a spontaneous model for Sjøgren's syndrome (Tsubata et al. 1996). Mice homozygous for an autosomal recessive mutation aly (alymphoplasia) lack both lymph nodes an Peyer's patches and show defects in both humoral and cellular immunity. Histopathological analyses revealed chronic inflammatory changes in exocrine organs such as the salivary gland, lacrimal gland and the pancreas.

The **Palmerston North autoimmune mouse strain** which exhibits both spontaneous systemic autoimmune disease and otic capsule bone formation has been proposed as a model for otic capsule osteogenesis and otosclerosis (Hertler and Trune 1990; Traynor et al. 1992).

In aging **BDF1 mice**, Hayashi et al. (1988) described spontaneous development of autoimmune sialadenitis.

Robison et al. (1994) examined the relationship between orchitits and aspermatogenesis in various strains of H_2 congenic mice and defined a genetic predisposition to spontaneous aspermatogenesis.

Motheaten mice. Mice homozygous for the autosomal recessive motheaten (me) or the allelic viable motheaten (me^v) mutations develop severe and early-age onset of systemic autoimmune and inflammatory disease (Green and Shultz 1975; Shultz et al. 1984; Shultz 1988; Su et al. 1998).

The genetic, hormonal and behavioural influence on spontaneously developing arthritis in normal mice has been reviewed by Holmdahl et al. (1992).

Non-obese diabetic mouse (NOD mouse) (Makino et al. 1980; Miyazaki et al. 1985; Leiter et al. 1987). The inbred NOD mouse is considered a good model for type I diabetes mellitus. Mononuclear cells infiltrate the pancreatic islets of Langerhans from 6–8 weeks of age, followed by a progressive and

selective destruction of insulin-producing β-cells and the onset of IDDM from the 12th week of age onwards.

Itoh et al. (1997) studied the requirement of Fas for the development of autoimmune diabetes in nonobese diabetic mice.

Quartey-Papafio et al. (1995) showed that aspartate at position 57 of nonobese diabetic I-A(g7) β-chain diminishes the spontaneous incidence of insulin-dependent diabetes mellitus in the NOD mouse.

The NOD mouse was also recommended to study the pathogenesis of autoimmune thyroiditis (Many et al. 1996).

Bio-breeding rat (BB rat) (Like et al. 1982; Field 1983; Yale and Marliss 1984). On the basis of clinical and histopathological parameters, the BB rat is considered a useful model for human IDDM. The disease in the BB Rat is characterized by infiltration of lymphocytes and macrophages into the islets of Langerhans.

Allen and Thupari (1995) described spontaneous autoimmune lymphocytic thyroiditis in*BB/Wor rats.*

Obese strain chicken (OS chicken) (van Tienhoven and Cole 1962; Cole 1966; Cole et al. 1968, 1970; Wick et al. 1974). The OS chicken is perhaps the best studied model for an organ-specific, spontaneously occurring autoimmune disease, viz. spontaneous autoimmune thyroiditis, which closely resembles human Hashimoto thyroiditis. The spontaneous autoimmune thyroiditis in obese chicken was further studied by Neu et al. 1986; Kroemer et al. 1989; Cihak et al. 1995; Hala et al. 1996; Dietrich et al. 1997.

Chickens of the University of California line 200 **(UCD-200 chickens)** develop an inherited inflammatory fibrotic disease that closely resembles human progressive systemic sclerosis (scleroderma) (Gershwin et al. 1981; Van de Water et al. 1984; Brezinscheck et al. 1993).

Schumm-Draeger and Fortmeyer (1996) described **autoimmune thyroiditis in the cat** as a spontaneous disease model.

Spontaneous autoimmune thyroiditis was found in **Mastomys** (*Praeomys coucha*) by Solleveld et al. (1985) and recommended as an animal model of human disease.

I.2.2.2 Acute Systemic Anaphylaxis in Rats

PURPOSE AND RATIONALE

Rats are immunized with ovalbumin and *Bordetella pertussis* suspension as adjuvant. After 11 days the animals are challenged by intravenous injection of ovalbumin. The shock symptoms can by inhibited by corticosteroids and intravenous disodium cromoglycate.

PROCEDURE

Female Sprague-Dawley rats weighing 120 g are immunized by i.m. injection of 10 mg/kg highly purified ovalbumin. Simultaneously 1 ml of *Bordetella pertussis* suspension (2×10^{10} organisms) is injected intraperitoneally. IgE antibodies are induced and attached to the surface of mast cells and basophilic granulocytes. Eleven days later the animals are challenged by intravenous injection of 25 mg/kg highly purified ovalbumin. This results in formation of antigen-antibody-complexes on the surface of mast cells and basophilic granulocytes in blood and in all organs with immediate release of various mediators of anaphylaxis, such as histamine, serotonin, SRS-A, prostaglandins; in shock symptoms and 80% lethality. Corticosteroids, e. g. dexamethasone 1–10 mg/kg s.c. are given 18 h prior to challenge, or 30 mg/kg disodium cromoglycate i.v. before injection of ovalbumin. Ten–20 animals are used for each group.

EVALUATION

The shock symptoms are scored and mortality counted. Results after treatment are compared with untreated controls. Pretreatment with corticosteroids or disodium cromoglycate can inhibit death and ameliorate shock symptoms. Statistical calculation is performed using the χ^2-test.

MODIFICATIONS OF THE METHOD

Desensitization by repeated 'microshocks' of constant strength in guinea pigs has been reported by Herxheimer (1952).

Acute systemic anaphylaxis experiments have also been performed in guinea pigs and in mice. In guinea pigs anaphylactic bronchospasm can be measured with the Konzett and Rössler method (see D.2.2.1) (Davies and Evans 1973).

Moreover, anaphylactic bronchospasm can be measured in isolated guinea pig lungs according to the method of Bhattacharya and Delaunois (1955).

Anaphylaxis can be measured in the chopped guinea pig lung by assay of the supernatant in the isolated guinea pig ileum in the presence of 2×10^{-7} M atropine (Austen and Brocklehurst (1961).

Ufkes and Ottenhof (1984) sensitized Brown-Norway rats with a suspension of trinitrophenyl haptenized ovalbumin together with $AlPO_4$ as adjuvant. Bronchial and cardiovascular function were studied after treatment with anti-allergic agents and antigen challenge.

Elwood et al. (1992) studied the effect of dexamethasone and cyclosporin A on allergen-induced airway hyperresponsiveness and inflammatory cell responses in sensitized Brown-Norway rats.

I.2.2.3 Anti-Anaphylactic Activity (Schultz–Dale Reaction)

PURPOSE AND RATIONALE

Guinea pigs are sensitized against egg albumin. Challenge after 3 weeks causes in isolated organs release of mediators, e. g. histamine, which induce contraction in isolated ileum.

PROCEDURE

Guinea pigs of either sex weighing 300–350 g are sensitized with alum precipitated egg albumin. Alum egg albumin is prepared by dissolving egg albumin (1 mg/ml) in six percent aluminum hydroxide gel, suspended in saline. The mixture is stirred and kept at room temperature. Each animal receives at the same time injections of 0.125 ml of this mixture in each foot pad and 0.5 ml subcutaneously. After 4 weeks the animals are killed and the ileum is dissected out. Cleaned pieces, about 2–3 cm long, are mounted in an organ bath containing Tyrode solution at 37°C. The strips are allowed to equilibrate for 15 min. The contractility of the ileum strips is tested by adding 10^{-4} g/ml $BaCl_2$ solution. To one organ bath the standard (2×10^{-6} g/ml final concentration of Tribenosid = 1-O-ethyl-3,5,6-tri-O-benzyl-D-glucofuranoside = Glyvenol CIBA) and to other vials the test compounds (final concentration up to 10^{-5} g/ml) are added. One organ bath serves as control. After 3 min ovalbumin in a final concentration of 2×10^{-6} g/ml is added. The contractions are recorded with strain gauges by a polygraph.

EVALUATION

The results are expressed as presence or absence of blocking activity (percentage inhibition). If anti-anaphylactic activity is observed, ED_{50} values using different doses are calculated.

CRITICAL ASSESSMENT OF THE METHOD

Positive results can also be achieved with spasmolytics, local anesthetics, antihistaminics, and sympathicomimetics.

MODIFICATIONS OF THE METHOD

The method has been modified by testing histamine release in the lung after challenging with egg albumin. Either lung strips from sensitized guinea pigs are suspended in an organ bath and their contractions are measured after addition of egg albumin or the entire lung tissue is dissected out and washed free from blood by perfusing with warm oxygenated Tyrode solution via the pulmonary artery. The lung tissue is chopped and washed with Tyrode solution in order to remove the remaining blood. The chopped lung tissue is divided into 24 samples, each of approximately 100 mg wet weight. These are incubated at 37°C in Tyrode solution for 15 min with continuous agitation by rocking, after which, 1 mg/ml of egg albumin is added to

the reaction mixture. After shaking for 10 min at 37°C, the supernatant is collected and assayed for histamine with guinea pig ileum. Atropine sulfate 2 mg/ml is added in Tyrode solution. The residual histamine is obtained by boiling the tissue in 5 ml Tyrode solution for 10 min. The tubes are then placed on ice for 1 h to allow complete diffusion. Released histamine is expressed as a percentage of total histamine content.

Koppel et al. (1981) developed a method to induce contraction of immunologically sensitized mouse trachea by antigen (Schultz–Dale reaction).

The trachea of sensitized guinea pigs was used by Omote et al. (1994).

I.2.2.4 Passive Cutaneous Anaphylaxis

PURPOSE AND RATIONALE

Passive cutaneous anaphylaxis is a immune reaction of the immediate type. By passive immunization of rats in the skin with rat anti-ovalbumin serum and a challenge 2 days later with ovalbumin at the same skin area antigen-antibody complexes are formed in the mast cells inducing release of mediators. This results in vasodilatation, increase in permeability of the vessel walls and leakage of plasma. To make the allergic reaction visible, Evan's blue dye is administered along with the antigen. Evan's blue dye is attached to the albumin fraction of plasma, producing a blue spot. This blue spot indicates that an anaphylactic reaction has taken place in the skin.

PROCEDURE

For preparation of antiserum male rats weighing 200–250 g are adrenalectomized and are allowed to recover for 3 days. Thereafter, animals are sensitized with egg albumin (1 mg/animal) using aluminium hydroxide gel (200 mg) as adjuvant. Alum egg albumin is prepared by dissolving 1 mg/ml of egg albumin in 20% aluminium hydroxide gel, suspended in saline. Each animal simultaneously receives 0.125 ml of the above solution in each foot pad and 0.5 ml subcutaneously. After 8 days, the animals are bled and antiserum is collected.

For the test, the antiserum is diluted in such a manner as to give a wheal of 15–20 mm diameter in a preliminary titration. Aliquots of 100 µl of appropriate dilution of antiserum are injected intradermally into the shaved dorsal skin of normal male rats weighing about 100 g. After 24 h of latent period each animal is challenged with the intravenous administration of 0.1 ml of 2.5% Evans blue dye containing 25 mg/ml of egg albumin. In the case of intravenous administration, the test compound is administered simultaneously with the antigen and the dye. In case of oral testing, the compound is given orally 1 h prior to challenge. The animals are sacrificed 30 min after the challenge. The amount of Evans blue dye leaked at the site of passive cutaneous anaphylactic reaction is extracted and determined colorimetrically at 620 µm wavelength.

EVALUATION

The amount of Evans blue extracted from passive cutaneous anaphylactic reaction is taken as 100 percent. Percent inhibition of passive cutaneous anaphylactic reaction in the rats treated with the test compound is calculated. The standard disodium cromoglycate at a dose of 3 mg/kg i.v. or 30 mg/kg orally results in 80–100% inhibition. Using different doses, ED_{50} values can be calculated.

MODIFICATIONS OF THE METHOD

Goose and Blair (1969) used *Bordetella pertussis* and extracts of the worm *Nippostrongylus brasiliensis* as antigens in passive cutaneous anaphylaxis experiments in the rat.

Patterson et al. (1971) tested passive cutaneous reactivity to antihuman IgE in rhesus monkeys.

Without immunization, plasma extravasation after bradykinin injection can be tested in anesthetized Sprague-Dawley rats (Lembeck et al. 1991). Evans blue dye is injected to stain plasma proteins. After injection of bradykinin antagonists followed by bradykinin injection, the rats are perfused with phys-

iological saline. The trachea, the urinary bladder, and the duodenum are resected, weighed and incubated for 48 h in formamide at 50°C (Saria et al. 1983). The amount of Evans blue extracted is measured photometrically at 620 nm.

Vascular reactions to histamine, histamine-liberator and leukotaxine in the skin of guinea pigs using pontamine sky blue 6X as indicator were studied by Miles and Miles (1952).

I.2.2.5 Arthus Type Immediate Hypersensitivity

PURPOSE AND RATIONALE

The immune complex induced Arthus reaction comprises inflammatory factors that have been implicated in the acute responses in joints of rheumatic patients. Complement and polymorphonuclear neutrophiles are activated via precipitating antigen-antibody complexes leading to an inflammatory focus characterized by edema, hemorrhage and vasculitis. Arthus reaction of the immediate type becomes maximal 2–8 h after challenge.

PROCEDURE

Ovalbumin Suspension

1700 mg ovalbumin are suspended in 100 ml paraffin oil. 4.38 ml pertussis vaccine are suspended in 70 ml 0.9% NaCl-solution. Both suspensions are mixed to form an emulsion.

Wistar or Sprague-Dawley rats of either sex weighing 220–280 g can be used. Seven days prior to start of the experiment rats are sensitized by i.m. administration of 0.5 ml of the ovalbumin suspension. They are housed in groups of eight with standard food and water ad libitum.

Twenty-four hours and one hour prior to induction of the Arthus reaction, test compounds are administered to groups of 8 animals. The rats are challenged by injection of 0.1 ml of 0.04% solution of highly purified ovalbumin in the left hind paw. Swelling of the paw occurs which reaches a maximum after a few hours. The footpad thickness can be measured by calipers. One group of sensitized animals treated with solvent alone serves as positive control, one group of non-sensitized animals treated with solvent alone serves as negative control. Standard doses are 30 mg/kg cortisone or 10 mg/kg prednisolone p.o.

EVALUATION

The change in footpad thickness is expressed as the percent change from the vehicle control group. Comparison of experimental group to positive control is evaluated statistically using Student's *t*-test.

MODIFICATIONS OF THE METHOD

Instead of ovalbumin, sheep red blood cell suspensions can be used for immunization and for challenge in mice (Omote et al. 1994).

Nagakawa et al. (1990) sensitized mice by s.c. injection of bovine serum albumin in complete Freund's adjuvant and boosted on day 21 by an intradermal injection of BSA. On day 28, the Arthus reaction was elicited by intradermal injection of BSA. Four hours later, an erythematous skin reaction over an area of more than 8 mm^2 was regarded as positive.

Kamei et al. (1991) immunized guinea pigs by injection of a mixture of egg albumin and Freund's complete adjuvant subcutaneously into the food pad or i.m. into the hind leg. The injection was repeated 4 times at 7 day intervals. Ten days after the last immunization, 0.2 ml of 2.5% egg albumin was injected sc. into the dorsal skin of the animals. The intensity of the Arthus reaction was evaluated by measuring the inflamed area according to scores.

I.2.2.6 Delayed Type Hypersensitivity

PURPOSE AND RATIONALE

Delayed type hypersensitivity is a reaction of cell mediated immunity and becomes visible only after 16–24 h. The same methods as for testing immediate type hypersensitivity can be used.

PROCEDURE

Rats are sensitized in the same way by i.m. administration of 0.5 ml ovalbumin suspension 7 days prior to the start of the experiment as described for testing immediate type hypersensitivity. They are challenged by injection of 0.1 ml of 0.04% solution of highly purified ovalbumin in the left hind paw. Footpad thickness is measured immediately and 24 h after ovalbumin administration.

MODIFICATIONS OF THE METHOD

Mizukoshi et al. (1994) injected female CDF1 mice intradermally with a suspension of 2×10^8 sheep red blood cells/50 µl into the left foot pad. A second booster of the same dose was given to the right foot pad on day 4. The thickness of the foot pads was measured on the following day, and the difference in the thickness between the right and the left food pads was taken as the degree of swelling.

Kamei et al. (1991) immunized mice by applying 0.15 ml of 7% picryl chloride/ethanol solution to the skin of the shaved abdomen. The second immunization was performed 6 days later. One week after the second immunization, 1 drop of 1% picryl chloride olive oil solution was applied to the ear and the thickness of the ear was measured by a thickness gauge 24 h later.

I.2.2.7 Reversed Passive Arthus Reaction

PURPOSE AND RATIONALE

In the reversed passive Arthus reaction the antigen is injected intravenously followed by a local injection – either intradermally or into the pleural space – of the respective antibody. Generation of an immune-mediated reverse passive Arthus reaction in the rat pleural cavity results in a classic acute inflammatory response. The methods are used to evaluate new anti-inflammatory agents.

PROCEDURE

Male Lewis rats weighing 200–250 g are fasted overnight prior to use with free access to water. The animals receive 5 mg bovine serum albumin in 0.2 ml sterile saline intravenously, followed 30 min later by injection of 1 mg rabbit anti-BSA in 0.2 ml sterile saline into the right pleural cavity under light halothane anesthesia. Drugs or vehicle controls are administered by gastric gavage in 1 ml/100 g body weight at different times prior to the anti-BSA. The animals are sacrificed at various intervals after anti-BSA injections by CO_2 inhalation (after 5 min for thromboxane B_2 determination, after 10 min for leukotriene B_4 determination, and after 4 h at the peak time of neutrophil infiltration). The fluid exudate is removed from the pleural cavity by gentle vacuum aspiration and the volume is recorded. Eikosanoids in the pleural exudate are quantitated by commercial RIA kits.

EVALUATION

The values after treatment with various doses of test compounds are compared with those of vehicle controls.

MODIFICATIONS OF THE METHOD

The antibody can be injected intradermally into the shaved skin of rats after intravenous injection of the antigen (e. g., human albumin) together with Evans blue dye solution. Extravasated dye is determined in skin punches (Camussi et al. 1990; Burch et al. 1992; Okamoto et al. 1992).

Bailey and Sturm (1983) induced the reverse passive Arthus reaction in rats using bovine serum albumin as antigen into the tail vein and rabbit anti-bovine serum albumin into the skin site. One hour after oral dosing with vehicle or drug, animals were lightly anesthetized and their hair was shaved from the mid-dorsal region with electric clippers. Each animal was injected intradermally with 40 µl on the left side of the mid-dorsal line and with 40 µl of rabbit anti-bovine serum albumin (5.0 mg/ml antibody protein), diluted 1:4 with phosphate-buffered saline on the right side of the dorsal midline. Immediately following the intradermal challenge, each rat received 0.5 ml phosphate-buffered saline containing 1.0 mg bovine serum albumin injected in the tail vein. Four hours after intradermal challenge, the animals were sacrificed. The full thickness skin was removed from the back and discs 8 mm in diameter were punched out with a metal punch. Wet weight of the samples from the phosphate-buffered saline- and antibody-injected site was determined and the edema induced by the reverse passive Arthus reaction calculated as the difference between both weights.

I.2.2.8 Adjuvant Arthritis in Rats

PURPOSE AND RATIONALE

Adjuvant arthritis in rats has been described by Pearson and Wood (1959) exhibiting many similarities to human rheumatoid arthritis. Injections of complete Freund's adjuvant into the rat paw induces inflammation as primary lesion with a maximum after 3 to 5 days. Secondary lesions occur after a delay of approximately 11 to 12 days which are characterized by inflammation of non-injected sites (hindleg, forepaws, ears, nose and tail), a decrease of weight and immune responses. The procedure has been modified by several authors in order to differentiate between anti-inflammatory and immunosuppressive activity (e. g. Perper et al. 1971). Anti-inflammatory compounds do not inhibit secondary lesions, which are prevented or diminished by immunosuppressive agents. Two protocols, termed "preventative" (or "prophylactic") and "therapeutic" (or "established") adjuvant arthritis, have gained wide usage for assessing a drug's potential anti-arthritic activity (Schorlemmer et al. 1999).

PROCEDURE

The choice of the animal strain has been found to be very important for the performance of this test.

Wistar–Lewis rats have been proven to be very suitable in contrast to other sub strains. Male rats with an initial body weight of 130 to 200 g are used. On day 1, they are injected into the sub plantar region of the left hind paw with 0.1 ml of complete Freund's adjuvant. This consists of 6 mg mycobacterium butyricum (Difco) being suspended in heavy paraffin oil (Merck) by thoroughly grinding with mortar and pestle to give a concentration of 6 mg/ml. Dosing with the test compounds or the standard is started on the same day and continued for 12 days. Paw volumes of both sides and body weight are recorded on the day of injection, whereby paw volume is measured plethysmographically with equipment as described in the paw edema tests. On day 5, the volume of the injected paw is measured again, indicating the primary lesion and the influence of therapeutic agents on this phase. The severity of the induced adjuvant disease is followed by measurement of the non-injected paw (secondary lesions) with a plethysmometer. Purposely, from day 13 to 21, the animals are not dosed with the test compound or the standard. On day 21, the body weight is determined again and the severity of the secondary lesions is evaluated visually and graded according the following scheme:

		score
ears:	absence of nodules and redness	0
	presence of nodules and redness	1
nose:	no swelling of connective tissue	0
	intensive swelling of connective tissue	1
tail:	absence of nodules	0
	presence of nodules	1
forepaws:	absence of inflammation	0
	inflammation of at least 1 joint	1
hind paws:	absence of inflammation	0
	slight inflammation	1
	moderate inflammation	2
	marked inflammation	3

EVALUATION

a) For primary lesions: The percent inhibition of paw volume of the injected left paw over vehicle control is measured at day 5.
b) For secondary lesions: The percentage inhibition of paw volume of the non-injected right paw over controls is measured at day 21.
c) An arthritic index is calculated as the sum of the scores as indicated above for each animal. The average of the treated animals is compared with the control group.
d) The total percentage change is calculated as follows by addition of:
   percent inhibition of the injected paw on day 5 + percent inhibition of the non-injected paw on day 21 + percent change of the arthritic index.

Doses of 0.3 mg/kg indomethacin p.o. and 20–50 mg/kg phenylbutazone p.o. are effective on the primary lesions when dosage is started at the day of injection of the irritant. They are not effective on the secondary lesions.

In contrast, immunosuppressants like cyclophosphamide at a dose of 7 mg/kg inhibited the secondary lesions even when started at day 9 or later.

CRITICAL ASSESSMENT OF THE METHOD

Evidence was given that adjuvant arthritis in the rat is associated with chronic pain (Colpaert 1987) The measure of pain in this model still presents some technical problems since the evaluation is based on the somewhat biased observation of the behavioral responses.

MODIFICATIONS OF THE METHOD

A review was given by Gardner (1960) on the experimental production of arthritis.

Moran et al. (1999) compared adjuvant arthritis and selected animal models of arthritis to rheumatoid arthritis with special emphasis on the mechanism of joint destruction.

Kazuna and Kawai (1975) and Rooks et al. (1982) used rats with established lesions to test analgesics in the arthritic flexion pain test. The method is claimed to be specific by detecting only central analgesics and nonsteroidal anti-inflammatory drugs but not other classes such as CNS-depressant or antihistaminic drugs.

Brackertz et al. (1977) established antigen-induced arthritis in the mouse by immunization with methylated bovine serum albumin in complete Freund's adjuvant with B pertussis vaccine.

A streptococcal cell wall-induced arthritis in rats has been described by Wilder et al. (1982, 1987) and Yocum et al. (1986).

Lewis et al. (1997) studied degradation of articular cartilage in a rat monoarthritis model induced by an intra-articular injection of *Propionibacterium acnes*.

Crossley et al. (1989) reported on a monoarticular antigen-induced arthritis in rabbits and mice.

α-2-Glycoprotein levels have been recommended as parameter for severity and inhibition of experimental immunoarthritis in the rat by Sandow et al. (1971).

Pircio et al. (1975) recommended a method for the evaluation of analgesic activity using adjuvant-induced arthritis in rats. The degree of vocalization

was recorded from 5 rats placed together in a counting chamber.

Cruwys et al. (1994) sensitized rats on day 0 and 7 with multiple intradermal injections of methylated bovine serum albumin emulsified in Freund's complete adjuvant. On day 21, the animals were challenged by the intra-articular injection of 100 µl 0.5% solution of methylated bovine serum albumin into the right knee. The progress of the monoarticular arthritis was monitored by daily measurement of joint diameter.

Butler et al. (1991) described a limited arthritic pain model for chronic pain and inflammation studies using injections of 0.05 ml of complete Freund adjuvant into the left tibio-tarsal joint of Sprague-Dawley rats.

Issekutz et al. (1994) studied the role of tumor necrosis factor-alpha and IL-1 in polymorphonuclear leukocyte and T lymphocyte recruitment to joint inflammation in adjuvant arthritis.

Esser et al. (1995) measured radiographic changes in adjuvant-induced arthritis in rats by quantitative image analysis. Digitized radiographs of the calcaneus were examined for changes in the mean and in the distribution of gray values. Periostal new bone formation was measured as an increase in image area of the calcaneus.

Mercuric chloride ($HgCl_2$) induces a syndrome of autoimmunity in Brown-Norway rats characterized by a variety of IgG antibodies, very high concentrations of serum IgE, proteinuria, leukocytoclastic vasculitis which predominantly affects the caecum, and an inflammatory polyarthropathy (Kiely et al. 1995, 1996).

Kawahito et al. (2000) reported that 15-deoxy-$\Delta^{12,14}$-PGJ_2 which activates PPAR-α, induces synoviocyte apoptosis and suppresses adjuvant-induced arthritis in rats. Cuzzocrea et al. (2002) found that prostaglandin 15-deoxy-$\Delta^{12,14}$-prostaglandin J_2 attenuates the development of acute and chronic inflammation.

Bolon et al. (2004) described a method for rapid quantification of intralesional osteoclasts in the hind paws of Lewis rats with adjuvant-induced arthritis. A 4-µm-thick section of the decalcified hind paw was stained to demonstrate osteoclasts using an indirect immunoperoxidase method and a rabbit anti-human monoclonal antibody directed against the osteoclast marker cathepsin K, which is an osteoclast protease primarily responsible for the resorption of bone. The sections were evaluated using tiered, semi-quantitative criteria to grade bone erosions and intralesional osteoclasts.

Kong et al. (1999), Campagnuolo et al. (2002), and Bolon et al. (2002a, 2002b) used Lewis rats with adjuvant arthritis to describe the effects of osteoprotegerin, an endogenous antiosteoclast factor for protecting bone in rheumatoid arthritis.

Francischi et al. (2000) described anti-inflammatory and analgesic effects of the phosphodiesterase 4 inhibitor rolipram in the rat model of adjuvant-induced arthritis.

Boyle et al. (2001) reported anti-inflammatory effects of a non-nucleoside adenosine kinase inhibitor in rat adjuvant arthritis.

Fujisawa et al. (2002) demonstrated the effects of highly water-soluble matrix metalloproteinase inhibitors in a rat adjuvant-induced arthritis model.

Wei et al. (2004) described effects and mechanisms of a dual inhibitor of interleukin-1 and tumor necrosis factor on adjuvant arthritis in rats.

Boe et al. (1999) reported that interleukin 6 knockout **mice** are resistant to antigen-induced experimental arthritis.

Gauldie et al. (2004) described a robust model of adjuvant-induced chronic unilateral arthritis in two mouse strains. DBA/1 and C57BL/6 male mice were injected intra-articularly into a stifle joint with FCA (5 µg in 5 µl) once per week for 4 weeks. Measurement of joint diameter and joint histopathology were used to monitor the course of arthritis. Inflammatory hyperalgesia was assessed as the pressure causing a limb withdrawal. Standard drugs, such as indomethacin or prednisolone, caused a decrease in joint inflammation and associated hyperalgesia.

Consden et al. (1971), Cook and Jasin (1972), Cook et al. (1972), Jasin and Cook (1977) produced a chronic experimental monoarthritis by intra-articular injection of antigens into previously immunized **rabbits**.

Henderson et al. (1990) induced monoarticular arthritis in ovalbumin-sensitized rabbits by intraarticular injection of ovalbumin (antigen-induced arthritis) or in naive rabbits by injecting hyaluronic acid mixed with the polycation poly-D-lysine (polycation-induced arthritis).

Arner et al. (1995) compared the alterations in proteoglycan metabolism in antigen-induced arthritis and polycation-induced arthritis in rabbits and determined the involvement of interleukin-1 in the cartilage degradation that occurs in these models of rheumatoid arthritis.

Lewthwaite et al. (1995) studied the antifibrotic action of interleukin-1 receptor antagonist in antigen-induced monoarticular arthritis in New Zealand White rabbits.

Arthritis occurs in **pigs** due to infection with *Erysipelothrix rhusiopathiae* (Ajmal 1969). Experimental erysipelothrix infection in pigs can be used as a model for rheumatism research (Schulz et al. 1975a, b, 1977). Infections are established by oral or parenteral administration of standardized serotype B erysipelas strains.

Erysipelothrix arthritis could also produced in rats and **rabbits** (White et al. 1975; Glynn 1977).

Arthritis due to infection with *Mycoplasma synoviae* occurs naturally among domestic poultry (Olson et al. 1954, 1964). Arthritis in **chickens** after mycoplasma infection has been used as experimental model (Kerr and Olson 1970; Cullen 1977).

Experimental models of arthritis due to streptococcal infections have been proposed for various species: **mice** (Cayeux et al. 1966; Hook et al. 1960; Ohanian et al. 1969), **rats** (Jasmin 1967; Koga et al. 1973), **rabbits** (Cecil et al. 1939; Cook and Fincham 1966; Ginsburg et al. 1968, 1977; Norlin 1960; Shimizu et al. 1958; Stein et al. 1973), **pigs** (Roberts et al. 1968, 1969).

Avridine-Induced Arthritis

The injection of avridine [*N*,*N*-dioctadecyl-N′,N′-bis (2-hydroxyethyl) propanediamine / CP-20961], emulsified in Freund's adjuvant, at the base of the tail is arthritogenic in susceptible rat strains (Meacock et al. 1994; Brun et al. 1995; Vingsbo et al. 1995; Lorentzen and Klareskog 1997; Joe and Wilder 1999; Van Bilsen et al. 2004).

I.2.2.9 Collagen Type II Induced Arthritis in Rats

PURPOSE AND RATIONALE

As reported by Trentham et al. (1977) intradermal injection of homologous or heterologous type II collagen in incomplete Freund's adjuvant results in an inflammatory polyarthritis in rats. The demonstration of antibodies to collagen in patients with rheumatic polyarthritis suggests that autoimmunity may contribute to the pathophysiology of synovitis and joint destruction. Because of the similarities of the symptoms in rats to human disease the test is considered to be useful to detect anti-inflammatory and immunosuppressive properties of test compounds.

PROCEDURE

Bovine type II collagen is prepared from nasal septum cartilage, which is cut into small fragments, frozen in liquid nitrogen, and pulverized in a freezer mill. Proteoglycans are extracted overnight by stirring 25 g of pulverized cartilage in 1 liter of 0.2 N NaOH. Following centrifugation at 20,000 *g* for 30 min, the residue is washed with 250 ml of absolute ethanol, the supernatant aspirated, and the residue vacuum dried. Hundred mg pepsin are added to 150 ml of 0.5 M acetic acid, after which 1.0 g of cartilage is added to reach a cartilage to pepsin ratio of 10:1 (w/w). The mixture is stirred 18 h at room temperature and centrifuged at 20,000 *g* for 1 h. Acid soluble collagen present in the supernatant is precipitated by adding NaCl to reach a final concentration of 0.9 M, followed by centrifugation at 20,000 *g* for 1 h. The precipitate from 1.0 g car-

tilage is dissolved in 100 ml 1.0 N NaCl/0.005 M Tris-HCl, pH 7.5, and stirred for 3 days. Then, the solution is dialyzed against 0.02 M Na_2HPO_4, pH 9.4, and the precipitate collected by centrifugation at 30,000 *g* for 1 h. The pellet is dissolved in 0.5 M acetic acid, dialyzed against 6 liters of 0.01 M acetic acid, and lyophilized. All procedures, unless otherwise stated are performed at 4°C.

Test procedure. Collagen is dissolved in a concentration of 2.0 mg/ml in 0.1 M acetic acid overnight at 4°C. This solution is added dropwise to an equal volume of chilled incomplete Freund's adjuvant. Six to 12 male Wistar rats with an initial weight of about 120 g are used for each group. On day 1, each rat receives a total of 0.5 mg collagen in 0.5 ml, equally divided, in 5 sites. All injections are intradermal, one at the base of each appendage and one in the nape of the neck. Seven days post-immunization, the animals receive identical booster injections. Control animals receive only the incomplete Freund's adjuvant diluted with 0.1 M acetic acid.

The volume of both hind paws is measured plethysmographically on day 20. To minimize the possibility of including animals with minimal transient disease, only animals with a paw volume of 1.8 ml or greater are used for further testing. From days 20–40, the animals receive the test compounds p.o. once a day. On day 41, the paw volumes are recorded again.

EVALUATION

The paw volumes of treated animals are recorded plethysmographically. The increase versus day 20 is calculated. The increase is compared with that of controls or animals treated with a standard drug. Otherwise, arthritic scores can be determined. Nonsteroidal anti-inflammatory drugs such as indomethacin in a dose of 2 mg/kg p.o. or phenylbutazone in a dose of 150 mg/kg p.o., but not acetylsalicylic acid in a dose of 50 mg/kg p.o. have been found to be active. Likewise, corticosteroids and immunosuppressives, but not D-penicillamine, were active.

CRITICAL ASSESSMENT OF THE METHOD

Non-steroidal and steroidal anti-inflammatory compounds are detected by this method which, however, does not allow a separation between this two groups.

MODIFICATIONS OF THE METHOD

From studies with a neutrophil elastase inhibitor Janusz and Durham (1997) concluded that of the destruction of the joints in rat collagen-induced arthritis is at least partially due to neutrophil elastase.

Romas et al. (2002) reported that osteoprotegerin reduces osteoclast numbers and prevents bone erosion in collagen-induced arthritis in Dark Aguti rats.

Studies in Mice

Hom et al. (1988), Takagishi et al. (1986, 1992), Cannon et al. (1990), Nemoto et al. (1992) and Carlson et al. (1992) described the effects of immunomodulating agents in collagen-induced arthritis in mice.

Wooley et al. (1993) investigated the anti-arthritic effect of recombinant human interleukin-1 receptor antagonist protein on type II collagen-induced arthritis and antigen-induced arthritis in mice.

Joosten et al. (1994) found an accelerated onset of collagen-induced arthritis in DBA_1 lac/J mice by remote inflammation.

Miesel et al. (1993, 1994a, b) studied the effects of an active center analogue of Cu_2Zn_2-superoxide dismutase in collagen type II-induced arthritis. Furthermore, the authors described a model potassium peroxochromate-induced inflammation in rats and mice. One to 3 µmol/kg K_3CrO_8 was administered by intraplantar application into the left hind-paws of anesthetized rats or mice. Arthritis index was assessed by a score system or the inflammatory response was quantified scintigraphically under a gamma camera by intravenous injection of 500 µCi $Na^{99m}TcO_4$.

Kumar et al. (1997) compared the cellular mechanisms involved in the control of collagen II-induced arthritis and experimental autoimmune encephalomyelitis in mice.

Ruchatz et al. (1998) studied the role of IL-15 in development of antigen-induced immunopathology in collagen-induced arthritis in DBA/1 mice. A soluble fragment of IL-15 receptor profoundly suppressed the symptoms of collagen-induced arthritis.

Joosten et al. (1999) immunized male DBA-1 mice with 100 µg bovine type II collagen in CFA enriched with *Mycobacterium tuberculosis* H37Ra (4 mg/ml) at the base of the tail. The mice were boosted i.p. with 100 µg collagen dissolved in saline. After disease onset on day 28, the mice were treated either with dimerically linked PEGylated soluble p55 TNFR1 receptor or with purified rabbit anti-murine IL-1α and anti IL-1β. IL-1$\alpha\beta$ blockade prevented cartilage and bone destruction, whereas TNF-α blockade only ameliorated joint inflammation.

Using a similar protocol, Plater-Zyberg et al. (2001) found a therapeutic effect of neutralizing endogenous IL-18 activity in the collagen-induced model of arthritis and Lubberts et al. (2004) after treatment with a neutralizing anti-murine interleukin-17 antibody.

Cuzzocrea et al. (2003) found a reduction in the evolution of murine type II collagen-induced arthritis by treatment with rosiglitazone, a ligand of PPARγ.

McIntyre et al. (2003) reported that a highly selective inhibitor of IκB kinase blocked both inflammation and destruction in collagen-induced arthritis in mice.

Chen et al. (2003) tested orally active inhibitors of TNF synthesis as anti-rheumatoid arthritis drugs using collagen-induced arthritis in male DBA/1J mice.

Nakae et al. (2002, 2003) generated IL-17-deficient mice and found a suppression of collagen-induced arthritis.

Podolin et al. (2005) described attenuation of murine collagen-induced arthritis by a selective small molecule inhibitor of IκB kinase 2, occurring via reduction of proinflammatory cytokines and antigen-induced T cell proliferation.

Kuno et al. (2006) reported anti-inflammatory activity of a non-nucleoside adenosine deaminase inhibitor in mice.

I.2.2.10 Proteoglycan-Induced Progressive Polyarthritis in Mice

PURPOSE AND RATIONALE

Glant et al. (1987, 1992), Mikecz et al. (1987, 1990), Poole (1989) described a proteoglycan-induced progressive arthritis and spondylitis in BALB/c mice as an animal model displaying similarities to human rheumatoid arthritis and ankylosing spondylitis as indicated by clinical assessments, immunological parameters and histopathological studies of diarthrodial joints and spine.

PROCEDURE

High buoyant density cartilage proteoglycans are prepared from fetal and adult human, canine or bovine articular cartilages as well as from 1-week-old mouse epiphyseal cartilage. Fetal human articular cartilage proteoglycan digested with chondroitinase ABC (Hascall and Heinegård 1974) is used to induce arthritis in female BALB/c mice. The mice are sensitized by intraperitoneal injection of 100 µg of chrondroitinase ABC-treated proteoglycan in 100 µl of phosphate buffered saline, pH 7.2, and in Freund's complete adjuvant in a 1:1 emulsion. They are re-injected twice more with the antigen in incomplete Freund's adjuvant after one and three weeks. All BALB/c mice immunized with human articular cartilage proteoglycan develop arthritis in diarthrodial joints after the third antigen injection. Sera from mice with progressive polyarthritis are tested for antibodies to arthritogenic proteoglycans during weeks 12–18 of immunization. The limbs of all mice are examined daily to record clinical arthritic changes. Swelling and redness, as the first symptoms of arthritis, and the thickness (diameter) of the knee, ankle (intermalleolar diameter), wrist and the dorsovolar thickness of the paw are recorded three times a week. The most objective joint diameter is the intermalleolar one. The animals are treated with test drug or vehicle for 12 weeks and serum samples taken by retroorbital puncture for determination of antibodies to proteoglycans. Seven weeks later, the mice are sacrificed, limbs, tails and lumbar spine are fixed, decalcified and embedded in paraffin for histological examination.

EVALUATION

Mean values of intermalleolar diameter and antibody titers of treated and non-treated animals are compared by non-parametric statistics.

MODIFICATIONS OF THE METHOD

Stimpson and Schwab (1989) described a chronic remittent erosive arthritis in rats induced by bacterial peptidoglycan-polysaccharide structures.

I.2.2.11 Pristane-Induced Arthritis in Mice

PURPOSE AND RATIONALE

The mineral oil 2,6,10,14-tetramethylpentadecne (known as **pristane**) induces a chronic inflammatory arthritis in **mice** after intraperitoneal injection (Potter and Wax 1981; Hopkins et al. 1984; Wooley et al. 1989; Chapdelaine et al. 1991; Wooley and Whalen 1991; Levitt et al. 1992; Abe et al. 1995; Thompson et al. 1998; Wooley et al. 1998; Vigar et al. 2000). The immunological involvement in the pathogenesis of pristane-induced arthritis was studied by several authors (Bedwell et al. 1987; Thompson et al. 1990; Ghoraishian et al. 1993; Nishikaku et al. 1994; Vingsbo et al. 1996; Stasiuk et al. 1997; Morgan et al. 2004). Moreover, the genetic basis for the susceptibility to pristane-induced arthritis was studied (Lu et al. 2002; Olofsson et al. 2003; Brenner et al. 2005; Jensen et al. 2006). Not only in mice, but also in **rats**, arthritis could be induced by pristane injections (Vingsbo et al. 1996; Zheng et al. 2002, 2003; Wester et al. 2003; Holmberg et al. 2006).

Patten et al. (2004) characterized the model of pristine-induced arthritis (PIA) in mice by studying the response to antirheumatic agents, expression of joint cytokines, and immunopathology.

PROCEDURE

Induction and Characterization of PIA

Male DBA/101aHsd mice were placed under isoflurane anesthesia and injected intraperitoneally with 0.5 ml of pristane (Sigma-Aldrich, Poole, UK), and an identical booster injection was given 7 weeks thereafter. The severity of arthritis was graded visually by assessing the level of swelling in each paw, including the tarsus (ankle) or carpus (wrist) joints. The following scoring system was used: 0.5 = swelling of toes only or very slight ankle/wrist swelling; 1 = slight swelling of paw; 2 = moderate swelling of paw; 3 = marked swelling of paw; and 4 = substantial swelling of paw. Thus, the maximum total score per animal was 16. All batches also contained animals that were not treated with pristane, and these served as comparators for all studies undertaken.

Mice were observed for paw or toe swelling in a time-course study lasting up to 180 days after the first pristane injection. After study termination, the initially swollen hind paws were obtained for histologic assessment and allocated to different study groups according to the duration of swelling. The remaining three paws of each animal were used in cytokine studies.

Drug preparation and Administration Schedules

The effects of administration of established and novel antirheumatic compounds were assessed using a therapeutic dosing schedule. Separate batches of mice for each drug study were monitored weekly for the development of swollen paws from day 80 after the first injection of pristane. Mice were included in the drug studies only if they developed a score of $\geqslant 1$ in a hind paw on two consecutive weekly observations between day 120 and day 134 after the first injection of pristane ($n = 7$–13 per treatment group). At study termination, paws were obtained for histologic and cytokine assessments, normally at 1 h after the final drug administration.

All orally administered treatments were undertaken by gavage. Prednisolone was suspended in 0.5% methylcellulose and administered orally once daily at a dose of 2 mg/kg. Methotrexate was dissolved in physiologic saline and administered intraperitoneally 3 times per week at a dose of 9 mg/kg. Indomethacin and diclofenac were suspended in 1% methylcellulose and given orally once daily at doses of 3 mg/kg and 2 mg/kg, respectively. Celecoxib was suspended in a solution of 66% polyethylene glycol, 33% water, and 1% dimethylsulfoxide, and was administered orally twice daily at a dose of 30 mg/kg. Etanercept was dissolved in the supplied vehicle according to the instructions of the manufacturer and diluted using physiologic saline, and was administered intraperitoneally 3 times per week at doses of 300 µg and 100 µg per mouse. Murine sTNFR, consisting of two murine p75 receptors fused to murine IgG2a, was dissolved in physiologic saline and administered intraperitoneally 3 times per week at doses of 300 µg and 100 µg per mouse. The selective p38 MAPK inhibitor SB242235 (synthesized at the US GSK Research Center) was suspended in 0.5% tragacanth and 0.03M hydrochloric acid and given orally twice daily at doses of 30 mg/kg and 15 mg/kg.

Joint Cytokine Messenger RNA (mRNA) and Protein Assays

The levels of mRNA and protein for the pro-inflammatory cytokines TNFα, IL-1β, and IL-6 were measured in disaggregated joints by TaqMan real-time reverse transcription-polymerase chain reaction (PCR) and enzyme-linked immunosorbent assays (ELISAs),

respectively. At study termination and, in the drug studies, 1 h after the final drug treatment administration, the primary ankle joint was removed for histology and the remaining paws were removed and snap-frozen in liquid nitrogen (six to eight mice per group). For cytokine assessment, the paw showing the highest score for swelling was selected with the proviso that it had also been swollen at the start of the drug study. If the remaining three paws exhibited no swelling at study termination, then the remaining ankle was selected for assay. Whole paws were frozen and pulverized using a mortar and pestle filled with liquid nitrogen.

For the mRNA studies, total RNA was isolated from homogenized paws using RNeasy Mini-kits (Qiagen, Crawley, UK). Samples were treated with 10 units of RNase-free DNase (Qiagen) for 15 min during the RNA isolation process. Reverse transcription of mRNA was carried out using TaqMan reverse transcription reagents in an MJ Research PTC-200 PCR Peltier Thermal Cycler. TaqMan probes and forward and reverse primers for the genes of interest (TNFα, IL-1β, and IL-6) and for housekeeping genes (GAPDH and cyclophilin) were designed with Primer Express TM software (PE Applied Biosystems). Cytokine mRNA expression levels were quantified by TaqMan real-time PCR using the ABI Prism 7900 Sequence Detector System (PE Applied Biosystems).

Measurement of Serum Antibody Levels

Blood was withdrawn from all mice before pristane injection and monthly thereafter. Levels of antibodies were determined by ELISA. Plates were coated with 100 µl of coating buffer (0.4 M phosphate buffer, pH 7.6) containing 5 µg of each antigen, at 4°C overnight. The antigens assessed were bovine aggrecan, bovine biglycan, human endoplasmic reticulum molecular chaperone protein, bovine chondroitin sulfate A, bovine chondroitin sulfate B, bovine type I collagen, chick type II collagen, murine type II collagen peptide, bovine decorin, bovine double-stranded DNA, human fibronectin, lupine glucose-6-phosphate isomerase, mycobacterial 65-kDa heat-shock protein, murine aggregated IgG, joint extract from normal mice, and joint extract from arthritic mice. Plates were washed 3 times with 0.05% Tween 20 in PBS and nonspecific binding was blocked by 5% non-fat milk in PBS overnight at 4°C. Serum samples from at least six individual mice per time point were used. Since 1:100 was the dilution determined to produce the optimal response to high-density proteoglycans, mouse serum diluted 1:100 in 5% milk/PBS was added to each well and incubated overnight at 4°C. Subsequently, the plates were washed 6 times with 0.05% Tween 20 in PBS and incubated with alkaline phosphatase-conjugated goat anti-mouse IgG (Southern Biotechnology Associates, Birmingham, Ala., USA) at 37°C for 1 h. Plates were again washed 6 times and developed for 40 min in the dark, using *p*-nitrophenyl phosphate as a chromatogen substrate. The optical density was measured at 405 nm ($OD_{405\,nm}$) using an ultraviolet max spectrophotometer (Molecular Devices, Sunnyvale, Calif., USA). To ensure uniformity of the assay, negative control sera obtained prior to blood withdrawal and a standard mouse anti-type II collagen antiserum were titered on each plate. Antibody binding was expressed as the $OD_{405\,nm}$ in units-blank.

Isolation of Splenocytes and Cell Proliferation Assays.

Spleens were excised and immediately immersed in PBS. Tissue was mechanically disrupted to release cells, which were suspended in 10 ml of sterile PBS and centrifuged for 10 min at 1,500 rpm. Prior to resuspension in medium, red blood cells were removed from the spleen preparations by adding distilled water for 10 s and then adding PBS. Spleen cells were then counted using a hemocytometer, and washed and resuspended in RPMI at a final concentration of 2.5×10^6/ml.

Next, 100 µl of spleen cell aliquots (2.5×10^6/ml) were transferred to 96-well plates with 50 µg/ml of each antigen (aggrecan, biglycan, chondroitin sulfate A, chondroitin sulfate B, type I collagen, type II collagen, type II collagen peptide, decorin, fibronectin, and heat-shock protein; all were derived from the same species as described for the serum antibody studies) in complete RPMI 1640 medium. Cells were incubated for 72 h at 37°C in the presence of antigen. Then 20 µl of MTT solution (a mitochondrial enzyme substrate) was added to each well (5 mg/ml). After a 6-h incubation, the culture supernatant was discarded and 200 µl of 10% sodium dodecyl sulfate solution was added to each well. After incubation at 37°C overnight, the $OD_{590\,nm}$ was read by microplate photospectrometer (Molecular Devices). The mean OD values were recorded for each cell sample as a measure of antigen stimulation. Antigen-specific responses were calculated as follows: ($OD_{590\,nm}$ [stimulated culture]) – ($OD_{590\,nm}$ [spontaneous proliferation culture]).

Histopathologic Evaluation

In all studies, the primary ankle joint that was swollen at the beginning of the time-course study or drug study was excised and fixed in 10% neutral buffered formalin. The tissues were decalcified with formic acid and

embedded in paraffin blocks. Sections (4–7 μm) were cut along a longitudinal axis, mounted, and stained with hematoxylin and eosin or toluidine blue, and representative slides for each animal were assessed. The following features were scored in six to ten animals per group: inflammatory exudate, neutrophil and mononuclear cell infiltration, bone resorption, and synovial hyperplasia. For drug studies, the effects of the agents on the pristane-induced pathologic condition were scored as follows: + = mild inhibition of pathologic features, ++ = moderate inhibition of pathologic features, +++ = marked inhibition of pathologic features.

EVALUATION

Graphic and tabular data are expressed as the mean ± SEM. Statistical significance was tested by application of the Kruskal-Wallis test for clinical scores, and by analysis of variance followed by Dunnett's test for the cytokine mRNA and protein time-course results. Antibody and cell proliferation studies were analyzed using the least-squares significant difference post hoc test.

MODIFICATIONS OF THE METHOD

Brenner et al. (2006) published thermal signature analysis as a novel method for evaluating inflammatory arthritis activity using rats with Freund's adjuvant-induced monoarthritis and pristane-induced arthritis. The thermal imaging system employs a platinum silicide 256 × 256 pixel detector array filtered to be sensitive to infrared radiation at a wavelength of 3–5 μm.

Lange et al. (2005) investigated the mode of action of methotrexate in different models for rheumatic arthritis, such as fibroblast-induced arthritis in SCID mice, collagen-induced arthritis and anticollagen-II-antibody-induced arthritis in rats, pristane-induced arthritis in DA rats, and models of multiple sclerosis, such as experimental autoimmune encephalomyelitis in (Balb/c x B10.Q)F1 and B10.Q mice.

Pristane induces lupus-like kidney and pulmonary disease in mice (Satoh et al. 1995; Richards et al. 1998; Lin et al. 2004; Chae et al. 2006).

I.2.2.12 Experimental Autoimmune Thyroiditis

PURPOSE AND RATIONALE

Immunization of rats or mice with porcine thyroglobulin results in thyroiditis (Vladutiu 1971, 1983; McGregor et al. 1983; Hassman et al. 1985; Salamero et al. 1987; Fournier et al. 1990).

PROCEDURE

Crude porcine thyroglobulin (PTg) solution is emulsified in complete Freund's adjuvant in a 1:1 ratio. Female mice (6–8 weeks old) are primed with 50 µg PTg given s.c. into four or five sites of injection and are boosted 14 days later with the same dose of PTg (s.c.) emulsified in incomplete Freund's adjutant. The test compounds are administered from day 0 (at priming) until day 21. Mice are bled on day 21 and on day 28 after priming. The sera are tested for the levels of anti-PTg antibodies using an enzyme-linked immunosorbent assay (ELISA). On day 28, the animals are sacrificed and the thyroid glands prepared. Five-micrometer thick sections are stained with Masson-Goldner's trichrome solution.

EVALUATION

The histological severity of experimental autoimmune thyroiditis is graded as a function of mononuclear cell thyroid infiltration indices:

1. interstitial accumulation of inflammatory cells distributed between two ore more follicles.
2. one or two foci of inflammatory cells reaching at least the size of one follicle
3. 10 to 40% of the thyroid replaced by inflammatory cells.
4. more than 40% of the thyroid replaced by inflammatory cells.

Mean values of treated animals are compared with controls.

MODIFICATIONS OF THE METHOD

Castagliola et al. (1994) induced autoimmune thyroid disease in BALB/c mice by immunizing with the extracellular domain of the human TSH receptor expressed as a maltose-binding protein fusion in bacteria. This type of thyroiditis could be transferred to naive BALB/c and NOD mice (Castagliola et al. 1996).

Green et al. (1995) described a spontaneous model of autoimmune thyroiditis in MRL-lpr/lpr mice.

Furthermore, Green et al. (1996) induced thyroiditis in Lewis rats by immunization with thyroid extract and thyroglobulin. A reduction of the gap junction proteins connexin 43, connexin 32 and connexin 26 was found in diseased thyroid tissue.

I.2.2.13 Coxsackievirus B3-Induced Myocarditis

PURPOSE AND RATIONALE

The effects of immunosuppressant drugs can be studied in the murine model of Coxsackie virus B-3 myocarditis.

PROCEDURE

Three week old male BALB/c mice are kept for 7 days before the experiment in a single, self-contained animal isolation unit to exclude pre-diseased animals. They are maintained in disposable, filter-topped cages and handled with gloves by gowned and masked personnel. The intraperitoneal route is used for injection of virus in a 0.5 ml volume.

The CVB3 virus strain is grown on either Hep-2 or VERO cells, aliquotted, and maintained at –70°C until use. At the time of infection, seed virus is grown on either VERO or LLC-MK-2 cells with Dulbecco's modified Eagle medium, 12% fetal calf serum and gentamycin. Virus is harvested and adjusted to an inoculum of 1.75×10^7 plaque forming units/0.5 ml RPMI-1640. The test drugs are given subcutaneously daily for 8 days. On day 8, the animals are sacrificed, the hearts rapidly removed and divided into two equal cross sections. The basal portion is snap frozen for isolation of virus and determination of drug level. The apical portion is fixed in 10% formalin, dehydrated and embedded in paraffin. Five mm sections are stained with hematoxylin-eosin and Masson's trichrome stains. The bases of the individual hearts are minced with a sterile scalpel, suspended in 1 ml RPMI-1640, and homogenized in a glass tissue grinder. The suspension is centrifuged at 8000 *g* for 10 min at 4°C. Supernatants are harvested and frozen at –70°C until assay. Serial 10-fold dilutions of heart homogenates in minimum essential medium are layered on confluent, 72-h-old VERO cells, that had been grown in 96-well microtiter plates. Monolayers are checked daily for 7 days for presence or absence of virus and rate of cell destruction.

EVALUATION

The slides are examined by two observers blinded to the slide code, and inflammation and necrosis are quantitated.

MODIFICATIONS OF THE METHOD

Lane et al. (1991) showed that lipopolysaccharides promote CB3-induced myocarditis in otherwise resistant B10.A mice.

Beisel et al. (1991) identified a putative shared epitope between Cocksackie virus B4 and mouse alpha cardiac myosin heavy chain.

Gauntt et al. (1993) found that epitopes shared between Coxsackie virus B3 and normal heart tissue contribute to CVB3-induced myocarditis in mice.

Instead of Coxsackie virus B-3, Monrad et al. (1986) used encephalomyocarditis virus to induce experimental myocarditis in mice.

I.2.2.14 Porcine Cardiac Myosin-Induced Autoimmune Myocarditis in Rats

PURPOSE AND RATIONALE

Pummerer et al. (1991), Inomata et al. (1995), Suzuki 1995; Dimitrijevic et al. (1998) described autoimmune myocarditis in rats induced by porcine cardiac myosin.

PROCEDURE

Male Sprague Dawley or Lewis rats at the age of 8 to 10 weeks are immunized with porcine cardiac myosin either purchased from Sigma (St. Louis, MO, USA) or prepared from the ventricular muscle of porcine hearts according to Murakami et al. (1976). The cardiac myosin fraction is dissolved in phosphate buffer at a concentration of 10 mg/ml. The antigen solution is emulsified with equal volume of complete Freund's adjuvant supplemented with heat-killed mycobacterium tuberculosis. Rats are injected subcutaneously into the foot pad with an immunizing dose of 5 mg of antigen in complete Freund's adjuvant/kg of body weight. Rats are injected intraperitoneally with test compounds either from day 0 to 6 (early treatment group) or from day 14 to 20 (late treatment group).

Immunized rats are sacrificed on days 8, 16, 21, and 34, respectively. Disease course and severity are analyzed by macroscopic findings of the hearts, heart weight/bodyweight ratio, as well as by histological and immunohistochemical analysis. Macroscopic findings are scored as follows: 0: normal finding; 1: presence of focal discolored area on the surface; 2: presence of diffuse discolored areas (Kodama et al. 1995).

The hearts are removed and weighted immediately after the rats are sacrificed, fixed in 10% buffered formalin and embedded in paraffin. Serial section (5 µm in thickness) are stained with hematoxylin-eosin. The severity of myocarditis is determined according the following scoring system: 0, no inflammation; 1: histological cross section infiltrated up to 5%; 2: 5–10% infiltrates/section; 3: 10–20% infiltrates/section; more than 20% infiltrates/section.

For immunohistochemical staining, heart samples are embedded in OCT compound (Miles, Elkhart, IN) and rapidly frozen. Cryostat sections are cut sequentially at 7 µm in thickness, mounted on glass slides and prepared for immunoperoxidase staining. Sections are fixed in cold acetone for 10 min and extensively washed in 0.1 M Tris buffer solution, pH 7.6. Murine monoclonal antibodies specific for different rat molecules are added at appropriate concentrations. After incubation at 4°C over night and further buffer washes, the sections are incubated with peroxidase-conjugated anti-mouse immunoglobulins for 60 min. Peroxidase reaction is visualized with 0.05% diaminobenzidine in 0.01% H_2O_2 for 7–8 min. The color development is stopped by washing slides in running water. All samples are lightly counterstained with hematoxylin, mounted in gelatin/glycerol medium and assessed by light microscopy.

EVALUATION

Macroscopic and microscopic scores are expressed as mean values. Body weights, heart weights and heart weight/body weight ratio are expressed as mean ± SD. Student's *t*-test for paired samples is used for comparison data within groups in reference to time, while two-sample *t*-test is used for comparison data between groups.

MODIFICATIONS OF THE METHOD

Koyama et al. (1995) immunized Lewis rats with human cardiac myosin suspended in complete Freund's adjuvant and induced severe active myocarditis with acute and chronic heart failure. The baseline left ventricular pressure was significantly lower in the chronic phase group and peak dP/dt was significantly lower in both the acute phase group and the chronic phase group than in the respective controls. The animal model was recommended to study both acute heart failure related to acute myocarditis and chronic heart failure due to diffuse myocardial fibrosis.

Neu et al. (1990, 1991ab; Penninger et al. 1993) induced severe autoimmune myocarditis in some mouse

strains by immunization with cardiac myosin in complete Freund's adjuvant.

Wahed et al. (2005) used the method of immunization with porcine cardiac myosin to test the effects of eplerenone, a selective aldosterone blocker, on the progression of left ventricular dysfunction and remodeling in rats with dilated cardiomyopathy.

I.2.2.15 Experimental Allergic Encephalomyelitis

PURPOSE AND RATIONALE

Experimental allergic encephalomyelitis was first produced in laboratory animals by Rivers et al. in 1933. This pathological model is an immunologic disease arising from a delayed hypersensitivity reaction to nervous tissue. In many respects, the model resembles autoimmune diseases, especially demyelinating diseases, in man. The method is used for evaluation of immunosuppressive properties of drugs.

PROCEDURE

Preparation of the encephalitogen: 3 g of spinal cord from guinea pigs or rats are homogenized with 7.5 ml bidistilled water, 3.8 ml phenol and 7.5 ml complete Freund's adjuvant under cooling.

Groups of 6–12 male Wistar–Lewis rats with an initial body weight of 130–200 g are used. On day 0, experimental allergic encephalomyelitis is induced by subplantar injection of 0.1 ml of the encephalitogen into the left hind paw. An equal volume of *Bordetella pertussis* vaccine concentrate (200×10^9 organisms/ml) is injected into the same foot. From days 1–2, the animals receive the test compound or vehicle only or the standard drug by oral administration once a day. Body weights of the animals are recorded every second day. The clinical signs of experimental allergic encephalomyelitis consist of ataxia or paresis, i. e., grossly irregular gait and weakness of one or both hind legs followed by flaccid paralysis of the hindquarters, urinary incontinence, fecal impaction and abdominal wall flaccidity. Animals showing one of these clinical signs are considered positive for the purpose of evaluation.

EVALUATION

Starting from day 7, the severity of clinical signs and mortality are determined daily and scored according to the following scheme:

	score
per 20 g loss of weight	1
paralysis of the tail	1
paralysis of the hind paw	3
complete paralysis	5
death	6

Calculation of the Results

The delay of onset of the paralytic symptoms is determined. The total score per day is recorded for treated and control groups. On the day of maximal clinical symptoms occurring among control animals, the total scores of the treated groups is compared to the total score of the control group. The percentage change is evaluated.

Doses of 0.5 mg/kg p.o. methotrexate, 1 mg/kg p.o. hydrocortisone, 2.5 mg/kg p.o. cyclophosphamide were found to be active, whereas non-steroidal anti-inflammatory compounds were inactive.

CRITICAL ASSESSMENT OF THE METHOD

The model of experimental allergic encephalomyelitis in rats is suitable to distinguish between immunosuppressive and anti-inflammatory drugs. Experimental autoimmune encephalomyelitis is considered as a rodent model of the autoimmune disease multiple sclerosis (Pearson et al. 1997; Deng et al. 2002).

MODIFICATIONS OF THE METHOD

The phosphodiesterase inhibitor pentoxifylline was found to prevent induction of experimental autoimmune encephalomyelitis in Lewis rats (Rott et al. 1993).

Martin and Near (1995) studied the protective effect of the interleukin-1 antagonist IL-1ra on experimental allergic encephalomyelitis in Lewis rats.

Experimental autoimmune encephalomyelitis in different strains of mice was described by Heremans et al. (1996), Glabinski et al. (1997), Liblau et al. (1997).

Baker et al. (1990, 1991, 2000) induced experimental allergic encephalomyelitis in Biozzi AB/H mice by sensitization with 1 mg of mouse spinal cord homogenate emulsified in Freund's complete adjuvant on days 0 and 7. The disease is characterized by relapsing-remitting episodes similar to multiple sclerosis in human beings. Biozzi AB/H mice also develop spasticity and tremor which can be antagonized by cannabinoids.

A chronic relapsing-remitting form of experimental autoimmune encephalomyelitis was induced in the common marmoset Callithrix jacchus following a single immunization with human white matter by Massacesi et al. (1995), Genain and Hauser (1997) and recommended as a new model for multiple sclerosis. This model has been used for histopathological characterization of magnetic resonance imaging-detectable white matter lesions in a primate model of multiple sclerosis by 't Hart et al. (1998, 2004) (see E.10.3.2).

Experimental allergic neuritis in several animal species has been described by Waksman and Adams 1955, 1956; King et al. 1983; McCombe et al. 1990; Nakayasu et al. 1990). This disorder has been considered to show similarities to the Guillain-Barré syndrome in man. The demyelating process initiated by the injected antigens is a lymphocyte-mediated reaction in which activated macrophages strip myelin off the axons. Hartung et al. (1987) described the adoptive transfer experimental autoimmune neuritis in Lewis rats by injection of P2-reactive T lymphocyte cell lines.

Mix et al. (1992) studied the effect of stilbene-type anion channel blockers on the immune response during experimental allergic neuritis induced by bovine peripheral myelin.

Kojima et al. (1994) investigated the pathogenic potential of autoimmune T cell responses to nonmyelin autoantigens in the Lewis rat using the astrocyte-derived calcium-binding protein S100β, as a model non-myelin autoantigen. In contrast to the experimental autoimmune encephalomyelitis induced by the adoptive transfer of myelin basic protein-specific T line cells, S100β-specific T cell transfer induced intense inflammation not only in the spinal cord but also throughout the entire CNS and also in the uvea and retina of the eye.

Gautam et al. (1992) reported that a polyalanine peptide with only five native basic protein residues induces autoimmune encephalomyelitis in mice. This peptide, called myelin basic protein (MBP) Ac1–11, has been used by several authors for further studies on experimental autoimmune encephalomyelitis (Ratts et al. 1999; Matejuk et al. 2003).

Pearson et al. (1997) reported the induction of a heterogeneous T-cell receptor repertoire in (PL/JXSJL/J)F2 mice by myelin basic protein peptide Ac1–11 and its analog Ac1–11[4A].

Deng et al. (2002) found that expression of the tyrosine phosphatase Src homology 2 domain-containing protein tyrosine phosphatase 1 determines the T cell activation threshold and severity of experimental autoimmune encephalomyelitis.

Maron et al. (2002) investigated the immunological properties of Cop1 (glatiramer acetate) to determine the degree to which its effects were antigen specific using myelin basic protein T-cell receptor transgenic mice. Immunization of these mice fed glatiramer acetate, myelin basic protein or MBP Ac1–11 resulted in decreased proliferation, and IL-2, IL-6, and IFN-γ production, and increased secretion of IL-10 and TGF-β in glatiramer acetate-fed animals.

Gilgun-Sherki et al. (2003) reported that riluzole suppresses myelin oligodendrocyte glycoprotein-induced experimental autoimmune encephalomyelitis in mice.

Pollak et al. (2003) studied the experimental allergic encephalitis-associated behavioral syndrome and the modulation by anti-inflammatory treatments.

Diab et al. (2004) found that ligands for the PPAR-γ and the retinoid X receptor exert additive anti-inflammatory effects on experimental autoimmune encephalomyelitis. Duckers et al. (1997) studied the effect of a neurotropic treatment on cortical lesion development in experimental allergic encephalomyelitis in rats by longitudinal *in vivo* magnetic resonance imaging methods.

I.2.2.16
Acute Graft Versus Host Disease (GVHD) in Rats

PURPOSE AND RATIONALE

The intravenous injection of a mixture of parental splenocytes into healthy inbred F_1-rats results in graft-versus-host (GVH) induced immune abnormalities. This is due to T-lymphocytes in the donor inoculum that recognize the major histocompatibility alloantigens expressed by the F_1-animals. The host F_1 T-cells are genetically unable to recognize antigens of the parental donor as foreign, thus the response involves only donor recognition of host and not host recognition of donor. The ensuing immune abnormalities lead to clinical symptoms of an acute, lethal GVH-disease (GVHD), i. e. profound immunodeficiency, anemia, hypogamma-globulinemia and runting.

PROCEDURE

Three to 4 month old, male F_1-hybrid rats of the inbred strains Lewis (Rt-1 l) and Brown Norway (BN, Rt-1n) (Zentralinstitut für Versuchstierkunde Hannover Germany) are used as hosts for cell grafts from the Lewis parental strain. The bone marrow cells are obtained by flushing hind femur bone shafts with culture medium. These cells are then pooled together with spleen cells (ratio 2 bones: 1 spleen). The cell viability, determined by trypan exclusion, has to be more than 90%. Each recipient is injected with about 40×10^7 cells in a 1.5 ml-suspension volume. The route of injection is the penis vein, allowing an optimal control of correct intravenous application.

Prophylactic Drug Application

For this experiment, 2 groups of 6 F_1-hybrids each are injected with the above mentioned bone marrow/spleen cell suspension. One group receives the test drug orally and daily until the end of the experiment, homogeneously suspended in 1% carboxymethylcellulose (CMC) solution. The other group receives CMC alone and, thus, serving as the GVHD control group. The experiment is terminated two weeks after disease induction i. e. 1 week after the first appearance of GVHD-symptoms. All animals are sacrificed and clinical aspects documented, spleens weighed, histology of the skin, liver, spleen and lymph-nodes performed and organs photographed.

Therapeutic Drug Application

In this experiment, rats are separated into four groups treatment begins with the first sign of GVHD-symptoms (beginning of the second week). Because of

the expected, greater therapeutic difficulty, the daily dose of the test drug has to be doubled, again for 2 weeks duration.

The experiment is terminated either by sacrificing those rats that are too sick to be able to move around the cage, or at the end of the 4 week observation period, regardless of the clinical condition of the animals. The clinical-chemical parameters are determined by routine procedures conducted with a HITACHI autotechnicon.

EVALUATION

The tested parameters of therapeutic success or disease, respectively, are survival rate (%), spleen weight (g), and body weight (g) as well as clinical-chemical parameters (bilirubin, alkaline phosphatase, creatinine, white cell count) after 2 and 3 weeks.

MODIFICATIONS OF THE METHOD

Gelpi et al. (1994) established a chronic graft vs host disease in (C5BL/10 x DBA/2)F_1 mice with an injection of lymphoid cells from the parent DBA/2 strain. Most of the animals developed antibodies against transfer RNA/protein particles.

Mosier et al. (1988) reported transplantation of human peripheral blood lymphocytes (PBL) into severe combined immunodeficient (scid) mice to construct hu-PBL-scid mice. Kim et al. (1997) suggested these mice for routine immunotoxicity investigations using lymph nodes of intestines as the lymphocyte sources.

Ford et al. (1970), Schorlemmer et al. (1997, 1998) used the popliteal lymph node assay to study the local graft vs. host reaction. The test is based on the enlargement of the draining popliteal lymph nodes as a result of injecting immuno-competent cells (1×10^8 parental Lewis spleen cells) into the hind foot pad of Lewis × Brown-Norway F1 recipients. The reaction is measured at day 6 after challenge as a gain in lymph node weights.

I.2.2.17 Influence on SLE-Like Disorder in MRL/lpr Mice

PURPOSE AND RATIONALE

Systemic lupus erythematosus (SLE) is an autoimmune disease in man that affects multiple body organs and is characterized by the development of certain types of self antigens. Primarily, the antibodies formed against double-stranded DNA (dsDNA), the most prevalent in this ailment, complex together and, with complement, deposit in the small blood vessels, leading to widespread vasculitis. MRL Mpf lpr/lpr

(MRL/lpr)-mice spontaneously develop a severe disease with many symptoms very similar to human SLE, i. e. hypergamma-globulinemia, and glomerulonephritis (Theofilopoulos and Dixon 1981).

PROCEDURE

Female MRL/lpr-mice (originally from Jackson Laboratories, USA), displaying distinct symptoms of SLE (between 12 and 13 weeks of age) are randomized and divided into groups of 12 animals each. At this age, the animals have already clinical manifestations of the SLE-like illness, as determined by the disease index, but have not yet developed proteinuria. Animals with early symptoms of disease are treated with various drugs, e. g., leflunomide, cyclosporin A, azathioprine, cyclophosphamide or prednisolone for 11 weeks and the survival rate and disease index of these animals are followed for 24 weeks. The disease index and urine protein level are determined once weekly.

Disease Index

The subsequent clinical parameters are taken into consideration:

1. Ears: reddening of the skin, deterioration of the pinna.
2. Nose: loss of hair, wasting of the skin.
3. Lymph nodes: detection of swollen lymph nodes on any part of the body, especially neck and extremities.
4. Fur: general condition of fur (e. g. shabby, mangy, etc.), loss of hair.
5. Skin: inflammation of the skin, scab and/ or granuloma formation.
6. Eyes: exophthalmos, deterioration due to inflammation, tumor formation around the eye, swelling of the eyelid with eventual closure of the eye.
7. Paws: reddening of the skin, swelling of the paw.

EVALUATION

A score for each of the above described parameters is given according to the severity of the symptoms as follows:

Points for clinical index

Involvement	Detectable	Moderate	Severe
Ears (each)	0.5	1.0	1.5
Nose	1.0	2.0	3.0
Lymph node (each)	1.0	2.0	3.0
Fur	1.0	2.0	3.0
Skin	1.0	2.0	3.0
Eyes (each)	1.0	2.0	3.0
Paws (each)	0.5	1.0	1.5

Body weight (one point for 5 g difference from week to week)

The determination of the disease index is performed, weekly, by the same individual, but without knowledge of the group being evaluated. The points, for each animal, are registered and the total score, of each group, summarized. The average score for the group is calculated, significance between the experimental group and the untreated diseased group is determined using the Student *t*-test.

Proteinuria

Pooled urine is collected from each experimental group and the amount of protein in the urine is calculated.

MODIFICATIONS OF THE METHOD

In addition to a lupus-like syndrome and massive T cell proliferation. MRL-1pr/1pr (MRL/1) mice develop an arthritic process very similar serologically and histologically to human rheumatoid arthritis. Boissier et al. (1989) found that in these animals mouse type II collagen is antigenic, but not arthritogenic.

Holmdahl et al. (1991) studied the involvement of macrophages and dendritic cells in synovial inflammation of collagen induced arthritis in DBA/1 mice and spontaneous arthritis in MRL/Lpr mice.

Rordorf-Adam et al. (1985) used serum amyloid P component and autoimmune parameters in the assessment of arthritis in MRL/lpr/lpr mice.

Furukawa et al. (1996) studied the autoimmune disease-prone genetic background in relation to Fas-defect in MRL/lpr mice.

Kanno et al. (1992) found spontaneous development of pancreatitis in the MRL/Mp strain of mice.

Kusakari et al. (1992) compared hearing acuity and inner ear disorders of MRL/lpr mice with those of BALB/c mice and found a significantly higher auditory brain stem response threshold. They recommended this as a model of sensorineuronal hearing loss.

Bundick and Eady (1992) investigated the effects of an immunosuppressive agent on the development of spontaneous lupus disease in female NZBW F_1 hybrid mice.

Walker et al. (1996) reported a powerful suppressive effect of testosterone on the autoimmune disease analogous to systemic lupus erythematodes spontaneously developed by F1-hybrids of New Zealand Black (NZB) × New Zealand White (NZW) mice. A model was developed in which NZB dams carrying NZB/NZW fetuses were treated with testosterone

in a dose adequate to masculinize the external genitalia in female fetuses.

Zoja et al. (1998) investigated bindarit, a compound devoid of immunosuppressive properties, in NZB/W F1 hybrid mice developing an immune complex glomerulonephritis with proteinuria and progression to renal insufficiency.

Kiberd and Stadnyk (1995) studied the role of endogenous interleukin-1 in established lupus nephritis in MRL lpr/lpr mice by administration of the IL-1 receptor antagonist IL-1ra.

Gleichmann et al. (1982), Schorlemmer et al. (1997) induced a systemic lupus erythematodes-like disease in mice by abnormal T- and B-cell cooperation. A chronic graft versus host reaction with the pathologic symptoms of severe glomerulonephritis is induced in B6D2 (C5Bl/6 × DBA/2) F1 hybrid mice receiving four i.v. injections (one per week) of 1×10^8 parental lymphoid spleen cells from DBA/2 donors. The inoculation of splenocytes into the BDF1 hybrid mice results in the development of a chronic GvH reaction with lymphoid hyperplasia, autoantibody production and immune-complex glomerulonephritis.

Chan et al. (1995) described ocular changes occurring in mice with experimental lupus erythematodes. The ocular disease is characterized by bilateral subacute and chronic inflammation of the eyelids (blepharitis) and hypertrophic Meibomian glands. The severity of the ocular changes is strain dependent. The authors recommend this experimental eye disease as an animal model for chronic blepharitis in humans.

The changes of lacrimal and salivary glands found in MRL/lpr mice and other mouse strains with autoimmune disorders were also regarded as model of Sjögren's syndrome in human (Sullivan and Edwards 1997; Toda et al. 1999).
