Weich et al. (2004) described an ELISA for quantification of vascular endothelial growth factor-C.

PROCEDURE

Materials and Methods

The fully processed rat protein dNdC-VEGF-C and dNdC-VEGF-D were produced in insect cells and purified from supernatants (Kirkin et al. 2001). Human dNdC-VEGF-C and soluble VEGFR-3 production was achieved according to (Joukov et al. 1997; Hornig et al. 1999). A polyclonal antibody against rat VEGF-C was developed in rabbits (antibody 4080; BioGenes Berlin). A total amount of 1.2 mg rat VEGF-C (containing a C-terminal 6His-tag) was used for immunization of two New Zealand white rabbits. After immunization with 0.1 mg protein, each rabbit was boosted on days 7, 14, 28, 56 and 84 with the same amount. The dilution of the serum for half-maximal titer was 1:10,000. Total IgG from rabbit serum was isolated using HiTrap Protein A Sepharose columns (Amersham Bioscience, Freiburg).

Generations of Cell Lines, Serum-Free Cell Culture Supernatants, Lysates and Tissue Sample Preparation

Experiments were conducted using three human (PC-3 cells, 293 cells, COLO 800 cells) and four rat (10AS, ARIP, BRL3A, MT-450) tumour cell lines and 1640 medium (Gibco-BRL, Bethesda, Md., USA). Stable transfected clones were selected and tested for VEGF-

C expression and secretion using a polyclonal anti-VEGF-C antiserum.

The cells were grown to 80% confluence in 75-cm^2 tissue culture flasks (Nunc, Roskilde, Denmark). Conditioned media was collected under low-serum (2%) growth conditions. Tumor tissues were snap-frozen in liquid nitrogen and homogenized in RIPA buffer (0.1% SDS, 1% IGEPAL CA-630, 0.5% Na-deoxycholate, protease-inhibitor cocktail in phosphate-buffered saline).

VEGF-C Sandwich-ELISA

The VEGF-C antibody 4080 was isolated from serum using HiTrap Protein-A Sepharose columns. Then, depletion of the anti-his antibody fraction was done by antigen-affinity purification using 10 mg of immobilized 6H-tagged TxnTb protein [Tryparedoxin (Txn) from *Trypanosoma brucei* (Tb)]. Antigen-affinity purification for the antibody 4080 was performed by immobilizing 1 mg rat VEGF-C on an NHS-activated HiTrap column (Amersham Bioscience, Freiburg). The development of a highly sensitive and specific sandwich ELISA for VEGF-C was done using standard methods. Rabbit IgG 4080 (10 µg/ml) was used for coating and the antigen-affinity purified and biotinylated antibody 4080 at 1 µg/ml was used as a detector antibody. Biotinylation of antibody 4080 was done with 6 mg IgG in 100 mM carbonate buffer, pH 8.5 at 3 mg/ml with using biotin-amidohexanoic acid NHS (Sigma, St. Louis, Mo., USA). The molecular ratio biotin:protein was 30:1. As a standard, human and rat dNdC-VEGF-C was used over a concentration range between 0.1 and 6.25 ng/ml. For visualization of the detector, streptavidin-enzyme conjugate was used (Endogen, Woburn, Mass., USA) followed by the addition of TMB (tetra-methyl-benzidine; Roche Mannheim, Germany).

EVALUATION

After stopping the reaction with 1 M H_2SO_4, the absorbance was measured at 450 and 620 nm with an ELISA plate reader (Labsystems, Finland). Generally, the samples were analyzed in different dilutions, measuring each dilution in duplicate. Samples were diluted at least 1:2 with sample diluent (BenderMedSystems, Vienna).

MODIFICATIONS OF THE METHOD

Rissanen et al. (2003) found that VEGF-D is the strongest angiogenesis and lymphangiogenetic factor among VEGFs delivered into skeletal muscle via adenoviruses.

A.8.4.8 Inhibitors of Vascular Endothelial Growth Factor

PURPOSE AND RATIONALE

Inhibitors of vascular endothelial growth factor have gained therapeutic interest (Whittles et al. 2002; Gingrich et al. 2003; Hamma-Kourbali et al. 2003; Verheul and Pinedo 2003;

Fernandez et al. 2004; Roberts et al. 2004; Baka et al. 2006). In particular, VEGF Trap, a soluble decoy receptor comprising portions of VEGF receptors 1 and 2, has been studied (Wulff et al. 2001; Holash et al. 2002; Kim et al. 2002; Hood and Cheresh 2003; Saishin et al. 2003; Fukasawa and Korc 2004; Fraser et al. 2005; Hu et al. 2005; Lau et al. 2005).

Byrne et al. (2003) found that vascular endothelial growth factor-Trap decreases tumor burden, inhibits ascites, and causes dramatic vascular remodeling in an ovarian cancer model.

PROCEDURE

Cell Lines

Ascites fluid from athymic mice previously inoculated with OVCAR-3 cells was used. Cells from the SKOV-3 human cystadenocarcinoma cell line were grown in McCoy's 5a medium with 1.5 mM L-glutamine, penicillin, and streptomycin, supplemented with 10% FCS. Cells were grown to confluence and harvested by trypsinization with 0.25 mg/ml trypsin/EDTA and suspended in PBS before inoculation into mice.

Animals

Athymic Balb c *nu/nu* mice were housed under pathogen-free conditions and fed autoclaved pellets and water.

Retroviral Constructs

The pLZR Phoenix vector was modified by the addition of a MCS followed by an internal ribosome entry sequence-GFP cassette (Rommel et al. 1999). Thus, genes subcloned into the MCS produce bicistronic constructs under the control of the viral 5′ long terminal repeat. The entire coding sequence of $mVEGF_{164}$ was inserted into the MCS for the construct used to transduce cells with VEGF, whereas the MCS was left empty for the GFP-only vector. Constructs were transfected into Amphotrophic packaging lines to produced infective virus using standard techniques (Grignani et al. 1998).

SKOV-3 MODEL

SKOV-3 cell lines were infected with Amphotrophic viruses encoding either $mVEGF_{164}$ and GFP or GFP only. Cells that were successfully transduced with the retroviruses were collected by FACS using a Cytomation MoFlo (Fort Collins, Colo., USA) with fluorescence emission from GFP measured with a 530/540 nm bandpass filter. More than 50% of the cells were GFP positive after infection, allowing $> 4.0 \times 10^5$ cells to be collected and used to establish cell lines. To verify viral transduction, cells were resorted several days later and found to be > 80% positive for GFP expression. Cells were then expanded, aliquoted, and frozen. All experiments were performed with an aliquot expanded by four to five passages and tested for viability before injection.

In Vivo Adenoviral and SKOV-3 Studies

Adenoviral constructs were achieved according to Thurston et al. (2000). Adenoviral plaque-forming units (5.0×10^8) or 1.0×10^7 SKOV-3 cells were suspended in a volume of 300–400 µl of PBS or serum-free cell culture medium and injected i.p. into female nude mice. VEGF-Trap or control buffer was delivered twice weekly at 25 mg/kg via s.c. injection in a volume of 50–200 µl. Mice were assessed daily for general health and development of ascites and weighed at least twice weekly. Animals were sacrificed if they had lost > 10% of body weight or had persistent ascites on three consecutive assessments. After sacrifice, ascites was removed with a sterile thin caliber plastic transfer pipette and quantified, and hematocrit was measured.

OVCAR-3 MODEL

OVCAR-3 cells obtained from ascites fluid were prepared (Hu et al. 2002). Briefly, 2×10^6 cells in 500 µl of RPMI 1640 were injected i.p. into athymic Balb/C nude (*nu/nu*) mice. Fourteen days after inoculation, blinded administration of VEGF-Trap or human Fc as control was initiated at a dose of 25 mg/kg. Injections were given s.c. in the nape of the neck using a 28.5-gauge needle and a 0.5-ml insulin syringe. Injections (0.05 ml) were administered twice weekly throughout the experimental period. Body weight and abdominal circumference were quantified twice weekly. In addition, animals were monitored daily for evidence of advanced disease (listlessness, extensive swelling of the abdominal cavity). At the end of the experiment, all remaining mice underwent euthanasia with CO_2 followed by cervical dislocation. The volume of ascites was measured, and tumors were excised and weighed. Immediately before sacrifice, mice received i.v. injection with FITC lycopersicon lectin (see below).

Tumor Vasculature

According to Holash et al. (2002) s.c. tumors were established. After small s.c. tumors became palpable (1 week after implantation), treatment with the VEGF-Trap was initiated. VEGF-Trap or an equivalent volume of vehicle was delivered twice weekly s.c. at the nape of the neck. Tumor vasculature was visualized by using antibodies to platelet-endothelial cell adhesion molecule for immunohistochemistry.

VEGF-Trap-treated OVCAR-3 tumor-bearing mice and control, untreated tumor-bearing mice were anesthetized by i.m. injection with ketamine (87 mg/kg) and xylazine (13 mg/kg), followed by i.v. injection with 100 µl of FITC lycopersicon lectin or 100 µg of Cy3 albumin (Jackson Immunology Research, West Grove, Pa., USA). Then 10 min later, mice were perfused through the ascending aorta with 4% paraformaldehyde in PBS for 2 min. Tumors and control organs were extracted and placed in fixative for 1–2 h followed by immersion in 30% sucrose/PBS

overnight, embedded in OCT, cryostat sectioned, and viewed by fluorescence microscopy.

Chapter B
Pharmacological Assays in Thrombosis and Haemostasis[1]

[1] Contributed by Shaker A. Mousa based on contributions by M. Just and V. Laux.

B.1 General Introduction

Cardiovascular, cerebrovascular, and venous thromboembolic disorders continue to be the leading causes of death throughout the world. Over the past two decades, great advances have been made in the pharmacological treatment and prevention of arterial and venous thrombotic disorders (e. g., tissue plasminogen activators, platelet GPIIb/IIIa antagonists, and ADP receptor antagonists such as clopidogrel, low-molecular weight heparins, and direct thrombin inhibitors). New research is leading to the next generation of antithrombotic compounds such as direct coagulation FVIIa inhibitors, tissue factor pathway inhibitors, gene therapy, and orally active direct thrombin inhibitors and coagulation factor Xa (FXa) inhibitors. In vitro assays as well as animal models of thrombosis have played and will continue to play crucial roles in the discovery and validation of novel drug targets, the selection of new agents for clinical evaluation, and the provision of dosing and safety information for clinical trials. In addition, these models have provided valuable information regarding the mechanisms of these new agents and the interactions between antithrombotic agents that work by different mechanisms. This comprehensive manual presents the pivotal models that led to the development of drugs that have proven to be effective clinically. The major issues regarding the use of animal models of thrombosis—such as the use of positive controls, appropriate pharmacodynamic markers of activity, safety evaluation, species-specificity, and pharmacokinetics—are highlighted. Finally, the use of genetic models in thrombosis/hemostasis research and pharmacology is also presented.

B.2 In Vitro Tests

B.2.1 Blood Coagulation Tests

PURPOSE AND RATIONALE

The coagulation cascade consists of a complex network of interactions resulting in thrombin-mediated conversion of fibrinogen to fibrin, which is one major component of a thrombus. The coagulation cascade can be initiated either by the "exogenous pathway," the release of thromboplastin (tissue factor) leading to activation of factor VII to the tissue factor/factor VIIa complex, or by the "endogenous pathway," so-called contact activation leading via factors XII, XI and IX to the assembly of the tenase complex consisting of activated factors VIII and IX and Ca^{2+} on a phospholipid surface. Both complexes can activate factor X, which induces the formation of the prothrombinase complex consisting of factor X_a, factor Va and Ca^{2+} on a phospholipid surface. The latter leads to the activation of thrombin, which, in turn, cleaves fibrinogen to fibrin. The three coagulation tests (prothrombin time [PT], activated partial thromboplastin time [APTT], and thrombin time [TT]) allow one to differentiate between effects on the exogenous or endogenous pathway or on fibrin formation. The influence of compounds on the plasmatic blood coagulation is determined by measuring the coagulation parameters PT, APTT, and TT *ex vivo*.

PROCEDURE

Male Sprague-Dawley rats weighing 200–220 g receive the test compound or the vehicle (controls) by oral, intraperitoneal, intravenous, or other route of administration. After the end of the absorption time, they are anesthetized by intravenous injection of 60 mg/kg sodium pentobarbital. The caudal caval vein is exposed by a midline incision or by cardiac puncture and 1.8 ml blood is collected into a plastic syringe containing 0.2 ml 100 mM citrate buffer pH 4.5 (Behring Werke, Marburg). The sample is immediately agitated and centrifuged in a plastic tube at 1500 × *g* for 10 min. Plasma is transferred to another plastic tube and the coagulation tests for the determination of TT, PT, and APTT are performed within 3 h.

In general, citrated plasma is coagulated by the addition of the respective compounds (see below), and the time to clot formation is determined in the coagulometer (= coagulation time).

For detailed laboratory diagnosis of bleeding disorders and assessment of blood coagulation see Palmer (1984) and Nilsson (1987).

Prothrombin Time (PT). An aliquot of 0.1 ml of citrated plasma is incubated for 1 min at 37°C. Then 0.2 ml of human thromboplastin (Thromborel, Behring Werke, Marburg) is added and the coagulometer (Schnittger+Gross coagulometer, Amelung, Brake) is started. The time to clot formation is determined. The PT measures effects on the exogenous pathway of coagulation.

Activated Partial Thromboplastin Time (APTT). To 0.1 ml of citrated plasma 0.1 ml of human placenta lipid extract (Pathrombin, Behring Werke, Marburg) is added and the mixture is incubated for 2 min at 37°C.

The coagulation process is initiated by the addition of 0.1 ml 25 mM calcium chloride when the coagulometer is started and the time to clot formation is determined. The APTT measures effects on the endogenous pathway of coagulation.

Thrombin Time (TT). To 0.1 ml of citrated plasma 0.1 ml of diethylbarbiturate-citrate buffer, pH 7.6 (Behring Werke Marburg) is added and the mixture is incubated for 1 min at 37°C. Then 0.1 ml of bovine test-thrombin (30 IU/ml, Behring Werke Marburg) is added and the coagulometer is started. The time to clot formation is determined. The TT measures effects on fibrin formation.

EVALUATION

Mean values of TT, PT, and PTT are calculated in dosage groups and vehicle controls. Statistical evaluation is performed by means of the unpaired Student's *t*-test.

B.2.2 Thrombelastography

PURPOSE AND RATIONALE

Thrombelastography (TEG) was developed first by Hartert (1948). The thrombelastograph (Haemoscope Corp, Skokie, Illinois, USA) is a device that provides a continuous recording of the process of blood coagulation and subsequent clot retraction. The blood samples are transferred to cuvettes and maintained at 37°C. The cuvettes are set in motion around their vertical axes. Originally, a torsion-wire suspended mirror in the plasma remains immobile as long as the plasma is fluid. The cuvette and the mirror become dynamically related as fibrin forms, resulting in transmission of cuvette motion to the mirror. The mirror then oscillates with an amplitude governed by the specific mechanical properties of the clot and reflects its light to a thermopaper. The modern thrombelastograph transfers the analogous recording to a digital signal that is evaluated by a computer program.

PROCEDURE

TEG can be performed in either whole blood or in citrated platelet-rich or platelet-poor plasma after recalcification. Blood samples are obtained from Beagle dogs weighing 12–20 kg, from rabbits weighing 1.7–2.5 kg, from Wistar rats weighing 150–300 g, or from humans. The test subjects receive the compound by intravenous (i.v.), subcutaneous (s.c.), or oral administration. Ten or 20 min post dosing (i.v., s.c. administration) or 60, 90 or 180 min post dosing (oral administration) blood is collected. The blood samples are mixed with 3.8% trisodium citrate solution (1 part citrate solution to 9 parts blood) as anticoagulant. The citrated whole blood is recalcified by adding 0.4 ml isotonic calcium chloride solution. An aliquot of 0.36 ml of the recalcified whole blood is transferred to the prewarmed cup of the thrombelastograph. After the apparatus has been correctly adjusted and the samples sealed with liquid paraffin to prevent drying, the time for the whole procedure is noted. The thrombelastogram is recorded for 2 h.

EVALUATION

The following measurements are the standard variables of TEG:

1. Reaction time (*r*): the time from sample placement in the cup until onset of clotting (defined as amplitude of 1 mm). This represents the rate of initial fibrin formation.
2. Clot formation time (*k*): the difference from the 1 mm *r* to 20 mm amplitude. *k* represents the time taken for a fixed degree of viscoelasticity achieved by the forming clot, caused by fibrin build up and cross linking.
3. Alpha angle ($\alpha°$): angle formed by the slope of the TEG tracing from the *r* to *k* value. It denotes speed at which solid clot forms.
4. Maximum amplitude (*MA*): greatest amplitude on the TEG trace. *MA* represents the absolute strength of the fibrin clot and is a direct function of the maximum dynamic strength of fibrin and platelets.
5. Clot strength (*G* in dynes per square centimeter): defined by $G = (5000\,MA)/(96 - \mathrm{s}MA)$. In a tissue factor-modified TEG (Khurana et al. 1997), clot strength is clearly a function of platelet concentration.
6. Lysis 30, Lysis 60 (*Ly30*, *Ly60*): Reduction of amplitude relative to maximum amplitude at 30 and 60 min after time of maximum amplitude. These parameters represent the influence of clot retraction and fibrinolysis.

TEG Parameters	TF (25 ng)	LPS (0.63 ug)	Xa (0.25 nM)	Thrombin (0.3 mU)
		Mean ± SEM		
R (minutes)	29.7 ± 2.3	23.4 ± 1.4	15.6 ± 2.9	3.4 ± 0.6
K (minutes)	5.8 ± 1.0	7.6 ± 0.9	4.8 ± 0.5	5.5 ± 0.8
α (angle)	45.0 ± 2.6	47.8 ± 3.2	61.5 ± 2.1	57.8 ± 2.9
MA (mm)	58.2 ± 1.7	50.0 ± 2.0	65.0 ± 0.8	50.1 ± 2.4

Citrated human whole blood plus 2 mM calcium. Data represent mean for n = 6 ± SEM.

Table 1 Effect of various stimulus on platelet/fibrin clot dynamics as shown by Mousa et al. (2000)

MODIFICATIONS OF THE METHOD

Bhargava et al. (1980) compared the anticoagulant effect of a new potent heparin preparation with a commercially available heparin by TEG *in vitro* using citrated dog and human blood. Barabas et al. (1993) used fibrin plate assay and TEG to assess the antifibrinolytic effects of synthetic thrombin inhibitors. Scherer et al. (1995) described an endotoxin-induced rabbit model of hyper-coagulability for the study of the coagulation cascade and the therapeutic effects of coagulation inhibitors using various parameters, including TEG.

Khurana et al. (1997) introduced tissue factor-modified TEG to study platelet glycoprotein IIb/IIIa function and to establish a quantitative assay of platelet function. With this modification, Mousa et al. (2000) found two classes of glycoprotein IIb/IIIa (GPIIb/IIIa) antagonists, one with high binding affinity for resting and activated platelets and slow platelet dissociation rates (class I) demonstrating potent inhibition of platelet function, in contrast to those with fast platelet dissociation rates (class II). Additionally, Mousa et al. (2005) utilized the TEG in phase II clinical trial in monitoring the efficacy of oral platelet GPIIb/IIIa antagonist on platelet/fibrin clot dynamics.

CRITICAL ASSESSMENT OF THE METHOD

Zuckerman et al. (1981) compared TEG with other common coagulation tests (fibrinogen, prothrombin time, activated thromboplastin time, platelet count, and fibrin split products) and found that there is a strong relationship between the thrombelastographic variables and these common laboratory tests. Mousa et al. (2005) and others expanded the use of TEG in differentiating among different antiplatelets, anticoagulants, and optimal combinations of both. Moreover, TEG has an increased sensitivity for detecting blood clotting anomalies; it contains additional information on the hemostatic process. This is due to the following: (1) the fact that most laboratory measurements end with the formation of the first fibrin strands while TEG measures the coagulation process on whole blood from initiation of clotting to the final stages of clot lysis and retraction, and (2) the ability of TEG to use whole non-anticoagulated blood without influence of citrate or other anticoagulants.

B.2.3 Chandler Loop

PURPOSE AND RATIONALE

The Chandler loop technique allows the production of *in vitro* thrombi in a moving column of blood (Chandler 1958). The thrombi generated in the Chandler device show morphology very similar to that of human thrombi formed *in vivo* (Robbie et al. 1997), with platelet-rich upstream sections (“white heads”) that are

relatively resistant to t-PA-mediated thrombolysis in contrast to the red blood-cell-rich downstream parts ("red tails") (Stringer et al. 1994).

PROCEDURE

One millimeter of non-anticoagulated whole blood is drawn directly into a polyvinyl tube with a length of 25 cm and an internal diameter of 0.375 cm (1 mm = 9.9 cm tubing). The two ends of the tube are then brought together and closed by an outside plastic collar. The circular tube is placed and centered on a turntable, tilted to an angle of 23°, and rotated at 17 rpm. At the moment the developing thrombus inside the tube becomes large enough to occlude the lumen, the blood column becomes static and moves around in the direction of rotation of the tube.

EVALUATION

Time to occlusion of the tube by the thrombus establishes a definite end point in this system.

MODIFICATIONS OF THE METHOD

Stringer et al. (1994) used this method to determine the influence of an anti-PAI-1 antibody (CLB-2C8) on the t-PA-induced lysis of Chandler thrombi *in vitro*. They used citrated blood and supplemented it with 5.8 µM [^{125}I]-labeled fibrinogen prior to recalcification. After generation in the Chandler loop, the thrombi were washed with isotonic saline and then cut transversally into an upstream (head) and a downstream part (tail). The radioactivity of both parts was determined in a gamma counter (pre-value). The head and the tail were then subjected to thrombolysis by adding 300 µl phosphate-buffered saline containing plasminogen (2 µM) and t-PA (0.9 nM). During the observation time of 240 min, aliquots of 10 µl were taken at 30, 60, 120, 180 and 240 min, and the radioactivity was determined. The relation of the measured radioactivity to the pre-value was expressed as percentage of clot lysis.

Van Giezen et al. (1998) used this method to differentiate the effect of an anti-PAI-1 polyclonal antibody (PRAP-1) on human or rat thrombi.

B.2.4 Platelet Aggregation and Deaggregation in Platelet-Rich Plasma or Washed Platelets (Born Method)

PURPOSE AND RATIONALE

Platelets play a crucial role in primary hemostasis by forming hemostatic plugs at sites of vascular injury. Moreover, they contribute to intravascular thrombus formation mostly upon rupture of an atherosclerotic plaque. The contact of unactivated platelets to exposed subendothelial tissue leads to adhesion via two main mechanisms: binding of subendothelial von Willebrand factor (vWF) to the platelet GPIb-IX-V-complex at high shear rates and binding of collagen to two receptors, integrin $\alpha 2\beta 1$ and GPVI. Platelet adhesion initiates the reactions of shape change, secretion, and activation of GPIIb-IIIa-ligand binding sites. These reactions result in the formation of platelet aggregates. Activation of GPIIb-IIIa is also achieved through signaling by a number of agonists that bind to G-protein-coupled receptors. Consequently, for the measurement of platelet aggregation, platelets are activated by the addition of one of the following agonists to platelet-rich plasma (PRP) or washed platelets: ADP, arachidonic acid (forming thromboxane A2) or U 46619, collagen, thrombin or TRAP, serotonin, epinephrine, PAF. The formation of platelet aggregates with stirring leads to changes in optical density that are monitored photometrically, usually for 4 min. The test has been developed originally by Born (1962a, and 1962b) and is used to evaluate quantitatively the effect of compounds on induced platelet aggregation *in vitro* or *ex vivo*. For *in vitro* studies, human PRP is preferred.

PROCEDURE

The test is carried out either *ex vivo* or *in vitro*. There are other commercial sources for the various agonists listed.

Table 2 Materials and solutions

Anticoagulating substances	
Hirudin (Sigma) or PPAK	200 µg/ml
Trisodium citrate	0.11 M
ACD solution	
Citric acid	38 mM
Sodium citrate	75 mM
Glucose	124 mM
Platelet-aggregating substances (final concentrations in the test)	
ADP: for reversible or biphasic aggregation	0.1–5 µM
ADP: for irreversible aggregation (Sigma)	3–10 µM
Sodium arachidonate (Biodata)	0.3–1 mM
Calcium ionophore A 23187 (Calbiochem)	10 µM
Collagen (Hormonchemie)	3 µg/ml
PAF-acether (C 16-PAF, Bachem)	0.1 µM
Thrombin (Sigma)	0.02–0.05 IU/ml
TRAP (SFLLRNP, Bachem)	1–10 µM
U 46619 (ICN)	1–10 µM
Ristocetin	0.1–1 mg/ml
GPRP (fibrin antipolymerant, Bachem)	0.5 mM
4-channel aggregometer (PAP 4, Bio Data)	

For *ex vivo* assays, mice, rats, or guinea pigs from either sex receive the test compound or the vehicle (for controls) by oral, intraperitoneal or intravenous administration. At the end of the absorption time, blood is collected by caval venipuncture under pentobarbital sodium anesthesia and xylazine (8 mg/kg i.m.) premedication.

From rabbits (Chinchilla strain, weighing 3 kg), blood is withdrawn by cardiopuncture under xylazine (20 mg/kg i.m.) sedation. The first blood sample (control) is collected before administration of the test compound, the second sample at the end of the absorption time of the test agent.

For *in vitro* assays, human blood is collected from the antecubital vein of adult volunteers who had not received any medication for the last two weeks.

PREPARATION OF PRP, PPP, AND WP

The entire procedure is performed in plastic (polystyrene) tubes and carried out at room temperature. Freshly collected venous blood is anticoagulated with hirudin (1 volume + 9 volumes of animal blood) or ACD solution (1 volume + 9 volumes of human blood) and centrifuged at 150 × *g* for 15 min to obtain platelet-rich plasma (PRP). The PRP-supernatant is carefully removed, and the rest is further centrifuged at 1500 × *g* for 10 min to obtain platelet-poor plasma (PPP). PRP is diluted with PPP to a platelet count of 3×10^8/ml before use in the aggregation assays. To obtain washed platelets (WP), 8.5 volumes of human blood are collected into 1.5 volumes of ACD and centrifuged as for PRP. PRP is acidified to a pH of 6.5 by addition of approximately 1 ml ACD to 10 ml PRP. Acidified PRP is centrifuged for 20 min at 430*g*. The pellet is resuspended in the original volume with Tyrode's solution (mM: NaCl 120, KCl 2.6, $NaHCO_3$ 12, NaH_2PO_4 0.39, HEPES 10, glucose 5.5; albumin 0.35%) and set to platelet count of 3×10^8/ml.

For *ex vivo* assays, duplicate samples of 320µl PRP from drug-treated and vehicle control subjects (for rabbits: control samples before drug administration) are inserted into the aggregometer at 37°C under continuous magnetic stirring at 1000 rpm. After the addition of 40 µl physiological saline and 40 µl aggregating agent, changes in optical density are monitored continuously at 697 nm.

For *in vitro* assays, 40 µl of the test solution are added to samples of 320 µl PRP or WP from untreated subjects. The samples are inserted into the aggregometer and incubated at 37°C for 2 min under continuous magnetic stirring at 1000 rpm. After the addition of 40 µl aggregating agent, changes in optical density are monitored continuously at 697 nm either for 4 min or until constant values for aggregation are achieved. In cases of thrombin activation of PRP, glycine-proline-aspartate-proline (GPRP) is added in order to avoid fibrin formation. In order to measure deaggregation, experimental compounds are added to stimulated PRP at 70 or 100% of control aggregation and monitoring is performed for further 10 min. Deaggregation is measured by the decrease of light transmission (see Haskel et al. 1989).

Studies should be completed within 3 hours after blood withdrawal.

EVALUATION

The transmission maximum serves as a scale for platelet aggregation (0% = transmission of PRP, 100% = transmission of PPP).

For *in vitro* assays:

1. Percent inhibition of platelet aggregation is determined in concentration groups relative to vehicle controls. Statistical significance is evaluated by means of the unpaired Student's t-test.
2. IC_{50} values are determined from the non-linear curve fitting of concentration-effect relationships.

IC_{50} is defined as the concentration of test drug for half maximal inhibition of aggregation.

3. Percent deaggregation is determined at 10 min after addition of compound; IC_{50} is calculated from the concentration-effect relationship.

For *ex vivo* assays:

1. Mean values for aggregation in dosage groups are compared to the vehicle control groups (for rabbits: control values before drug administration). Statistical significance is evaluated by means of the Student's *t*-test (paired for rabbits; unpaired for others).
2. ED_{50} values are determined from the dose-response curves. ED_{50} is defined as the dose of drug leading to 50% inhibition of aggregation in the animals.

CRITICAL ASSESSMENT OF THE METHOD

The assay, introduced by Born (1962a and 1962b), has become a standard method in clinical diagnosis of platelet function disorders and of aspirin intake. Furthermore, the method is used in the discovery of antiplatelet drugs with the advantage of rapid measurement of a functional parameter in intact human platelets. However, processing of platelets during the preparation of PRP, washed or filtered platelets from whole blood results in platelet activation and separation of large platelets. Additionally, there is no standardization among the different laboratories due to variation in use of different tubes, different final agonist concentrations, and other technical differences.

MODIFICATIONS OF THE METHOD

Several authors have described modifications of the assay procedure. Breddin et al. (1975) described spontaneous aggregation of platelets from vascular patients in a rotating cuvette. Klose et al. (1975) measured platelet aggregation under laminar flow conditions using a thermostated cone-plate streaming chamber in which shear rates are continuously augmented and platelet aggregation is measured from light transmission through a transilluminating system. Marguerie et al. (1979, 1980) developed a method of measuring two phases of platelet aggregation after gel filtration of a platelet suspension (see below). Lumley and Humphrey (1981) described a method to measure platelet aggregation in whole blood (see below). Fratantoni and Poindexter (1990) performed aggregation measurements using a microtiter plate reader with specific modification of the agitation of samples. Comparison of the 96-well microtiterplate method with conventional aggregometry showed similar dose-response curves for thrombin, ADP, and arachidonic acid.

Ammit and O'Neil (1991) used a quantitative bioassay of platelet aggregation for rapid and selective measurement of platelet-activating factor. Mousa et al. (1994, 1998) and others utilized this assay for *in vitro* screening and *ex vivo* and antiplatelet efficacy in various species and in humans for platelet GPIIb/IIIa antagonists.

Yamanaka et al. (2005) performed platelet aggregations assays using an eight channel aggregometer (NBS HEMA TRACER 801, Nikobioscience, Tokyo, Japan) to test structure-activity relationships of potent GPIb/IIIA antagonists.

Francischetti et al. (2000) used the Microplate Reader for studying a platelet aggregation inhibitor from the salivary gland of the blood-sucking bug, *Rhodnius prolixus*.

B.2.5 Platelet Aggregation After Gel Filtration (Gel-Filtered Platelets, GFP)

PURPOSE AND RATIONALE

Triggering of platelet activation by low concentrations of ADP, epinephrine or serotonin—so-called weak platelet agonists—in plasma- and fibrinogen-free platelet suspensions does not result in platelet aggregation unless exogenous fibrinogen is added. As opposed to this, platelet aggregation induced by thrombin, collagen or prosta-glandin-endoperoxide—so-called strong agonists—is independent of exogenous fibrinogen because these substances lead to the secretion of intracellular platelet ADP and fibrinogen. Studies of platelet aggregation in gel-filtered platelets are performed in cases where the adhesive ligand fibrinogen or vWF is needed in a defined concentration or where plasma proteins could negatively interfere with the effect of compounds. The assay is mostly used to evaluate the influence of compounds on platelet GPIIb-IIIa or other integrins or on GPIb-IX-V. Mousa et al. (1994, 1998) and others have extensively utilized this assay to determine the impact of plasma protein binding on antiplatelet efficacy by comparing inhibition of platelet aggregation in GFP versus PRP.

PROCEDURE

Preparation of Gel-Filtered Platelets

The entire procedure is performed in plastic (polystyrene) tubes at room temperature according to Marguerie et al. (1979).

Blood is drawn from healthy adult volunteers who had no medication for the last two weeks. Venous blood (8.4 ml) is collected into 1.4 ml ACD-solution and centrifuged for 10 min at 120 *g*. The platelet-rich plasma (PRP) is carefully removed, the pH adjusted to 6.5 with ACD-solution, and centrifuged at 285 *g* for 20 min. The resulting pellet is resuspended in Tyrode's buffer (approx. 500 µl buffer/10 ml PRP). The platelet suspension is applied immediately to a Sepharose CL 2B column; equilibration and elution at 2 ml/min flow rate is done with Tyrode's buffer without hirudin and apyrase. Platelets are recovered in the void volume. Final platelet suspension is adjusted to 4×10^8/ml. Gel filtered platelets (GFP) are kept at room temperature for 1 h until the test is started.

Table 3 Materials and solutions

Acid-citrate-dextrose (ACD) solution	
Citric acid	0.8%
Sodium citrate	2.2%
Glucose	2.45%
Hirudin	0.6 U/ml
Tyrode's solution	
NaCl	137 mM
KCl	2.7 mM
$MgCl_2$	5.5 mM
NaH_2PO_4	3.0 mM
HEPES	3.5 mM
Glucose	5.5 mM
Albumin	0.2%
Hirudin	0.06 U/ml
Apyrase	40 µg/ml
pH	7.2
ADP	10 µM
Thrombin	0.02–0.05 U/ml
$CaCl_2$	0.5 mM
Fibrinogen (American Diagnostica)	1 mg/ml
von Willebrand factor	10 µg/ml
Sepharose CL 2B (Pharmacia)	
Acrylic glass column (Reichelt Chemietechnik, 3 cm inner diameter, 18 cm length)	
Aggregometer (PAP 4, Biodata)	

Experimental Course

For the aggregation studies, GFP in Tyrode's buffer is incubated with $CaCl_2$ (final concentration 0.5 mM) with or without fibrinogen (final conc. 1 mg/ml) in polystyrene tubes. After 1 min, 20 µl of the test compound or the vehicle (controls) are added, and the samples are incubated for another 2 min. After the addition of 20 µl platelet agonist, changes in light transmission are recorded. The whole procedure is done under continuous magnetic stirring at 37°C (1000 rpm) in the aggregometer. Samples with added $CaCl_2$ but without fibrinogen identify proper exclusion of plasma proteins if neither spontaneous aggregation occurs nor aggregation in the presence of weak agonists. Full aggregatory response of GFP to 10 µM ADP shows intact platelets (with only minor pre-activation with gel filtration).

EVALUATION

The transmission maximum serves as a scale for platelet aggregation. Each test compound is assayed with at least two different donor-GFPs; in the case of an anti-aggregating effect, the test is performed with 4–6 GFPs.

Mean values of the dosage groups are compared to the controls. Statistical significance is evaluated by means of the Student's *t*-test.

The percent inhibition of platelet aggregation in the dosage groups is calculated relative to the vehicle controls.

IC_{50} values (50% inhibition of aggregation) are determined from the concentration-effect curves.

For detailed methodology and evaluation of different agents see Marguerie et al. (1979 and 1980), Markell et al. (1993), and Mousa et al. (1994 and 1998).

B.2.6 Platelet Aggregation in Whole Blood

PURPOSE AND RATIONALE

The method uses a whole blood platelet counter that counts single platelets and does not require their separation from other blood cell types. Platelet aggregation is induced in anti-coagulated human whole blood samples by the addition of the aggregating agents arachidonic acid or collagen. The number of platelets is determined in drug-treated and vehicle control samples; the percentage of inhibition of aggregation and IC_{50} values are calculated in dosage groups. The effect of compounds on other blood cells that secondarily can influence platelet aggregation is included in this test system. The method has been described by Lumley and Humphrey (1981) and by Cardinal and Flower (1980).

PROCEDURE

The entire procedure is performed in plastic (polystyrene) tubes and carried out at room temperature. Blood is drawn from healthy adult volunteers who had not received medication for the last 2 weeks; 9 ml venous blood is anti-coagulated with 1 ml of sodium citrate and kept in a closed tube at room temperature for 30–60 min until the start of the test.

Table 4 Materials and solutions

Anticoagulant: sodium citrate to induce platelet aggregation	3.8%
Sodium arachidonate (Biodata)	3.6×10^{-4} M
Collagen (Hormonchemie)	10 µg/ml
Serono Hematology System 9000 or Sysmex Micrcellcounter F 800	

For the aggregation studies, 10 µl test substance or vehicle (control) is added to 480 µl citrated blood. Samples in closed tubes are pre-incubated for 5 min in a 37°C water shaker bath at 75 strokes/min. Then, 10 µl aggregating agent are added, and samples are incubated for another 10 min. The number of platelets (platelet count) is determined in 10 µl samples immediately before and 10 min after the addition of the aggregating agent ('initial platelet count', '10-min-platelet count' after adding platelet agonist ± antagonist) in a hematology cell counter.

The following samples for the determination of the platelet count are prepared in duplicate:

- control aggregation = spontaneous aggregation (without aggregating agent): 480 µl blood + 20 µl vehicle. Blood samples with >20% spontaneous aggregation are not used to test for induced aggregation.
- maximal aggregation: 480 µl blood + 10 µl vehicle + 10 µl aggregating agent. Values represent the maximal induced aggregation rate of the blood sample.
- test substance aggregation: 480 µl blood + 10 µl test substance + 10 µl aggregating agent.

EVALUATION

From the samples for maximal aggregation (vehicle), the percentage of maximal aggregation is calculated according to the following formula:

$$\%\ \text{maximal aggregation} = 100 - \frac{\text{10-min-platelet count} \times 100}{\text{initial plateletcount}}$$

From the samples for test substance induced aggregation, the percentage of aggregation in dosage groups is

calculated according to the following formula:

$$\%\ \text{aggregation} = \frac{\text{10-min-platelet count} \times 100}{\text{initial platelet count}}$$

IC_{50} values (50% inhibition of aggregation) are determined from the dose-response curves (log concentration test substance versus % inhibition of aggregation).

B.2.7 Platelet Micro- and Macro-Aggregation Using Laser Scattering

PURPOSE AND RATIONALE

- A new highly sensitive method to study platelet aggregation based on the measurement of mean radius or particle size makes it possible to record kinetics of formation of micro- and macro-aggregates in real time
- Sensitivity in measurements of spontaneous aggregation is higher than in routine light transmittance.

A new platelet aggregometer (AG-10; Kowa, Japan) that uses a laser-light-scattering beam has been introduced (Tohgi et al. 1996). Platelet aggregates, the size of which can be measured as total voltage of light-scatter intensity at 1.0-sec intervals for a 10-min period, can be divided into 3 ranges: small aggregates (diameter 9 to 25 µm), medium (26 to 50 µm), and large (>50 µm). Using laser scatter aggregation, it was found that young smokers had an increased number of small platelet aggregates, which cannot be detected with a conventional aggregometer based on the turbidometric method (Matsuo et al. 1997). This device detects platelet aggregation in the small-aggregate size range by the addition of unfractionated heparin (UFH), and the aggregates are disaggregable in incubation with protamine sulfate. When platelet aggregation induced by UFH at a final concentration of 0.5 U/mL was observed in 36 normal subjects with no history of heparin exposure, 13 had a positive response in excess of 0.5 V of light intensity in the small-aggregate size range. In chronic hemodialysis patients in whom heparin had been used regularly for many years, a positive response with heparin-induced aggregates was noted in 37 of 59 patients, which was increased compared with that of normal subjects. The light intensity in the small-aggregate size range was enhanced during heparinized dialysis. In patients with a positive heparin response, the intensity of aggregates after heparin was significantly increased compared with that in nonresponders to heparin. Also, we obtained the same results by this system: that enhanced platelet aggregation response to heparin was not inhibited by aspirin or argatroban but was inhibited by anti-glycoprotein IIb/IIIa antibodies or small molecule antagonists. The findings of enhanced platelet aggregation during heparin infusion could be directly obtained without the addition of ADP or TRAP using laser aggregometry (Xiao and Théroux 1998).

LIMITATIONS

This technique can not be applied in whole blood yet but can be used with PRP, washed platelet, or GFP

MODIFICATIONS OF THE METHOD

For functional characterization of an acid platelet aggregation inhibitor and hypotensive phopsholipase A_2 from *Bothrops jararacussu* snake venom, Andrião-Escarso et al. (2002) measured platelet aggregation in rabbit blood using a whole blood Lumi-Aggregometer.

B.2.8 Fibrinogen Receptor Binding

PURPOSE AND RATIONALE

The assay is used to evaluate the binding characteristics of drugs at the fibrinogen receptor. A constant concentration of the radioligand ^{125}I-fibrinogen (30–50 nM) is incubated with increasing concentrations of a non-labeled test drug (0.1 nM–1 mM) in the presence of gel-filtered human platelets. If the test drug exhibits any affinity to fibrinogen receptors, it is able to compete with the radioligand for receptor binding sites. Thus, the lower the concentration range of the test drug, in which the competition reaction occurs, the more potent the test drug. Platelets are activated with 10 mmol/l ADP to stimulate the ^{125}I-fibrinogen binding at the GPIIb/IIIa receptor.

PROCEDURE

Preparation of Gel-Filtered Platelets

From a healthy volunteer, 200 ml blood is collected. Ana aliquot of 8.4 ml blood is mixed with 1.4 ml ACD-buffer in polystyrol tubes and centrifuged at $150 \times g$ for 15 min. The resulting platelet-rich plasma (PRP) is collected, and an aliquot is taken for platelet counting. Then, 10 ml PRP are mixed with 1 ml ACD-buffer (ACD-PRP, pH ~ 6.5); 5 ml portions of ACD-PRP are transferred to plastic tubes and centrifuged at $1500 \times g$ for 15 min. The resulting supernatant is decanted, and each pellet is resuspended in 500 µl Tyrode buffer C. An aliquot is taken for platelet counting to calculate the loss of platelets. The platelet suspension is then transferred to a Sepharose-packed column that has been eluted with approx. 100 ml degassed Tyrode buffer B (2 ml/min). The column is closed and eluted with degassed Tyrode buffer B (2 ml/min). The first platelets appear after 18–20 min and are then collected for 10 min in a closed plastic cup. Gel-filtered platelets (GFP) are set to 4×10^8 platelets/ml with Tyrode buffer B and kept at room temperature until the start of the test (Mousa et al. 1994 and 2001).

EXPERIMENTAL COURSE

For each concentration, samples are tested in triplicate (test tubes No. 72708, Sarstedt).The total volume of each incubation sample is 500 µl. The concentration of ^{125}I-fibrinogen is constant for all samples (10 µg/500 µl).

COMPETITION EXPERIMENTS

The competition reaction is characterized by one buffer value (bidistilled water) and various concentrations of non-labeled fibrinogen or test compound.

- 100 µl ^{125}I-fibrinogen
- 100 µl non-labeled fibrinogen or test drug (various concentrations, 10^{-10}–10^{-3} M)
- 5 µl ADP.

Non-specific-binding: The non-specific binding of ^{125}I-fibrinogen is defined as the radioligand binding in the presence of 10^{-5} M of non-labeled fibrinogen.

The binding reaction is started by adding 250 µl GFP (4×10^8 platelets/ml). The samples are incubated for 30 min at room temperature. Subsequently, a 100 µl aliquot of the incubation sample is transferred to a microtainer tube containing 400 µl glucose solution. The tubes are centrifuged at $1{,}500 \times g$ for 2 min to separate ^{125}I-fibrinogen bound at the platelet glycoprotein IIb–IIIa receptor from free radioligand. The supernatant is carefully decanted and is allowed to run off for approx. 30 min. Radioactivity of the platelet pellets is counted for 1 min in a gamma counter with an efficiency of 65.3%.

MATERIALS AND SOLUTIONS

See Table 5.

EVALUATION

The quantity of the specific ^{125}I-fibrinogen binding results from the difference between the total and the non-specific binding.

Platelet glycoprotein IIb-IIIa receptor binding is given as fmol ^{125}I-fibrinogen/10^8 platelets or ^{125}I-fibrinogen molecules bound per platelet.

The dissociation constant (K_i) of the test drug is determined from the competition experiment of ^{125}I-fibrinogen versus non-labeled drug by a computer-supported analysis of the binding data.

$$K = \frac{K_D^{125}\mathrm{I} \times IC_{50}}{K_D^{125}\mathrm{I} + [^{125}\mathrm{I}]}$$

IC_{50} = concentration of the test drug, which displaces 50% of the specifically glycoprotein IIb-IIIa receptor bound ^{125}I-fibrinogen in the competition experiment.

[^{125}I] = concentration of ^{125}I-fibrinogen in the competition experiment.

$K_D{}^{125}$I = dissociation constant of ^{125}I-fibrinogen, determined from the saturation experiment.

The K_i-value of the test drug is the concentration, at which 50% of the fibrinogen receptors are occupied by the test drug.

For detailed methodology and evaluations of various mechanisms and agents see the following selected

Table 5 Materials and solutions

Solutions for platelet preparation		
Stock solution I	Citrate	0.8%
	Sodium citrate	2.2%
Stock solution II	NaCl	120 mM
	KCl	2.8 mM
	NaH_2PO_4	10.0 mM
	HEPES	10.0 mM
ACD-buffer	Stock solution I	2.45%
	+ glucose	
	+ hirudin	0.06 U/ml
Tyrode buffer A	Stock solution II	
	+ $NaHCO_3$	12 mM
Tyrode buffer B	Stock solution II	
	+ $NaHCO_3$	12 mM
	+ glucose	5.5 mM
	+ bovine albumin	0.35%
Tyrode buffers A and B are degassed by aspiration for approx. 1 h after setting the pH to 7.2.		
Tyrode buffer C	Tyrode buffer B (degassed)	
	+ apyrase	40 µg/ml
	+ hirudin	0.06 U/ml
Chromatography column	Acryl glass column (200 × 170 mm, 30 mm diameter), closed with 3 perlon filters, pore sizes 63, 90 and 230 µm, and gauze 50 µm filled with degassed Sepharose CL2B-suspen-sion (Pharmacia LKB); equilibrated with 500 ml degassed Tyrode buffer A (2 ml/min)	
Incubation buffer		
Stock solution	NaCl	120 mM
	KCl	2.6 mM
	NaH_2PO_4	0.39 mM
	HEPES	10.0 mM
	$CaCl_2$	0.5 mM
Incubation buffer, pH 7.2	stock solution	
	+ $NaHCO_3$	12 mM
	+ glucose	5.5 mM
	+ human albumin	0.35%
Glucose solution (in incubation buffer)		
Radioligand	^{125}I-fibrinogen specific activity 3.7 Mbq/mg fibrinogen (100 µCi/mg fibrinogen) (Amersham), 1 mg radio-labeled fibrinogen is dissolved in 10 ml incubation buffer	
Non-labeled fibrinogen (mw 340000, grade L, Sigma; in bidistilled water)		10^{-3}–10^{-10} M
ADP (in incubation buffer)		10 µM
Gamma-counter (1282 Compugamma CS, LKB)

B.2.9 Euglobulin Clot Lysis Time

PURPOSE AND RATIONALE

The euglobulin lysis time is used as an indicator for the influence of compounds on the fibrinolytic activity in rat blood according to Gallimore et al. (1971). The euglobulin fraction of plasma is separated from inhibitors of fibrinolysis by acid precipitation and centrifugation. Euglobulin predominantly consists of plasmin, plasminogen, plasminogen activator and fibrinogen. By addition of thrombin to this fraction, fibrin clots are formed. The lysis time of these clots is determined as a measurement of the activity of activators of fibrinolysis (e. g. plasminogen activators). Thus, compounds that stimulate the release of tissue-type plasminogen activator from the vessel wall can be detected.

PROCEDURE

Rats are anesthetized by intraperitoneal injection of 60 mg/kg pentobarbital sodium and placed on a heating pad (37°C). At the same time, the test solution or the vehicle (controls) is administered intravenously or intraperitoneally. Twenty-five minutes later, the animals receive another intraperitoneal injection of 12 mg/kg sodium pentobarbital to keep them in deep narcosis for 45 min.

Plasma Preparation

After the test compound is absorbed, blood is withdrawn from the inferior caval vein exposed by a midline excision. Blood (1.8 ml) is removed with a plastic syringe containing 0.2 ml 3.8% sodium citrate solution. The sample is thoroughly mixed, transferred to a plastic tube and immediately immersed in ice. Plasma is prepared by centrifugation at 2000 *g* for 10 min at 2°C.

Euglobulin Preparation

A 0.5 ml portion of plasma is added to 9.5 ml of ice-cold distilled water; the pH is brought to 5.3 by the addition of 0.13 ml of 1% acetic acid. The diluted plasma is kept on ice for 10 min, and the precipitated euglobulin fraction is collected by centrifugation at 2000 *g* for 10 min at 2°C. The supernatant is discharged, and the remaining fluid is removed by drying the tube on a filter paper for 1 min. The euglobulin precipitate is dissolved in 1 ml of 0.12 M sodium acetate solution.

Euglobulin Lysis Assay

Aliquots (0.45 ml) of the euglobulin solution are transferred to test tubes, and 0.05 ml thrombin (Test Thrombin, Behring Werke) (25 U/ml) are added. The tubes are transferred to a water bath at 37°C. The time interval between the addition of thrombin and the complete lysis of the clots is measured. For details see Gallimore et al. (1971) and Singh et al. (2005).

EVALUATION

The lysis time (min) is determined. Euglobulin lysis test (ELT) is shortened when activators of fibrinolysis are increased.

Percent lysis time is calculated in dosage treated groups as compared to controls.

Statistical evaluation is performed by means of the Student's *t*-test.

B.2.10 Flow Behavior of Erythrocytes

PURPOSE AND RATIONALE

The deformation of erythrocytes is an important rheological phenomenon in blood circulation according to Teitel (1977) and Nash (1990). It allows the passage of normal red cells through capillaries with diameters

smaller than that of the discoid cells and reduces the bulk viscosity of blood flowing in large vessels. In the following test, the initial flow of filtration is taken as a criterion for erythrocyte deformability. A prolonged time of filtration can be due to 2 basic pathologic phenomena: an increased rigidity of the individual red cells or an increased tendency of the cells to aggregate. To simulate decreased red blood cell deformability, the erythrocytes are artificially modified by one (or by the combination) of the following stress factors:

- addition of calcium ions (increase in erythrocyte rigidity)
- addition of lactic acid (decrease in pH value)
- addition of 350–400 mmol NaCl (hyperosmolarity)
- storing the sample for at least 4 h (cellular ageing, depletion of ADP)

The following procedure can be used to evaluate the effect of test compounds on the flow behavior of erythrocytes.

PROCEDURE

Apparatus

Erythrocyte filtrometer MF 4 (Fa. Myrenne, 52159 Roetgen, Germany) Membrane filter (Nuclepore Corp.) pore diameter: 5–10 µm, pore density: 4×10^5 pores/cm^2.

Ex Vivo

Blood is collected from Beagle dogs weighing 12–20 kg, from rabbits weighing 1.2–2.5 kg, or from Wistar rats weighing 150–300 g. The test subjects receive the test compound by oral, subcutaneous or intravenous administration 15, 60, 90 or 180 min before the withdrawal of blood.

In Vitro

Following addition of the test compound, blood is incubated at 37°C for 5 or 30 min.

Freshly collected venous blood is anticoagulated with K-EDTA (1 mg/ml blood) or heparin (5 IU/ml heparin sodium) and centrifuged at $250 \times g$ for 7 min. The supernatant (plasma) and the buffy coat are removed and discarded. The packed erythrocytes are resuspended in autologous plasma containing 0.25% human albumin, and the haematocrit value is fixed at 10%. The red blood cells are altered by one or several of the stress factors mentioned above.

A sample of 2 ml of the stressed suspension is applied to the filtrometer and the initial flow rate is determined. The filtration curve is plotted automatically.

EVALUATION

The cumulative volume of the filtered suspension is recorded per time unit (10 min)

The slope of the curve is determined at different time intervals.

The initial flow rate (10% of the cell suspension having passed the filter) is recorded.

Statistics

Data of each set are first tested for normal distribution using the Kolmogoroff/Smirnow test. The normal distribution hypothesis is eliminated if the data having a significance level of 5% are not normally distributed. In case that both data sets to be compared are normally distributed, the F-test is applied. The hypothesis of homogeneity of variance of both test series is eliminated when the significance level for homogeneity of variance is 5%. The *t*-test for paired and non-paired data is performed when homogeneity of variance is present. In any case, a paired difference test (for paired data) or the U-test (for non-paired data) is likewise carried out (paired of difference test = Wilcoxon test; U-test = Wilcoxon-Mann-Whitney or Mann-Whitney test, respectively).

B.2.11 Filterability of Erythrocytes

PURPOSE AND RATIONALE

The Single Erythrocyte Rigidometer (SER) allows the measurement of deformability of individual red blood cells by determining their passage time through a pore under constant shear stress. In this test, the passage times of single erythrocytes through one pore in a synthetic membrane are determined according to Kiesewetter et al. (1982), Roggenkamp et al. (1983), and Seiffge et al. (1986). The pore in the membrane practically represents a capillary with defined diameter and length. The driving pressure is produced by the constant shear stress. The passage of the red blood cells is measured with the help of an electrical device. A constant current of 50–200 nA is applied. When an erythrocyte passes through the pore, the current is interrupted. The test is used to detect compounds that improve filterability of erythrocytes. To simulate decreased red blood cell deformability, the erythrocytes

are artificially modified either by one or by a combination of the following stress factors:

- addition of calcium ions (increase in erythrocyte rigidity)
- addition of lactic acid (decrease in pH value)
- addition of 350–400 mmol NaCl (hyperosmolarity)
- storing the sample for at least 4 h (cellular ageing, depletion of ADP).

PROCEDURE

Apparatus

Single erythrocyte rigidometer (Myrenne, 52159 Roetgen, Germany)

Data: driving pressure: $dp = 70$ Pa (dog, rabbit, rat), $dp = 100$ Pa (man); wall shear stress: $\tau = 3$ Pa.

Single pore membrane: length: 30 µm; diameter: 3.5 µm (rat), 4.0 µm (rabbit, dog), 4.5 µm (man)

Ex Vivo

Blood is collected from Beagle dogs weighing 12–20 kg, from rabbits weighing 1.2–2.5 kg, from Wistar rats weighing 150–300 g, or from humans. The test subjects receive the test compound by oral, subcutaneous or intravenous administration 15, 60, 90 or 180 min before the withdrawal of blood.

In Vitro

Following addition of the test compound, the blood samples are incubated at 37°C for 5 or 30 min.

The blood samples are mixed with K-EDTA (1 mg/ml blood) or heparin (5 IE/ml heparin sodium) to prevent clotting. The blood is centrifuged at $250 \times g$ for 7 min. The plasma and the buffy coat are removed and discarded. The packed erythrocytes are resuspended in filtrated HEPES-buffer containing 0.25% human albumin, and the haematocrit value is fixed to <1%. The red blood cells are altered by one or several stress factors mentioned above. A sample of 2 ml of the stressed suspension is applied to the measuring device, and the passage time of a population of 250 erythrocytes (tm) is determined. Cells remaining in the pore for more than 100 ms (tm >100 ms) lead to a rheological occlusion.

Untreated red blood cell suspensions serve as control.

EVALUATION

The mean passage time of 250 single erythrocytes and the number of rheological occlusions/250 erythrocytes is determined.

Statistics

The statistical significance is evaluated according to the procedure described for flow behavior of erythrocytes described above.

B.2.12 Erythrocyte Aggregation

PURPOSE AND RATIONALE

The aggregation of red blood cells into rouleaux and from rouleaux into 3-dimensional cell networks is a rheological parameter that decisively influences the flow behavior of blood, especially in disturbed microcirculation. In the following procedure, an apparatus (erythrocyte aggregometer) is used to measure erythrocyte aggregation. The transparent measuring chamber (cone/plate configuration) is transilluminated by light of a defined wave length. The intensity of the transmitted light, which is modified by the aggregation process, is recorded. The method can be used to determine the effect of test compounds on erythrocyte aggregation according to Kiesewetter et al. (1982) and Schmid-Schoenbein et al. (1973).

PROCEDURE

Apparatus

Selective Erythrocyte Rigidometer (Fa. Myrenne, 52159 Roetgen, Germany)

Ex Vivo

Blood is collected from Beagle dogs weighing 12–20 kg, from rabbits weighing 1.2–2.5 kg, or from Wistar rats weighing 150–300 g. The test subjects receive the test compound by oral, subcutaneous or intravenous administration 15, 60, 90 or 180 min before the withdrawal of blood.

In Vitro

Following addition of the test compound, the blood sample is incubated at 37°C for 5 or 30 min.

Blood is obtained from the test subjects by venipuncture and mixed with K-EDTA (1 mg/ml) or heparin (5 IU/ml heparin sodium) to prevent clotting. Erythrocyte aggregation is determined in whole blood. A sample of 40 µl blood is transferred to the measuring device. The red cells are dispersed at a shear rate of 600/s. After 20 s, flow is switched to stasis, and the extent of erythrocyte aggregation is determined photometrically.

EVALUATION

Statistics

The statistical significance is evaluated according to the procedure described for flow behavior of erythrocytes (see above).

B.2.13 Determination of Plasma Viscosity

PURPOSE AND RATIONALE

One of the principal methods for measuring viscosity is based on the rate of flow of a liquid through an orifice according to Harkness (1971). In this test, a defined volume of plasma is transferred into a capillary viscometer, and the efflux time required for the plasma to flow from the upper to the lower mark is measured. Using this procedure, the effect of test compounds on the viscosity of blood plasma can be determined. The test can be carried out either *ex vivo* or *in vitro.*

PROCEDURE

Ex Vivo

Beagle dogs weighing 12–20 kg, rabbits weighing 2.0–3.0 kg, or Wistar rats weighing 150–300 g of either sex are used as test animals. Likewise, the test procedure can be performed in humans. The test subjects receive the test compound by oral, subcutaneous or intravenous administration 15, 60, 90 or 180 min before the withdrawal of blood.

In Vitro

Following addition of the test compound, plasma (obtained as described below) is incubated at 37°C for 5 or 30 min.

Freshly collected venous blood is anticoagulated with 1 mg/ml blood K^+-EDTA or heparin sodium (5 IU/ml blood) and centrifuged at $250 \times g$ for 5 min. The supernatant (plasma) is removed, and a sample of 0.9 ml plasma is transferred into a capillary viscometer (Coulter Harkness, Coulter Electr., LTD, England) provided with a glass capillary of 0.5 mm inside diameter. The temperature during measurement is 37°C. The flow time, t, required for the plasma to flow through the capillary is measured. Untreated plasma serves as control.

EVALUATION

The viscosity of each sample can be determined using the following formula:

$$\eta = K \times t \times \rho$$

where η = viscosity of plasma, K = calibration constant of viscometer, t = flow time of 0.9 ml plasma, and ρ = density of plasma.

The change in viscosity relative to the control group is determined.

Statistical evaluation is carried out using the Student's t-test.

B.3 In Vitro Models of Thrombosis

PURPOSE AND RATIONALE

There is abundant evidence suggesting that platelets play a pivotal role in the pathogenesis of arterial

thrombotic disorders, including unstable angina (UA), myocardial infarction (MI) and stroke. The underlying pathophysiological mechanism of these processes has been recognized as the disruption or erosion of a vulnerable atherosclerotic plaque leading to local platelet adhesion and subsequent formation of partially or completely occlusive platelet thrombi.

The specific platelet surface receptors that support these initial adhesive interactions are determined by the local fluid dynamic conditions of the vasculature and the extracellular matrix constituents exposed at the sites of vascular injury. Konstantopoulos et al. (1998) and Alveriadou et al. (1993) demonstrated that under high shear conditions, the adhesion of platelets to exposed subendothelial surfaces of atherosclerotic or injured vessels presenting collagen and von Willebrand factor (vWF) is primarily mediated by the platelet glycoprotein (GP)Ib/IX/V complex. This primary adhesion to the matrix activates platelets, leading ultimately to platelet aggregation mediated predominantly by the binding of adhesive proteins such as fibrinogen and vWF to GPIIb/IIIa. In addition, direct platelet aggregation in the bulk phase under conditions of abnormally elevated fluid shear stresses, analogous to those occurring in atherosclerotic or constricted arterial vessels, as shown by Turitto (1982), may be important. Shear-induced platelet aggregation is dependent upon the availability of vWF and the presence of both GPIb/IX and GPIIb/IIIa on the platelet membrane. It has been postulated that at high shear stress conditions, the interaction of vWF with the GPIb/IX complex is the initial event leading to platelet activation, which also triggers the binding of vWF to GPIIb/IIIa to induce platelet aggregate formation.

A variety of methods have been utilized to assess the *ex vivo* and/or *in vitro* efficacy of platelet antagonists, including photometric aggregometry, whole blood electrical aggregometry and particle counter methods, as described in the above segments. In photometric aggregometry, a sample is placed in a stirred cuvette in the optical light path between a light source and a light detector. Aggregate formation is monitored by a decrease in turbidity, and the extent of aggregation is measured as percent of maximal light transmission. The major disadvantage of this technique is that it cannot be applied in whole blood since the presence of erythrocytes interferes with the optical responses. Furthermore, it is insensitive to the formation of small aggregates. Particle counters are used to quantitate the size and the number of particles suspended in an electrolyte solution by monitoring the electrical current between two electrodes immersed in the solution. Aggregation in this system is quantitated by counting the platelets before and after stimulation, and it is usually expressed as a percentage of the initial count, as shown by Jen and McIntire (1984). However, the disadvantage of this technique is that it cannot distinguish platelets and platelet aggregates from other blood cells of the same size. Thus, one is limited to counting only a fraction of single platelets, as well as aggregates that are much larger than erythrocytes and leukocytes. The technique of electrical aggregometry allows the detection of platelet aggregates as they attach to electrodes immersed in a stirred cuvette of whole blood or platelet suspensions. Such an attachment results in a decrease in conductance between the two electrodes that can be quantitated in units of electrical resistance. However, a disadvantage of this method is that it is not sensitive in the detection of small aggregates, as demonstrated by Sweeney et al. (1989).

This segment discusses two complementary *in vitro* flow models of thrombosis that can be used to accurately quantify platelet aggregation in anticoagulated whole blood specimens and to evaluate the inhibitory efficacy of platelet antagonists: (1) a viscometric-flow cytometric assay to measure direct shear-induced platelet aggregation in the bulk phase, as demonstrated by Konstantopolous et al. (1995); and (2) a parallel-plate perfusion chamber coupled with a computerized videomicroscopy system to quantify the adhesion and subsequent aggregation of human platelets in anticoagulated whole blood flowing over an immobilized substrate (e. g. collagen I), as shown by Konstantopolous et al. (1995), and Mousa et al. (2002). Furthermore, Mousa et al. (2002) demonstrated a third *in vitro* flow assay in which surface-anchored platelets are pre-incubated with a GPIIb/IIIa antagonist, and unbound drug is washed away prior to the perfusion of THP-1 monocytic cells, thereby enabling one to distinguish agents with markedly distinct affinities and receptor-bound lifetimes.

PROCEDURE

Isolation of Human Platelets

The steps described in subsequent subheadings outline the procedure for isolation and purification of platelets from whole blood obtained by venipuncture from human volunteers. Obtain blood sample by venipuncture from an antecubital vein into polypropylene syringes containing either sodium citrate (0.38% final concentration) or heparin (10 U/ml final concentration). Centrifuge anticoagulated whole blood at $160 \times g$ for 15 min to prepare platelet-rich plasma (PRP).

Isolation of Washed Platelets

PRP specimens are subjected to a further centrifugation (1,100 *g* for 15 min) in the presence of 2 μM PGE_1 (Evangelista et al. 1996).

The platelet pellet is resuspended in HEPES-Tyrode buffer containing 5 mM EGTA and 2 μM PGE_1.

Platelets are then washed via centrifugation (1,100 *g* for 10 min), resuspended at 2×10^8/mL in HEPES-Tyrode buffer, and kept at room temperature for no longer than 4 hours before use in aggregation/adhesion assays.

MATERIALS

- Anticoagulant solution (sodium citrate, porcine heparin, PPACK etc.)
- Fluorescently labeled platelet-specific antibody
- Dulbecco's phosphate-buffered saline (D-PBS) (with and without Ca^{2+}/Mg^{2+}).
- Formaldehyde
- Type I collagen, from bovine Achille's tendon
- 0.5 mol/L glacial acetic acid in water
- Glass coverslips (24 × 50 mm; Corning; Corning, NY)
- Silicone sheeting (gasket) (0.005-in or 0.010-in thickness; Specialty Manufacturing Inc; Saginaw, MI)
- Quinacrine dihydrocholride
- Prostaglandin E_1 (PGE_1) and EGTA
- Thrombin
- Bovine serum albumin
- HEPES-Tyrode buffer (129 mM NaCl, 9.9 mM $NaHCO_3$, 2.8 mM KCl, 0.8 mM K_2PO_4, 0.8 mM $MgCl_2 \cdot 6H_2O$, 1 mM $CaCl_2$, 10 mM HEPES, 5.6 mM dextrose)
- 3-aminopropyltriethoxysilane (APES)
- Acetone
- 70% nitric acid in water
- THP-1 monocytic cells
- Platelet antagonists such as abciximab

EVALUATIONS

The methods described below (Sections 2.1–2.3) outline different dynamic adhesion/aggregation assays used to assess the *in vitro* and/or *ex vivo* efficacy of platelet antagonists: (1) a viscometric-flow cytometric assay to measure shear-induced platelet-platelet aggregation in the bulk phase, (2) a perfusion chamber coupled with a computerized videomicroscopy system to visualize in real time and quantify (a) the adhesion and subsequent aggregation of platelets flowing over an immobilized substrate (e. g. extracellular matrix protein) and (b) free-flowing monocytic cell adhesion to immobilized platelets.

B.3.1 Cone-and-Plate Viscometry Under Shear-Flow Cytometry

PURPOSE AND RATIONALE

The cone-and-plate viscometer is an *in vitro* flow model used to investigate the effects of bulk fluid shear stress on suspended cells. Anticoagulated whole blood specimens (or isolated cell suspensions) are placed between the two platens (both of stainless steel) of the viscometer. Rotation of the upper conical platen causes a well-defined and uniform shearing stress to be applied to the entire fluid medium, as described by Konstantopolous et al. (1998). The shear rate (γ) in this system can be readily calculated from the cone angle and the speed of the cone using the formula:

$$\gamma = \left(\frac{2\pi\omega}{60\theta_{cp}} \right)$$

where γ is the shear rate in sec^{-1}, ω is the cone rotational rate in revolutions per minute (rev/min) and θ_{cp} is the cone angle in radians. The latter is typically in the range of 0.3 to 1.0°. The shear stress, τ, is proportional to shear rate, γ, as shown by: $\tau = \mu \cdot \gamma$, where μ is the viscosity of the cell suspension (the viscosity of anticoagulated whole blood is ~0.04 cp at 37°C). This type of rotational viscometer is capable of generating shear stresses from ~2 dyn/cm^2 (venous level) to greater than 200 dyn/cm^2 (stenotic arteries).

PROCEDURE

Single platelets and platelet aggregates generated upon shear exposure of blood specimens are differentiated from other blood cells on the basis of their characteristic forward-scatter and fluorescence (by the use of fluorophore-conjugated platelet specific antibodies) profiles by flow cytometry, as described by Konstantopolous et al. (1995). This technique requires no washing or centrifugation steps that may induce artifactual platelet activation, and it allows the study of platelet function in the presence of other blood elements. The procedure used to quantify platelet aggregation induced by shear stress is as follows:

- Incubate anticoagulated whole blood with platelet antagonist or vehicle (control) at 37°C for 10 min.
- Place a blood specimen (typically ~500 µl) on the stationary platen of a cone-and-plate viscometer maintained at 37°C.
- Take a small aliquot (~3 µl) from the pre-sheared blood sample, fix it with 1% formaldehyde in D-PBS (~30 µl).
- Expose the blood specimen, in the presence or absence of a platelet antagonist, to well-defined shear levels (typically 4000 sec^{-1} to induce significant platelet aggregation in the absence of a platelet antagonist) for prescribed periods of time (typically 30 to 60 sec).
- Take a small aliquot (~3 µl) from the sheared blood specimen, and immediately fix it with 1% formaldehyde in D-PBS (~30 µl).
- Incubate the fixed blood samples with a saturating concentration of a fluorescently labeled platelet-specific antibody, such as anti-GPIb(6D1)-FITC, for 30 min in the dark.
- Dilute specimens with 2 ml of 1% formaldehyde, and analyze them by flow cytometry.

Flow cytometric analysis is used to distinguish platelets from other blood cells on the basis of their characteristic forward scatter and fluorescence profiles, as shown in Fig. 1. Data acquisition is then carried out on each sample for a set period (usually 100 sec), thereby allowing equal volumes for both the pre-sheared and sheared specimens to be achieved. As a result, the percent platelet aggregation can be determined by the disappearance of single platelets into the platelet aggregate region using the formula: $\%\ Platelet\ Aggregation = (1 - Ns/Nc \times 100)$, where *Ns* represents the single platelet population of the sheared specimen and *Nc* represents the single platelet population of the pre-sheared specimen. By comparing the extents of platelet aggregation in the presence and absence of a platelet antagonist, its antiplatelet efficacy can be readily determined.

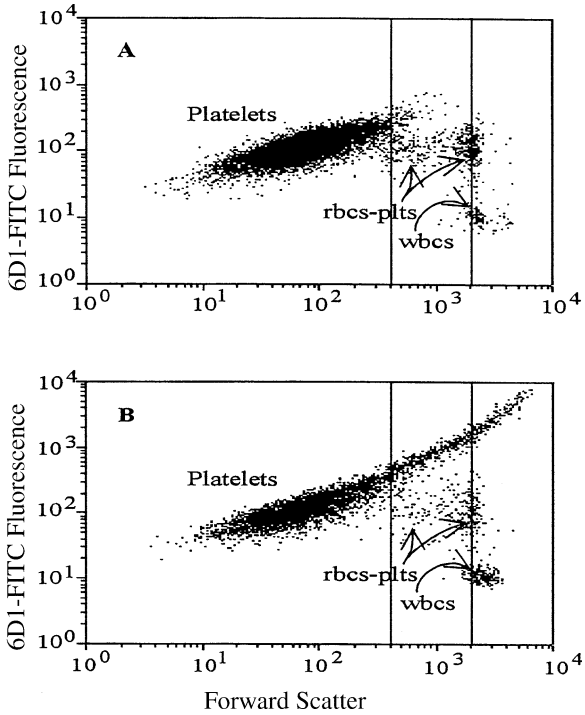

Figure 1 Quantification of shear-induced platelet aggregation by flow cytometry. Panel A corresponds to an unsheared blood specimen. Panel B corresponds to a blood specimen that has been subjected to a pathologically high level of shear stress for 30 sec. As can be seen in the figure, there are three distinct cell populations. The upper population consists of platelets and platelet aggregates. The "rbcs-plts" population corresponds to platelets associated with erythrocytes and leukocytes. The "wbcs" population consists of some leukocytes that have elevated levels of FITC autofluorescence. The left vertical line separates single platelets (≤ 4.5 µm in diameter) from platelet aggregates, whereas the right vertical line separates "small" from "large" platelet aggregates. The latter were defined to be larger than 10 µm in equivalent sphere diameter

B.3.2 Platelet Adhesion and Aggregation Under Dynamic Shear

PURPOSE AND RATIONALE

The steps described and outlined an *in vitro* flow model of platelet thrombus formation, which can be used to evaluate the *ex vivo* and/or *in vitro* efficacy of platelet antagonists. Thrombus formation may be initiated by platelet adhesion from rapidly flowing blood onto exposed subendothelial surfaces of injured vessels containing collagen and von Willebrand factor (vWF), with subsequent platelet activation and aggregation. Konstantopolous et al. (1995) described the use of a parallel-plate flow chamber that provides a controlled and well-defined flow environment based on the chamber geometry and the flow rate through the chamber. The wall shear stress, τ_w, assuming a Newtonian and incompressible fluid, can be calculated using the formula:

$$\tau_w = \frac{6\mu Q}{wh^2}$$

where Q is the volumetric flow rate, μ is the viscosity of the flowing fluid, h is the channel height, and b is the channel width. A flow chamber typically consists of a transparent polycarbonate block, a gasket whose thickness determines the channel depth, and a glass coverslip coated with an extracellular matrix protein such as type I fibrillar collagen. The apparatus is held together by vacuum. Shear stress is generated by flowing fluid (e. g. anticoagulated whole blood or isolated cell suspensions) through the chamber over the immobilized substrate under controlled kinematic conditions using a syringe pump. Mousa et al. (2002) combined the parallel-plate flow chamber with a computerized epi-fluorescence videomicroscopy system that enables one to visualize in real time and separately quantify the adhesion and subsequent aggregation of human platelets in anticoagulated whole blood (or isolated platelet suspensions) flowing over an immobilized substrate.

PROCEDURE

Preparation of Collagen-Coated Surfaces

- Dissolve 500 mg collagen type I from bovine Achille's tendon into 200 ml of 0.5 mol/L acetic acid in water, pH 2.8.
- Homogenize for 3 hours.
- Centrifuge the homogenate at 200*g* for 10 min, collect supernatant, and measure collagen concentration by a modified Lowry analysis.
- Coat glass coverslips with 200 µl of fibrillar collagen I suspension on all but first 10 mm of the slide length (coated area = 12.7 × 23), and place in a humid environment at 37°C for 45 min.
- Rinse excess collagen with 10 ml of D-PBS maintained at 37°C before assembly into the flow chamber (Folie et al. 1988).

Platelet Perfusion Studies

- Add the fluorescent dye quinacrine dihydrochloride to anticoagulated whole blood samples at a final concentration of 10 µM immediately after blood collection.
- Prior to the perfusion experiment, incubate blood with either a platelet antagonist or vehicle (control) at 37°C for 10 min.
- Perfuse anticoagulated whole blood through the flow chamber for 1 min at wall shear rates ranging from 100 sec^{-1} (typical of venous circulation) to 1500 sec^{-1} (mimicking partially constricted arteries) for prescribed periods of time (e. g. 1 min). Platelet-substrate interactions are monitored in real time using an inverted microscope equipped with an epifluorescent illumination attachment and silicon-intensified target video camera, and recorded on videotape. The microscope stage and flow chamber are maintained at 37°C by an incubator heating module and incubator enclosure during the experiment.

EVALUATION

Videotaped images are digitized and computer analyzed at 5, 15 and 60 sec for each perfusion experiment. The number of adherent individual platelets in the microscopic field of view during the initial 15 sec of flow is determined by image processing and used as the measurement of platelet adhesion that initiates platelet thrombus formation. The number of platelets in each individual thrombus is calculated as the total thrombus intensity (area × fluorescence intensity) divided by the average intensity of single platelets determined in the 5-sec images. By comparing the extents of platelet aggregation in the presence and absence of a platelet antagonist, its antiplatelet efficacy can be de-

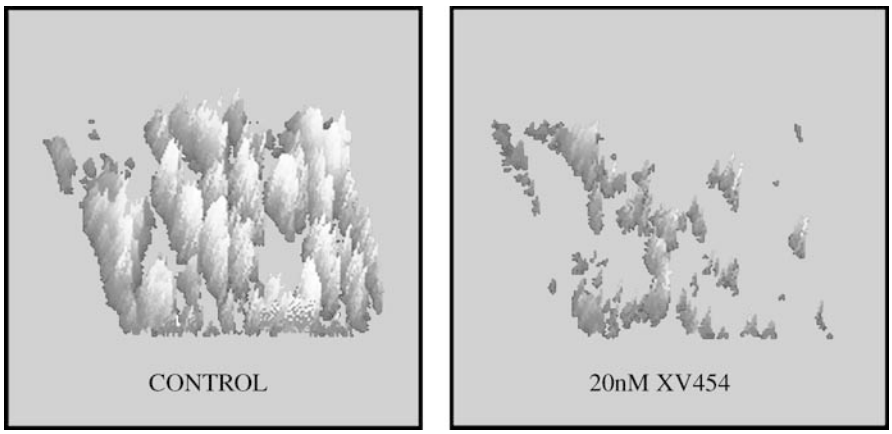

Figure 2 Three-dimensional computer-generated representation of platelet adhesion and subsequent aggregation on collagen I/von Willebrand factor from normal heparinized blood perfused in the absence (control) or presence of a GPIIb/IIIa antagonist (XV454) at 37°C for 1 min at 1,500 sec^{-1}

termined (Fig. 2). Along these lines, any potential inhibitory effects of a platelet antagonist on platelet adhesion can be readily assessed.

B.3.3 Cell Adhesion to Immobilized Platelets: Parallel-Plate Flow Chamber

PURPOSE AND RATIONALE

In this assay, immobilized platelets are pretreated with a GPIIb/IIIa antagonist, and any unbound drug is washed away before the perfusion of monocytic THP-1 cells. Mousa et al. (1998) demonstrated that agents with slow platelet off-rates such as XV454 ($t_{1/2}$ of dissociation = 110 min; K_d = 1 nM) and abciximab ($t_{1/2}$ of dissociation = 40 min; K_d = 9.0 nM) that are distributed predominantly as receptor-bound entities with little unbound in the plasma, can effectively block these heterotypic interactions as shown by Abulencia et al. (2001) and by Mousa et al. (2002). In contrast, agents with relatively fast platelet dissociation rates such as orbofiban ($t_{1/2}$ of dissociation = 0.2 min; K_d >110 nM), whose antiplatelet efficacy depends on the plasma concentration of the active drug, do not exhibit any inhibitory effects, as described by Mousa et al. (2002).

PROCEDURE

Preparation of 3-Aminopropyltriethoxysilane (APES)-Treated Glass Slides

- Soak glass coverslips overnight in 70% nitric acid.
- Wash coverslips with tap water for 4 hours.
- Dry coverslips by washing once with acetone, followed by immersion in a 4% solution of APES in acetone for 2 min.
- Repeat the step above, followed by a final rinse of the glass coverslips with acetone.
- Wash coverslips three times with water, and allow them to dry overnight.

Immobilization of Platelets on 3-APES-Treated Glass Slides

- Layer washed platelets or platelet-rich plasma (2×10^8 cells/ml) on the surface of a coverslip at ~30 µl/cm^2.
- Allow platelets to bind to APES-treated coverslip in a humid environment at 37°C for 30 min.

Monocytic THP-1 Cell-Platelet Adhesion Assay

- Assemble the platelet-coated coverslip on a parallel-plate flow chamber, which is then mounted on the stage of an inverted microscope equipped with a CCD camera connected to a VCR and TV monitor.
- Perfuse the antiplatelet antagonist at the desirable concentration or vehicle (control) over surface-bound platelets, and incubate for 10 min. The extent of platelet activation can be further modulated by the presence of chemical agonists such as thrombin (0.02–2 U/ml) during the 10 min incubation. The microscope stage and flow chamber are maintained

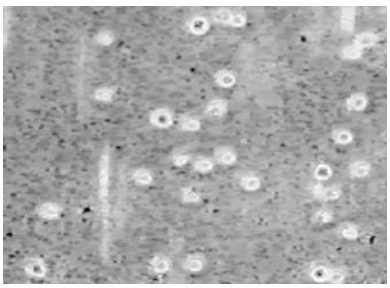

Figure 3 Phase-contrast photomicrograph of THP-1 cells (phase bright objects) attached to a layer of thrombin-treated platelets (phase dark objects) after THP-1 cell perfusion for 3 min at a shear stress level of 1.5 dyn/cm^2

at 37°C by an incubator heating module and incubator enclosure during the experiment.

- In some experiments, unbound platelet antagonist is removed by a brief washing step (4 min) prior to the perfusion of the cells of interest over the platelet layer. In others, the desirable concentration of the platelet antagonist is continuously maintained in the perfusion buffer during the entire course of the experiment.
- Perfuse cells (e. g. THP-1 monocytic cells, leukocytes, tumor cells, protein-coated beads, etc.) over surface-bound platelets, either in the presence or absence of a platelet antagonist (see above), at the desirable flow rate for prescribed periods of time. THP-1 cell binding to immobilized platelets is monitored in real time and recorded on videotape.
- Determine the extent of THP-1 cell tethering, rolling and stationary adhesion to immobilized platelets, as well as the average velocity of rolling THP-1 cells. By comparing the corresponding extents of THP-1 cell tethering, rolling and stationary adhesion to immobilized platelets in the presence and absence of a platelet antagonist (Fig. 3), its antiplatelet efficacy can be determined as shown by Mousa et al. (1995).

EVALUATION

Low-speed centrifugation results in the separation of platelets (top layer) from larger and more dense cells such as leukocytes and erythrocytes (bottom layer). To minimize leukocyte contamination in PRP specimens, slowly aspirate the uppermost two thirds of the platelet layer. Furthermore, certain rare platelet disorders, such as Bernard-Soulier Syndrome (BSS), are characterized by larger than normal platelets which must therefore be isolated by allowing whole blood to gravity separate for 2 hours post-venipuncture.

The mechanical force most relevant to platelet-mediated thrombosis is shear stress. The normal time-averaged levels of venous and arterial shear stresses range between 1–5 dyn/cm^2 and 6–40 dyn/cm^2, respectively. However, fluid shear stress may reach levels well over 200 dyn/cm^2 in small arteries and arterioles partially obstructed by atherosclerosis or vascular spasm. The cone-and-plate viscometer and parallel-plate flow chamber are two of the most common devices used to simulate fluid mechanical shearing stress conditions in blood vessels.

Due to the large concentration of platelets and erythrocytes in whole blood, small aliquots (~3µl) of pre-sheared and post-sheared specimens must be obtained and processed prior to the flow cytometric analysis. This will minimize an artifact produced as a platelet and an erythrocyte pass through the light beam of a flow cytometer at the same time.

The "rbcs-plts" population represents 3–5% of the displayed cells. A small fraction (~5%) of this population seems to be leukocyte-platelet aggregates, as evidenced by the use of an anti-CD45 monoclonal antibody. The remaining events correspond to erythrocytes associated with platelets. However, it appears that the majority of the latter population is an artifact generated by the simultaneous passage of a platelet and an erythrocyte through the beam of a flow cytometer. This concept is corroborated by the fact that further dilution of pre-sheared and sheared blood specimens and/or reduction of the sample flow rate during the flow cytometric analysis results in a dramatic relative decrease of the "rbcs-plts" population.

The collagen density remaining on glass coverslips after D-PBS rinsing can be measured by the difference in weight of 20 clean uncoated slides versus 20 collagen-treated slides.

Experiments are optimally monitored ~100–200 µm downstream from the collagen/glass interface using a 60 × FLUOR objective and 1 × projection lens, which gives a 3.2×10^4 µm^2 field of view. A field of view closer to the interface may lead to non-reproducible results due to variations in the collagen layering in that region. In contrast, positions farther downstream are avoided in order to minimize the effects of upstream platelet adhesion and subsequent aggregation on both the fluid dynamic environment as well as bulk platelet concentration.

The digitization of a background image (at the onset of perfusion prior to platelet adhesion to the collagen I surface) and its subtraction from a subsequent image acquired 5 sec after an initial platelet adhesion event allows the determination of the fluorescence in-

tensity emitted by a single platelet. The intensity level of each single platelet is measured as a mean gray level between 0 (black) and 255 (white) through the use of an image processing software (e. g. OPTIMAS; Agris-Schoen Vision Systems, Alexandria, VA), and is multiplied by its corresponding area (total number of pixels covered by each single platelet). The aforementioned products are then averaged for all single platelet events detected at the 5-sec time point, thus enabling us to calculate the average intensity of single platelets.

A single field of view ($10 \times 0.55\,mm^2$) is monitored during the 3 min period of the experiment; at the end, five additional fields of view ($0.55\,mm^2$) are monitored for 15 sec each. The following parameters can be quantified: (a) the number of total interacting cells per mm^2 during the entire 3-min perfusion experiment; (b) the number of stationary interacting cells per mm^2 after 3 min of shear flow; (c) the percentage of total interacting cells that are stationary after 3 min of shear flow; and (d) the average rolling velocity (μm/sec) of interacting cells. The number of interacting cells per mm^2 is determined manually by reviewing the videotapes. Stationary interacting cells per mm^2 are considered as those that move <1-cell radius within 10 sec at the end of the 3-min attachment assay. To quantify their number, images can be digitized from a videotape recorder using an imaging software package (e. g. OPTIMAS). Rolling velocities can be computed as the distance traveled by the centroid of the rolling THP-1 cell divided by the time interval using image processing.

B.4 In Vivo or Ex Vivo Models

PURPOSE AND RATIONALE

The general understanding of the pathophysiology of thrombosis is based on the observations of Virchow in 1856. He proposed three factors responsible for thrombogenesis: obstruction of blood flow, changes in the properties of blood constituents (hypercoagulability), and vessel wall injury. Experimental models of thrombosis focus on one, two or all three factors of Virchow's triad. Therefore, they differ with respect to the prothrombotic challenge—either stenosis, stasis, vessel wall injury (mechanical, electrical, chemical, photochemical, laser light), insertion of foreign surface, or injection of a prothrombotic factor, and they differ with respect to the vessel type and with respect to the animal species.

Roughly, two types of models can be differentiated (Didisheim 1972; Kaiser et al. 1999; Mousa et al. 1998; Perzborn et al. 2005): (1) models in which thrombi are produced in veins by stasis and/or injection of a procoagulant factor, resulting in fibrin-rich "red" venous type thrombi; or (2) models in which thrombi are produced in arteries by vessel wall injury and/or stenosis, resulting in platelet-rich "white" mural thrombi. But the differentiation is not strict because platelets and the coagulation system influence each other. Drugs preventing fibrin formation may well act in arterial models and vice versa. Thrombosis models are usually performed in healthy animals. The underlying chronic diseases in humans, namely atherosclerosis or thrombophilias, are not included in the models. Thus, any model is limited regarding its clinical relevance. The pharmacological effectiveness of a new antithrombotic drug should be studied in more than one animal model. In spite of these limitations, animal models predict clinical effectiveness of drugs for the treatment and prevention of thrombotic diseases fairly well. A list of such drugs is presented in a recent review by Leadley et al. (2000). Furthermore, the clinical usefulness of an antithrombotic drug is determined by its safety/efficacy ratio regarding the bleeding risk. Assessment of a parameter of the hemostatic system should therefore be included in the models if possible.

The development of antithrombotic agents requires pre-clinical assessment of the biochemical and pharmacologic effects of these drugs. It is important to note that the second- and third-generation antithrombotic drugs are devoid of *in vitro* anticoagulant effects, yet *in vivo*, by virtue of endogenous interactions, these drugs produce potent antithrombotic actions. The initial belief that an antithrombotic drug must exhibit *in vitro* anticoagulant activity is no longer valid. This important scientific observation has been possible only because of the availability of animal models.

Several animal models utilizing species such as rats, rabbits, dogs, pigs and monkeys have been made available for routine use. Other animal species such as the hamster, mouse, cat and guinea pig have also been uti-

lized. Species variations are an important consideration in selecting a model and interpreting the results as these variations can result in different antithrombotic effects. Rats and rabbits are the most commonly used species in which both arterial and venous thrombosis has been investigated. Both pharmacologic and mechanical means have been used to produce a thrombogenic effect in these models. Both rat and rabbit models for studying bleeding effects of drugs have also been developed. The rabbit ear blood loss model is most commonly used to test the hemorrhagic effect of drugs. The rat tail bleeding models have also been utilized for the study of several antithrombotic drugs.

These animal models have been well established and can be used for the development of antithrombotic drugs. It is also possible to use the standardized bleeding and thrombosis models to predict the safety and efficacy of drugs. Thus, in addition to the evaluation of *in vitro* potency, the endogenous effect of antithrombotic drugs can also be investigated. Such standardized methods can be recommended for inclusion in pharmacopoeial screening procedures. Numerous models have now been developed to mimic a variety of clinical conditions where antiplatelet and antithrombotic drugs are used, including myocardial infarction, stroke, cardiopulmonary bypass, trauma, peripheral vascular diseases and restenosis. While dog and primate models are relatively expensive, they have also provided useful information on the pharmacokinetics and pharmacodynamics of antithrombotic drugs. The primate models, in particular, have been extremely useful, as the hemostatic pathways in these species are comparable to those in humans. The development of such agents as the specific glycoprotein IIb/IIIa inhibitor antibodies relies largely on these models. These models are, however, of pivotal value in the development of antithrombotic drugs and provide extremely useful data on the safety and efficacy of new drugs developed for human usage.

PROCEDURE

Animal Models of Thrombosis

In most animal models of thrombosis, healthy animals are challenged with thrombogenic (pathophysiologic) stimuli and/or physical stimuli to produce thrombotic or occlusive conditions. These models are useful for the screening of antithrombotic drugs.

I. Stasis-Thrombosis Model: Since its introduction by Wessler et al. (1959), the rabbit model of jugular stasis thrombosis has been extensively used for the pharmacologic screening of antithrombotic agents. This model has also been adapted for use in rats (Meuleman et al. 1991). In the stasis thrombosis model, a hypercoagulable state is mimicked by administration of one of a number of thrombogenic challenges, including human serum (Carrie et al. 1994), thromboplastin (Walenga et al. 1986), activated prothrombin complex concentrates (Vlasuk et al. 1991), factor Xa (Millet et al. 1994) and recombinant relipidated tissue factor (Callas et al. 1995). This administration serves to produce a hypercoagulable state. Diminution of blood flow achieved by ligating the ends of the vessel segments serves to augment the prothrombotic environment. The thrombogenic environment produced in this model simulates venous thrombosis where both blood flow and the activation of coagulation play a role in the development of a thrombus.

II. Models Based on Vessel Wall Damage: The formation of a thrombus is not solely induced by a plasmatic hypercoagulable state. In the normal vasculature, the intact endothelium provides a nonthrombogenic surface over which the blood flows. Disruption of the endothelium not only limits the beneficial effects enumerated above, but also exposes subendothelial tissue factor and collagen that serve to activate the coagulation and platelet aggregation processes, respectively. Endothelial damage can be induced experimentally by physical means (clamping, catheter), chemical means (FITC, Rose Bengal, ferrous chloride), thermal injury or electrolytic injury.

EVALUATION

Each setting in the design of an animal model can answer specific question in relation to certain thrombotic disorders in human. However, the ultimate model of human thrombosis is in human.

B.4.1 Stenosis- and Mechanical Injury-Induced Coronary Thrombosis: Folts Model

PURPOSE AND RATIONALE

Thrombosis in stenosed human coronary arteries is one of the most common thrombotic diseases leading to unstable angina, acute myocardial infarction or sudden death. Treatment with angioplasty, thrombolysis, or by-pass grafts can expose new thrombogenic surfaces and re-thrombosis may occur. The mechanisms responsible for this process include interactions of platelets with the damaged arterial wall and platelet aggregation.

In order to study new drugs for their antithrombotic potential in coronary arteries, Folts and Rowe (1974) developed the model of periodic acute platelet thrombosis and cyclic flow reductions (CFRs) in stenosed canine coronary arteries. Uchida et al. described a similar model in 1975. The model includes various aspects of unstable angina pectoris (i. e. critical stenosis, vascular damage, downstream vasospasm induced by vasoconstrictors released or generated by platelets). The cyclic variations in coronary blood flow are a result of acute platelet thrombi that may occlude the vessel but that either embolize spontaneously or can easily be embolized by shaking the constricting plastic cylinder. They are not a result of vasospasm (Folts et al. 1982). Clinically, aspirin can reduce the morbidity and mortality of coronary thrombotic diseases but its effect is limited. Similarly, CFRs in the Folts model are abolished by aspirin but the effect can be reversed by increases in catecholamines and shear forces (Folts and Rowe 1988). As part of an expert meeting on animal models of thrombosis, a review of the Folts model has been published (Folts 1991).

Five different protocols are described in the following section for the induction of coronary thrombosis.

Coronary Thrombosis Induced by Stenosis

The described preparations are characterized by episodic, spontaneous decreases in coronary blood flow interrupted by restorations of blood flow. CFRs, which are alterations in coronary blood flow, are associated with transient platelet aggregation at the site of the coronary constriction and abrupt increase in blood flow after embolization of platelet-rich thrombi.

Damage of the vessel wall is produced by placing a hemostatic clamp on the coronary artery; a fixed amount of stenosis is produced by an externally applied obstructive plastic cylinder upon the damaged part of the vessel. In dogs, the stenosis is critical, i. e. the reactive hyperemic response to a 10-sec occlusion is abolished (protocol 1); in pigs, the stenosis is subcritical, i. e. there is a partial reactive hyperemia left (Just and Schönafinger 1991; protocol 2).

For some animals, especially for young dogs, damage of the vessel wall and stenosis is not sufficient to induce thrombotic cyclic flow variations. In these cases, an additional activation of platelets by infusion of epinephrine (protocol 3) is required, leading to the formation of measurable thrombi. In another preparation (protocol 4), thrombus formation is induced by subcritical stenosis without prior clamping of the artery and infusion of platelet activating factor (PAF), according to the model described by Apprill et al. (1985). In addition to these protocols, coronary spasms induced by released platelet components can influence coronary blood flow. Therefore, this model includes the main pathological factors of unstable angina pectoris.

Coronary Thrombosis Induced by Electrical Stimulation

In this preparation, coronary thrombosis is induced by delivery of low-amperage electrical current to the inti-

mal surface of the artery, according to the method described by Romson et al. (1980a). In contrast to the stenosis protocols, an occluding thrombosis is formed gradually without embolism after some hours (protocol 5). As a consequence of this time course, the thrombi formed are of the mixed type and contain more fibrin than the platelet thrombi with critical stenosis.

PROCEDURE

Coronary Thrombosis Induced by Stenosis

Protocol 1: Critical Stenosis Dogs of either sex weighing 15–40 kg, at least 8 months of age, are anesthetized with pentobarbital sodium (bolus of 30–40 mg/kg and continuous infusion of approx. 0.1 mg/kg/min); respiration is maintained through a tracheal tube using a positive pressure respirator. The heart is exposed through a left thoracotomy at the fourth or fifth intercostal space, the pericardium is opened and the left circumflex coronary artery (LCX) is exposed. An electromagnetic or Doppler flowprobe is placed on the proximal part of the LCX to measure coronary blood flow. Distal to the flowprobe, the vessel is squeezed with a 2-mm hemostatic clamp for 5 sec. A small cylindrical plastic constrictor, 2–4 mm in length and with an internal diameter of 1.2–1.8 mm (depending on the size of the LCX) is then placed around the artery at the site of the damage. Usually, the constrictor has to be changed several times (2–5 times) until the appropriate narrowing of the vessel is achieved, and cyclic flow variations are observed. In case of an occlusion of the artery without spontaneous embolization of the formed thrombus, reflow is induced by shortly lifting the vessel with a thread placed beneath the stenotic site.

Only dogs with regularly repeated CFRs of similar intensity within a pre-treatment phase of 60 min are used in these experiments.

The test substance is then administered by intravenous bolus injection or continuous infusion, or by intraduodenal application. CFRs are registered for 2–4×60 min and compared to pre-treatment values.

Prior to testing, preparations for additional hemodynamic measurements are performed (see below).

Protocol 2: Subcritical Stenosis Male castrated pigs (German landrace, weighing 20–40 kg) are anesthetized with ketamine (2 mg/kg i.m.), metomidate (10 mg/kg i.p.) and xylazine (1–2 mg/kg i.m.). In order to maintain the stage of surgical anesthesia, animals receive a continuous i.v. infusion of 0.1–0.2 mg/kg/min pentobarbital sodium. Respiration is maintained through a tracheal tube using a positive pressure respirator. The heart is exposed through a left thoracotomy at the fourth and fifth intercostal space, the pericardium is opened and the left descending coronary artery (LAD) is exposed. An electromagnetic or Doppler flowprobe is placed on the proximal part of the LAD to measure coronary blood flow. Distal to the flowprobe, the vessel is squeezed with a 1-mm hemostatic clamp for 5 sec. A small cylindrical plastic constrictor, 2 mm in length, is then placed around the artery at the site of the damage. Usually, the constrictor has to be changed several times until the appropriate narrowing of the vessel is achieved, which produces cyclic flow reductions. CFRs are similar to those in dogs; pigs, however, show a reactive hyperemic response. If embolization does not occur spontaneously, the formed thrombus is released at reduction of blood flow by shortly lifting the vessel with forceps.

Only pigs with regularly repeated CFRs of similar intensity within a pre-treatment phase of 60 min are used in these experiments.

The test substance is then administered by intravenous bolus injection or continuous infusion, or by intraduodenal application. CFRs are registered for 2×60 min and compared to pre-treatment values.

Protocol 3: Stenosis+Epinephrine Infusion If protocol 1 does not lead to CFRs, additionally epinephrine (0.2 µg/kg/min) is infused into a peripheral vein for twice over 60 minutes (60 min before and 60 min following drug administration). CFRs are registered and compared in the 60 min post-drug phase to the 60 min pre-drug phase.

Protocol 4: Stenosis+PAF Infusion The LCX is stenosed without prior mechanical wall injury. This preparation does not lead to thrombus formation (subcritical stenosis). For the induction of CFRs, PAF (C 16-PAF, Bachem) (0.2 nmol/kg/min) is infused into a cannulated lateral branch of the coronary artery.

After 30 min, PAF infusion is terminated and blood flow returns to its normal, continuous course. Thirty minutes later, the test substance is concomitantly administered and a second PAF infusion is started for 30 min.

CFRs are registered and compared in the drug-treated, second PAF phase to the pre-drug, first PAF phase.

Coronary Thrombosis Induced by Electrical Stimulation

Protocol 5 The LCX is punctuated distal to the flow probe with a chrome-vanadium-steel electrode (3-

mm length, 1-mm diameter). The electrode (anode) is placed in the vessel in contact with the intimal lining and connected over a Teflon coated wire to a 9 V battery, a potentiometer and an amperemeter. A disc electrode (cathode) is secured to a subcutaneous thoracal muscle layer to complete the electrical circuit. The intima is stimulated with 150 µA for 6 hours. During this time, an occluding thrombosis is gradually formed.

The test substance or the vehicle (control) is administered either at the start of the electrical stimulation or 30 min following the start.

The time interval until the thrombotic occlusion of the vessel occurs and the thrombus size (wet weight measured immediately after removal at the end of the experiment) are determined.

Prior to testing, preparations for additional hemodynamic measurements are performed (see below).

For all protocols, the following preparations and measurements are performed:

- To measure peripheral arterial blood pressure (BP [mm Hg]), the right femoral artery is cannulated and connected to a Statham pressure transducer.
- Left ventricular pressure (LVP [mm Hg]) is determined by inserting a microtip-catheter via the carotid artery retrogradely.
- Left ventricular end-diastolic pressure (LVEDP [mm Hg]) is evaluated through sensitive amplification of the LVP.
- Contractility (LV dp/dt max [mm Hg/s]) is determined from the initial slope of the LVP curve.
- Heart rate (min^{-1}) is determined from the pulsatile blood pressure curve.
- The ECG is recorded in lead II.
- Arterial pH and concentrations of blood gases are kept at physiological levels by adjusting respiration and infusion of sodium bicarbonate.
- Blood hematocrit values (37%–40%) and number of erythrocytes are kept constant by infusion of oxypolygelatine in dogs and electrolyte solution in pigs.
- Body temperature is monitored with a rectal thermistor probe and kept constant by placing the animals on a heated metal pad with automatic regulation of temperature.
- Template buccal mucosal bleeding time is carried out using the Simplate$^{\hat{a}}$ device.

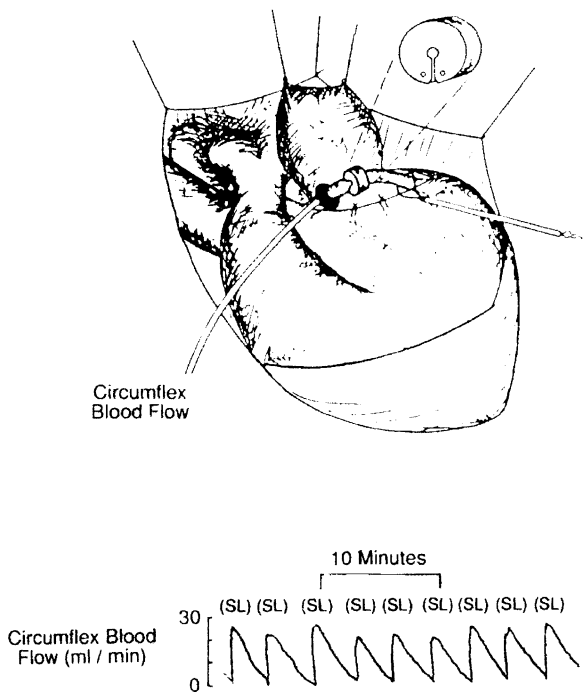

Figure 4 Technique for monitoring platelet aggregation in the partially obstructed left circumflex coronary artery of the dog. Electromagnetic flow probes measure blood flow. Partial obstruction of the coronary artery with a plastic Lexan cylinder results in episodic cyclical reductions in coronary blood flow that are due to platelet-dependent thrombus formation. Every 2–3 mm the thrombus must be mechanically shaken loose to restore blood. For detailed application of the Folts model, see Folts, Rowe (1974, 1988); and Folts et al. (1976, 1982)

EVALUATION

For all protocols, the mean maximal reduction of blood pressure (systolic/diastolic [mm Hg]) is determined.

Protocols 1–4 The following parameters are determined to quantify stenosis-induced coronary thrombosis:

- Frequency of CFRs = cycle number per time
- Magnitude of CFRs = cycle area (mm^2)

Percent change in cycle number and cycle area after drug treatment is calculated compared to pre-treatment controls.

Statistical significance is assessed by the paired Student's t-test.

Protocol 5 The following parameters are determined to quantify electrically-induced coronary thrombosis:

- Occlusion time (min) = time to zero blood flow
- Thrombus size (mg) = wet weight of the thrombus immediately after removal.

Percent change in mean values for occlusion time and thrombus size in drug-treated groups is compared to the control group.

Statistical significance is assessed by the non-paired Student's *t*-test.

CRITICAL ASSESSMENT

Both, the stenosis (Folts) and the electrical (Romson/Lucchesi) model of coronary thrombosis are widely used to study the role of mediators in the thrombotic process and the effect of new antithrombotic drugs. Bush and Patrick (1986) reviewed the role of the endothelium in arterial thrombosis and the effect of some inhibitors and mediators in the Folts model, e. g. thromboxane, prostacyclin, cyclooxygenase, serotonin, NO-donors and other vasodilators. The effect of an NO-donor could be reversed by the NO-scavenger oxyhemoglobin indication that indeed NO was responsible for the anti-thrombotic action (Just and Schönafinger 1991). Recent mechanisms of antithrombotic drug action that have been studied in either of the two coronary thrombosis models are the oral GP IIb/IIIa antagonist DMP 728 (Mousa et al. 1996); the LMWH enoxaparin (Leadley et al. 1998), which inhibited CFRs in contrast to unfractionated heparin; the thrombin inhibitors PEG-hirudin (Ruebsamen and Kirchengast 1998) and melagatran (Mehta et al. 1998); an anti-P-selectin antibody (Ikeda et al. 1999); and activated protein C (Jackson et al. 2000).

The clinical relevance of studies in the Folts model has been questioned because the model is very sensitive to antithrombotic compounds. However, the lack of a reversal of the effect by epinephrine or increase in degree of stenosis differentiates any new drug from aspirin. Electrical coronary thrombosis is less sensitive: e. g. aspirin has no effect, and with some drugs higher dose levels are required; however, in principle, most drug mechanisms act in both models if at all.

MODIFICATIONS OF THE METHOD

Romson et al. (1980b) described a simple technique for the induction of coronary artery thrombosis in the conscious dog by delivery of low-amperage electric current to the intimal surface of the artery.

Benedict et al. (1986) modified the electrical induction of thrombosis by use of two Doppler flow probes proximal and distal to the needle electrode in order to measure changes in blood flow velocity. The electrical current was stopped at 50% increase in flow velocity, and thrombosis then occurred spontaneously. The important role of serotonin was demonstrated by increases in coronary sinus serotonin levels just prior to occlusion.

Warltier et al. (1987) described a canine model of thrombin-induced coronary artery thrombosis, as well as the effects of intracoronary streptokinase on regional myocardial blood flow, contractile function, and infarct size.

Al-Wathiqui et al. (1988) described the induction of cyclic flow reduction in the coronary, carotid, and femoral arteries of conscious chronically instrumented dogs.

The method of Folts thrombosis has also been applied to carotid arteries in monkeys. Coller et al. (1989) induced CFRs in carotid arteries of anesthetized cynomologus monkeys and showed abolition by the GP IIb/IIIa antibody abciximab.

B.4.2 Stenosis- and Mechanical Injury-Induced Arterial and Venous Thrombosis: Harbauer-Model

PURPOSE AND RATIONALE

Harbauer et al. (1984) and Harbauer and Allendorf (1988) first described a venous model of thrombosis induced by mechanical injury and stenosis of the jugular vein. In a modification, both arterial and venous thrombosis is produced in rabbits by stenosis of the carotid artery and the jugular vein with simultaneous mechanical damage of the endothelium. This activates platelets and the coagulation system and leads to changes in the bloodstream pattern. As a consequence, occluding thrombi are formed as detected by blood flow measurement. The dominant role of platelets in this model is shown by the inhibitory effect of an antiplatelet serum in both types of vessels (Just 1986). The test is used to evaluate the antithrombotic capacity of compounds in an *in vivo* model of arterial and venous thrombosis where thrombus formation is highly dependent on platelet activation.

PROCEDURE

Male Chinchilla rabbits weighing 3–4 kg receive the test compound or the vehicle (controls) by oral, intravenous or intraperitoneal administration. The first ligature (vein, preparation see below) is performed at the end of absorption (i.p. approx. 30 min, p.o. approx. 60 min, i.v. variable).

Sixty-five minutes before stenosis, the animals are sedated by intramuscular injection of 8 mg/kg xylazine (Rompun) and anesthetized by intravenous injection of 30–40 mg/kg pentobarbital sodium 5 min later. During the course of the test, anesthesia is maintained by continuous infusion of pentobarbital sodium (30–40 mg/kg/h) into one femoral vein. A Statham pressure transducer is placed into the right femoral artery for continuous measurement of blood pressure. Spontaneous respiration is maintained through a tracheal tube. One jugular vein and one carotid artery are exposed on opposite sides. Small branches of the vein are clamped to avoid blood flow in spite of vessel occlusion. Electromagnetic or Doppler flow probes are placed on the vein (directly central to the vein branching) and on the artery (as far central as possible). Blood flow (ml/min) is measured continuously. After reaching steady state (approx. 15–30 min), a metal rod with a diameter of 1.3 mm is placed on the jugular vein (2 cm central to the vein branching) and a ligature is tightened. After 1 min, the rod is removed from the ligature. Immediately thereafter (approx. 1.5 min), the carotid artery is damaged by briefly squeezing it with forceps. Then a small plastic constricting cylinder 1.2 mm wide and 2 mm long is placed around the site of the endothelial damage.

In addition, the template bleeding time is measured at various time interval before and after drug treatment (depending on the route of administration) in the shaved inner ear using the Simplate device. Care is taken to select parts of the skin without larger vessels.

EVALUATION

Percent thrombus formation (= thrombosis incidence) is judged by determination of the number of occluded vessels (blood flow = 0).

Percent inhibition of thrombosis incidence is calculated in dosed groups as compared to vehicle controls. Thrombosis incidence is always 100% in vehicle controls.

Statistical significance is assessed by means of the Fisher exact test.

If initial values for blood flow do not significantly differ in dosage and control groups, the area below the blood flow curves is measured by planimetry in addition, and mean values in dosed groups are compared to controls by means of the unpaired Student's *t*-test. Mean values of occlusion times [min] in dosage and

control groups are calculated and compared by means of the t-test.

The maximal change in systolic and diastolic blood pressure during the period of stenosis as compared to the initial values before drug administration is determined. There is no standardized assessment score. As an example, a reduction of systolic blood pressure by 30 mm Hg and of diastolic blood pressure by 20 mm Hg is quoted as a strong reduction in blood pressure.

CRITICAL ASSESSMENT OF THE METHOD

Two main factors of arterial thrombosis are essential in this model: high-grade stenosis and vessel wall damage. In the absence of either, no thrombus is found. The occlusive thrombus is formed fast and in a highly reproducible manner. In both vessels thrombus formation is equally dependent on platelet function, as shown by antiplatelet serum. Therefore, the jugular vein thrombosis in this model differs from stasis-induced deep vein thrombosis with predominant fibrin formation. On the other hand, these occlusive thrombi are more stable than the pure platelet thrombi in the Folts model since carotid blood flow cannot be restored by shaking the constrictor. The following antithrombotic drugs are effective: (i) antiplatelet drugs like ticlopidine, prostacyclin/iloprost, NO-donors (SNP, molsidomine) but not aspirin, thromboxane-synthase-inhibitors; (ii) anticoagulants like hirudin, high-dose heparin, warfarin; and (iii) streptokinase/t-PA (Bevilacqua et al. 1991, Just 1986). In contrast, drugs that only lower blood pressure—such as hydralazine, clonidine, and prazosin—have no effect on thrombus formation in this model.

MODIFICATIONS OF THE METHOD

Bevilacqua et al. (1991) performed the same model in rabbit carotid arteries but compared the procedure in one artery before drug treatment with the contralateral artery after drug treatment. Heparin, the synthetic thrombin inhibitor FPRCH2Cl, iloprost and t-PA inhibited carotid occlusion in this model but not aspirin.

Spokas and Wun (1992) produced venous thrombosis in the vena cava of rabbits by vascular damage and stasis. The vascular wall was damaged by crushing with hemostat clamps. A segment of the vena cava was looped with two ligatures, 2.5 cm apart. At 2 h after ligation, the isolated venous sac was dissected and the clot removed for determination of dry weight.

Lyle et al. (1995) searched for an animal model mimicking the thrombotic reocclusion and restenosis occurring in several cases after successful coronary angioplasty in man. The authors developed a model of angioplasty-induced injury in atherosclerotic rabbit femoral arteries. Acute ^{111}indium-labelled platelet deposition and thrombosis were assessed 4 hours after balloon injury in arteries subjected to prior endothelial damage (air desiccation) and cholesterol supplementation (1 month). The effects of inhibitors of factor X_a or platelet adhesion, heparin, and aspirin on platelet deposition were studied.

Thrombosis Induced by Cooling

Lindenblatt et al. (2005), Meng (1975), Meng and Seuter (1977) and Seuter et al. (1979) described a method to induce arterial thrombosis in rats by chilling of the carotid artery. Rats were anesthetized; the left carotid artery was exposed and occluded proximal by means of a small clamp. The artery was placed for 2 min into a metal groove which was cooled to –15°C. The vessel was compressed by a weight of 200 g. In addition, a silver clip was fixed to the vessel distally from the injured area to produce a disturbed and slow blood flow. After 4 min, the proximal clamp was removed and the blood flow reestablished in the injured artery. In the rabbit, slightly different conditions were used: the chilling temperature was –12°C for a period of 5 min, and the compressing weight was 500 g. The wound was closed, and the animal was allowed to recover from anesthesia. Antithrombotic compounds were administered in various doses at different time intervals before surgery. After 4 hours, the animals received heparin and were reanesthetized. The lesioned carotid artery was removed and thrombus wet-weight was immediately measured.

B.4.3 Electrical-Induced Thrombosis

PURPOSE AND RATIONALE

The use of electrical current to induce thrombosis in hamster and dog has been described in the early 1950s by Lutz et al. (1951) and Sawyer et al. (1953a, b). In general, two different approaches exist. One method produces electrical damage by means of two externally applied hook-like electrodes (Hladovec 1973, Philp et al. 1978). The other method uses a needle electrode that is advanced through the walls of the blood vessels and positioned in their lumen; the second electrode is placed into a subcutaneous site completing the circuit (Salazar 1961, Romson et al. 1980, Benedict et al. 1986).

PROCEDURE

Anaesthetized rats weighing 200–300 g are intubated, and a femoral artery is cannulated for administration of drugs. One carotid artery is isolated from surrounding tissues over a distance of 10–15 mm.

A pair of rigid stainless-steel wire hook-like electrodes with a distance of 4 mm are adjusted to the artery by means of a rack and pinion gear manipulator. The artery is raised slightly away from the surrounding tissue. Isolation of the electrodes is achieved by the insertion of a small piece of parafilm under the artery. Blood flow is measured with an ultrasonic Doppler flowmeter (Transonic, Ithaca NY, USA); the flow probe (1RB) is placed proximal to the damaged area.

Thrombus formation is induced in the carotid arteries by the application of an electrical current (350 V, DC, 2 mA) delivered by an electrical stimulator (Stoelting Co, Chicago, Cat. No 58040) for 5 min to the exterior surface of the artery.

EVALUATION

- Blood flow before and after induction of thrombus for 60 min
- Time to occlusion (min): the time between onset of the electrical current and the time at which blood flow decreases under 0.3 ml/min
- Patency of the blood vessel over 30 min.

CRITICAL ASSESSMENT OF THE METHOD

The electrical-induced thrombus is composed of densely packed platelets with some red cells. Moreover, the electrical injury causes extensive damage to intimal and subintimal layers. The endothelium is completely destroyed, and this damage extends to subendothelial structures including smooth muscle cells. The deep damage could reduce the possibility of discrimination between drugs on the basis of their antithrombotic activity. However, Philp et al. (1978) could show that unfractionated heparin completely blocked thrombus formation, whereas other antiplatelet agents displayed differentiated antithrombotic action. He concluded that this relatively simple model of arterial thrombosis might prove a useful screening test for drugs with antithrombotic potential.

MODIFICATIONS OF THE METHOD

The technique described by Salazar et al. (1961) uses a stainless steel electrode that is inserted into a coronary artery in the dog and that delivers anodal current to the intravascular lumen. The electrode is positioned under fluoroscopic control, which complicates the method. The technique was modified by Romson et al. (1980). They placed the electrode directly into the coronary artery of open-chest anaesthetized dogs.

Rote et al. (1993, 1994) used a carotid thrombosis model in dogs. A calibrated electromagnetic flow meter was placed on each common carotid artery proximal to both the point of insertion of an intravascular electrode and a mechanical constrictor. The external constrictor was adjusted with a screw until the pulsatile flow pattern decreased by 25% without altering the mean blood flow. Electrolytic injury to the intimal surface was accomplished with the use of an intravascular electrode composed of a Teflon-insulated silver-coated copper wire connected to the positive pole of a 9-V nickel-cadmium battery. The cathode was connected to a subcutaneous site. Injury was initiated in the right carotid artery by application of a 150 µA continuous pulse anodal direct current to the intimal sur-

face of the vessel for a maximum duration of 3 hours or for 30 min beyond the time of complete vessel occlusion, as determined by the blood flow recording. Upon completion of the study on the right carotid, the procedure for induction of vessel wall injury was repeated on the left carotid artery after administration of the test drug.

Benedict et al. (1986) introduced a procedure in which anodal current is discontinued when mean distal coronary flow velocity increased by approximately 50%, reflecting disruption of normal flow by the growing thrombus. Occlusive thrombosis occurred within 1 hour after stopping the electrical current. It was observed that the final phase of thrombosis occurred independently of electrical injury.

A ferret model of acute arterial thrombosis was developed by Schumacher et al. (1996). A 10-min anodal electrical stimulation of 1 mA was delivered to the external surface of the carotid artery while measuring carotid blood flow. This produced an occlusive thrombus in all vehicle-treated ferrets within 41 ± 3 min, with an average weight of 8 ± 1 mg. Thrombus weight was reduced by aspirin or a thromboxane receptor antagonist.

Guarini (1996) produced a completely occlusive thrombus in the common carotid artery of rats by applying an electrical current to the arterial wall (2 mA for 5 min) while simultaneously constricting the artery with a hemostatic clamp placed immediately downstream from the electrodes.

Sturgeon et al. (2006) adapted the Folts and the electric methods of arterial thrombosis in small animals. Mousa et al. (1999) used the same animal pre- and post-treatment by using left and right arterial sides.

B.4.4 $FeCl_3$-Induced Thrombosis

PURPOSE AND RATIONALE

A variety of chemical agents has been used to induce thrombosis in animals. Topical $FeCl_3$ was described by Reimann-Hunziger (1944) and recently by Wang et al. (2006) as thrombogenic stimulus in veins. Kurz et al. (1990) showed that the thrombus produced with this method in the carotid arteries of rats is composed of platelets and red blood cells enmeshed in a fibrin network. This model is used as a simple and reproducible test for evaluation of antithrombotic (Broersma et al. 1991) and profibrinolytic test compounds (van Giezen et al. 1997).

PROCEDURE

Rats weighing between 250 and 300 g are anaesthetized with Inactin (100 mg/kg), and a polyethylene catheter (PE-205) is inserted into the trachea via a tracheotomy to facilitate breathing. Catheters are also placed in the femoral artery for blood samples and measurement of arterial blood pressure and in the jugular vein for administration of test agents. The right carotid artery is isolated and an ultrasonic Doppler flowprobe (probe 1RB, Transonic, Ithaca NY, USA) is placed on the vessel to measure blood flow. A small piece of Parafilm "M" (American Can Co, Greenwich,

CT) is placed under the vessel to isolate it from surrounding tissues throughout the experiment.

The test agent is administered by gavage or as an intravenous injection at a defined time prior to initiation of thrombus formation. Thrombus formation is induced by the application of filter paper (2 × 5 mm), saturated with 25% $FeCl_3$ solution, to the carotid artery. The paper is allowed to remain on the vessel 10 min before removal. The experiment is continued for 60 min after the induction of thrombosis. At that time, the thrombus is removed and weighed.

EVALUATION

- Blood flow before and after induction of thrombus for 60 min
- Time to occlusion (min): the time between $FeCl_3$ application and the time at which blood flow decreases under 0.3 ml/min
- Thrombus weight after blotting the thrombus on filter paper

B.4.5 Thrombin-Induced Clot Formation in Canine Coronary Artery

PURPOSE AND RATIONALE

A canine model of thrombin-induced clot formation was developed by Gold et al. (1984) in which localized coronary thrombosis was produced in the LAD. This is a variation of the technique described by Collen et al. (1983) who used radioactively labeled fibrinogen to monitor the occurrence and extent of thrombolysis of rabbit jugular veins clots. The vessel was intentionally de-endothelialized by external compression with blunt forceps. Snare occluders were then placed proximal and distal to the damaged site, and thrombin (10 U) was injected into the isolated LAD segment in a small volume via a previously isolated side branch. Autologous blood (0.3–0.4 ml) mixed with calcium chloride (0.05 M) also was injected into the isolated LAD segment, producing a stasis-type red clot superimposed on an injured blood vessel. The snares were released 2–5 min later, and total occlusion was confirmed by selective coronary angiography. This model of coronary artery thrombosis relies on the conversion of fibrinogen to fibrin by thrombin. The fibrin-rich thrombus contains platelets, but at no greater concentration than in a similar volume of whole blood. Once the thrombus is formed, it is allowed to age for 1–2 hours, after which a thrombolytic agent can be administered to lyse the thrombus and restore blood flow.

PROCEDURE

In the initial study described by Gold et al. (1984), recombinant t-PA was characterized for its ability to lyse 2-hour-old thrombi. Tissue plasminogen activator was infused at doses of 4.3, 10, and 25 µg/kg/min, i.v, and resulted in reperfusion times of 40, 31, and 13 min, respectively. Thus, in this model of canine coronary thrombosis, t-PA exhibited dose-dependent coronary thrombolysis. Furthermore, it is possible to study the effect of different doses of t-PA on parameters of systemic fibrinolytic activation, such as fibrinogen, plasminogen, and a_2-antiplasmin, as well as to assess myocardial infarct size. For example, Kopia et al. (1988) demonstrated that streptokinase (SK) elicited dose-dependent thrombolysis in this model.

Subsequently, Gold et al. (1986 and 1988) modified the model to study not only reperfusion but also acute reocclusion. Clinically, reocclusion is a persistent problem after effective coronary thrombolysis, which is reported to occur in 15–45% of patients (Goldberg et al. 1985). Thus, an animal model of coronary reperfusion and reocclusion would be important from the standpoint of evaluating adjunctive therapies to t-PA to hasten and/or increase the response rate to thrombolysis as well as prevent acute reocclusion.

Thrombin-Induced Rabbit Femoral Artery Thrombosis: Localized thrombosis can also be produced in rabbit peripheral blood vessels such as the femoral artery by injection of thrombin, calcium chloride, and fresh blood via a side branch (Shebuski et al. 1988).

Either femoral artery is isolated distal to the inguinal ligament and traumatized distally from the lateral circumflex artery by rubbing the artery with the

jaws of forceps. An electromagnetic flow probe is placed distal to the lateral circumflex artery to monitor femoral artery blood flow (FABF). The superficial epigastric artery is cannulated for induction of the thrombus and subsequent infusion of thrombolytic agents. Localized thrombi distal to the lateral circumflex artery with snares approximately 1 cm apart are induced by the sequential injection of thrombin, $CaCl_2$ (1.25 mmol), and a volume of blood sufficient to distend the artery. After 30 min, the snares are released and FABF is monitored for 30 mm to confirm total obstruction of flow by the thrombus.

EVALUATION

The model of thrombin-induced clot formation in the canine coronary artery was modified such that a controlled high-grade stenosis was produced with an external constrictor. Blood flow was monitored with an electromagnetic flow probe. In this model of clot formation with superimposed stenosis, reperfusion in response to t-PA occurs with subsequent reocclusion. The monoclonal antibody against the human GPIIb/IIIa receptor developed by Coller et al. (1983) and tested in combination with t-PA in the canine thrombosis model hastened t-PA-induced thrombolysis and prevented acute reocclusion (Yasuda et al., 1988). These actions *in vivo* were accompanied by abolition of ADP-induced platelet aggregation and markedly prolonged bleeding time.

B.4.6 Laser-Induced Thrombosis

PURPOSE AND RATIONALE

Thrombus formation in rat or rabbit mesenteric arterioles or venules is induced by laser beams. The test can be performed in normal or pretreated (induction of arteriosclerosis or adjuvant arthritis) animals. The mediators for thrombus formation in this method are platelet adhesion to the injured endothelial vessel wall on one hand and ADP-induced platelet aggregation on the other. Most probably, ADP is primarily released by laser beam-lysed erythrocytes, due to the fact that erythrocyte hemoglobin exerts strong adsorbability to frequencies emitted by laser beams. There is a further, secondary, aggregation stimulus following the release reaction induced by the platelets themselves.

PROCEDURE

Apparatus

- 4 W argon laser (Spectra Physics, Darmstadt, FRG); wave length: 514.5 nm; energy below the objective: 15 mW; duration of exposure: 1/30 or 1/15 sec
- Microscope ICM 405, LD-Epipland 40/0.60 (Zeiss, Oberkochen, FRG)
- Video camera (Sony, Trinicon tube)
- Recorder (Sony, U-matic 3/4")
- Videoanalyzer and correlator to determine blood flow velocity

In Vivo Experiment

Male Sprague Dawley or spontaneously hypertensive stroke-prone Wistar or Lewis rats with adjuvant induced arthritis weighing 150–300 g or New Zealand rabbits with arteriosclerosis induced by cholesterol feeding for 3 months are used. The animals receive the test compound by oral, intravenous, intraperitoneal, or subcutaneous administration. Control animals are treated with vehicle alone. Prior to thrombus induction, the animals are pretreated by s.c. injection of 0.1 mg/kg atropine sulfate solution and anaesthetized

by intraperitoneal administration of 100 mg/kg ketamine hydrochloride and 4 mg/kg xylazine.

Thrombus formation is induced 15, 30, 60 or 90 min post dosing. Investigations are performed in arterioles or venules of 13±1 µm in diameter of the fat-free ileocaecal portion of the mesentery. During the test procedure, the mesenterium is superfused with physiological saline solution or degassed paraffin liquid (37°C). The ray of the argon laser is led into the inverted ray path of the microscope by means of a ray adaptation and adjusting device. The frequency of injuries is 1 per 2 min. The exposure time for a single laser shot is 1/30 or 1/15 sec. The number of injuries necessary to induce a defined thrombus is determined. All thrombi formed during the observation period with a minimum length of 13 µm or an area of at least 25 μm^2 are evaluated. All measuring procedures are photographed by a video system.

Standard compounds:

- acetylsalicylic acid (10 mg/kg, per os)
- pentoxifylline (10 mg/kg, per os)

For detailed description and evaluation of various agents and mechanisms see the following references: Arfors et al. (1968), Herrmann (1983), Seiffge and Kremer (1984 and 1986), Seiffge and Weithmann (1987), and Weichert et al. (1983).

EVALUATION

The number of laser shots required to produce a defined thrombus is determined. Mean values and SEM are calculated.

B.4.7 Photochemical-Induced Thrombosis

PURPOSE AND RATIONALE

In 1977, Rosenblum and El-Sabban reported that ultraviolet light can produce platelet aggregation in cerebral microvessels of the mouse after intravascular administration of sodium fluorescein. They found that in contrast to heparin, both aspirin and indomethacin prolonged the time to first platelet aggregate. Herrmann (1983) provided a detailed study in which he showed that scavengers of singlet oxygen, not of hydroxyl radicals, inhibited platelet aggregation induced by the photochemical reaction. He postulated that by exciting the intravascularly administrated fluorescein, singlet oxygen damages endothelial cells, which subsequently leads to platelet adhesion and aggregation.

PROCEDURE

Studies are performed in mesenteric arteries of 15–30 µm diameter in anesthetized rats. After intravenous injection of fluorescein isothiocyanate-dextran 70 (FITC-dextran, Sigma, 10%, 0.3 ml), the FITC-dextran in arterioles is exposed to ultraviolet light (wavelength of excitation 490 nm, wavelength of emission 510 nm).

EVALUATION

Thrombus formation is quantitated by determining the time between onset of excitation and appearance of the first platelet aggregate adhering to the vessel wall.

CRITICAL ASSESSMENT OF THE METHOD

In contrast to other thrombosis induction methods, photochemically induced thrombosis can be easily used in smaller animals. Thrombi are composed primarily of platelets; however, the primary target of the photochemical insult is the endothelial cells by means of oxygen radical damage.

MODIFICATIONS OF THE METHOD

Matsuno et al. (1991) report a method to induce thrombosis in the rat femoral artery by means of a photochemical reaction after injection of a fluorescent dye (rose Bengal, 10 mg/kg i.v.) and transillumination with a filtered xenon lamp (wave length: 540 nm). Blood flow is monitored by a pulsed Doppler flow meter. Occlusion is achieved after approximately 5–6 min. Pretreatment with heparin dose-dependently prolongs the time required to interrupt the blood flow. The model also enables one to study thrombolytic mechanisms, which had been evaluated with t-PA. A comparative

data for hirudin in various models was carried out by Just et al. (1991).

B.4.8 Foreign-Surface-Induced Thrombosis

The presence of foreign materials in the circulation produces activation of the coagulation and the platelet system. Various prothrombotic surfaces have been used to develop experimental animal models. In contrast to many other thrombosis models, the thrombosis induced by foreign surfaces does not presuppose endothelial damage.

B.4.8.1 Wire Coil-Induced Thrombosis

PURPOSE AND RATIONALE

A classical method to produce thrombosis is based on the insertion of wire coils into the lumen of blood vessels. The model was first described by Stone and Lord (1951) in aorta of dogs and was further modified to be used in arterial coronary vessels of opened-chest dogs. The use in venous vessels was described by Kumada et al. (1980).

The formation of thrombotic material around the coil is reproducible and can be easily standardized to study pharmacological agents (Just and Schönafinger 1991, Mellott et al. 1993, Rübsamen and Hornberger 1996).

Venous thrombosis is produced in rats by insertion of a stainless steel wire coil into the inferior caval vein. Platelets as well as plasmatic coagulation are activated on the wire coil. Thrombus formation onto the wire is quantitated by measuring the protein content of the thrombotic material isolated. The kinetics of thrombus formation show an increase in weight and protein content within the first 30 min, followed by a steady state between thrombus formation and endogenous thrombolysis leading to a constant protein content of thrombi between 1 and up to 48 hours following implantation of the wire coil. Thrombosis incidence in untreated control animals in this model is 100%. The test is used to evaluate antithrombotic and thrombolytic properties of compounds in an *in vivo* model of venous thrombosis in rats.

PROCEDURE

Male Sprague-Dawley rats weighing 260–300 g receive the test compound or the vehicle (controls) by oral, intravenous or intraperitoneal administration. At the end of absorption (i.v. 1 min, i.p. 30 min, p.o. 60 min), the animals are anesthetized by intraperitoneal injection of 1.3 g/kg urethane. Through a midline incision the caudal caval vein is exposed and a stainless steel wire coil (a dental pate carrier, Zipperer size 40(st), Zdarsky Erler KG, München) is inserted into the lumen of the vein just below the left renal vein branching by gently twisting of the wire toward the iliac vein. The handle of the carrier is cut off so as to hold the back end of the wire at the vein wall. The incision is sutured and the animal is placed on its back on a heating pad (37°C). The wound is reopened after 2 hours; the wire coil is carefully removed together with the thrombus on it and rinsed with 0.9% saline. The thrombotic material is dissolved in 2 ml alkaline sodium carbonate solution (2% Na_2CO_3 in 0.1 N NaOH) in a boiling water bath for 3 min. The protein content is determined in 100 µl aliquots by the colorimetric method of Lowry. See figure below (Fig. 5).

Thrombolysis

In addition to the described preparation, for continuous infusion of a thrombolytic test solution a polyethylene catheter is inserted in the jugular vein. One and a half hours after implantation of the wire coil, the test compound or the vehicle (controls) is infused for up to 2.5 hours. The wire coil is then removed and the protein content of thrombi is determined (see above). Bernat et al. (1986) demonstrated the fibrinolytic activity of urokinase and streptokinase-human plasminogen complex in this model.

EVALUATION

Thrombosis incidence (= number of animals with thrombi in dosage groups as compared to vehicle controls) is assessed.

The mean protein content (mg) of the thrombotic material in dosage groups and vehicle controls is deter-

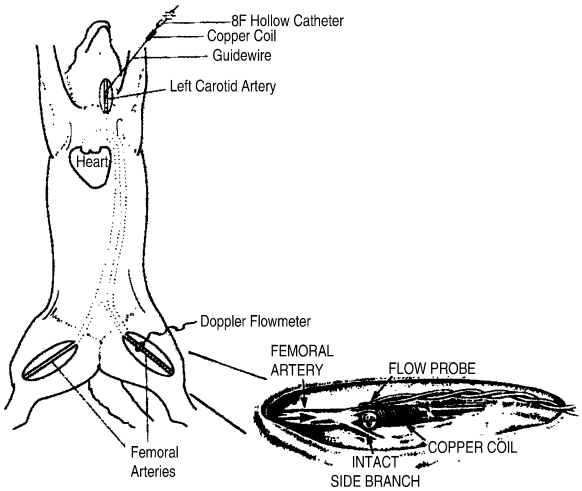

Figure 5 Schematic diagram of the canine femoral artery copper coil model of thrombolysis. A thrombogenic copper coil is advanced to either femoral artery via the left carotid artery. By virtue of the favorable anatomical angles of attachment, a hollow polyurethane catheter advanced down the left carotid artery nearly always enters the descending aorta, and with further advancement, into either femoral artery without fluoroscopic guidance. A flexible, Teflon-coated guidewire is then inserted through the hollow catheter and the latter is removed. A copper coil is then slipped over the guidewire and advanced to the femoral artery (see inset). Femoral artery flow velocity is measured directly and continuously with a Doppler flow probe placed just proximal to the thrombogenic coil and distal to a prominent sidebranch, which is left patent to dissipate any dead space between the coil and the next proximal sidebranch. Femoral artery blood flow declines progressively to total occlusion over the next 10–12 mm after coil insertion

mined. Percent change in protein content is calculated in dosage groups as compared to controls.

Statistical significance is assessed by means of the unpaired Student's *t*-test.

B.4.8.2 Eversion Graft-Induced Thrombosis

PURPOSE AND RATIONALE

The eversion graft model for producing thrombosis in the rabbit artery was first described by Hergrueter et al. (1988) and later modified by Jang et al. (1989, 1990) and Gold et al. (1991). A 4- to 6-mm segment of the rabbit femoral or the dog left circumflex artery is excised, everted and then reimplanted into the vessel by end-to-end anastomoses. After restoration of the blood flow, a platelet-rich occlusive thrombus forms rapidly, leading to complete occlusion of the vessel. This model mimics a deep arterial injury since the adventitial surface is a non-endothelial tissue containing tissue factor and collagen. The rabbit model described here uses a carotid graft inserted into the femoral graft to avoid vasoconstriction often occurring in the inverted femoral segments.

PROCEDURE

In anaesthetized New Zealand White rabbits, the right carotid artery is exposed. After double ligation, a 3-mm segment of the artery is excised, everted and immersed in prewarmed (37°C) isotonic saline. Thereafter, the right femoral artery is exposed and occluded by means of a double-occluder (2-cm distance). The femoral artery is transected and the everted graft from the carotid artery is inserted by end-to-end anastomosis using 12 sutures with 9–0 nylon (Prolene, Ethicon, Norderstedt, Germany) under a surgical microscope (Wild M650, Leitz, Heerbrugg, Switzerland). Perfusion of the graft is measured by means of an ultrasonic flowmeter (Model T106, Transonic, Ithaca, NY, USA). The flow probe is positioned 2 cm distal from the graft. After a stabilization period of 15 min, the test substance is given intravenously through the catheterized right jugular vein. Ten minutes after substance administration, the vessel clamps are released and the blood flow is monitored by the flowmeter for 120 min.

Arterial blood is collected from the left carotid artery at baseline (immediately before substance administration), 10 min, 60 min and 120 min after substance administration.

EVALUATION

- Time until occlusion (time after restoring of vessel

blood flow until occlusion of the vessel, indicated by a flow less than 3.0 ml/min)
- Patency (time during which perfusion of graft is measured related to an observation period of 120 min after administration of test compounds).

Statistical Analysis

Time until occlusion and patency are expressed as median and the interquartile range/2 (IQR/2). Significant differences ($p < 0.05$) are calculated by the non-parametric Kruskal-Wallis test.

CRITICAL ASSESSMENT OF THE METHOD

The eversion graft is very thrombogenic, although technically difficult and time consuming. The deep occlusive thrombi can prevented only by intraarterially administered thrombolytics or aggressive antithrombotic treatments such as recombinant hirudin at high dosages, or PEG-hirudin. The adventitial surface is a non-endothelial tissue containing tissue factor and collagen. Thus, both the coagulation system and blood platelets are activated.

MODIFICATIONS OF THE METHOD

Gold et al. (1991) modified the model to be used in thoracotomized dogs in partial obstructed left circumflex coronary arteries. The combination of reduced blood flow due to the constrictor, along with an abnormal non-endothelial surface, produces total thrombotic occlusion within 5 min.

B.4.8.3 Arteriovenous Shunt Thrombosis

PURPOSE AND RATIONALE

A method for the direct observation of extracorporal thrombus formation was introduced by Rowntree and Shionoya (1927) and extensively utilized by others (Rushkin et al. 2003; Tang et al. 2003). These first studies could provide evidence that anticoagulants like heparin and hirudin do inhibit thrombus development in arteriovenous shunts. Since today, the A-V-shunt thrombosis models have been often used to evaluate the antithrombotic potential of new compounds in different species including rabbits (Knabb et al. 1992), rats (Hara et al. 1995), pigs (Scott et al. 1994), dogs and cats (Best et al. 1938), and non-human primates (Yokoyama et al. 1995).

PROCEDURE

Rats are anaesthetized and fixed in supine position on a temperature-controlled heating plate to maintain body temperature. The left carotid artery and the right jugular vein are catheterized with short polyethylene catheters. The catheters are filled with isotonic saline solution and clamped. The two ends of the catheters are connected with a 2-cm glass capillary with an internal diameter of 1 mm. This glass capillary provides the thrombogenic surface. At a defined time after administration of the test compound, the clamps that are occluding the A-V-shunt are opened.

The measurement of the patency of the shunt is performed indirectly with a NiCrNi-thermocouple, which is fixed distal to the glass capillary. If blood is flowing, the temperature rises from room temperature to body temperature. In contrast, decreases of temperature indicate the formation of an occluding thrombus. The temperature is measured continuously over 30 min after opening of the shunt.

CRITICAL ASSESSMENT OF THE METHOD

It has been shown by Best et al. (1938) that the thrombi formed in the AV-shunt are to a greater part white arterial thrombi. This might be due to the high pressure and shear rate inside the shunts; in those cases, the thrombi tend to be more arterial in character (Chi et al. 1999).

B.4.8.4 Thread-Induced Venous Thrombosis

PURPOSE AND RATIONALE

Compared to the arterial system, it seems to be more difficult to develop a thrombosis model in venous blood vessels with respect to reproducibility and variability (Chi et al. 1999). Complete stasis together with a thrombogenic stimulus (Wessler-type) is used by numerous investigators to evaluate the effect of compounds on venous thrombosis. Hollenbach et al. (1994) developed a rabbit model of venous thrombosis by inducing cotton threads into the abdominal vena cava of rabbits. The cotton threads serve as a thrombogenic surface, and a thrombus forms around it, growing to a maximum mass after 2–3 hours. The prolonged non-occlusive character of thrombogenesis in this model focuses on progression of thrombus formation rather than initiation. Therefore, the conditions more closely resemble pathophysiology in humans because blood continues to flow throughout the experiment (Chi et al. 1999).

PROCEDURE

Rabbits weighing between 2.5 and 3.5 kg are anaesthetized with isofluorane inhalation anesthesia, and a polyethylene catheter is inserted into the left carotid artery. A polyethylene tube (PE 240, inner diameter 1.67 mm) of 14 cm length is filled with isotonic saline, and a copper wire with 5 fixed cotton threads (length 6 cm) is inserted into the tube (after determination of the net weight of the cotton threads). A laparotomy is performed and the vena cava and iliac vein are dissected free from surrounded tissue. The test agent is administered by a rabbit intragastric tube 60 min (depending on the *ex vivo* study) prior to initiation of thrombus formation. Blood samples will be measured at 60, 90, 120, 150 and 210 min after oral administration of the test compound.

Thrombus formation is induced by the inserting the thrombosis catheter into the caval vein via the iliac vein (7 cm). Then the copper wire is pushed forward 3 cm to liberate the cotton threads into the vessel lumen. One hundred fifty minutes after thrombus initiation, the caval segment containing the cotton threads and the developed thrombus will be removed, longitudinally opened and the content blotted on filter paper. After weighing the cotton thread with the thrombus, the net thread weight will be subtracted to determine the corrected thrombus weight.

EVALUATION

- Corrected thrombus weight after blotting the thrombus on filter paper and subtraction of the net weight of the cotton thread
- Mean arterial blood pressure
- APTT, HepTest, antiFIIa and antiFXa activity.

CRITICAL ASSESSMENT OF THE METHOD

The composition of the cotton-threaded thrombus shows a composition of fibrin together with tightly aggregated and distorted erythrocytes, thus being in accordance with human deep-vein thrombosis structure. Non-occlusive thrombus formation has been successfully inhibited by heparins, prothrombinase complex inhibitors and thrombin inhibitors (Hollenbach et al. 1994, 1995).

MODIFICATIONS OF THE METHOD

In addition to the originally described method, it is possible to measure blood flow by means of an ultrasonic flow probe, attached distally to the position of the cotton threads on the vein.

B.4.8.5 Thrombus Formation on Superfused Tendon

PURPOSE AND RATIONALE

In all models that include vessel wall damage, blood gets in contact with adhesive proteins of the subendothelial matrix, i. e. von Willebrand factor, collagens, fibronectin, laminin and others. Gryglewski et al. (1978) described an *in vivo* method where blood of an unanesthetized animal is in contact *ex vivo* with a foreign surface consisting mainly of collagen. The foreign surface is produced out of the tendon of another animal species. After superfusion of the tendon, blood is recirculated to the unanesthetized animal. The method aims at the quantitation of the antiplatelet potency of drugs based on the formation of platelet thrombi onto the surface of the tendons or of aortic strips from atherosclerotic rabbits.

PROCEDURE

Blood was withdrawn from the carotid artery of anesthetized and heparinized cats by a roller pump at a speed of 6 ml/min. After a passage through a warmed jacket (37°C), blood was separated into 2 streams, each flowing at a speed of 3 ml/min superfusing in parallel 2 twin strips of the central part of longitudinally cut rabbit Achilles tendon (30 × 3 mm). The blood superfusing the strips dripped into collectors and by its gravity was returned to the venous system of the animals through the left jugular vein. The tissue strips were freely suspended in air and the upper end was tied to an auxotonic lever of a smooth muscle/heart Harvard transducer, while the lower end was loaded with a weight (1–2 g) to keep the lever with its counterweight in a neutral position. When superfused with blood, the strips were successively covered with clots changing the weight of the strips. The weight changes were continuously recorded. After a control period of 30 min, the formed thrombi were gently removed and fixed in formalin for histological examination. Then, the strips were superfused with Tyrode solution and the animals injected with the antithrombotic drug. After 10 min, blood superfusion was renewed for another 30 min.

EVALUATION

The ratio of an increase in weight of the strips after the drug treatment to the increase in weight before drug treatment was considered as an index of antiaggregatory activity.

B.4.9 Stasis-Induced Thrombosis (Wessler Model)

PURPOSE AND RATIONALE

The "Wessler model" is a classical method of inducing venous thrombosis in animals. Wessler (1952, 1953, 1955a & b, 1957) and Wessler et al. (1959) combined local venous stasis with hypercoagulability produced by injection of human or dog serum into the systemic circulation of dogs or rabbits. The jugular vein of these animals is occluded by clamps 1 min after the injection of the procoagulatory stimulus into the circulation. Within a few minutes after clamping, a red clot is formed in the isolated venous segment. Fareed et al. (1985) summarized a variety of substances that can be used as pro-coagulatory stimuli. Aronson and Thomas (1985) found an inverse correlation between the duration of stasis and the amount of the hypercoagulating agents to produce the clot.

PROCEDURE

Anaesthetized rabbits are fixed in supine position on a temperature-controlled (37°C) heating table. Following cannulation of both carotid arteries (the left in cranial direction) and the right femoral vein, segments of 2 cm length of the two external jugular veins are exposed and isolated between two loose sutures. Then, 0.3 ml/kg calcium thromboplastin (SIGMA, Deisenhofen, Germany, FRG) is administered via the left carotid artery. Meticulous care is taken to maintain a standard injection time of 30 sec followed by injection of 0.5 ml physiological saline within 15 sec; 45 sec later, both jugular vein segments are occluded by distal and proximal sutures. Stasis is maintained for 30 min. Blood samples are taken immediately before occlusion and 30 sec before end of stasis. After excision, the occluded vessel segments are placed on a soaked sponge and opened by a longitudinal incision.

EVALUATION

The size of the clots is assessed using a score system: (0: blood only; 1: very small clot piece[s], filling out at most 1/4 of the vessel; 2: larger clot piece[s], filling out at most 1/2 of the vessel; 3: very large clot[s], filling out at most 3/4 of the vessel; 4: one large clot, filling out the whole vessel). The scores of the left and the right jugular vein are added, forming the thrombus size value of one animal. Additionally, the thrombus weight is measured after blotting the thrombus on filter paper.

Thrombus score is expressed as median (minimum–maximum). Thrombus weight is given as mean ± SEM. For the statistical evaluation of the antithrombotic effect, the nonparametric U-Test of Mann and Whitney (thrombus score) or Student's *t*-test for unpaired samples (thrombus weight) is used. Significance is expressed as $p < 0.05$.

CRITICAL ASSESSMENT OF THE METHOD

Breddin (1989) described the Wessler model because of its static character as the retransformation of an *in vitro* experiment into a very artificial test situation. One of the major drawbacks is the relative independence of platelet function and hemodynamic changes that largely influence thrombus formation *in vivo*. However, the model has been shown to be very useful for evaluation of the antithrombotic effect of compounds like heparin and hirudin.

MODIFICATIONS OF THE METHOD

There are a number of different procoagulant agents that had been used to induce thrombosis in this model, such as human serum, Russel viper venom, thromboplastin, thrombin, activated prothrombin complex concentrates and factor X_a (Aronson and Thomas 1985, Fareed et al. 1985). The sensitivity and accuracy of the model can be improved by injecting iodinated fibrinogen into the animals before injecting the thrombogenic agent and then measuring the specific radioactivity in the clot.

The general drawback of the Wessler model is the static nature of the venous thrombus development. To overcome this problem some investigators have developed more dynamic models with reperfusion of the occluded vessel segments after clot development. Depending on the time of test compound administration (pre- or post-thrombus initiation), the effect on thrombus growth and fibrinolysis can be evaluated. Levi et al. (1992) have used this model to assess the effects of a murine monoclonal anti-human PAI-1 antibody, and Biemond et al. (1996) compared the effect of thrombin-and factor X_a-inhibitors with a low molecular weight heparin.

Venous reperfusion model: New Zealand white rabbits weighing 2.5 kg are anesthetized with 0.1 ml atropine, 1.0 mg/kg diazepam, and 0.3 ml Hypnorm (Duphar, 10 mg/ml fluanisone and 0.2 ml fentanyl). Further anesthesia is maintained with 4 mg/kg i.v. thiopental. The carotid artery is cannulated after exposition through an incision in the neck. The jugular vein is dissected free from tissue, and small side branches are ligated over a distance of 2 cm. The vein is clamped proximally and distally to isolate the vein segment. Citrated rabbit blood (from another rabbit) is mixed with ^{131}I-radiolabeled fibrinogen (final radioactivity, approximately 25 mCi/ml). Then, 150 µl of this blood is aspirated in a 1-ml syringe containing 25 µl thrombin (3.75 IU) and 45 µl 0.25 mol $CaCl_2$, and 200 µl of the clotting blood is immediately injected into the isolated segment. The vessel clamps are removed 30 min after clot injection, and blood flow is restored. ^{125}I-radio-labeled fibrinogen (approximately 5 µCi) is injected through the cannula in the carotid artery, (in case of the fibrinolysis studies immediately followed by 0.5 mg/kg recombinant tissue-type plasminogen activator). For each dosage group, four thrombi are analyzed. The extent of thrombolysis is assessed by measurement of the remaining ^{131}I-fibrinogen in the clot and compared with the initial clot radioactivity. The comparison between blood and thrombus ^{125}I-radioactivity reveals the extent of thrombus growth (blood volume accreted to the blood). The thrombus lysis and extension are monitored 60 or 120 min after thrombus formation and are expressed as percentage of the initial thrombus volume. Statistics is performed as variance analysis and the Newman-Keuls test. Statistical significance is expressed at the level of $p < 0.05$.

B.4.10 Disseminated Intravascular Coagulation (DIC) Model

PURPOSE AND RATIONALE

DIC is another model that is also used widely in rats and mice. It is a model of systemic thrombosis or disseminated intravascular coagulation (DIC), which is induced by tissue factor, endotoxin (lipopolysaccharide), or FXa (Herbert et al. 1996, Yamazaki et al. 1994, Sato et al. 1998). After systemic administration of the thrombogenic stimulus, this model can be performed with or without mechanical vena caval stasis. When stasis is used, the major parameter is the thrombus mass, but when stasis is not used, the readouts are fibrin degradation products, fibrinogen, platelet count, PT, and APTT, among others. As shown by the many and varied parameters, when used without stenosis, the post-experimental analysis can be time-consuming and technically demanding. Although rodents are useful as a primary efficacy model, limitations such as the ability to withdraw multiple blood samples over the course of the experiment and the difference in activity of at least some FXa inhibitors in human compared to rat plasma *in vitro* require that compounds be characterized further in more advanced *in vivo* models of thrombosis.

B.4.11 Microvascular Thrombosis in Trauma Models

PURPOSE AND RATIONALE

Successful replantation of amputated extremities is dependent in large degree on maintaining the microcirculation. A number of models have been developed in which blood vessels are subjected to crush injury with or without vascular avulsion and subsequent anastomosis (Fu et al. 1997, Korompilias et al. 1997, Stockmans et al. 1997). In the model of Stockmans (1997), both femoral veins are dissected from the surrounding tissue. A trauma clamp, which has been adjusted to produce a pressure of 1,500 g/mm^2, is positioned parallel to the long axis of the vein. The anterior wall of the vessel is grasped between the walls of the trauma clamp and the two endothelial surfaces are rubbed together for a period of 30 sec as the clamp is rotated. Formation and dissolution of platelet-rich mural thrombi are monitored over a period of 35 min by transillumination of the vessel. By using both femoral veins, the effect of drug therapy can be compared to control in the same animal, minimizing intra-animal variations.

The models of Korompilias et al. (1997) and Fu et al. (1997) examine the formation of arterial thrombosis in rats and rabbits, respectively. In these models, either the rat femoral artery or the rabbit central ear artery is subjected to a standardized crush injury. The vessels are subsequently divided at the midpoint of the crushed area and then anastomosed. Vessel patency is evaluated by milking the vessel at various time points post-anastomosis. These models have been used to demonstrate the effectiveness of topical administration of LMWH in preventing thrombotic occlusion of the vessels. Such models, while effectively mimicking the clinical situation, are limited by the necessity of a high degree of surgical skill to effectively anastomose the crushed arteries.

B.4.12 Cardiopulmonary Bypass Models

PURPOSE AND RATIONALE

Cardiopulmonary bypass (CPB) models have been described in baboons (Van Wyk et al. 1998), swine (De-

wanjee et al. 1996) and dogs (Henny et al. 1985). In each model, the variables that can affect the hemostatic system—such as anesthesia, shear stresses caused by the CPB pumps and the exposure of plasma components and blood cells to foreign surfaces (catheters, oxygenators, etc)—are comparable to that observed with human patients. With these models, it is possible to examine the potential usefulness of novel anticoagulants in preventing thrombosis under relatively harsh conditions where both coagulation and platelet function are altered. The effectiveness of direct thrombin inhibitors (Van Wyk et al. 1998), LMWHs (Murray 1985) and heparinoids (Henny et al. 1985) has been compared to standard heparin. Endpoints have included the measurement of plasmatic anticoagulant levels, the histological determination of microthrombi deposition in various organs, the formation of blood clots in the components of the extracorporeal circuit and the deposition of radiolabeled platelets in various organs and on the components of the extracorporeal circuit. These models, therefore, can be used to assess the antithrombotic potential of new agents for use in CPB surgery and also to assess the biocompatability of components used to maintain extracorporeal circulation. For detailed protocols and evaluations see Callas et al. (1995), Carrie et al. (1994), Fu et al. (1997), Korompilias et al. (1997), Meuleman et al. (1991), Millet et al. (1994), Stockmans et al. (1997), Vlasuk et al. (1991), Walenga et al. (1987), and Wessler et al. (1959).

B.4.13 Extracorporeal Thrombosis Models

PURPOSE AND RATIONALE

These models employ passing blood over a section of damaged vessel (or other selected substrates) and recording the thrombus accumulation on the damaged vessel histologically or by scintigraphic detection of radiolabeled platelets or fibrin (Badimon and Badimon 1989). This model is interesting because the results can be directly compared to the *in vivo* deep arterial injury model (Wysokinski et al. 1996) results and to results from a similar extracorporeal model used in humans (Dangas et al. 1998; Ørvim et al. 1995). Dangas et al. (1998) used this model to characterize the antithrombotic efficacy of abciximab, a monoclonal antibody-based platelet glycoprotein IIb/IIIa inhibitor, after administration to patients undergoing percutaneous coronary intervention. They demonstrated that abciximab reduces both the platelet and fibrin components of the thrombus, thereby providing further insight into the unique long-term effectiveness of short-term administration of this drug. Ørvim et al. (1995) also used this model in humans to evaluate the antithrombotic efficacy of rTAP, but instead of evaluating the compound after administration of rTAP to the

patient, the drug was mixed with the blood immediately as it flowed into the extracorporeal circuit prior to flowing over the thrombogenic surface. By changing the thrombogenic surface, they were able to determine that rTAP was more effective at inhibiting thrombus formation on a tissue-factor coated surface compared to a collagen-coated surface. These results suggest that optimal antithrombotic efficacy requires an antiplatelet approach along with an anticoagulant. Although this model does not completely represent pathological intravascular thrombus formation, the use of this "human model" of thrombosis may be very useful in developing new drugs because it directly evaluates the *ex vivo* antithrombotic effect of a drug in flowing human blood.

B.4.14 Experimental Thrombocytopenia or Leucocytopenia

PURPOSE AND RATIONALE

Intravenous administration of collagen, arachidonic acid, ADP, platelet activating factor (PAF) or thrombin activates thrombocytes leading to a maximal thrombocytopenia within a few minutes. The effect is reinforced by additional injections of epinephrine. Activation of platelets leads to intravasal aggregation and temporary sequestration of aggregates in the lungs and other organs. Depending on the dose of agonist, this experimentally induced reduction of the number of circulating platelets is reversible within 60 min after induction. Following administration of PAF, a leucocytopenia is induced in addition. The assay is used to test the inhibitory capacity of drugs against thrombocytopenia or leucocytopenia as a consequence of *in vivo* platelet or leukocyte stimulation.

PROCEDURE

Male guinea pigs (Pirbright White) weighing 300–600 g, or male NMRI mice (25–36 g), or Chinchilla rabbits of either sex weighing 2–3 kg are used. Animals receive the test compound or the vehicle (controls) by oral, intraperitoneal or intravenous administration. After the end of the absorption time (p.o. 60 min, i.p. 30 min, i.v. variable), the marginal vein of the ear of rabbits is cannulated and the thrombocytopenia-inducing substances collagen or arachidonic acid are injected slowly. Blood is collected from the ear artery.

Guinea pigs, hamsters, or mice are anesthetized with pentobarbital sodium (i.p.) and Rompun (i.m.) and placed on an electrically warmed table at 37°C. The carotid artery is cannulated for blood withdrawal and the jugular vein is cannulated to administer the thrombocytopenia-inducing substances collagen+adrenaline (injection of the mixture of both within 10 sec) or PAF or thrombin. In mice, collagen + adrenaline are injected into a tail vein.

Approximately 50–100 µl blood is collected into potassium-EDTA-coated tubes at times –1, 1 and 2 min (guinea pigs and mice) or 5, 10 and 15 min (rabbits) following the injection of the inducer. The number of platelets and leukocytes is determined within 1 hour after withdrawal in 10 µl samples of whole blood using a microcellcounter suitable for blood of various animal species.

EVALUATION

The percentage of thrombocytes (or leukocytes) is determined in vehicle control and dosage groups at the different times following injection of the inducer relative to the initial value of control or dosage group, respectively. Calculated percent values of controls are taken as 100%.

Percent inhibition of thrombocytopenia (or leucocytopenia) is calculated in dosage groups relative to controls.

Statistical significance is evaluated by means of the unpaired Student's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

The method of collagen+epinephrine-induced thrombocytopenia is presently widely used to study the phenotype of mice knocked out for a specific gene with suspected role in hemostasis/thrombosis. A recent example is the *Gas* 6 –/– mouse (Angelillo-Scherrer et al. 2001) and mice lacking the gene for the G protein G(z) (Yang et al. 2000). The advantage of the method for this purpose is the simple experimental procedure

and the small volume of blood necessary. In general, application of the method in small animals (mice, hamsters) needs only small amounts of drug substance. The model is a useful first step of *in vivo* antithrombotic efficacy of antiplatelet drugs.

B.4.15 Collagenase-Induced Thrombocytopenia

PURPOSE AND RATIONALE

Intravenous administration of the proteolytic enzyme collagenase leads to formation of endothelial gaps and to exposure of deeper layers of the vessel wall. This vascular endothelial injury is mainly involved in triggering thrombus formation by activation of platelets through contact with the basal lamina. As a consequence, thrombocytopenia is induced, which is maximal within 5–10 min following collagenase injection and reversible within 30 min after induction. The model is used to test the inhibitory capacity of compounds against thrombocytopenia in a model of collagenase-induced thrombocytopenia in rats as an alternative to the model described before.

PROCEDURE

Male Sprague-Dawley rats weighing 260–300 g are used. The animals receive the test compound or the vehicle (controls) by oral, intraperitoneal or intravenous administration. After the end of the absorption time (i.p. 30 min, p.o. 60 min, i.v. variable), rats are anesthetized with pentobarbital sodium (i.p.). One carotid artery is cannulated for blood withdrawal and one jugular vein is cannulated for inducer injection. The animals receive an intravenous injection of heparin and 20 min later, approximately 100 µl blood is collected (initial value). Ten minutes later, the thrombocytopenia-inducing substance collagenase is administered intravenously.

At times 5, 10, 20 and 30 min following the injection of collagenase, samples of approximately 100 µl blood are collected into potassium-EDTA-coated tubes. The number of platelets is determined in 10 µl samples of whole blood within 1 hour after blood withdrawal, using a microcellcounter. See Völkl and Dierichs (1986) for details.

EVALUATION

The percentage of platelets is determined in vehicle control and dosage groups at the different times following injection of collagenase relative to the initial value of control or dosage group, respectively. Calculated percent values of controls are set at 100%.

Percent inhibition of thrombocytopenia is calculated in dosage groups relative to controls.

Statistical significance is evaluated by means of the unpaired Student's *t*-test.

B.4.16 Reversible Intravital Aggregation of Platelets

PURPOSE AND RATIONALE

Isotopic labeling of platelets can be employed to monitor platelet aggregation and desegregation *in vivo*. Adenosine diphosphate (ADP), platelet activating factor (PAF), arachidonic acid, thrombin and collagen are known to induce platelet aggregation. In the following procedure, labelled platelets are continuously monitored in the thoracic (A) and abdominal (B) region of test animals. Administration of aggregation promoting agents produces an increase in counts in A and a fall in counts in B. This observation implies that platelets are being aggregated within the vascular system and accumulate in the pulmonary microvasculature. The *in vivo* method can be used to evaluate platelet antiaggregatory properties of test compounds.

PROCEDURE

Preparation of Labeled Platelets

Blood is obtained from rats by cardiopuncture. After centrifugation at 240 *g* for 10 min, the platelet-rich plasma (PRP) is transferred into a tube and suspended in calcium-free Tyrode solution containing 250 ng/ml PGE_1. The suspension is centrifuged at 640 *g* for 10 min. The supernatant is discarded and the sediment is suspended by gentle shaking with calcium-free Tyrode solution containing 250 ng/ml PGE_1. ^{51}Cr is added to 1 ml of the platelet suspension. Following a 20-min incubation period at 37°C, the suspension is again centrifuged at 640 *g* for 10 min. The supernatant

is removed, and the labeled platelets are finally resuspended in 1 ml calcium-free Tyrode solution containing 250 ng/ml PGE_1.

In Vivo Experiment

Male Sprague-Dawley or stroke-prone spontaneously hypertensive rats weighing 150–300 g are used. The animals are anaesthetized with pentobarbital sodium (30 mg/kg, i.p.). Following tracheotomy, the vena femoralis is exposed and cannulated. The labeled platelets are administered via the cannula. The circulating platelets are monitored continuously in the thoracic (A) and abdominal (B) region. The counts are collected using a dual-channel gamma spectrometer (Nuclear Enterprise 4681) incorporating a microcomputer (AM 9080A). One hour after administration of labeled platelets (when counts in A and B have stabilized), the aggregation-promoting agent (ADP, PAF, arachidonic acid, thrombin or collagen) is administered twice by intravenous injection. One hour is allowed to elapse between each i.v. injection.

The test compound is administered 2 hours after platelet injection concurrently with the fourth administration of the aggregating agent. Thirty minutes (ADP, PAF, arachidonic acid, thrombin), or 1 hour (collagen) after compound administration another control injection of the aggregating agent is given. This injection is either used as an additional control or it may reveal long-term efficacy of a test compound.

EVALUATION

The microcomputer continuously reveals information about aggregation and desegregation of labeled platelets.

The following parameters are recorded:
A = counts over thorax
B = counts over abdomen
Difference: *A*–*B*
ratio: *A/B*.

The time course of response is shown in a curve. The area under the curve is calculated by a computer program.

Statistical significance is calculated using the Student's *t*-test.

MODIFICATION OF THE METHOD

Oyekan and Botting (1986) described a method for monitoring platelet aggregation *in vivo* in rats, using platelets labeled with indium^{3+} oxine and recording the increase in radioactivity count in the lung after injection of adenosine diphosphate or collagen.

Smith et al. (1989) monitored continuously the intrathoracic content of intravenously injected ^{111}indium-labeled platelets in anesthetized guinea pigs using a microcomputer-based system.

B.5 Bleeding Models

B.5.1 Subaqueous Tail Bleeding Time in Rodents

PURPOSE AND RATIONALE

The damage of a blood vessel results in the formation of a hemostatic plug, which is achieved by several different mechanisms including vascular spasm, formation of a platelet plug, blood coagulation, and growth of fibrous tissue into the blood clot.

A diagnostic parameter for specific defects of the hemostatic system and for the influence of drugs affecting hemostasis is the length of time that it takes for bleeding to stop from a standard incision, the so-called bleeding time.

Bleeding-time measurements in animals are used to evaluate the hemorrhagic properties of antithrombotic drugs. The transection of the tail of a rodent was first established by Döttl and Ripke (1936) and is commonly used in experimental pharmacology.

PROCEDURE

Anaesthetized rats are fixed in supine position on a temperature-controlled (37°C) heating table. Following catheterization of a carotid artery (for measurement of blood pressure) and a jugular vein, the test compound is administered. After a defined latency period, the tail of the rat is transected with a razor-blade mounted on a self-constructed device at a distance of 4 mm from the tip of the tail. Immediately after transection, the tail is immersed into a bath filled with isotonic saline solution (37°C).

EVALUATION

The time until bleeding stops is determined within a maximum observation time of 600 sec.

CRITICAL ASSESSMENT OF THE METHOD

There are numerous variables that can influence rodent's bleeding time measurements, as discussed by Dejana et al. (1979): position of the tail (horizontal or vertical), the environment (air or saline), temperature, anesthesia, or procedure of injury (Simplate method, transsection). All these variables are responsible for the different results reported in literature on compounds like aspirin and heparin under different assay condition (Stella et al. 1975; Minsker and Kling 1977).

Furthermore, it is impossible to transect exactly one blood vessel, because the transected tail region consists of a few major arteries and veins with mutual interaction between one another.

B.5.2 Arterial Bleeding Time in Mesentery

PURPOSE AND RATIONALE

Arterial bleeding is induced by micropuncture of small arteries in the area supplied by the mesenteric artery. Bleeding is arrested in living blood vessels by the formation of a hemostatic plug due to the aggregation of platelets and to fibrin formation. In this test, compounds are evaluated that inhibit thrombus formation, thus prolonging arterial bleeding time. The test is used to detect agents which interfere with primary hemostasis in small arteries.

PROCEDURE

Male Sprague-Dawley rats weighing 180–240 g receive the test compound or the vehicle (controls) by oral, intraperitoneal or intravenous administration. After the end of the absorption time (i.p. 30 min, p.o. 60 min, i.v. variable), the animals are anesthetized by intraperitoneal injection of 60 mg/kg pentobarbital sodium. Rats are placed on an electrically warmed table at 37°C.

The abdomen is opened by a mid-line incision and the mesentery is lifted to display the mesenteric arteries. The mesentery is draped over a plastic plate and superfused continuously with Tyrode's solution maintained at 37°C. Bleeding times are determined with small mesenteric arteries (125–250 µm external diameter) at the junction of mesentery with intestines. Adipose tissue surrounding the vessels is carefully cut with a surgical blade.

Arteries are punctured with a hypodermic needle (25 gauge: 16 × 5/10 mm). The bleeding time of the mesenteric blood vessels is observed through a microscope at a magnification of 40×. The time in seconds is determined from the puncturing until the bleeding is arrested by a hemostatic plug.

EVALUATION

1. Mean values of bleeding times are determined for each dosage group (4–6 animals, 4–6 punctures each) and compared to the controls.
2. The significance of the results is assessed with the unpaired Student's *t*-test.
3. The percent prolongation of bleeding time in dosage groups relative to the vehicle controls is calculated.

For further details on methods and evaluations of various mechanisms or agents see the following: Butler et al. (1982), Dejana et al. (1979), and Zawilska et al. (1982).

B.5.3 Template Bleeding Time Method

PURPOSE AND RATIONALE

The template bleeding time method is used to produce a standardized linear incision into the skin of humans to detect abnormalities of primary hemostasis due to deficiencies in the platelet or coagulation system. The method has been modified with the development of a spring-loaded cassette with two disposable blades (Simplate II, Organon Teknika, Durham, NC). These template devices ensure reproducibility of length and depth of dermal incisions. Forsythe and Willis (1989) described a method that enables the Simplate tech-

nique to be used as a method to analyze the bleeding time in the oral mucosa of dogs.

PROCEDURE

The dog is positioned in sternal or lateral recumbency. A strip of gauze is tied around both the mandible and maxilla as a muzzle. The template device is placed evenly against the buccal mucosa, parallel to the lip margin, and triggered. Simultaneously, a stopwatch is started. Blood flow from the incision is blotted using circular filter paper (Whatman No. 1, Fisher Scientific Co, Clifton, NJ) held directly below, but not touching the wounds. The position of the filter paper is changed every 15 sec. The end point for each bleeding is determined when the filter paper no longer develops a red crescent.

EVALUATION

The time from triggering the device until blood no longer appears on the paper is recorded as the bleeding time. The normal range lies between 2 to 4 min.

CRITICAL ASSESSMENT OF THE METHOD

The template bleeding time varies considerably between laboratories as well as between species and strains. Therefore, it is important to perform the incisions and the blotting in an identical fashion. Prolonged bleeding times in dogs have been recognized with thrombocytopenia, von Willebrand's disease, uremia, treatment with aspirin, anticoagulants, and dextran (Forsythe and Willis 1989, Klement et al. 1998). Brassard and Meyers (1991) describe the buccal mucosa bleeding time as a test that is sensitive to platelet adhesion and aggregation deficits. Generally, results of antithrombotic drugs in bleeding time models in animals do not exactly predict bleeding risks in clinical situations. But the models allow comparison between drugs with different actions (Dejana et al. 1979, Lind 1991).

MODIFICATIONS OF THE METHOD

The Simplate device can also be used to perform incisions at the shaved inner ear of rabbits, taking care to avoid major vessels. The normal range of bleeding time in anaesthetized rabbits is approximately 100 sec.

Klement et al. (1998) described another ear bleeding model in anaesthetized rabbits. The shaved ear was immersed in a beaker containing saline at 37°C. Five full-thickness cuts were made with a no. 11 Bard-Parker scalpel blade, avoiding major vessels, and the ear was immediately re-immersed in saline. At different times thereafter (5 to 30 min) aliquots of the saline solution were removed, red cells were sedimented and lysed, and cyanohemoglobin was determined as a measure of blood loss. In this study, hirudin produced more bleeding than standard heparin.

A cuticle bleeding time (toenail bleeding time) measurement in dogs has been described by Giles et al. (1982). A guillotine-type toenail clipper is used to sever the apex of the nail cuticle. A clean transection of the nail is made just into the quick, to produce a free flow of blood. The nail is left to bleed freely. The time until bleeding stops is recorded as the bleeding time. Several nails can be cut at one time to ensure appropriate technique. The normal range lies between 2 to 8 min.

Kubitza et al. (2005) and others extended the use of the model in humans.

B.6 Genetic Models of Hemostasis and Thrombosis

PURPOSE AND RATIONALE

Recent advances in genetic molecular biology have provided tools allowing scientists to design genetically altered animals that are deficient in certain proteins involved in thrombosis and hemostasis (so-called "knock-outs", or "nulls") (Carmeliet and Collen 1999, Pearson and Ginsburg 1999). These animals have been extremely useful for identifying and validating novel targets for therapeutic intervention. That is, by examin-

ing the phenotype (e.g, spontaneous bleeding, platelet defect, prolonged bleeding after surgical incision, etc.) of a specific knock-out strain, scientists can identify the role of the knocked-out protein. Then if the phenotype is favorable (e.g, not lethal), pharmacological agents can be designed to mimic the knock-out. More recently, novel gene medicine approaches have also benefited greatly from the availability of these models, as discussed below. The following section briefly summarizes some of the major findings in thrombosis and hemostasis using genetically altered mice and concludes with an example of how these models have been used in the drug discovery process.

The majority of these gene knock-outs result in mice that develop normally, are born in the expected Mendelian ratios, and are viable (as defined by the ability to survive to adulthood). Although seemingly normal, these knock-out mice display alterations in hemostatic regulation, especially when challenged. Deletion of FVIII, FIX, vWF, and the β_3-integrin (Bi et al. 1996, Denis et al. 1998, Hodivala-Dilke et al. 1999, Wang et al. 1997) all result in mice that bleed upon surgical challenge, and despite some minor differences in bleeding susceptibility, these mouse knock-out models mirror the human disease states quite well (hemophilia A, hemophilia B, von Willebrand disease, and Glanzmann's thrombasthenia, respectively). In addition, deletion of some hemostatic factors results in fragile mice with severe deficiencies in their ability to regulate blood loss. Prenatally, these mice appear to develop normally, but they are unable to survive the perinatal period due to severe hemorrhage, in most cases due to the trauma of birth.

Genetic knock-outs have also been useful in dissecting the role of individual signaling proteins in platelet activation. Deletion of the β_3-integrin (Hodivala-Dilke et al. 1999) or of $G_{\alpha q}$ (Offermanns et al. 1997) results in dramatic impairment of agonist-induced platelet aggregation. Alteration of the protein-coding region in the β_3-integrin carboxy-tail, β_3-DiY, at sites that are thought to be phosphorylated upon platelet activation, also results in unstable platelet aggregation (Law et al. 1999). Deletion of various receptors such as thromboxane A_2, P-selectin, P2Y1, and PAR-3 demonstrate diminished responses to some agonists while other platelet responses are intact (Thomas et al. 1998, Subramaniam et al. 1996, Leon et al. 1999, Kahn et al. 1998). Deletion of PAR-3, another thrombin receptor in mice, has little effect on hemostasis. This indicated the presence of yet another thrombin receptor in platelets and led to the identification of PAR-4 (Kahn et al. 1998).

Given that knock-outs of prothrombotic factors yield mice with bleeding tendencies, it follows that deletion of factors in the fibrinolytic pathway results in increased thrombotic susceptibility in mice. Plasminogen (Bugge et al. 1995; Ploplis et al. 1995), tissue plasminogen activator (t-PA), urokinase-type plasminogen activator (u-PA), and the combined t-PA/u-PA knock-out (Carmeliet et al. 1994) result in mice that demonstrate impaired fibrinolysis, susceptibility for thrombosis, vascular occlusion, and tissue damage due to fibrin deposition. Interestingly, due to fibrin formation in the heart, these mice may provide a good model of myocardial infarction and heart failure caused by thrombosis (Christie et al. 1999). Intriguingly, mice deficient in PAI-1, the primary inhibitor of plasminogen activator, demonstrate no spontaneous bleeding and a greater resistance to venous thrombosis due to a mild fibrinolytic state (Carmeliet et al. 1993), suggesting that inhibition of PAI-1 might be a promising approach for novel antithrombotic agents.

In addition to their role in the regulation of hemostasis, several of these genes are important in embryonic development. For example, deletion of tissue factor (Bugge et al. 1996; Toomey et al. 1996; Carmeliet et al. 1996), tissue factor pathway inhibitor (Huang et al. 1997), or thrombomodulin (Healy et al. 1995) results in an embryonic lethal phenotype. These and other (Connolly et al. 1996, Cui et al. 1996) hemostatic factors also appear to contribute to vascular integrity in the developing embryo. These data suggest that initiation of coagulation and generation of thrombin is important at a critical stage of embryonic development, yet other factors must contribute since some of these embryos are able to progress and survive to birth.

Clearly, genetically altered mice have provided valuable insight into the roles of specific hemostatic factors in physiology and pathophysiology. Results of these studies have provided rationale and impetus for attacking certain targets pharmacologically. These types of models have also provided excellent model systems for studying novel treatments for human diseases. For example, these models provided exceptional systems for studying gene therapy for hemophilia. Specifically, deletion of FIX, generated by specific deletions in the *FIX* gene and its promoter, results in mice that mimic the human phenotype of hemophilia B (Lin et al. 1997). When these mice are treated with adenoviral mediated transfer of human FIX, the bleeding diathesis is fully corrected (Kung et al. 1998). Similarly, selectively bred dogs that have a characteristic point mutation in the sequence encoding the catalytic domain of FIX also have a severe hemophilia B that is

phenotypically similar to the human disease (Evans et al. 1989). When adeno-associated virus-mediated canine FIX gene was administered to these dogs intramuscularly, therapeutic levels of FIX were measured for up to 17 months (Herzog et al. 1999). Clinically relevant partial recovery of whole blood clotting time and APTT was also observed over this prolonged period. These data provided support for initiating the first study of adeno-associated virus-mediated FIX gene transfer in humans (Kay et al. 2000). Preliminary results from this clinical study provided evidence for expression of FIX in the three hemophilia patients studied and also provided favorable safety data to substantiate studying this therapy at higher doses. Although it is likely that there are differences between the human disease and animal models of hemophilia (or other diseases), it is clear that these experiments have provided pharmacological, pharmacokinetic, and safety data that were extremely useful in developing this approach and designing safe clinical trials.

Gene therapy approaches to rescuing patients with bleeding diatheses are further advanced than gene therapy for thrombotic indications. However, promising preclinical data indicates that local overexpression of thrombomodulin (Waugh et al. 1999a) or tissue plasminogen activator (Waugh et al. 1999b) inhibits thrombus formation in a rabbit model of arterial thrombosis. Similarly, local gene transfer of tissue factor pathway inhibitor prevented thrombus formation in balloon-injured porcine carotid arteries (Zoldhelyi et al. 2000). These and other studies (Vassalli et al. 1997) suggest that novel gene therapy approaches will also be effective for thrombotic indications, but these treatments will need to be carefully optimized for pharmacokinetics, safety and, efficacy in laboratory animal studies prior to administration to humans.

Genetically Modified Animals

Development and application of animal models of thrombosis has played a crucial role in discovering and validating novel drug targets, selecting new agents for clinical evaluation, and providing dosing and safety information for clinical trials. In addition, these models have provided valuable information regarding the mechanisms of these new agents and the interactions between antithrombotic agents that work by different mechanisms. The development and application of small and large animal models of thrombosis to the discovery and development of novel antithrombotic agents is described in this review. The methods and major issues regarding the use of animal models of thrombosis, such as positive controls, appropriate pharmacodynamic markers of activity, safety evaluation, species-specificity, and pharmacokinetics, are highlighted. Finally, the use of genetic models of thrombosis/hemostasis is presented using gene-therapy for hemophilia as an example of how animal models have aided in the development of therapies that are presently being evaluated clinically.

B.6.1 Knock-Out Mice

PURPOSE AND RATIONALE

Genetically modified animals, in particular knock-out mice, help in the understanding of the role of various factors in blood clotting, thrombolysis, and platelet function. They are useful to verify the mode of action of new drugs.

Factor I (Fibrinogen)

Phenotype

Born in normal appearance, ~10% die shortly after birth and another 40% around 1–2 months after birth due to bleeding, failure of pregnancy, blood samples failing to clot or support platelet aggregation *in vitro* (Suh et al. 1995).

REFERENCES AND FURTHER READING

Suh TT, Holmback K, Jensen NJ et al (1995) Resolution of spontaneous bleeding events but failure of pregnancy in fibrinogen-deficient mice. Genes Dev 9:2020–2033

Factor II (Prothrombin)

Phenotype

Partial embryonic lethality: 50% between embryonic day (E) 9.5–11.5; at least 1/4 survive to term, but fatal hemorrhage few days after birth; factor II important in maintaining vascular integrity during development as well as postnatal life (Sun et al. 1998, Xu et al. 1998).

REFERENCES AND FURTHER READING

Sun WY, Witte DP, Degen JL et al (1998) Prothrombin deficiency results in embryonic and neonatal lethality in mice. Proc Natl Acad Sci USA 95:7597–7602
Xu J, Wu Q, Westfield L et al (1998) Incomplete embryonic lethality and fatal neonatal hemorrhage caused by prothrombin deficiency in mice. Proc Natl Acad Sci USA 95:7603–7607

Factor V

Phenotype

Half of the embryos die at E9–10, possibly as a result of abnormal yolk sac vasculature, remaining 50% progress normally to term, but die from massive hemorrhage within 2 hours of birth, more severe in mouse than in human (Cui et al. 1996; Yang et al. 2000).

REFERENCES AND FURTHER READING

Yang TL, Cui J, Taylor JM et al (2000) Rescue of fatal neonatal hemorrhage in factor V deficient mice by low level transgene expression. Thromb Haemost 83:70–77

Factor VII

Phenotype

Develop normally but suffer fatal perinatal bleeding (Rosen et al. 1997).

REFERENCES AND FURTHER READING

Rosen ED, Chan JCY, Idusogie E et al (1997) Mice lacking factor VII develop normally but suffer fatal perinatal bleeding. Nature 390:290–294

Factor VIII

Phenotype

Mild phenotype compared with severe hemophilia A in humans; no spontaneous bleeding, illness or reduced activity during the first year of life; have residual clotting activity (APTT), as shown by Bi et al. (1995).

REFERENCES AND FURTHER READING

Bi L, Lawler AM, Antonarakis SE et al (1995) Targeted disruption of the mouse factor VIII gene produces a model of haemophilia A. Nat Genet 10:119–121

Factor IX

Phenotype

Factor IX coagulant activities (APTT): +/+ 92%, +/– 53%, –/– <5%; bleeding disorder (extensive bleeding after clipping a portion of the tail, bleeding to death if not cauterized (Kundu et al. 1998, Wang et al. 1997).

REFERENCES AND FURTHER READING

Wang L, Zoppe M, Hackeng TM et al (1997) A factor IX-deficient mouse model for hemophilia B gene therapy. Proc Natl Acad Sci USA 94:11563–11566

Factor X

Phenotype

Partial embryonic lethality (1/3 died on E11.5–12.5); fatal neonatal bleeding between postnatal day (P) 5–20, as shown by Dewerchin et al. (2000).

REFERENCES AND FURTHER READING

Dewerchin M, Liang Z, Moons L et al (2000) Blood coagulation factor X deficiency causes partial embryonic lethality and fatal neonatal bleeding in mice. Thromb Haemost 83:185–190

Factor XI

Phenotype

APTT prolonged in –/– (158–200 sec) compared with +/+ (25–34 sec) and +/– (40–61 sec); no factor XI activity and antigen, did not result in intrauterine death, –/– similar bleeding as +/+ with a tendency to prolongation (Gailani et al. 1997).

REFERENCES AND FURTHER READING

Gailani D, Lasky NM, Broze GJ (1997) A murine model of factor XI deficiency. Blood Coagul Fibrinolysis 8:134–144

TF (Tissue Factor)

Phenotype

Abnormal circulation from yolk sac to embryo ~E8.5 leading to embryo wasting and death; TF has a role in blood vessel development (Bugge et al. 1996, Carmeliet et al. 1996, Toomey et al. 1996, 1997).

REFERENCES AND FURTHER READING

Toomey JR, Kratzer KE, Lasky NM, Broze GJ (1997) Effect of tissue factor deficiency on mouse and tumor development. Proc Natl Acad Sci USA 94:6922–6926

TFPI (Tissue Factor Pathway Inhibitor)

Phenotype

None survive the neonatal period; 60% die between E9.5–11.5 with signs of yolk sac hemorrhage (Huang et al. 1997).

REFERENCES AND FURTHER READING

Huang ZF, Higuchi D, Lasky N, Broze GJ (1997) Tissue factor pathway inhibitor gene disruption produces intrauterine lethality in mice. Blood 90:944–951

Thrombin Receptor

Phenotype

50% die at E9–10; 50% survive and become grossly normal adult mice with no bleeding diathesis; –/– platelets strongly respond to thrombin; –/– fibroblast loose their ability to respond to thrombin⟶ second TR must exist, as shown by Connolly et al. (1996) and by Darrow et al. (1996).

REFERENCES AND FURTHER READING

Darrow AL, Fung-Leung WP, Ye RD et al (1996) Biological consequences of thrombin receptor deficiency in mice. Thromb Haemost 76:860–866

Thrombomodulin

Phenotype

Embryonic lethality before development of a functional cardiovascular system; die before E9.5 due to retardation of growth; TM+/– mice develop normal without thrombotic complications (Christie et al. 1999, Healy et al. 1995, 1998, Weiler-Guettler et al. 1998).

Weiler-Guettler H, Christie PD, Beeler DL et al (1998) A targeted point mutation in thrombomodulin generates viable mice with a prethrombotic state. J Clin Invest 101:1983–1991

Protein C

Phenotype

KO mice appeared to develop normally macroscopically, but possessed obvious signs of bleeding and thrombosis; did not survive beyond 24 hours after delivery; microvascular thrombosis in the brain and necrosis in the liver; plasma clottable fibrinogen was not detectable, suggesting fibrinogen depletion and secondary consumptive coagulopathy (Jalbert et al. 1998).

REFERENCES AND FURTHER READING

Jalbert LR, Rosen ED, Moons L et al (1998) Inactivation of the gene for anticoagulant protein C causes lethal perinatal consumptive coagulopathy in mice. J Clin Invest 102:1481–1488

Plasminogen

Phenotype

Severe spontaneous thrombosis; reduced ovulation and fertility; cachexia and shorter survival; severe glomerulonephritis; impaired skin healing; reduced macrophage and keratinocyte migration (Bugge et al. 1995, Ploplis et al. 1995).

REFERENCES AND FURTHER READING

Alpha$_2$-Antiplasmin

Phenotype

Normal fertility, viability and development; no bleeding disorder; spontaneous lysis of injected clots; $\longrightarrow$ enhanced fibrinolytic potential; significant reduction of renal fibrin deposition after LPS (Lijnen et al. 1999).

REFERENCES AND FURTHER READING

Lijnen HR, Okada K, Matsuo O et al (1999) Alpha$_2$-antiplasmin gene deficiency in mice is associated with enhanced fibrinolytic potential without overt bleeding. Blood 93:2274–2281

T-PA (Tissue-Type Plasminogen Activator)

Phenotype

Extensive spontaneous fibrin deposition; severe spontaneous thrombosis; impaired neointima formation; reduced ovulation and fertility; cachexia and shorter survival; severe glomerulonephritis; abnormal tissue remodeling (Carmeliet et al. 1998, Christie et al. 1999).

REFERENCES AND FURTHER READING

PAI-1 (Plasminogen Activator Inhibitor-1)

Phenotype

Reduced thrombotic incidence; no bleeding; accelerated neo-intima formation; reduced lung inflammation; reduced atherosclerosis. Detailed studies on PAI-1 are reported by Carmeliet et al. (1993), Eitzman et al. (1996), Erickson et al. (1990), Kawasaki et al. (2000), and Pinsky et al. (1998).

TAFI (Thrombin Activatable Fibrinolysis Inhibitor)

Not described.

Vitronectin

Phenotype

Normal development, fertility, and survival; serum is completely deficient in "serum spreading factor" and PAI-1 binding activities; delayed arterial and venous thrombus formation (Eitzman et al. 2000, Zheng et al. 1995).

REFERENCES AND FURTHER READING

Zheng X, Saunders TL, Camper SA et al (1995) Vitronectin is not essential for normal mammalian development and fertility. Proc Natl Acad Sci USA 92:12426–12430

Urokinase, U-PA (Urinary-Type Plasminogen Activator)

Phenotype

Single u-PA deficiency: viable, fertile, normal life span; occasionally spontaneous fibrin deposits in normal and inflamed tissue; higher incidence of endotoxin-induced thrombosis. Combined t-PA and u-PA deficiency: mice survive embryonic development; retarded growth, reduced fertility, shortened life span; spontaneous fibrin deposits more extensively and in more organs (Carmeliet et al. 1998, Heckel et al. 1990).

Transgenic mice carrying the u-PA gene linked to the albumin enhancer/promoter exhibit spontaneous intestinal and intraabdominal bleeding directly related to transgene expression in the liver and elevated plasma u-PA level; 50% die between 3 and 84 hours after birth; severe hypofibrinogenemia, loss of clotting function.

UPAR (Urinary-Type Plasminogen Activator Receptor)

Phenotype

Phenotype normal; attenuated thrombocytopenia and mortality associated with severe malaria (Bugge et al. 1995, 1996, Dewerchin et al. 1996, Piguet et al. 2000).

REFERENCES AND FURTHER READING

Gas 6 (Growth Arrest-Specific Gene 6 Product)

Phenotype

Mice are viable, fertile, appear normal; do not suffer spontaneous bleeding or thrombosis; have normal tail bleeding time. Platelets fail to aggregate irreversibly to ADP, collagen, or U 46619. Arterial and venous thrombosis is inhibited and mice are protected from fatal thromboembolism after injection of collagen plus epinephrine (Angelillo-Scherrer et al. 2001).

REFERENCES AND FURTHER READING

Angelillo-Scherrer A, DeFrutos PG, Aparicio C et al (2001) Deficiency or inhibition of Gas6 causes platelet dysfunction and protects mice against thrombosis. Nat Med 7:215–221

GPIbalpha (Glycoprotein Ib Alpha, Part of the GP Ib-V–IX Complex)

Phenotype

Bleeding, thrombocytopenia and giant platelets (similar to human Bernard Soulier syndrome). See Ware et al. (2000) for details.

REFERENCES AND FURTHER READING

Ware J, Russell S, Ruggeri ZM (2000) Generation and rescue of a murine model of platelet dysfunction: the Bernard-Soulier syndrome. Proc Natl Acad Sci USA 97:2803–2808

GPV (Glycoprotein V, Part of the GP Ib-V–IX Complex)

Phenotype

Increased thrombin responsiveness, GpV–/– platelets are normal in size, normal amounts in GpIb-IX, functional in vWF-binding; platelets are hyperresponsive to thrombin$\longrightarrow$ increased aggregation response; shorter bleeding time;$\longrightarrow$GpV = negative modulator of platelet function (Ramakrishnan et al. 1999).

REFERENCES AND FURTHER READING

lacking glycoprotein V. Proc Natl Acad Sci USA 96:13336–13341

GPIIb (Integrin Alpha IIb, Glycoprotein IIb, Part of the GP IIb–IIIa Complex)

Phenotype

Bleeding disorder similar to Glanzmann thrombasthenia in man; platelets failed to bind fibrinogen, to aggregate and to retract a fibrinogen clot; α-granules do not contain fibrinogen (Tronik-Le Roux et al. 2000).

REFERENCES AND FURTHER READING

Tronik-Le Roux D, Roullot V, Poujol C et al (2000) Thrombasthenic mice generated by replacement of the integrin alpha$_{IIb}$ gene: demonstration that transcriptional activation of this megakaryocytic locus precedes lineage commitment. Blood 96:1399–1408

GP IIIa (Integrin Beta3, Glycoprotein IIIa, Part of the GP IIb–IIIa Complex)

Phenotype

Viable, fertile, increased fetal mortality; features of Glanzmann thrombasthenia in man, e. g. defective platelet aggregation, clot retraction; spontaneous bleeding, prolonged bleeding times; dysfunctional osteoclasts, development of osteosclerosis with age (Hodivala-Dilke et al. 1999, McHugh et al. 2000).

REFERENCES AND FURTHER READING

Hodivala-Dilke KM, McHugh KP, Tsakiris DA et al (1999) Beta3-integrin-deficient mice are a model for Glanzmann thrombasthenia showing placental defects and reduced survival. J Clin Invest 103:229–238

McHugh KP, Hodivala-Dilke K, Zheng MH et al (2000) Mice lacking beta3 integrins are osteosclerotic because of dysfunctional osteoclasts. J Clin Invest 105:433–440

GP IIa (Glycoprotein IIa, Integrin Beta 1, Part of the GP Ia–IIa Complex)

Phenotype

Integrin beta1 null platelets from conditional knockout mice develop normally, platelet count is normal. Collagen induced platelet aggregation is delayed but otherwise normal; tyrosine phosphorylation pattern is normal but phosphorylation is delayed. Bleeding time in bone marrow chimeric mice is normal; no major *in vivo* defects (Nieswandt et al. 2001).

REFERENCES AND FURTHER READING

Nieswandt B, Brakebusch C, Bergmeier W et al (2001) Glycoprotein VI but not alpha2beta1 integrin is essential for platelet interaction with collagen. EMBO J 20:2120–2130

VWF (von Willebrand Factor)

Phenotype

Factor VIII levels strongly reduced due to defective protection by vWF; highly prolonged bleeding time, hemorrhage, spontaneous bleeding; mice useful for investigating the role of vWF; delayed platelet adhesion in ferric-chloride-induced arteriolar injury (Denis et al. 1998, Ni et al. 2000).

REFERENCES AND FURTHER READING

Ni H, Denis CV, Subbarao S et al (2000) Persistence of platelet thrombus formation in arterioles of mice lacking both von Willebrand factor and fibrinogen. J Clin Invest 106:385–392

Thromboxane A2 Receptor (TXA2r)

Phenotype

Mild bleeding disorder and altered vascular responses to TXA2 and arachidonic acid (Thomas et al. 1998).

REFERENCES AND FURTHER READING

Thomas DW, Mannon RB, Mannon PJ et al (1998) Coagulation defects and altered hemodynamic responses in mice lacking receptors for thromboxane A2. J Clin Invest 102:1994–2001

Prostacyclin Receptor (PGI2r)

Phenotype

Viable, fertile, normotensive; increased susceptibility to thrombosis; reduced inflammatory and pain responses (Murata et al. 1997).

REFERENCES AND FURTHER READING

Murata T, Ushikubi F, Matsuoka T et al (1997) Altered pain reception and inflammatory response in mice lacking prostacyclin receptor. Nature 388:678–682

PECAM (Platelet: Endothelial Cell Adhesion Molecule)

Phenotype

Normal platelet aggregation; prolonged bleeding time as described by Duncan et al. (1999) and by Mahooti et al. (2000).

REFERENCES AND FURTHER READING

Duncan GS, Andrew DP, Takimoto H et al (1999) Genetic evidence for functional redundancy of platelet/endothelial cell adhesion molecule-1 (PECAM-1) CD31-deficient mice reveal PECAM-1-dependent and PECAM-1-independent functions. J Immunol 162:3022–3030

Mahooti S, Graesser D, Patil S et al (2000) PECAM-1 (CD 31) expression modulates bleeding tome *in vivo*. Am J Pathol 157:75–81

Pallid (Pa)

Phenotype

Among 13 hypopigment mouse mutants with storage pool deficiency, the pallid mouse is a model of the human Hermansky Pudlak syndrome (the beige mouse is a model of the Chediak Higashi syndrome). Pallid mice exhibit prolonged bleeding time, pigment dilution, kidney lysosomal enzyme elevation serum alpha 1 antitrypsin deficiency and abnormal otolith formation. The gene defective in pallid mice encodes the highly charged 172-amino acid protein pallidin, which interacts with syntaxin 13, a protein mediating vesicle docking and fusion (Huang et al. 1999).

REFERENCES AND FURTHER READING

Huang L, Kuo YM, Gitschier J (1999) The pallid gene encodes a novel, syntaxin 13-interacting protein involved in platelet storage pool deficiency. Nat Genet 23:329–332

G Alpha(q) (Guanyl Nucleotide Binding Protein G Alpha q)

Phenotype

Defective aggregation in response ADP, TXA2, thrombin, collagen; shape change normal (Offermans et al. 1997, Ohlmann et al. 2000).

REFERENCES AND FURTHER READING

Offermans S, Toombs CF, Hu YH, Simon MI (1997) Defective platelet activation in G alpha(q)-deficient mice. Nature 389:183–186

Ohlmann P, Eckly A, Freund M et al (2000) ADP induces partial platelet aggregation without shape change and potentiates collagen-induced aggregation in the absence of Galphaq. Blood 96:2134–2139

G z (Member of the Gi Family of G Proteins)

Phenotype

Impaired platelet aggregation to epinephrine; resistance to fatal thromboembolism; exaggerated response to cocaine, reduced effect of morphine and antidepressant drugs (Yang et al. 2000).

REFERENCES AND FURTHER READING

Yang J, Wu J, Kowalska MA et al (2000) Loss of signaling through G protein, Gz, results in abnormal platelet activation and altered responses to psychoactive drugs. Proc Natl Acad Sci USA 97:9984–9989

Phospholipase C Gamma

Phenotype

Viable, fertile, decreased mature B cells; defective B cell and mast cell function; defective Fc_{gamma} receptor signaling, therefore, loss of collagen-induced platelet aggregation (Wang et al. 2000).

REFERENCES AND FURTHER READING

Wang D, Feng J, Wen R et al (2000) Phospholipase Cgamma2 is essential in the functions of B cell and several Fc receptors. Immunity 13:25–35

CD39 (Vascular Adenosine Triphosphate Diphosphohydrolase)

Phenotype

Viable, fertile; prolonged bleeding times but minimally perturbed coagulation parameters; reduced platelet interaction with injured mesenteric vasculature *in vivo*. Platelets fail to aggregate to standard agonists *in vitro* associated with purinergic P2Y1 receptor desensitization; fibrin deposition at multiple organ sites (Enjyoji et al. 1999).

REFERENCES AND FURTHER READING

Enjyoji K, Sevigny J, Lin Y et al (1999) Targeted disruption of cd39/ATP diphosphohydrolase results in disordered hemostasis and thromboregulation. Nat Med 5:1010–1017

Protein Kinase, cGMP-Dependent

Phenotype

Viable, fertile; unresponsive to cGMP and NO; defective VASP-phosphorylation; increased adhesion and aggregation of platelets *in vivo* in ischemic/reperfused mesenteric microcirculation; no compensation by cAMP kinase system (Massberg et al. 1999).

REFERENCES AND FURTHER READING

Massberg S, Sausbier M, Klatt P et al (1999) Increased adhesion and aggregation of platelets lacking cyclic guanosine 3′,5′-monophosphate kinase I. J Exp Med 189:1255–1264

Vasodilator-Stimulated Phosphoprotein (VASP)

Phenotype

Viable, fertile; mild platelet dysfunction with megakaryocyte hyperplasia, increased collagen/thrombin activation, impaired cyclic nucleotide mediated inhibition of platelet activation (Aszodi et al. 1999, Hauser et al. 1999).

REFERENCES AND FURTHER READING

Aszodi A, Pfeifer A, Ahmad M et al (1999) The vasodilator-stimulated phosphoprotein (VASP) is involved in cGMP- and cAMP-mediated inhibition of agonist-induced platelet aggregation, but is dispensable for smooth muscle function. EMBO J 18:37–48

Arachidonate 12-Lipoxygenase (P-12LO)

Phenotype

Platelets exhibit a selective hypersensitivity to ADP, manifested as a marked increase in slope and percent aggregation in *ex vivo* assays and increased mortality in an ADP-induced mouse model of thromboembolism (Chen et al. 1994, Johnson et al. 1998).

REFERENCES AND FURTHER READING

Arachidonate 5-Lipoxygenase (P-5LO)

Phenotype

Develop normally and are healthy. No difference in their reaction to endotoxin shock; however, they resist the lethal effects of shock induced by platelet-activating factor. Inflammation induced by arachidonic acid is markedly reduced (Chen et al. 1994, Johnson et al. 1998).

REFERENCES AND FURTHER READING

Thrombopoietin

Phenotype

TPO –/– and c-mpl –/–: both exhibit a 90% reduction in megakaryocyte and platelet levels, but even with these small platelet levels the mice do not have excessive bleeding; all platelets that are present are morphologically normal+functionally; *in vivo* TPO is required for control of megakaryocyte and platelet number but not for their maturation (Lawler et al. 1998).

REFERENCES AND FURTHER READING

B.7
Critical Issues in Experimental Models

B.7.1
The Use of Positive Control

Clearly, there are many antithrombotic agents that can be used to compare and contrast the antithrombotic efficacy and safety of novel agents. The classic antithrombotic agents are heparin, warfarin, and aspirin. However, new, more selective agents such as hirudin, low molecular weight heparins, and clopidogrel are commercially available that will either replace or augment these older treatments. Novel antithrombotic agents should certainly be demanded to demonstrate better efficacy than currently available therapy in animal models of thrombosis. This should be demonstrated by performing dose-response experiments that include maximally effective doses of each compound in the model. At the maximally effective dose, parameters such as APTT, PT, template bleeding time, or other, more sensitive measurements of systemic hypocoagulability or bleeding should be compared. A good example of this approach is a study by Schumacher et al. (1996), who compared the antithrombotic efficacy of argatroban and dalteparin in arterial and venous models of thrombosis. Consideration of potency and safety compared to other agents should be taken into account when advancing a drug through the testing funnel.

The early *in vivo* evaluation of compounds that demonstrate acceptable *in vitro* potency and selectivity requires evaluation of each compound alone in order to demonstrate antithrombotic efficacy. The antithrombotic landscape is becoming complicated by so many agents from which to choose that it will become increasingly difficult to design preclinical experiments that mimic the clinical setting in which polyantithrombotic therapy is required for optimal efficacy and safety. Consequently, secondary and tertiary preclinical experiments will need to be carefully designed in order to answer these specific, important questions.

B.7.2
Evaluation of Bleeding Tendency

Although the clinical relevance of animal models of thrombosis has been well-established in terms of efficacy, the preclinical tests for evaluating safety, i.e, bleeding tendency, have not been as predictable. The difficulty in predicting major bleeding, such as intracranial hemorrhage, resulting from antithrombotic or thrombolytic therapy stems from the complexity and lack of understanding of the mechanisms involved in this disorder. Predictors of anticoagulant-related intracranial hemorrhages are advanced age, hypertension, intensity and duration of treatment, head trauma, and prior neurologic disease (Stieg and Kase 1998, Sloan and Gore 1992). These risk factors are clearly difficult, if not impossible, to simulate in laboratory animals. Consequently, more general tests of anticoagulation and primary hemostasis have been employed.

Coagulation assays provide an index of the systemic hypocoagulability of the blood after administration of antithrombotic agents; however, as indicated earlier, the sensitivity and specificity of these assays varies from compound to compound, so these assays do not provide a consistent safety measure across all mechanisms of inhibition. Consequently, many laboratories have attempted to develop procedures that provide an indication of bleeding risk by evaluating primary hemostasis after generating controlled incisions in anesthetized animals. Some of the tests used in evaluating FXa inhibitors include template bleeding time, tail transection bleeding time, cuticle bleeding time, and evaluation of clinical parameters such as hemoglobin and hematocrit. Unfortunately, template bleeding tests, even when performed in humans, have not been good predictors of major bleeding events in clinical trials (Bernardi et al. 1993, Bick 1995, Rodgers and Levin 1990). However, these tests have been able to demonstrate relative advantages of certain mechanisms and agents over others. For example, hirudin, a direct thrombin inhibitor, appears to have a narrow therapeutic window when used as an adjunct to thrombolysis in clinical trials, producing unacceptable major bleeding when administered at 0.6 mg/kg, i.v. bolus, plus 0.2 mg/kg/hr (Antman et al. 1996, GUSTO Investigators 1996). When the dose of hirudin was adjusted to avoid major bleeding (0.1 mg/kg and 0.1 mg/kg/hr), no significant therapeutic advantage over heparin was observed. If the relative improvement in the ratio between efficacy and bleeding observed preclinically with Xa inhibitors compared to thrombin inhibitors such as hirudin is supported in future clinical trials, this will establish an important safety advantage for FXa inhibitors and provide valuable information for evaluating the safety of new antithrombotic agents in preclinical experiments.

B.7.3
Selection of Models Based on Species-Dependent Pharmacology/Physiology

As alluded to earlier, species selection for animal models of disease is often limited by the unique physiology of a particular disease target in different species or by the species specificity of the pharmacological agent for the target. For example, it was discovered relatively early in the development of platelet GPIIb/IIIa antagonists that these compounds were of limited use in rats (Cox et al. 1992) and that there was a dramatic species-dependent variation in the response of platelets to GPIIb/IIIa antagonists (Bostwick et al. 1996, Cook et al. 1993, Panzer-Knodle et al. 1993). This discovery lead to the widespread use of larger animals (particularly in dogs, whose platelet response to GPIIb/IIIa antagonists resembles humans) in the evaluation of GPIIb/IIIa antagonists. Of course the larger animals required more compound for evaluation, which created a resource problem for medicinal chemists. This was especially problematic for companies that generated compounds by combinatorial parallel synthetic chemistry in which many compounds can be made, but usually in very small quantities. However, some pharmacologists devised clever experiments that partially overcame this problem. Cook et al. (1996) administered a GPIIb/IIIa antagonist orally and intravenously to rats, and then mixed the platelet-rich plasma from the treated rats with platelet-rich plasma from untreated dogs. The mixture was then evaluated in an agonist-induced platelet aggregation assay and the resulting inhibition of canine platelet aggregation (rat platelets were relatively unresponsive to this GPIIb/IIIa antagonist) was due to the drug present in the plasma obtained from the rat. Using this method, only a small amount of drug is required to determine the relative bioavailability in rats. However, the animal models chosen for efficacy in that report (guinea pigs and dogs) were selected based on their favorable platelet response to the GPIIb/IIIa antagonist.

Similarly for inhibitors of FXa, there are significant variations in the activity of certain compounds against FXa purified from plasma of different species and in plasma-based clotting assays using plasma from different species. DX-9065 is much more potent against human FXa (Ki = 78 nM) than against rabbit (Ki = 102 nM) and rat (Ki = 1980 nM) FXa. Likewise, in the PT assay, DX-9065a was very potent in human plasma (concentration required to double PT, PTx2, was 0.52 μM) and in squirrel monkey plasma ($PT \times 2 = 0.46\,\mu M$), but was much less potent in rabbit, dog, and rat plasma ($PT \times 2 = 1.5$, 6.5, and 22.2 μM, respectively). Other FXa inhibitors have also demonstrated these species-dependent differences in activity (Tidwell et al. 1980, Nutt et al. 1991, Taniuchi et al. 1998). Regardless, the investigator must be aware of these differences so that appropriate human doses can be extrapolated from the laboratory animal studies.

Although in many cases the exact mechanism for the species-dependent differences in response to certain therapeutic agents remains unclear, these differences must be examined to determine the appropriate species to be used for preclinical pharmacological evaluation of each agent. This evaluation can routinely be performed by *in vitro* coagulation or platelet aggregation tests prior to evaluation in animal models.

B.7.4 Selection of Models Based on Pharmacokinetics

Much debate surrounds the issue as to which species most resembles humans in terms of gastrointestinal absorption, clearance, and metabolism of therapeutic agents. Differences in gastrointestinal anatomy, physiology, and biochemistry between humans and commonly used laboratory animals suggest that no single animal can precisely mimic the gastrointestinal characteristics of humans (Kararli 1995). Due to resource issues (mainly compound availability) and animal care and use considerations, small rodents, such as rats, are usually considered for primary *in vivo* evaluation of pharmacokinetics for novel agents. However, there is great reservation about moving a compound into clinical trials based on oral bioavailability data derived from rat experiments alone. Usually, larger animals such as dogs or non-human primates, which have similar gastrointestinal morphology compared to humans, are the next step in the evaluation of pharmacokinetics of new agents. The pharmacokinetic characteristics of FXa inhibitor, YM-60828, have been studied extensively in a variety of laboratory animals. YM-60828 demonstrated species-dependent pharmacokinetics, with oral bioavailability estimates of approximately 4%, 33%, 7%, and 20% in rats, guinea pigs, beagle dogs, and squirrel monkeys, respectively**.** Although these results suggest that YM-60828 has somewhat limited bioavailability, evaluating the pharmacokinetic profile of novel agents in a number of species (Sanderson et al. 1998) is a well-established approach used to aid in identifying compounds for advancement to human testing. That is, acceptable bioavailability in a number of species suggests that a compound will be bioavailable in humans. Which of the laboratory species adequately represents the bioavailability of a specific compound in humans can only be determined after appropriate pharmacokinetic evaluation in humans. Nevertheless, preclinical pharmacokinetic data are important in selecting the appropriate animal model for testing the antithrombotic efficacy of compounds because the ultimate proof-of-concept experiment is to demonstrate efficacy by the intended route of administration.

B.7.5 Clinical Relevance of Data Derived from Experimental Models

Animal models of thrombosis have played a crucial role in the discovery and development of a number of compounds that are now successfully being used for the treatment and prevention of thrombotic diseases. The influential preclinical results using novel antithrombotics in a variety of laboratory animal experiments are listed in Table 7 below, along with the early clinical trials and results for each compound. This table intentionally omits many compounds that were tested in animal models of thrombosis, but failed to be successful in clinical trials or, for other reasons, did not become approved drugs. However, these negative outcomes would not have been predicted by animal models of thrombosis because the failures were generally due to other shortcomings of the drugs (e.g, toxicity, narrow therapeutic window, or undesirable pharmacokinetics or pharmacodynamics) that are not always clearly presented in the scientific literature due to proprietary restrictions in this highly competitive field.

Nonetheless, it is clear that animal models have supplied valuable information for investigators responsible for evaluating these drugs in humans, providing pharmacodynamic, pharmacokinetic, and safety data that can be used to design safe and efficient clinical trials. For detailed applications see the following references: Bugge et al. (1995), Bugge et al. (1996), Carmeliet et al. (1993), Carmeliet et al. (1994), Carmeliet et al. (1996), Christie et al. C.1 Diuretic and Saluretic Activity

C.1.1 In Vitro Methods

C.1.1.1 Carbonic Anhydrase Inhibition In Vitro

PURPOSE AND RATIONALE

Acetazolamide (Diamox) was one of the first synthetic non-mercurial diuretics. The mode of action was found to be inhibition of carbonic anhydrase. Carbonic anhydrase is a zinc-containing enzyme that catalyzes the reversible hydration (or hydroxylation) of CO_2 to form H_2CO_3 which dissociates non-enzymatically into HCO_3^- and H^+. The enzyme is located within the cytoplasm and at the apical and basolateral membranes of proximal tubules as well as on the apical (lumenal) surface of distal tubules and in the thick ascending limb of the loop of Henle. Its primary function is to enhance H^+ secretion into the urine. At least three isoenzymes, designated as I, II and II or A, B and C, are known to exist..

Carbonic anhydrase inhibitors were originally used as diuretics but are no longer used for this purpose except in limited circumstances (metabolic alkalosis accompanied by edema). Chronic inhibition of carbonic anhydrase results in significant hypokalemia and metabolic acidosis due to bicarbonate wasting and thus inhibition of carbonic anhydrase may be mechanistically important if these effects are noted in *in vivo* studies or clinically (Okusa and Ellison, 2000). Numerous isoenzymes exist, of which CA II is the most abundant in proximal tubules and erythrocytes. The activity of carbonic anhydrase in erythrocytes is significantly higher than that in the kidney, and the enzyme is easily harvested by lysing mammalian whole blood. Thus, examination of the degree of inhibition of erythrocyte carbonic anhydrase may serve as a suitable surrogate for examination of effects on renal activity (Maren 1967; Armstrong et al. 1966).

In spite of the fact that newer diuretics are based on other modes of action, the test for inhibition of carbonic anhydrase should be performed for evaluation of a new compound. Moreover, the specific use of carbonic anhydrase inhibitors as antiglaucoma drugs has been described (Friedland and Maren 1984; Caprioli 1985). The mechanism by which carbonic anhydrase inhibitors lower intraocular pressure is through a reduction in aqueous humor formation, by affecting electrolyte and water balance in the nonpigmented ciliary epithelium (Friedland and Maren 1984; Caprioli 1985). Although many methods to measure carbonic anhydrase activity have been developed (Philpot and Philpot 1936), the micro method described by Maren (1960) is relatively simple, sensitive and reliable. The enzyme source are red cells, a rich source of the same isoenzymes found in the eye (Maren 1967; Armstrong et al. 1966; Wistrand et al. 1986; Wistrand and Knuutila 1980).

PROCEDURE

The analytical method is based on the catalysis of the conversion of CO_2 to H_2CO_3 by the enzyme, with resultig decrease in pH being monitored colorimetrically (Philpot and Philpot, 1936).

Materials and Solutions

- phenol red indicator solution: 12.5 mg phenol red/liter 2.6 mM $NaHCO_3$, pH 8.3 + 218 mM Na_2CO_3
- 1 M sodium carbonate/bicarbonate buffer, pH 9.8
- Enzyme: Carbonic anhydrase from dog blood; Blood is collected into a heparinized tube and diluted 1:100 with deionized water.
- Equipment
  - Reaction vessel – custom made by Labglass Inc., Vineland, NJ, USA
  - Monostat bench mounted flowmeter
  - 30% CO_2 – M& G Gases, Branchburg, NJ, USA

Assay

CO_2 flow rate is adjusted to 30 (45) ml/min. The following solutions are added to the reaction vessel:

400 µl phenol red indicator solution

100 µl enzyme

200 µl H_2O or appropriate drug concentration after 3 min for equilibration:

100 µl carbonate/bicarbonate buffer is added.

The following parameters are determined in duplicate samples:

T_u = (uncatalyzed time) = time for the color change to occur in the absence of enzyme.

T_e = (catalyzed time) = time for the color change to occur in the presence of the enzyme.

$T_u - T_e$ = enzyme rate

T_i = enzyme rate in the presence of various concentrations of inhibitor

EVALUATION

Percent inhibition of carbonic anhydrase is calculated according to the following formula:

$$\%\text{Inhibition} = 1 - \frac{(T_u - T_e) - (T_i - T_e)}{T_u - T_e} \times 100$$

Standard data:

- Compound IC_{50}[M]
- Acetazolamide 9.0×10^{-9}
- Chlorothiazide 9.0×10^{-7}

CRITICAL ASSESSMENT OF THE METHOD

Determination of carbonic anhydrase inhibition is of value to characterize the activity spectrum of sulfonamide diuretics.

MODIFICATIONS OF THE METHOD

Landolfi et al. (1997) reported a modified procedure for the measurement of carbonic anhydrase activity. The measure of carbonic anhydrase activity is based on the rate of CO_2 hydration by the enzyme. Such transformation was monitored by a procedure which consists in the measure of time necessary for the pH of an appropriate buffer to decrease from 8 to 7.5 in the presence of a constant CO_2 flow: such time period is dose-dependently reduced by the addition of the enzyme and further modified in the presence of carbonic anhydrase inhibitory compounds. The time required for a specific change in pH can be determined electrochemically as opposed to colorimetrically. This requires the use of a well-calibrated pH meter with a fast-reacting electrode. Activity is expressed in enzyme units, defined as a doubling of the time needed for the pH change in the absence of enzyme. These methods are much more sensitive than the colorimetric determination (Maren, 1960; Landolfi et al., 1997; Lukasi, 2005).

C.1.2 In Vivo Methods

C.1.2.1 Diuretic Activity in Rats (LIPSCHITZ Test)

PURPOSE AND RATIONALE

A method for testing diuretic activity in rats has been described by Lipschitz et al. (1943). The test is based on water and sodium excretion in test animals and compared to rats treated with a high dose of urea. The "Lipschitz-value" is the quotient between excretion by test animals and excretion by the urea control.

PROCEDURE

Male Wistar rats weighing 100–200 g are used. Three animals per group are placed in metabolic cages provided with a wire mesh bottom and a funnel to collect the urine. Stainless-steel sieves are placed in the funnel to retain feces and to allow the urine to pass. The rats are fed with standard diet (Altromin pellets) and water ad libitum. Fifteen hours prior to the experiment food and water are withdrawn. Three animals are placed in one metabolic cage. For screening procedures two groups of three animals are used for one dose of the test compound. The test compound is applied orally at a dose of 50 mg/kg in 5.0 ml water/kg body weight. Two groups of 3 animals receive orally 1 g/kg urea. Additionally, 5 ml of 0.9% NaCl solution per 100 g body weight are given by gavage. Urine excretion is recorded after 5 and after 24 h. The sodium content of the urine is determined by flame photometry. Active compounds are tested again with lower doses.

EVALUATION

Urine volume excreted per 100 g body weight is calculated for each group. Results are expressed as the "Lipschitz-value", i. e., the ratio T/U, in which T is the response of the test compound, and U, that of urea treatment. Indices of 1.0 and more are regarded as a positive effect. With potent diuretics, Lipschitz values of 2.0 and more can be found. Calculating this index for the 24 h excretion period as well as for 5 h indicates the duration of the diuretic effect. Similar to urine volume, quotients can be calculated for sodium excretion. Dose-response curves can be established using various doses. Loop diuretics are characterized by a steep dose-response curve. Saluretic drugs, like hydrochlorothiazide, show Lipschitz values around 1.8, whereas loop diuretics (or high ceiling diuretics) like furosemide, bumetanide or piretanide reach values of 4.0 and more.

CRITICAL ASSESSMENT OF THE METHOD

The Lipschitz test has been proven to be a standard method and a very useful tool for screening of potential diuretics.

MODIFICATIONS OF THE METHOD

The method has been modified in various ways by several authors. Cummings et al. (1960) recommended a sequential procedure with criteria for acceptance or rejection of test drugs. Kau et al. (1984) recommended a method for screening diuretic agents in the rat using normal saline (4% body weight) as hydrating fluid.

Homozygous Brattleboro rats exhibit symptoms of diabetes insipidus (Valtin et al. 1965). The condition is due to the failure of hypothalamic neurons to produce vasopressin, which is due to a single base point deletion in the vasopressin gene (Schmale and Richter 1984). The abnormal quinine drinking aversion in the Brattleboro rat with diabetes insipidus is reversed by a vasopressin agonist (Laycock et al. 1994).

These animals can be used to study vasopressin agonism and antagonism and the aquaretic effects of synthetic drugs.

Klatt et al. (1975) described a method of collecting urine excreted by cats. On the basis of urine funnel used in rats, an appropriate larger metabolism cage made out of transparent, rigid polyvinyl chloride was used. The cage was improved by a built-in sieve cone which assured good separation of urine and feces. A device to measure and record the time and amount of voided urine was attached. Urine was collected in a vessel with a hose connection from the bottom to a pressure sensor. An attached overflow tube could be occluded. The initial pressure of the sensor was fed into a linear recorder. Before the test, the recorder was calibrated with a sufficient amount of distilled water to adjust the number of division intervals for direct measurement of voided urine in milliliters. This allowed calculation of the time point of voiding from the chart speed.

C.1.2.2 Saluretic Activity in Rats

PURPOSE AND RATIONALE

Excretion of electrolytes is as important as the excretion of water for treatment of peripheral edema and ascites in congestive heart failure as well as for treatment of hypertension. Potassium loss has to be avoided. As a consequence, saluretic drugs and potassium-sparing diuretics were developed. The diuresis test in rats was modified in such a way that potassium and chloride as well as osmolality are determined in addition to water and sodium. Ratios between electrolytes can be calculated indicating carbonic anhydrase inhibition or a potassium sparing effect.

PROCEDURE

Male Wistar rats weighing 100–200 g fed with standard diet (Altromin pellets) and water ad libitum are used. Fifteen hours prior to the test, food but not water is withdrawn. Test compounds are applied in a dose of 50 mg/kg orally in 0.5 ml/100 g body weight starch suspension. Three animals are placed in one metabolic cage provided with a wire mesh bottom and a funnel to collect the urine. Two groups of 3 animals are used for each dose of a test drug. Urine excretion is registered every hour up to 5 h. The 5-h urine is analyzed by flame photometry for sodium and potassium and argentometrically by potentiometrical end point titration (Chloride-Titrator Aminco) for chloride. To evaluate compounds with prolonged effects the 24 h urine is collected and analyzed. Furosemide (25 mg/kg p.o.), hydrochlorothiazide (25 mg/kg p.o.), triamterene (50 mg/kg p.o.), or amiloride (50 mg/kg p.o.) are used as standards.

EVALUATION

- The sum of Na^+ and Cl^- excretion is calculated as parameter for saluretic activity.
- The ratio Na^+/K^+ is calculated for natriuretic activity. Values greater than 2.0 indicate a favorable natriuretic effect. Ratios greater than 10.0 indicate a potassium-sparing effect.
- The ratio

$$\frac{Cl^-}{Na^+ + K^+}$$

(ion quotient) is calculated to estimate carbonic anhydrase inhibition.
- Carbonic anhydrase inhibition can be excluded at ratios between 1.0 and 0.8. With decreasing ratios slight to strong carbonic anhydrase inhibition can be assumed.

MODIFICATIONS OF THE METHOD

Adrenalectomized rats treated with DOCA or aldosterone can be utilized to test **aldosterone antagonists**. Spironolactone has no effect in the absence of a mineralocorticoid, but reverses in a dose-related manner the effect of DOCA on the Na^+/K^+ ratio in the urine (Kagawa et al. 1957; Bicking et al. 1965).

C.1.2.3 Diuretic and Saluretic Activity in Dogs

PURPOSE AND RATIONALE

Dogs have been extensively used to study renal physiology and the action of diuretics. Renal physiology of the dog is claimed to be closer to man than that of rats. Oral absorbability of diuretic substances can appropriately be studied in dogs. Using catheters, interval collections of urine can be made with more reliability than in rats. Simultaneously, blood samples can be withdrawn to study pharmacokinetics.

PROCEDURE

Beagle dogs of either sex have to undergo intensive training to be accustomed to accept gavage feeding

and hourly catheterization without any resistance. The dogs are placed in metabolic cages. At least 4 dogs are used as controls receiving water only, as standard controls (1 g/kg urea p.o. or 5 mg/kg furosemide p.o.) or the test drug group. Twenty-four hours prior to the experiment food but not water is withheld. On the morning of the experiment, the urine bladder is emptied with a plastic catheter. The dogs receive 20 ml/kg body weight water by gavage, followed by hourly doses of 4 ml/kg body weight drinking water. The bladder is catheterized twice in an interval of 1 h and the urine collected for analysis of initial values. Then, the test compound or the standard is applied either orally or intravenously. Hourly catheterization is repeated over the next 6 h. Without further water dosage the animals are placed in metabolic cages overnight. Twenty-four hours after dosage of the test compound, the dogs are catheterized once more and this urine together with the urine collected over night in the metabolic cage registered. All urine samples are analyzed by flame photometry for sodium and potassium and by argentometry (Chloride Titrator Aminco) for chloride content. Furthermore, osmolality is measured with an Osmometer.

EVALUATION

Urine volume, electrolyte concentrations and osmolality are averaged for each group. The values are plotted against time to allow comparison with pretreatment values as well as with water controls and standards. The non-parametric U-test is used for statistical analysis.

C.2 Assessment of Renal Function

C.2.1 In Vitro Methods

C.2.1.1 Patch Clamp Technique in Kidney Cells[2]

PURPOSE AND RATIONALE

In the different parts of the kidney (proximal tubules, distal tubules, collecting ducts) fluid is reabsorbed and substances may be transported either from the tubule lumen to the blood side (reabsorption) or vice versa (secretion). Besides active transport and coupled transport systems, ion channels play an important role in the function of kidney cells. The various modes of the patch clamp technique (cell-attached, cell-excised, whole-cell mode) (Neher and Sakmann 1976; Hamill et al. 1981) allow the investigation of ion channels. In addition, the investigation of other electrogenic transport mechanisms, such as the sodium-coupled alanine transport can be studied.

PROCEDURE

The patch clamp technique can be applied to cultured kidney cells (Merot et al. 1988), to freshly isolated kidney cells (Hoyer and Gögelein 1991) or to cells of isolated perfused kidney tubules (Gögelein and Greger 1984). The latter method shall be described in more detail.

Segments of late superficial proximal tubules of rabbit kidney are dissected and perfused from one end with a perfusion system (Burg et al. 1966; Greger and Hampel 1981). The non-cannulated end of the tubule is freely accessible to a patch pipette. Under optical control (differential interference contrast optics with 400× magnification) the patch pipette can be moved through the open end into the tubule lumen and is brought in contact with the brush border membrane. After slight suction of the patch electrode, gigaseals form instantaneously and single potassium or sodium channels can be recorded in the cell-attached or inside-out cell-excised mode (Gögelein and Greger 1984; Gögelein and Greger 1986a).

In order to obtain exposed lateral cell membranes suitable to the application of the patch clamp method, pieces of the tubule are torn off by means of a glass pipette (diameter about 40 µm). As to facilitate the tearing off, the tubules are incubated for about 5 min in

[2] Contribution by H. Gögelein.

0.5 g/l collagenase (Sigma, C 2139) at room temperature. After tearing off part of the cannulated tubule, clean lateral cell membranes are exposed at the non-cannulated end. The patch pipette can be moved to the lateral cell membrane and gigaseals can be obtained. It was possible, to investigate potassium channels (Gögelein and Greger 1987) and nonselective cation channels (Gögelein and Greger 1986b) in these membranes.

As cells are still part of an epithelial layer and, therefore, are intracellularly coupled, the whole-cell technique is not appropriate in this preparation. On the other hand, cotransport systems can only be investigated by the whole-cell method because the transport rate of a single event is much too small to be resolved in a similar manner as single ion channel events. Consequently, cells of rabbit proximal tubules are isolated as described in detail elsewhere (Hoyer and Gögelein 1991; Heidrich and Dew 1977). After cervical dislocation the kidneys are rapidly excised and placed in ice-cold solution [mmol/l]: 150 K-cyclamate, 10 HEPES, 1 $CaCl_2$, 1 $MgCl_2$, pH 7.4. The following steps are performed on ice: After decapsulation, superficial cortical slices of about 0.5 mm thickness are dissected and minced with a scalpel. The tissue is homogenized in a Dounce homogenizer by three strokes with a loose-fitting pestle. The homogenate is then poured through graded sieves (250, 75 and 40 µm) to obtain a population of single cells. Since the predominant tubule section of the cortex of the rabbit kidney is the pars convoluta of the proximal tubule, it can be concluded that the majority of the isolated cells in the cell suspension are of proximal tubule origin. By light microscopy cells are identified by long microvilli distributed over the entire cell surface and can easily be discriminated from remaining erythrocytes, cell detritus and tubular fragments.

By application of the whole-cell mode of the patch clamp technique to freshly isolated cells of convoluted proximal tubules, the sodium-alanine cotransport system could be investigated in detail (Hoyer and Gögelein 1991).

EVALUATION

In isolated perfused renal tubules, concentration response curves of drugs which inhibit ion channels can be obtained with the patch clamp technique. In isolated cells of the proximal tubule, the whole-cell mode of the patch clamp technique enables the investigation of the sodium-alanine cotransport system. The apparent K_m values for sodium and L-alanine can be recorded.

MODIFICATIONS OF THE METHOD

Schlatter (1993) recorded membrane voltages of macula densa cells with the fast or slow whole-cell patch-clamp method. The effects of diuretics and the conductance properties of these cells were examined.

C.2.1.2 Perfusion of Isolated Kidney Tubules[3]

PURPOSE AND RATIONALE

The various tubule segments: proximal tubule (PT, S1–S3); descending thin limb of the loop of Henle (DTL); ascending thin limb of the loop of Henle (ATL); thick ascending limb of the loop of Henle (TAL); distal convoluted tubule (DCT); connecting tubule (CNT); cortical collecting duct (CCD); medullary collecting duct (MCD); papillary collecting duct (PCD) have different functional properties. The *in*

[3] Contribution by R. Greger (first edition) and M. Bleich (second edition).

vitro perfusion of isolated tubule segments (Burg et al. 1966) is the method of choice if one has to identify the site and the mechanism of action of a pharmacological agent which has been shown to act on kidney function in clearance and micropuncture studies.

PROCEDURE

After its invention by Burg et al. (1966) this technique has been used successfully in the kidney tubule segments of several species: man; rabbit; rat; mouse; hamster; snake; birds etc. The tubule segments are dissected from thin kidney slices (<1 mm thickness). Usually dissection can be done using sharpened forceps or needles without the addition of proteases (collagenase). The segment is identified by its anatomical location and by its appearance. A 20–50× lens is used for dissection. Dark field illumination is helpful for the identification of the segment under study. PT, TAL, DCT, CNT, CCD, MCD can all be dissected quite easily. The dissection of DTL, ATL and PCD is much more difficult because these segments are damaged easily by the mechanical dissection. Dissection is usually performed at 4°C in a Ringer type solution.

The dissected segment is transferred into the perfusion chamber by a transfer pipette. The perfusion chamber is mounted in the stage of an inverted microscope (20–400×). The chamber is usually kept at 37°C, and the bath perfusate is also preheated to this temperature. The bath perfusate will depend on the tubule segment under study. In most instances it will contain HCO_3^- and will be bubbled with CO_2. The metabolic substrate will be acetate for PT and D-glucose for TAL, CCD etc. The actual perfusion is performed with two sets of concentric glass pipettes, one set at the perfusion end; and one at the collection end of the segment. These pipettes are manufactured with special glass forges. The most refined one has been designed by Hampel and Greger. The glass tube is rotated at approximately 1 rps, is moved in perpendicular direction by a remote control, and the heating filament is moved in xy direction also by a remote control. The shaping of the glass is observed continuously by a lens (5–50×). The pulling force is provided by weights fixed on the lower end of the glass tube. The pipettes are cut either by a diamond or by the pulling force of a small glass bead, fixed on the edge of a vertical platinum filament and melted sidewise on the pipette. When the heating current of the platinum filament is switched off the filament retracts and brakes the pipette a the desired site. Greger and Hampel (1981) have modified the original perfusion system of Burg and co-workers. Their device is optimized inasmuch as it guarantees concentric alignment of the various pipettes. The forward and backward movement is controlled by small electric motors. At the perfusion side they use 4 concentric pipettes. The outermost one contains sylgard and is driven over the perfused end of the tubule in order to seal this end. The tubule is held by a holding pipette with appropriate dimensions. The tubule is sucked into this pipette up to the constriction. Then the perfusion pipette with a tip diameter smaller than the inner diameter of the perfused segment is advanced into the segment held by the holding pipette. The perfusion pipette is put under hydrostatic pressure of a few to 100 cm to achieve a perfusion rate of 1–20 nl/min. Usually the collapsed tubule lumen opens when the perfusion pipette is advanced. The pipette is advanced in the lumen until it reaches an area of the segment where it appears intact by inspection (200–400×). Within its lumen the perfusion pipette contains yet another pipette, the fluid exchange pipette. With this pipette the composition of the perfusate can be replaced very rapidly (Greger and Schlatter 1983). The collection end of the tubule segment is sucked into a holding pipette. A sylgard pipette is advanced to seal the collection site. The holding pipette at the collection site will contain mineral oil in flux measurements. Then a collection pipette is advanced through the oil to quantitatively collect the perfusate delivered by the tubule.

The **measured parameters** can be as follows:

Flux measurements (Schafer et al. 1974). The collection rate (V_c, nl/min) can be measured by the constant bore collection pipette by timed collections. Radioactive tracers can be added to the lumen or bath fluid. For instance, radioactively labelled inulin can be added to the perfusate (In_p) and can be used to measure volume absorption (ΔV = perfusion rate (V_i–V_c). Unidirectional fluxes, bath to lumen and lumen to bath, for any given substance can be quantified, and permeabilities (P_x) can be determined:

$$P_x = (V_i - V_c)L^{-1}[\ln(x_p In_c x_c^{-1} In_p) + 1]$$

where L is the length of the segment; x_p and x_c are the concentrations of x in the perfusate and in the collected fluid; and In_c is the inulin concentration in the collected fluid. Net fluxes of x can be determined as the difference of the unidirectional fluxes or by the chemical determination of Δx (perfusate–collected fluid). This requires very sensitive methods. Electron probe analysis of Na^+, K^+, Ca^{2+}, Mg^{2+} etc. has been used to determine the net transport of these ions in various tubule segments (Wittner et al. 1988). Flux studies are usually performed at low luminal perfusion rates of a few nl/min. Substances under study can be added

to the luminal and bath perfusate, and paired data can be obtained under control and experimental conditions (Burg and Green 1973; Stoner et al. 1974; Burg 1980; Burg and Stoner 1976; Dillingham et al. 1993).

Transepithelial electrical measurements. The perfusion pipette can be connected to the high impedance input of an electrometer. The voltage is referenced to the grounded bath. The connections are usually made with agar bridges (80 g agar in 1 l Ringer's solution), and appropriate corrections for liquid junction voltages must be applied. With identical solutions in the bath and in the lumen and with high luminal perfusion rates (> 10 nl/min), any transepithelial voltage (V_{te}) must be caused by active transport = active transport potential (Frömter 1984). Hence, the effectiveness of putative inhibitors of active transport can also be examined by the measurement of V_{te}. According to Ohm's law the determination of the flux of ions also requires the measurement of transepithelial resistance. Greger (1981) has introduced a method which utilizes a dual channel perfusion pipette, made of Q-shaped glass. One channel is used for perfusion and the other for current (I_{te}) injection. The current is defined by a resistor chosen such that the deflection in V_{te} generated by this pulse is in the order of 10–20 mV. Transepithelial resistance (R_{te}) can now be calculated from ΔV_{te} and I_{te}. The ratio of V_{te} and R_{te} is called equivalent short circuit current. It is directly proportional to active transport (Greger 1985). The measurement of V_{te} and R_{te} is much more efficient than flux studies for pharmacological screening, provided that the process under study produces a transepithelial voltage. Several substances can be examined in one single tubule in strictly paired fashion (Schlatter et al. 1983; Wangemann et al. 1986). The time resolution of the measurements is on the order of 1 s, whereas that of flux studies is several minutes at best.

Intracellular electrical measurements. Greger and Schlatter (1983) have developed a method for the use of impalement techniques in the isolated perfused tubule. Very fine tip microelectrodes (Ø < 100 nm) are used to impale the tubule cell across the basolateral membrane. The actual impalement is performed by a piezo stepper which accelerates the microelectrode to high speed, which makes it possible to penetrate the rigid basal membrane. The simultaneous measurement of V_{te}, R_{te}, and basolateral membrane voltage (V_{bl}) allows for a complete analysis of voltages and resistances (Greger 1985; Ullrich and Greger 1985). Ion selective microelectrodes can also be used in impalement studies, and the cytosolic ion activities for e. g. Na^+, K^+, Cl^- can also be determined (Greger 1985). These methods are all rather difficult to perform. They are of high relevance for the understanding of the function of a given tubule segment and for the detailed description of the mechanism of action of a drug, which, in preceding studies has been shown to act in a given tubule segment.

Patch clamp studies. The combination of *in vitro* perfusion of renal tubules and patch clamp analysis of ion channels in the luminal and basolateral membranes is described in Sect. C.2.1.1.

Fluorescent dyes in the isolated perfused tubule. Several fluorescent dyes for the monitoring of Na^+, K^+, Cl^-, Ca^{2+}, pH have become available during the past few years. These dyes can be used in the *in vitro* perfused tubule (Nitschke et al. 1991). The inverted microscope is equipped with an appropriate illumination and filter wheel for excitation. The emission is measured by photon counting or by a video camera. When compared with impalement methods, these techniques are probably easier for routine use.

EVALUATION

For each of the above protocols paired measurements of one or several given parameters of tubule transport are obtained under control conditions and in the presence of a substance under study. Also concentration response curves can be obtained in one single preparation (Schlatter et al. 1983; Wangemann et al. 1986; Wittner et al. 1987). Intracellular measurements are usually required to define the mechanism of action (Greger 1985). Especially the electrical and optical measurements have a very high reproducibility. For screening usually 3 preparations are sufficient. Approximately 10 preparations are required for concentration response curves.

C.2.1.3 Isolated Perfused Kidney

PURPOSE AND RATIONALE

Isolated kidney is a good tool for studying proximal tubule, but of limited value for distal tubule function. The kidney can be perfused *in situ* and isolated *in vitro*. The isolated kidney can be perfused by a pump using blood or plasma-like solutions. One specific problem of the blood-perfused dog kidney *in vitro* is its instability. After only 1 h of perfusion, glomerular filtration and renal blood flow decline markedly. It was reported that *in situ*-perfused isolated dog kidney seems to be more stable. In isolated perfused rat kidney plasma-like solutions are used for perfusion. This system, by inclusion of a dialyzing unit, provides optimal conditions for maintaining a constant electrolyte composition of the perfusate. However, function of distal tubule is also grossly impaired in this rat model. The isolated kidney does not acidify tubular fluid, and the concentrating ability is reduced.

PROCEDURE

Kidneys are obtained from anaesthetized male rats with a body weight of 300 to 400 g. The donor animals are fasted overnight prior to surgery, but have free access to water. After the abdominal cavity is exposed by a ventricular incision, the right ureter is cannulated with PE-50 polyethylene tubing and heparin is injected into the vena cava (500 U/kg body weight). The venous cannula is introduced into the vena cava below the right renal vein. The right kidney is freed from the perirenal fat, not disrupting the renal capsule. The renal artery is cannulated via the superior mesenteric artery without interruption of flow. Thereafter, the kidney is continuously perfused with a perfusion solution fed from the gravity system situated 130 cm above the cannula. Ligatures around the renal artery and vena cava above the renal pedicle are tied. The kidney is then removed from the animal and placed in a Plexiglas chamber. A perfusion pressure of 80–90 mm Hg in the renal artery is maintained by adjusting the speed of the perfusion pump. For more details see references.

EVALUATION

After the equilibration period, clearance periods of 20 min are used. Urine samples are collected and perfusate is obtained at midpoint of the clearance period for the evaluation of overall kidney function. For determination of glomerular filtration rate (GFR) and fluid transport, ^{3}H-labelled polyethylene glycol is added to a modified Krebs-Henseleit bicarbonate buffer. Electrolytes are determined in urine by standard flame photometry. Fractional excretions of water, electrolytes and test compounds are calculated.

LIMITATIONS OF THE METHOD

Isolated perfused dog kidneys have been reported to be less stable than those of other species, with glomerular filtration and renal flow markedly decreasing after only one hour of perfusion. The *in situ*-perfused isolated dog kidney seems to be more stable. Distal tubule functions are impaired in isolated perfused kidneys in all species. Urine acidification, concentration and dilution functions are also abnormal, and effects on these cannot be assessed in these models (Kirkpatrick and Gandolfi 2005).

MODIFICATIONS OF THE METHOD

Tarako et al. (1991) evaluated oxygen supply and energy state in the isolated perfused rat kidney.

Metabolic activities of the isolated perfused rat kidney were described by Nishiitsutsuji-Uwo et al. (1967).

Cox et al. (1990) used the isolated perfused rat kidney as a tool in the investigation of renal handling and effects of nonsteroidal anti-inflammatory drugs.

C.2.2 In Vivo Methods

C.2.2.1 Clearance Methods

PURPOSE AND RATIONALE

Investigations of clearance represent indirect methods for the evaluation of renal function and provide information on the site of action of diuretics and other pharmacological agents within the nephron. The discovery of the countercurrent multiplier system as the mechanism responsible for the concentration and dilution of the urine has been the prerequisite for the identification of the site of action of diuretic drugs. A drug that acts solely in the proximal convoluted tubule, by causing the delivery of the increased amounts of filtrate to the loop of Henle and the distal convolution, would augment the clearance of solute-free water (C_{H2O}) during water diuresis and the reabsorption of solute-free water (T_{CH2O}) during water restriction. In contrast, drugs that inhibit sodium reabsorption in Henle's loop would impair both C_{H2O} and T_{CH2O}. On the other hand, drugs that act only in the distal tubule would reduce C_{H2O} but not T_{CH2O}.

PROCEDURE

Clearance experiments are performed either in conscious or anaesthetized beagle dogs under conditions of water diuresis and hydropenia. The status of water diuresis and hydropenia may be accomplished as described by Suki et al. (1965). Water diuresis is induced by oral administration of 50 ml of water per kg body weight and maintained by continuos infusion into jugular vein of 2.5% glucose solution and 0.58% NaCl solution at 0.5 ml/min per kg body weight. When water diuresis is well established, the glucose infusion is discontinued and control urine samples are collected by urethral catheter. Blood samples are obtained in the middle of each clearance period. After the control period, compounds to be tested are administered and further clearance tests are performed.

Hydropenia is induced by withdrawing the drinking water 48 h before experiment. On the day before the experiment 0.5 U/kg body weight of vasopressin in oil is injected intramuscularly. On the day of the experiment 20 mU/kg vasopressin is injected i.v., followed by infusion of 50 mU/kg per hour vasopressin. To accomplish constant urine flow 5% NaCl solution is infused at 1 ml/min per kg body weight up to i.v. administration of a compound to be tested, followed by i.v. infusion of 0.9% NaCl solution at a rate equal to the urine flow. Glomerular filtration rate (GFR) and renal plasma flow (RPF) are measured by the clearance of inulin and para-aminohippurate, respectively. Therefore, appropriate infusion of inulin (bolus of 0.08 g/kg followed by infusion of 1.5 mg/kg per min) and para-aminohippurate (bolus 0.04 g/kg followed by infusion of 0.3 mg/kg per min) are initiated. Inulin and para-aminohippurate are measured according to Walser et al. (1955) and Smith and al (1945), respectively.

Tracers are administered intravenously to achieve near steady-state concentrations; a priming dose loads the plasma and extracellular compartments, and subsequent infusion replaces renal losses. Once steady state plasma tracer levels are approached, a series of timed urine collections (clearance periods) are performed, with blood samples collected at the either the midpoint or beginning and end of the clearance periods. The urine and blood (plasma or serum) samples are analyzed for tracer(s) and the test compound.

Tracers for the determination of GFR must be freely filtered and then neither secreted nor reabsorbed. This allows the assumption that the amount of plasma cleared of the tracer per unit time represents that which has been filtered through the glomeruli (i.e., GFR). The fructose polysaccharide, inulin (mw ~5200) is the most commonly used tracer in all species and serves as the 'gold standard' to which others are compared (Finco 1983; Ragan and Weller, 1999). Other indicators include isotopes of vitamin B_{12}, sodium iodothalamate, iohexol and radiolabelled metal chelates of ethylenediamintetracetate (EDTA) and diethylaminotriaminepentaacetate (DPTA) (Sarkar et al. 1988, 1991; Gaspari et al. 1997; Ragan and Weller 1999).

Tracers for the assessment of renal plasma flow must be completely cleared (combination of filtration and efficient tubular secretion to the urine) on first pass through the kidney. This allows the assumption that the volume of plasma cleared per unit time represents that which was either filtered by the glomeruli or bypassed the glomeruli and perfused the tubules. *p*-aminohippurate (PAH) is used for the assessment of RPF, because it is both freely filtered by the glomeruli and actively secreted by the organic acid transport pathway of the proximal tubule. First-pass PAH extraction by the kidneys varies from about 70% to 90% in rats, dogs, and humans (Brenner et al. 1976), but for the purpose of estimating RBF it is assumed to be 100%. Using this assumption, RPF is always slightly underestimated. Tetraethylammonium bromide (TEA), a substrate for the renal cation transporter, may also be used, and is subject to the same limitations (Ragan and Weller 1999).

Inulin is measured colorimetrically, either by acid hydrolysis to generate a green product, or by a series of enzymatic reactions based on inulinase with subsequent reduction of NADH. HPLC methods are used for the remaining exogenous GFR tracers. PAH and TEA are measured colorimetrically (Newman and Price 1999).

EVALUATION

Renal clearance (Cl) of any compound (X) can be determined by comparing the urinary excretion rate of compound X to the plasma concentration of compound X.

The urinary excretion rate is calculated as:

$$\text{Urinary excretion rate (mg/min)} = U_x\text{(mg/ml)} \times V\text{(ml/min)}$$

Where U_x represents the concentration of substance X in urine (in mg/ml) and V represents the volume of urine collected per unit time (in ml/min). Thus, the clearance equation may be constructed:

$$Cl_x\text{(ml/minute)} = U_x\text{(mg/ml)} \times V\text{(ml/min)}/P_x\text{(mg/ml)}$$

Where P_x is the concentration of compound X in plasma (in mg/ml)

GFR is estimated by calculating the clearance of the tracer or endogenous substance. RPF estimated using PAH clearance is often designated effective renal plasma flow (ERPF). Renal plasma flow is converted to renal blood flow (RBF) by dividing ERPF by the plasma fraction of whole blood, as estimated from the hematocrit (Hct):

$$RBF = ERPF/(1 - Hct)$$

The clearances of other compounds can be compared with inulin clearances to determine how the kidney functions in the elimination of the test compound. A clearance ratio is constructed by dividing the renal clearance of the test compound (X) by the renal clearance of inulin:

$$\text{Clearance Ratio} = CL_x,\ \text{(ml/min)}/Cl_{inulin},\ \text{(ml/min)}$$

A clearance ratio < 1.0 indicates reabsorption of the test substance following filtration, whereas active secretion will result in a clearance ratio of > 1.0.

MODIFICATIONS OF THE METHOD

Endogenous compounds can administered exogenously in place of tracer substances. This has been done for the dog using creatinine (Sapirstein et al. 1955; Finco et al. 2001) and for the rat using cystatin C (Tenstad et al. 1996). Either urine or plasma clearance methods can be used for the former. For the latter, plasma clearance was used to estimate GFR due to the fact that cystatin C is reabsorbed and degraded by the proximal tubule and does not appear in the urine.

Rönnhedh et al. (1996) described a simple method to perform serial renal clearance studies without urine collection in rats. This was applied to non-radiolabeled para-aminohippurate sodium and iothalamate sodium which were used respectively to estimate renal blood flow and glomerular filtration rate.

Gabel et al. (1996) described fast and accurate assays for measuring glomerular filtration rate and effective renal blood flow in conscious rats. An enzymatic method was developed for the determination of inulin

and a colorimetric method was developed for determination of p-aminohippurate in the plasma and urine of rats.

Hropot et al. (1985) described clearance methods in monkeys. Chimpanzees weighing 30.7 ± 10.6 kg were anesthetized with 1 mg/kg Sernylan i.m. Food was withdrawn 24 h prior to the experiment and the animals received only tap water ad libitum. In the morning before the experiment, the urinary bladder of the animals was emptied by catheterization. The urine was discarded. To determine the glomerular filtration rate (inulin clearance), a bolus injection of 50 mg/kg inulin i.v. was given and followed by a continuous infusion of 3 ml/min inulin dissolved in Ringer lactate solution. After an equilibrium of 60 min, urine and blood samples were collected for two control clearance periods of 30 min each. The control periods were followed by intravenous administration of the test preparation in a dose of 20 mg/kg. Thereafter, urine and blood samples were collected during 6 clearance periods. The following parameters were determined: urine excretion, inulin clearance and urate clearance [ml/kg/min], fractional excretion of urate and plasma urate [mmol/l].

Tanaka et al. (1990) evaluated uricosuric and diuretic properties of diuretic agents using clearance studies in urate-loaded dogs and urate-loaded rabbits.

LIMITATIONS OF THE METHOD

First-pass extraction of PAH is highly variable both between species and between individuals within a species, which adds to the inherent inaccuracy of the estimate of RBF by this method. Furthermore, the test compound may interfere with the extraction of either PAH or TEA by competing for transport by the organic anion or cation transporters (Newman and Price, 1999; Ragan and Weller, 1999).

The limitations of the Jaffe method for creatinine determination have been discussed in section 1.1.1. Exogenous creatinine clearance compensates for the insensitivity of the method as well as the interference by endogenous chromagens by artificially increasing the plasma creatinine concentration (Finco 1997).

C.2.2.2
Assessment of Glomerular Filtration Rate (GFR) and Renal Blood Flow (RBF)

C.2.2.2.1
Assessment of GFR by Plasma Chemistry

PURPOSE AND RATIONALE

Estimation of the glomerular filtration rate (GFR) is considered a sensitive index of functional nephron

mass (Newman and Price, 1999). Point measurements of the plasma levels of several endogenous small molecules (urea, creatinine, 2-(a-mannopyranosyl)-L-tryptophan) or small (less than 66 kDa) proteins (cystatin C (γ-trace), prostaglandin D synthase (β-trace protein), α_1-microglobulin, β_2-microglobulin, and retinol binding protein) have been used to assess GFR in many species.

PROCEDURE

Serum or plasma samples are collected from the test animals (if plasma is used, blood should be collected in heparinized tubes). Assay methods vary, and are outlined below:

Urea is most commonly assayed by combined urease methods, in which the urea is first converted to two ammonium ions. The ammonium generated is then measured by either enzymatic or chemical methods. Urea nitrogen values determined by this method (mg/ml) are converted to urea values by the use of appropriate factors (2.14 for urea in mg/ml, 0.357 for urea in mmol/L) (Emeigh Hart and Kinter 2005).

Creatinine is most commonly measured by the Jaffe reaction of creatinine with picrate to generate an orange chromogen. Several enzymatic assays (based on reactions with creatinase or creatinine deaminase) have also been developed. These are equal in sensitivity to the Jaffe method but are considered less likely to be subject to interference by endogenous or exogenous chromogens (Finco et al. 1995; Finco 1997; Newman and Price, 1999). Chromatography (HPLC or LC-MS/MS) assay methods are more sensitive than the Jaffe method and are not subject to interference by endogenous chromagens (Dunn et al. 2004; Owen and Keevil, 2007).

2-(a-mannopyranosyl)-L-tryptophan (MPT) is measured by HPLC (Takahira et al. 2001). Cystatin C assays are all antibody based (nephelometric, agglutination or sandwich ELISA) (Pergande and Jung, 1993; Finney et al. 1997; Jensen et al. 2001), and have been used successfully in dogs, rats, mice and cats (Hakansson et al. 1996; Boekenkamp et al. 2001; Braun et al. 2002; Martin et al. 2002). The other small molecular weight proteins are detected by immunoassays as well.

EVALUATION

Analyte levels are compared either to those of a concomitant control group (using appropriate statistical methods of the group size is large enough) or to laboratory-specific reference intervals for the species, strain, age and sex in question. Elevation of analyte levels outside of the reference range indicate a decrease in GFR, with the magnitude of the elevation being roughly proportional to the degree of the decrement.

Additionally, algorithms can be used to convert plasma creatinine to creatinine clearance, which provides a reasonably accurate estimate of GFR in humans (Cockroft and Gault, 1976):

$$\text{GFR} \approx (140 - \text{age}) \times \text{weight (kg)} \times K72 \times \text{Serum creatinine (mg/dL)}$$

Where $K = 0.85$ for women, 1.00 for men

A similar algorithm has been generated for dogs of either gender (Finco et al., 1995):

$$\text{GFR} \approx 2.6/\text{Serum creatinine (mg/dL)}$$

LIMITATIONS OF THE METHOD

Effects on prerenal (dehydration, blood loss, altered vasomotor tone, age-related decreases in renal blood flow in rats) and/or postrenal factors (obstruction or extravasation of urine to the peritoneal cavity) may cause elevations of the commonly measured analytes that do not reflect effects on the GFR or loss of functional nephron mass (Baum et al. 1975; Corman and Michel, 1987; Finco, 1997; Newmann and Price, 1999).

Urea and creatinine elevations in plasma are in general not sensitive enough to detect low-level alterations (less than 75% loss) of GFR, due to the contribution of renal secretion and/or reabsorption to their overall excretion, (which can compensate for their decreased filtration), to wide variations in baseline levels of some analytes, and to inherent imprecision in the assays used (Finn and Porter, 1998; Price, 2002; Starr et al. 2002; Shemesh et al. 1985). In particular, urea will underestimate GFR (due to extensive tubular reabsorption with decreased GFR) (Baum et al., 1975; Kaplan and Kohn, 1992; Newman and Price, 1999), and creatinine tends to overestimate GFR (because it is secreted by the tubule in many species and secretion increases with reduced GFR) (Shemesh et al. 1985; Andreev et al. 1999; Newman and Price, 1999; Star et al. 2002). In addition, creatinine synthesis is regulated by feedback inhibition which limits the degree of elevation than can occur in plasma (Watson et al. 2002).

The Jaffe reaction for creatinine is subject to interference by numerous endogenous substrates and drugs or compounds (Schwendenwein and Gabler, 2001; Sonntag and Scholer, 2001; Dunn et al. 2004). This effect can be minimized by using appropriate substrate extraction or by the use of kinetic assessments. The urease assay is specific for urea, but increased circulating ammonia (such as occurs in aged plasma samples,

metabolic disorders and portocaval shunting) will react with the subsequent reaction and result in falsely elevated plasma levels (Newman and Price, 1999).

Baseline levels of urea and creatinine are variable, as they are subject to influences on their extrarenal synthesis and release. Plasma urea reflects hepatic synthesis rate and will be elevated with increased protein catabolism (increased dietary protein intake, gastrointestinal hemorrhage, fever, severe burns, corticosteroid administration, sustained exercise or muscle wasting), and decreased with low or poor quality protein diets, modest food restriction in rodents or hepatic insufficiency (Pickering and Pickering, 1984; Finco 1997; Hamberg, 1997; Tauson and Wamberg, 1998; Newman and Price, 1999). Baseline creatinine reflects muscle catabolism and will be elevated in individuals with higher muscle mass or following sustained exercise or acute muscle damage; it will be lower in individuals with loss of muscle mass (Finco, 1997; Newman and Price, 1999). Drugs which compete with creatinine for renal excretion may falsely elevate plasma levels in the absence of renal injury (Andeev et al. 1999).

2-(a-mannopyranosyl)-L-tryptophan (MPT) appears to be less likely to be affected by muscle mass than creatinine. Point-in-time measurements of this tryptophan glycoconjugate correlated extremely well with the inulin clearance, suggesting it may be a superior indicator of GFR. However, the renal handling of MPT has not been examined to determine if plasma levels may be influenced by either reabsorption or secretion (Horiuchi et al. 1994; Gutsche et al. 1999; Takahira et al. 2001).

Pitt et al. (2006) reported the pharmacological profile and toxicity of fluorescein-labelled sinsitrin, a novel marker for GFR measurements.

Cystatin C does not appear to be a sensitive index of GFR in the cat (Martin et al. 2002).

The other small protein markers of GFR are detected by immunoassays with reagents specific for the human proteins; the cross-reactivity of these reagents with other species and the usefulness of these markers in animal models have not been well established (Loeb, 1998).

C.2.2.2.2 Assessment of RBF by Intravascular Doppler Flow Probes

PURPOSE AND RATIONALE

Probes utilizing electromagnetic or Doppler technology may be positioned around or within a renal artery to allow direct measurement of renal blood flow (Yagil 1990; Haywood et al. 1981). Detection of blood flow using Doppler systems is based on changes in the emitted ultrasonic frequency, a Doppler shift, caused by reflection of the signal of moving blood cells. The Doppler shift is proportional to the velocity of blood flow, as indicated by the following equation:

$$\Delta f = \frac{2 f_0 v \cos\theta}{c}$$

Where Δf = Doppler peak frequency shift, f_0 = transmission frequency, v = instantaneous peak velocity, θ = angle of incidence of the beam to the bloodstream (assumed to be 0^o for linear probes) and c = speed of sound in blood (1570 m/sec) (Chilian et al. 1982).

This technique is particularly useful when rapid or continuous assessment of effects on renal blood flow or assessment of renal vasoreactivity need to be assessed.

PROCEDURE

Doppler probes have been applied to rats, rabbits, cats, dogs, pigs, monkeys and humans; these must be appropriately calibrated prior to experimental use. Animals are anesthetized and the probes are placed within the renal artery via the abdominal aorta, which may be accessed via the femoral or carotid arteries. The diameter of the renal artery at the placement site of the Doppler probe must be determined simultaneously to correct velocity measurements for determination of renal blood flow (see Evaluation).

EVALUATION

A number of parameters can be derived from the Doppler measurements, most commonly including average peak velocity (APV), pulsatility index (PI) and resistive index (RI). Renal blood flow (in mL/min) can be calculated as follows:

$$\mathrm{RBF} = \frac{\mathrm{APV} \times \pi \times \mathrm{D}^2 \times 60}{4}$$

Where D = renal arterial diameter (Doucette et al. 1992).

Resistive index (RI) has been shown in several species to be positively correlated with tubular disfunction or postrenal obstruction and its return to normal may serve as a prognostic indicator of resolution of tubular disease (Rivers et al. 1997; Shokeir et al. 1996; Tsuji and Taira, 2001).

LIMITATIONS OF THE METHOD

Dopper probe assessment of velocity is accurate primarily in straight blood vessels of small diameter (< 4.76 mm) and at relatively low flow rates (< 200 mL/min), both of which may be exceeded in normal renal arteries in many species (Lerman and Rodriguez-Porcel, 2001).

In dogs, acute, severe normovolaemic anaemia significantly altered renal artery Doppler parameters without having an influence on Doppler assessment of splanchnic blood flow; the technique may thus be inaccurate in anemic animals (Koma et al., 2006). Furthermore, it is invasive and the size of the test species to which it can be applied depends on the availability of appropriately sized and calibrated probes (Lerman and Rodriguez-Porcel 2001).

C.2.2.2.3 Assessment of GFR and RBF by Scintigraphic Imaging

PURPOSE AND RATIONALE

Radioactive indicators (^{99c}Tc-DPTA, ^{113m}In-DPTA, ^{99c}Tc-mercaptoacetyltriglycine) may be used to measure renal blood or plasma flows or glomerular filtration rate (Reba et al. 1968). These techniques require intraarterial or intravenous administration of the tracer followed by monitoring of the amount of tracer in the kidneys with an external gamma camera (Fommei and Volterrani 1995).

In species where extrarenal clearance of tracers used in the determination of GFR or RPF is high or variable, external detection methods may actually be more accurate than plasma clearance methods because the extrarenal component of plasma removal is elminated (Drost et al. 2003).

PROCEDURE

The selected radiotracer is injected either intravenously or intraarterially. External measurements of radioactivity retained in the kidney are made either at timed intervals (rate of accumulation, or slope method) or at a selected interval, usually corresponding to either first pass or peak level of the tracer (percent accumulation, or integral method) (Kampa et al. 2002).

LIMITATIONS OF THE METHOD

These techniques do not yield absolute flow, but rather flow per unit volume or tissue mass. However, algorithms can be developed in the species of interest to allow conversion of tissue uptake to GFR or RBF expressed in standard units by simultaneous determination of plasma clearance of the tracer in preliminary experiments (Kelleher et al. 1991; Kampa et al. 2003), as the correlations between methods for any given tracer are in general high (Delpassand et al. 2000).

In general, assessment of GFR or RBF by external detection methods is less accurate than assessment by clearance methods, although the correction algorithm used for the external detection method can influence the degree of accuracy achievable (DeSanto et al. 1993; Itoh et al. 2000; Itoh, 2003). Integral methods (calculated based on the percent of the dose accumulated) are in general more accurate because they eliminate variability resulting from variable durations of the uptake phase (Kampa et al. 2003). Manual selection of the region of interest (ROI) for the collection of the scintigraphy data also improves the accuracy (Kampa et al. 2002).

MODIFICATIONS OF THE METHOD

Depending on the tracer used, either GFR or RBF can be estimated from the results. The table below lists different tracers that can be used for the assessment of either GFR or RBF (Emeigh Hart and Kinter, 2005):

C.2.2.3 Assessment of Renal Tubule Functions

C.2.2.3.1 Urinalysis

PURPOSE AND RATIONALE

More than 99% of the reabsorption of glucose, protein and electrolytes occurs in the proximal tubule. Electolyte concentrations can be affected by other tubule segments, but even low-level changes in proximal tubular function will be reflected by increased urinary excretion of protein and glucose (Stonard et al. 1987; Finco, 1997; Loeb and Quimby, 1999; Newman and Price, 1999; Aleo et al. 2002). Standard and modified urinalysis techniques can be successfully used to assess the effects of compounds on proximal tubule uptake processes (Katsuno et al. 2007).

PROCEDURE

Collection of a good quality sample from the test species is paramount to obtaining high quality data from the urinalysis. Samples must be collected in clean containers and must be kept free of contamination from food, drinking water, feces, blood and bacteria. For best results, samples should be analyzed promptly (ideally within one hour) after collection, but where analysis must be delayed, the sample must be protected from chemical degradation and evaporation, best accomplished by using collection containers that are appropriately sized for the species in question, tightly sealing the containers when possible, and keeping the specimen cold (4°C) until analysis. If chilled or frozen, samples must be allowed to slowly equilibrate to room temperature before analysis.

Point-in-time samples can easily be collected from most species, either by free-catch, urethral catheterization, manual compression of the bladder or cystocentesis (withdrawal of urine from directly from the bladder with a needle and syringe). Catheterization may require sedation or anesthesia, especially in females of all species and in male pigs whose urethral recess makes this process difficult (Van Metre and Angelos, 1999). Manual compression of the bladder can also be performed on rodents, and cystocentesis may also be performed by a skilled operator using a small (25 gauge) needle and syringe (Loeb and Quimby, 1999).

Timed urine collections in all species (including large animals) can also be obtained by the use of specially designed metabolism cages. A metabolism cage consists of an animal chamber mounted above an excrement collection system. The animal chamber must be equipped with feeder and waterer units if an animal is to be housed in the metabolism cage for more than a few hours. These need to be sized appropriately to the test species of interest (especially regarding the collection container, which must minimize surface

area available for evaporation) and designed to eliminate contamination of the urine by food, drinking water, or feces. In selecting the size of the collection container, the anticipated urine volume should be considered: a mouse will produce 0.25–1 ml in 24 hours of urine, a rat, 10 ml, a hamster, 5–8 ml, a rabbit, 600 ml and a dog or minipig, 500 ml or more (Loeb, 1998; McClure, 1999; Van Metre and Angelos, 1999). Whatever type of metabolism cage is used, the following general precautions are offered:

1. For studies of >24 hours duration, test animals should be acclimated to the metabolism cage for several days prior to study initiation. During this period, animals should be monitored frequently to insure that they learn to use the feeder and waterer systems properly. Test animals should be maintaining or gaining weight prior to study initiation.
2. Feeder and waterer systems should provide ample food and water to meet the animal's needs for the duration of urine collection and all separator systems should function properly. For chronic studies (>5–7 days duration) it is useful to have a complete exchange of feeder, waterer, and urine/feces collector and separator systems so that soiled units may be rapidly exchanged with clean, dry/filled units at regular intervals.
3. Cages should be decontaminated, cleaned, rinsed with distilled/deionized water, and thoroughly dried prior to use. Surfaces used to collect urine may be siliconized or sprayed with a suitable hydrophobic material (PAM, General Foods) to facilitate urine collection.
4. All surfaces contacting urine should be rinsed with distilled/deionized water or appropriate solvents to collect any residuals at appropriate intervals.
5. To preserve the quality of the specimens during prolonged collection times, the opening of the collection vial needs to be small to prevent evaporation and the vial should be surrounded either with wet ice or frozen cold packs to chill the sample promptly once it is deposited (Loeb, 1998; Loeb and Quimby, 1999). Urine may also be collected under mineral oil to prevent evaporative losses. For very small or antidiuretic animals (eg. hamsters, gerbils) placing the cage over a shallow pan of oil and skim feces from the surface may be necessary while collecting urine with a pipette from under the oil. To maximize the volume of the sample collected in rodents in metabolism cages, food should be withheld (this also reduces the risk of contamination of the sample) and water provided (Lee et al. 1998).

Routine urinalysis consists of visual assessment (color, clarity), volume, specific gravity or osmolality, pH, and quantitative or semiquantitative determination of total protein and glucose and microscopic evaluation of urine sediment (Weingand et al., 1996). Urine constituents can be measured semiquantitatively using commercially available "dipstick" test strips (Chemstrips, Roche Diagnostics or Multistix, Bayer Heath Care Diagnostics) which contain reagents for the determination of specific gravity, protein, glucose, ketones, bilirubin, urobilinogen, hemoglobin, nitrite and leukocyte esterases (Newman and Price, 1999). These strips may be read manually or using automated analyzers specific to each product.

If quantitative assessment of urine analytes is required (see under "Evaluation"), either urine volume or urine creatinine concentration must be measured and used to "normalize" the concentration of the measured analyte. This will negate the effects of differences in urine concentration between animals and allow for accurate comparison of the results. Creatinine can be measured by the same methods used for plasma..

EVALUATION

Urine volume, combined with assessment of urine concentration (specific gravity or osmolality) can serve as an index to renal function. With severe acute loss of functional nephron mass, urine output is decreased (oliguria) or absent (anuria), while loss of the ability of the kidney to adequately concentrate urine results in the excretion of large volumes of dilute urine.

The commercially available dipstick reagents do not detect the low levels of glucose found in normal urine and thus positive results indicate significant glucosuria in most species (the exception is the gerbil, where dipstick positive glucosuria is normal) (McClure, 1999). If glucosuria is detected, time-matched plasma glucose levels are needed to rule out that this result has not resulted from an increase in the filtered glucose load. If plasma glucose is normal, the appearance of glucose in the urine may indicate a functional deficit in the proximal tubule (Stonard et al. 1987; Finco 1997; Loeb and Quimby 1999; Newman and Price, 1999; Aleo et al. 2002).

Because of inherent inaccuracies in the dipsticks when applied to animal urine (see below under "Limitations of the Method"), positive results by dipstick for protein must be followed by detailed qualitative and quantitative assessment.

Quantitative assessment of urinary protein excretion is necessary to rule out a contribution from

glomerular malfunction. In general, excretion of markedly elevated levels of protein is indicative of glomerular disease, whereas low-level proteinuria indicates tubular damage or very early/lowgrade glomerular injury (Peterson et al. 1969; Finco, 1997).

A number of different methods have been developed for quantitative assessment, including turbidometric, colorimetric (Biuret and Lowry assays as examples) and dye binding assays. All have their advantages and limitations; in general, biuret assays tend to detect all types of proteins with equal sensitivity but require fairly large sample volumes, turbidometric assays can suffer from lack of precision with variations in urine ionic strength, and dye-based methods may suffer from interference with exogenous and endogenous urine substances. The Folin phenol (Lowry), Coomassie brilliant blue and Ponceau S methods have been recommended as being particularly precise for urine samples (Petersen et al., 1969; Dilena et al. 1983; Finco, 1997; Newman and Price, 1999).

Qualitative assessment (identification of the proteins excreted) is necessary to determine if low-level proteinuria has resulted from glomerular or tubular malfunction. Concomitant elevation of albumin and one or more of the low molecular weight proteins (which are freely filtered by the normal glomerulus) indicates that the proteinuria has resulted from decreased tubular reabsorption of proteins, while albumin elevation alone or concurrently with a high molecular weight protein (normally excluded from the filtrate by the glomerulus) indicates primary glomerular injury (Petersen et al. 1969; Finn and Porter, 1998; Gruder et al. 1998; Umbreit and Wiedemann, 2000). Commonly used filtered low molecular weight proteins include retinol binding protein (Price, 2000, 2002; Aleo et al. 2002, 2003), α_2- or β_2-microglobulin (Viau et al. 1986; Loeb, 1998; Finn and Porter, 1998; Price, 2000, 2002) or cystatin C (Finn and Porter, 1998; Herget-Rosenthal et al. 2001; Uchida and Gotoh, 2002).

LIMITATIONS OF THE METHOD

Because the commercially available dipsticks are designed for clinical use, they are inaccurate for a number of parameters in animal urine. The specific gravity reagents are completely inaccurate in all species. Dipsticks which use a glucose oxidase method for urine glucose can show a false positive result in species such as the dog and mouse with high urinary ascorbate levels or in urine contaminated with hypochlorite used as a disinfectant (Finco, 1997; Loeb and Quimby, 1999). For all glucose detection methods, test article formulations that contain glucose or other metabolizable sugars in quantities, should be avoided, as they may transiently overwhelm tubule reabsorption mechanisms and generate false positive test results. Protein detection is based on a bromphenol blue method that is most sensitive for albumin (Newman and Price, 1999), which means that proteinuria that does not result primarily from an increased albumin excretion may not be detected by this method. Furthermore, since these tests are designed for human urine, false positives are frequent in species like the dog, whose normal urine protein levels are just above the lower limits for humans (Finco, 1997), and dipstick tests are invariably positive in male rats and mice which have normal high proteinuria (Loeb and Quimby, 1999).

The sensitivity of the quantitative protein assays to the protein(s) of interest depends in large measure on which protein is used to generate the standard curve. Albumin is most commonly used because it is the most abundant protein in urine and while it is adequate for most methods (Dilena et al. 1983), it will in general underestimate the abundance of many other proteins of interest in urine (Guder and Hofman, 1992).

Qualitative assessment of urine proteins other than albumin is hampered in many species by the lack of suitable immunoassays; with the exception of cystatin C, commerically available antibodies do not cross react with the animal proteins (Loeb and Quimby, 1999; Uchida and Gotoh, 2002). Assessment of urinary retinol excretion has been shown to be a sensitive index to retinol binding protein excretion in the rat (Aleo et al. 2002, 2003).

MODIFICATIONS OF THE METHOD

Point-in-time samples from laboratory rodents may be obtained by taking advantage of the fact that these animals frequently urinate when they are handled or shortly after being removed from their home cage. A skilled, quick and prepared operator with a ready small container or plain microcapillary tube may be able to obtain a small sample in the first instance (Loeb and Quimby, 1999); in the second, the animal can be placed in a small confined space on plastic food wrap and observed carefully for urination, as it has been shown that most rodents will urinate within 20 minutes after removal from their home cages. The sample thus generated can be collected by micropipette (Kurien and Scofield, 1999).

For repeated point-in-time urine samples from rats over short periods of time (one to two weeks after the surgery), the urethra or the ureter can be cannulated. Cannulated rats can also be used to collect accurate

and complete timed urine samples (Mandavilli et al. 1991; Horst et al. 1988).

C.2.2.3.2 Electrolyte Excretion

Since one of the kidney's primary functions is maintaining electrolyte and mineral homeostasis in the face of fluctuating dietary intake and body needs, examination of plasma and urine electrolyte levels will provide some insight into renal function. Because of the large functional mass of the kidney, alteration of plasma electrolyte levels are usually not detected until the effect on renal functional is significant (pathologic). In contrast, urine electrolyte levels examined with knowledge of plasma levels and dietary intake can serve as an extremely sensitive index to the effect of drugs or chemicals on the functional state of the kidney.

In animal studies the diet can be carefully controlled and thus the intake (and hence the plasma electrolyte levels) can be assumed to be fairly constant. Provided there are no sources of significant electrolyte loss resulting from the experimental manipulations (e. g., vomiting, diarrhea, salivation), urine electrolyte levels will reflect the effects of the compound on either GFR (determines the filtered load) or tubular secretion or reabsorption (determines the final urine electrolyte composition).

C.2.2.3.3 Fractional Excretion Methods

PURPOSE AND RATIONALE

Fractional excretion (FE) is the proportion of the filtered load of any analyte that is excreted from the plasma. If both tubular function and plasma electrolyte values are normal, increases in electrolyte FE values clearly reflect a decrement in GFR. With tubular malfunction, the direction of the change in FE values depends on the net direction of electrolyte transport (i. e.,

FE will increase for electrolytes that are primarily reabsorbed and will decrease for secreted electrolytes) (Finco, 1997; Stockham and Scott, 2002).

PROCEDURE

FE assessments can be performed in any species, as it requires only carefully timed complete urine collections and a concurrent assessment of GFR. FE will be unitless if the urine collection period is expressed in minutes, thus (Finco,1997):

$$\begin{aligned}\text{FE} = &\big(\text{urine electrolyte concentration (mmol/L)}\\ &\times \text{urine (mL/collection period)}\big)\\ &/\big(\text{GFR (mL/min)}\\ &\times \text{plasma electrolyte concentration (mmol/L)}\big)\end{aligned}$$

To eliminate the need for both complete timed urine collections (difficult to do in most animals) and concurrent assessment of GFR, FE values are usually calculated based on point-in-time urine collections by using creatinine excretion during the same time period as an estimator of GFR (Finco, 1997).

Animals are placed in appropriately-sized metabolism cages for an appropriate period of time to allow collection of an adequate volume of urine. At the midpoint of the collection period a blood sample is obtained under appropriate anesthesia (note: the use of CO_2 will falsely elevate plasma potassium levels and render the method inaccurate) for determination of electrolyte and creatinine levels.

Plasma and urine electrolytes and creatinine are determined by standard methods (Durst and Siggard-Andersen, 1999; Newman and Price, 1999; Scott et al., 1999). FE is calculated from the results as outlined below (Stockham and Scott 2002):

$$\begin{aligned}\text{FE} = &\big(\text{urine electrolyte concentration}\\ &\times \text{plasma creatinine concentration urine}\big)\\ &/\big(\text{creatinine concentration}\\ &\times \text{plasma electrolyte concentration}\big)\end{aligned}$$

LIMITATIONS OF THE METHOD

If the Jaffe method for creatinine is used, the investigator must be aware of potential interference due to endogenous chromogens (the error is magnified in species where these chromogens are present in higher concentration in the plasma than in the urine (dog, mouse) (Finco, 1997; Dunn et al. 2004) or possibly the test compound (Sonntag and Scholer, 2001). Additionally, plasma electrolyte levels may fluctuate as the result of eating or due to diurnal rhythms (Finco, 1997). The impact of inaccuracies can be minimized by consistent timing of urine collection, fasting of animals before and during urine collection and the inclusion of a concurrent untreated (vehicle control) group in all studies.

MODIFICATIONS OF THE METHOD

Although FE of sodium is most commonly used to assess tubular function, FE of magnesium has been shown to be the most sensitive index in detecting low-level tubular injury in humans (Barton et al., 1987; Futrakul et al. 1999; Kang et al. 2000; Oladipo et al. 2003). Increased FE of calcium has also been shown to serve as a sensitive index of effects on renal function unrelated to overt renal injury (Lam and Adelstein 1986; Tuso and Nortman, 1992; Eliott et al. 2000)

FE of urea has been recently shown to be more useful than the FE of sodium in distinguishing between prerenal and renal azotemia in humans (Carvounis et al. 2002) and thus may also be useful in making this distinction in animal models. Changes in the FE of urea also reflect changes in urine flow rates (in general, these values move parallel to each other) and can be used as an estimate of this parameter (Finco, 1997). The methods used to detect urea in urine are the same as those used in serum (Newmann and Price, 1999).

FE of anions (ammonium, bicarbonate) can be used to determine the potential mechanism underlying systemic acid base imbalances (Rothstein et al. 1990; Kim et al. 2001).

C.2.2.3.4 Quantitative Electrolyte Excretion

PURPOSE AND RATIONALE

Fractional excretion methods are useful in that they can identify alterations in analyte excretion with relative ease, as they require only point-in-time assessment of analyte concentration and don't require complete and timed urine collection. Greater sensitivity, however, is obtained with quantitative evaluation of electrolyte excretion. This method is more difficult, requiring carefully timed, complete urine collection, and because plasma levels are not evaluated there needs to be reasonable assurance that the changes in excretion seen do not result from alteration of the filtered load of the analyte in question (e. g., plasma levels and GFR remain consistent). In animal studies where the diet is carefully controlled these factors are not usually of concern.

PROCEDURE

The method can be used on any species, although rats are most commonly used. Animals are usually fasted but allowed access to water; if anesthetized animals are used, intravenous administration of balanced electrolyte solutions (e. g., lactated Ringer's solution) or 0.9% NaCl solution can be administered by intravenous infusion to ensure that plasma volume (and thus GFR) and electrolyte levels are maintained.

Urine is collected by any appropriate method over a specified period of time. If possible, the urinary bladder should be emptied before collection of test urine is initiatied and at the end of the collection period; this can be accomplished in dogs by catheterization and in rodents by handling or manual expression of the bladder. If metabolism cages are used, special care must be taken to avoid evaporation of urine and contamination of the vials with feces or drinking water, as accurate determination of volume is important. The volume of urine collected is determined gravimetrically, and urine electrolytes are measured by standard methods (Durst and Siggard-Andersen, 1999; Scott et al. 1999).

EVALUATION

The volume of urine collected over the time period is defined as the urine flow rate:

$$V = \text{volume collected/time period (expressed in mL/min)}$$

and electrolyte excretion (U_XV) is defined as:

$$U_X V = \{[(\text{concentration of } X \text{ in urine}) \times V] / \text{body weight in g}\} \times 100 \quad (\text{expressed in mmol/min/100 g})$$

As a general rule, $U_{Na}V + U_K V = U_{Cl}V$. If it does not, the assumption must be made that there are additional anions in the urine. Carbonic anhydrase inhibition (i. e., excess urinary bicarbonate may be the culprit if the ratio:

$$\frac{U_{Cl}V}{U_{Na}V + U_K V}$$

is less than 0.8.

Net natriuretic activity can be assessed by evaluation of the ratio:

$$\frac{U_{Na}V}{U_K V}.$$

Values greater than 2.0 indicate a favorable natriuretic effect, and values greater than 10.0 indicate a potassium-sparing effect.

C.2.2.3.5 Assessment of Tubular Transport Processes using Transport Substrates and Inhibitors

PURPOSE AND RATIONALE

A number of transporters for organic anions and cations are present on both the lumenal and basolateral surfaces of the proximal tubules. These are essential to the secretion and/or reabsorption of a number of endogenous substrates as well as functioning in the elimination of xenobiotics. These transporters frequently function as ion exchangers and their activity is thus bi-directional, so that the net direction of transport (i. e., secretion or reabsorption) for any given substrate depends not only on the numbers and activity of the transporters on either side of the tubule but also on the presence and concentration of competing or co-transported substrates. This feature of tubular transport has been one of the major challenges in the development of uricosuric agents for the treatment of hyperuricemia (Terkeltaub et al. 2006). Compounds that affect either the expression or activity of transporters, are competitive substrates for them, or act as inhibitors of transport thus may affect not only the clearance of therapeutic agents but also that of endogenous metabolites (Wright and Danzler, 2003).

PROCEDURE

The choice of substrate or inhibitor used depends on the transport process or specific transporter of interest. The table below lists the most commonly used substrates and their transporters (note: most inhibitors act competitively and are themselves substrates for the transporter in question).

Transport studies can be performed in any animal model from which urine and plasma may be collected readily. Inhibitors are administered 30 minutes to 1 hour before the administration of the test substance. Substrates are usually administered intravenously, and are detected in urine and plasma most commonly by colorimetric methods.

EVALUATION

Standard clearance or excretion methods are used to assess the effects.

LIMITATIONS OF THE METHOD

Significant sex differences exist in renal transporter expression and activity in rodents and rabbits (Sekine et

Compound	Most Common Use	Transporter Affected	Comments
Tetraethylammonium (TEA)	Substrate	OCT1, OCT2, OCT3	Most commonly used substrate
1-methyl-4-phenylpyridinium (MPP^+)	Substrate	OCT1, OCT2	Can be used to differentiate OCT3-mediated transport
Tributylmethylammonium (TBuMA)	Substrate	OCT3	Can be used to differentiate OCT3-mediated transport
Urate	Substrate	URAT1, OAT1, OAT3	URAT1 is selective for urate in human kidney but has other OA transport functions in other species
p-aminohippurate (PAH)	Substrate	OAT1, OAT2, OAT3(?), OAT4	Most commonly used substrate. Questionable substrate for OAT3
Estrone sulfate	Substrate	OAT3, OAT4, Oatp1	Oatps are homologs of bile acid transporters in the liver
Lucifer yellow	Substrate	OAT1	Can be detected spectrofluorometrically
Phenolsulfonphthalein (Phenol red)	Substrate	OAT3	Clearance has traditionally been used as a surrogate for urate transport
Probenecid	Inhibitor	OAT1, OAT2, OAT3, URAT1	Used therapeutically and experimentally
Cimetidine	Inhibitor	OAT3	Used to correct creatinine clearance for the contribution of tubular secretion
Benzbromarone	Inhibitor	URAT1	

al. 2006). Many of the substrates, and all of the inhibitors, are not specific enough for accurate determination of the exact transporter affected by the test compound.

MODIFICATIONS OF THE METHOD

The listed substrates and inhibitors may also be used in *in vitro* modles such as isolated tubules or kidney slices. In the latter model, net transport is usually assessed by measuring either the disappearance of the substrate from the medium or, more commonly, the degree or rate of accumulation of the substrate over time in the tissue slice (Kirkpatrick and Gandolfi, 2005).

C.2.2.4
Assessment of Renal Concentrating Ability

C.2.2.4.1
Solute-Free Water Excretion and Reabsorption

PURPOSE AND RATIONALE

Investigations of the clearance of solute-free water represent indirect methods for the evaluation of several aspects of renal function and provide information on the site and mechanism of action of agents within the nephron. The discovery of the countercurrent multiplier system as the mechanism responsible for the concentration and dilution of the urine has been the prerequisite for the identification of the site of action of diuretic drugs. A drug that acts solely in the proximal convoluted tubule, by causing the delivery of the increased amounts of filtrate to the loop of Henle and the distal convoluted tubule, would augment the clearance of electrolyte-free water (EC_{H2O}) during water diuresis and the reabsorption of electrolyte-free water (ETC_{H2O}) during water restriction. In contrast, drugs that inhibit sodium reabsorption in Henle's loop would impair both EC_{H2O} and ETC_{H2O}. On the other hand, drugs that act only in the distal tubule would reduce EC_{H2O} but not ETC_{H2O}.

PROCEDURE

These tests may be performed in any species from which urine and plasma can be readily collected, although low-level changes in concentrating ability may be more readily manifest in rats than in dogs (Sharrat and Frazer 1963; Osbourne et al. 1983). The general procedure involves initially placing the animals in a metabolism cage with unlimited access to water. After collection of a urine sample (16–24 hours is best), the water is withdrawn and the urine is collected for the next 12–16 hours. The urine specific gravity (or preferentially, urine osmolality) is measured and compared both with the value from the hydrated animal and the mean values from the water-deprived control group (Ragan and Weller, 1999).

Assessment of renal urine diluting ability is more cumbersome but can be accomplished in rats by administration of an oral dose of water by gavage representing 5% of the animal's body weight. The animals are then placed in metabolic cages and the urine is collected every 30 minutes for the next 2 hours (Sharrat and Frazer 1963). In dogs, water diuresis can be induced by oral administration of 50ml of water per kg body weight and maintained by continuous infusion into jugular vein of 2.5% glucose solution and 0.58% NaCl solution at 0.5ml/min per kg body weight. When water diuresis is well established, the glucose infusion is discontinued and control urine samples are collected by urethral catheter (Suki et al. 1965). The volume and specific gravity (or osmolality) of the collected urine is measured and the results expressed as the percent of the administered dose of water excreted during the time period. Time-matched plasma samples are collected for the determination of plasma osmolality.

EVALUATION

In addition to gross assessment of renal dilution or concentrating ability (as described above), quantita-

tive evaluation of either osmolar clearance, freewater clearance (C_{H2O}), or solute-free water clearance (EC_{H2O}) may add additional sensitivity to the evaluation of these functions.

Osmolar clearance can be calculated as follows:

$$C_{osm} = (U_{osm} X\ V)/P_{osm}$$

where C_{osm} = osmolar clearance, U_{osm} = urine osmolality (in mosm/kg water), V = urine flow (measured in ml/min) and P_{osm} = plasma osmolality (measured in msom/kg water). C_{osm} is expressed in ml/min. C_{osm} less than V indicates excretion of a dilute urine (i. e., excess water is being excreted), but C_{osm} greater than V indicates excretion of concentrated urine (i. e., excretion of excess solute).

Freewater clearance (C_{H2O}) provides an estimate of the amount of urine being excreted in excess that needed to clear solutes, and is calculated traditionally as follows:

$$C_{H2O} = V\ X[(1 - U_{osm})/P_{osm}]$$
(Wesson and Anslow, 1952)

More accurate assessment of the ability of the kidney to appropriately regulate plasma tonicity and/or respond appropriately to antidiuretic hormone (ADH) can be made by calculation of electrolyte-free water clearance (EC_{H2O}). This formula takes into account only water needed to excrete excess "effective" osmolytes (in general, monovalent electrolytes and their associated anions) and is calculated as follows:

$$EC_{H_2O} = V\ X\{1 - ([Na^+ + K^+]_{urine} / [Na^+ + K^+]_{plasma})\}$$ (Shoker, 1994)

LIMITATIONS OF THE METHOD

In general the sensitivity of either urine concentration or dilution tests to detect the effects of test compounds on renal function is quite low, regardless of species (Ragan and Weller, 1999). Furthermore, these tests (especially the urine dilution test) may be significantly altered by extrarenal effects (e. g., vomiting, diarrhea, delayed GI absorption, altered adrenal cortical function). Calculation of osmolar, freewater and electrolyte-free water clearances require accurate assessment of urine flow rates, which will require accurate and complete collection of all urine produced during the time interval, not always easily accomplished in small animal species. Catheterized models should be utilized in this circumstance. In addition, calculated electrolyte-free water clearances may be influenced by the presence of excess effective osmolytes in either urine or plasma (e. g., in circumstances of hyperglycemia or metabolic acidosis/alkalosis) and the formula must be corrected to account for these if they are known to be present (Shoker 1994; Nguyen and Kurtz, 2005).

C.2.2.4.2 Assessment of Medullary Osmolarity and Blood Flow

PURPOSE AND RATIONALE

The ability of the kidney to concentrate urine depends entirely on the maintenance of the renal medullary interstitium in a hypertonic state. Hypertonicity reflects two phenomena; water-uncoupled transport of osmotically active substances (sodium and urea, primarily) into the medullary interstitium, and the trapping of those solutes in the interstitium by the vasa recta countercurrent multiplier system. The hypertonic gradient is created by the active transport of sodium into the interstitium in the ascending loop of Henle, and a combination of passive and facilitated transport of urea located in the collecting duct; the magnitude and effectiveness of the gradient is determined by the rate of plasma flow through the vasa recta (Pallone et al. 2003; Sadowski and Dobrowolski 2003). The method described allows simultaneous assessment of both parameters.

PROCEDURE

Male Wistar rats have been used in these experiments. Under appropriate anesthesia, the femoral artery and vein are cannulated for measurement of aortic blood

pressure and infusion of fluids and test compounds, respectively. The left kidney is exposed and placed in a plastic cup as for micropuncture experiments (see 1.2.1.4.), except that the dorsal surface is placed at the top of the cup, facing the operator. The ureter is catheterized and a platinum-iridium admittance electrode is inserted along the corticopapillary axis from the dorsal surface of the kidney (the probe is sized to ensure correct placement of the recording surfaces within the inner renal medulla). The capsule is incised and a needle laser-Doppler (LD) probe is inserted adjacent to the admittance probe. Animals are maintained in intravenous infusions of balanced electrolyte solution to maintain plasma volume and ensure adequate renal perfusion.

Medullary blood flow (MBF) is assessed by the LD probe, which is connected to a perfusion monitor (Periflux 4001, Perimed). The number and velocity of erythrocytes moving between the two optical fibers of the LD probe is determined. Admittance (the reciprocal of impedence) is measured between the tip of the LD probe and the admittance electrode by a conductance meter connected to both of these, following the application of a measuring current at a frequency of 24 Hz. Following the experiment, the kidney is dissected to verify that the LD and electrode have been correctly placed.

EVALUATION

Medullary blood flow (MBF) is expressed in arbitrary perfusion units (PU), based on the voltage generated by the Doppler flux of the blood cells moving beneath the LD probe (roughly, the product of cell number X velocity). By definition, a 10V signal from the detector is considered 1000 PU. Admittance (Y) is expressed in millisiemens (mS), and is directly related to the ionic tonicity of the tissue (primarily due to the NaCl content). Effects in treated animals are expressed relative to those in untreated controls. If desired, urine may be collected from the ureteral cannula for excretion determinations.

LIMITATIONS OF THE METHOD

Because MBF is expressed in arbitrary units, only relative changes within a single animal can be detected, thus each animal must serve as its own control (although results between animals in the same study can be compared with the use of a calibration algorithm). Significant tissue damage, resulting in non-functional mephrons, does result from the placement of the equipment and thus the technique can only be applied to the innermost medulla (where the glomeruli originate below the depth of the damaged zone). The admittance recordings reflect only the concentration of NaCl in the medulla and thus changes in tonicity resulting strictly from changes in urea concentration cannot be detected by this method.

MODIFICATION OF THE METHOD

Regional changes in medullary tonicity and the steepness of the osmotic gradient can be detected using a system of three needle electrodes that allows assessment of admittance in the outer and inner medulla separately. This arrangement cannot be coupled with the LD probe because excessive tissue damage would result (Sadowski and Portalska, 1983).

An admittance electrode surrounded by a steel cannula fitted to syringe pumps may be used in place of the needle electrode. This setup allows for direct infusion of test substances into the medulla so that local effects may be monitored (Dowbrowolski and Sadowski, 2004).

C.2.2.5 Micropuncture Techniques in the Rat[4]

PURPOSE AND RATIONALE

Micropuncture techniques have been applied to the direct investigation of the effect of diuretics on single nephron function. The observed changes in tubular fluid reabsorptive rates and electrolyte concentrations can be used to asses the mechanism of action. The rat is the model of choice since proximal and distal tubules as well as collecting ducts are accessible for micropuncture.

[4] Contribution by M. Hropot.

PROCEDURE

Clearance and free-flow micropuncture studies are performed in rats with a body weight of about 250 g, anaesthetized by the intraperitoneal injection of thiopentone (Trapanal 50 mg/kg). The animals are fasted for 16 h before the beginning of the experiment, but have free access to tap water. After anesthesia the animals are placed on a thermostatically heated table. Thereafter rats are tracheotomized and carotid artery and jugular vein are cannulated for blood pressure recording, blood sampling, and for infusion of compounds, respectively. The left kidney is carefully exposed by a flank incision, embedded in a small plastic vessel with cotton wool, and bathed with paraffin oil at 37°C. The ureter is cannulated and rectal temperature monitored continuously. A bolus injection of 75 µCi inulin ^{3}H in 0.7 ml NaCl solution is given, followed by 0.85% NaCl solution at a rate of 2.5 ml/min per 100 g body weight. The sustained infusion delivers 75 µCi inulin ^{3}H per hour. The control puncture of tubules is performed 45 min after beginning of the intravenous infusion. The direct collection of tubular fluid samples from proximal and distal tubules is carried out with glass capillaries of 8 to 10 µm external diameter using a micromanipulator and microscopic observation. Distal tubules are identified by intravenous injection of lissamine green. The control period is followed by the test period. After an equilibration period of 30 min with the compound to be tested, micropuncture is performed again and tubular fluid is collected. The uretral urine is collected and blood sampling is performed in the middle of each clearance period.

The infusion rate/volume is determined by the size of the animal. Distal collection is done by identification of the perfused segment by its dye content; a second micropipette is then inserted, a distal oil or wax block is placed and the infusion fluid can be collected for subsequent analysis (Knox and Marchand 1976; Ramsey et al. 1996; Lorenz et al. 1999; Wang et al. 1993, 1999).

EVALUATION

The following parameters may be determined: inulin clearance (GFR), single nephron GFR, fractional delivery of water, sodium and potassium in proximal and distal tubules and in urine.

Fluid reabsorption (J_v) is assessed by comparing the inulin concentration in the perfusate to that in the collected sample, thus (Wang et al., 1993):

$$J_v = V_0 - VL,$$

Where VL is the collected fluid volume (normalized for the length of the tubular segment over which it was collected), and:

$$V_0 = VL(INL/IN_0),$$

Where INL = concentration of inulin in the collected sample, and IN_0 is the inulin concentration in the perfusate.

The net flux of the desired analyte (J_X, where X is the anlyte of interest – Na, K, HCO_3, glucose, etc.), is calculated thus:

$$J_X = V_0[X]_0 - VL[X]_L,$$

Where $[X]_0$ is the concentration of the analyte in the perfusion fluid, and $[X]_L$ is the concentration of the analyte in the collected fluid.

All data are expressed as mean values ± SEM. Comparison of the effects of compounds to be tested with controls is performed by one way analysis of variance and by Student's *t*-test for paired and unpaired data.

MODIFICATION OF THE METHOD

Inulin conjugated to fluorescein isothiocyanate (FITC) may be used in place of the radiolabelled inulin. The inulin concentration in the sample is assessed by comparing the fluorescence in the sample to a standard curve (Lorenz and Gruenstein, 1999).

This technique can be applied to distal tubules as well as to proximal tubules. Distal tubules are identified at the surface of the isolated kidney following micropuncture and perfusion of a proximal tubule as described above. Once the dye reaches the superficial portion of the distal tubule, it is blocked with oil or wax and accessed both proximally and distally as described above (Levine 1985).

C.2.2.6
Stop-Flow Technique[5]

PURPOSE AND RATIONALE

This procedure is of considerable value in the localization of transport processes along the length of the nephron. During clamping of the ureter, glomerular filtration is grossly reduced. The contact time for the tubular fluid in the respective nephron segments increases, and the concentration of the constituents of tubular fluid should approximate the static-head situation. After release of the clamp, the rapid passage of the tubular fluid should modify the composition of the fluid only slightly. The first samples should correspond to the distal nephron segment, the latest to glomerular fluid. However, with introduction of the micropuncture technique, the stop-flow method appears less attractive.

PROCEDURE

This method can be performed in different animals during anesthesia and was originally described by Malvin et al. (1958). The ureter of an animal undergoing intense osmotic diuresis is clamped for several minutes allowing a relatively static column of urine to remain in contact with the various tubular segments for longer than the usual periods of time. Thus, the operation of each segment on the tubular fluid is exaggerated. Then the clamp is released, and the urine is sampled sequentially. Small serial samples are collected rapidly, the earliest sample representing fluid which had been in contact with the most distal nephron segment. Substances examined are administered along with inulin before the application of uretral occlusion. However, tubular segments downstream from the proximal segments may modify the tubular fluid during its egress.

EVALUATION

In each sample the concentration of a glomerular marker, such as inulin, and the concentration of the substance under study are measured. Fractional excretion of the substance and the glomerular marker are plotted versus the cumulative urinary volume.

MODIFICATIONS OF THE METHOD

Shinosaki and Yonetani (1989), Shinosaki et al. (1994) performed stop-flow studies on tubular transport of uric acid in rats treated with pyrazinoic acid, an inhibitor of tubular urate secretion.

Tanaka et al. (1990) used stop-flow experiments to test uricosuric and diuretic activities of new compounds in dogs.

Stop flow techniques can be performed in isolated perfused tubular segments using micropuncture techniques. The proximal and distal micropunctures are performed as described, but instead of immediately collecting fluid from the distal micropipette, pressure is applied equal to that of the perfusion pressure at the proximal pipette, until flow ceases at the infusing pipette. Sampling occurs following a period in which the perfusate remains static in the perfused tubule segment. Care must be taken, especially in mice, to prevent tubular leaking with excessive stop-flow pressures or infusion rates (Schnermann, 1999).

C.3
Impaired Renal Function

C.3.1
Chronic Renal Failure in the Rat

PURPOSE AND RATIONALE

Chronic renal failure is a frequent pathological condition in man. An animal model as described by Acott

[5] Contribution by M. Hropot.

et al. (1987) is of value to test new diuretics under these conditions.

PROCEDURE

Sprague-Dawley rats weighing 150–200 are anesthetized by i.m. injection of ketamine (40 mg/kg) and droperidol/fentanyl (Inovar) 0.25 mg/kg. Through a 6-cm midline incision in the abdominal wall the small bowel and cecum are lifted and placed on saline-soaked gauze sponges. The exposed right kidney is dissected from the retroperitoneal area and the vascular and ureteric pedicles are ligated with 2–0 silk sutures, transected, and the kidney is removed. The renal artery of the left kidney is dissected into the hilum to expose the three main segmental renal arteries. The kidney is not dissected out of the peritoneum. The anterior caudal branch of the artery is then temporarily ligated to establish the volume of renal tissue supplied. The area of ischemia becomes demarcated within 10–15 s. If this approximates 1/4 to 1/3 of the kidney, a permanent ligature is placed. The viscera are then carefully replaced in the abdomen and peritoneum and linea alba are closed with a continuous suture. The skin is closed with stainless-steel clips.

Blood for serum creatinine is collected by retro-orbital puncture under anesthesia at various time intervals up to 12 months. In association with this, 24-hour urines are collected for measurement of creatinine, protein, and specific gravity.

EVALUATION

Serum creatinine increases up to 500 µM/l after 12 months, whereas creatinine clearance decreases. Significantly increased urine volumes are accompanied by decreased urine specific gravity indicating a decreased concentrating ability. Proteinuria is significantly increased. Terminal uremia occurs after 14–15 months.

CRITICAL ASSESSMENT OF THE METHOD

The method may be used for special pharmacological studies as well as for evaluation of renal toxicity of new chemicals.

MODIFICATIONS OF THE METHOD

Sancho et al. (1989) used a similar procedure in rats ligating two of the three terminal branches of the left renal artery, followed by right nephrectomy.

Freeman (1971) induced azotemia combined with hypothermia in rats by ligation of the urinary bladder at the base.

William et al. (1997) described renal ischemia-reperfusion injury in rats. The animals were anesthetized and subjected to 45 min of bilateral renal occlusion using atraumatic vascular clamps before renal perfusion was reestablished. After various time interval (up to 1 week) blood urea nitrogen, creatinine and myeloperoxidase activity in the kidney were determined. The protective effects of an intracellular adhesion molecule monoclonal antibody were tested.

Ishidoya et al. (1995), Klahr and Morrissey (1997) induced interstitial renal fibrosis by unilateral ureteral obstruction in Sprague Dawley rats and tested the effect of ACE inhibitors and angiotensin II receptor antagonists.

Hartenbower and Coburn (1972) described a method for producing chronic renal insufficiency in the *chick*. By urethral ligation, the function of one kidney was completely eliminated, and the functional mass of the other was reduced by two-thirds. The method resulted in elevation of plasma concentration of uric acid, the major product of protein catabolism in avian plasma, to levels 2–4 times normal for periods as long as 3 weeks.

Two to 3 weeks old White Leghorn cockerels are anesthetized with ether, and the abdominal feathers are clipped. The chick is placed supine on a small operating board with hips flexed and legs extended over the head. An incision is made along the left side of the abdomen extending into the peritoneal cavity. Self-retaining retractors are used to maintain exposure. The right ureter is identified and ligated just proximal to its junction with the cloaca. The left ureter and renal vein are ligated with a single suture near the middle of the left kidney.

The degree of azotemia is assessed by measuring uric acid levels in blood samples 0.2–0.3 ml, obtained by cardiac puncture at intervals of 2–6 days after surgery.

Uric acid blood levels are compared between operated and sham-operated animals. Histological examination is performed after sacrifice of the animals.

C.3.2
Chronic Renal Failure After Subtotal (Five-Sixths) Nephrectomy in Rats

PURPOSE AND RATIONALE

Subtotal (five-sixths) nephrectomy in rats has been used by many authors as model for chronic renal failure. Levine et al. (1997) used this model to evaluate the hypothesis that under these conditions endogenous angiotensin II modulates *in vivo* bicarbonate reabsorption (J_{tCO2}) in distal tubules via H^+-adenosinetriphosphatase and Na^+H^+-exchange. Bicarbonate reabsorption (J_{tCO2}) in distal tubules is significantly increased in five-sixths nephrectomized rats.

PROCEDURE

Surgical Procedure

Male Sprague-Dawley rats weighing 230–280 g are anesthetized with halothane via a face mask. Prior to the first incision, the animal is given 20 ml/kg normal saline subcutaneously. On a heated table, a midline laparatomy is performed 2 cm below the xiphoid bone cartilage and the abdomen is opened. The right kidney is isolated and brought out of the abdomen by grasping the fat at the lower pole of the kidney. This fat is blunt dissected (sparing the adrenal gland), and three silk 4-0 ligatures are passed under the ureter, renal artery, and renal vein, tying one distally and two proximally. The ureter, renal artery and renal vein are then cut between the ligatures, the proximal ties are cut short, and the distal tie is pulled out, removing the kidney. After the area is checked for bleeding, the left kidney is the similarly isolated and brought out of the abdomen. The fat around the kidney is blunt dissected, avoiding excessive handling of the kidney or damage to the ureter, and the left and right renal poles are removed (two-thirds nephrectomy). The left remnant kidney is then returned to the abdomen and moistened with 5 ml of normal saline. The abdomen is closed with sutures and the skin with autoclips. Sham rats undergo the same procedure, except that the kidneys are only touched by the instruments. All rats are allowed 13–16 days recovery prior to microperfusion.

Microperfusion Experiments

The rats are anesthetized with 100 mg/kg thiobutabarbital sodium and placed on a heated operating table. After tracheostomy, using a PE-240 tubing, the left carotid artery is cannulated for continuous blood pressure measurement and collection of blood for acid-base and electrolyte analyses while the left jugular vein is cannulated with three lines for infusion of fluid, pentobarbital sodium anesthetic and 10% Lissamine green (Levine et al. 1996). The left kidney is exposed by flank incision, carefully dissected from the adrenal gland, and immobilized in a stainless steel cup covered with mineral oil. The ureter is catheterized with PE-50 tubing to ensure proper urine flow.

To replace surgical fluid losses, the rats are infused at 1% body wt/h for 30 min via the jugular vein with donor plasma from control rats. The animals are then maintained on 0.9% saline at 1% body wt/h for the remainder of the experiment.

Two-loop perfusable surface distal tubules are identified by injecting a bolus of 1% Lissamine green into surface proximal loops and observing its passage through the nephron. The distal tubules are perfused at 15 nl/min with a hypotonic solution containing (in mM) 28 HCO_3, 26 Cl, 56 Na, 2 K, 1.8 Ca, 22 urea, and 4 gluconate, as well as 0.05% FD and C green dye no. 3 (Keystone, Chicago, IL) and 0.1% albumin. The perfused bicarbonate load, higher than in free flow, is chosen to more easily reveal the effect of inhibitors. Sample collections are quantitative and timed. A 10-min preperfusion period precedes all collections.

Groups of five-sixths nephrectomized rats are treated with various agents, e. g., angiotensin II, angiotensin$_1$ receptor antagonists, or Na^+/H^+ antiporter inhibitors.

Analyses

Whole blood and urine pH and P_{CO2} are measured quantitatively by an electrode blood-gas system and HCO_3 concentrations are calculated. Plasma and urine Na^+ and K^+ concentrations are measured by flame photometry and Cl^- concentrations by electrotitration. Plasma total protein concentrations and urine specific gravity are measured by refractometry, and hematocrits are determined by a microcapillary reader. Urine osmolalities are determined by freezing-point osmometry. Plasma creatinine concentrations are determined by the Jaffé method without deproteinization.

Perfusate and sample total CO_2 concentrations are measured by microcalorimetry (Levine et al. 1996). A standard curve is run before sample analysis, and standard samples bracket the determination of sample and perfusate CO_2 determination.

EVALUATION

The perfusion rate (R_P) is calculated as the product of the measured collection rate (R_C) and the ratio of inulin concentration in collected tubular fluid and perfusate. Water absorption (J_V) is calculated as the difference between the calculated perfusion rate and the measured collection rate (R_P minus R_C). J_{tCO2} is calculated as

$$J_{tCO2} = [(R_P C_P) - (R_C C_C)/L$$

whereby C_P and C_C are the measured CO_2 concentrations in perfusate and collected fluid, respectively, and L is the tubular length in millimeters, measured by dissection after latex injection.

Data are expressed as the means ± SE. Statistical significance is assessed by two-tailed unpaired Student's *t*-test or one way analysis of variance (ANOVA) followed by either Dunnett's test for multiple comparisons vs. control or the Newman-Keuls test for all pairwise comparisons. Tests indicating a value of $P < 0.05$ indicate a statistically significant difference between groups.

MODIFICATIONS OF THE METHOD

Function of the remnant kidney after subtotal (5/6) nephrectomy in **rats** has been used for many purposes:

- to test the potential benefit of calcium antagonists (Tolins and Raij 1990; Jarusiripipat et al. 1992; Van den Branden et al. 1997) or antioxidants (Vaziri et al. 1998),
- to verify the effect of ACE-inhibitors (Pelayo et al. 1990; Kakinuma et al. 1992; Ashab et al. 1995; Liu et al. 1996; Ali et al. 1998; Cohen et al. 1998; MacLaughlin et al. 1998), angiotensin antagonists (Kohzuki et al. 1994, 1995; Brooks et al. 1995; Barreto-Chaves and Mello-Aires 1996; Noda et al. 1997; Lariviere et al. 1998; Roczniak et al. 1999) and endothelin receptor antagonists (Nabokov et al. 1996; Potter et al. 1997; Wolf et al. 1999; Brochu et al. 1999; Shimuzu et al. 1999), or Na^+/H^+ antiporter inhibitors (Fernandez et al. 1994),
- to study the influence of hormones, such as parathyroid hormone (Fukagawa et al. 1991; Urena et al. 1994; Yi et al. 1995; Schaefer et al. 1996), growth hormone (Santo et al. 1992; Garcia de Boto et al. 1996), insulin-like growth factor I (Hazel et al. 1994; Mak and Pak 1996; Tonshoff et al. 1997), vasopressin (Bardoux et al. 1999), atrial natriuretic factor (Wong and Wong 1991, 1992), Luk et al. 1995) or erythropoietin (Poux et al. 1995; Zhou et al. 1997), during development of chronic renal failure.

Kimura et al. (1999) reported a model of progressive chronic renal failure in *rats*, produced by a single injection of microspheres (20 to 30 µm in diameter) into the left renal artery after right nephrectomy.

Cowley et al. (1996) described the **Han:SRPD rat** strain which develops autosomal dominant polycystic kidney disease with chronic renal failure that resembles human autosomal dominant polycystic kidney disease.

Chronic renal failure can be induced by feeding a lithium containing diet (40–50 mmol/kg) to newborn *rats* until an age of 55–65 weeks (Christensen et al. 1992, 1997; Nyengaard et al. 1994).

Stockelman et al. (1998) described chronic renal failure in a **mouse** model of human adenine phosphoribo-syltransferase deficiency. Hamilton and Cotes (1994) used a partial nephrectomy model in *mice* with two-thirds of total renal mass excised to evaluate erythropoiesis and erythropoietin production from extrarenal sources such as the submandibulary salivary gland. Koumegawa et al. (1991) suggested the DBA/2FG-pcy *mouse*, which develops numerous cysts in kidney cortex and medulla, a progressive anemia and an elevation of blood urea nitrogen, as useful spontaneous model of progressive renal failure.

Brown et al. (1990) studied the metabolism of erythropoietin in normal and uremic **rabbits** with 5/6 nephrectomy. Bonilla-Felix used *rabbits* after 75% nephrectomy to study the response of cortical collecting ducts from remnant kidneys to arginine vasopressin.

Fine et al. (1990), Vaneerdeweg et al. (1992) described surgical techniques for kidney resection to produce chronic renal failure in **dogs**.

C.3.3
Experimental Nephritis

C.3.3.1
General Considerations

Various experimental procedures were described as models for glomerulonephritis in human beings. Most of them were developed in rats and rabbits. They involve the reactions of antibodies against renal components, such as Masugi nephritis (Masugi and Sato 1934), Heymann nephritis (Heymann 1959), nephrotoxic serum nephritis (Unanue and Dixon 1967), crescentic type anti-glomerular membrane nephritis (Nagoe et al. 1994, 1998), anti-Thy1 nephritis (Chen et al. 1999).

Moreover, MRL Mpf lpr/lpr (MRL/lpr)-mice were described which spontaneously develop a severe disease with many symptoms very similar to human systemic lupus erythematodes, i. e. hypergammaglobulinemia, and glomerulonephritis (Theofilopoulos and Dixon 1981; see also I.2.2.16).

C.3.3.2
Nephrotoxic Serum Nephritis

PURPOSE AND RATIONALE

Nephrotoxic serum nephritis is produced in animals by administration of heterologous antibody against glomerular basement membrane. This is regarded as an experimental model of human glomerular immune injury resulting in glomerulonephritis (Unanue

and Dixon 1967). The glomerular lesions induced by nephrotoxic serum nephritis vary with species. The Wistar–Kyoto rat is susceptible to the induction of a crescentic glomerulonephritis following small doses of nephrotoxic serum (Kushiro et al. 1998; Suzuki et al. 1998).

PROCEDURE

Preparation of Nephrotoxic Serum

Normal Wistar rat kidneys are fully perfused with physiologic saline through a catheter placed in the aorta. Renal cortical tissue is removed, homogenized and diluted with physiological saline at about 20% suspension. Two ml of renal cortical homogenate are emulsified with an equal volume of Freund's complete adjuvant. This emulsion is injected subcutaneously into rabbits twice a month for two months. Seven days after the last injection, the rabbits are bled from the carotid artery under anesthesia. The sera are decomplemented for 30 min at 56°C and absorbed with freshly harvested rat erythrocytes.

Experimental Protocol

Male Wistar–Kyoto rats weighing 150 g receive either continuous administration of the test drug by an osmotic pump (ALZA Co., Palo Alto, USA) or saline. Twenty-four hours later, the rats are injected with 1 ml of nephrotoxic serum. At 9, 12, and 14 days, urine samples are collected and urinary protein levels are measured using the Lowry method. At 14 days the rats are sacrificed under ether anesthesia, and both kidneys are removed. Portions of these tissues are processed for light microscopy, immunofluorescence staining and immunoperoxidase staining.

For light microscopy, tissues are fixed and embedded in paraffin. Sections are stained with hematoxylin and eosin, and periodic acid Schiff's reagent. Twenty glomeruli are examined per rat and number of glomeruli which forms crescent is counted.

Indirect immunofluorescence studies are performed on 3 µm-thick cryostat sections which are air dried and incubated with anti-rat intercellular adhesion molecule-1 (ICAM-1) antibody (Tamatani and Miyasaka 1990) for 60 min at room temperature. After washing the antibody binding is visualized by incubating the sections for 30 min with fluorescein isothiocyanate-labeled goat anti-mouse IgG.

Direct immunofluorescence studies are performed on 4 µm thick cryostat sections, which are incubated with fluorescein isothiocyanate-labeled goat anti-rat IgG, goat anti-rat C3, goat anti-rat fibrinogen and goat anti-rabbit IgG.

The staining intensity of 20 glomeruli per rat is semiquantitatively assessed into 4 grades.

For **immunoperoxidase staining** the distribution of leukocytes is examined using an immunoperoxidase ABC kit (Vector Lab, Burlingame, USA). Nonspecific protein binding is blocked by incubating the cryostat sections with 10% bovine serum in Tris-buffered saline for 20 min. Nonspecific staining is blocked by 15 min incubation with avidin and then biotin using the avidin-biotin blocking kit (Vector Lab). Endogenous peroxidase activity is inhibited by incubating the sections in methanol containing 0.3% H_2O_2 for 20 min. Sections are first incubated for 60 min with primary antibodies at room temperature, incubating monoclonal antibodies against rat monocytes/macrophages (ED-1), rat CD4 and rat CD8. Then the sections are incubated with biotinylated donkey anti-mouse IgG for 30 min at room temperature. Biotinylated horseradish peroxidase is applied for 30 min at room temperature. Peroxidase activity is developed in 3,3-diaminobenzidine and hydrogen peroxide. The sections are then counterstained with Mayer's hematoxylin. The number of ED-1 positive cells, CD4 positive cells and CD8 positive cells per glomerular cross-section is counted in 20 glomeruli per rat.

EVALUATION

All data are expressed as mean ± SEM. Significance of differences between groups is determined using Wilcoxon's test.

MODIFICATIONS OF THE METHOD

Masugi and Sato (1934), Krakower and Greenspon (1951), Heyman et al. (1959, 1965), Eddington et al. (1968) already described experimental allergic glomerulonephritis in rats.

Ito et al. (1983), Nagao et al. (1994, 1998) induced crescentic type antiglomerular basement membrane nephritis in male Sprague Dawley rats by injecting 6.5 mg rabbit gamma-globulin in 0.25 ml Freund's complete adjuvant into the hind foot pads, following the injection of 0.6 ml of rabbit anti-rat glomerular basement membrane serum into the tail vein.

Couser et al. (1978) studied the development of immune deposits on the subepithelial surface of the glomerular capillary wall in isolated rat kidneys perfused at controlled perfusion pressure, pH, temperature, and flow rates with recirculating oxygenated perfusate containing bovine serum albumin in buffer and sheep antibody to rat proximal tubular epithelial cell brush border antigen.

Hayashi et al. (1996) tested the effects of a flavonoid in original-type anti-glomerular basement membrane antibody associated glomerulonephritis in male Sprague Dawley rats on upregulation of intracellular adhesion molecule expression and on increase in leukocyte function-associated antigen positive cells in nephritic glomeruli.

Nagamatsu et al. (1999) found beneficial effects of an angiotensin II type I receptor antagonist in anti-glomerular basement membrane antibody-associated nephritis in rats.

Sanaka et al. (1997) evaluated the effects of a free radical scavenger on the progression of nephrotoxic serum nephritis in male Sprague Dawley rats. The rat glomerular basement membrane was prepared according to the method of Krakower and Greenspon (1951) who localized the nephrotoxic antigen within the isolated renal glomerulus.

Kawasaki et al. (1992) induced crescentic glomerulonephritis with a small dose of nephrotoxic serum in WKY rats, which was characterized by the early infiltration of CD8 positive cells in glomeruli. *In vivo* depletion of CD8 positive cells completely prevented proteinuria and crescent formation.

Okuda et al. (1990) provided evidence of an elevated expression of transforming growth factor-β, proteoglycans and fibronectin in glomerulonephritis induced in rats by injection of anti-thymocyte serum.

Hamada and Nagase (1996), Chen et al. (1999) induced anti-Thy1 nephritis with the antibody to the Thy-1 antigen which is present in the mesangial cells of the glomeruli. The early pathobiological cellular events are characterized by invasion of platelets, polymorphonuclear leukocytes, and monocytes into the glomerulus which occurs within hours after induction of nephritis. Complement-dependent mesangiolysis then ensues between day 1 and 3.

Liebler et al. (2004) induced acute anti-Thy1.1-mesangioproliferative glomerulonephritis by administering 500 µg of Moab 1-22-3 dissolved in PBS as a single-shot injection into the tail vein of the rats on day 0. Moab 1-22-3 is a monoclonal antibody directed against the Thy1.1-like antigen on the surface of rat mesangial cells.

Passive Heymann nephritis (Heymann 1959) was used a model by Hara et al. (1991), Nagao et al. (1996), Heise et al. (1998). The disease is induced in rats by heterologous antibody to crude renal border antigen Fx1A. The model is characterized by granular deposition of heterologous and homologous antibody and complement along the glomerular capillary wall and as a counterpart, extensive electron-dense subepithelial deposits are seen at the ultrastructural level. Massive proteinuria develops after a latent period of 2 to 4 days in the absence of glomerular hypercellularity.

Kawasaki et al. (1995) studied the therapeutic effect of combined treatment with monoclonal antibodies against intercellular adhesion molecule 1 (ICAM-1) and lymphocyte-function-associated antigen 1 (LFA-1) in **Masugi nephritis** of Wistar–Kyoto rats.

Thaiss et al. (1989) evaluated the effect of the immunosuppressant cyclosporin A on an active model of *in situ* immune complex glomerulonephritis. Wistar rats were preimmunized with human IgG and 2 weeks after the last antigen injection, the left kidney was perfused with cationized human IgG in order to induce unilateral *in situ* immune complex glomerulonephritis.

Okubo et al. (1990) studied the immunosuppressive effects of FK506 on active Heymann's nephritis and the autologous phase of Masugi nephritis.

Rennke et al. (1994) developed a model system of acute nephritis in the rat whereby a chemically reactive form of the hapten azobenzenearsonate is introduced directly in to the left kidney of pre-immunized Brown Norway rats.

C.3.4 Experimental Nephrosis

PURPOSE AND RATIONALE

Some compounds used in antineoplastic therapy induce nephrosis in animals, like the antibiotic adriamycin (=doxorubicin) (Milner et al. 1991, 1994; Chagnac et al. 1994; Wapstra et al. 1996; De Boer et al. 1999; Mutti et al. 1999) or daunomycin (Kimura et al. 1993), the aminonucleoside puromycin (Yayama et al. 1993; Guoji et al. 1994; Magil 1996; Ebihara et al. 1997; Nosaka et al. 1997; Park et al. 1998; Asami et al. 1999; Pedraza-Chaverri et al. 1999) or cisplatin (Abdel-Gayoum et al. 1999).

These models allow to test the protective effects of drugs even after the renal disease in established, i. e. mimic the clinical situation (Wapstra et al. 1996).

PROCEDURE

Male Wistar rats with an initial weight of about 300 g receive a single intravenous dose of 2 mg/kg adriamycin. Twice a week during a 12-weeks period, the animals are weighed, 24-h urine is collected and blood pressure is measured by the tail-cuff method.

During the first 5 weeks, all animals are kept on a low sodium diet with tap water ad libitum. After stabilization of proteinuria (5 weeks), animals are divided into 2 groups receiving either low sodium or normal sodium diet. After a week stabilization on these diets, animal receive different doses of treatment in their drinking water. These regimen is continued until the end of the study (week 12), at which time all animals are sacrificed and blood samples and kidney tissue are obtained.

During each blood pressure measurement session, five measurements are recorded for each animal. The blood pressure is taken as the mean of the last 3 recordings. Urinary protein is determined by the Pyrogallol Red-molybdate method (RA-1000 Technicon). Urinary sodium, creatinine and urea and serum electrolytes, creatinine, albumin, cholesterol and triacylglycerols are measured by a standard autoanalyser technique. Kidney samples are fixed in paraformaldehyde and embedded in paraffin. Sections

are stained with the periodic acid/Schiff technique. Focal glomerular sclerosis is scored semiquantitatively by light microscopy.

EVALUATION

Analysis of co-variance is used to compare the experimental groups (defined by diet or dose of drug) after 2 weeks of treatment (week 8) and the end of the study (week 12) with the baseline value (week 6) as a co-variable. Tuckey's method is used for comparison of groups receiving different doses of drug. The other statistical comparisons are performed using Student's *t*-test.

MODIFICATIONS OF THE METHOD

Fawn-Hooded rats develop systemic hypertension and spontaneous age-dependent glomerulosclerosis with proteinuria (Mackenzie et al. 1997).

Spontaneous nephrosis with proteinuria occurs in Dahl salt-sensitive rats fed on a normal sodium diet (Yoneda et al. 1998).

Mizuno et al. (1999) studied the ICGN mouse strain as a unique model for naturally occurring nephrotic syndrome.

Focal segmental glomerulosclerosis with heavy proteinuria has been found in mice in which the Mpv17 gene was inactivated ($Mpv17^{-/-}$ mice). Binder et al. (1999) recommended these animals as model of steroid-resistant nephrosis sensitive to radical scavenger therapy.

Kimura et al. (1993) described strain specificity in the susceptibility of mice to daunomycin-induced nephrosis.

Klahr and Morrissey (1997) described the effects of ACE inhibitors and angiotensin II receptor antagonists on various parameters associated with renal interstitial fibrosis induced by unilateral ureteral obstruction in rats.

C.4
Uricosuric and Hypo-Uricemic Activity

C.4.1
In Vitro Methods

C.4.1.1
Inhibition of Xanthine Oxidase In Vitro Indicating Hypouricemic Activity

PURPOSE AND RATIONALE

Synthesis of uric acid primarily occurs in the liver, but the kidney has an important role in the pathophysiology of hyperuricemic syndromes. Because uric acid is poorly soluble, excessive amounts in the circulation may precipitate out into the tissues, particularly the joints, resulting in a painful arthropathy ("gout"). In humans, this condition is usually the result of faulty tubular transport of urate, resulting in increased net reabsorption. Attempts to treat hyperuricemia with tubular transport inhibitors (theoretically increasing urinary excretion of urate) frequently exacerbate the condition because tubular transport is bi-directional; reduction of net uric acid synthesis by inhibition of xanthine oxidase is the preferred therapeutic approach. Furthermore, in renal hypoxic conditions, xanthine oxidase contributes to renal injury by the generation of oxygen free radicals and xanthine oxidase inhibition has been shown to be useful in such conditions (Shinosaki and Yonetani, 1991; Rhoden et al. 2000;Terkeltaub et al. 2006).

Xanthine oxidase catalyzes the oxidation of hypoxanthine and xanthine to uric acid. Xanthine oxidase is a complex metalloflavoprotein containing one molybdenum, one FAD and two iron-sulfur centers of the ferredoxine type in each of its two independent subunits. Usually, the enzyme is isolated from cow's milk. The enzyme is inhibited by allopurinol and related compounds. The production of uric acid from the substrate (xanthine) can be determined by measuring the change in optical density in the UV range.

PROCEDURE

The test compound is incubated with xanthine oxidase (usually derived from milk, sometimes derived from rat liver or small intestine), EDTA and phosphate buffer solution (pH 7.8) at 37°C. Control solutions without test compound are incubated under identical conditions. Following addition of xanthine, the change in absorbance is determined.

Assay conditions:

- wavelength: 293 nm
- line path: 10 mm
- final volume: 1.0 ml

EVALUATION

The percent inhibition of xanthine oxidase is determined relative to control solutions.

IC_{50} values of test compounds are calculated.

Standard data:

- Allopurinol: IC_{50}: ca 10^{-8} mol/l

C.4.1.2
Urate Uptake in Brush Border Membrane Vesicles

PURPOSE AND RATIONALE

The urate-anion exchanger system in brush border membrane vesicle, which mediates hydroxyl ion gradient-dependent urate uptake, is the most likely route for the mediation of urate transport in the first step of urate reabsorption in the proximal tubules. Luminal drugs which inhibit urate reabsorption are inhibiting the transport of urate by blocking the urate/anion exchanger.

PROCEDURE

Male Sprague Dawley rats weighing 320–380 g are sacrificed by decapitation and the kidneys are removed immediately. All steps for the preparation of brush border membrane vesicles are carried out at 4°C. Renal cortex is homogenized for 2 min in a medium containing 250 mmol/l mannitol, 10 mmol/l Tris, 16 mmol/l HEPES buffer (pH 7.5) using a Physcotron homogenizer. The homogenate is centrifuged at 2400 *g* for 10 min and the supernatant is centrifuged at 2800 *g* for 20 min. Subsequently, the supernatant is discarded and the loosely packed membrane-rich layer is flushed off from the bottom densely packed brown pellet. The membrane-rich layer is resuspended manually

in 250 mmol/l mannitol containing 10 mmol/l Tris-HEPES (pH 7.5) using a Dounce homogenizer and $MgSO_4$ is added to a final concentration of 10 mmol/l. After standing for 20 min, the suspension is centrifuged at 2400 *g* for 20 min and the supernatant containing brush border membranes is recentrifuged two more times at 2400 *g* for 20 min. The final supernatant is centrifuged at 28,000 *g* for 20 min and the pellet is suspended in a small amount of medium containing 150 mmol/l mannitol, 50 mmol/l potassium phosphate buffer (pH 7.5) and 2 mmol/l $MgSO_4$ to a final protein concentration of 4–8 mg/ml. The brush border membrane vesicle preparation is frozen and stored at –80°C until use.

After preincubation of the brush border membrane vesicle preparation for 2 h, [2-^{14}C]urate uptake is initiated by adding 200 µl of incubation medium to 20 µl of the membrane suspension. The incubation medium has the following composition (mmol/l): 150 mannitol, 2 $MgSO_4$, 50 potassium phosphate buffer, pH 6.0 or 7.5, 0.02 [2-^{14}C]urate, and various concentrations of the inhibitor. At 10 s after the addition of the incubation medium, 200 µl portions of the suspension are pipetted onto the center of prewetted cellulose acetate filters kept under suction. The vesicles retaining on the filter are washed immediately with 5 ml of an ice-cold solution containing 150 mmol/l mannitol and 50 mmol/l potassium phosphate buffer, pH 6.0 or 7.5, which is used at the same pH as the incubation medium. Preincubations and incubations are performed at 23 ± 1°C. Each experiment is performed in triplicate. Corrections are made for the radioactivity bound to the filters in the absence of membrane vesicles. The term of the OH^- gradient-dependent urate uptake is defined as the difference between the uptakes in the incubation medium at pH 6.0 and that at pH 7.5. The OH^- gradient-dependent urate uptake at 10 s is assumed to present an initial velocity.

EVALUATION

From a concentration-response curve relating log concentration of drug to the logit activity of the OH^- gradient-dependent urate uptake for 10 s, IC_{50} (concentration producing 50% of inhibition) is determined by least-squares regression analysis.

C.4.2 In Vivo Methods

C.4.2.1 Diuretic and Uricosuric Activity in Mice

PURPOSE AND RATIONALE

Renal excretion of uric acid consists of three components: complete filterability of uric acid in the glomerulus, subsequent tubular reabsorption, and tubular secretion (Gutman and Yü 1961). Pronounced species differences have been described in uric acid metabolism including man. Mice were recommended for primary screening of uricosuric drugs.

PROCEDURE

Male NMRI mice weighing 25–30 g are used. On the evening prior to the experiment, food but not water is withheld. In the morning, the mice are orally loaded with 50 ml/kg 0.9% NaCl-solution. Together with the sodium load the test compound is applied by gavage in 2% starch suspension. Controls receive saline and starch suspension only. Groups of 5 mice are placed into metabolism cages. Urine is collected over 4 h. In the urine sodium and potassium are determined by flame photometry, chloride by argentometrically with potentiometrical end point titration (Chloride titrator, Aminco), uric acid by the Uriquant-method, creatinine by the Jaffé-reaction, as well as pH and osmolality.

EVALUATION

Urine excretion is calculated in ml/kg. Uric acid-, creatinine- and ion-excretions are calculated in mmol/kg and expressed as percent changes versus controls. The changes are evaluated statistically using Student's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

Some saluretic-diuretic agents, like ethacrynic acid, are inactive in the rat, when given orally. Moreover, uricosuric activity in mice is less reliable than that in primates.

C.4.2.2 Hypouricemic Activity After Allantoxanamide Treatment in Rats

PURPOSE AND RATIONALE

Most species used for pharmacological experiments have rather low blood levels of uric acid. Experimental hyperuricemia can by induced by inhibition of the enzyme uricase. In most species uricase metabolizes uric acid to allantoin. Allantoxanamide blocks uricase and increases endogenously synthesized uric acid. This increase is blocked by compounds like allopurinol.

PROCEDURE

Non fasted male Sprague Dawley rats weighing 230–280 g are treated by intraperitoneal injection of 250 mg/kg allantoxanamide suspended in 5 ml/kg sesame oil. The test compound is applied orally in a dose of 50 mg/kg in 40 ml/kg water. Likewise, the standard compound allopurinol is given in a dose of 50 mg/kg. Eight rats are used for the each dose of test drugs and standard. The animals are placed individually into metabolism cages with free access to food and water. Urine is collected during the periods of 1 to 6 and 7 to 24 h. Blood is withdrawn by retroorbital puncture prior and 2, 6 and 24 h after compound administration. Uric acid is determined with the Uric-aquant-method in plasma [mmol/l] and urine [mmol/l].

EVALUATION

Mean values of uric acid concentrations in plasma at the different time intervals and mean values of uric acid excretion after 6 and 24 h of the test group are compared with the control group (allantoxanamide treated only) using Student's *t*-test.

C.4.2.3 Hypouricemic and Uricosuric Activity After Potassium Oxonate Treatment in Rats

PURPOSE AND RATIONALE

Increase of uric acid in serum of rats is induced by a special diet and the uricase inhibitor potassium oxonate. Uric acid concentration in serum and uric acid excretion in urine prior and after three experimental days are determined.

PROCEDURE

Male Wistar rats weighing 250 g are placed individually in metabolic cages. They are offered a special diet containing 5% fructose, 3% uric acid, 2% potassium oxonate (2,4-dihydroxy-1,3-triazine-6-carbonic acid) and 0.001% artificial sweetener. Drinking water consists of a 0.5% solution of potassium oxonate. The animals are treated orally with 50 or 100 mg/kg of the test compound or the standard (allopurinol) dissolved in 5 ml/100 g body weight of 0.5% potassium oxonate solution. The treatment is repeated on the second day. On the third day 24 h urine is collected and the animals are sacrificed by exsanguination. Concentrations of uric acid and electrolytes (Na^+, K^+, Cl^-) are determined in blood and urine.

EVALUATION

Concentrations of uric acid and electrolytes in blood and urine of animals treated with the test compound are compared statistically with control and standard drug treated animals.

MODIFICATIONS OF THE METHOD

Clearance techniques in oxonate-treated rats were used by Yonetani et al. (1987), Shinosaki et al. (1991), Dan et al. (1994).

Sugino and Shimada (1995) tested uricosuric effects in oxonate-loaded rats, in the pyrazinoic acid suppression test and in the phenolsulfonphthalein test.

C.4.2.4 Phenol Red Excretion in Rats

PURPOSE AND RATIONALE

Phenol red (= phenolsulfonphthalein) excretion is an indirect test for uricosuric activity. After intravenous injection phenol red is mainly eliminated by active secretion in the proximal tubulus of the kidney. Treatment with uricosuric agents decreases the secretory activity of tubulus cells resulting in a delayed excretion of phenol red. Plasma values of phenol red are increased in treated animals as compared to controls.

PROCEDURE

Male Wistar rats weighing 120–150 g are treated orally with the test compound or the standard 30 min prior to intravenous injection via the tail vein with 2.5 ml/kg of a 3% aqueous solution of phenolsulfonphthalein. For intravenous application, 5.0 ml/kg of the test drug solution are injected immediately after the phenolsulfonphthalein injection followed by flushing with 2.5 ml/kg saline. By retro-orbital puncture blood samples are withdrawn after 30, 60 and 180 min. Blood (0.2 ml) is diluted with 2 ml 0.9% NaCl-solution and centrifuged. To 1 ml of the supernatant 1 ml of 1% sodium carbonate solution and 8 ml of saline are added. Using a spectrophotometer (Eppendorf, Hamburg) extinction at 546 nm is determined.

EVALUATION

Extinction values are calculated for total blood. At each time interval the values in treated rats are compared statistically with those of controls.

C.4.2.5 Uricosuric Activity in Dalmatian Dogs

PURPOSE AND RATIONALE

Most species have low plasma levels and low renal excretion of uric acid. The Dalmatian dog is an exception with excessive uric acid excretion, but with relatively high plasma levels. Explanations are a genetically determined defect in tubular reabsorption of the filtered urate (Friedman and Byers 1948; Kessler et al. 1959) and a defective hepatic uricase activity (Yü et al. 1971). The Dalmatian dog is being used for studies of uricosuric agents.

PROCEDURE

Conscious male Dalmatian dogs with a body weight of about 20 kg are used. Food but not water is withheld 24 h prior to the experiment. The animals are placed individually in metabolic cages. The urinary bladder is emptied by catheterization. Twenty ml/kg drinking water is applied by gavage. Every 2 h the animals are catheterized again, blood is withdrawn from a jugular vein and additional 8 ml/kg drinking water is applied by gavage. The urine and blood values obtained after the first 2 h serve as control. Then, the test compound is applied either i.v. or orally. Up to 8 h blood and urine samples are collected every 2 h. No water is given af-

ter the last sampling. The dogs stay over night in the metabolic cages. Twenty-four hours after beginning of the experiment, venous puncture and catheterization is performed once more. Blood and urine samples are analyzed for uric acid (Uricaquant-method), creatinine (Jaffé reaction), sodium and potassium (flame photometry), calcium and magnesium (atom absorption method), and chloride (argentometry) as well as for osmolality.

EVALUATION

The values after application of the drug are compared with predrug values.

CRITICAL ASSESSMENT OF THE METHOD

Dalmatian dogs bred by commercial breeders are not always homozygous. Therefore, not every dog is suitable for experiments on uric acid excretion.

C.4.2.6 Uricosuric Activity in Cebus Monkeys

PURPOSE AND RATIONALE

The Cebus monkey is described not to possess uricase (Simkin 1971) and to have different metabolic conditions for uric acid than other experimental animals. This species is chosen for special studies of anti-uricopathic drugs since it resembles more closely human uric acid metabolism.

PROCEDURE

Cebus monkeys (*Cebus albifrons*) of either sex weighing 3.0 to 5.0 kg are used. Twenty-four h prior to the test, food is withheld, but water is available ad libitum. On the morning of the experiment, the animals receive 20 ml/kg drinking water by gavage, followed by oral application of the test compound. Control animals receive water only. The animals are placed in individual metabolism cages and the spontaneously voided urine is collected after 2, 6, and 24 h. After 2 and 6 h, additional 4 ml/kg water is given by gavage. From a cubital vein blood is withdrawn prior to the experiment and 2, 6 and 24 h after application. Urine and serum samples are analyzed for uric acid (Uricaquant-method), creatinine (Jaffé reaction), sodium and potassium (flame photometry), calcium and magnesium (atom absorption method), and chloride (argentometry) as well as for osmolality.

EVALUATION

Allopurinol and probenicide are used as standard drugs and are compared with test compounds.

CRITICAL ASSESSMENT OF THE METHOD

The use of the Cebus monkey as animal model has been proven to be the most valuable method to test putative hypouricemic compounds (Hropot 1988).

MODIFICATIONS OF THE METHOD

Onuma et al. (1988) used Cebus monkeys for evaluation of uricosuric effects of an aryloxyacetic derivative.

Yonetani et al. (1987) performed clearance experiments with uricosuric drugs in anesthetized chimpanzees.

Dan et al. (1989) tested the activity of AA-193, an uricosuric agent in rats, mice and Cebus monkeys.

C.5 Influence on Lower Urinary Tract

C.5.1 In Vivo Studies

C.5.1.1 Micturition Studies

PURPOSE AND RATIONALE

Urinary incontinence is a major psychosocial, medical, and economic problem. The most common condition to be treated pharmacologically is incontinence due to detrusor instability. The response of the urinary bladder to filling with increasing volumes of fluid (cystometrogram) is a common procedure for evaluating bladder function in both animals and humans. The response of the vesico-urethral complex can be arbitrarily divided into the collection and expulsion phases. The nervous control of the detrusor, the internal and the external sphincter has been reviewed by Kuru (1965). A detailed description of the nervous control of the urinary bladder of the cat has been given by De Groat (1975). The pharmacology of lower urinary tract muscles and penile erectile tissues has been reviewed by Anderson (1993). Ferguson and Christopher (1996) reviewed urine bladder function and drug development. Urine storage and timely expulsion of bladder content are produced through the coordinated activation of a series of reflexes involving cholinergic, sympathetic, and, possibly, purinergic, serotonergic, and peptidergic innervation. In view of this complexity, *in vivo* models were developed for the quantitative analysis of the effects of drugs on the function of the vesico-urethral complex (Maggi et al. 1983, 1985, 1986, 1987a, b, 1992).

PROCEDURE

Male Wistar rats weighing 340–360 g are anesthetized by subcutaneous injection of 1.2 g/kg urethane. The left jugular vein is cannulated for drug injection. Body temperature is kept constant by means of a heating pad maintained at 37°C. Through a midline incision of the abdomen, the urinary bladder is exposed and emptied of urine by application of a slight manual pressure. A 20-gauge needle is inserted through the apex of the bladder dome for 3–4 mm into its lumen. The needle is connected to a pressure transducer by means of a polyethylene tubing (1.5 mm OD and 1.0 mm ID) and the whole system filled with saline. The tubing is provided with an internal coaxial polyethylene tubing (0.6 mm OD and 0.3 mm ID) inserted through a side hole and sealed by a drop of epoxy resin. The second tubing serves for intravesical infusion of fluid and is connected, through a peristaltic pump, to a saline reservoir.

Intraluminal pressure signals are delivered to an amplifier and displayed on a four channel polygraph. Warm saline-soaked cotton wool swabs are laid around the exteriorized organ to maintain its temperature and to keep it moist in experiments involving the topical application of substances on the bladder dome.

After a 15-min equilibration period at zero volume, variations in intraluminal pressure are recorded in response to continuous infusion of saline at a rate of 2.8 ml/h at 37°C for 30–40 min by means of a peristaltic pump connected to the polyethylene tubing inserted into the bladder. This infusion rate simulates the maximal hourly diuresis within the physiological range. In each preparation the infusion is continued until micturition occurs. Micturition is referred as the emission of several drops of fluid during a sustained phasic contraction of the detrusor muscle which is followed by return to zero or, in any case, to a value lower than that recorded just before micturition.

For both intravenous and topical administration, substances are dissolved in saline.

EVALUATION

In each experiment, the following parameters are evaluated:

1. pressure threshold = intraluminal pressure value recorded just before micturition
2. volume threshold = the volume of infused saline required to obtain micturition
3. maximal amplitude of micturition contraction
4. residual volume after micturition

The effect of substances on the compliance of the bladder wall is evaluated by comparing the volume-pressure-relationship of treated animals with that of controls.

Statistical analysis of the data is performed by means of the Student's *t*-test for paired or unpaired data, or by means of analysis of variance followed by the Tukey test. Statistical analysis of nonparametric data is made by the chi square test.

MODIFICATIONS OF THE METHOD

Either chemical (6-hydroxydopamine, reserpine) or surgical (section of hypogastric nerves) sympathectomy produces a picture of detrusor hyperreflexia and urine dropping, mimicking cystometric finding in human disease (Maggi et al. 1987a).

Postius and Szelenyi (1983) described a model for *in vivo* screening of spasmolytic compounds using the rat bladder.

Dray (1985) used the spontaneous, volume-induced contractions of the urinary bladder in the anesthetized rat to assess the central activity of substances with opioid properties.

Pietra et al. (1990) studied the effects of some antidepressants on the volume-induced reflex contractions of the rat urinary bladder. The urinary bladder of anesthetized rats was filled via the recording catheter by incremental volumes of warmed saline until bladder contractions occurred as a result of central activity. Volume-induced contractions were then recorded and occurred rhythmically and reproducibly for 2–3 h. Drug activity was assessed in each animal against the background frequency of bladder contractions, for a 15-min time period following intravenous administration of different doses.

Harada et al. (1992) proposed a method for rapid evaluation of the efficacy of pharmacologic agents and their analogs in enhancing bladder capacity and reducing the voiding frequency. Conscious rats were placed in a restrainer over a urine collector. The collector was secured to an Statham UC3 strain transducer, the output of which was amplified by a Gould bridge amplifier. Data were monitored on a polygraph. This method has been simplified by the use of an infared photodiode sensor and matched phototransistor than can detect the appearance of urine flowing from the bottom of a metabolic cage, recodrig the frequency of these events. This method produces results comparable to the original cup-fore transducer methods (Argentieri and Argentieri 2002).

Conte et al. (1991) proposed a method for simultaneous recording of vesical and the external urethral sphincter pressure in urethane-anesthetized rats.

Angelico et al. (1992) reported *in vivo* effects of different antispasmodic drugs on the rat bladder contractions induced by topically applied KCl.

Oyasu et al. (1994) measured spontaneous bladder contractions caused by raising the intravesical volume in anesthetized rats.

Yaksh et al. (1986) described a chronic model for study of micturition in unanesthetized rats. A bladder catheter was implanted chronically through laparatomy and externalized percutaneously.

Horváth et al. (1994) reported an ultrasonic method to study the influence of drugs on micturition in intact rats.

Tillig and Constantinou (1996) described videomicroscopic imaging of urethral peristaltic function in anesthetized rats. Cystometrograms were performed by recording continuously the bladder pressures while detecting micturition using a sensor placed at the orifice of the urethra. Renal pelvic pressure was measured during continuous perfusion using a nephrostomy inserted through the parenchyma. A catheter was placed in the femoral vein for intravenous drug administration. The left pyelo-ureteric junction and the upper part of the ureter were visualized using a stereomicroscope equipped with a video camera and a tape recorder. One syringe pump was used for filling the bladder to perform continuous cystometrograms. An other syringe pump was used for infusion of indigo carmine to assist the visualization of the bladder pressure.

Conte et al. (1988) developed a cystometric technique for quantitative studies on physiopharmacology of micturition in conscious, freely moving rats.

Seif et al. (2004) performed urinary bladder volumetry by means of a single retrosymphysically implantable ultrasound unit.

Peterson et al. (1989), Noronha-Blob et al. (1991) described *in vivo* cystometrogram studies in urethane-anesthetized and conscious **guinea pigs**.

Moreau et al. (1983) described simultaneous cystometry and uroflowmetry for evaluation of the caudal part of the urinary tract in **dogs**.

Imagawa et al. (1989) reported an *in vivo* procedure for functional evaluation of sympathetically mediated responses in lower urinary tract of dogs.

Häbler et al. (1990, 1992) examined the functional properties of unmyelinated and myelinated primary afferent neurons innervating the pelvic viscera in anesthetized **cats**. The axons were isolated from the intact dorsal root and the intact or chronically de-efferented ventral root of segment S2. The responses of the neurons were studied with natural stimulation of the urinary bladder using innocuous or noxious increases of intravesical pressure.

Tai et al. (2004). Decribed bladder and urethral sphincter responses evoked by microstimulation of S2 sacral spinal cord in spinal cord intact and chronic spinal cord injured **cats.**

C.5.2 Studies in Isolated Organs

C.5.2.1 Studies on Renal Pelvis

PURPOSE AND RATIONALE

Periodic contraction of the renal pelvic wall is important to the process of concentration of urine in the renal medulla as well as the propulsion of urine from the kidney into the bladder (Santicioli and Maggi, 1997, 1998; Knepper et al. 2003). The isolated renal pelvis of the guinea pig has been used to examine the effects of compounds an this activity. (Maggi and Giuliani 1991, 1992; Maggi et al. 1992a, b, 1992c, 1994, 1995; Giuliani and Maggi 1996; Santicioli et al. 1995, 1997; Patachini et al. 1998; Bigoni et al. 1999).

PROCEDURE

Male albino guinea pigs weighing 250–300 g are used. Following appropriate anesthesia and euthanasia, one whole kidney and attached ureter are removed and placed in oxygenated Krebs solution. The renal pelvis is carefully dissected from the renal parenchyma, separated from the ureter, cut and connected to threads

to record motility along the circular axis. The preparation is suspended in a 5 ml organ bath and mechanical activity recorded by means of an isotonic transducer (load 1 mN). Transmural electrical field stimulation is made by means of platinum wire electrodes placed at the top and the bottom of the organ bath and connected to a GRASS S 88 stimulator. Square wave pulses (pulse width 0.5 ms, 60 V) are delivered in trains of 10 s duration at frequencies of 5 to 10 Hz.

Experiments commence after a 60 to 90 min equilibrium period after which amplitude and frequency of spontaneous activity has reached a steady state. *In vitro* capsaicin desensitization is made by exposure of the preparation to 10 μM for 15 min, followed by washing out and further equilibration for 30–60 min.

Concentration response curves to noradrenaline and acetylcholine are performed by non-cumulative addition to the bath at 20 min intervals. Contact time of drugs is 15 min.

EVALUATION

The amplitude and frequency of spontaneous contractions are assessed and the Motility Index (MI) is calculated as follows:

$$MI = (\Sigma amp/5) \times F$$

where Σamp/5 is the mean amplitude of five contractions (in mN) and F is the frequency (in min^{-1}) of those five contractions. Concentration-response curves are generated by plotting the concentration versus the MI (either raw or expressed as a percent of control, using the parallel incubation as the control) (Davidson and Lang, 2000).

MODIFICATIONS OF THE METHOD

Zhang and Lang (1994), Lang et al. (1995), Lang and Zhang (1996) Teele and Lang (1998) recommended circumferentially cut strips from the proximal renal pelvis of guinea pigs since these strips contract more frequently than strips cut from the mid region.

Kimoto and Constantinou (1990, 1991) studied contractility of smooth muscle strips from the pacemaker regions and pelviureteric junction of renal pelvis from **rabbits**.

Kondo et al. (1992) determined the effects of dobutamine and terbutaline on adenylate cyclase activity and cyclic AMP content in the renal pelvis of rabbits.

Seki and Suzuki (1990) made intracellular recordings to study the electrical properties of smooth muscle cells in the rabbit renal pelvis.

Zwergel et al. (1991) developed an intact **canine** model to measure renal pelvic pressure after complete ureteral obstruction with a balloon catheter inflated in the distal ureter.

C.5.2.2 Propagation of Impulses in the Guinea Pig Ureter

PURPOSE AND RATIONALE

The mammalian ureter provides one of the clearest examples of electromechanical coupling in smooth muscle. The ureter smooth muscles are electrically and mechanically quiescent but, when depolarized to threshold, they fire an action potential characterized by an unusually long-lasting potential and generate a phasic contraction (Shuba 1977; Brading et al. 1983; Meini et al. 1995). Both the action potential and the accompanying contraction critically depend upon the influx of extracellular calcium through voltage-sensitive L-type channels, which are enhanced and blocked by dihydropyridine drugs, Bay K 8644 and nifedipine, respectively. The model predicts that suppression of action potentials at any site of the ureter will suppress the propagation of contraction and peristalsis. (Weiss 1992).

PROCEDURE

A number of species (most commonly rats and guinea pigs) have been used for whole-mount or strip preparations. Following appropriate anesthesia, the whole kidney and ureter are excised and placed in a Petri dish containing oxygenated Krebs solution for dissection. A 4–5 cm long piece of ureter is dissected from the inferior renal pole and placed in a three-compartment organ bath which enables a separate superfusion of different parts of the organs. Two Perspex partitions are used to separate the renal-, middle- and bladder-sites. They include a window covered with condom rubber: a small hole (about 300 µm) is made in the rubber to enable the passage of the ureter. Proximal to each partition, the renal and bladder ends are pinned to a Sylgard support. The distal portions of the renal and bladder ends are connected via a pulley to isotonic transducers (Basile 7006, load 2 mN) for recording of mechanical activity on a two-channel polygraph. Each compartment is perfused by means of a peristaltic pump at a rate of 1 ml/min with oxygenated Krebs solution at 34°C.

The frequency and amplitude of spontaneous contractions are recorded. Alternatively, electrical field stimulation is applied to either compartment by means of two wire platinum electrodes positioned in parallel with the two sides of the ureter. Square wave pulses (5–25 ms pulse width, 20 V) are automatically delivered every 100 s by means of a GRASS S88 stimulator.

Drugs are applied by superfusion at the middle site. Amplitudes of contraction are recorded.

EVALUATION

The amplitude and frequency of contractions are assessed and the Motility Index (MI) is calculated as follows:

$$\mathrm{MI} = (\Sigma \mathrm{amp}/5) \times F$$

where Σ amp/5 is the mean amplitude of five contractions (in mN) and F is the frequency (in min^{-1}) of those five contractions.

Data are expressed as a percent of the control value and appropriate statistical analysis is performed. Concentration-response cuves may be plotted and pA_2 or pD_2 values may be calculated. Hill coefficients and EC_{50} values may also be calculated (Weiss et al. 2002).

MODIFICATIONS OF THE METHOD

Ureter preparations have been made from pig or human tissues collected at slaughter or following surgery, respectively. Ideally, no more than 20 minutes should elapse between tissue collection and incubation. Tissues are placed into cold (4°C) Krebs buffer or suitable balanced electrolyte solution and cut into rings of 0.5 to 1 cm in length. The rings are attached to a force transducer, suspended in an organ bath at 37°C, and

allowed to equilibrate for up to 1.5 hours while the frequency and amplitude of spontaneous contraction is measured. If the preparation demonstrates acceptable and stable frequenct and amplitude of spontaneous contraction within this time period it is considered suitable for experimental use. In pigs, the washout period between treatments is variable and thus the preparation is monitored for return to pre-treatment baseline before the next treatment is applied. In human tissue, spontaneous contraction seldom occurs and electrical stimulation (trains of 300 ms at an interval of 200 s and impulses of 200 mA with a duration of 6 ms at a frequency of 50 H) is required. A washout period of 20 minutes between treatments is used (Weiss et al. 2002).

The evaluation of regional differences in response, and the effect of regional responses on adjacent regions, can be evaluated in a whole ureter preparation where each region remains physically attached but can be isolated for the application of test compounds or stimuli. The entire ureter is dissected and placed in a three-compartment organ bath which enables a separate superfusion of different parts of the organs. Two Perspex partitions are used to separate the proxima (renal), middle, and distal (bladder) ends. They include a window covered with condom rubber: a small hole (about 300mm) is made in the rubber to enable the passage of the ureter. The proximal portions of each segment are pinned to a Sylgard support, and the distal portions are connected to isotonic transducers for recording of mechanical activity. Each compartment is perfused separately and electrical field stimulation can be applied to any compartment by means of two wire platinum electrodes positioned in parallel with the two sides of the ureter (Meini et al. 1995).

Tomiyama et al. (2003) characterized functional muscarinic cholinoceptors in the isolated ureter of **dogs.**

C.5.2.3 Studies on Urinary Bladder and Internal Urethral Sphincter

PURPOSE AND RATIONALE

Several authors investigated the influence of drugs on isolated parts of the lower urinary tract. Ueda et al. (1984) studied the effects on smooth muscle of the rabbit bladder dome, trigone and proximal urethra.

PROCEDURE

Male New Zealand rabbits weighing 2–3 kg are sacrificed and the abdomen is opened to remove the bladder and the urethra. After excess fat and connective tissue is removed, the bladder and the urethra are dissected into dome, trigone and proximal urethral preparations. All strips are cut transversely being approximately 2×6 mm unstretched. Ligatures are placed on both ends of the strips and one end is attached to a tissue holder and the other to a strain gauge force-displacement transducer connected to a polygraph on which isometric tension changes are recorded. Each of the strips is then placed into a 20 ml tissue bath containing Krebs-Ringer solution bubbled with 95% O_2+5% CO_2 at 37°C. Resting tension is adjusted to 1 g during an equilibrium period of at least 2 h. The contractile and relaxant responses are measured as increases or decreases from the resting tension. Doses-response curves are performed in a cumulative matter. Tissues are pretreated with an antagonist 20 min before the addition of an agonist.

EVALUATION

The values are expressed or plotted as the means ± SE and pA_2 values are calculated according to Arunlakshana and Schild (1959). Data are analyzed using the *t*-test, analysis of variance, Dunnett's test and regression analysis.

MODIFICATIONS OF THE METHOD

Rats and guinea pigs have been used for whole bladder preparations. Following appropriate anesthesia, the abdomen is opened to remove the bladder and the urethra. After excess fat and connective tissue is removed, the preparation is placed *en bloc* into appropriate bal-

anced electrolyte solution (Tyrode's or Krebs buffer) bubbled with 5% CO_2 and 95% O_2. The urethra is cannulated and connected to a pressure transducer, and the bladder is filled with a volume of solution adequate to evoke a contractile response. The bladder preparation is allowed to equilibrate for 30 minutes before any experimental manipulations are performed. The amplitude and frequency of pressure changes are recorded (Birder et al. 1999; Drake et al. 2003).

Alternatively, contractility can be assessed visually. Surface blood vessels or externally applied markings (India ink or carbon particles) are used as landmarks. Video image recording of the bladder preparations are made during the experimental manipulations. Still images from the video are evaluated and the change in linear distance between pairs of landmarks is used as an index of contractility (Drake et al. 2003).

Pietra et al. (1990) studied the effects of some antidepressants by the *in vitro* inhibition of carbachol-induced contractions of rat detrusor strip preparations. The detrusor muscle tissue (bladder dome) was cut in a semicircular direction and further dissected into strip preparations measuring approximately 2 × 20 mm.

The preparation of the isolated, innervated urinary bladder of the rat was reported by Hukovic et al. (1965). Electrical stimulation was performed by a bipolar electrode from the nerves running close to the ureter.

Mapp et al. (1990) used the isolated rat urinary bladder to study the pharmacological modulation of the contractile response to toluene diisocyanate.

Maggi et al. (1985) used isolated detrusor strips of rat bladder connected to an isometric strain gauge and stimulated by field stimulation.

Anderson (1978) recommended the **rabbit** detrusor muscle a an unique *in vitro* smooth muscle preparation. Rabbit detrusor muscles are thin and devoid of underlying submucosal tissue with parallel fiber orientation. The tissue exhibits autorhythmicity, characteristic of most single unit type smooth muscle preparations and can be employed in either isometric or isotonic organ bath recording systems.

Honda and Nakagawa (1986) studied the effects of the optical isomers of an alpha-1 adrenoceptor antagonist in rabbit lower urinary tract and prostate.

Khanna et al. (1977, 1981) evaluated the *in vitro* responses of three segments of rabbit lower urinary tract, e. g., the bladder body, the bladder base and the proximal urethra.

Ferguson and Marchant (1995) studied the inhibitory actions of GABA on rabbit urinary bladder muscle strips.

Andersson et al. (1983) studied the electrically induced relaxation of the noradrenaline contracted isolated urethra from rabbit and man. In rabbits, two circular transverse sections, each 4 mm long, were taken from the middle and upper parts of the urethra. Human urethral preparations were obtained from male patients undergoing cysto-urethrectomy en bloc because of bladder cancer. Rings of tissue were taken from the membranous and supra- and infra-collicular parts of the prostatic urethra.

Andersson et al. (1992) used transversal strips from the middle and upper part of rabbit urethra to study the involvement of nitric oxide in the electrically-induced, nerve-mediated relaxation.

Contractile responses to nervous stimulation can be assessed in whole isolated bladder preparations. The pudendal nerve remnants can be identified near the ureter and can be attached to electrodes for stimulation of the bladder. Alterations in the contractile responses by the test compound are considered to result from effects at the neuromuscular junction (Hukovic et al. 1965; Weetman, 1972; Dhattiwala and Dave, 1975).

Inci et al. (2003) used a coaxial bioassay system to test the effect of inflammation on rat urinary bladder-dependent relaxation. In this bioassay model, the bladder was the donor organ for the assays and rat anococcygeus muscle was the assay tissue. The rat bladders removed from control or treatment groups were used in its original shape after making small cuts at bladder neck and dome. The rat anococcygeus muscle was always isolated from control group of rats. The anococcygeus muscle was placed in the lumen of the bladder, so that freely enveloped by the bladder, and mounted under a resting tension of 1 g in a 20 ml organ bath filled with Krebs-Henseleit solution at 37°C and gassed with 95% O_2–5% CO_2.

Denervated urinary bladder preparations (whole or strips) can be used to determine the degree of effect on nervous system inputs. Following appropriate anesthesia, the pelvic plexus is accessed in rats by a ventral midline incision and both pelvic ganglia are obliterated by electrocauterization. The animals are allowed to recover for at least four days before the urinary bladder is harvested as described above; during this period, the neurotransmitters downstream from the nervous system inputs become inactive and only the autonomous inputs remain. Differences in response between the denervated urinary bladder preparation and one harvested from a sham-operated animal are considered to result from neural inputs. The urinary bladders of the denervated animals must be manually emptied on a daily basis during the four day

recovery period (Birder et al. 1998; Brauerman et al. 2006).

Inputs from the urothelium can be assessed in isolated urinary bladder smooth muscle preparations. Following preparation of strips from the urinary bladder, the urothelium is gently peeled away from the cut surface and the strips are mounted as described above. Effects on the capsaicin-mediated nitric oxide pathways located in the urothelium can be assessed in these preparations (Birder et al. 1998). Effects on the release of neurotransmitter substances from the epithelial strips removed from these preparations can also be examined; following isolation, the epithelial strips are incubated in Krebs buffer of suitable balanced electrolyte solution. Following a 20 minute equilibration period, the strips are stimulated either mechanically (by stoking with a glass rod or pinching with forceps) or electrically (using field stimulation of the incubation medium). The neurotransmitter substance of interest is analyzed in the bath solution and dose-response curves are generated (Downie and Karmazyn, 1984).

Ukai et al. (2006) investigated the participation of endogenous endothelin and ET_A receptor in premicturation contractions in rats with bladder outlet obstruction, a model for bladder overactivity.

Weetman (1972) described the preparation of the isolated, innervated urinary bladder in **guinea pigs**. Contractions of the tissue induced by nerve stimulation could be blocked by local anesthetics and by tetrodotoxin.

Isolated innervated, rat and guinea pig hemi-urinary bladder preparations were described by Dhattiwala and Dave (1975).

Burnstock et al. (1978) used recorded isometric tension of mucosal-free strips of the detrusor of the bladder from guinea pigs *in vitro* after electrical field stimulation.

Von Heyden et al. (1997) tested urethral relaxation after electrostimulation in guinea pigs. Male Hartley guinea pigs weighing 350–450 g were sacrificed and bladder, urethra and penis were dissected out. From each animal 4–6 urethral rings 1–2 mm thick were cut. The urethral rings were mounted according to their anatomical order: in channel 1 the most proximal ring (near the bladder neck) and in channel 6 the most distal ring (near the penile crura). The urethral rings were stretched by two spring-wire clips (Harvard Apparatus, South Natick, MA) whose tips closed in the urethral lumen. The manner in which the urethral rings were cut and mounted ensured that only the circularly oriented, mostly striated fibers contributed to the tension measured. Detrusor muscle was cut as a horizontal ring proximal to the trigone and mounted in the same way. The clips were connected with 4-O silk to a glass tissue support hook on one side and to an isometric force transducer (Föhr Medical Instruments GmbH, D-64342 Seeheim, Germany) on the other. A double-chambered bath (Föhr Medical Instruments GmbH, D-64342 Seeheim, Germany) was used in which the working chamber was connected to a second chamber, in which the gas (95% O_2 and 5% CO_2) was fed. The gas flow induced fluid circulation. Forces lower than 0.1 g could be measured without bubble artifacts in the working chamber. The transducer signals were fed into a thermal array recorder (Dash 10, Astro-Med, 63110 Rodgau, Germany). For tissue stimulation, vertical, L-shaped custom-made platinum electrodes (20 mm long, 0.3 mm diameter) 10 mm apart were used with a custom-made stimulator. The tissue was mounted parallel with the electrodes. Bipolar, monophasic balance-charged rectangular pulses of 0.8-ms duration and 75 mA current were used.

Kunisawa et al. (1985) performed a pharmacological study of alpha adrenergic receptor subtypes in smooth muscle of **human** urinary bladder base and prostatic urethra.

Wuest et al. (2005) studied the effect of a potassium channel opener on contraction of detrusor strips from **mouse, pig** and **man** in the presence and absence of urothelium..

Thornbury et al. (1992) reported on the mediation of nitric oxide of neurogenic relaxation of the urinary bladder neck muscle in **sheep**. Urinary bladders of sheep of either sex were obtained approximately 15 min after slaughter. Circularly oriented rings were cut from the region of the bladder just above the trigone. These were opened and the mucosa removed by sharp dissection to give strips with approximate dimensions of $10 \times 4 \times 4$ mm. The strips were mounted in organ baths and perfused with Krebs solution. Tension was measured with isometric transducers after field stimulation via platinum ring electrodes.

Hills et al. (1984) used isolated strips of the bladder from female **pigs**. Bladder neck strips were cut longitudinally and horizontally from the region of the bladder just below the trigone. The preparations were stripped of mucosa and trimmed to give a muscle strip of about 2×15 mm.

Klarskov (1987) studied the non-cholinergic, non-adrenergic inhibitory nerve responses of bladder outlet smooth muscle from female Danish Landrace pigs *in vitro*. Trigone strips were taken in an oblique direction from the internal urethral orifice and medially to one of the ureteric orifices, bladder neck strips transversal

from the posterior half of the borderline between bladder and urethra, and urethral strips longitudinal from the proximal posterior part.

Teramoto et al. (1997) examined the membrane potential in the proximal urethra of pigs by use of the microelectrode technique.

C.5.2.4 Effects on Isolated Urethra

PURPOSE AND RATIONALE

The relaxation response in the urethra results in a combination of decreased intraurethral pressure, increased urethral diameter and urethral shortening resulting in a flaring of the urethral orifice. A number of neurotransmitters and mediators are involved in this process, with each affecting a different stage of the process.

(Brading 1999: Andersson and Wein, 2004) The urethra is difficult to study *in situ* because of the large amount of surrounding connective tissue, which can be overcome by the use of a whole-mount preparation (Jankowski et al. 2004).

PROCEDURE

Female rats or guinea pigs have been used. Following appropriate anesthesia, the bladder and urethra are exposed via a lower midline incision, and a catheter is inserted in the urethral lumen, extending the entire axial length and exiting from a hole placed in the bladder dome. The urethra is secured to the tubing with sutures at both ends to maintain the correct *in vivo* length after dissection, and is measured. The pubic bone is then cut at a position lateral to the urethra and then separated and resected. The exposed urethra was gently removed from the ventral vaginal wall and the whole bladder-urethra unit was immediately placed in cold, oxygenated suitable balanced electrolyte solution bubbled with 21% O2-5% CO2-74% N2.

The catheter is removed so that the urethra may be secured inside the experimental apparatus, which provides a controlled fixed intraluminal pressure via an adjustable static fluid reservoir (the intraluminal pressure is controlled by adjusting the height of the reservoir). The mounted urethra is then enclosed in a bathing chamber filled with the same gassed, balanced electrolyte solution at 37°C. The preparation is allowed to equilibrate for at least 30 min before testing. A laser micrometer is positioned to measure urethral outer diameter at chosen locations along the axial length. Proximal, mid, and distal regional measurements were performed by positioning the laser at axial positions 25, 50, and 75%, respectively, from the apex of the bladder, based on *in vivo* length. Both pressure and outer diameter (OD) measurements are recorded simultaneously.

The test compound of interest is added to the bath and pressure and OD measurements are obtained following a 30 minute equilibration period. Pressure-diameter (P-D) responses are generated by incrementally increasing the pressure, in 2 mm Hg steps, from 0 to 18 mm Hg, and OD data are collected at 10 Hz over a 1-min period for each 2-mmHg step. The OD data are then averaged for each incremental increase to obtain a discrete value for each value of applied pressure.

Contractile responses can be evaluated in this preparation as well. The urethra is exposed to a fixed intraluminal pressure of 8 mmHg, which causes the tissue to be predilated and allows for a contractile response to be generated. The OD resulting from this 8-mmHg applied pressure is measured at a single axial location (i. e., proximal, mid, or distal) 30 min after pressurization. The test chemical of interest is added to the bath and the preparation is exposed for 30 minutes; at the end of this time, a series of 100 OD measurements (taken at 1 Hz) are collected at the same location and are averaged.

EVALUATION

The P-D response data are used to generate tissue compliance (C) as follows:

$$C = [D_{max} - D_{min}/D_{min}]\, X\, (P_{max} - P_{min})^{-1}$$

where D_{max} and D_{min} represent the OD at the maximum (P_{max}, 18 mm Hg) and minimum (P_{min}, 0 mm Hg) applied pressures, respectively.

Contractile responses are assessed by determining the percent change in mean OD before and after the addition of the test compound.

MODIFICATION OF THE METHOD

With careful dissection, the pudendal nerves can be identified and left intact during the diisction of the urethra from the guinea pig. These nerves can then be attached to electrodes and alterations of effects of neural inputs can be assessed. In this preparation, contractile responses were assessed by measuring changes in isometric tension and intraluminal pressure changes were also recorded (Walters et al., 2006).

Triguero et al. (2003) studied the relaxation effects of scorpion venom in the isolated urethra of **sheep**.

Michel et al. (2006) performed in vivo studies on the effects of α_1-adrenoceptor antagonists on pupil diameter and urethral tone in **rabbits**.

C.5.2.5 Effects on External Urethral Sphincter

PURPOSE AND RATIONALE

In contrast to the smooth musculature of the internal urethral sphincter, the external urethral sphincter is a striate muscle and a part of the urogenital diaphragm (Kuru 1965). Judged from electromyographic studies it is generally accepted that the preponderance of continence depends on the external urethral sphincter. The external urethral sphincter shows a steady tonic discharge under resting conditions. As the bladder fills, there is initially an increase in this activity. When the rise in tension in the bladder wall leads to reflex contraction, the activity in the external urethra sphincter ceases and in remains quiescent during voiding. Parlani et al. (1992) used the external urethral sphincter of the rat as an *in vitro* model to evaluate the activity of drugs on the smooth and striated components of the urinary bladder outlet.

PROCEDURE

Male Wistar rats weighing 360–400 g are sacrificed by decapitation and exsanguination. Through a midline incision of the lower abdomen, the external urethral sphincter (Watanabe and Yamamoto 1979) is isolated from the perineal muscles and surrounding connective tissue and removed in toto. The preparation is placed in oxygenated Krebs solution, and a ring is taken from its middle region. In this area the urethra is encircled by bundles of striated muscle fibers partly interlaced with urethral smooth muscle. The rings are cut to obtain strips that are suspended in a 5-ml organ bath containing Krebs solution at 37°C. A mixture of 96% O_2 and 4% CO_2 is bubbled into the organ bath. The preparations are connected by means of a silk thread to an isometric strain gauge under a constant load of 1 g. The contractile activity is recorded on a polygraph. Field stimulation is carried out by means of two platinum wire electrodes placed at the top and the bottom of the organ bath and connected to a Grass S11 stimulator. The preparations are allowed to equilibrate for at least 60 min. Square wave pulses are delivered at an intensity between 10 and 60 V, a frequency between 0.1 and 3 Hz, and a duration between 0.1 and 1 s; trains are of 5 s every 5 min. After three consecutive reproducible responses are obtained, drugs are added to the organ bath. The effect of drugs is expressed as the percent of inhibition of contractile response before exposure to drugs and is evaluated as soon as the maximum effect is reached.

EVALUATION

Means ± standard error of the mean are calculated. Statistical evaluation is performed by using Student's *t*-test for paired or unpaired data.

MODIFICATIONS OF THE METHOD

In some studies, denervation of the external urethral sphincter was performed (Somma et al. 1989; Parlani et al. 1992). Rats were anesthetized with 30 mg/kg penthotal i.p., then the major pelvic ganglia, known to provide both sympathetic and parasympathetic innervation to the urinary bladder and the external urethral sphincter (Hulsebosh and Goggeshall 1982; Purinton et al. 1973; Watanabe and Yamamoto 1979) are isolated and bilaterally removed through a small incision of the lower abdomen.

In the same preparations, somatic denervation of the external urethral sphincter was obtained by cutting the pudendal nerves. The paravertebral muscles were carefully dissected through an incision of the skin to exteriorize the sacral plexus. The pudendal nerves were isolated, and 2–3 mm of the nerve were removed. An absorbable sponge soaked with amikain solution was left in place to prevent bleeding and infection. The muscles and the skin were sutured with cat gut. The rats were allowed to recover for 10 to 15 days in individual cages with free access to water and food.

Chapter D
Respiratory Activity

D.1 In Vitro Tests

D.1.0.1 Histamine (H_1) Receptor Binding

PURPOSE AND RATIONALE

Histamine receptors have been classified on the basis of pharmacological analysis (Hill et al. 1997). Histamine exerts its action via at least four receptor subtypes. The H_1 receptor couples mainly to $G_{q/11}$, thereby stimulating phospholipase C, whereas the H_2 receptor interacts with G_s to activate adenylyl cyclase. The histamine H_3 and H_4 receptors couple to G_i proteins to inhibit adenylyl cyclase, and to stimulate MAPK (Hough 2001).

Histamine is considered to play a major role in asthmatic attacks (Bryce et al. 2006). H_1-antagonists have been used since decades as therapeutic agents. This as-

say is used to determine the affinity of test compounds to the histamine H_1 receptor by measuring their inhibitory activities on the binding of the H_1 antagonist ^{3}H-pyrilamine to a plasma membrane preparation from guinea pig brain.

PROCEDURE

Brains from guinea-pigs are homogenized in ice-cold Tris buffer (pH 7.5) in a Potter homogenizer (1 g brain in 30 ml buffer). The homogenate is centrifuged at 4°C for 10 min at 50,000 *g*. The supernatant is discarded, the pellet resupended in buffer, centrifuged as before, and the final pellets resupended in Tris buffer (1 g fresh weight/5 ml). Aliquots of 1 ml are frozen at –70°C.

In the competition experiment, 50 µl ^{3}H-pyrilamine (one constant concentration of 2×10^{-9} M), 50 µl test compound (>10 concentrations, 10^{-5}–10^{-10} M) and 100 µl membrane suspension from guinea pig whole brain (approx. 10 mg wet weight/ml) per sample are incubated in a shaking bath at 25°C for 30 min. Incubation buffer: 50 mM Tris-HCl buffer, pH 7.5.

Saturation experiments are performed with 11 concentrations of ^{3}H-pyrilamine ($0.1–50 \times 10^{-9}$ M). Total binding is determined in the presence of incubation buffer, non-specific binding is determined in the presence of mepyramine or doxepin (10^{-5} M).

The reaction is stopped by rapid vacuum filtration through glass fibre filters. Thereby the membrane-bound is separated from the free radioactivity. The retained membrane-bound radioactivity on the filter is measured after addition of 3 ml liquid scintillation cocktail per sample in a liquid scintillation counter.

EVALUATION OF RESULTS

The following parameters are calculated:

- total binding of ^{3}H-pyrilamine
- non-specific binding: binding of ^{3}H-pyrilamine in the presence of mepyramine or doxepin
- specific binding = total binding–non-specific binding
- % inhibition of ^{3}H-pyrilamine binding: 100–specific binding as percentage of control value

The dissociation constant (K_i) and the IC_{50} value of the test drug are determined from the competition experiment of ^{3}H-pyrilamine versus non-labeled drug by a computer-supported analysis of the binding data.

MODIFICATIONS OF THE METHOD

De Backer et al. (1993) reported genomic cloning, heterologous expression in COS-7 cells and pharmacological characterization of a human H_1-receptor.

D.1.0.2 Muscarinic Receptor Binding

PURPOSE AND RATIONALE

Muscarinic receptors in the airways are important in both the normal physiology and the pathophysiology of pulmonary function. Acetylcholine released from parasympathetic nerve terminals causes contraction of airway smooth muscle. Animals with asthma or other chronic inflammation of the airways exhibit hypersensitivity of the airways to muscarinic agonists, and muscarinic antagonists are used therapeutically in patients with asthma and chronic obstructive pulmonary disease (Nathanson 2000). Muscarinic receptors are present in neurons in the central and peripheral nervous system, cardiac and smooth muscles, and a variety of exocrine glands. Mammals possess genes encoding five different subtypes of mAChR, termed M_1–M_5, which can be divided into two broad functional categories: the M_1, M_3, and M_5 receptors preferentially couple to the Gq family of G-proteins whereas the M_2 and M_4 receptors preferentially couple to the Gi family of G-proteins.

For involvement of acetylcholine receptors in the gastrointestinal tract see J.3.6.1.2.

Several papers deal with the distribution of muscarinic receptors in the lung, their role in pulmonary disease and the use of muscarinic antagonists for the

treatment of obstructive airways disease (Mak and Barnes 1990; Barnes 1993, 2001, 2004; Disse 2001; Disse et al. 1993, 1999; Haddad et al. 1994; Barnes et al. 1995, 1997; Patel et al. 1995; Peták et al. 1996; Alabaster 1997; Matsumoto 1997; Chelala et al. 1998; Hislop et al. 1998; Okazawa et al. 1998; Wale et al. 1999; Rees 2002; Sarria et al. 2002; Tohda et al. 2002; Costello et al. 2006).

Hirose et al. (2001) described the pharmacological properties of a muscarinic antagonist with M_2-sparing antagonistic activity.

PROCEDURE

Binding Affinity for Human and Rat Muscarinic Receptor Subtypes

In competition studies, specific binding of [^{3}H]*N*-methylscopolamine (NMS; New England Nuclear, Boston, Mass., USA) was determined using membranes from Chinese hamster ovary (CHO) cells expressing cloned human m1, m2, m3, m4, or m5 receptors (Receptor Biology, Baltimore, Md., USA), rat m1 or m3 receptors (American Type Culture Collection, Manassas, Va., USA), and rat heart tissue. These CHO cells expressing cloned rat m1 or m3 receptors, and rat heart tissue were homogenized in 3 vols of 50 mM Tris-HCl (pH 7.4) and 1 mM EDTA containing 20% sucrose with a Polytron PT-10. The homogenates were centrifuged at 10,000 *g* for 30 min at 4°C. The supernatants were centrifuged at 100,000 *g* for 60 min at 4°C. The pellets were suspended in 50 mM Tris-HCl (pH 7.4) and 5 mM $MgCl_2$ and centrifuged at 100,000 *g* for 60 min at 4°C. The pellets were resuspended in the above-mentioned buffer (25 mg/ml for CHO cells expressing cloned rat m1 or m3, and 50 mg/ml for rat heart tissue) and stored at –80°C as membrane preparations. In the binding assay, the membrane preparations were incubated with 0.19 to 0.2 nM [^{3}H]NMS in 50 mM Tris-HCl, 10 mM $MgCl_2$, and 1 mM EDTA (pH 7.4) for 2 h at room temperature. Final protein concentrations were 22 µg/ml (human m1), 70 µg/ml (human m2), 54 µg/ml (human m3), 20 µg/ml (human m4), 116 µg/ml (human m5), 481 µg/ml (rat m1 and m3), and 2500 µg/ml (rat heart). Assays were performed in a total volume of 500 µl. Non-specific binding was measured in the presence of 1 µM NMS and it was less than 2% of total binding. Free and membrane-bound [^{3}H]NMS were separated by filtration over glass filters (UniFilter-GF/C; Packard Instruments, Meriden, Conn., USA) using a cell harvester (Filtermate 196; Packard Instruments). Radioactivity was counted by a liquid scintillation counter (TopCount; Packard Instruments).

EVALUATION

For saturation studies, membranes from CHO cells expressing human m3 were incubated with an increased concentration of [^{3}H]NMS (0.1–3.2 nM) in the presence or absence of 10 nM compound A, and specific binding of [^{3}H]NMS was determined after incubation for 2 h.

Competition binding data were analyzed by a nonlinear regression fitting program using GraphPad Prism Software (San Diego, Calif., USA). Saturation binding data were transformed to make a Scatchard plot and analyzed by a linear regression fitting program using GraphPad Prism Software.

The K_i values were calculated from the IC_{50} values by using the following equation:

$$K_i = IC_{50}/(1 + [L]/K_d)$$

where K_d is the dissociation constant of [^{3}H]NMS in each receptor subtype, and [*L*] is the concentration of [^{3}H]NMS (Cheng and Prussoff 1973). K_d values of [^{3}H]NMS in each receptor subtype were determined by Scatchard plot analysis. The K_d and B_{max} values below were used in this study. Data of human cloned receptors were extracted from Receptor Biology's Product Information Sheets (Receptor Biology).

Human m1 receptor	K_d = 51 pM	B_{max} = 1.28 pmol/mg of protein
Human m2 receptor	K_d = 290 pM	B_{max} = 1 pmol/mg of protein
Human m3 receptor	K_d = 86 pM	B_{max} = 0.65 pmol/mg of protein
Human m4 receptor	K_d = 56 pM	B_{max} = 1.44 pmol/mg of protein
Human m5 receptor	K_d = 200 pM	B_{max} = 0.59 pmol/mg of protein
Rat m1 receptor	K_d = 62 pM	B_{max} = 0.039 pmol/mg of wet weight
Rat m2 receptor	K_d = 210 pM	B_{max} = 0.0090 pmol/mg of wet weight
Rat m3 receptor	K_d = 72pM	B_{max} = 0.019 pmol/mg of wet weight

In saturation studies, the K_i value was calculated using the following equation:

$$K_i = K_d/(K'_d - K_d) \times [C]$$

where K'_d or K_d is the dissociation constant of [^{3}H]NMS in human m3 receptors in the presence or absence of an inhibitor, respectively, and [*C*] is the concentration of the test drug (Nishikibe et al. 1999).

MODIFICATIONS OF THE METHOD

Struckmann et al. (2003) investigated the role of muscarinic receptor subtypes in the constriction of peripheral airways by studies on receptor-deficient mice.

D.2 Effects on Air Ways

D.2.1 Tests in Isolated Organs

D.2.1.1 Spasmolytic Activity in Isolated Guinea Pig Lung Strips

PURPOSE AND RATIONALE

Several autacoids such as histamine and leukotrienes, induce bronchoconstriction. Histamine is an important mediator of immediate allergic and inflammatory reactions. It causes bronchoconstriction by activating H_1-receptors. Calcium ionophores induce the release of leukotrienes via the 5-lipoxygenase pathway. Leukotrienes are powerful bronchoconstrictors that appear to act on smooth muscles via specific receptors. In this method, drugs are tested for their capability of inhibiting bronchospasm induced by histamine or calcium ionophore. It is used to detect H_1- and leukotriene receptor blocking properties of test compounds.

PROCEDURE

Albino guinea-pigs of either sex weighing 300–450 g are sacrificed with an overdose of ether. The chest cavity is opened and the lungs are removed. They are cut into strips of 5 cm and placed into a physiological saline solution. Thereafter, the lung strips are mounted in an organ bath containing a nutritive solution. The bath is bubbled with carbogen and maintained at 37°C. Under a pre-load of 0.5 g–3 g, the tissue is left to equilibrate for 30–60 min. Prior to testing, carbachol is added to the bath to test the lung strips' ability of contraction. Twenty min later, two prevalues are obtained by adding the spasmogen

- histamine dihydrochloride 10^{-6} g/ml for 5 min, or
- Ca – ionophore 5×10^{-6} g/ml for 5 min, or
- Leukotriene LTC_4 10^{-9}–10^{-8} g/ml for 10 min, or
- Leukotriene LTD_4 10^{-9}–10^{-8} g/ml for 10 min

to the bath and recording the contractile force at its maximal level. Following a 20 min equilibration period, the spasmogen is administered again. Five minutes thereafter, the test compound is added in cumulative doses from 10^{-8} to 10^{-4} g/ml at 5 or 10 min intervals. The contractile response is determined isometrically.

Test Modification: Inhibition of Prostaglandin Synthesis

This procedure is identical to the test described above with the exception that the prostaglandin synthesis is inhibited by addition of indomethacin at 10^{-6} g/ml prior to spasmogen administration.

EVALUATION

The percent inhibition of spasmogen induced contraction is calculated.

MODIFICATIONS OF THE METHOD

Lung parenchyma strips from various species were used to measure bronchoactivity by Kleinstiver and Eyre (1979).

A descriptive model of the events occurring during an inflation-deflation cycle using excised rat lungs was proposed by Frazer et al. (1985).

Barrow (1986) measured volume-pressure cycles in air-filled or liquid-filled rabbit lungs ranging from intact lungs with the rib cage immobilized to isolated lungs.

D.2.1.2 Spasmolytic Activity in Isolated Trachea

PURPOSE AND RATIONALE

The isolated tracheal chain of guinea pigs can be used to test for β-blocking activity (see Sect. A.1.2.7). In addition, this model can be used to test compounds which inhibit bronchospasms. It is used to detect β-sympathomimetic, H_1-receptor blocking and leukotriene receptor blocking properties of test drugs.

Carbachol is a cholinergic agonist that produces contraction of bronchial smooth muscle by muscarinic stimulation.

Histamine is an important mediator of immediate allergic (type 1) and inflammatory reactions. It causes bronchoconstriction by activating H_1-receptors.

Calcium ionophores induce the release of leukotrienes via the 5-lipoxygenase pathway. Leukotrienes are powerful bronchoconstrictors that appear to act on smooth muscle via specific receptors.

To asses a compound's ability to inhibit carbachol induced bronchospasm via β-receptor activation, a β-receptor blocking agent (for example propranolol) must be added. If relaxation of bronchial smooth muscle is brought about by β-receptor activation, the spasmolytic effect will decrease following propranolol administration.

The effect of bradykinin can be abolished by bradykinin antagonists (Hock et al. 1991).

The effects of potassium channel openers can also be studied in this test (Englert et al. 1992).

PROCEDURE

Albino guinea pigs of either sex weighing 300–550 g are sacrificed by CO_2 narcosis. The entire trachea is

dissected out and cut into individual rings (2–3 cartilaginous rings wide). Twelve–fifeteen rings are tied together with silk threads and mounted in the organ bath containing Krebs-Henseleit solution. The tissue is maintained at 37°C under a tension of 0.5 g and gassed with carbogen. Isometric contractions are recorded via a strain-gauge transduced on a polygraph. Forty-five minutes are allowed for equilibration before the addition of the spasmogen.

The following spasmogens are used:

- carbachol (2×10^{-7} g/ml)
- histamine (10^{-7} g/ml)
- Ca – ionophore for release of leukotrienes
- leukotriene LTC_4 (10^{-9}–10^{-8} g/ml)
- leukotriene LTD_4 (10^{-9}–10^{-8} g/ml)

When the contraction has reached its maximum (initial spasm) after 10–12 min, the standard drug, e. g., isoprenaline (1 ng/ml) or aminophylline (10 ng/ml) is administered. The bronchial responses are allowed to plateau and are recorded. The tissue is rinsed thoroughly and control contractions are induced again by adding spasmogen. After obtaining the initial spasm again, the test drug is added and the contractile force is recorded at its maximal level.

Determination of mechanism of action (testing for β-sympathomimetic effect). After obtaining the initial carbachol induced spasm, propranolol is administered 5 min before the addition of the test drug. Three minutes later, the tissue is challenged by carbachol administration.

EVALUATION

The percent inhibition of carbachol or other spasmogen induced contractions is calculated. From dose-response curves ED_{50} values can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

The isolated guinea pig trachea has been proven to be an useful tool for several purposes, e. g., screening procedures and studies on mode of action, e. g., of potassium channel openers.

MODIFICATIONS OF THE METHOD

The molecular mechanisms of β-adrenergic relaxation of airway smooth muscle were described by Kotlikoff and Kamm (1996).

Farmer et al. (1986) studied the effects of epithelium removal on the sensitivity of **guinea-pig** isolated trachealis to bronchodilator drugs.

Wilkens et al. (1992) described a bioassay system for a tracheal smooth muscle-constricting factor using an isolated guinea pig trachea which was cannulated from both sides, mounted in an organ bath and monitored by a TV camera attached to a microscope. The picture was digitized continuously, and the diameter of the trachea calculated and displayed on a monitor throughout the experiment.

Coleman and Nials (1989) described a versatile, eight-chamber superfusion system for the evaluation of spasmogenic and spasmolytic agents using guinea pig isolated tracheal smooth muscle.

Goldie et al. (1986a) studied the influence of the epithelium on responsiveness of guinea pig isolated trachea to contractile and relaxant agonists.

Lee et al. (1997) studied the effects of bupivacaine and its isomers on guinea pig tracheal smooth muscle. The trachea from the larynx to the carina was removed and cut into single rings. Seven tracheal rings were tied together with the circular muscle running on the same side of the chain, placed into an organ bath containing Krebs Ringer's solution and connected to a force placement transducer for measurement of isometric tension.

Wong et al. (1997) tested the effects of tyrosine kinase inhibitors on antigen challenge of guinea pig lung *in vitro*. Guinea pigs were passively sensitized by a single i.p. injection of 1 mg/kg rabbit IgG antibody against ovalbumin. Bronchial rings, 3 mm in length, were obtained from the hilar bronchi of sacrificed animals and suspended isometrically in an organ bath in Krebs bicarbonate buffer with a resting load of 2 g. To determine maximum antigen-induced contractions, bronchial rings were exposed to increasing concentrations of ovalbumin. To evaluate the role of protein tyrosine kinase in mediating smooth muscle anaphylactic contraction, protein tyrosine kinase inhibitors were preincubated with bronchial rings 30 min before addition of ovalbumin.

Eltze and Galvan (1994) compared the inhibition of preganglionic and postganglionic contraction of the **rabbit** isolated bronchus/trachea by antagonists with selectivity for different muscarinic receptor subtypes with their affinities at M_1, M_2, M_3, and M_4 receptors (Barnes 1993).

For **experiments with vagus nerve stimulation**, the vagi were isolated with rings of the proximal main stem bronchi and a small portion of the distal trachea. The tissues were hung on stainless steel hooks, which passed through the lumen, and were placed in a water-jacketed organ bath filled with Krebs solution plus 2×10^{-5} M choline chloride to promote resynthesis of acetylcholine, 10^{-5} M indomethacin to prevent generation of cyclo-oxygenase products, and 10^{-6} M

DL-propranolol to block possible β-adrenoceptor-mediated effects. The preparation was fixed under a resting tension of 1 g for isometric contraction measurement using a force transducer. The vagi were passed around bipolar platinum electrodes held at the surface of the bath. Electrical stimulation was performed with trains (20 Hz, 0.3 ms at 20 V) elicited every 20 min.

For experiments with **field stimulation**, two-ring preparations from the distal trachea of the rabbit were suspended in organ bath in Krebs solution with the above mentioned additions under a resting tension of 1 g. Isometric contractions were elicited at 1 h intervals by continuous electrical field stimulation via platinum electrodes (20 Hz, 0.3 ms at 20 V) for an average 3–7 min to reach a stable plateau.

Vaali et al. (1996) studied in isolated tracheal rings of **rats** and guinea pigs the bronchorelaxing effects of nitric oxide donors. The epithelium of some rings was removed by gentle rubbing. Rat mesenteric rings were cut from the same animals as the bronchi and similarly prepared by removing the endothelium by gently rubbing of the intimate surface.

Farmer et al. (1994) used the isolated trachea from male **ferrets** weighing 1.5–2.5 kg to study the effects of bradykinin receptor agonists.

Toews et al. (1997) assessed the effects of the phospholipid mediator lysophosphatidic acid on the contractile responsiveness of isolated tracheal rings from **rabbits** and **cats**.

Tamaoki et al. (1993) used isolated rings of segmental bronchi from **dogs** to study atypical β-adrenoceptor-(β_3-adrenoceptor)mediated relaxation.

The preparation of **bovine** tracheal smooth muscle for measuring airway responsiveness *in vitro* was described by Hashjin et al. (1995).

Wali (1987) used tracheal strips from 2- to 4-week-old **chicks** to study inhibition of cholinergic and noncholinergic neural and muscular contractions by local anesthetics.

Lulich and Paterson (1980) used **human** isolated bronchial muscle preparations and compared the effects of histamine and other drugs with the effects observed on the central and peripheral airways of the rat.

Goldie et al. (1986b) measured the responses of human bronchial strip preparations to contractile and relaxant agonists in preparations from non-diseased and from asthmatic lung obtained 3–15 h post mortem.

Hulsman and de Jongste (1993) reviewed the methods to study human airways *in vitro*.

D.2.1.3 Reactivity of the Isolated Perfused Trachea

PURPOSE AND RATIONALE

The mechanism by which the epithelium affects the reactivity of tracheal musculature can be studied using the isolated perfused trachea preparation. Contractile agonists can be added either to the serosal (extraluminal) or to the mucosal (intraluminal) surface (Fedan and Frazer 1992).

PROCEDURE

A 4-cm segment of the trachea of male guinea pigs is removed after sacrifice of the animal and placed for cleaning in modified Krebs-Henseleit solution at 37°C containing (millimolar) NaCl 113.0, KCl 4.8, $CaCl_2$ 2.5, KH_2PO_4 1.2, $MgSO_4$ 1.2, $NaHCO_3$ 25.0, and glucose 5.7 (pH 7.4) being gassed with 95% O_2/5% CO_2. The trachea is then attached to a stainless-steel perfusion holder (Munakata et al. 1988), extended to its *in situ* length and placed in an organ chamber (the serosal compartment) at 37°C containing 25 ml of gassed modified Krebs-Henseleit solution. This solution is also pumped at a constant rate of 30 ml/min through the lumen (mucosal compartment). Responses of the tracheal musculature are obtained by measuring changes in inlet-outlet ΔP between the side holes of indwelling catheters, while the trachea as perfused at a constant rate of modified Krebs-Henseleit solution. The inlet and outlet catheters are connected to the positive and negative sides, respectively, of a differential pressure transducer.

Agonists are added in step-wise increasing, cumulative concentrations. Two consecutive dose-response curves are obtained after the addition either to the serosal or mucosal compartment. The second dose-response curve is obtained 1.5 h after the end of the first, the preparation being washed every 15 min during the intervening period.

EVALUATION

Responses are quantified as ΔP in centimeters of H_2O. Geometric EC_{50} values are determined from least-square analysis of a logit model and are presented along with 95% confidence intervals.

MODIFICATIONS OF THE METHOD

Baersch and Frölich (1996) measured continuously the changes of the diameter of isolated guinea pig tracheal tubes by a newly developed imaging bioassay system. The tracheal tube between larynx and bifurcation was prepared to a length of 1.8–2.5 cm, cannulated at both ends and mounted in a 15 ml organ bath filled and perfused with oxygenated Krebs solution at 37°C. The lumen of the trachea was perfused with warm (37°C) Krebs solution from a reservoir that was isolated from the tissue bath. Changes in diameter of the trachea were assessed by computerized video microscopy. The tracheal diameter was used as marker for airway size, thus allowing calculation of muscle contractions under experimental conditions. Following a 30-min equilibrium period, a contraction was induced by intraluminal application of methacholine (0.1 mmol/l) as reference contraction. After washout and return to a stable baseline, cumulative concentration-response curves were obtained by luminal or extraluminal drug application.

Yang et al. (1991) studied the role of epithelium in airway smooth muscle responses to relaxant agents. The results suggested that the epithelium is a relatively weak barrier for lipophilic agents but has a major role as a diffusion barrier to hydrophilic substances.

Munataka et al. (1988, 1989) developed an *in vitro* system to assess the role of epithelium in regulating airway tone using the intact **guinea pig** trachea. The responses to histamine, acetylcholine and hypertonic KCl when stimulated from the epithelial or serosal site were first examined in tracheae with intact epithelium. Then the responses to these agonists were registered after epithelial denudation.

Pavlovic et al. (1989) studied the role of airway epithelium in the modulation of bronchomotor tone in the isolated trachea of **rats**. An organ bath was constructed that permitted independent circulation of fluid within the lumen or around the exterior of the tracheal segment. In one-half of the preparations the epithelium was mechanically removed.

Fernandes et al. (1989) described a co-axial bioassay system, whereby rat cross-cut aorta strip preparations were set up in co-axial assemblies under 500 mg resting tension within a guinea pig tracheal segment serving as donor of the smooth muscle relaxant factor from guinea-pig tracheal epithelium.

Lewis and Broadley (1995) investigated the influence of spasmogen inhalation by guinea pigs upon subsequent demonstration of ovalbumin-induced hyperreactivity in isolated airway tissues. Guinea pigs were sensitized with ovalbumin (i.p.) 14 days before use. *In vitro* airway hyperreactivity induced by ovalbumin inhalation was determined by challenging with aerosolized spasmogen (5-HT, methacholine, the thromboxane-mimetic U-46619, or adenosine) 24 h before and again 18–24 h after the ovalbumin inhalation. One h later, the animals were sacrificed and isolated airways perfused lung halves and tracheal spirals were set up for determination of tissue sensitivity to carbachol, histamine, and adenosine.

Sparrow and Mitchell (1991) used bronchial segments obtained from the lungs of Large-white-/Landrace-cross **pigs** to study the modulation by the epithelium of the extent of bronchial narrowing produced by substances perfused through the lumen.

Mitchell et al. (1989) compared the reactions of perfused bronchial segments and bronchial strips of *pigs* to histamine and carbachol.

Hulsman et al. (1992) recommended the perfused **human** bronchiolar tube as a suitable model.

Omari et al. (1993) studied the responsiveness of human isolated bronchial segments and its relationship to epithelial loss.

D.2.1.4 Bronchial Perfusion of Isolated Lung

PURPOSE AND RATIONALE

Bronchial perfusion of the isolated lung was described by Sollmann and von Oettingen (1928) as a simple method for studying pharmacological reactions of bronchiolar muscle. The method consists in perfusing fluid down the trachea through the bronchi, and allowing it to escape from the alveoli through scratches on the surface of the lungs. Bronchoconstriction results in a reduced rate of flow, bronchodilatation is indicated by an increased flow. The method has been used to evaluate sympathomimetic drugs by Tainter et al. (1934) and by Luduena et al. (1957).

PROCEDURE

Guinea pigs weighing about 200 g are sacrificed by a head blow. The chest is opened, the trachea cut at the upper end and removed with the lung. The trachea is attached to the cannula of an perfusion apparatus. Only one lung is perfused, the other being tied off. The lower part of the lower lobe is cut off and the rest of the lung surface is scratched deeply assuring maximal pre-medication flow.

The perfusion fluid has the following composition in percentage of anhydrous salts: NaCl 0.659, $NaHCO_3$ 0.252, KCl 0.046, $CaCl_2$ 0.005, $MgCl_2$ 0.0135, NaH_2PO_4 0.01, Na_2HPO_4 0.008, glucose 5%, pH 8.0. The temperature of the perfusion medium is 37.5°C and the lung is enclosed in

a glass cylinder to be protected from variations in the environmental temperature.

The trachea is attached to the cannula of a perfusion apparatus which pumps the solution at a constant rate into a manometric tube connected with the perfused organ. Resistance to the flow (bronchoconstriction) results in an increase in the height of the column of fluid in the manometer. The intensity of bronchodilator effect is measured by the fall of the column in the manometer.

After the lung is attached to a T-shaped cannula, the pump is set in motion and the fluid, after filling the lung, flows out of the system through the third opening of the cannula. By gentle pressure air bubbles are forced out of the lung into the overflow. The lung is then treated in the aforesaid manner, and the upper outlet of the cannula closed. Histamine HCl is added in a concentration of 1:2500000 as soon as the perfusion starts and the flow is adjusted to obtain a constant progressive increase in pressure.

The drugs are injected near the cannula when the perfusion pressure reaches a level of 500–650 ml of water. The volume injected is always 0.1 ml.

Each drug is tested for bronchodilating activity against the bronchoconstriction induced by histamine in parallel with l-arterenol following a Latin square, including three doses of each drug and three doses of l-arterenol graded at 0.5 log intervals.

EVALUATION

Activity ratios of bronchodilating agents versus the standard can be calculated with a 3 + 3 point assay including confidence limits.

D.2.1.5 Vascular and Airway Responses in the Isolated Lung

PURPOSE AND RATIONALE

The isolated perfused rat lung allows the simultaneous registration of pulmonary vascular and airway responses to various drugs.

PROCEDURE

Male Sprague-Dawley rats weighing 300–350 g are intraperitoneally anesthetized with pentobarbital sodium (50 mg/kg). The trachea is cannulated with a short section of polyethylene tubing, connected to a rodent ventilator, and ventilated with room air enriched with 95% O_2/5% CO_2, with a tidal volume of 4–5 ml/kg and 2 cm H_2O positive end-respiratory pressure. The rats are heparinized with 1000 units of intravenous heparin and are rapidly exsanguinated by withdrawing blood from the carotid artery.

The lung is exposed by median sternotomy, and a ligature is placed around the aorta to prevent systemic loss of blood. The main pulmonary artery is catheterized, and the lung is removed en block and suspended in a warmed (39°C), humidified (100%) water-jacketed chamber. An external heat exchanger is used to maintain the temperature of the perfusate and the isolated lung chamber constant throughout the experiment. The perfusate solution (15 ml of heparinized blood and 5 ml modified Krebs-Henseleit solution) is placed in a reservoir and mixed constantly by a magnetic stirrer. The lungs are perfused with a peristaltic roller pump at a flow rate of 8–14 ml/min to maintain a physiological baseline pulmonary arterial perfusion pressure of 15 ± 0.5 mmHg. Pulmonary arterial perfusion pressure, airway pressure, and reservoir blood level are continuously monitored, electronically averaged and recorded with a polygraph.

EVALUATION

Changes (increase or decrease) in pulmonary arterial pressure and in airway pressure after injection of test compounds are measured in mm Hg and compared with baseline values.

MODIFICATIONS OF THE METHOD

Bernard et al. (1997) described an isolated perfused lung model with real time data collection and analysis of lung function. Male Sprague Dawley rats were anesthetized with 130 mg/kg pentobarbital i.p. The trachea was cannulated and then ventilated with 5% CO_2 and 95% air at e rate of 60 breath/min and a tidal volume of 2.5 ml. An injection of 650–700 units/kg of heparin was made into the right ventricle. A cannula was placed into the main pulmonary artery. The left ventricle was incised and the lungs were washed free of blood with warmed Krebs-Henseleit bicarbonate buffer with 4.5% BSA and 0.1% glucose. The left atrium was then cannulated to allow outflow of the perfusate. The lung was then removed and suspended in a chamber for perfusion. The flow rate of the perfusate

was adjusted to 8–10 ml/min/kg. Ventilation was maintained at 60 breaths/min with humidified and warmed gas. The lung was allowed to recover for 15 min at which time the lung mechanic parameters of flow, volume, transpulmonary pressure, pulmonary artery pressure, weight, resistance, elastance, and positive enddiastolic pressure were measured.

Hauge (1968) studied the conditions governing the pressor responses to ventilation hypoxia in isolated perfused rat lungs.

Uhlig and Heiny (1995) measured the weight of the isolated perfused rat lung during negative pressure ventilation for quantitating edema formation in the isolated lung.

Uhlig and Wollin (1994) described an improved setup for the isolated perfused rat lung. Breathing mechanic, such as tidal volume, pulmonary compliance, and pulmonary resistance, as well as perfusate characteristics, such as pulmonary vascular resistance, pulmonary pre- and postcapillary resistance, perfusate pH, P_{O2}, and P_{CO2}, and the capillary filtration coefficient were determined.

Byron et al. (1986) used the isolated perfused rat lung preparation for the study of aerosolized drug deposition and absorption.

Hendriks et al. (1999) published a modified technique of isolated left lung perfusion in the rat.

Riley et al. (1981) determined the tissue elastic properties of saline-filled isolated hamster lungs by measuring the pressure-volume relationships and studied the prevention of bleomycin-induced pulmonary fibrosis by *cis*-4-hydroxy-L-proline.

Lewis and Broadley (1995) tested the influence of spasmogen inhalation by **guinea pigs** upon subsequent demonstration of albumin-induced hyperreactivity in isolated airway tissues, such as perfused lung halves and tracheal spirals.

Corboz et al. (2000) used the isolated guinea pig lung to study the inhibition of capsaicin-induced bronchoconstriction by nociceptin. The lungs and the heart were removed en bloc from guinea pigs euthanized with an intraperitoneal overdose of sodium pentobarbital. The trachea and pulmonary artery were rapidly cannulated and half of the heart was cut to facilitate drainage. The lungs were then placed inside a warmed (37°C) glass chamber and suspended from a force displacement (Grass FT-03). They were mechanically ventilated with room air using a small animal ventilator. The respiratory rate was set at 60 strokes/min with a volume of 2.0 ml/stroke. Pulmonary inflation pressure was continuously monitored with a pressure transducer connected to a side arm of the tracheal cannula. Perfusion pressure was maintained with a peristaltic pump at a rate of 4.5–5.0 ml/min to produce a baseline pulmonary arterial pressure of between 6 and 14 cmH_2O. The pulmonary artery pressure was continuously monitored using a pressure transducer connected to the side arm of the pulmonary artery cannula. Transducers were connected to a polygraph for continuous monitoring of variables. The lungs were perfused with Tyrode's solution maintained at 37°C. Cumulative dose–response curves were constructed by adding increasing doses of capsaicin or the tachykinin NK_2 receptor agonist neurokinin A directly into the pulmonary artery. Test drugs were perfused 30 min before the addition of increasing doses of capsaicin or neurokinin A.

Anglade et al. (1998) measured the pulmonary capillary filtration coefficient in isolated **rabbit** lungs which were suspended by a string tied around the tracheal cannula from a counterbalanced force transducer to perform continuous weight measurement. To measure the pulmonary capillary filtration coefficient, pulmonary venous pressure was raised stepwise which results in an initial large weight gain for a few seconds followed by a slower rate of weight gain. The pulmonary capillary filtration coefficient was calculated on the slow phase of the weight curve by a time zero extrapolation or from the slope of the curve.

Nakamura et al. (1987) studied neurogenic pulmonary edema in lung perfusion preparations *in situ* in the **dog**.

Allen et al. (1993) studied the cardiovascular effects of a continuous prostacycline administration into an isolated *in situ* lung preparation in the dog.

Pogrebniak et al. (1994) investigated the influence of tumor necrosis factor in an isolated lung perfusion model in **pigs**.

The fluid filtration coefficient before and after infusion of *Escherichia coli* endotoxin was measured in excised **goat** lungs by Winn et al. (1988).

D.2.2 In Vivo Tests

D.2.2.1 Bronchospasmolytic Activity in Anesthetized Guinea Pigs (Konzett–Rössler method)

PURPOSE AND RATIONALE

The principle war first described by Kiese (1935). Konzett and Rössler (1940) published a method suitable for screening procedures which found worldwide acceptance. A survey on the history and further modifications was given by Döring and Dehnert (1997).

The method is based on registration of air volume changes of a living animal in a closed system consisting of the respiration pump, of the trachea and the bronchi as well as of a reservoir permitting measurement of volume or pressure of excess air. Bronchospasm decreases the volume of inspired air and increases the volume of excess air. Thus, the degree of bronchospasm can be quantified by recording the volume of excess air. Administration of spasmogens like acetylcholine, histamine, bradykinin, serotonin, ovalbumin, PAF, substance P, methacholine or leukotrienes, results in contraction of bronchial smooth muscle.

The method permits the evaluation of a drug's bronchospasmolytic effect by measuring the volume of air, which is not taken up by the lungs after bronchospasm.

PROCEDURE

Guinea-pigs of either sex weighing 250–500 g are anaesthetized with 1.25 g/kg i.p. urethane. Pentobarbital (60 mg/kg s.c.) and alcuronium chloride (1 mg/kg s.c.) are to be preferred when the bronchospasm is elicited by PAF or substance P. Anesthesia has to be deep enough in order to prevent influence of spontaneous respiration. The trachea is cannulated by means of a two way cannula, one arm of which is connected to the respiratory pump and the other to a Statham P23 Db transducer. The animal is artificially respired using a Starling pump with an inspiratory pressure set at 90–120 mm of water, an adequate tidal volume of 3 ml/100 g body weight and a frequency of 60 strokes per minute. Excess air, not taken up by the lungs, is measured and recorded on a polygraph. The internal jugular vein is cannulated for the administration of spasmogens and test compounds. The carotid artery is cannulated for measuring blood pressure.

Testing

Guinea-pigs receive the following spasmogens by i.v. administration:

- acetylcholine hydrochloride (20–40 µg/kg), or
- methacholine (20–40 µg/kg), or
- histamine dihydrochloride (5–20 µg/kg), or
- bradykinin triacetate (10–20 µg/kg), or
- ovalbumin (1 mg/kg), or
- PAF (25–50 ng/ml), or
- leukotrienes LTC_4, LTD_4 (about 1 µg/kg), or
- substance P (0.5 µg/kg).

After obtaining two bronchospasms of equal intensity, test compounds are administered i.v., p.o., s.c. or intraduodenally.

The spasmogen is given again at the following time intervals:

- 5, 15 and 30 min after i.v. administration of the drug
- 15, 30 and 60 min after intraduodenal administration of the drug
- 30 and 60 (sometimes also 120) min after p.o. administration of the drug.

The following standard compounds are used:

- atropine sulfate (0.01 mg/kg, i.v.) to inhibit acetylcholine or methacholine induced spasms
- aminophylline (6 mg/kg, i.v.) to inhibit bradykinin induced spasms
- tolpropamine-HCl (0.2 mg/kg) to inhibit histamine induced spasms
- imipramine-HCl (3–5 mg/kg) to inhibit serotonin-kreatinin-sulphate induced spasms.

EVALUATION

Results are expressed as percent inhibition of induced bronchospasm over the control agonistic responses. The ED_{50} value is calculated.

CRITICAL ASSESSMENT OF THE METHOD

The "Konzett-Roessler"-method has been proven to be a standard procedure in respiratory pharmacology being modified by several authors (Rosenthale and Dervinis 1968).

MODIFICATIONS OF THE METHOD

Forced insufflation was proposed as a simple but accurate inhalation procedure for investigating the activity of anti-asthmatic drugs in guinea pigs by Schiantarelli et al. (1982).

Lundberg et al. (1983), Belvisi et al. (1989), Miura et al. (1994) determined airway opening pressure (P_{ao}) as an index for tracheobronchial resistance to air flow.

Orr and Blair (1969) and Riley et al. (1987) sensitized rats intravenously with a potent antiserum to ovalbumin, obtained by infecting ovalbumin-sensitized donor rats with the parasitic nematode *Nippostrongylus brasiliensis* in order to boost IgE antibody production. The anesthetized animals were challenged with ovalbumin 48 h after sensitization and the subsequent increase in tracheal pressure was recorded.

Collier et al. (1993), Collier and James (1967) published a modification of the Konzett-Rössler-method using the forced re-inflation to overcome the severe bronchoconstriction occurring in sensitized guinea pigs.

Further modifications are by Schliep et al. (1986), Marano and Doria (1993).

Groeben and Brown (1996) measured changes in the cross-sectional area of conducting airways by cumulative doses of ipratropium with and without gallamine, a selective M_2 muscarinic receptor blocker, and after metaproterenol in anesthetized **dogs** using high-resolution computed tomography. Using a Somatom Plus scanner (Siemens), 50 to 55 contiguous scans were obtained, starting approximately 5 mm above the origin of the right upper lobe bronchus from the trachea and proceeding caudally using 1-mm table feed and 2-mm slice thickness. The dogs were anesthetized with thiopental. After paralysis was induced by succinylcholine, the trachea was intubated and the lungs ventilated with a volume-cycled ventilator with 100% oxygen. During the scans, the dogs were apneic at function residual capacity (approximately 2 min). Images were reconstructed using a high-spatial frequency algorithm.

D.2.2.2 Effect of Arachidonic Acid or PAF on Respiratory Function In Vivo

PURPOSE AND RATIONALE

Based on the classical method of Konzett and Rössler (1940), Lefort and Vargafting (1978), Vargafting et al. (1979) studied the effects of arachidonic acid and PAF on respiratory function of guinea pigs *in vivo*.

Arachidonic acid is metabolized into thromboxane (TXA_2) and prostacyclin (PGI_2). TXA_2 produced in the lung leads to bronchoconstriction, which is independent from circulating platelets and leukotrienes; TXA_2 produced intracellularly in platelets induces a reversible thrombocytopenia. PGI_2 produced in the vessel wall leads to the reduction of systolic and diastolic blood pressure. All three effects are inhibited by drugs which block cyclo-oxygenase. In contrast, agents which block thromboxane synthetase inhibit bronchoconstriction and thrombocytopenia, but lead to a potentiation of blood pressure reduction.

In contrast to arachidonic acid, PAF as inducer leads to bronchoconstriction, which is platelet-dependent. In addition, PAF induces thrombocytopenia, leukocytopenia, reduction of blood pressure and increase of hematocrit. These effects are also reversible, but more persistent than those induced by arachidonic acid, and quickly result in tachyphylaxis. The test allows to evaluate the sites of action of drugs, which interfere with the mechanisms of bronchoconstriction and thrombocytopenia; in an *in vivo*-model guinea pigs are challenged with the spasmogens and platelet-aggregating substances arachidonic acid or PAF (platelet activating factor).

PROCEDURE

Male guinea pigs (Pirbright White) weighing 300–600 g are anesthetized with 60 mg/kg pentobarbital sodium (i.p.). One of the jugular veins is cannulated for the administration of spasmogen and test compound. Both external carotid arteries are cannulated; one is connected to a pressure transducer to register blood pressure, the other is used for blood withdrawal. The trachea is connected to a Starling pump with an inspiratory pressure set of 80 mm H_2O, an adequate tidal volume of approx. 10 ml/kg body weight and a frequency of 70–75 strokes/min. Spontaneous respiration is inhibited by intravenous injection of pancuronium (4 mg/kg) or gallamine (2 mg/kg) on time.

In some experiments, pulmonal β-receptors are blocked by intraperitoneal administration of propranolol (2 mg/kg).

Excess air, not taken up by the lungs, is conducted to a transducer with bronchotimer (Rhema, Germany) which translates changes in air flow to an electrical signal. Changes in air flow and arterial blood pressure are recorded continuously.

Animals receive multiple intravenous injections of the same dose of arachidonic acid (Sigma, 250–600 µg/kg prepared from a stock solution 10 mg/ml ethanol, 1:20 dilution with Na_2CO_3) until two bronchospasms of equal intensity are obtained. The test compound is administered intravenously and the spasmogen is given again at the following intervals: 2, 10, 20 and, if necessary, 30 min after administration of the drug.

Ordinarily, the lung has to be passively dilated (bronchotimer) after each of the bronchoconstrictions. Immediately before and 30–45 s after each of the arachidonic acid applications, approx. 50 µl blood are collected into Na-EDTA-coated tubes. The number of thrombocytes is determined with a platelet analyzer (Becton Dickinson Ultra-Flo-100 or Baker 810) in 10 µl samples of whole blood.

PAF (Paf-acether C16, Bachem, 0.03–0.04 µg/kg in 0.9% saline+0.1% human serum albumin) as inducer is injected intravenously 60 min before, 5 min and, if necessary, 60 min after intravenous drug administration. Blood samples are collected 30 s before and 15 s after each of the PAF applications. The number of leukocytes and hematocrit values are determined automatically (TOA-microcell counter CC 108, Colora Meßtechnik).

Standard compounds:

- dazoxiben HCl (inhibitor of thromboxane synthetase, TSI)
- acetylsalicylic acid (inhibitor of cyclo-oxygenase, COI)

EVALUATION

Percent inhibition or increase of bronchospasm, reduction of blood pressure, thrombocytopenia, leukocytopenia and hematocrit following test drug administration are calculated in comparison to control values before drug treatment. For the reduction of blood pressure, both the magnitude [mm Hg, systolic and diastolic] and the duration [min] are determined. Even a sole increase in duration of blood pressure reduction is considered as an increase of the effect. From the pattern profile of the influence on bronchoconstriction, thrombocytopenia and blood pressure reduction, the mechanism of action of a test drug is concluded:

- inhibitor of thromboxane synthetase
- inhibitor of cyclo-oxygenase
- other effect = no profile

In addition, the inherent action of the test substance on blood pressure is determined before arachidonic acid- or PAF-administration.

MODIFICATIONS OF THE METHODS

Kagoshima et al. (1997) used a modification of the Konzett-Rössler-method to test the suppressive effects of a PAF-antagonist on asthmatic responses in guinea pigs actively sensitized with ovalbumin. The immediate and the late asthmatic response were measured by the oscillation method according to Mead (1960).

Pauluhn (1994, 2004) described inhalation systems, mainly for toxicological studies, by which large numbers of animals can be studied simultaneously.

D.2.2.3 Bronchial Hyperreactivity

PURPOSE AND RATIONALE

Symptoms like asphyctic convulsions resembling bronchial asthma in patients can be induced by inhalation of histamine or other bronchospasm inducing agents in guinea pigs. The challenging agents are applied as aerosols produced by an ultra-sound nebulizer. The first symptoms are increased breathing frequency, forced inspiration, and finally asphyctic convulsions. The occurrence of these symptoms can be delayed by antagonistic drugs. Pre-convulsion time, i. e. time until asphyctic convulsions, can be measured.

PROCEDURE

Ten male albino guinea pigs weighing 300–400 g per group are used. The inhalation cages consist of 3 boxes each ventilated with an air flow of 1.5 l/min. The animal is placed into box A to which the test drug or the standard is applied using an ultra-sound nebulizer LKB NB108 which provides an aerosol of 0.2 ml solution of the test drug injected by an infusion pump within 1 min. Alternatively, the animal is treated orally or subcutaneously with the test drug or the standard. Box B serves as a sluice through which the animal is passed into box C. There, the guinea pig is exposed to an aerosol of a 0.1% solution of histamine hydrochloride provided by an ultra-sound nebulizer (De Vilbiss, Model 35 A). Time until appearance of asphyctic convulsions is measured. Then, the animal is immediately withdrawn from the inhalation box. The aerosols are removed from the back wall of the boxes by applying low pressure.

EVALUATION

Percent of increase of pre-convulsion time is calculated versus controls. ED_{50} values can be found, i. e. 50% of increase of pre-convulsion time.

CRITICAL ASSESSMENT OF THE METHOD

The "guinea pig asthma" has been applied as useful method in various modifications by many laboratories.

MODIFICATIONS OF THE METHODS

Simple methods to test bronchospasmolytic activity in conscious animals, called "thoracography" were described by Herxheimer (1956) Olsson (1971), Beume et al. (1985). A silicon tube with a diameter of 1 mm is filled with mercury and serves as strain gauge applied as belt around the thorax of conscious guinea pigs. Changes in electrical resistance due to breathing

movements of the thorax are registered. The animals are exposed in a Plexiglas chamber to acetylcholine nebulized by an ultrasonic device. Time until onset of coughing indicated by an increase of signal amplitude and of severe asthmatic dyspnoea is registered.

Immunological factors are involved in bronchial hyperreactivity (Reynolds 1991).

Harris et al. (1976) immunized rabbits with thermophilic actinomyces antigen (Micropolyspora faeni). Lesions resembling hypersensitivity in man were found, characterized by a mononuclear cell interstitial reaction and a marked increase in the number of intra-alveolar cells.

Ufkes et al. (1983) induced bronchial and cardiovascular anaphylaxis in Brown-Norway rats, sensitized with trinitrophenyl haptenized ovalbumin and $AlPO_4$ as adjuvant 12 days prior to challenge with trinitrophenyl haptenized bovine serum albumin intravenously.

Raeburn et al. (1992) gave a survey on techniques for drug delivery to the airways and the assessment of lung functions in animal models including parameters such as lung compliance and airway resistance.

Elwood et al. (1992) studied the effects of dexamethasone and cyclosporin A on the airway hyperresponsiveness and the influx of inflammatory cells into bronchoalveolar lavage fluid seen 18 to 24 h after exposure to aerosolized ovalbumin in actively ovalbumin-sensitized Brown-Norway rats.

Schmiedl et al. (2003) found an increase of inactive intra-alveolar surfactant subtypes in lungs of asthmatic Brown Norway rats. The volume fractions of surfactant subtypes and the epithelial surface fraction covered with alveolar edema were determined by point and intersection counting. The surface activity of surfactant from broncho-alveolar lavage was determined as the minimum surface tension at minimal bubble size with a pulsating bubble surfactometer.

Pahl et al. (2002) and Kuss et al. (2003) exposed ovalbumin-sensitized Brown Norway rats to an ovalbumin-containing aerosol in a nose-only inhalation system (TSE, Bad Homburg, Germany) for 1 h to provoke an influx of inflammatory cells into the airways. At the time of maximal influx of eosinophilic granulocytes into the airways (48 h later), the animals were sacrificed and a broncho-alveolar lavage was performed.

A model of bronchial hyperreactivity after active anaphylactic shock in conscious guinea pigs has been described by Tarayre et al. (1990). The guinea pigs were sensitized by an intramuscular injection of a large dose of ovalbumin in Freund's adjuvant. The administration of ovalbumin to induce anaphylactic shock was by aerosol. Bronchial hyperreactivity to histamine was observed 3–6 h after the anaphylactic shock.

Bolser et al. (1995) sensitized guinea pigs by intraperitoneal injection of 200 µg/kg ovalbumin mixed with 200 mg/kg aluminum hydroxide. The animals were placed 28 days later in a transparent plastic chamber and exposed to aerosols of ovalbumin (0.1%–1%) at an airflow of 4 l/min to elicit coughing. Coughs were detected by a microphone placed in the chamber and connected to an audio monitor and chart recorder. The number of coughs elicited during a 4-min exposure was counted by visual inspection of the chart record.

Pons et al. (2000) described a guinea pig model of asthma. Animals were sensitized by two intraperitoneal injections of 20 µg ovalbumin and 100 mg aluminum hydroxide given 24 h apart. The sensitized animals were anesthetized and mechanically ventilated. Air flow was measured with a pneumotachograph, along with transpulmonary pressure and arterial pressure. Lung resistance and dynamic compliance were calculated. Then, 30 min after administration of test drug, the animals were challenged by inhaled ovalbumin (5 mg/ml).

The importance of eosinophil activation for the development of allergen-induced bronchial hyperreactivity was underlined by Santing et al. (1994). A significant increase in bronchoreactivity to histamine was observed at 6 h after allergen exposure, which was associated with an increase of eosinophils in the bronchoalveolar lavage and an increase in the eosinophil peroxidase activity.

The increased pulmonary vascular permeability may be related to the adult respiratory distress syndrome in man (Snapper and Christman 1989).

The infusion of small amounts of *Escherichia coli* endotoxin into chronically instrumented awake **sheep** results in well-characterized pulmonary dysfunction (Brigham and Meyrick 1986).

One animal model associated with both increased airway responsiveness and pulmonary inflammation is endotoxemia in sheep (Hutchinson et al. 1983).

The effect of a platelet activating factor receptor antagonist on the sheep's response to endotoxin was studied by Christman et al. (1987).

Chiba and Misawa (1995) characterized muscarinic cholinoceptors in airways of antigen-induced airway hyperresponsive rats. The animals were sensitized with 2,4-dinitrophenylated *Ascaris suum* extract together with *Bordetella pertussis* (2×10^6 as an adjuvant and were boosted with 2,4-dinitrophenylated *Ascaris suum* extract 5 days later. Isometric contractions of the circu-

lar muscle of isolated bronchial rings after addition of increasing doses of acetylcholine were measured with a force-displacement transducer.

Laboratory infection of **primates** with *Ascaris suum* may provide a model of allergic bronchoconstriction (Patterson et al. 1983; Pritchard et al. 1983; Eady 1986).

Richards et al. (1986) used various models of airway hypersensitivity, such as inhalation of *Ascaris suum* antigen in monkeys and dogs.

Rylander and Marchat (1988) studied the effect of a corticosteroid on an acute inflammation in the lungs of guinea pigs exposed to an aerosol of bacterial endotoxin. The subsequent inflammatory response was evaluated counting the number of cells obtained from airway lavage and in the lung interstitium as well as the chemotactic effect of alveolar macrophages.

Hatzelmann et al. (1996) reported on automatic leukocyte differentiation in broncho-alveolar lavage fluids of guinea pigs and Brown-Norway rats using an automatic cell analyzing system (Cobas Helios 5Diff; Hoffmann-La Roche; Grenzach-Wyhlen, Germany).

Minshall et al. (1993) demonstrated that neonatal immunization of **rabbits** with *Alternia tenuis* can lead to the development of persistent airway hyperresponsiveness.

Okada et al. (1995) studied late asthmatic reactions in **guinea pigs** sensitized with *Ascaris* antigen. They evaluated interleukin-1 production by immunostaining with anti-IL-1β antibody and elucidated the action of IL-1 in late asthmatic reactions with recombinant IL-1 receptor antagonist.

Folkerts et al. (1995) found that intratracheal inoculation of *parainfluenza type 3 virus* to guinea pigs induces a marked increase of airway responsiveness to increasing doses of intravenous histamine. In spontaneously anesthetized breathing guinea pigs, inhalation of an aerosol containing the nitric oxide precursor L-arginine completely prevented the virus-induced hyperresponsiveness to histamine.

Fryer et al. (1994, 1997) measured M_2 muscarinic receptor function in anesthetized and paralyzed guinea pigs by electrical stimulation of both vagus nerves producing bronchoconstriction (measured as pulmonary inflation pressure) and bradycardia.

D.2.2.4 Body Plethysmography and Respiratory Parameters After Histamine-Induced Bronchoconstriction in Anesthetized Guinea Pigs

PURPOSE AND RATIONALE

Guinea pigs can be placed in a plethysmograph for measurement of respiratory parameters. Respiratory frequency and respiratory amplitude are recorded. The decrease of respiratory amplitude (diminished respiratory volume due to bronchoconstriction) and the reflectory increase of respiratory frequency after histamine inhalation are attenuated by bronchodilatatory drugs. Additional respiratory parameters can be recorded using a Fleisch tube and a catheter inserted into the pleural cavity (Englert et al. 1992). The method can be used for various purposes, e. g., to evaluate the antagonism against bradykinin-induced bronchoconstriction (Wirth et al. 1991, 1993) or the bronchodilator effects of potassium channel openers (Englert et al. 1992) or to measure the effect of morphine on respiration in rats (Kokka et al. 1965).

PROCEDURE

Guinea pigs of either sex weighing 400–600 g are anesthetized with 70 mg/kg pentobarbital i.p. The trachea, pleural cavity, jugular vein, and carotid artery are prepared and cannulated. The animals are mechanically ventilated with a Starling respiratory pump which delivers an inspiration volume that represents a tracheal pressure of 8 cm water at a rate of 60 strokes/min. Succinylcholine chloride at a dose of 1 mg/kg is given i.v. to prevent interference from spontaneous respiration. The guinea pigs are placed inside a whole body plethysmograph and tracheal, pleural, venous and arterial catheters are connected to onset ports in the wall of the plethysmograph box. The tracheal port is then connected with the respiration pump. **Airflow rate** into and out of the plethysmograph are measured as pressure difference with a No. 000 Fleisch tube and a differential pressure transducer (Fa. Hellige, PM 97 TC). Airflow is calibrated by passing compressed air through a rotameter. The **tidal volume** (V_T) is calculated from the flow signal. **Transpulmonary pressure** (P_{TP}) is measured with a differential pressure transducer (Hellige, PM 97 TC), with one side attached to a catheter inserted into the right pleural cavity and the other side connected to a side port of the tracheal cannula. P_{TP} is calibrated with a water manometer. Signals from airflow, tidal volume and transpulmonary pressure are fed into an on-line computer system (PO-NE-MAH, Model PF-1, Storrs) for calculation of **pulmonary resistance** (R_L) and **dynamic lung compliance** (C_{DYN}). These parameters are calculated for each breath with a sampling rate of $100\,s^{-1}$ for each circle. Flow and pressure signals for computation are obtained from a PLUGYS measuring system (Fa. Hugo Sachs Elektronik, Freiburg, Germany). Systemic arterial pressure is measured using a Statham pressure transducer (P 23 Db). Heart rate is computed from pressure pulses (Döring and Dehnert 1997).

Three doses of test compound or standard are injected intravenously. Saline injections serve as con-

trols. Intravenous injections of histamine (0.5–2 µg/kg) lead to a short decrease in C_{DYN} and to a short increase in R_L by approximately 200% compared with baseline. Challenges are repeated at 5-min intervals, yielding the same increase in R_L during the whole 1-h experimental period. After 3 reproducible responses the test agent is administered intravenously 1 min before the histamine injection.

To evaluate test compounds for inhalation route, aerosols are generated with an ultrasonic nebulizer (LKB, model NB 108) and are administered to the animals through a shunt in the afferent limb of the respiratory pump, allowing the inspired air to pass through the nebulizer chamber before entering the animals lungs.

EVALUATION

Inhibition of histamine induced bronchoconstriction by various doses of test compound and standard is recorded. ED_{50} values for inhibition in R_L are calculated. Furthermore, the time course of histamine antagonism can be evaluated. Compounds can be tested either after iv. injection of histamine (prevention) or during intravenous infusion of histamine (intervention).

CRITICAL ASSESSMENT OF THE METHOD

Whole body plethysmography has been proven to be a useful tool in respiratory pharmacology for studies on the antagonism against various bronchoconstrictors, such as histamine and bradykinin, as well as for airway pharmacology of potassium channel openers.

MODIFICATIONS OF THE METHOD

Several authors use body plethysmography to study respiratory functions in animals (Amdur and Mead 1958; Blümcke et al. 1967), Pennock et al. 1979; Agarwal (1981), James and Infiesto (1983), Kisagawa et al. (1984), Griffith-Johnson (1988), Danko and Chapman (1988), Ball et al. (1991), Chand et al. (1993).

The effect of β-blockers on pulmonary function and bronchoconstrictor responsiveness in **guinea pigs** and rats has been studied by Chapman et al. (1985).

Finney and Forsberg (1994) developed a technique for quantification of nasal involvement in a guinea pig plethysmograph. Nasal and lower respiratory system conductance could be measured simultaneously in anesthetized animals.

A whole body plethysmograph for conscious animals has been described by Elliott et al. (1991) and improvements by Linton (1991).

Studies of bronchospasmolytic agents with aerosol challenge in conscious guinea pigs using a double chamber plethysmograph box have been reported by Schlegelmilch (1991).

Ball et al. (1991) described a method for the evaluation of bronchoactive agents in the conscious guinea pig. The method involves the use of "head out" whole body plethysmographs from which respiratory rate can be recorded by monitoring respiration-related changes in pressure within the body chamber.

Hey et al. (1995) used a head-out, whole body plethysmograph to examine the effects of $GABA_B$ receptor agonists on minute ventilation, tidal volume and respiratory rate due to room air and carbon dioxide-enriches gas hyperventilation in conscious guinea pigs.

Murphy et al. (1998) developed a method for chronic measurement of pleural pressure in conscious **rats**. Pleural pressures were measured by surgically implanting a fluid-filled polyurethane catheter attached to a pressure-sensitive radiotelemetry transmitter (Model TA11PA-C40, Data Sciences Int., St. Paul, MN) beneath the pleural surface. A compatible receiver (Model RLA0120) and a data acquisition and analysis software system (LabPRO, Version 3) sampling at a rate of 500 Hz were used to analyze the telemetric signals.

Sinnett et al. (1981) described a fast integrated flow plethysmograph for small animals (**mice**).

Glaab et al. (2001) used tidal mid-expiratory flow in a head-out body plethysmograph as a measure of airway hyperresponsiveness in allergic mice.

Simple methods to determine respiratory parameters in small animals were described by Schütz (1960), Höbel et al. (1971).

Schlenker (1984) and Schlenker and Metz (1989) evaluated ventilatatory parameters in dystrophic **Syrian hamsters**.

Wasserman and Griffin (1977) studied bronchoactivity in the intact anesthetized **dog**.

Paré et al. (1976) determined pulmonary resistance and dynamic lung compliance in **rhesus monkeys**.

Wegner et al. (1984) measured dynamic respiratory mechanics in monkeys by forced oscillations generated by a loudspeaker in an airtight chamber.

D.2.2.5 Pneumotachography in Anesthetized Guinea Pigs

PURPOSE AND RATIONALE

The use of a pneumotachograph based on the principle of the Fleisch-tube and of additional pressure transducers allows simultaneous measurements of several respiratory and circulatory parameters in anesthetized guinea pigs (de la Motta 1991).

PROCEDURE

Guinea pigs (Pirbright white) weighing 300–400 g are anesthetized with 1.5 g/kg urethane i.p. The animals are shaved ventrally at the neck, placed on a heated operating table, and fixed at the upper extremities. A metal cannula with a blunted tip is inserted into the trachea and secured with a loop within the caudal section of the trachea. A thin plastic catheter is inserted into the esophagus and the tip located inside the thorax in order to register intrathoracic pressure. Furthermore, the cephalic vein at one side and the carotid artery on the opposite side are cannulated. The tracheal cannula is connected with pieces of tubing to a Fleisch tube (pneumotachograph), size 0000. In or-

der to avoid water condensation, the Fleisch tube is heated. The Fleisch tube is connected with a sensitive differential pressure transducer with a range of 2 cm H_2O (Validyne, model MP 45 -xx-871). One side of another pressure differential transducer with a range of 20 ml H_2O is connected with the esophageal catheter, the other side remaining open to room air. Both Validyne pressure transducers are connected to a separate preamplifier. For recording of the arterial blood pressure a Gould pressure transducer, Type P23Gb, is used. The signals for airflow and esophageal pressure are monitored at the output of the preamplifier with a digital 2-channel oscilloscope. To obtain various respiratory and circulatory parameters from the three primary signals they are calculated by certain formulae by an analogue computer (Buxco Pulmonary Mechanics Analyzer, Model 6). The following parameters are presented at the output of the instrument as analogue electrical signals:

Circulation

Systolic blood pressure, diastolic blood pressure, mean blood pressure

Respiration

Tidal volume, respiratory volume per minute, respiratory rate

Pulmonary Mechanics

Airway resistance, dynamic compliance, end-respiratory work.

A multi-channel recorder (Graphtec Linearcorder Mark VII) serves a functional check on the Buxco Analyzer and as analogue presentation of the calculated parameters. Data processing is performed by a 12-channel A/D converter (Buxco Data Logger, Model D/C-12 F/V) which digitizes the analogue output signals of the Buxco Analyzer and sends them through a serial interface (RS232) to an IBM PC. A special software program (Lomask 1987; Hastings 1990a, b) provides a flexible facility for data reduction and statistical evaluation.

EVALUATION

For each individual experiment the data of the last 5 min before the first substance application are averaged and used as controls. The response values after substance application are then expressed as percentages of the controls. In this way each animal serves as its own control. For an analysis of the results the response values are averaged over certain time intervals.

CRITICAL ASSESSMENT OF THE METHOD

The method described in great detail by de la Motta (1991) may be modified using different equipment according to individual needs.

MODIFICATIONS OF THE METHOD

Measurement of respiratory parameters is based on earlier studies to be mentioned for historical reasons (Gad 1880; Pflüger 1882; Zwaardemaker and Ouwehand 1904; Jaquet 1908; Rohrer 1915; Gildemeister 1922; Fleisch 1925; v. Neergaard and Wirz 1927; survey by Döring HJ 1991).

Lorino et al. (1988) assessed respiratory mechanics of histamine bronchopulmonary reactivity in guinea pigs.

O'Neil et al. (1981) published a comparative study of respiratory responses to bronchoactive agents in rhesus and cynomolgus monkeys.

Rayburn et al. (1989) described a computer-controlled pulmonary function system for studies in large animals.

Five methods of analyzing respiratory pressure-volume curves have been compared by Lai and Diamond (1986).

A specially designed pneumotachograph that is placed inside the trachea of guinea pigs was described by Santing et al. (1992) allowing the evaluation of airway functions in conscious, unstressed animals.

Lorino et al. (1993) estimated the changes in end-respiratory lung volume accompanied histamine-induced bronchoconstriction in anesthetized, paralyzed, and mechanically ventilated guinea pigs from measurements of thoracic cross-sectional area, assessed from the voltage induced by an external uniform magnetical field in a pickup coil encircling the rib cage.

Gozzard et al. (1996) evaluated the effects of PDE-inhibitors in **New Zealand White rabbits** which were immunized within 24 h of birth with *Alternaria tenuis* antigen. Spontaneously breathing rabbits were intubated in neuroleptanalgesia with a cuffed endotracheal tube connected to a thermoregulated Fleisch pneumotachograph to allow measurement of tidal air flow. An oesophageal balloon catheter was inserted to provide a measure of intra-pleural pressure and transpulmonary pressure. Antigen challenge was performed with inhaled *Alternaria tenuis* extract.

An excellent survey on various methods and equipment to measure air flow is given by Döring and Dehnert (1997).

D.2.2.6 Airway Microvascular Leakage

PURPOSE AND RATIONALE

Plasma exudation in guinea-pig airways *in vivo* can be determined by Evans Blue dye and is fairly correlated with radiolabelled albumin (Rogers et al. 1989). This method can be used to study the antagonism against bradykinin- and platelet-activating factor-induced airway microvascular leakage and vagal stimulation-induced airway responses (Sakamoto et al. 1992, 1994).

PROCEDURE

Female Dunkin-Hartley guinea pigs weighing 380–600 g are anesthetized with an initial dose of 1.5 g/kg urethane injected i.p. Additional urethane is given i.v. 30 min later to achieve an appropriate level of anesthesia. A tracheal cannula is inserted into the lumen of the cervical trachea, a polyethylene catheter into the left carotid artery to monitor blood pressure and heart rate and another polyethylene catheter into the external jugular vein for administration of drugs. The animals are connected to a constant volume mechanical ventilator and then given an injection of 1.0–1.5 mg/kg suxamethonium i.v. to prevent interference with spontaneous respiration. A tidal volume of 10 ml/kg and a frequency of 60 strokes/min are used.

Lung resistance is measured as an index of airway function and monitored throughout the experiment. Transpulmonary pressure is measured with a pressure transducer with one side attached to a catheter inserted into the right pleural cavity and the other side attached to the side port of the intratracheal cannula. Airflow is measured by a pneumotachograph connected to a pressure transducer. The signals of the transducers are used for instantaneous calculation of lung resistance by an appropriate computer program.

The test compound (bradykinin receptor antagonist) is given intravenously. Ten min later, Evans Blue dye (20 mg/ml) is injected i.v. for 1 min. After 1 min, bronchoconstriction and microvascular leakage is induced by injection of bradykinin or by inhalation of bradykinin or PAF or vagal stimulation.

Six min after induction of leakage, the thoracic cavity is opened, and a cannula is inserted into the

aorta through a ventriculotomy. Perfusion is performed with 100–150 ml 0.9% saline at a pressure of 100–120 mm Hg in order to remove the intravascular dye from the systematic circulation. Blood and perfusion liquid are expelled through an incision in the right and left atrium. Subsequently, the right ventricle is opened, and the pulmonary circulation is perfused with 30 ml of 0.9% saline. The lungs are then removed, and the connective tissue, vasculature, and parenchyma are gently scraped. The airways are divided into 4 components: lower part of the trachea, main bronchi, the proximal 5 mm portion, and the distal intrapulmonary airways. The tissues are blotted dry, and then weighed. Evans Blue dye is extracted in 2 ml of formamide at 40°C for 24 h, and measured in a spectrophotometer at 620 nm.

EVALUATION

Evans Blue dye concentration, expressed as ng/mg tissue, as well as lung resistance are compared by statistical means (unpaired Student's *t*-test or Mann-Whitney U test) between treated groups and controls receiving the challenge only.

MODIFICATIONS OF THE METHOD

Boschetto et al. (1989) tested the effect of antiasthma drugs on microvascular leakage in guinea pig airways. Microvascular leakage was induced by intravenous injection of platelet-activating factor (50 ng/kg) which acts directly on venular endothelial cells, and measured by quantifying extravasation of Evans blue dye.

Xu et al. (1998) induced pulmonary edema in rats by injection of 20 µg/kg angiotensin I and studied the suppression by ACE-inhibitors, ATII antagonists and α-adrenergic receptor blockers.

Rapidly developing pulmonary edema was induced by intravenous injection of 1.2 mg/kg of the GABA agonist bicuculline in rats and the role of endogenous endothelin was examined by Herbst et al. (1995).

D.2.2.7 Isolated Larynx In Situ

PURPOSE AND RATIONALE

The *in situ* isolated larynx of rats has been recommended by Willette et al. (1987) for evaluation peripheral opiate receptor antagonists. Peripheral opioid-induced laryngospasm and central opioid-induced respiratory depression can be measured simultaneously. Fentanyl citrate stimulates both peripheral and central opiate receptors, whereas [D-Ala^2-Met^5]-enkephalinamide stimulates only peripheral opiate receptors. Compounds that inhibit both laryngeal and respiratory effects of fentanyl, e. g., naloxone HCl, can be considered both central and peripheral opiate antagonists. Compounds that inhibit only the peripheral effects of fentanyl, e. g., naltrexone methylbromide, can be considered peripheral opiate receptor antagonists.

PROCEDURE

Laryngeal resistance experiments are carried out in male Sprague Dawley rats weighing 340–360 g and anesthetized with urethane (900 mg/kg, i.p.) The animals are secured in supine position and the left femoral artery and the left and right femoral veins are cannulated for recording of arterial blood pressure and administration of drugs. A right-angle polyethylene cannula (ID 1.67 mm, OD 2.42 mm) is inserted into the caudal trachea at the level of the manubrium for measuring tracheal flow via a small animal pneumotachograph. Care has to be taken to avoid damaging surrounding blood vessels or adjacent bilateral laryngeal nerves. Tracheal air flow is continually sampled (300 ml/min) for the breath to breath analysis of end tidal carbon dioxide with an infrared gas analyzer.

Laryngeal resistance in the rat is determined using a modification of the methods described by Stransky et al. (1973), Bartlett et al. (1973), and Willette et al. 1982b). The rostral portion of the trachea is cannulated with a right-angle polyethylene tube (ID 1.67 mm, OD 2.42 mm). This cannula is carefully advanced towards the larynx and secured with a suture (4–0 silk). A constant flow ($V = 30$ ml/min) of compressed air, maintained with a flow meter, is delivered through a cannula. Pre-laryngeal pressure is measured with

a needle tipped pressure transducer inserted into the lumen of the flow cannula. A 1.75-cm segment of polyethylene tubing (OD 8.4 mm, ID 4.6 mm) is placed into the mouth to retract resistive components in the nasopharyngeal region.

Laryngeal resistance (*LR*) is calculated by the following equation:

$$LR = (P_L P_i - P_L P_0)/V$$

where $P_L P_i$ is the laryngeal pressure in the cannula directing a constant flow (V) through the larynx. $P_L P_0$ is the pressure in the cannula when it is removed from the trachea.

The agonist fentanyl is administered through the left femoral vein at a dose of 12 µg/kg which is equivalent to 1.5 times the ED_{99} in the conscious rat tail flick assay. The enkephaline analogue [D-Ala^2-Met^5]-enkephalinamide is injected at a dose of 250 µg/kg which acts peripherally and increases laryngeal resistance (Willette 1982a). The opiate receptor antagonists are administered similarly into the right femoral vein.

At the conclusion of the experiment, the pulmonary afferent stimulant, phenyldiguanide (25 µg/kg, i.v.) is injected into the right femoral vein to elicit laryngospasm and to determine the viability of the preparation.

EVALUATION

All summary values are expressed as the mean plus or minus the standard error of the mean (SEM) Comparisons are made with independent and paired two-tailed *t*-tests.

MODIFICATIONS OF THE METHOD

Inagi et al. (1998) assessed the effect of botulin toxin in the rat larynx be measurement of the optical density of PAS-stained laryngeal muscle after electrical stimulation, spontaneous laryngeal muscle activity, and laryngeal movement.

O'Halloran et al. (1994) studied the effects of upper airway cooling and CO_2 on breathing and on laryngeal and supraglottic resistance in anesthetized rats.

González-Barón et al. (1989) studied the modifications of larynx resistance changing bronchial tone in cats evoked by intravenous administration of 10 µg/kg carbachol as bronchoconstrictor and by fenterol (10 µg/kg) or isoproterenol (0.1 mg/kg) as bronchodilators.

Wang et al. (1999) developed an isolated, luminally perfused laryngeal preparation in anesthetized paralyzed cats in order to compare the effects of solutions with varying levels of pH and pCO_2 on pressure-sensitive laryngeal receptor sensitivity.

D.2.2.8 Animal Models of Asthma

D.2.2.8.1 Treatment of Asthma

PURPOSE AND RATIONALE

Several authors described asthma models in mice. Hammad et al. (2004) found in a mouse model of asthma that activation of peroxisome proliferator-activated receptor-γ (PPAR-γ) in dendritic cells inhibits the development of eosinophilic airway inflammation.

PROCEDURE

Bone Marrow Dendritic Cells

OVA-TCR transgenic mice (DO10.11) on a BALB/c background, bred at the Erasmus University (Rotterdam) (Murphy et al. 1990), are used. Femurs and tibiae of female mice are removed and flushed with RPMI 1640. Vigorous pipetting disintegrates clusters within the marrow suspension. The cells are washed, enumerated, and plated in Petri dishes. Cell-culture medium (TCM) is supplemented with gentamicin (60 µg/ml), 2-mercaptoethanol (5×10^{-5} mol/l) and 5% fetal calf serum (Lutz et al. 1999). At day 0 of the culture, cells are seeded at a concentration of 2×10^6/dish in medium containing granulocyte-macrophage colony-

stimulating factor (GM-CSF, 200 IU/ml). At days 6 and 8, half of the medium is collected, centrifuged, and the pellet is resuspended in TCM containing 200 IU/ml of recombinant murine GM-CSF.

At day 9 of the culture, dendritic cells (Banchereau and Steinman 1998) are pulsed overnight with ovalbumin containing the vehicle (dimethylsulfoxide, DMSO) in which the standard PPAR-γ agonist (e. g., rosiglitazone) is suspended or with medium alone as control. Other plates are treated with the test drug or a PPAR-γ antagonist. After antigen pulsing overnight, non-adherent dendritic cells are collected, washed to remove free ovalbumin, and resuspended in phosphate-buffered saline at a concentration of 12.5×10^6 cells/ml.

Eosinophilic Airway Inflammation

For intratracheal injection of dendritic cells (Lambrecht et al. 2000), mice are anesthetized with Avertin and 80 µl of the cell suspension (1×10^6 dendritic cells) is instilled through the opening vocal cords. Mice are injected with unpulsed dendritic cells, ovalbulmin-treated dendritic cells or dendritic cells treated additionally with the PPAR-γ antagonist. From days 10–13, mice are exposed to 30-min ovalbumin aerosols. They are sacrificed 24 h after the last aerosol. Broncho-alveolar lavage is performed with 3×1 ml of Ca^{2+}- and Mg^{2+}-free buffer supplemented with 0.1 mmol/l sodium EDTA. The broncho-alveolar lavage is centrifuged; the cells are resuspended in buffer and enumerated with a hemocytometer. They are differentiated (Vremec and Shortman 1997) by staining for 30 min with anti-I-Ad/I-Ed FITC (macrophages), anti-CCR3 PE (eosinophils), antiCD3-cy-chrome, anti-B220 cytochrome (T and B cells, respectively) and anti-CD11c APC (macrophages) in PBS containing 0.5 bovine serum albumin and 0.01% sodium azide. Cells are washed and analyzed by flow cytometry (Van Rijt et al. 2002).

EVALUATION

The difference between the groups is calculated using the Mann–Whitney *U*-test for unpaired data.

MODIFICATIONS OF THE METHOD

Iwasaki et al. (2001) recommended atopic NC/Nga mice as a model for allergic asthma: after immunization with ovalbumin, severe allergic responses were elicited by a single intranasal challenge.

For testing PPAR agonists, Trifilieff et al. (2003) used a murine model of asthma using lung inflammation induced by ovalbumin or by LPS (Trifilieff et al. 2000). Female BALB/c mice (4 weeks old) were immunized with ovalbumin on days 0 and 14, exposed to an aerosol challenge of ovalbumin or phosphate-buffered saline (PBS) on day 21 and killed on day 23 for measurement of inflammatory cells in the broncho-alveolar lavage. Animals were intranasally treated with compounds 1 h before the aerosol exposure using PBS containing 2% DMSAO as vehicle.

For LPS-induced lung inflammation mice were challenged intranasally with 0.3 mg/kg of LPS (*Salmonella typhosa*) in 50 ml of sterile PBS or with sterile PBS alone and killed 3 h later for broncho-alveolar lavage. Tumor necrosis factor alpha (TNF-α) and the neutrophil chemokine KC levels were measured using an enzyme-linked immunosorbent assay kit (R&D Systems, Abingdon, UK). Animals were intranasally treated with compounds 1 h before the aerosol exposure using PBS containing 2% DMSO as vehicle.

Mueller et al. (2003) reported that **peroxisome proliferators-activated receptor γ ligands** attenuate immunological symptoms of allergic asthma. For asthma induction, Balb/c mice were injected with 10 µg of ovalbumin in Alum twice on days 1 and 5 (Zhang et al. 1999). On day 10, they were challenged intranasally with 40 µg ovalbumin in sterile saline, every day for 3 days. On the day after the last intranasal challenge, the mice were sacrificed. The degree of inflammation in the lung was evaluated by histopathology. Gene expression was tested by microarray analysis, and serum IgE determined by ELISA.

Regal et al. (2001) described trimellitic anhydride-induced eosinophilia in a mouse model of occupational asthma. Trimellitic anhydride was conjugated to mouse serum albumin. Female BALB/c mice were sensitized on days 1 and 3 intradermally with 0.1 ml of 0.3% ovalbumin suspended in corn oil. On day 12, animals were additionally sensitized intratracheally with 0.04 ml ovalbumin, trimellitic anhydride conjugated to mouse serum albumin, or mouse serum albumin dissolved in water. For elicitation of the allergic response, mice were challenged intratracheally beginning on day 19 with 0.04 ml of aqueous solutions of ovalbumin, trimellitic anhydride conjugated to mouse serum albumin, or mouse serum albumin under ketamine/xylazine anesthesia. After the last intratracheal instillation, the mice were anesthetized with pentobarbital, EDTA plasma was collected by cardiac puncture, the trachea was cannulated and the lungs were lavaged with two 0.9-ml aliquots of PBS to obtain bronchial lavage fluid. The lungs were removed for homogenization and analysis of eosinophil peroxidase and myeloperoxidase.

Churg et al. (2001) studied anti-inflammatory effects of alpha-1 antitrypsin and a metalloprotease inhibitor in C57 BL/6 mice or macrophage metalloelastase knockout mice after intratracheal instillation of a single 7-mg dose of crystalline silica (α-quartz, Minusil-5; US Silica Corporation, Clarkstown, W.Va., USA). This dose produced a rapid and persisting acute inflammatory infiltrate. Mice were euthanized 2 or 24 h after dust exposure by halothane overdose and the lungs removed from the chest cavity. A 20-gauge catheter was inserted into the trachea and the lungs lavaged six times with 1 ml of ice-cold saline. For inflammatory cell measurements, the saline lavage was centrifuged at 200 *g* at 4°C for 10 min. The supernatants were decanted, and the cell pellets were resuspended in 200 µl of saline. Total cell counts were performed using a hemocytometer and differential cell counts were performed on a 10-µl drop of the cell suspension heat-fixed on a slide and stained with hematoxylin-eosin. Lavage samples were analyzed for desmosine and hydroxyproline.

De Sanctis and Drazen (1997) discussed the genetics of native airway responsiveness in mice.

Several animal species have been used such as **rats**.

Misawa et al. (1987) found strain differences among Wistar, Lewis and Fischer 344 rats in an allergic asthma model.

Misawa and Sugiyama (1993) described an airway hyperresponsiveness model in rats, inducing allergic asthma with DNP-Ascaris extract.

Uhlig et al. (1998) reported the effects of long-term oral treatment with leflunomide on allergic sensitization, lymphocyte activation, and airway inflammation in rats.

Birrell et al. (2003) investigated the nitric-oxide synthase isoform involved in eosinophilic inflammation in a rat model of Sephadex-induced airway inflammation. The rat model of Sephadex-induced airway inflammation was also used by Belvisi et al. (2005) for preclinical studies on ciclesonide, an inhaled corticosteroid for the treatment of asthma.

Many authors used sensitized **Brown Norway rats** in experimental models of asthma (Elwood et al. 1992; Steerenberg et al. 1999; Nonaka et al. 2000; Xu et al. 2000; Blesa et al. 2002; Glaab et al. 2002; Huang et al. 2002; Belvisi et al. 2005; Valstar et al. 2006).

Guinea pigs have been used as animal models for asthma by many authors. Most studies were performed with sensitization either by injection with ovalbumin suspended in an adjuvant (Santives et al. 1976; Banner et al. 1996; Lawrence et al. 1998; Regal et al. 2000; Li et al. 2001; Santing et al. 2001; Mukaiyama et al. 2004; Boskabady and Zarei 2004; Ikezono et al. 2005; Tang et al. 2005) or by repetitive sensitization with inhaled ovalbumin (Sagara et al. 1996, 1997; Smith et al. 1996; Liu et al. 1997; Tohda et al. 1998; Cheng et al. 2001; Zhang et al. 2002) and then challenge by inhaled ovalbumin.

Fujimura et al. (1997) described a guinea pig model of ultrasonically nebulized distilled-water-induced bronchoconstriction. Guinea pigs sensitized by intradermal injection of ovalbumin in Freund's adjuvant were treated with aerosols of physiological saline generated by an ultrasonic nebulizer.

Zhou et al. (1998) reported a dose–response relationship between exposure to cockroach allergens and induction of sensitization in an experimental asthma in Hartley guinea pigs.

Larsen and Regal (2002) studied trimellitic anhydride dust-induced airway obstruction and eosinophilia in non-sensitized guinea pigs.

Nishitsuji et al. (2004) described a guinea pig model of cough variant asthma. Bronchial responsiveness to methacholine and cough reflex sensitivity to capsaicin were measured 72 h after ovalbumin inhalation in actively sensitized guinea pigs.

Dogs were used as animal models for asthma by several authors. Many studies preferred the **Basenji Greyhound dog**, which manifests various characteristics of human asthma, including airway hypersensitivity to low concentrations of methacholine (Hirshman et al. 1980; Hirshman and Downes 1981; Chan et al. 1985; Darowski et al. 1989; Emala et al. 1993, 1996).

Redman et al. (2001) studied pulmonary immunity to ragweed in a **Beagle dog** model of allergic asthma.

Some studies were reported using **cats** as an animal model for asthma. Norris et al. (2003) and Norris-Reinero et al. (2004) described an experimental model of allergic asthma in cats sensitized to the house dust mite and Bermuda grass allergen.

Several studies were performed using **monkeys** as animal models for asthma. *Ascaris suum*-sensitive monkeys were used by Mauser et al. (1995) and Zou et al. (2002). Rhesus monkeys (*Macaca mulatta*) were used by Patterson et al. (1975) and Patterson and Harris (1981, 1990, 1992). Turner et al. (1996) used *Macaca fascicularis* to demonstrate *in vitro* and *in vivo* effects of leukotriene B_4 antagonism in primates.

D.2.2.8.2 Prevention of Allergic Asthma Reaction

PURPOSE AND RATIONALE

Type 1 allergy is an abnormal reaction to protein substances that occur naturally. B-lymphocytes produce an antibody against the allergen. An allergic reaction occurs every time the body is exposed to the allergen causing release of histamine. Allergic reactions can be asthma, hay fever or nettle rash. Sensitization to normally harmless environmental antigens (e. g., pollen, house-dust mite) is the prerequisite for initiating the inflammatory cascade in bronchial asthma. Inflammation of the airway mucosa is orchestrated by Th-2 type T cells, which produce Th-2 cytokines (IL-4, IL-5, IL-9, IL-13, and IL-15), which regulate both IgE production and airway inflammation. At present, no cure of asthma disease is available, but primary and secondary prevention is the therapy of choice (Cieslewicz et al. 1999). Specific immunotherapy is performed by injection of increasing amounts of allergens to induce hyporesponsiveness to the respective allergen. By mucosal application of soluble antigen, mucosal tolerance can be achieved (van Halteren et al. 1997; Astori et al. 2000). Many studies have been performed in spite of the fact that no animal model is available that resembles all features of human bronchial asthma (Herz et al. 1998). In particular, models using recombinant allergens were described (Hoyne et al. 1997, 2000; Herz et al. 2004).

These studies concern specific allergens, such as **ovalbumin** (Renz et al. 1992; Marth et al. 2000; Neuhaus-Steinmetz et al. 2000; Raap et al. 2003; Reader et al. 2003; Wegmann et al. 2005), **mite dust allergen** (Hoyne et al. 1996; Clarke et al. 1999; Yasue et al. 1998a, 1998b, 1998c, 1999; Jarnicki and Thomas 2002), **pollen allergen** (Hirahara et al. 1998; Wiedermann et al. 1999, 2001; Batanero et al. 2002; Repa et al. 2004; Hufnagl et al. 2005; Winkler et al. 2006), **latex protein allergen** (Thakker et al. 1999; Woolhiser et al. 2000; Meade and Woolhiser 2002; Hufnagl et al. 2003), **bee venom allergen** (Von Garnier et al. 2000), and **cat allergen** (Briner et al. 1993; Treter and Luqman 2000).

Wegmann et al. (2005) studied involvement of distal airways in a chronic model of experimental asthma.

PROCEDURE

Animals

Pathogen-free female BALB/c mice (Harlan Winkelmann, Hannover, Germany), weighing 18–22 g and 6–8 weeks of age, were used in all experiments. The animals were maintained under standard housing conditions, fed an ovalbumin- (OVA-) free diet and supplied with food and water ad libitum.

Sensitization Protocol

Mice were sensitized to OVA by three intraperitoneal injections [10 µg OVA grade VI (Sigma, Deisenhofen, Germany) adsorbed to 1.5 mg $Al(OH)_3$ diluted in 200 µl phosphate-buffered saline (PBS)] on days 1, 14, and 21. The mice were challenged with OVA (grade V) aerosol (1% wt/vol in PBS) via the airways twice a week on two consecutive days over a period of 12 weeks (Renz et al. 1992). Sham sensitization and challenges were carried out with sterile $Al(OH)_3$ in PBS. Animals were analyzed after 1 or 12 weeks of OVA aerosol challenge. To investigate persistence of airway inflammation and lung physiological changes mice were analyzed after 6 weeks of OVA aerosol challenge discontinuation following 12 weeks of OVA aerosol challenge.

Differential Cell Counts in Broncho-Alveolar Lavage Fluid

At 48 h after the last allergen challenge broncho-alveolar lavage (BAL) was performed and analyzed (Renz et al. 1992).

Measurement of Cytokines in BAL Fluid

IL-4, IL-5 and tumor necrosis factor alpha (TNF-α) were measured in cell-free lavage fluids by cytometric bead array (CBA, BD Biosciences, San Diego, Calif., USA). The detection limit for each of the cytokines was 10 pg/ml. Complete BAL transforming growth factor beta (TGF-β) was measured after acidic activation using chicken anti-human TGF-β in a standard ELISA protocol. The detection limit for TGF-β was 20 pg/ml.

Lung Histology

Lungs were fixed *ex situ* with 4% (wt/vol) paraformaldehyde via the trachea, removed and stored in 4% paraformaldehyde. Lung tissues were embedded into paraffin, and 3 µm sections were stained with haematoxylin and eosin or periodic acid-Schiff staining. For localization of collagen fibrils, Sirius red staining was performed according to Uhal et al. (1998).

Immunohistochemistry

Indirect immunohistochemistry was used to stain lung sections for smooth muscle cells and myofibroblasts (mouse monoclonal IgG against α-SMA, clone 1A4, Immunotech, Marseilles, France), and nerve cells

(polyclonal rabbit antiserum against protein gene product 9.5, Biogenesis, Poole, UK) according to Fehrenbach et al. (2002). To distinguish smooth muscle cells from myofibroblasts a rat monoclonal IgG against fibroblast-specific peptide (clone ER-TR7; Biogenesis) was utilized.

Quantitative Morphology

Paraffin sections stained with Fast Green/Sirius Red and for α-SMA, respectively, were used to quantify changes in airway epithelial cell, collagen and smooth muscle cell layers of distal airways according to standard stereological methods. A distal airway was defined as the segment of a terminal bronchiolus that, starting at the broncho-alveolar duct transition, extended up to five alveoli along the proximal direction. Using a PC-based Olympus light microscope BX 51 equipped with a CAST-Grid System (Visiopharm, Hoersholm, Denmark), all distal airways of a given section were delineated (at a magnification of $\times 426$), and the fields of view to be analyzed (at a final magnification of $\times 1.700$) were automatically defined according to systematic uniform random sampling. The arithmetic mean thicknesses were determined as the volume of the respective component, determined by counting all points hitting airway epithelium, Sirius Red- and α-SMA-positive components, respectively. Results were referred to the reference surface determined by counting all intersections with the airway epithelial basal membrane (Reader et al. 2003). The arithmetic mean thicknesses were calculated.

Electron Microscopy and Definition of Proximal and Distal Airways

For analysis of airway wall ultrastructure, lungs of mice chronically challenged with OVA and control mice challenged with PBS ($n = 3$ per group) were fixed by instillation of 4% (wt/vol) paraformaldehyde via the trachea. Beginning at the lobar bronchus, the airways were microdissected along the axial pathway according to Plopper et al. (2001). For histopathological and ultrastructural analysis, proximal airways were defined as the lobar bronchi and the axial pathway down to the fourth intrapulmonary branch point. Mid-level airways were defined as the axial pathways between the intrapulmonary branch points 6–12. Terminal bronchioles with direct connection to the alveolar ducts were defined as distal airways (Postlethwait et al. 2000).

Non-invasive Measurement of Mid-Expiratory Airflow at Baseline and of Bronchial Responsiveness to Methacholine

The mid-expiratory airflow (EF_{50}) was measured 24 h after the last OVA aerosol challenge using head-out body plethysmography (Glaab et al. 2001).

EVALUATION

Results are presented as mean values $\pm$SD unless stated otherwise. One-way ANOVA test or Student's unpaired *t*-test was used to determine the significance of differences between animal groups.

D.2.2.9 Bleomycin-Induced Pulmonary Fibrosis

PURPOSE AND RATIONALE

Pulmonary fibrosis has been induced by bleomycin in various species: golden Syrian **hamsters** (Giri et al. 1986; Chen et al. 1997; Gurujeyalakshmi et al. 1999; Iyer et al. 1999, 2000), **mice** (Taooka et al. 1997; Tamagawa et al. 2000; Keerthisingam et al. 2001; Terasaki et al. 2000; Terasaki 2001; Atzori et al. 2004) and **rats** (Howell et al. 2001; Simler et al. 2002; Wang et al. 2002; Morcillo and Bulbena 2003).

Iyer et al. (1999) determined the effects of pirfenidone on procollagen gene expression at the transcription level in a bleomycin **hamster** model of lung fibrosis.

PROCEDURE

Treatment of Animals

Male golden Syrian hamsters weighing 90–110 g were housed in groups of four in facilities with filtered air and constant temperature and humidity. A 12-h/12-h light/dark cycle was maintained, and the animals had access to water and either pulverized Rodent Laboratory Chow 5001 or the same pulverized chow containing pirfenidone (0.5% w/w). The hamsters were fed these diets 2 days before intratracheal instillation and throughout the study period. Hamsters were instilled intratracheally with saline or bleomycin (7.5 units/kg per 5 ml). The animals were sacrificed at 3, 7, 10, 14, and 21 days after the bleomycin or saline instillation by decapitation, and their lungs were removed and freeze-clamped, dropped in liquid nitrogen, and stored at –80°C. The major portion of the sample was used for direct total RNA isolation, and the remainder was used for other biochemical studies.

Tissue Processing for Biochemical Study

The frozen lungs were thawed and homogenized in 0.1 M KCl/0.02 M Tris·HCl buffer, pH 7.6, with a Polytron homogenizer. After recording the total homogenate volume (5–6 ml), it was mixed, divided into aliquots, and stored at –80°C, except for the aliquots for lipid peroxidation and hydroxyproline assays, which were processed and assayed the same day on which the lungs were homogenized.

Determination of Lipid Peroxidation

The lung malondialdehyde equivalent (MDAE) level, an index of lipid peroxidation, was determined in the whole homogenate according to the method of Ohkawa et al. (1979)

Determination of Prolyl Hydroxylase Activity

The method for prolyl hydroxylase assay is based on the release of tritiated water from 3,4-[^{3}H]proline-labeled unhydroxylated procollagen substrate prepared *in vitro* using 10-day-old embryonic chick tibiae (Giri et al. 1983). During the reaction, tritium is released in stoichiometric proportion to prolyl hydroxylation as tritiated water, which is collected and counted as a measure of the prolyl hydroxylase activity (Hutton et al. 1966). The activity was expressed as the total dpm released/lung per 30 min.

Determination of Prolyl Hydroxylase Activity In Vitro

Control hamsters not subjected to any treatment were first anesthetized with sodium pentobarbital (80–100 mg/kg). Their lungs were perfused with ice-cold isotonic saline; then, all lung lobes were dissected out and rinsed in saline. They were immediately homogenized in buffer containing 0.1 M Tris and 0.05% Triton X. The homogenate was spun down at 6000 g for 20 min at 4°C. The supernatant was gently aspirated and used to determine prolyl hydroxylase activity and its protein content. The procedure to measure the prolyl hydroxylase activity was essentially the same as described above. Briefly, the reaction mixture in a total volume of 2.2 ml consisted of 200 µl of α-ketoglutarate (0.001 M), 200 µl of ferrous ammonium sulfate (0.005 M), 250 µl of supernatant as enzyme source, 200 µl of pirfenidone to produce the desired final concentration, 200 µl of Tris·HCl (1 M), and 20 µl of ^{3}H-unhydroxylated PC substrate (400,000 cpm). The reaction mixture was first preincubated with pirfenidone at different concentrations for 30 min at 37°C in a shaking water bath. The reaction was started by adding 200 µl of ascorbic acid (0.005 M); 30 min later, the reaction was terminated by adding 200 µl of 50% trichloroacetic acid. The tritiated water released was collected by vacuum distillation. Then 1 ml of the tritiated water was mixed with 10 ml of Ready Safe liquid scintillation cocktail (Beckman), and the radioactivity was determined at 45% counting efficiency in a scintillation counter. The protein content of the supernatant was determined according to the method of Lowry et al. (1951). The prolyl hydroxylase activity was expressed as total dpm associated with tritiated water released in the reaction mixture/mg protein per 30 min.

Determination of Hydroxyproline

For assay of lung hydroxyproline as a measure of collagen content, 1 ml of whole homogenate was precipitated with 0.25 ml of ice-cold 50% (w/v) trichloroacetic acid and centrifuged, and the precipitate was hydrolyzed in 2 ml of 6 N HCl for 18 h at 110°C. The hydroxyproline content was measured according to the method of Woessner (1961).

EVALUATION

All data are expressed as mean ± SEM. Bleomycin treatment increases the amount of proteins of extrapulmonary origin that can result in the artificial lowering of all values (Karlinski and Goldstein 1980; Goldstein and Fine 1986). Thus, the *in vivo* data are expressed on a per-lung basis. The data were compared within the groups at the corresponding times using the two-way

ANOVA where four groups were involved, and the *t* test between the two groups. A value of $P \leq 0.05$ was considered to be the minimum level of statistical significance.

MODIFICATIONS OF THE METHOD

Howell et al. (2001) induced pulmonary fibrosis in **rats**. Male Lewis rats, aged 6 weeks and weighing 140–170 g, were anesthetized by intramuscular injection of 0.75–1.0 ml/kg Hypnorm (fentanyl citrate, 0.315 mg/ml, and fluanisone, 10 mg/ml). Bleomycin sulfate was administered by a single intratracheal injection (l.5 mg/kg body weight in 0.3 ml of sterile saline). Control animals received 0.3 ml of saline alone. In initial experiments, groups of six rats were killed by pentobarbitone overdose after 6 days to allow assessment of thrombin levels in broncho-alveolar lavage fluid. Separate groups of two rats were sacrificed 1, 3, 6, and 14 days after bleomycin instillation for immunohistochemical assessment of thrombin and protease-activated receptor1. Lungs were fixed by intratracheal instillation of 4% paraformaldehyde, the trachea ligated, and the inflated lungs and heart removed *en bloc*. Tissues were fixed and transferred to 15% sucrose in phosphate-buffered saline, before alcohol dehydration and embedding in paraffin wax. An additional series of animals was killed 6 days after bleomycin or saline instillation for measurement of blood coagulation parameters, total and differential cell counts in broncho-alveolar lavage fluid, and for Northern blot analysis of lung tissue connective tissue growth factor and α_1(I) procollagen mRNA levels. For measurement of coagulation parameters, blood was collected from the inferior vena cava of animals after laparotomy, and was immediately mixed 10:1 with a solution of 3.8% trisodium citrate (w/v). For measurement of total lung collagen and connective tissue growth factor and procollagen mRNA levels, the vasculature was perfused with 5 ml of sterile saline containing 100 U/ml heparin. The lungs were removed, weighed, and immediately snap-frozen in liquid N_2 after removing the trachea and major airways.

Adachi et al. (2003) and Azoulay et al. (2003) studied the effects of granulocyte colony-stimulating factor (G-CSF) on lung injury induced by various doses of bleomycin in rats.

Sogu et al. (2004) found that endosteine, an antioxidant, prevents bleomycin-induced pulmonary fibrosis in rats.

Chen et al. (2006) reported that short courses of low-dose dexamethasone delay bleomycin-induced lung fibrosis in rats.

Chaudhary et al. (2006) described the time course of inflammation and fibrosis in the rat bleomycin model and studied the effect of timing of anti-inflammatory and antifibrotic treatments on efficacy.

Barrio et al. (2006) studied *in vitro* tracheal hyperresponsiveness to muscarinic receptor stimulation by carbachol in the rat model of bleomycin-induced pulmonary fibrosis.

Terasaki et al. (2000) and Terasaki (2001) studied the effect of epimorphin in bleomycin-induced pulmonary fibrosis in **mice**. Pulmonary fibrosis was induced in 8-week-old male ICR mice by a single intratracheal instillation of bleomycin. On selected days after injection (days 0, 3, 7, 14, 21, 28, 35, 42, and 56), the lungs were harvested and investigated. Immunohistochemical analysis was performed for epimorphin using light microscopy and confocal microscopy and also the analysis by immunoelectron microscopy and *in situ* hybridization.

Avivi-Green et al. (2006) reported that discoidin domain receptor 1-deficient mice are resistant to bleomycin-induced lung fibrosis. Matsuyama et al. (2006) found that suppression of discoidin domain receptor 1 by RNA interference attenuates lung inflammation induced by intratracheal instillation of bleomycin in mice.

Inayama et al. (2006) reported that a Iκ B kinase-β inhibitor ameliorates bleomycin-induced pulmonary fibrosis in mice.

D.2.2.10 Influence of Cytokines on Lung Fibrosis

PURPOSE AND RATIONALE

Several cytokines (Murphy et al. 2000) are involved in development of pulmonary fibrosis, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), tumor necrosis factor alpha (TNFα), and transforming growth factor beta (TGFβ) (Kelly et al. 2003; Agostini and Gurrieri 2006).

GM-CSF is involved in fibrotic reactions of the lung (Xing et al. 1996; Adachi et al. 2002, 2003).

TGFβ is a central modulator of pulmonary and airway inflammation and fibrosis (Sime et al. 1997; Kolb et al. 2002; Gauldie et al. 2003; Xu et al. 2003; Yao et al. 2004; Hardie et al. 2006; Lee et al. 2006; Sheppard 2006).

Smad proteins are involved in the TGFβ-mediated pulmonary fibrosis (Zhao et al. 2000; Bonniaud et al. 2004, 2005; Kobayashi et al. 2006).

TNFα induces TGFβ (Sime et al. 1998; Warshamana et al. 2001; Sullivan et al. 2005).

Xing et al. (1996) reported that the **transfer of** GM-CSF **gene** to rat lung induces eosinophilia, monocytosis, and fibrotic reactions.

PROCEDURE

Construction of Recombinant Adenovirus Vectors

An 800-bp fragment of murine GM-CSF cDNA was isolated from pCDSRα by digestion with *Bam*HI and *Dra*I. The shuttle plasmid pACCMV contain-

ing 0 to 17 mu human type 5 adenovirus genome with a CMV promoter (760 bp), multicloning sites and SV40 splicing junction/polyA signal (430 bp) inserted in the E1 region of viral genome was first digested with *Sal*I, and the ends were repaired using T4 kinase and dNTPs (New England Biolabs, Beverly, Mass., USA), followed by a secondary digestion with *Bam*HI to generate the 3′ complimentary ends. The GM-CSF fragment was then subcloned into the *Bam*HI/*Sal*I site in PACCMV using T4 ligase (New England Biolabs) to generate the recombinant plasmid PACCMVmGM-CSF. The presence of the GM-CSF insert was confirmed by restriction digestions. The PACCMVmGM-CSF was co-transfected, following a standard procedure described previously (Graham and Prevec 1991), into 293 cells along with a plasmid pAdBHG10 which contained the most rightward sequences (3.7 to 100 mu) of human type 5 adenovirus genome with a partial deletion in the E3 region (Bett et al. 1994). The recombinant replication-deficient adenovirus Ad5E1PACCMVmGM-CSF (Ad5E1GM-CSF) was rescued by homologous recombination. The presence of GM-CSF cDNA in the viral genome was verified by analyzing viral genome fragments upon *Hind*III digestion and by Southern hybridization (Graham and Perec 1991). The control virus Ad5dl70–3 was constructed and characterized as previously described (Bett et al. 1994), and, similar to Ad5E1GM-CSF, this virus had the E1 region crippled, hence incapable of replication.

High titers of the above viruses were generated (Graham and Prevec 1991). Briefly, viruses purified by two rounds of CsCl gradient centrifugation were subjected to chromatography using PD-10 Sephadex columns (Pharmacia Biotech, Baie d'UrFe,Quebec, Canada) to remove CsCl. The virus fractions were collected in PBS containing 10% glycerol, measured for conductance to ensure complete removal of CsCl, pooled, titered, aliquoted and stored at –70°C until use.

Characterization of Recombinant Adenovirus Vector Expressing GM-CSF In Vitro

GM-CSF transgene mRNA was examined by Northern hybridization analysis (Xing et al. 1993) using total RNA from 293 cells infected with 10 plaque-forming units (pfu)/cell of Ad5E1GM-CSF for 24 and 48 h. The supernatants from these cells and from infected rat alveolar macrophages were assayed for GM-CSF using an ELISA kit (Endogene, Cambridge, Mass., USA). This ELISA was specific for mouse GM-CSF without crossreactivity with rat GM-CSF, with a sensitivity of 4 pg/ml.

Delivery of Recombinant Adenovirus Vectors to the Lung

Following a standard procedure (Xing et al. 1994), 300 µl of Ad5E1GM-CSF or control virus Ad5dl70–3 diluted in PBS to a concentration of 1×10^9 pfu was instilled intratracheally to the lung of Sprague Dawley male rats weighing 220–280 g (Charles River Laboratories, Ottawa, Canada). At the end of 1, 2, 4, 7, 12, 18, and 24 days after gene transfer, rats were anesthetized, blood samples were taken from the abdominal aorta, and serum preparation and bronchoalveolar lavage (BAL) were performed.

Transgene and Transgene Protein Expression in the Lung

The left lung of rats obtained at each time point was snap-frozen in liquid nitrogen. Total lung RNA extraction and Northern hybridization were performed. Reverse transcription-polymerase chain reaction (RT-PCR) was performed to examine transgene mRNA expression with total lung RNA using PCR reagents from Promega (Madison, Wis., USA) following the standard protocol. The specific primers for PCR were chosen to ensure the amplification of the transgene-specific GM-CSF mRNA but not the endogenous rat GM-CSF mRNA (Miyatake et al. 1985; Smith et al. 1994). The sense and anti-sense primer sequences were 5′-GTCTCTAACGAGTTCTCCTTCAAG-3′ and 5′-TTCAGAGGGCTATACTGCCTTCCA-3′, respectively. The primers for rat GAPDH were designed as described by Rosenfeld et al. (1992). BAL samples were collected at various times and assayed for transgene protein GM-CSF by ELISA as described above or for TNFα by ELISA specific for both murine and rat TNFα (Genzyme, Cambridge, Mass., USA). Serum samples collected from the same animals were also assayed for circulating levels of GM-CSF by ELISA.

Cytologic Examination of BAL and Blood Samples

Total cell numbers in BAL were determined using a hematocytometer. Differential cell types were determined on cytospins stained with Diff-Quik (Baxter, McGaw Park, Ill., USA) by randomly counting 300–400 cells/cytospin. To analyze the total peripheral blood leukocyte counts and differentials, blood samples were collected into heparin-coated tubes. Total leukocyte numbers were counted on a hematocytometer after lysing red blood cells with a lysis buffer containing 94% H_2O, 3% acetic acid, and 3% Diff-Quik purple stain. Differential leukocytes were determined on blood smears stained with Diff-Quik by counting 500–700 cells/blood smear.

Histopathologic Examination of Lung and other Tissues

The right lung and in some instances the whole lung of each animal were fixed by perfusion with 10% formalin (Fisher Scientific, Fairlawn, N.J., USA). Tissues from heart, liver, spleen, and kidney were also fixed in 10% formalin. Multiple sections from different lobes of the lung or from other organs were stained with hematoxylin/eosin for routine histopathology, with Congo Red for identification of tissue eosinophils, or with Elastic van Gieson for collagen and elastin.

MODIFICATIONS OF THE METHOD

Underwood et al. (2000) demonstrated in guinea pigs and rats that a p38 MAPK inhibitor reduces neutrophilia, inflammatory cytokines, MMP-9, and fibrosis in lung.

Kolb et al. (2001) reported that the proteoglycans decorin and biglycan differentially modulate TGF-β-mediated fibrotic responses in the lung of mice.

Uhal et al. (2003) showed that in rats amiodarone induced lung fibrosis and alveolitis, which could be partially inhibited by angiotensin system antagonists.

Jiang et al. (2004) described regulation of pulmonary fibrosis by the chemokine receptor CXCR3, which is the receptor for the interferon-γ-inducible C-X-C chemokines MIG/CXCL9, IP-10/CXCL10, and I-TAC/CXCL11.

Kim et al. (2006) tested the alveolar epithelial-to-mesenchymal cell transition, which develops *in vivo* during pulmonary fibrosis, and found regulation by the extracellular matrix.

Shi-Wen et al. (2006) found that constitutive ALK5-independent c-Jun N-terminal kinase activation contributes to endothelin-1 overexpression in pulmonary fibrosis and gave evidence of an autocrine endothelin loop operating through the endothelin A and B receptors.

D.2.2.11 Emphysema Models

PURPOSE AND RATIONALE

Several animal models of genetically determined emphysema are known, such as the **tight-skin mouse** (Rossi et al. 1984; Martorana et al. 1989; Gayraud et al. 2000), beige mutants of the C57BL6J strain (O'Donnell et al. 1999; Lucattelli et al. 2003), the **blotchy mouse** (Ranga and Kleinerman 1981; McCartney et al. 1988), and **homozygous mutant *klotho*** (***KL***$^{--}$) **mice** (Suga et al. 2000).

Hoyle et al. (1999) described emphysematous lesions, inflammation, and fibrosis in the lungs of transgenic mice overexpressing platelet-derived growth factor. Le Cras et al. (2004) reported that vascular endothelial growth factor causes pulmonary hemorrhage, hemosiderosis, and air space enlargement in neonatal mice. Tsa et al. (2004) reported that overexpression of placenta growth factor contributes to the pathogenesis of pulmonary emphysema in mice.

Blanco et al. (1989), Whitney et al. (1999), Massaro et al. (1995), Massaro and Massaro (2000, 2003), and Dirami et al. (2004) reported that in **rats** septation of gas-exchange saccules occurs during the first two postnatal weeks. Treatment with dexamethasone irreversibly impairs septation. Treatment with all-*trans*-retinoid acid prevents the dexamethasone-induced inhibition of septation.

Hind and Maden (2004) and Maden and Hind (2004) found that retinoic acid induces alveolar regeneration in the adult mouse lung after damage by disulphiram treatment. These data could not be confirmed in an elastase-induced emphysema model by Fujita et al. (2004).

Several authors used elastase instillation to produce emphysema-like lesions in **rats** (Tepper et al. 2000; March et al. 2004), **mice** (Inoue et al. 2003; Murakami et al. 2005), **rabbits** (Qi et al. 2004), and **dogs** (Morino et al. 2005).

Kuraki et al. (2002) described inhibition of human neutrophil elastase-induced emphysema in rats by an oral neutrophil elastase inhibitor.

PROCEDURE

Rat Emphysema Model

Male Wistar rats weighing 228± 15 g were divided into controls (saline treated), low-dose group (treated with 200 U human neutrophil elastase), and a high-

dose group (treated with 400 U human neutrophil elastase). Human neutrophil elastase was sprayed above the carina of the trachea using a microsprayer without tracheotomy. Eight weeks after human neutrophil elastase application, rats were sacrificed and lungs were dissected out to evaluate the morphologic changes.

Effects of Neutrophil Elastase Inhibitor

Rats were divides into four groups: saline control, human neutrophil elastase + CMC, human neutrophil elastase + low dose of inhibitor, and human neutrophil elastase + high dose of inhibitor given orally. Six hours after human neutrophil elastase, lung hemorrhage and neutrophil accumulation in the lung were determined. Eight weeks after the application, the functional and morphologic changes were determined.

Lung Hemorrhage and Neutrophil Accumulation in the Lung

After tracheostomy, broncho-alveolar lavage was performed for determination of neutrophil counts and hemoglobin in lavage fluid. In addition, neutrophil accumulation was estimated using the myeloperoxidase activity.

Lung Volume and Pulmonary Mechanics

Eight weeks after human neutrophil elastase application, rats were anesthetized and tracheotomy was performed. Using a whole-body plethysmograph for small animals, the functional residual capacity (FRC), total lung capacity and static lung compliance were determined.

EVALUATION

Data were presented as mean ± SD. Differences between groups were evaluated for statistical significance using one-way analysis of variance.

MODIFICATIONS OF THE METHOD

Boström et al. (1996) showed that platelet-derived growth factor A signaling is a critical event in lung alveolar myofibroblast development and alveogenesis.

Kirschvink et al. (2005) induced production of pulmonary MMP-2 and MMP-9 and emphysema by repeated cadmium nebulizations in rats.

Corteling et al. (2002) studied the migration and activation of neutrophils into the airway in pathological conditions such as pulmonary emphysema in BALB/c and C57BL/6 **mice** and in **golden hamsters**. The animals were sequentially treated intranasally with 0.3 mg/kg lipopolysaccharide and with 0.5 mg/kg *N*-formyl-Met-Leu-Phe.

Selman et al. (2003) induced emphysema in **guinea pigs** by exposure to the whole smoke of 20 cigarettes per day, 5 days per week, for 1 month, 2 months, and 4 months through a whole-body exposure chamber. Half of the animals received a matrix metalloproteinase inhibitor. After death, the lungs were lavaged with saline solution, and matrix metalloproteinases in the lavage fluid were determined by zymography and immunoblot. Lungs were fixed for histology, immunochemistry, and morphometry.

Lucattelli et al. (2003) described collagen phagocytosis by lung alveolar macrophages in animal models of emphysema.

D.2.2.12 Models of Chronic Obstructive Pulmonary Disease (COPD)

PURPOSE AND RATIONALE

Chronic obstructive pulmonary disease (COPD) is a severe respiratory condition that is increasing in prevalence worldwide. The disease is characterized by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and associated with abnormal inflammatory response of the lungs to noxious particles and gases. Three conditions comprise COPD, namely mucus hypersecretion, emphysema and bronchiolitis. Cigarette smoking is the major risk factor for development of COPD and accounts for the majority of cases (Donnelly and Rogers 2003). The relevance of the present animal models for COPD has been questioned (Canning 2003). Several authors used chronic cigarette-smoke exposure in mice (Hautamaki et al. 1997; Cavarra et al. 2001a, 2001b; Wright and Churg 2002; Bartalesi et al. 2005; Martorana et al. 2005), in rats (Escolar et al. 1995; Lee et al. 2005), in guinea pigs (Wright 2001; Meshi et al. 2002), or in dogs (Frasca et al. 1983).

Lee et al. (2005) reported inhibition of cigarette-smoking-induced emphysema and pulmonary hypertension in rat lungs by a HMG-CoA reductase inhibitor.

Martorana et al. (2005) found that a selective phosphodiesterase-4 (PDE4) inhibitor fully prevents emphysema in mice chronically exposed to cigarette smoke.

PROCEDURE

Six-week-old C57Bl/6J male mice were, in acute studies, exposed either to room air or the smoke of five cigarettes (Virginia filter cigarettes: 12 mg of tar and 0.9 mg of nicotine) for 20 min. In chronic studies, the mice were exposed to either room air or to the smoke of three cigarettes/day for 5 days/week for 7 months. Antioxidant capacity was assessed at the end of exposure in broncho-alveolar lavage fluid. Cytokines and chemokines were determined.

In acute studies, mice were divided in three groups of 40 animals each. These groups were then divided

into four subgroups of 10 mice: no treatment/air exposed; no treatment/smoke exposed; low dose of test compound/smoke exposed; high dose of test compound/smoke exposed.

In chronic studies, five groups of animals were used: no treatment/air exposed; drug treatment/air exposed; no treatment/smoke exposed; low dose of test compound/smoke exposed; high dose of test compound/smoke exposed. After 7 months, animals were sacrificed and the lungs fixed intratracheally with 5% formalin at a pressure of 20 cmH_2O. Lung volume was measured by water displacement. Assessment of emphysema included mean linear intercept and internal surface area. The volume density of macrophages, marked immunohistochemically with antimouse Mac-3 monoclonal antibodies, was determined by point counting.

EVALUATION

The significance of the differences was calculated using one-way analysis of variance.

MODIFICATIONS OF THE METHOD

Kumar et al. (2003) compared a selective PDE4 inhibitor with pentoxifylline (a non-selective phosphodiesterase inhibitor) and dexamethasone in ameliorating the lesions of chronic asthma in BALB/c mice sensitized to ovalbumin and chronically challenged with aerosolized antigen for 6 weeks.

Kodavanti et al. (2000) reported that the combination of elastase and sulfur dioxide exposure causes COPD-like lesions in the rat.

The potential of tachykinin receptor antagonists in airways diseases was discussed by Joos and Pauwels (2001).

Sturton and Fitzgerald (2002) reviewed PDE4 inhibitors for the treatment of COPD.

Billah et al. (2002) described the pharmacology of an orally active PDE4 inhibitor.

Pitfalls and opportunities for modeling allergic asthma in mice were discussed by Kumar and Foster (2002).

Inoue et al. (2003) described an impaired pulmonary inflammation response as a prominent feature of streptococcal pneumonia in mice with experimental emphysema.

Dual dopamine D_2 receptor and β_2-adrenoreceptor agonists were proposed for the treatment of COPD (Dougall et al. 2003; Ind et al. 2003).

Lessons from transgenic mice for the relationship between asthma and COPD were discussed by Elias (2004).

Lappalainen et al. (2005) found that interleukin-1β causes pulmonary inflammation, emphysema, and airway remodeling in the adult murine lung.

Romano (2005) discussed selectin antagonists for their therapeutic potential against asthma and COPD.

Jones et al. (2002) described a model for the continuous monitoring of polymorphonuclear leukocyte trapping in the pulmonary vasculature of the **rabbit**.

D.3 Antitussive Activity

D.3.0.1 Antitussive Activity After Irritant Inhalation in Guinea Pigs

PURPOSE AND RATIONALE

Cough is thought to be caused by a reflex. The sensitive receptors are located in the bronchial tree, particularly in the bifurcation of the trachea. These receptors can be stimulated mechanically or chemically, e. g., by inhalation of various irritants. Nerve impulses then activate the cough center in the brain. Several animals species and several irritants have been used, most frequently the citric acid induced cough in guinea pigs (Charlier et al. 1961; Karlsson et al. 1989 Braga et al. 1993). The pharmacology of cough was reviewed by Reynolds et al. (2004).

PROCEDURE

Guinea pigs of either sex weighing 300–400 g are used. The animal is placed in a cylindrical glass vessel, with 2 tubes at either ends. One serves as the entrance of the aerosol, the other for its efflux. The latter tube has a side-arm connecting to a tambour, from which changes in pressure can be registered. A pinch-clamp with a variable screw is placed on the efflux tube beyond the side arm, permitting the regulation of the sensitivity of the system, so that the normal respiration is not registered, while the displacement of air in the enclosure caused by coughing of the animal is registered. The guinea pig is exposed to the aerosol of 7.5% citric acid in water for 10 min. Each animal is tested first to obtain the control response. The number of tussive responses is registered. One hour later, the test substance is applied either s.c. or orally, and 30 min later the guinea pig is subjected to the aerosol again. The number of coughs during 10 min is recorded.

EVALUATION

The number of coughs after treatment is expressed as percentage of the control period. Using various doses, ED_{50} values can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

The citric acid induced coughing in guinea pigs has been proven to be an effective method to test antitussive agents.

MODIFICATIONS OF THE METHOD

The citric cough model in guinea pigs was used by Adcock et al. (1988) to study the effects of codeine, morhine and an opioid pentapeptide, by Hay et al. (2000) to study a potent and selective neurokinin-3 receptor antagonist, and by Brown et al. (2004) to study antitussive activity of sigma-1 receptor agonists.

Cough elicited by capsaicin inhalation in guinea pigs was used by Bolser et al. (1993, 1997) to study antitussive effects of $GABA_B$ agonists or NK1 and NK2 tachykinin receptor antagonists, by McLeod et al. (1998) to study the antitussive action of antihistamines, and by Trevisani et al. (2004) to investigate the activity of iodo-resiniferatoxin, an ultra potent antagonist of the transient receptor potential vanilloid-1.

Forsberg et al. (1988) studied cough and bronchoconstriction mediated by aerosols of capsaicin or citric acid or nicotine or histamine in guinea pigs.

Püschmann and Engelhorn (1978) studied the inhibition of the coughing reflex induced by inhalation of a citric acid spray in ***rats***.

Other irritants have been used to induce cough, e. g. ammonia in dogs, guinea pigs, and cats (Rosiere et al. 1956; Källqvist and Melander 1957; Chen et al. 1960; Sallé and Brunaud 1960; Ellis et al. 1963), or nebulized sulfuric acid or sulfur dioxide in guinea pigs, rats, cats or dogs (Eichler and Smiatek 1940; May and Widdicombe 1954; Winter and Flakater 1952, 1954; Friebel et al. 1955; Reichle and Friebel 1955; Wiedemeijer et al. 1960; Chermat et al. 1966; Karttunen et al. 1982). Capsaicin aerosol was used by Forsberg and Karlsson (1986), Gallico et al. (1997).

Winter and Flakater (1955) exposed sensitized guinea pigs to aerosol of a specific antigen.

Kamei et al. (1989) induced cough in rats by a nebulized solution of capsaicin. The cough reflex was measured as airflow into or out of the chamber of a body plethysmograph by a pneumotachometer head.

Carotis sinus excitation in dogs induced by injection of lobeline resulting in coughing could be suppressed by codeine (Gross 1957).

Sanzari et al. (1968) induced cough in cats anesthetized with α-chloralose by intravenous injection of 1,1-dimethyl-4-phenylpiperazinium iodide (DMPP), a ganglionic stimulant which is more potent than lobeline and possesses only marginal ganglionic blocking properties. The number of coughs was found to be a linear function of the dose of the irritant. Coughs were recorded as spikes superimposed on the respiratory pattern. The method is suitable for quantitative evaluation of antitussive activity.

D.3.0.2 Cough Induced by Mechanical Stimulation

PURPOSE AND RATIONALE

Cough can be induced by mechanical stimulation of the trachea in anesthetized guinea pigs (Takagi et al. 1960; Gallico et al. 1994).

PROCEDURE

Male guinea pigs weighing 350–400 g are maintained in conditioned quarters (temperature 21 ± 2°C, relative humidity 55 ±10%, 12 h on-12 h off light cycle) with food and water ad libitum for at least 1 week before use.

After overnight fasting with water ad libitum, the guinea pigs are lightly anesthetized with 25% urethane (4 ml/kg i.p.) which induces surgical levels of analgesia without depressant effects on respiratory function. Analgesia is monitored throughout the experiment as the disappearance of head shaking in response to ear pinch. The animals are maintained at a constant body temperature of 37°C by means of a heated plate. A thin steel wire is gently inserted into the trachea through a small incision near the cricoid cartilage. Coughs are evoked by pushing the steel wire to reach the bifurcation of the trachea 35 and 5 min before oral drug administration and 30, 60 and 120 min after treatment. One violent cough occurs upon each stimulation. Only those animals that respond to both mechanical stimulations before dosing are selected and then randomly assigned to receive the test drug at various doses or the standard (codeine 15, 30 and 60 mg/kg). Ten animals per dose are used.

EVALUATION

Evaluation of the statistical significance of the results is performed with Student's *t*-test for paired data. ED_{50} values are determined by logit transformation.

MODIFICATIONS OF THE METHOD

Several other ways of mechanical stimulation have been used, e. g., by a nylon-bristled stimulator thrust into the trachea in **dogs** (Kasé 1952, 1954), or by a silver thread in **decerebrated guinea pigs** (Lemeignan et al. 1966), or by vibration of an iron slung in the trachea of a dog induced by an electromagnet (Tedeschi et al. 1959) or electrical stimulation of the trachea via a bronchoscope (Gross et al. (1958) or through implanted copper electrodes (Stefko and Benson 1953; Benson et al. 1953; Granier-Doyeux et al. 1959; Stefko et al. 1961).

Hara and Yanaura (1959), Yanaura et al. (1974, 1982) induced cough in unrestrained animals after implantation of electrodes in the trachea.

Combined mechanical and chemical stimulation has been applied by Kroepfli (1950).

Bolser et al. (1999, 2001) and McLeod et al. (2002) studied the influence of antitussive drugs on the cough motor pattern in anesthetized cats. Coughing was produced by mechanical stimulation of the intrathoracic trachea with a thin flexible polyethylene cannula for 10 s per stimulus trial. During each trial, the cannula was repetitively moved in the trachea at a frequency of ~ 2 Hz. EMGs from the diaphragm and rectus abdominis muscles were recorded with the use of bipolar tungsten-wire electrodes. The diaphragm electrodes were placed through a small midline abdominal incision, which was subsequently closed. Cough is characterized by coordinated bursts of activity in inspiratory and expiratory muscles. Cough was defined as a large burst of EMG activity in the diaphragm that is immediately followed by a burst of EMG activity in the rectus abdominis muscle. This definition differentiates augmented breaths, the aspiration reflex, or the expiration reflex from cough. The antitussive activity of selected drugs was evaluated from cumulative dose responses after intravertebral artery administration of

each compound. The protocol consisted of the application of five consecutive mechanical stimulus trials after vehicle administration. Stimulus trials were applied at 1-min intervals after each dose of compound, for a total of five stimulus trials between doses. Approximately 7 min elapsed between each dose of compound.

Kasé et al. (1976) studied the antitussive activity of d-3-methyl-N-methylmorphinan in conscious mongrel **dogs**. Coughing was induced by mechanical stimulation with a stimulator consisting of 5 hog bristles on the mucosa of tracheal bifurcation through a chronically-built tracheal fistula and in lightly anesthetized cats with a stimulator consisting of 5 whiskers of a rabbit.

D.3.0.3 Cough Induced by Stimulation of the Nervus Laryngicus Superior

PURPOSE AND RATIONALE

The probable pathways in the cough reflex arc are receptors in the area of the trachea and the large bronchi, afferent nerves mainly in the branches of the vagus nerve, a "cough center" located in the medulla oblongata, and efferent nerves closing the glottis and reinforcing the expiratory thrust. Stimulation of the Nervus laryngicus superior induces coughing. Antitussive agents with predominantly central action suppress the coughing reflex.

PROCEDURE

Cats of either sex weighing 2–3 kg are anesthetized with 40 mg/kg i.p. pentobarbital, placed on a heated operating table and their extremities secured. Since deep anesthesia suppresses coughing the dose of pentobarbital has to be adjusted. The fur is shaved ventrally at the neck. Small incisions are made at both sides of the larynx. The superior laryngeal nerves (forming a loop) are prepared carefully. After a median skin incision, the trachea is exposed and cannulated. The cannula is connected with a Fleisch-tube (size 00). One femoral artery is cannulated for registration of blood pressure via a Statham pressure transducer. One femoral vein is cannulated for intravenous application of test substances. Small hook electrodes are attached to each laryngeal nerve. At the end of an inspiration square wave impulses with a frequency of 50 Hz, an impulse width of 0.5 ms, an amplitude of 0.2–1.0 Volt, and a duration of 1–10 s are applied every 5 min. The intensity of the forced expiration is measured by the Fleisch pneumotachograph and recorded simultaneously with blood pressure on a polygraph. Prior to the intravenous application of the test compound, the response to three stimuli is recorded serving as control. After injection of the test compound or the

standard the stimuli are repeated every 5 min. Suppression or diminution of the forced expiration is recorded over 1 h. Then, the next dose or the standard (codeine phosphate 1–2 mg/kg i.v.) is applied.

EVALUATION

Total or partial suppression of the forced expiration are recorded over time and expressed as percentage of control. Intensity and duration of the effect are compared with the standard.

CRITICAL ASSESSMENT OF THE METHOD

The method described by Domenjoz (1952) is very useful to detect centrally active antitussive agents like codeine, but by definition can not determine compounds which act on cough receptors in the bronchial area. Moreover, even light anesthesia influences the cough reflex.

MODIFICATIONS OF THE METHOD

Several other assays have been described which elicit the cough reflex by central or nerve stimulation. Toner and Macko (1952) also stimulated the superior laryngeal nerve in anesthetized cats to induce a definite cough as indicated by rapid contractions of the abdominal musculature.

Mattalana and Borison (1955), Chakravarty et al. (1956) used decerebrated cats to study the central effects of antitussive drugs on cough and respiration. Cough responses were obtained by electrical stimulation of the dorsolateral region of the medulla with bipolar needle electrodes oriented by means of a stereotactic instrument.

Lindner and Stein (1959) evaluated derivatives of diphenyl-piperidono-propan, a series of antitussive drugs using a modification of the method originally described by Domenjoz (1952).

Schröder (1951) and Bobb and Ellis (1951) elicited cough in **conscious dogs** by stimulation of the vagus nerve in a surgically prepared skin loop. In anesthetized cats, coughs were elicited by electrical stimulation of the dorsolateral region in the upper medulla (Kasé et al. 1970).

D.4
Effects on Tracheal Cells and Bronchial Mucus Secretion and Transport

D.4.0.1
In Vitro Studies of Mucus Secretion

PURPOSE AND RATIONALE

Mucus secretion has been studied in isolated tracheas from ferrets and dogs (Borson et al. 1980; Kyle et al. 1987).

PROCEDURE

Ferrets of either sex weighing 0.6 to 1.5 kg are anesthetized with sodium barbital intraperitoneally. The trachea is exposed and cannulated with a special Perspex cannula about 5 mm below the larynx. The animal is then sacrificed with an overdose of the anesthetic and the chest is opened along the midline. The trachea is exposed to the carina, cleared of adjacent tissue, removed from the animal and cannulated just above the carina. The trachea, with its laryngeal end down, is then mounted in a water-jacketed organ bath and bathed on its submucosal site with Krebs-Henseleit solution plus 0.1% glucose at 37°C and bubbled with 95% O_2 and 5% CO_2. The lumen of the trachea remains air-filled. A plastic catheter is inserted into the lower cannula to form an airtight seal into which secretions can periodically be withdrawn and collected. Volumes of secretions are estimated by the weight difference of catheter lengths with and without secretions.

Simultaneous measurements of both mucus secretion and changes in tissue volume *in vitro* are achieved by mounting portions of ferret trachea cut longitudinally along the posterior wall, flattened out and pinned to a Perspex chamber. Krebs-Henseleit solution at

37°C and gassed with 95% O_2 and 5% CO_2, is circulated on the submucosal side of the tissue, while the luminal side is exposed to the atmosphere. The surface area of the exposed tissue is about 50 mm^2. Mucus secretion is promoted by electrical field stimulation at 50–100 V, 20 Hz, 1–2 ms duration, applied through the pins holding the tissue. Before the start of each experiment, surface fluid is gently wiped off from the luminal surface with a tissue pledglet. The epithelium is coated with a layer of powdered tantalum dust; as mucus secretion from submucosal glands occurs through gland ducts, the layer of tantalum effectively traps the secreted mucus above the duct and under the tantalum layer. Nearly hemispherical hillocks are formed. The surface is photographed at intervals through a dissecting microscope and hillock diameters are measured. Assuming the hillocks to be hemispheres, the secretion volume per unit area is calculated. Drugs are added to the submucosal bath.

EVALUATION

Secretory response after electrical stimulation in the presence or absence of drugs is recorded after 45, 90, and 135 min.

MODIFICATIONS OF THE METHOD

Quinton (1979) used isolated tracheae from cats. A segment of the trachea was mounted in a chamber such that the serosal side was constantly bathed in Ringer solution, whereas the epithelial surface was coated with water-saturated paraffin oil. Secretion was stimulated by adding appropriate drug concentrations to the bath. Under a dissecting microscope, small droplets of secretory fluid were observed to form on the tracheal epithelial surface shortly after stimulation. Timed collection of droplets secreted from three to four glands were taken up between oil blocks in constant-bore capillaries (78 µm inner diameter), and droplet volumes were measured for rate determinations usually over a period of 5 min.

CRITICAL ASSESSMENT OF THE METHODS

Both modifications of the *in vitro* methods need at least as many animals and are as time consuming as the *in vivo* methods.

D.4.0.2 Acute Studies of Mucus Secretion

PURPOSE AND RATIONALE

Many diseases of the respiratory tract cause both qualitative and quantitative changes in the mucus that covers and protects the airway epithelium. To study the influence of drugs, methods of collecting bronchial mucus are necessary (Braga 1988). Perry and Boyd (1941) described a method for collecting bronchial mucus from the rabbit.

PROCEDURE

Rabbits weighing 2.5 to 3.5 kg are anesthetized by intraperitoneal injection of 1.1 to 1.4 g/kg urethane. The trachea is exposed by blunt dissection and half opened, 2 cm below the cricoid cartilage. One arm of a T cannula with a large enough diameter to slightly distend the trachea is inserted into the trachea. The perpendicular arm is connected to an air outlet of a humidifier (temperature 35–38°C, relative humidity 80%). The other arm is connected to a collection tube. The rabbit is restrained in the supine position on a 60-degree inclined board with his head downward. Respiratory tract fluids are collected in centrifuge tubes at one hour intervals. Mucus secretion can be stimulated by vagal stimulation or by ammonium chloride given by stomach tube or by pilocarpine given i.p.

EVALUATION

Time response curves after stimulants of mucus secretion are compared with data from untreated animals.

MODIFICATIONS OF THE METHOD

A method for collecting mucus from cats, using a segment of cervical trachea about 5 cm long isolated *in situ*, with nerve and blood supplies intact and a glass cannula inserted to each end, has been described by Gallagher et al. (1975).

A method to collect mucus from the upper tract trachea and the nasopharynx in dogs in acute experiments has been proposed by Proctor et al. (1973).

Engler and Szelenyi (1984) described a new method for screening mucosecretolytic compounds using tracheal phenol red secretion in **mice**. Phenol red at a dose of 500 mg/kg was injected intraperitoneally to male mice. Thirty min later, the animals were sacrificed by carbon dioxide. The whole trachea was dissected free from surrounding tissue and excised. Each trachea was washed for 30 min in 1 ml physiological saline. Afterwards, 0.1 ml 1 M NaOH was added to the washing to stabilize the pH of the lavage fluid. The concentration of phenol red was measured photometrically. Agonists were administered subcutaneously 15 min or intragastrally 30 min before phenol red was injected. Antagonists were given 5 min prior to the administration of agonists.

Other dyes, such as Evans blue or sodium fluorescein also are reported to be eliminated in the respiratory tract fluid of mice (Graziani and Cazzulani 1981).

Dye methods reported for mice can also be used for rats (Quevauviller and Vu-Ngoc-Huyen 1966). Alcian blue was used to stain the normal bronchial tree. After chronic treatment with sulfur dioxide, there were changes in bronchial coloration. Administration of drugs protected against the effects of sulfur dioxide.

Secretion from tracheal submucosal glands can be studied in **dogs** (Davis et al. 1982; Johnson and McNee 1983, 1985). In anesthetized dogs the epithelial surface of the upper trachea is exposed and coated with powdered tantalum. Secretions from the submucosal gland ducts form elevations (hillocks) in the tantalum layer. The number of hillocks that appear in a 1.2 cm^2 field is counted.

A micropipette method for obtaining secretions from single submucosal gland ducts *in vivo* in **cat** tracheas has been described (Ueki et al. 1979, 1980; Leikauf et al. 1984). In anesthetized cats an endotracheal tube was inserted into the lower trachea and connected to a constant volume respirator. The remainder of the trachea above the endotracheal tube was then dissected open by a midline incision. Paraffin oil equilibrated with HEPES buffer was then placed on the exposed mucosa to prevent drying and to aid visualization of the gland duct openings. The secretions from the gland duct openings were collected with constant-bore (99 µm ID) glass micropipettes. The volume and the viscosity of the secreted mucus were determined.

CRITICAL ASSESSMENT OF THE METHODS

For the methods of mucus collection in rabbits, cats or dogs a rather high number of animals is necessary to achieve data suitable for statistical analysis. For screening procedures the methods using dye elimination into the trachea of mice or rats seem to be preferable.

D.4.0.3 Studies of Mucus Secretion With Chronic Cannulation

PURPOSE AND RATIONALE

Several techniques have been developed for chronic collection of mucus (Wardell et al. 1970; Yankell et al. 1970; Scuri et al. 1980).

PROCEDURE

Beagle dogs weighing 9–11 kg are anesthetized by intravenous injection of 35–40 mg/kg pentobarbital sodium. The cervical trachea is exposed by a midline skin incision and blunt dissection of the muscles. A segment approximately 10 rings in length,

with an intact blood and nerve supply, is transected. The cephalic and caudal parts of the trachea are anastomosed end-to-end with interrupted gut sutures to reestablish a patent airway. The isolated segment is loosened slightly from the surrounding tissue and turned 180° to reverse cilia movement. A funnel-shaped silicone cannula is attached to the outer surface of the proximal end of the tracheal segment with surgical mesh and sutured in place. With cannulation completed, the tracheal segment is placed in a pocket below the sternohyoid muscle and the cannula brought to the surface and exteriorized through a stab wound. Alternatively, the isolated segment is closed at its caudal end with interrupted gut sutures. The mucosal surface of the cervical end of the isolated tracheal segment is sutured with interrupted silk sutures to the overlying subcutaneous tissue through a small incision in the cervical skin. Muscles and skin are sutured normally. In two or three weeks the skin heals over the small stoma resulting in a subcutaneous pouch of functioning tracheal tissue. Mucus samples can be collected for months. In this modification, a balloon can be placed into the pouch. Pressure changes in the balloon due to contraction of the smooth tracheal muscles after physostigmine injection or vagal stimulation or relaxation after atropine injection are recorded demonstrating parasympathetic innervation.

EVALUATION

Parasympathomimetic stimulation (0.5 mg/kg pilocarpine s.c.) increases the flow rate of tracheal fluids. Pressure changes in the balloon after injection of parasympathomimetic or sympathomimetic drugs are compared with baseline values.

MODIFICATIONS OF THE METHOD

Scuri et al. (1980) inserted a T-shaped cannula into the trachea of anesthetized rabbits. The wound was sutured, the third arm was connected with a collecting tube, and after 3 days of antibiotic administration, the mucus was collected at different times to establish basal production. For the experiments, mucus was collected during a 4 h control period, then drugs were given intravenously, orally or as aerosol inhalation. Mucus was further collected during the periods of 0 to 4 and 4 to 24 h and analyzed for sialic acid, fucose, and protein content.

A tracheal pouch method in ferrets has been described by Barber and Small (1974).

Several authors published methods to determine **viscoelastic properties and rheological behavior of tracheal and bronchial mucus**: Philippoff et al. (1970), Lopez-Vidriero and Das (1977), Martin et al. (1980) Kim et al. (1982), Braga (1988), King (1988), Majima et al. (1990).

CRITICAL ASSESSMENT OF THE METHODS

The methods using pouches in dogs may be useful for physiological studies, but for pharmacological purposes the rabbit method of Scuri et al. (1980) seems preferable.

D.4.0.4 Bronchoalveolar Lavage

PURPOSE AND RATIONALE

Isolation of bronchial cells from bronchoalveolar lavage was described by Myrvik et al. (1961), Bassett et al. (1988), Fryer et al. (1994, 1997), Wang et al. (1997).

PROCEDURE

After determination of mechanical respiratory parameters in anaesthetized guinea pigs, bronchoalveolar lavage is performed via the tracheal cannula. The lungs are lavaged with 5 aliquots of 10 ml phosphate-buffered saline containing 3 mM EDTA and 100 µM isoproterenol (pH 7.2–7.4). The recovered lavage fluid (40–45 ml) is centrifuged, the cells are resuspended in 20 ml of phosphate-buffered saline, and total cells are counted using a hemacytometer. The remaining aliquot is centrifuged again and cells are stained to determine cell differentials.

EVALUATION

The differences in cells recovered from bronchoalveolar lavage between treatment groups are tested by use of a one-factor analysis of variance. $P < 0.05$ is considered significant.

MODIFICATIONS OF THE METHOD

Gossart et al. (1996) determined TNF-α activity in the supernatant of bronchoalveolar lavage by the cytotoxicity against TNF-α-sensitive L929 murine fibroblasts.

D.4.0.5 Ciliary Activity

PURPOSE AND RATIONALE

Ciliary activity is a natural defense mechanism of the mucosa in the respiratory tract against harmful extraneous agents resulting in a continuous transportation of secreted mucus. Many attempts have been made to visualize and to quantify this phenomenon. Several authors used the light beam reflex method which can be used for *in vivo* as well as for *in vitro* experiments (Dalhamn 1956, 1964; Dalhamn and Rylander 1962; Hakansson and Toremalm 1963; Mercke et al. 1974; Baldetorp et al. 1976; Lopez-Vidriero et al. 1985).

PROCEDURE

Rats are anesthetized by intraperitoneal injection of tribromo-ethanol (Avertin). The trachea is exposed and its soft parts are incised by electrocoagulation so that bleeding is avoided. The cartilaginous rings are opened sufficiently to permit microscopy. The rat is immediately placed in a moist chamber. The trachea opening is linked to a microscope (Leitz Ultropak) by means of a rubber bellows which is fitted around the lens of the microscope and is made to embrace the trachea by means of a piece of rubber tubing that is slit along its length and secured to the bellows. The beam of an illuminating lamp is concentrated to a surface of about one mm^2. By placing a heat-reflecting filter in the path of the beam the rise in temperature can be reduced. For registration of the reflected light high speed cameras with a speed of 220 exposures are used. Alternatively, the reflected light from the microscope is directed to a TV camera and amplified to be displayed on a TV screen. The frequency of ciliar beats is recorded over one hour.

EVALUATION

The beat frequency of treated animals is compared with that of controls.

MODIFICATIONS OF THE METHOD

Mercke et al. (1974) described a stroboscopic method for standardized studies of mucociliary activity in rabbit tracheal mucosa.

Lierle and Moore (1935) inserted windows into anesthetized rabbits for observation of the ciliary activity in the maxillary sinus of living animals.

With modern equipment, a similar technique has been used by Hybbinette and Mercke (1982a–c), Lindberg and Mercke (1986), Lindberg et al. (1986), Mercke et al. (1987) to study the role of several pharmacologic agents in the mucociliary defense of the rabbit maxillary sinus.

Corssen and Allen (1958) compared the toxic effects of various local anesthetic drugs on human ciliated epithelium *in vitro* by observation of rotating globes of human tracheal epithelium in tissue culture.

Cheung (1976) performed high speed cinemicrographic studies on rabbit tracheal (ciliated) epithelia.

Iravani (1967, 1971, 1975) studied the ciliary activity in the intrapulmonary airways of rats by incident light microscopy.

Lee and Verdugo (1976), Verdugo et al. (1980) recommended laser light-scattering spectroscopy for the study of ciliary activity.

Manawadu et al. (1978) studied the effects of local anesthetics on ciliary activity using ferret tracheal rings *in vitro*. The ferret possesses a long neck, and 100 or more tracheal rings can be obtained from a single ferret. The tracheal rings were maintained in sterile tubes. The ciliary activity was graded by determining the percentage of cilia beating on each ring, using transmitted light and the 10 × objective of an inverted microscope.

Rutland and Cole (1980) and Hesse et al. (1981) used a non-invasive method for obtaining nasal ciliated epithelium which is suitable for measurement of ciliary beat frequency.

Van de Donk et al. (1980) used isolated chicken embryo tracheas to measure the effects of preservatives on ciliary beat frequency. Maurer et al. (1982) studied the role of ciliary motility in acute allergic mucociliary dysfunction in cultivated ciliated cells from sheep.

Lopez-Vidriero et al. (1985) studied the effect of isoprenaline on the ciliary activity of an *in vitro* preparation of rat trachea.

Braga et al. (1986) described a simple and precise method for counting ciliary beats directly from the TV monitor screen using specimens of human ciliated epithelium obtained by brushing the nasal mucosa.

Curtis and Carson (1992) used pieces of human nasal epithelium for computer-assisted video measurement of ciliary beat frequency *in vitro*. Ciliary beat frequency was viewed with a microscope equipped with a phase contrast objective. The microscopic image was recorded by a camera and data stored by a videorecorder. For measuring ciliary beating, tapes were displayed with amplification on a monitor. A photoelectric transducer was positioned over the video image of the cilia. Movement of the cilia interrupting the light path caused changes in light intensity recorded by the photocell transducer.

D.4.0.6 Studies of Mucociliary Transport

PURPOSE AND RATIONALE

Mucus flow has been studied in *in vitro* and *in vivo* experiments (Iravani 1971; Ahmed et al. 1979). The rate of mucus flow can be estimated by measuring the time needed for certain particles to travel a known distance in the trachea. Numerous substances have been used such as charcoal particles (Dalhamn 1956), Teflon discs (Ahmed et al. 1979), and other pulverized materials (Deitmer 1989). The effect of local radioactivity on tracheal mucous velocity of sheep has been studied *in vitro* and *in vivo* by Ahmed et al. (1979).

PROCEDURE

For *in vitro* experiments, sheep are sacrificed during anesthesia, the trachea is exposed, clamped, and resected just below the cricoid cartilage. The chest is opened and the trachea is resected at the level of the carina. Then the trachea is slit open along the posterior membranous wall, pinned with gentle stretching on a board, and slanted upward at an angle of 25°. A metric ruler is placed along the board as a measuring reference. The board is then placed in a Plexiglas chamber with a constant temperature of 37°C and 100% humidity. Teflon discs are spread on the mucous layer. Tracheal mucus velocity is estimated by filming the movements of the radioopaque Teflon discs visualized on a television monitor connected to a camera. Disc motion is recorded for 1–2 min on a videotape, and the distance measured during the elapsed time is obtained from the videomonitor.

For *in vivo* measurements of tracheal mucus velocity, the roentgenographic method of Friedman et al. (1977), Sackner et al. (1977) is used. The sheep are restrained, and their heads are immobilized with a sling. The nasal mucosa is sprayed with a 2% lidocaine solution for topical anesthesia. A bronchofiberscope is inserted transnasally, and its tip is placed just below the vocal cords. Radioopaque Teflon discs 1.0 mm in diameter, 0.8 mm thick, and weighing 1,76 mg are blown through the inner channel of the bronchofiberscope onto the tracheal mucosa in a circumferential distribution. The cervical trachea containing the discs is visualized in the lateral projection with a television monitor. Disc motion is recorded on a videotape while the time is displayed on a digital clock. The disc image is marked to obtain the distance traveled. This distance is measured with a ruler, and the linear velocity of the disc is computed by dividing the distance by the elapsed time. This procedure is repeated for all discs in the field of view. To compute a mean tracheal mucus velocity, data from 10–15 discs are obtained in each filmed run.

EVALUATION

Disc velocities measured *in vitro* or *in vitro* are compared before and after treatment.

MODIFICATIONS OF THE METHOD

Mucociliary transport has been studied on the hard palate of decapitated frogs measuring the transport velocity of small particles, e. g., pieces of cork or charcoal (Kochmann 1930; Sadé et al. 1970).

Suzuki (1966) measured the movement of a standard object (1 mm^2 aluminum foil) on the ciliated surface of the palate of frogs.

Mucociliary clearance by the *in vitro* frog method was used by Leitch et al. (1985) to study the effects of ethanol.

Movement of poppy seeds in rabbit tracheal preparations was studied by Kensler and Battista (1966).

In chicken nasal mucosa the interaction between mucociliary transport and the ciliary beat was studied by Ukai et al. (1985).

Mucus transport in the respiratory tract of anesthetized cats was measured with uniform particles of lycopodium spores triturated with lamp black (Carson et al. 1966).

Mucociliary clearance velocities were determined by a radioisotopic method in dogs (Giordano et al. 1977, 1978).

D.4.0.7
Culture of Tracheal Epithelial Cells

PURPOSE AND RATIONALE

Marked morphological changes of the airway epithelium, up to severe damage, are frequently observed in inflammatory airway diseases and appear to play an important role in the pathogenesis of the broncho-obstructive symptoms (Webber and Corfield 1993; Hay et al. 1994). Freitag et al. (1996) studied the effects of lipopolysaccharides (LPS) and TNF-α on cultured rat tracheal epithelial cells and determined NO synthase activity.

PROCEDURE

Trachea of newborn rats, cut into small pieces, are explanted with the epithelial surface downwards onto 60 mm culture dishes (Lechner et al. 1985) and cultured in low-calcium (60–80 µmol/l) RPMI-1640 medium at 37°C and 5% CO_2. The medium containing 16% fetal calf serum is supplemented with epidermal growth factor and other growth promoting factors, such as 80 ng/ml cholera toxin, 2.6 ng/ml estradiol, 180 ng/ml hydrocortisone, 2.5 µg/ml insulin, 12.5 µg/ml transferrin, and 100 U/ml penicillin, 100 µg/ml streptomycin and 3.5 µg/ml amphotericin B to allow a selective outgrow of epithelial cells (Emura et al. 1990). Confluent epithelial layers are obtained after about 6–10 weeks at which time all cells show a positive staining with a pancytokeratin-antibody. Confluent cells of following passages are treated for four subsequent days with LPS (10 µg/ml) or TNF-α (500 U/ml).

The **morphology** of the cells is evaluated is evaluated by daily inspection using a phase contrast microscope with photographical documentation. Cell density in the culture is determined in each culture dish by counting daily the number of cells in four marked areas (each 2000 μm^2). For immunocytochemical staining, the cells are fixed by incubation in 100% methanol at –20°C for 20 min. The cells are washed with Ca/Mg-free phosphate buffered saline and several areas are marked of by nail-varnish. A solution of the anti-cytokeratin(pan)-antibody (monoclonal mouse IgG, Boehringer Mannheim) is added, incubated for 2 h at room temperature and after washing incubated for 30 min with a secondary antibody (FITC coupled, polyclonal rabbit anti-mouse IgG, Sigma). After washing, fluorescence microscopy is performed using a microscope with a FITC-specific filter combination. Unspecific fluorescence is excluded by performing the staining procedure in a different area of the same culture, but without the addition of the primary antibody.

For **determination of NO synthase activity**, confluent cultures are washed with oxygenated and prewarmed (37°C) Krebs-HEPES medium. Then the cells are incubated for 1 h in the same medium containing 37 kBq ^{3}H-L-arginine (100 nmol/l). After collection of the supernatants the cells are extracted in 1 ml of 0.4 mol/l $HClO_4$ for 2 h at 0–4°C.

By **HPLC analysis** ^{3}H-compounds (^{3}H-L-citrulline, ^{3}H-L-ornithine and ^{3}H-L-arginine) in incubation media and cell extracts are separated on a reverse phase column (length 250 mm, inner diameter 4.6 mm, pre-packed with Shadon ODS-Hypersil, 5 mm) using as mobile phase 0.1 mmol/l sodium phosphate buffer

(adjusted to pH 1.8) which contains octane sulphonic acid sodium salt (400 mg/l), Na_2EDTA (0.3 mmol/l) and methanol (6.25% v/v) with a flow rate of 1 ml/min (Hey et al. 1995). The eluate is collected in 1 min fractions into counting vials. After addition of a commercial scintillation cocktail the radioactivity is determined by liquid scintillation spectrophotometry. External standardization is used to correct for counting efficiency. The retention time is determined by the use of ^{14}C-labelled (L-citrulline or L-ornithine) or ^{3}H-labelled (L-arginine) standards. Protein content in cells is determined by a commercially available assay.

EVALUATION

The amounts of ^{3}H-L-citrulline in supernatants or cell extracts are expressed as DPM/µg protein. Changes in cell density are expressed as % of the density observed in each culture dish at the start of the experiment. Mean values are given ± SEM. The significance of difference is evaluated by Student's *t*-test.

D.4.0.8 Alveolar Macrophages

PURPOSE AND RATIONALE

Alveolar macrophages have been used for various purposes. A rat pulmonary alveolar macrophage cell line (NR8383) was initiated in culture by Helmke et al. (1987) in the presence of a gerbil lung conditioned medium and has been propagated continuously in culture. Sun et al. (1999) tested the inhibition of Ca^{2+} influx by pentoxifylline in NR8383 alveolar macrophages.

PROCEDURE

Cell Culture

The NR8383 alveolar macrophages cell line is grown in plastic tissue culture flasks in Ham's F12 medium containing 15% fetal bovine serum, 100 g/ml penicillin and 100 U/ml streptomycin sulfate. The alveolar macrophages are cultured at 37°C in an atmosphere of 5% CO_2 in air. The medium is routinely changed twice weekly. The viability of alveolar macrophages is routinely measured by trypan blue exclusion before and at 1.5 h after fura-2 loading, when all $[Ca^{2+}]_i$ determinations are completed.

Determination of $[Ca^{2+}]_i$

$[Ca^{2+}]_i$ is determined using the Ca^{2+}-sensitive fluorescent indicator fura-2 (Zhang et al. 1997; Mörk et al. 1998). NR8383 alveolar macrophages are loaded with fura-2 by incubation in PSS containing 2 mM (final concentration) fura-2/AM and 0.01% BSA for 20 min at 37°C. The cells are then rinsed twice with PSS containing 0.01% BSA and resuspended in the same medium (1.75×10^6 cells/ml). For $[Ca^{2+}]_i$ determination, a 2-ml aliquot of fura-2-loaded cells is centrifuged at 50 *g* for 2 min, resuspended in PSS containing 0.01% BSA and placed in a 4-ml cuvette. $[Ca^{2+}]_i$ is measured at 37°C using a PTI Deltascan fluorometer (PTI, South Brunswick, N.J., USA). The excitation wavelengths used are 340 and 380 nm and the emission wavelength is 505 nm. Calibration of $[Ca^{2+}]_i$ is performed for each measurement trace. Then, 1 mM $CaCl_2$ (for Ca^{2+}-free medium) and 50 mM ionomycin are added to obtain the limiting ratio for the Ca^{2+}-saturated form (R_{max}) of fura-2. Then, 0.0005% digitonin and 10 mM EGTA are added to obtain the limiting ratio for the free form of fura-2 (R_{min}. Fluorescence ratios of the 340- and 380-nm excitation and 505-nm emission are converted to $[Ca^{2+}]_i$ according to Grynkiewicz et al. (1985) using 224 nM as the K_d of fura-2 for Ca^{2+}.

Measurement of Store-Depletion-Activated Ca^{2+} Influx

The Ca^{2+} influx activated by depletion of the inositol 1,4,5-trisphosphate- (IP_3-) sensitive intracellular store is measured according to Zhang et al. (1997) and Zhu et al. (1998). Cells are exposed to either ATP or thapsigargin (TG) in Ca^{2+}-free medium for 5 min, and 1 mM Ca^{2+} is then added to initiate Ca^{2+} influx. The initial linear portion of $[Ca^{2+}]_i$ changes after addition of Ca^{2+} is used to calculate Ca^{2+} influx rate (nM/min).

EVALUATION

Results are presented as the mean± SEM of separate determinations using different cell preparations. Comparisons are made using the unpaired Student's *t*-test or the analysis of variance. *P* values <0.05 are considered significant.

MODIFICATIONS OF THE METHOD

Sirois et al. (2000) studied the influence of histamine in the cytokine network in the lung through H_2 and H_3 receptors. Alveolar macrophages from humans, Sprague Dawley rats and the alveolar macrophage cell line NR8383 were treated with different concentrations of histamine prior to their stimulation with suboptimal concentrations of lipopolysaccharide (LPS). Release of tumor necrosis factor (TNF) and interleukin-10 (IL-10) was measured.

Using the rat alveolar macrophage cell line NR8383, Gazin et al. (2004) found that uranium induces TNF-α secretion and activates the p38 mitogen-activated protein kinase (p38 MAPK).

Yang et al. (2004) studied in mice the synergy between a signal transducer and activator of transcription 3 and retinoic acid receptor-α in the regulation of the surfactant protein B gene in the lung.

Chapter E
Psychotropic and Neurotropic Activity

E.1
Effects on Behavior and Muscle Coordination

E.1.1
Spontaneous Behavior

E.1.1.1
General Considerations

The effects of drugs on the central and peripheral nervous systems can be easily recognized in normal animals. This does not necessarily mean that these effects can be used in therapy. Observing the global effects of drugs during LD_{50}-determinations, pharmacologists can detect psychotropic activity. Only, if these effects occur also in doses considerably below the LD_{50}, are further evaluations justified. This basic experience resulted in the development of a variety of observational tests and activity measurements.

E.1.1.2
Observational Assessment

PURPOSE AND RATIONALE

A systematic, quantitative procedure assessing the behavioral state of mice for the evaluation of drugs has been described by Irwin (1964, 1968). The method is applied in the beginning of pharmacological screening to detect psychotropic activities. It allows to identify and differentiate the profile pattern of various classes of pharmacological agents. Furthermore, observational assessment allows into the safety and potential toxicity profile of a new drug.

PROCEDURE

Mice of either sex (NMRI-strain) with a weight between 18 and 22 g are kept under standard laboratory conditions 5 days before the experiment. Animals tested for oral administration have water ad libitum but are deprived of food 16 h before the test. Animals for intravenous or intraperitoneal administration have access to food and water ad libitum until the test. For unknown substances the following doses are given:

- i.v. administration: 100, 200, 400 mg/kg
- i.p. administration: 300, 600, 1200 mg/kg
- oral administration: 500, 1000, 2000 mg/kg

Three animals are used for each dose. One group of 3 animals receiving the vehicle only, serves as control group.

Immediately after drug administration, the animals are closely observed for 2 h (following i.v. or i.p. administration) and for 5 h (following oral administra-

tion) by a "blind" observer. The following parameters are checked and compared to the vehicle control group:

Effects on CNS	Effects after manipulations
spontaneous motor activity	auditory stimulus response
restlessness	escape after touch
grooming behavior	righting reflex
squatting	paresis of hind limbs
staggering	paresis of forepaws
ataxic gait	catalepsy in induced positions
lying flat on the belly	Effects on reflexes
lying flat on the side	
lying flat on the back	pinna reflex
sleeping	corneal reflex
narcosis	pain following stimulation
bizarre behavior	Effects on autonomic nervous system
timidity	
Straubs's phenomenon	
writing	pupil diameter (constriction or dilatation)
tremors	eyelids (closure or exophthalmus)
twitches	secretion of sweat
opisthotonus	salivations
clonic convulsions	lacrimation
tonic convulsions	cyanosis
rolling and jumping convulsions	piloerection
	defecation
	urination

Depending on the route of administration, the observations are performed at different time intervals: after intravenous and after intraperitoneal administration during the first 30 min, and after 1 and 2 h; after oral administration during the first 60 min, and after 2 and 6 h. The number of deaths is counted during the first 24 h and after 7 days in order to evaluate acute and late toxicity. Arbitrary scores are chosen for each symptom. If positive effects are seen with the lowest dose, the experiment is repeated with lower doses being decreased by a factor of 3.

CRITICAL ASSESSMENT OF THE TEST

The test has been used by almost every laboratory in the world involved in screening of potential new drugs. Almost every laboratory has introduced its own modifications. In particular, the scores and the calculations differ from one laboratory to the other. Additional tests, such as grip strength or rotarod, described below, have been included into the primary screen. Graph-bar profiles have been established for known drugs in order to rate new substances accordingly. The test is definitively an useful tool for primary screening resulting in hints on psychotropic activity but also for actions on other systems. Nevertheless, this test can not substitute for more sophisticated tests for the evaluation of psychotropic activity.

MODIFICATIONS OF THE METHOD

Based on the guidelines of the United States Environmental Protection Agency (USEPA) (1991) Mattsson et al. (1996) described a performance standard for clinical and functional observational battery (FOB) for examinations of **rats.** The performance standard was an idealized composite of FOB data from experienced laboratory personnel, each person tested on a separate set of four groups of rats. The rats were examined in random order and treatments were either (a) saline, (b) chlorpromazine, (c) atropine, followed by physostigmine or (d) amphetamine.

Testing of neurotoxicity with new pharmaceuticals was reported by Haggerty (1991). He proposed a primary screen for rodents, consisting of a functional observation battery and an automated test for motor activity. In addition, a functional observation battery for dogs was developed. The rat tier I screen assesses such functions as home cage and open field activity, stimulus reactivity, and neuromuscular function. The dog tier I screen emphasizes evaluation of gait, postural reactions, and reflex function.

Rambert (2000) underlined the importance of some general conditions for general pharmacology of the CNS, such as choice of the animal species, administration route and controls of the experimental context (surroundings, temperature, schedules of the trials, interference with food-intake episodes, influence of noises and smells, expertise of the experimental staff).

Crawley and Paylor (1997), Crawley (2000) proposed a test battery and behavioral paradigms to investigate the behavioral phenotypes of transgenic and knockout mice. Several neurological and neuropsychological tests are described which can be used as first screen for behavioral abnormalities in mutant mice. Multiple behavioral paradigms are included for several categories, such as neurological reflexes, sensory abilities, motor functions, learning and memory, feeding, sexual behavior, analgesia, aggression, anxiety, depression, schizophrenia, and drug abuse.

Detailed procedure of the Irwin test performed in rats is given by Porsolt (2006).

E.1.1.3 Safety Pharmacology Core Battery

PURPOSE AND RATIONALE

Regulatory agencies (EMA 1997, 2000) have pointed out the necessity to perform safety pharmacology studies before application of a new drug to human beings and to assess most carefully any potential side effects. Organs or systems acutely necessary for life, i. e., the cardiovascular, respiratory and central nervous systems, are considered to be the most important to assess in safety pharmacology studies. The following parameters of CNS activity should be assessed appropriately: motor activity, behavioral changes, coordination, sensory/motor reflexes and body temperature.

Detailed descriptions of tests are found for

Observation tests:

E.1.1.2 Observational assessment

Motor activity and behavior:

E.1.2.2 Method of intermittent observations

E.1.2.3 Open field test

E.1.2.4 Hole-board test

E.1.2.5 Combined open field test

Coordination:

E.1.3.1 Inclined plane

E.1.3.2 Chimney test

E.1.3.3 Grip strength

E.1.3.4 Rotarod method

Sensory/motor reflexes:

E.1.3.6 Influence on polysynaptic reflexes

E.1.3.7 Masticatory muscle reflexes

Follow-up studies for CNS safety pharmacology are recommended, such as behavioral pharmacology, learning and memory, specific ligand binding, neurochemistry, visual, auditory and/or electrophysiology examinations. Detailed descriptions of these tests are found in the respective chapters, e. g.,

E.1.2.6 EEG analysis from rat brain by telemetry.

E.1.2 Effects on Motility (Sedative or Stimulatory Activity)

E.1.2.1 General Considerations

A survey on methods to evaluate depressants of the central nervous system has been published by Turner (1965). Many of these tests are still valid in spite of the fact that new classes of drugs have been introduced since that time which have not only augmented the therapeutic armamentarium but also changed the battery of pharmacological tests.

Sedative properties of drugs are tested mostly in mice or rats. Their spontaneous motor activity depends on various factors, such as the social situation (one or more animals), familiarity with the test environment, light and temperature. The term spontaneous motor activity includes different types of movements, such as locomotion, rearing, sniffing, grooming, eating and drinking. These phenomena can be well recognized by a skilled observer, but are difficult to record over long periods of time and to quantitate. Therefore, besides procedures based on observation many methods

for automatic registration have been developed. Almost every pharmacologist working in this field has designed his/her own apparatus. Several attempts have been made to measure not only simple locomotion, but also rearing and other types of movement. The conditions to characterize drug effects by measuring locomotor activity have been surveyed by Kinnard and Watzman (1966), Geyer (1990).

A special phenomenon, called "thigmotaxis" which means that rats have the tendency to remain close to the walls of the cage, has been described by Barnett (1963). Moreover, methods to measure curiosity have been recommended. Only a few examples of prototypic methods and equipment can be given.

E.1.2.2 Method of Intermittent Observations

PURPOSE AND RATIONALE

The method described by Ther (1953) was designed to study stimulant and sedative drugs. The use of 3 mice per group implied a special social situation of the animals. For testing sedative activity, the mice are additionally treated with a stimulant, and for testing stimulant activity with a sedative drug. Each group of mice is observed repeatedly only for a short period of time during one hour and compared to a control group by a "blind" observer.

PROCEDURE

Mice of either sex with an average weight of 25 g are deprived of food and water for 24 h before the test. To avoid any influence of the circadian rhythm the experiment is performed only between 8:00 and 12:00 A.M. Twelve animals are divided into groups of 3 mice. One group of 3 mice serves as control group, the other groups receive different doses of the test drug intraperitoneally. For testing sedative activity, the mice are injected after 10 min subcutaneously with 0.5 mg/kg methamphetamine. For testing stimulant activity, the mice are treated with 800 mg/kg paraldehyde. Ten minutes afterwards, each group is placed into a glass jar of 12 cm diameter and 20 cm height which in turn are placed in a wooden box of $130 \times 50 \times 30$ cm. The glass jars are illuminated from above. Ten minutes after administration of methamphetamine or paraldehyde the observation is started.

EVALUATION

During 1 h the observer looks every minute for 1 s to each jar and registers if none, one, two or all three mice show any characteristic change in locomotion, rearing, grooming or sniffing. The maximum count in 1 h would be 180. Generally, activity decreases within 1 h. Nevertheless, methamphetamine treated animals have a total count between 120 and 150. Groups treated with an effective sedative drug show a dose dependent decrease of total counts. The number of counts in the treated groups is calculated as percentage of controls. From dose-response curves ED_{50}-values can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

The method gives reliable results for sedative drugs and for compounds with central depressant activity, such as antihistaminics, neuroleptics and hypnotics. The disadvantage of the method lies in the fact that a skilled and trained observer is needed in order to get reproducible results. Therefore, several attempts have been made to automatize the method of intermittent observation.

MODIFICATIONS OF THE METHOD

Schaumann and Stoepel (1961) followed the principle of intermittent observation using a camera mounted above small wire cages (10×10 cm). The mice in the cages were photographed with an exposure time of 3 s every 7,5 min over a period of 2,5 h. Mice without movements give clear pictures, calculated as zero. Slight movements induce blurred contours, calculated as 1 point, and major movements give completely blurred pictures, calculated as 2 points. Normal mice show 20 or less points during 20 observations. Mice with more than 20 points are considered to be stimulated, mice with less than 5 points to be sedated. In this way ED_{50}-values can be calculated.

Vogel and Ther (1963) published an apparatus with automatic registration of intermittent observations. 18 cages are used which have a freely movable bottom with minimal weight which is supported by springs. A small permanent magnet attached below the floor induces an electrical current in a coil if the bottom is moved. Two mice are brought into each

cage. The control device registers during a variable period between 0.5 and 3 s if the bottom of one cage is moved or not. Within one minute, all 18 cages are registered successively. The number of movements within one hour is recorded for each cage. The sensitivity of the electric induction system is variable. A calibration is possible which picks up every movement of the animal, however, does not register the movements due to breathing. Dose-response curves can be established for stimulant and sedative drugs.

A similar apparatus was used by Hirabayashi and Tadokoro (1993) and Namina et al. (1999). The ambulatory activity of mice was measured by the tilting cage method using the Ambulometer, Model AMB-M1 (O'Hara, Tokyo, Japan).

Meyer (1962) measured the time until the exploration motility decreased to one third of the initial value.

Koek et al. (1987) used the principle of intermittent observations for various activities of rats such as locomotion, rearing, sniffing, licking, gnawing, grooming, loss of righting, Straub tail, ect. in order to compare the behavioral effects of drugs.

E.1.2.3 Open Field Test

PURPOSE AND RATIONALE

Interruption of light beams as a measure of movements of rats or mice in a cage ("open field") has been used by many authors such as Dews (1953), Saelens et al. (1968) Nakatsu and Owen, (1980). Recently developed devices allow to register not only general motor activity but also locomotion, rearing and the speed of locomotion (Barros et al. 1991; Ericson et al. 1991).

PROCEDURE

The rats are observed in a square open field arena ($68 \times 68 \times 45$ cm) equipped with 2 rows of 8 photocells, sensitive to infrared light, placed 40 and 125 mm above the floor, respectively. The photocells are spaced 90 mm apart and the last photocell in a row is spaced 25 mm from the wall. Measurements are made in the dark in a ventilated, sound-attenuating box. Interruptions of photocell beams can be collected by a microcomputer and the following variables can be evaluated:

- Motor activity: All interruptions of photo beams in the lower rows.
- Peripheral motor activity: Activation of photo beams in the lower rows, provided that the photo beams spaced 25 mm from the wall were also activated.
- Rearing: All interruption of the photo beams in the upper rows.
- Peripheral rearing: Interruption of photo beams in the upper rows, provided that the photo beams spaced 25 mm from the wall were also activated.
- Locomotion: Successive interruptions of photocells in the lower rows when the animal is moving in the same direction.
- Speed: The time between successive photo beam interruptions during locomotion collected in 0.1 s categories.

Adult male Sprague-Dawley rats with a weight between 280 and 320 g are used. Drugs are injected subcutaneously 10 to 40 min. before test. The rats are observed for 15 min whereby counts per min. are averaged for 3 min intervals.

EVALUATION

Dose-response curves can be obtained for sedative and stimulant drugs, whereby the various parameters show different results. The effects of various doses are compared statistically with the values of controls and among themselves.

CRITICAL ASSESSMENT OF THE METHOD

Measurement of several parameters in an open field device allows to differentiate between various types of sedative or stimulant drugs, but these differences can

only be detected if dose-response curves are obtained for each parameter.

MODIFICATIONS OF THE METHOD

Besides interruption of light beams, devices based on capacitance systems such as Animex (Columbus Instruments, Ohio, USA) and Varimexhave been developed and are widely used (Crunelli and Bernasconi 1979; Liu et al. 1985; Laviola G and Alleva E 1990; Honma et al. 1990; Magnus-Ellenbroek et al. 1993; Dauge et al. 1995; Petkov et al. 1995; Surmann et al. 1995; Gillies et al. 1996; Irifune et al. 1997; Ghelardini et al. 1998).

Nikodijevic et al. (1991) studied the behavioral effects of A_1- and A_2-selective adenosine agonists and antagonists in mice using a Digiscan activity monitor (Omnitech Electronics Inc., Columbus, OH) equipped with an IBM-compatible computer. The monitor included multiple activity monitor cages ($40 \times 40 \times 30.5$ cm), each of which was surrounded by horizontal and vertical sensors not detectable by the rodent.

Steiner et al. (1997) found that D_3 receptor deficient mice enter the center of an open field significantly more than their littermates suggesting an anxiolytic-like effect of the D_3 receptor mutation.

Vorhees et al. (1992) described a locomotor activity system for rodents. The system consists of a black, ventilated test chamber, internally lighted with a ceiling mounted video camera. The camera's image is transmitted to a contrast-sensitive tracker which maps the point of highest contrast and relays the digitalized coordinates to a PC. Dedicated software stores the information and simultaneously displays a map of the tracked subject.

Rex et al. (1996, 1998) described a modified open field test sensitive to anxiolytic drugs. Food-deprived rats were placed in one corner of the open field containing food in the center. The number of rats beginning to eat within the first 5 min was increased by known anxiolytic drugs.

Several authors used computerized systems, based on interruptions of infrared light beams, on magnetic field or on video-analysis such as the VideoMot2 system developed by TSE Systems, Bad Homburg, Germany, or systems available through Bilaney Consultants Ltd., St Julians, Sevenoaks, Kent, UK. (Sillaber et al. 1998; Wellmer et al. 2000; Kuzmin et al. 2003; Sienkiewicz-Jarosz et al. 2003; Strekalova et al. 2005).

Ströhle et al. (1997) mounted a video camera connected to a computer directly above six locomotor boxes (60×60 cm each). The distance traveled by the rat in a 20-min interval was determined with a video digitizer (TSE Systems, Bad Homburg, Germany).

Spooren et al. (2000), Stobrawa et al. (2001), Heijtz et al. (2002, 2004), Abo-Salem et al. (2004), Bilkei-Gorzo et al. (2004) measured motor activity (locomotion and rearing) in several animals (rats or mice) simultaneously by means of a multi-box detection system (ActiMot; TSE Systems, Bad Homburg Germany). This system use individual photocell activity units (48 x 48 cm) connected to a control unit. Each unit consists of a base frame with two pairs of light-barrier strips (each with 16/32 pairs of infrared transmitter and receiver diodes set at a distance of 28/14 mm; XY-coordinate). An additional pair of light-barrier strips (Z-coordinate) is used to detect rearing activity. Data for the number and sequence of photocell interruptions were collected on a computer.

A novel method for counting spontaneous motor activity in rats was proposed by Masuo et al. (1997). In the "Supermex" system, a sensor detects the radiant body heat of an animal.

E.1.2.4 Hole-Board Test

PURPOSE AND RATIONALE

The evaluation of certain components of behavior of mice such as curiosity or exploration has been attempted by Boissier et al. (1964) and Boissier and Simon (1964). They used an open field with holes on the bottom into which the animals could poke their noses. The "planche à trous" or "hole-board" test has become very well recognized and has been modified and automatized by many authors.

PROCEDURE

Mice of either sex (NMRI strain) with a weight between 18 and 22 g are used. The hole-board has a size of 40 × 40 cm. Sixteen holes with a diameter of 3 cm each are distributed evenly on the floor. The board is elevated so that the mouse poking its nose into the hole does not see the bottom. Nose-poking is thought to indicate curiosity and is measured by visual observation in the earliest description and counted by electronic devices in more recent modifications. Moreover, in the newer modifications motility is measured in addition by counting interruption of light beams. Usually, 6 animals are used for each dose and for controls. Thirty minutes after administration of the test compound the first animal is placed on the hole-board and tested for 5 min.

CALCULATION

The number of counts for nose-poking of treated animals is calculated as percentage of control animals.

CRITICAL ASSESSMENT OF THE METHOD

Poking the nose into a hole is a typical behavior of mice indicating a certain degree of curiosity. Evaluation of this component of behavior has been proven to be quite useful. Benzodiazepines tend to suppress nose-pocking at relatively low doses.

MODIFICATIONS OF THE METHOD

A hole-poke measuring system is commercially available from TSE Systems, Bad Homburg, Germany.

E.1.2.5 Combined Open Field Test

PURPOSE AND RATIONALE

The simultaneous determination of locomotion and curiosity by using a modification of the hole-board test and a photo-beam system has been proposed as a relatively simple test (Weischer et al. 1976). Several types of such equipment are commercially available.

PROCEDURE

Male mice (NMRI-strain) with an average weight of 30 g are used. Each animal is tested individually in an automated open-field box which consists of a black Plexiglas cage (35 × 35 × 20 cm) with a post (8 × 8 × 20 cm) in the center of the cage. Two evenly spaced photo cell beams perpendicular to the wall and 2 cm above the floor divide the box into 4 compartments. Every photo cell beam interruption is registered automatically as an activity count. Each wall of the cage contains 4 evenly spaced 2 cm diameter holes in a horizontal array 7 cm above the floor. A row of 4 photocell beams is mounted 1 cm outside of the holes and automatically records every exploratory nose-poke. Thirty min. after intraperitoneal

and 60 min. after oral administration of the test compound the animal is placed into the cage and the behavior recorded for a period of 5 min. Ten mice are used for each dose as well as for controls.

EVALUATION

Counts for motility (interruption of photo cell beams inside the cage) and for curiosity (interruption of photo cell beams outside the cage due to nose-poking) are recorded individually. The mean values of the treated groups are expressed as percentage of the control group. Using different doses, dose-response curves can be obtained.

CRITICAL ASSESSMENT OF THE METHOD

A dissociation between exploratory behavior and locomotion has been found with several drugs. Even well known stimulants can reduce exploratory behavior with a concomitant increase in locomotion. Depending on the dose, tranquilizers can reduce exploration without affecting locomotion. Due to the modifications of the equipment the results of different authors are often difficult to compare.

The limitations of photocell activity cages for assessing effects of drugs were discussed by Krsiak et al. (1970).

MODIFICATIONS OF THE TEST

Geyer (1982) described a similar device and reported different effects of amphetamine, caffeine, apomorphine and scopolamine. Adams and Geyer (1982) used this device to study the LSD-induced alterations of locomotor patterns and exploration in rats.

Geyer et al. (1986) described a behavioral monitor which was designed to assess the spatial and temporal sequences of locomotor movements in rats.

Other authors, e. g. Wolffgramm et al. (1988) used video recording of the movements of mice in the evening hours at low illumination and counted the locomotor activity as the number of field crossings and the exploratory activity as the number of rearings.

Ljungberg and Ungerstedt (1977) designed a testbox for the automatic recording of eight components of behavior in rats including compulsive gnawing induced by apomorphine.

Matsumoto et al. (1990) described a system to detect and analyze motor activity in mice consisting of a doughnut-shaped cage with 36 units of detectors radially arranged from the center of the cage. Each detector unit consisted of 4 pairs of photosensors (higher-, lower-, inner-, and outer-position sensors).

Schwarting et al. (1993) described a video image analyzing system for open-field behavior which measures turning behavior, thigmotactic scanning and locomotion in rats.

E.1.2.6 EEG Analysis From Rat Brain by Telemetry

PURPOSE AND RATIONALE

Field potential analysis of freely moving rats by radioelectroencephalography from different brain areas has been developed as a sensitive method in pharmacology (Dimpfel et al. 1986, 1989, 1990, 1992; Kropf et al. 1991).

PROCEDURE

Male adult rats are implanted with four stainless steel electrodes, mounted on a base plate, into the frontal cortex, striatum, thalamus, and reticular formation. The plate carries a microplug for a four-channel radiotransmitter. During the experimental sessions, which

start 2 weeks after surgery, the transmitted field potentials are analyzed in real time using Fast Fourier Transformations. The resulting power density spectra are segmented into six frequency bands, each representing the integrated power over a certain frequency band.

EVALUATION

The data from three pre-drug periods of 15 min each are compared with those from continuously monitored 15-min postdrug periods.

MODIFICATIONS OF THE METHOD

De Simoni et al. (1990) developed a miniaturized optoelectronic system of telemetry for data obtained in freely moving animals by *in vivo* voltammetry, an electrochemical technique that uses carbon fiber microelectrodes to monitor monoamine metabolism and release continuously (Justice 1987).

Krügel et al. (2001) tested functional recovery after neuronal injury by P2 receptor blockade. The functional changes in the neuronal activity were recorded by telemetric EEG (TSE Systems, Bad Homburg, Germany).

E.1.3 Tests for Muscle Coordination

E.1.3.1 Inclined Plane

PURPOSE AND RATIONALE

The method of Allmark and Bachinski (1949) using an inclined screen was originally developed for testing curare-like agents. Later on, it has been used by many authors (e. g. Randall et al. 1961) for testing compounds for muscle relaxant activity. The principle of an inclined plane has been used by Ther, Vogel and Werner (1959) for differentiating neuroleptics from other centrally active drugs. Rivlin and Tator (1977) also used an inclined plane to assess skeletal muscle relaxation.

PROCEDURE

The plane consists of two rectangular plywood boards connected at one end by a hinge. One board is the base, the other is the movable inclined plane. Two plywood side panels with degrees marked on their surface are fixed on the base. A rubber mat with ridges 0.2 cm in height is fixed to the inclined plane which is set at 65 degrees. Male mice (Charles River strain) with a body weight between 20 and 30 g are used. The test compound or the standard are administered to groups of 10 mice either i.p. or s.c. or orally. Thirty, 60 and 90 min thereafter, the mice are placed at the upper part of the inclined plane and are given 30 s to hang on or to fall off.

EVALUATION

The peak time is determined as the time at which a compound produces the maximum performance deficit. At this time interval, a range of doses is tested using 10 animals per group. ED_{50} values are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The method has been proven to be a simple assay for muscle relaxant activity. Although the muscle relaxant tests satisfy the criteria of sensitivity and relative potency compared with clinically effective doses, the effects of anxiolytics are not clearly differentiated from neuroleptics and even from neurotoxic compounds.

MODIFICATIONS OF THE METHOD

Instead of an inclined wooden board, an inclined screen has been used by Randall et al. (1961) and Simiand et al. (1989).

E.1.3.2 Chimney Test

PURPOSE AND RATIONALE

The "test de la cheminée" has been introduced by Boissier et al. (1960) as a simple test for tranquilizing and muscle relaxant activity.

PROCEDURE

Male mice (CD1, Charles River) weighing between 16 and 22 g are used in groups of 10 animals per dose. Pyrex-glass cylinders 30 cm long are required. The internal diameter varies with the animal's weight: for mice weighing 16 to 18 g, the diameter is 22 mm, for mice weighing 18 to 20 g, 25 mm; for mice weighing 20 to 22 g, 28 mm. Each tube has a mark 20 cm from its base. Initially, the tube is held in a horizontal position. At the end of the tube, near the mark, a mouse is introduced with the head forward. When the mouse reaches the other end of the tube, toward which it is pushed if necessary with a rod, the tube is moved to a vertical position. Immediately, the mouse tries to climb backwards and performs coordinated movements similar to an alpinist to pass a chimney in the mountains. This gave the name for the test. The time required by the mouse to climb backwards out at the top of the cylinder is noted.

EVALUATION

The ED_{50} (with 95% confidence limits), the dose for which 50% of the animals fail to climb backwards out of the tube within 30 s, is calculated by log-probit analysis.

CRITICAL ASSESSMENT OF THE METHOD

The chimney test can be used as an additional test with other tests determining muscle relaxant activity.

E.1.3.3 Grip Strength

PURPOSE AND RATIONALE

The test is being used to assess muscular strength or neuromuscular function in rodents which can be influenced not only by sedative drugs and muscle relaxant compounds but also by toxic agents.

PROCEDURE

The method was described as 'test de l'agrippement' by Boissier and Simon (1960). Male or female mice with an average weight of 22 g are used. In a preliminary experiment the animals are tested for their normal reactivity. The animals are exposed to a horizontal thin threat or metallic wire suspended about 30 cm into the air, which they immediately grasp with the forepaws. The mouse is released to hang on with its forelimbs. Normal animals are able to catch the threat with the hind limbs and to climb up within 5 s. Only animals who fulfill this criterion are included into the experiment. Ten mice are used in the control group and in the experimental groups. After oral or subcutaneous administration the animals are tested every 15 min. Animals which are not able to touch the threat with the hind limbs within 5 s or fall off from the threat are considered to be impaired. The test is continued for 2 h. The animals are observed for their behavior in the cages. Only if their behavior and their motility in the cage seem to be normal the disturbance of the grasping reflex can be considered as caused by central relaxation.

EVALUATION

The percentage of animals loosing the catching reflex is calculated. By use of different doses, ED_{50}-values are calculated. Likewise, time-response curves can be established.

CRITICAL ASSESSMENT OF THE METHOD

Only simultaneous observation of the animals under normal conditions gives the possibility to distinguish between central relaxation and toxic effects on neuromuscular function.

MODIFICATIONS OF THE METHOD

Kondziella (1964) described a method for the measurement of muscular relaxation in mice based on the capacity of hanging from a horizontal griddle.

Meyer et al. (1979) described a technique to measure the fore- and hind limb grip strength of rats and mice. The apparatus consists of an adjustable trough and a push-pull strain gauge with a triangular brass ring which is grasped by the animal with its forelimbs. The animal is pulled on the tail until the grip is broken. The animal continues to be pulled along the trough until the hind limbs grasp a T-shaped bar being also attached to push-pull strain gauge. The trial is completed when the grip of the hind limbs is also broken. Fore- and hind limb strength are measured. Dose-response curves could be established with various doses of chlordiazepoxide and phenobarbital.

Barcley et al. (1981) described the tight rope test for testing performance in mice.

Simiand et al. (1989) used a test originally described by Fleury (1957). A mouse held by the tail is placed on a small metallic grid which the animal gripped with its forepaws. The grid is than loaded with weights until the mouse could not longer support the weight of the grid. The endpoint is the maximal weight supported by the animal at least for 2 s. ED_{50}-values can be calculated for various centrally active skeletal muscle relaxants such as the benzodiazepines.

Deacon and Gardner (1984) described the pull-up test in rats. A rat is held by its hind legs in an inverted position. The time taken by the rat to pull itself up and grasp the hand of the experimenter is used as the test parameter.

Novack and Zwolshen (1983) tested muscle relaxants in various models, such as morphine-induced rigidity in rats, decerebrate rigidity in cats and the polysynaptic linguomandibular reflex in cats.

Montag-Sallaz and Montag (2003), Anderson et al. (2004), and Baier et al. (2004) used a Grip Strength Meter apparatus, designed by TSE Systems, Bad Homburg, Germany. If the animal releases the grip then the maximum force is shown on a digital display of a connected control unit.

E.1.3.4 Rotarod Method

PURPOSE AND RATIONALE

The test is used to evaluate the activity of drugs interfering with motor coordination. In 1956, Dunham and Miya suggested that the skeletal muscle relaxation induced by a test compound could be evaluated by testing the ability of mice or rats to remain on a revolving rod. This forced motor activity has subsequently been used by many investigators. The dose which impairs the ability of 50% of the mice to remain on the revolving rod is considered the endpoint.

PROCEDURE

The apparatus consists of a horizontal wooden rod or metal rod coated with rubber with 3 cm diameter attached to a motor with the speed adjusted to 2 rotations per minute. The rod is 75 cm in length and is divided into 6 sections by plastic discs, thereby allowing the simultaneous testing of 6 mice. The rod is in a height

of about 50 cm above the table top in order to discourage the animals from jumping off the roller. Cages below the sections serve to restrict the movements of the animals when they fall from the roller. Male mice (CD-1 Charles River strain) with an weight between 20 and 30 g undergo a pretest on the apparatus. Only those animals which have demonstrated their ability to remain on the revolving rod for at least 1 minute are used for the test. The test compounds are administered intraperitoneally or orally. Thirty minutes after intraperitoneal or 60 min after oral administration the mice are placed for 1 min on the rotating rod. The number of animals falling from the roller during this time is counted.

Using different doses, ED_{50} values can be calculated. Moreover, testing at various time intervals, time-response curves can be obtained.

CALCULATION

Percent animals falling from the rotarod within the test period is calculated for every drug concentration tested. ED_{50} is defined as the dose of drug at which 50% of the test animals fall from the rotarod.

CRITICAL ASSESSMENT OF THE TEST

Many central depressive drugs are active in this test. Benzodiazepines, such as diazepam and flurazepam, have ED_{50} values below 1 mg/kg i.p. The activity of neuroleptics, such as chlorpromazine or haloperidol, is in the same range. In this way, the test does not really differentiate between anxiolytics and neuroleptics but can evaluate the muscle relaxant potency in a series of compounds such as the benzodiazepines. Moreover, the test has been used in toxicology for testing neurotoxicity.

MODIFICATIONS OF THE METHOD

A comparison of the rotarod method in rats with other tests, such as blockade of morphine-induced rigidity in rats, decerebrate rigidity in cats, and polysynaptic-monosynaptic reflex preparations in cats was published by Novack and Zwolshen (1983).

Capacio et al. (1992) used the accelerating rotarod to assess motor performance decrement in rats after administration of candidate anticonvulsant compounds in nerve agent poisoning.

The accelerating rotarod system (TSE Systems, Bad Homburg, Germany) was also used by Augustin et al. (2001), Hosseinzadeh and Asl (2003), Dere et al. (2003), and Vitali and Clarke (2004).

Rozas et al. (1997) described a drug-free rotarod test that was used to evaluate the effects of unilateral 6-hydroxydopamine lesions, nigral grafts, and subrotational doses of apomorphine. The rotarod unit was automated and interfaced with a personal computer allowing automatic recording of the time that each rat was able to stay on the rod at different rotational speeds.

E.1.3.5 Treadmill Performance

PURPOSE AND RATIONALE

Treadmill experiments have been used in pharmacology and physiology for various purposes:

1. To evaluate the influence of drugs on endurance (Snider et al. 1983; Matthew et al. 1988; Ahlenius et al. 1977a, 1997b; Soares et al. 2003; Minami et al. 2004).
2. To study muscle metabolism (Balon and Nadler 1997; Zhou and Dohm 1997; Juel 1998; Foianini et al. 2000; Gosmanov et al. 2002; Saengsirisuwan et al. 2002; Steinberg et al. 2004).
3. To study influence on the cardiovascular system (Koller et al. 1995; Roth et al. 1998; Spier et al. 1999; Sun et al. 1994, 2002; Villanueva et al. 2003).

4. To study the effect of diet (Oudot et al. 1996) and of circadian rhythm (Marchant and Mistlberger 1996).

PROCEDURE

Minami et al. (2004) studied the effect of a high-salt diet or chronic captopril treatment on exercise capacity in normotensive rats. Male Sprague Dawley rats were submitted to stepwise increasing exercise on a motor treadmill at a speed of 10, 20 and 30 m/min, 0-grade incline, for 4 min with 2-min rest intervals. Exercise was stopped when rats were unable to continue running with exhaustion despite contact with a shock at the rear of the treadmill belt. Mean arterial pressure (MAP) and heart rate (HR) were recorded continuously at rest and during the three different intensities of exercise.

EVALUATION

Values obtained for MAP and HR during the 10 s before the beginning of exercise, when all values reached a stable state, and during the last 10 s at each exercise level were used for comparison. All results are expressed as mean ± SEM. One-way ANOVA was used to assess significant differences in means across groups at rest and at each exercise level.

TREADMILL SYSTEMS

A fully computerized electronically controlled treadmill system for small laboratory animals is provided by TSE Systems, Bad Homburg, Germany : The apparatus basically consists of a rotating running belt driven by a servo-controlled motor, which provides precise operator-defined tread speed. Separating panels divide the running surface into separate exercise lanes each suited for an individual animal. The floor grids can be used to apply and electric stimulus of variable length and intensity. The incline of the running surface can be steplessly adjusted to control the labor of the animal.

Columbus Instruments, Columbus, OH, offers the animal treadmill Exer 3/6, which is a general purpose treadmill for three rats or 6 mice utilizing a single belt construction with dividing walls suspended over the tread surface supplied with or without a stimulus assembly. Speed of the belt can be adjusted in the range of 6–100 m/m.

MODIFICATIONS OF THE METHOD

Treadmill experiments in **cats** were performed by Douglas et al. (1993).

Nakai et al. (2003) and Liu et al. (2004) used treadmill experiments to study walking dysfunction in the **rat neuropathic intermittent claudication model**. In this model, male Sprague Dawley rats were anesthetized with pentobarbital. L4–L6 vertebrae were surgically exposed and two small holes were drilled, one between L4–L5 and the second between L6–L6 intervertebral spaces. Two rectangular silicone rubber strips (1.25 mm × 4 mm, thickness: 1 mm) were then placed in the L4–L6 epidural spaces. The incision was closed in two layers and penicillin was administered systemically.

Antri et al. (2005) used treadmill experiments to study long-lasting recovery of locomotor function in chronic spinal rats following combined pharmacological stimulation of serotonergic receptors with 8-OHDPAT and quipazine.

E.1.3.6 Influence on Polysynaptic Reflexes

PURPOSE AND RATIONALE

Inhibition of polysynaptic reflexes is considered to be the major mode of action of muscle relaxants. Polysynaptic transmission can be measured by the flexor reflex of the hindpaw in anesthetized rats, whereas the monosynaptic Hoffmann reflex is measured by electromyographic recordings from the plantar foot muscle (Block and Schwarz 1994; Schwarz et al. 1994, 1996).

PROCEDURE

Male Wistar rats (250–280 g) are anesthetized with urethane (400 mg/kg i.p.) and α-chloralose (80 mg/kg i.p.). For the flexor reflex a hindpaw is stimulated with a pair of fine subcutaneous needle electrodes (5 square-wave shocks at 500 Hz, 0.2 ms duration and 3.0 reflex threshold). Electromyographic recordings are made with a pair of fine needle electrodes inserted into the ipsilateral tibialis muscle. Seven consecutive electromyographic recordings are amplified, and band-pass filtered (8–10 Hz), collected at a sample rate of 10 Hz, averaged and evaluated using a Signal Averager (CED, Cambridge, UK) on an IBM-compatible personal computer. Ten consecutive responses are averaged before and 20 min after i.p. application of drug.

For stimulation of the Hoffmann reflex a pair of needle electrodes is transcutaneously inserted into the surrounding of the tibial nerve (single square-wave shocks, 0.2 ms duration at 2.0 threshold). Electromyographic recordings are made with a pair of skin clip surface electrodes from the plantar foot muscle. Low intensity electrical stimulation of the tibial nerve elicits a reflex response similar to the human Hoffmann (H) reflex, which has been attributed to monosynaptic excitation of spinal α-motoneurons predominantly by primary muscle spindle afferent fibers. With increasing stimulus strength, the H-wave is preceded by an electromyographic wave, the M wave, which is due to a direct excitation of axons of α-motoneurons.

In all reflex experiments, values measured after solvent or drug application are expressed as a percentage of the corresponding pre-injection value.

EVALUATION

Statistical evaluation of group differences is performed using the Mann-Whitney U-test. Statistical analysis for dose dependency of drug effects is carried out by the Kruskal-Wallis test.

MODIFICATIONS OF THE METHOD

Ono et al. (1990), Farkas and Ono (1995), Hasegawa and Ono (1996), Otsu et al. (1998) recorded spinal reflexes from spinalized and non-spinalized rats anesthetized with α-chloralose and urethane. Laminectomy was performed in the lumbo-sacral region. Ventral and dorsal roots of the segments L4 and L5 were isolated. A skin pouch was formed at the site of the dissection to cover the exposed tissues with liquid paraffin kept at 36°C. The dorsal root of L5 was placed on bipolar silver wire electrodes for stimulation (0.2 Hz, 0.05 ms, supramaximal). The ipsilateral ventral root of L5 and the dorsal root of L4 were placed on bipolar wire electrodes for recording. Monosynaptic and polysynaptic reflexes and dorsal root-dorsal root reflexes were evoked in the L5 ventral root and in the L4 dorsal

root, respectively. These reflex potentials were amplified, displayed on an oscilloscope and averaged 8 times by an averaging computer.

Turski and Stephens (1993) recorded monosynaptic Hoffman reflexes in NMRI **mice** anesthetized with 80 mg/kg α-chloralose i.p. +400 mg/kg urethane i.p. The tibial nerve was stimulated with single square-wave pulses, 0.2 ms duration at 1.2–1.6 times the nerve threshold. Electromyogram recordings were made with a pair of skin clip surface electrodes from the plantar foot muscle. For recording polysynaptic flexor reflexes, the tibial nerve was stimulated with five square-wave pulses at 500 Hz, 0.2 ms duration at 3.0 times the nerve threshold. Electromyogram recordings were made with a pair of wire electrodes inserted percuteneously into the ipsilateral tibial muscle.

Furthermore, these authors used **genetically spastic rats**. A mutant strain of Wistar rats, which carries an autosomal recessive gene defect, is characterized by a progressive paresis of the hindlimbs with increased tone on the extensor muscles (Pittermann et al. 1976). This genetically determined syndrome of spasticity in the rat permits quantitative evaluation of the effect of drugs on muscle tone by recording activity in the electromyogram from a hindlimb extensor muscle (Klockgether et al. 1985; Turski et al. (1990).

Farkas et al. (1989), Tarnava et al. (1989) studied the effects of drugs on the reflex potentials evoked by afferent nerve stimulation and recorded from the spinal roots in unanesthetized spinal **cats**. An analog integrating method was used for quantitative evaluation of the reflex potentials. The amplified and band-pass filtered signals from the ventral root (monosynaptic reflex and polysynaptic reflex) and from the dorsal root (dorsal root reflex and dorsal root potential) were fed into signal-selectors, which transmitted the input signals only within the chosen post-stimulus intervals. Thus, the various components of the reflex potentials were separated according to their latencies.

Shakitama et al. (1997) recorded ventral root reflex potential in anesthetized rats and ventral and dorsal root potentials in anesthetized intact and spinalized cats.

Suzuki et al. (1995) studied the recovery of reflex potentials after spinal cord ischemia produced by occlusion of the thoracic aorta and the bilateral internal mammary arteries for 10 min in cats.

E.1.3.7 Masticatory Muscle Reflexes

PURPOSE AND RATIONALE

The temporomandibular joint dysfunction syndrome, characterized by pain and clicking in the temporomandibular joint and limitation of function, involves a condition caused by hypertonia combined with para-

functional habits, such as clenching or grinding of teeth and hyperreflexia (Laskin and Block 1986) which may be treated by muscle relaxants. Ozawa et al. (1996) studied the effects of a centrally acting muscle relaxant on *masticatory* muscle reflexes in rats. Both monosynaptic and polysynaptic reflexes can be studied using this model.

PROCEDURE

For recording the **monosynaptic tonic vibration reflex** of the masseter muscle, Wistar rats are anesthetized with ether, intubated with a tracheal cannula and fixed into a stereotactic apparatus. Decerebration is performed by radiofrequency lesion of the midbrain using a Lesion Generator (Radionics, RFG-4, USA) and a lesioning electrode inserted into the midbrain. After lesioning, ether anesthesia is discontinued. The tonic vibration reflex of the masseter muscle, recorded as electromyogram, is induced every 10–12 s by a sinusoidal vibration (100–500 Hz, 2 s) which is applied to the mandibula, and is delivered by a vibration generator driven by a low frequency oscillator and an amplifier. The evoked electromyogram is amplified by a biophysical amplifier and recorded on a thermal array recorder. The root mean square of the electromyogram is also recorded through an integrator.

For recording the **polysynaptic jaw opening reflex**, the animals are anesthetized by intraperitoneal pentobarbital-Na (50 mg/kg), fixed into position on their back and intubated with a tracheal cannula. Intrapulpal stimulation (0.5 Hz, 0.2 s in pulse duration, supramaximal intensity) delivered by an electrical stimulator is performed via a dental reamer inserted into the dental pulp of the mandibula. The jaw opening reflex recorded as phasic component of the electromyogram evoked in the ipsilateral digastric muscle is amplified by a biophysical amplifier and recorded on a thermal array recorder.

For recording of the **polysynaptic tonic periodontal masseteric reflex** (Funakoshi and Amano 1974) the animals are anesthetized by intraperitoneal injection of pentobarbital-Na (35 mg/kg), which is supplemented as required, intubated with a tracheal cannula and fixed onto a stereotaxic apparatus. The maxillary incisor is stimulated by pressing for 5 s every 5 min using a vibration generator driven by a trapezoid generator. The electromyogram responses to this stimulation are amplified by a biophysical amplifier and recorded on a thermal array recorder. The evoked electromyogram is transformed into square-wave pulses, fed into a staircase generator and recorded on a thermal array recorder.

EVALUATION

The significance of differences between the control and the drug-treated groups is evaluated with Dunnett's test.

MODIFICATIONS OF THE METHOD

Boucher et al. (1993) performed microinfusions of excitatory amino acid antagonists into the trigeminal sensory complex of freely moving rats while recording the long latency jaw opening reflex elicited by electrical stimulation of the dental pulp.

Bakke et al. (1998) studied in anesthetized rats neurokinin receptor mechanisms in the increased jaw muscle activity which can be evoked by injection of the small fiber excitant and inflammatory irritant mustard oil into the temporomandibular joint region.

Alia et al. (1998) preformed intra-oral administration of a NK_1 antagonist in freely moving guinea pigs during recording the short- (6–10 ms) and long-latency (18–26 ms) jaw-opening reflex elicited by electrical stimulation of the lower incisor tooth pulp.

Huopaniemi et al. (1988) determined the threshold of the tooth-pulp evoked jaw-opening reflex after naloxone in barbiturate-anesthetized cats.

E.2 Tests for Anxiolytic Activity

E.2.0.1 General Considerations

Definitions in psychopharmacology have been coined by the activity of special compounds or chemical

classes found in patients. This is not only true for the term "neuroleptic" but also for the term "anxiolytic". Other terms have been "ataractic" or "psycholeptic". Anxiolytics are derived from "tranquilizers", such as meprobamate which was used widely until the advent of benzodiazepines. The property which these drugs have in common is the alleviation of anxiety, thus explaining the term "anxiolytic". These agents are used for the relatively minor disorders of the nonpsychotic or neurotic type, whereas the antipsychotic agents (phenothiazines, butyrophenones) are given mainly to combat the more severe psychotic or schizophrenic reactions. Thus, the terms anti-anxiety and antipsychotic indicate a qualitative distinction in the clinical use and mode of action of the drug. Pathological anxiety in man has been defined by its interference with normal functions, by manifestations of somatic disorders, emotional discomfort, interference with productivity at work, etc. This complex characterization of anxiety in man already indicates the difficulties to find appropriate pharmacological models. Therefore, several tests have to be performed to find a spectrum of activities which can be considered to be predictive for therapeutic efficacy in patients. For *in vivo* studies, most investigators use a battery of anticonvulsive tests, anti-aggressive tests and evaluation of conditioned behavior.

Most of the actions of benzodiazepines are thought to be mediated by potentiation of g-amino-butyric acid (GABA). Two subtypes of GABA receptors ($GABA_A$ and $GABA_B$) have been described. Moreover, specific binding sites for benzodiazepines have been discovered near these GABA receptors in various areas of the brain. These sites occur in a macromolecular complex that includes GABA-receptors, benzodiazepine receptors and receptors for other drugs, and a chloride channel. The benzodiazepines potentiate the neurophysiological actions of GABA at the chloride ion channel by increasing the binding of GABA to $GABA_A$ receptors. This implies that the $GABA_A$ receptor is involved in anxiety and that its direct activation would have an anxiolytic effect. Based in these findings various *in vitro* tests have been developed.

More recently, research has focused on the therapeutic potential of blocking excitatory amino acids – in particular glutamate. Excitatory amino acid receptors have been classified into at least three subtypes by electrophysiological criteria: NMDA, quisqualic acid (QA) and kainic acid (KA) (Cotman and Iversen 1987; Watkins and Olverman 1987). Some methods are described in Sect. E.3 Anti-epileptic activity.

Serotonin may play a role in anxiety, since treatment with drugs that reduce serotoninergic function, including benzodiazepines, have anxiolytic effects in animal models (Dourish et al. 1986). Several subtypes of serotonin receptors have been elucidated, e. g. 5-HT_{1A}, 5-HT_{1B}. 5-HT_{1C}, 5-HT_{1D}, 5-HT_2, 5-HT_3. Further differentiation is underway. 5-HT_{1A}, 5-HT_{1B}, and 5-HT_3 receptors are considered to be involved in the effect of anti-anxiety and novel antipsychotic drugs (Peroutka 1988; Costall et al. 1988). Some *in vitro* methods are described in Sect. E.6 Antidepressant activity and Sect. E.5 Neuroleptic activity.

E.2.1 In Vitro Methods

E.2.1.1 GABA Receptor Binding

E.2.1.1.1 General Considerations

γ-Aminobutyric acid (GABA) is known to be an important inhibitory neurotransmitter in the brain. Abnormalities in the GABA system have been found in neurological and psychiatric diseases such as Hunt-

ingdon's chorea, anxiety, panic attacks, schizophrenia, and epilepsy. GABA is also implicated in the mechanism of benzodiazepines and related central nervous system (CNS) drugs.

GABA receptors have been divided into $GABA_A$, $GABA_B$ and $GABA_C$ receptor subtypes which by themselves form receptor families (Enna and Möller 1987; Matsumoto 1989; Möhler 1992).

Without doubt, GABA is the most important inhibitory transmitter in the CNS. One may expect important new developments from attempts to influence the GABAergic system specifically by synthetic compounds. In general, $GABA_A$ receptor agonists are CNS depressants, muscle relaxants, and possess some nociceptive properties, whereas the receptor antagonists are convulsants. Most benzodiazepine-binding sites seem to be associated with $GABA_A$ receptors combined with a chloride channel. Among $GABA_B$ receptor agonists, baclofen has achieved success in clinical use. Results of ongoing research with receptor subtypes will result in the development of new therapeutic agents.

Studies by Urwyler et al. (2001) demonstrated that the $GABA_B$ receptor can be modulated in an allosteric manner. These compounds are not receptor agonists but they appear to act on the heptahelical region of $GABA_{B2}$ to enhance the action of the receptor agonists GABA and baclofen.

$GABA_C$ receptors are ligand-gated chloride channels that are present in many parts of the brain including the superior colliculus, cerebellum, hippocampus, and, most prominently, the retina (Ragozzino et al. 1996; Bormann 2000; Qian and Ripps 2001; Chehib 2004; Schlicker et al. 2004; Yang 2004; Pan et al. 2005; Wang and Slaughter 2005).

The formation and plasticity of GABAergic synapses, their physiological mechanisms and pathophysiological implications are discussed by Fritschy and Brünig (2003).

E.2.1.1.2 In Vitro Assay for GABAergic Compounds: [^{3}H]-GABA Receptor Binding

PURPOSE AND RATIONALE

Radiolabeled GABA is bound to synaptic membrane preparations of mammalian brain. The labeling of the synaptic receptor with ^{3}H-GABA requires careful attention to possible interference from nonsynaptic binding since ^{3}H-GABA can also bind nonspecifically to plasma membranes. The most prominent of which is the sodium dependent binding of GABA to brain membranes, a process which appears to be associated with the transport (uptake) sites of GABA. Sodium-independent binding of ^{3}H-GABA has characteristics consistent with the labeling of GABA receptors. In addition, the relative potencies of several amino acids in competing for these binding sites parallel their abilities to mimic GABA neurophysiologically. Therefore, the sodium-independent binding of ^{3}H-GABA provides a simple and sensitive method to evaluate compounds for GABA-mimetic properties.

PROCEDURE

Reagents

- 0.05 M Tris-maleate buffer (pH 7.1)
- 6.05 g of Tris-base are dissolved in distilled water and made up to 1000 ml. 5.93 g of Tris- maleate are dissolved in 500 ml of water. The 0.05 M Tris

maleate, pH 7.1 buffer is prepared by slowly adding Tris maleate to the Tris-base solution until the pH reaches 7.1.

- 0.32 M Sucrose: 109.5 g of sucrose are dissolved in distilled water and filled up to 1000 ml. The solution is stored at 4°C.
- ^{3}H-GABA (specific activity approximately 40 Ci/mmol) is made up to a concentration of 780 nmol in distilled water and 20 µl is added to each test tube (yielding a final concentration of 15 nmol in the assay). Isoguvacine or muscimol is prepared by dissolving 8.35 mg of isoguvacine or 6.40 mg of muscimol in 10 ml water. Twenty µl of these solutions when added to 1 ml of incubation medium give a final concentration of 0.1 mM isoguvacine or muscimol.
- Test drugs: 1 mM stock solutions are initially prepared. These are serially diluted to the required concentrations prior to the addition to the incubation mixture. Final concentrations are usually from 2×10^{-8} to 1×10^{-5} M.

Tissue Preparation

Male Charles-River rats (100–150 g) are decapitated and their whole brains rapidly removed and homogenized in 15 vol of ice-cold 0.32 M sucrose. The homogenate is centrifuged at 1000 *g* for 10 min. The pellet (nuclear fraction) is discarded and the supernatant fluid is recentrifuged at 20,000 *g* for 20 min. The supernatant is discarded and the crude mitochondrial pellet is resuspended in 15 vol distilled water using a Tekmar homogenizer. The suspension is centrifuged at 8000 *g* for 20 min. The supernatant is collected and used to carefully resuspend, using a gentle squirling motion, the pellet's soft, upper, buffy layer. This suspension is then centrifuged at 48,000 *g* for 20 min. The final crude synaptic membrane pellets are resuspended (without homogenization) in 15 volumes of distilled water and centrifuged at 48,000 *g* for 20 min. The supernatant is discarded, and the centrifuge tubes containing the pelleted membranes are capped with parafilm and stored frozen at –70°C.

Assay Procedure

A frozen membrane pellet from one whole rat brain is resuspended in 15 volumes of 0.05 M Tris-maleate buffer (pH 7.1) by homogenization at 4°C. Triton X-100 is added to a final concentration of 0.05%. This suspension is then incubated at 37°C for 30 min followed by centrifugation at 48,000 *g* for 10 min. The supernatant is discarded and the pellet resuspended by homogenization in the same volume of 0.05 Tris-maleate buffer (pH 7.1) at 4°C. The preincubation with Triton enhances specific GABA receptor binding while lowering non-specific binding.

For the standard Na-independent ^{3}H-GABA binding assay procedure, aliquots of the previously frozen, Triton treated crude synaptic membranes are incubated in triplicate at 4°C for 5 min in 0.05 M Tris-maleate buffer (pH 7.1) containing 15 nM ^{3}H-GABA alone or in the presence of 0.1 mM isoguvacine or muscimol, or the test drug.

The procedure is as follows:

- 1 ml of the 0.05 M Tris-maleate homogenate
- 20 µl of ^{3}H-GABA
- 20 µl of test drug or 20 ml of 0.1 mM isoguvacine or muscimol.

After incubation at 4°C for 5 min, the reaction is terminated by centrifugation for 15 min at 5000 rpm. The supernatant fluid is aspirated and the pellet washed twice with 1 ml of the Tris-maleate buffer. Two ml of liquiscint are added to each tube which is then vigorously vortexed. The contents of the tubes are transferred to scintillation vials, and the tubes rinsed with an additional 2 ml of cocktail. An additional 6 ml of liquiscint are added to each scintillation vial. The radioactivity is measured by liquid scintillation photometry.

EVALUATION

Specific ^{3}H-GABA binding is defined as the radioactivity which can be displaced by a high concentration of unlabeled GABA and is obtained by subtracting from the total bound radioactivity the amount of radioactivity bound in the presence of 0.1 mM isoguvacine. Results are converted to percent of specifically bound ^{3}H-GABA displaced by a given concentration of test drug. IC_{50} values with 95% confidence limits are then obtained by computer derived linear regression analysis.

E.2.1.1.3 $GABA_A$ Receptor Binding

PURPOSE AND RATIONALE

Two subtypes of GABA receptors have been identified:

1. $GABA_A$ receptor for which muscimol is the typical agonist, whereas bicucculine, picrotoxin, and SR 95531 are antagonists, and
2. $GABA_B$ receptor, for which baclofen is the typical agonist.

The $GABA_A$ receptor directly gates a Cl^- ionophore and has modulatory binding sites for benzodiazepines, barbiturates, neurosteroids and ethanol. By contrast, $GABA_B$ receptors couple to Ca^{2+} and K^+ channels via G proteins and second messenger systems; they are activated by baclofen and are resistant to drugs that modulate $GABA_A$ receptors.

Several subtypes of $GABA_A$ receptors have been identified by ligand binding studies (Kleingoor et al. 1991; Turner et al. 1992; Gusti et al. 1993). Molecular biology techniques revealed the $GABA_A$ receptor to be assembled as a pentameric structure from different subunit (α, β, γ and δ subunit) families making it possible that a very large number of such heteromeric $GABA_A$ receptors exist in the mammalian central and peripheral nervous system (Krogsgaard-Larsen et al. 1994; Lambert et al. 1995; Smith and Olsen 1995; Costa 1998). A total of 19 genes encoding $GABA_A$ receptor subunits are known, while several additional isoforms can occur as splicing variants of some of these (Barnard 1998). Probably more than 500 distinct $GABA_A$ receptor subtypes exist in the brain (Sieghart 2000). Sequences of six α, three β, three γ, one δ, three ρ, one ε, one π and one θ $GABA_A$ receptor subunits have been reported in mammals (Barnard 2000; Alexander et al. 2001). More insight into the pharmacological functions of $GABA_A$ receptor subtypes is expected from studies in gene-knockout mice and by knock-in point mutations (Rudolph et al. 2001).

$GABA_C$ receptors were described as a pharmacologically distinct group by Bormann and Feigenspan (1995), Johnston (1996), Bormann (2000), Zhang et al. (2001). These receptors are Cl^- pores that are insensitive to both bicucculine and baclofen. An IUPHAR Committee has recommended in 1998, that the term $GABA_C$ should be avoided and classified bicucculine- and baclofen-insensitive GABA receptors as a minor subspecies of $GABA_A$ receptors of the 'AO' type.

Subtypes of $GABA_A$ receptors were classified on the basis of subunit structure and receptor function by Barnard et al. (1998).

In rat brain membranes, only the $GABA_A$ receptor is labeled with the $GABA_A$ selective radioligand ^{3}H-SR 95531 in the given concentration range. The assay allows specifically the estimation of the test drug's binding characteristics to the $GABA_A$ receptor subpopulation.

PROCEDURE

Materials

Radioligand: ^{3}H-SR 95531 (^{3}H-2-(3-carboxypropyl)-3-amino-6-(4-methoxyphenyl)-pyridazinium bromide (New England Nuclear, Boston)

Membrane Preparation

Rats are killed by decapitation, the brains are quickly dissected and after separation from the cerebellum placed into ice-cold sucrose solution. The brains (approximately 20 g wet weight) are then homogenized in a glass Teflon potter (1 g brain weight/15 ml 320 mM D(+)-sucrose solution), and centrifuged at 1000 *g* at 4°C for 10 min. The pellets are discarded and the supernatants centrifuged at 20,000 *g* for 20 min. The resulting supernatants are discarded and the pellets are lysed by hypoosmotic shock (addition of 20 volumes of ice-cold bidistilled water). After homogenization in a glass Teflon homogenizer, the suspension is stirred under cooling for 20 min, and centrifuged at 48,000 *g* for 20 min. The resulting pellets are resuspended in ice-cold bidistilled water, the suspension is stirred and recentrifuged as before. The final pellets are resuspended in the incubation buffer (50 mM Tris-HCl and 100 mM $MgCl_2 \times 6\,H_2O$, pH 7.4) corresponding to 1 g brain wet weight/1 ml buffer. The membrane suspension is immediately stored in aliquots of 1 ml at –20°C. Protein content of the membrane suspension is determined according to the method of Lowry et al. (1951) with bovine serum albumin as standard.

At the day of the experiment, the required volume of the membrane suspension is slowly thawed and diluted 1:20 with bidistilled water. After stirring for 10 min, the membrane suspension is centrifuged at 50,000 *g* for 10 min. The resulting pellets are resuspended in ice-cold incubation buffer, yielding a membrane suspension with a protein content of 1 mg/ml.

Assay

For each concentration, assays are performed in triplicate. The total volume of each incubation sample is 200 µl (microtiter plates).

Saturation Experiments

Total binding:

- 50 ml ^{3}H-SR 95531 (12 concentrations, 2×10^{-9} to 1×10^{-7} M)
- 50 ml incubation buffer

Non-specific binding:

- 50 ml ^{3}H-SR 95531 (4 concentrations, 2×10^{-9} to 1×10^{-7} M)
- 50 ml (+) bicucculine (10^{-4} M)

Competition Experiments

- 50 ml ^{3}H-SR 95531 (1 constant concentration, $8–10 \times 10^{-9}$ M)
- 50 ml incubation buffer without or with non-labeled test drug (15 concentrations, 10^{-10} to 10^{-3} M)

The binding reaction is started by adding 100 µl membrane suspension per incubation sample. The samples are incubated for 30 min at 4°C. The reaction is stopped by subjecting the total incubation volume to rapid vacuum filtration over glass fiber filters. Thereby, the membrane-bound radioactivity is separated from the free radioactivity. Filters are washed immediately with approximately 20 ml ice-cold rinse buffer (50 mM Tris HCl, pH 7.4) per sample. The membrane-bound radioactivity is measured after addition of 2 ml liquid scintillation cocktail per sample in a Packard liquid scintillation counter.

EVALUATION

The following parameters are calculated:

- total binding
- non-specific binding
- specific binding = total binding − non-specific binding.

The dissociation constant (K_i) of the test drug is determined from the competition experiment of ^{3}H-SR 95531 versus non-labeled drug by a computer-supported analysis of the binding data.

$$K_i = \frac{K_D{}^3\mathrm{H} \times \mathrm{IC}_{50}}{K_D{}^3\mathrm{H} + [^3\mathrm{H}]}$$

IC_{50} = concentration of the test drug, which inhibits 50% of specifically bound ^{3}H-SR 95531 in the competition experiment.

$[^3H]$ = concentration of ^{3}H-SR 95531 in the competition experiment.

$K_D{}^3H$ = dissociation constant of ^{3}H-SR 95531, determined from the saturation experiment.

The K_i-value of the test drug is that concentration, at which 50% of the receptors are occupied by the test drug.

MODIFICATIONS OF THE METHOD

Binding to the agonist site of the $GABA_A$ receptor can be measured with [^{3}H]muscimol (Snodgrass 1978; Williams and Risley 1979; Martini et al. 1983).

A membrane fraction of whole brains (except cerebellum) from male Wistar rats is prepared by standard techniques. Ten mg of membrane preparation is incubated with 1 nM [^{3}H]muscimol for 10 min at 0°C. Non-specific binding is estimated in the presence of 100 nM muscimol. Membranes are filtered and washed 3 times and the filters are counted to determine specifically bound [^{3}H]muscimol.

The $GABA_A$ receptor chloride channel can be studied by binding with [^{3}H]t-butylbicycloorthobenzoate ([^{3}H]TBOB) (Schwartz and Mindlin 1988; Lewin et al. 1989).

A membrane fraction of whole brains (except cerebellum) from male Wistar rats is prepared by standard techniques. 0.4 mg of membrane preparation is incubated with 3 nM [^{3}H]TBOB for 15 min at 15°C. Non-specific binding is estimated in the presence of 200 µM picrotoxin. Membranes are filtered and washed 3 times and the filters are counted to determine [^{3}H]TBOB specifically bound.

Cromer et al. (2002) presented a model for the extracellular, ligand-binding domain of the $GABA_A$ receptor that is based on the structure of a soluble acetylcholine-binding protein.

Kittler and Moss (2003) discussed modulation of $GABA_A$ receptor activity by phosphorylation and receptor trafficking and the implications for the efficacy of synaptic inhibition.

Lambert et al. (2003) reviewed neurosteroid modulation of $GABA_A$ receptors with special emphasis on pregnane steroids.

Lüscher and Keller (2004) described regulation of $GABA_A$ receptor trafficking, channel activity, and functional plasticity of inhibitory synapses.

Macdonald et al. (2004) reviewed mutations of the $\alpha 1$, $\gamma 2$ and δ subunits of the $GABA_A$ receptor that are associated with different idiopathic generalized epilepsy syndromes.

Mody and Pearce (2004) reviewed the diversity of inhibitory neurotransmission through $GABA_A$ receptors.

Rudolph and Möhler (2004) reported analysis of $GABA_A$ receptor function and dissection of the pharmacology of benzodiazepines and general anesthetics through mouse genetics. Whereas the knockout mice have provided information primarily with respect to the regulation of subunit gene transcription, receptor assembly, and some physiological functions of individual receptor subtypes, the point-mutated knockin mice in which specific $GABA_A$ receptors are insensitive to diazepam or some general anesthetics have revealed the specific contribution of individual receptor subtypes to the pharmacological spectrum of diazepam and cerebral anesthetics.

Among $GABA_A$ agonists and partial antagonists, Krogsgaard-Larsen et al. (2004) characterized THIP (Gaboxadol) as a non-opioid analgesic and a novel type of hypnotic.

Boehm et al. (2004) described γ-aminobutyric acid receptor subunit mutant mice, which offer new perspectives on alcohol actions.

E.2.1.1.4 $GABA_B$ Receptor Binding

PURPOSE AND RATIONALE

Baclofen, as an analogue of the inhibitory neurotransmitter γ-aminobutyric acid (GABA), binds as agonist to the subtype B of the GABA receptor. Baclofen is effective in the treatment of spasticity caused by multiple sclerosis or other diseases of the spinal cord, particularly traumatic lesions. Studies of similar compounds may lead to other effective antispasmodic drugs.

In rat cerebellar membranes, only the $GABA_B$ receptor is labeled in the given concentration range of the $GABA_B$ selective agonist ^{3}H-(–)baclofen. The assay allows specifically the estimation of the test drug's binding characteristics at the $GABA_B$ subtype receptor population.

The receptor on which baclofen acts is coupled via G_i/G_o proteins to Ca^{2+} and K^+ channels as well as adenyl cyclase in neurons and hence is classified as a metabotropic receptor.

As in other receptor families, heterogeneity of the $GABA_B$ receptor has been found (Scherer et al. 1988; Bittiger et al. 1992; Bonanno and Raiteri 1992, 1993a, b; Bowery 1993; Lanza et al. 1993). At least 3 distinct subtypes have be identified:

a) the postsynaptic receptor linked via a G-protein to a K^+ channel which upon stimulation by GABA hyperpolarizes the neuron,
b) the presynaptic autoreceptor at GABA nerve endings; blockade of this receptor augments the release of GABA in electrically stimulated rat cortical slices,
c) the presynaptic heteroreceptor at glutamate nerve endings; blockade with $GABA_B$ antagonists increases release of glutamate from K^+ stimulated cortical slices.

The structure of $GABA_B$ receptors was identified when isoforms were detected (Kaupmann et al. 1997). Potent $GABA_B$ antagonists were described (Bittiger et al. 1992, 1993; Froestl et al. 1996).

PROCEDURE

Materials

Radioligand: ^{3}H-(–)baclofen, specific activity 1.11–1.85 TBq/mmol (30–50 Ci/Mmol) New England Nuclear, Boston

Membrane Preparation

Rats are killed by decapitation, the cerebella quickly removed, and placed into ice-cold preparation buffer (50 mM Tris-HCl, pH 7.4). Approximately 5 g wet weight of the cerebella are homogenized using a glass Teflon potter, corresponding to 1 g cerebellum wet weight/50 ml buffer, and centrifuged at 48,000 *g* at 4°C for 10 min. The pellets are resuspended in approximately 270 ml preparation buffer, and centrifuged as before. The final pellets are dissolved in preparation buffer, corresponding to 1 g cerebellum wet weight/30 ml buffer. The membrane suspension is immediately stored in aliquots of 5–10 ml at –77°C. Protein content of the membrane suspension is determined according to the method of Lowry et al. with bovine serum albumin as a standard.

At the day of the experiment, the required volume of the membrane suspension is slowly thawed, and centrifuged at 50,000 *g* for 20 min. The pellets are resuspended in the same volume of incubation buffer, and stirred for 45 min at room temperature. The

suspension is recentrifuged as before. This washing step is repeated 3 times. The resulting pellets are resuspended in ice-cold incubation buffer in a volume, yielding a membrane suspension with a protein content of 1 mg/ml. The membrane suspension is stirred under cooling for 20–30 min until the start of the experiment.

Assay

For each concentration samples are used in triplicate. The total volume of each incubation sample is 200 µl (microtiter plates). The concentration of ^{3}H-(–)baclofen is constant in all samples ($1.8–2 \times 10^{-8}$ M).

Saturation Experiments

Total Binding

- 50 µl ^{3}H-(–)baclofen
- 50 µl non-radioactive racemic baclofen (15 concentrations, $0–1.2 \times 10^{-6}$ M)

Non-Specific Binding

The measurement of the non-specific binding is performed at the lowest concentration of the saturation range, i. e. 1.8×10^{-8} M of the ^{3}H-(–)baclofen without non-radioactive racemic baclofen.

- 50 µl ^{3}H-(–)baclofen
- 50 µl gamma-aminobutyric acid.

Competition Experiments

- 50 µl ^{3}H-(–)baclofen
- 50 µl incubation buffer without or with labeled test drug (15 concentrations, $10^{-10}–10^{-3}$ M)

The binding reaction is started by adding 100 µl membrane suspension per incubation sample (1 mg protein/1 ml). The samples are incubated for 60 min at 4°C. The reaction is stopped by subjecting the total incubation volume to rapid vacuum filtration over glass fiber filters. Thereby, the membrane bound is separated from the free radioactivity. The filters are washed with approximately 20 ml ice-cold buffer. The retained membrane bound radioactivity on the filter is measured after addition of 0.3 ml ethylene glycol monomethyl ether and 2 ml liquid scintillation cocktail per sample and an equilibration time of 1 h in a Packard liquid scintillation counter.

EVALUATION

The following parameters are calculated:

- total binding
- non-specific binding
- specific binding = total binding–non-specific binding.

The dissociation constant (K_i) of the test drug is determined from the competition experiment of ^{3}H-(–)baclofen versus non-labeled drug by a computer-supported analysis of the binding data.

$$K_i = \frac{K_D{}^3\mathrm{H} \times \mathrm{IC}_{50}}{K_D{}^3\mathrm{H} + [^3\mathrm{H}]}$$

IC_{50} = concentration of the test drug, which inhibits 50% of specifically bound ^{3}H-(–)baclofen in the competition experiment.

$[^3\mathrm{H}]$ = concentration of ^{3}H-(–)baclofen in the competition experiment

$K_D{}^3\mathrm{H}$ = dissociation constant of ^{3}H-(–)baclofen, determined from the saturation experiment.

The K_i-value of the test drug is the concentration, at which 50% of the receptors are occupied by the test drug.

MODIFICATIONS OF THE METHOD

Kaupmann et al. (1998) showed that $GABA_B$-receptor subtypes assemble into functional heteromeric complexes.

Bowery and Enna (2000) demonstrated that $GABA_B$ receptors are functional metabotropic heterodimers.

Molecular structure and physiological functions of $GABA_B$ receptors are reviewed by Bettler et al. (2003) and Bowery et al. (2003).

E.2.1.2 Benzodiazepine Receptor: [^{3}H]-Flunitrazepam Binding Assay

PURPOSE AND RATIONALE

Experiments using ^{3}H-diazepam or ^{3}H-flunitrazepam have demonstrated specific binding sites in CNS membrane preparations that satisfy the criteria for pharmacological receptors, e. g. saturability, reversibility, stereoselectivity and significant correlation with *in vivo* activities of the drugs in this class.

Heterogeneity of benzodiazepine receptors has been reported (Klepner et al. 1979; Supavilai and Karobath 1980; Hafely et al. 1993; Davies et al. 1994). There are four classes of benzodiazepine and non-benzodiazepine high affinity ligands for benzodiazepine recognition sites associated with $GABA_A$ receptors: The first class (e. g. diazepam, flunitrazepam, alprazolam) facilitates the action of GABA, increasing the opening frequency of Cl^- channels. These ligands are called full positive allosteric modulators, or full agonists. A second class of ligands, which includes the β-carbolines, can decrease the opening frequency of Cl^- channels. These ligands are known as full negative allosteric modulators, or full inverse agonists. A third class (e. g. flumazenil) binds with high affinity to ben-

zodiazepine recognition sites, but it can also prevent the GABA modulations elicited by positive or negative allosteric modulators; this class is called a modulator antagonist. A fourth class of ligands for benzodiazepine recognition sites is known to elicit either partial amplification or partial attenuation of GABA action at various $GABA_A$ receptors, and comprises the class called partial positive and partial negative allosteric modulators or partial agonists and partial inverse agonists, respectively.

The names **ω_1, ω_2, and ω_3-receptor subtypes** have been proposed to replace the nomenclature of benzodiazepine BZ_1, BZ_2, and BZ_p receptors (Langer and Arbilla 1988; Langer et al. 1990; Griebel et al. 1999a, b).

PROCEDURE

Reagents

- [Methyl-^{3}H]-Flunitrazepam (70–90 Ci/mmol) can be obtained from New England Nuclear.
- Clonazepam HCl can be obtained from Hoffmann La Roche

Tissue Preparation

Male Wistar rats are decapitated and the brains rapidly removed. The cerebral cortices are removed, weighed and homogenized with a Potter-Elvejhem homogenizer in 20 volumes of ice-cold 0.32 M sucrose. This homogenate is centrifuged at 1000 *g* for 10 min. the pellet is discarded and the supernatant is centrifuged at 30,000 *g* for 20 min. The resulting membrane pellet is resuspended in 40 volumes of 0.05 M Tris buffer, pH 6.9.

Assay

1 ml	0.05 Tris buffer, pH 6.9
560 µl	H_2O
70 µl	0.5 M Tris buffer, pH 6.9
50 µl	^{3}H-Flunitrazepam
20 µl	vehicle (for total binding) or 0.1 mM Clonazepam (for non-specific binding) or appropriate drug concentrations.
300 µl	tissue suspension.

The tubes containing ^{3}H-flunitrazepam, buffer, drugs and H_2O are incubated at 0–4°C in an ice bath. A 300 µl aliquot of the tissue suspension is added to the tubes at 10-s intervals. The timer is started with the addition of the mixture to the first tube. The tubes are then incubated at 0–4°C for 20 min and the assay stopped by vacuum filtration through Whatman GF/B filters. This step is performed at 10-s intervals. Each filter is immediately rinsed with three 5-ml washes of ice-cold buffer, pH 6.9. The filters are counted in 10 ml of liquid scintillation counting cocktail.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of clonazepam. Specific binding is approximately 97% of total ligand binding. The percent inhibition at each drug concentration is the mean of triplicate determinations. IC_{50} calculations are performed using log-probit analyses.

CRITICAL ASSESSMENT OF THE METHOD

Binding to the benzodiazepine receptor is not absolutely predictive for anxiolytic activity. A range of compounds have been discovered that do not have the benzodiazepine structure but that do interact with the benzodiazepine receptors (Gardner 1988; Byrnes et al. 1992). They may have a different pharmacological profile *in vivo*.

MODIFICATION OF THE METHOD

Takeuchi et al. (1992) developed a non-isotopic receptor assay for benzodiazepine drugs using the biotin-1012-S conjugate. The free conjugate in the supernatant was determined with a solid-phase avidin-biotin binding assay.

E.2.1.3 Serotonin Receptor Binding

E.2.1.3.1 General Considerations

Several surveys on 5-HT receptors and their classification have been published, e. g., by Humphrey et al. (1993), Peroutka (1993), Boess and Martin (1994), Hoyer et al. (1994), Kebabian and Neumeyer (1994), Martin and Humphrey (1994), Saxena (1994), Brancheck (1995), Sleight et al. (1995), Bockaert et al. (1997), Branchek and Zgombick (1997), Briley et al. (1997), Costal and Naylor (1997), Glennon and Dukat (1997), Göthert and Schlicker (1997), Hamon (1997), Hartig (1997), Hoyer and Martin (1997), Jacobs and Fornal (1997), Roth and Hyde (1997), Uphouse (1997), Martin (1998), Martin and Eglen (1998), Saxena et al. (1998), Barnes and Sharp (1999), Pauwels (2000), and Gershon (2004).

The classification has evolved from a scheme recognizing three classes (5-HT_{1like}, 5-HT_2 and 5-HT_3) to one accepted by the NC-IUPHAR subcommittee for 5-hydroxytryptamine (serotonin) receptors in which seven classes embrace 14 distinct receptor subtypes (Martin 1988; Martin and Eglen 1998). Some revisions of the nomenclature were made:

Renaming the 5-HT_{1C} receptor to 5-HT_{2C} on the basis of recognitory, transductional and structural identity with the 5-HT_2 family.

Alignment of the classification scheme with the human genome, meaning that human receptors are given pre-eminence in the nomenclature.

Renaming the 5-$HT_{1D\alpha}$ and 5-$HT_{1D\beta}$ subtypes to 5-HT_{1D} and 5-HT_{1B}, respectively.

Recognition that the '5-HT_{1like}' positively coupled to adenylate cyclase and mediating smooth muscle relaxation, is the 5-HT_7 receptor.

Use of a lower-case notation to describe a putative receptor defined only by gene product, with 'promotion' to an upper-case notation when the receptor is fully defined in terms of operational, recognitory and structural properties.

Up to 7 functional isoforms of the 5-HT_{2C} receptor, two functional isoforms of the 5-HT_4 receptor and four isoforms of the 5-HT_7 receptor were recognized.

Murphy et al. (1999) reviewed molecular biology-based alterations in 5-HT receptors including al-

tered characteristics of mice lacking different 5-HT receptors, e. g., 5-HT_{1B}-receptor-deficient mice, 5-HT_{2C} receptor-deficient mice, 5-HT_{1A}-receptor-deficient mice, 5-HT cell-membrane-transporter deficient mice and vesicular monoamine-transporter-deficient mice.

The role of 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1F}, 5-HT_{2B}, and 5-HT_7 receptors in cardiovascular physiology and pharmacology was discussed by Watts and Cohen (1999).

5-HT Receptor Types and Subtypes

5-HT_1 Subtypes. At least five *5-HT_1 subtypes* are described (5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-ht_{1E}, 5-ht_{1F}), which share 41–63% overall sequence identity and couple preferentially to $G_{i/o}$ to inhibit cAMP formation.

Hartig et al. (1996) suggested a revised nomenclature for 5-HT_{1B}, 5-$HT_{1D\alpha}$ and 5-$HT_{1D\beta}$ receptor subtypes.

5-HT_{1A} receptor agonists were described by Sills et al. (1984), Porsolt et al. (1992), Foreman et al. (1994), Wolff et al. (1997), Hamon (1997), 5-HT_{1A} receptor antagonists by Allen et al. (1997), 5-$HT_{1B/D}$ receptor antagonists by de Vries et al. (1997), 5-HT_{1D} receptor agonists by Macor et al. (1994), van Lommen et al. (1995), Valentin et al. (1996), 5-HT_{1D} receptor antagonists by Clitherow et al. (1994), de Vries et al. (1996), Rollema et al. (1996), Briley et al. (1997).

Ramboz et al. (1998) recommended serotonin receptor 1A knockout mice as an animal model of anxiety-related disorder.

Presynaptic receptors may be preferably involved in the anxiolytic effects of 5-HT_{1A} receptor agonists, whereas in the antidepressant effects postsynaptic receptors are strongly involved (De Vry 1991, 1995).

5-HT_1 receptors are involved in learning and memory processes (see F.3.3.7 and F.3.4.1).

An endogenous peptide interacting specifically with the serotonergic 1B receptor subtypes was identified (Rousselle et al. 1996).

5-HT autoreceptors, mainly of the 5-HT_{1D} subtype, were studied by Starke et al. (1989), Fink et al. (1995), Bühlen et al. (1996), Glennon et al. (1996), Roberts et al. (1996), Price et al. (1996).

Cushing et al. (1994) studied the role of a 5-HT_{1D}-like receptor in serotonin-induced contraction of canine coronary artery and saphenous vein.

Wainscott et al. (2005) and Lucaites et al. (2005) described [^{3}H]Y334370 as a radioligand for the 5-HT_{1F} receptor.

See E.2.1.3.2 and E.2.1.3.3 for binding assays of 5-HT_1 receptors.

5-HT_2 Receptors. *5-HT_2 receptors* have been subdivided into 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C} receptors, which exhibit 46–50% overall sequence identity and couple preferentially to $G_{q/11}$ to increase the hydrolysis of inositol phosphates and elevate cytosolic [Ca^{2+}]. (Humphrey et al. 1993; Hoyer et al. 1994; Kebabian and Neumeyer 1994; Martin and Humphrey 1994; Saxena 1994; Shih et al. 1994; Tricklebank 1996; Martin 1998). The human 5-HT_2 receptors were cloned and characterized (Chen et al. 1992; Carey et al. 1996). Species differences in receptors were described (Johnson et al. 1995). 5-HT_2 receptors play a role in the action of antipsychotics and hallucinogens.

Saucler and Albert (1997) identified an endogenous 5-hydroxytryptamine$_{2A}$ receptor in NIH-3T3 cells.

Wolf and Schutz (1997) found that the serotonin 5-HT_{2C} receptor is a prominent serotonin receptor in basal ganglia.

Bonhaus et al. (1995) described the pharmacology and distribution of human 5-hydroxytryptamine$_{2B}$ (5-HT_{2B}) receptor gene products and compared this with 5-HT_{2A} and 5-HT_{2C} receptors.

Chagraoui et al. (2003) reported that agomelatine (S20088) antagonizes the penile erections induced by the stimulation of 5-HT_{2C} receptors in Wistar rats.

See E.5.1.9. and E.5.1.10 for binding assays to 5-HT_2 receptors.

5-HT_3 Receptor. The *5-HT_3 receptor* is a pentameric, ligand-gated ion channel, activation of which promotes entry of Na^+ and Ca^{2+}, egress of K^+ and hence neuronal depolarization. It belongs to the transmitter-gated cation super-family of receptors and appears to be located exclusively in neuronal tissue where it mediates fast depolarization (Malone et al. 1991). Responses are blocked by a wide range of potent antagonists, which are highly selective with respect to other 5-HT receptors (Silverstone and Greenshaw 1996). The Bezold-Jarisch reflex can be elicited by 5-HT_3 receptor agonists and be blocked by 5-HT_3 antagonists (see A.1.3.19). 5-HT_3 receptor antagonists are used as anti-migraine drugs. 5-HT_3 receptors are involved in feeding behavior (see L.3.1.1) Furthermore, gastric emptying (see J4.4.2) and emesis (see J.5.0.1, J.5.0.2, J.5.0.3 and J.5.0.4) can be influenced by 5-HT_3 antagonists.

5-HT_3 receptor antagonists, such as **ondansetron** (Koulu et al. 1990; Ishizuka et al. 1993; Miyata et al. 1995; Cappelli et al. 1996), **granisetron** (Sanger and Nelson 1989; Ito et al. 1995; Endo et al. 1999; Yan and White 2005), **tropisetron** (Macor et al. 2001; de la

Vega et al. 2005), **zacopride** (Waeber et al. 1990; Kidd et al. 1992), and **alosetron** (Clayton et al. 1999) are used clinically in the prevention of cisplatin-induced emesis (Karim et al. 1996; Roila et al. 1997).

The synthesis and pharmacological profile of several selective 5-HT_3 receptor antagonists have been reported (Fitzpatrick et al. 1990; Rosen et al. 1990; Swain et al. 1991; Ito et al. 1992; Bachy et al. 1993; Heidempergher et al. 1997; Rival et al. 1998; Modica et al. 2004).

Boess et al. (1997) analyzed the ligand binding site of the 5-KT_3 receptor using site direction mutagenesis.

See E.2.1.3.4 for binding assays to the 5-HT_3 receptor.

5-HT_4 Receptors. The *5-HT_4 receptors* couple preferentially to G_S protein and activate adenylate cyclase, thereby increasing intracellular cAMP levels (Martin 1998). This induces long-term modulation of ion-channel activity, which is fundamental in learning and memory (Eglen et al. 1995; Eglen and Hedge 1996). Excitatory responses were found in guinea pig ileum and colon, inhibitory responses in rat esophagus (Ford and Clarke 1993).

The tunica muscularis mucosae preparation of the rat esophagus has been recommended for evaluation of 5-HT_4 receptor ligands since it possesses a homogeneous population of 5-HT_4 receptors which mediates a well defined relaxant response to 5-HT (see J.2.0.1)

5-HT_4 receptors may mediate arrhythmias (Kaumann 1994). Two splice variants have been identified (Gerald et al. 1995). Several selective 5-HT_4 receptors agonists and antagonists were described (Gaster et al. 1995; Eglen and Hedge 1996; Eglen 1997).

Dumuis et al. (1992) characterized DAU 6285, a novel 5-HT_4 receptor antagonist of the azabicycloalkyl benzamidazolone class.

Wardle et al. (1994) described the effects of SB 204070, a highly potent and selective 5-HT_4 receptor antagonist on guinea pig distal colon.

The 5-HT_4 binding site in human brain was characterized by Arranz et al. (1998).

López-Rodríguez et al. (1999) reported the synthesis and structure–activity relationships of new benzimidazole-4-carboxamides and carboxylates as potent and selective 5-HT_4 receptor antagonists.

Radioligand binding assays for 5-HT_4 receptors using [^{3}H]-GR113808 have been described by Grossman et al. (1993), Domenech et al. (1994), Schiavi et al. (1994), Katayama et al. (1995), Ansanay et al. (1996).

Brattelid et al. (2004) reported cloning, the pharmacological characterization and tissue distribution of a novel 5-HT_4 receptor splice variant, 5-HT_{4i}.

A survey on molecular biology and potential functional role of **5-HT_5, 5-HT_6, and 5-HT_7receptors** was given by Branchek and Zoombick (1997).

A review on 5-HT_5 receptors was given by Nelson (2004).

5-HT_6. The rat *5-HT_6* receptor has been cloned by Ruat et al. (1993). The distinguishing features of this receptor are the high affinity for a series of antipsychotic compounds as well as affinity for a number of cyclic antidepressants (Branchek 1995).

Bourson et al. (1995) used antisense oligonucleotides to determine the role of the 5-HT_6 receptor in the rat brain.

Boess et al. (1998) reported labelling of 5-hydroxytryptamine binding sites in rat and porcine striatum by the 5-HT_6 receptor-selective ligand [^{3}H]Ro 63–0563.

Branchek and Blackburn (2000) reviewed 5-HT_6 receptors as emerging targets for drug discovery.

A review on 5-HT_6 receptors was given by Wooley et al. (2004).

Routledge et al. (2000) characterized SB-271046 as a potent, selective and orally active 5-HT_6 receptor antagonist.

Wooley et al. (2003) reported the reversal of cholinergic-induced deficit in a rodent model of recognition memory by the selective 5-HT_6 receptor antagonist Ro 04–6790.

5-HT_7. Lovenberg et al. (1993), Shen et al. (1993), Gobbi et al. (1996), Villalón et al. (1997) described an adenyl cyclase-activating serotonin receptor (*5-HT_7*) implicated in the regulation of mammalian circadian rhythms.

A receptor autoradiographic and hybridization analysis of the distribution of the 5-HT_7 receptor in rat brain was reported by Gustafson et al. (1996).

Stowe and Barnes (1998) used [^{3}H]5$^-$carboxamidotryptamine for selective recognition sites in rat brain.

Three different splice variants of the 5-HT_7 receptor have been described both in rat and human tissues (Vanhoenacker et al. 2000).

Roth et al. (1994) described the binding of typical and atypical antipsychotic agents to 5-hydroxytryptamine-6 and 5-hydroxytryptamine-7 receptors.

Hedlund and Sutcliffe (2004) reviewed the functional, molecular, and pharmacological advances in 5-HT_7 receptor research.

Serotonin (5-HT_{1A}) Receptor: Binding of [^{3}H]-8-Hydroxy-2-(di-n-Propylamino)-Tetralin ([^{3}H]-DPAT)

PURPOSE AND RATIONALE

Determination of the affinity of test compounds for the 5-HT_{1A} receptor in brain may be useful for predicting compounds with novel anxiolytic or atypical anti-psychotic profiles.

The existence of at least two populations of 5-HT_1 receptors in rat brain was shown by differential sensitivity to spiroperidol (Pedigo et al. 1981). The spiroperidol-sensitive receptors were designated

as the 5-HT_{1A} subtype and the insensitive receptors were referred to as the 5-HT_{1B} subtype (Middlemis and Fozard 1983). Other 5-HT binding sites (5-HT_{1C}, 5-HT_{1D}, 5-HT_3 and 5-HT_4) have subsequently been identified in various species, based on differential sensitivity to 5-HT antagonists (Peroutka 1988).

Schlegel and Peroutka (1986) identified [^{3}H]DPAT as a selective ligand for the 5-HT_{1A} receptor. These authors reported that [^{3}H]DPAT labeled an autoreceptor. Lesion studies suggest that [^{3}H]DPAT labeled receptors are not terminal autoreceptors, but may be somatodendritic autoreceptors (Gozlan et al. 1983). Although DPAT decreases the firing rate in the raphe nucleus and inhibits 5-HT release, the actual location and function is somewhat controversial (Verge et al. 1986). These studies and the sensitivity of [^{3}H]DPAT binding to guanine nucleotides and effects on adenylate cyclase suggest that DPAT acts as an agonist at the 5-HT_{1A} receptor (Schlegel and Peroutka 1986).

Serotonin may play a role in anxiety, since drugs which reduce serotoninergic function have anxiolytic effects in animal models (Dourish et al. 1986). Since buspirone and its analogs have relatively higher affinity for the 5-HT_{1A} receptor than other receptors and no effect on the benzodiazepine site, their anxiolytic properties are attributed to activity at the 5-HT_{1A} receptor (Verge et al. 1986; Iversen 1984; Traber and Glaser 1987).

Besides 5-HT_{1A} receptor agonists (Misslin et al. 1990; Griebel et al. 1992; Hascoet et al. 1994; Stanhope and Dourish 1996), 5-HT_{1A} receptor antagonists (Traber and Glaser 1987; Fletcher et al. 1996; Johansson et al. 1997; Cao and Rodgers 1998), 5-HT_{2A} receptor antagonists (Griebel 1996), 5-HT_{2C} receptor antagonists (Jenck et al. 1998), mixed receptor agonists/antagonists (Kleven et al. (1997), 5-HT_3 receptor antagonists (Artais et al. 1995; Roca et al. 1995) and 5-HT_4 receptor antagonists (Kennett et al. 1997) exhibit anxiolytic properties (Handley and McBlane 1993).

Fletcher et al. (1995) described visualization and characterization of 5-HT receptors and transporters *in vivo* and in man.

Several 5-HT_{1A} receptor antagonists were described in preclinical studies, such as **NAN-190** (Deans et al. 1989; Rydelek-Fitzgerald et al. 1990; Neckelmann et al. 1996), **(–)-alprenolol** (Bjorvatn et al. 1992), **pindolol** (Bel et al. 1994; Dreshfield et al. 1996; Seifritz et al. (1997), **BMY 7378** (Sharp et al. 1990; Grasby et al. 1992), **WAY 100635** (Fletcher et al. 1996; Trillat et al. 1998; Harder and Ridley 2000; Smart and Biello 2001), **(–)tertatolol** (Jolas et al. 2004).

Millan et al. (1999, 2001), Mattson et al. (2003), and Gilbert et al. (2004) described specific 5-HT_{1A} receptor antagonists.

PROCEDURE

Reagents

1. Tris buffers, pH 7.7
   a) 57.2 g Tris HCl
      16.2 g Tris base
      q.s. to 1 liter with distilled water (0.5 M Tris buffer, pH 7.7)
   b) Make a 1:10 dilution in deionized H_2O (0.05 M Tris buffer, pH 7.7)
   c) 0.05 M Tris buffer, pH 7.7 containing 10 µM pargyline, 4 mM $CaCl_2$ and 0.1% ascorbic acid.
      0.49 mg pargyline HCl
      111 mg $CaCl_2$
      250 mg ascorbic acid
      q.s. to 250 ml with 0.05 M Tris buffer, pH 7.7 (reagent 1b)
2. [^{3}H]-DPAT (2-(N,N-Di[2,3(n)$^{-3}$H]propylamino)-8-hydroxy-1,2,3,4-tetrahydronaphthalene) (160–206 Ci/mmol) was obtained from Amersham. For IC_{50} determinations: a 10 nM stock solution is made up and 50 µl are added to each tube (final concentration = 0.5 nM).
3. Serotonin creatinine sulfate. 0.5 mM stock solution is made up in 0.01 N HCl and 20 µl added to 3 tubes for determination of nonspecific binding (final concentration = 10 µM).
4. 4. Test compounds:
   For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentrations in the assay range from 2×10^{-5} to 2×10^{-8} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used based on the potency of the drug.

Tissue Preparation

Male Wistar rats are sacrificed by decapitation. Hippocampi are removed, weighed and homogenized in 20 volumes of 0.05 M Tris buffer, pH 7.7. The homogenate is centrifuged at 48,000 *g* for 10 min and the supernatant is discarded. The pellet is resuspended in an equal volume of 0.05 M Tris buffer, incubated at 37°C for 10 min and recentrifuged at 48,000 *g* for 10 min. The final membrane pellet is resuspended in 0.05 M Tris buffer containing 4 mM $CaCl_2$, 0.1% ascorbic acid and 10 µM pargyline.

Assay

800 µl Tissue

130 µl 0.05 M Tris + $CaCl_2$ + pargyline + ascorbic acid

20 µl vehicle/5-HT/drug

50 µl [^{3}H]DPAT

Tubes are incubated for 15 min at 25°C. The assay is stopped by vacuum filtration through Whatman GF/B filters which are then washed 2 times with 5 ml of ice-cold 0.05 M Tris buffer. The filters are then placed into scintillation vials with 10 ml of Liquiscint scintillation cocktail and counted.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of 10 µM 5-HT. IC_{50} values are calculated from the percent specific binding at each drug concentration. The K_i value may then be calculated by the Cheng–Prusoff equation:

$$K_i = IC_{50}/1 + L/K_D$$

The K_D value for [^{3}H] DPAT binding was found to be 1.3 nM by Scatchard analysis in a receptor saturation experiment.

MODIFICATIONS OF THE METHOD

Yocca et al. (1987) described BMY 7378, a buspirone analog with high affinity, selectivity and low intrinsic activity at the 5-HT_{1A} receptor in rat and guinea pig hippocampal membranes.

Instead of the selective 5-HT_{1A} agonist 8-hydroxy-2-(di-n-propylamino)-tetralin (DPAT), selective antagonists to the 5-HT_{1A} receptor, 4-(methoxyphenyl)-1-[2′-(n-2″-pyridinyl)-p-iodobenzamido]-ethyl-piperazine ([^{125}I]p-MPPI), and [^{3}H]p-MPPF = 4-(2′-methoxy-)-phenyl-1-[2′-(*N*-2″-pyridyl)-*p*-fluorobenzamido] ethyl-piperazine have been recommended (Kung et al. 1994a, 1994b, 1995, 1996).

Several other selective 5-HT_{1A} receptor radioligands were recommended:

[^{3}H]lisuride (Sundaram et al. 1995); [^{3}H]WAY-100635 ([O-methyl-^{3}H]-N-(2-(4-(2-methoxyphenyl)-1-piperazinyl)ethyl)-N-(2-piridinyl)cyclohexane carboxamide trihydrochloride) (Laporte et al. 1994; Gozlan et al. 1995; Hume et al. 1995; Khawaja 1995; Khawaja et al. 1997); [^{3}H]Alnespirone (Fabre et al. 1997); [Carbonyl^{11}C]-Desmethyl-WAY 100635 (Pike et al. 1998); [^{3}H]S 15535 (4-(benzodioxan-5-yl)-1-(indan-2-yl)piperazine) (Newman-Tancredi et al. 1998a); NAD-299 (= (R)-3-N,N-dicyclobutylamino-8-fluoro-[6-^{3}H]-3,4-dihydro-2H-1-benzopyran-carboxamide) (Jerning et al. 1998; Sandell et al. 1999).

Newman-Tancredi et al. (1998b) performed autoradiographic studies with [^{35}S]-GTPγS and the selective radioligand [^{3}H]S 15535 for parallel evaluation of localization and functionality of the 5-HT_{1A} receptor.

Agonist-Stimulated [^{35}S]-GTPγS Binding

Agonist-stimulated [^{35}S]-GTPγS binding is the initial step in signal transduction following G protein activation (Elmendorf et al. 1998; Standaert et al. 1998; Lee et al. 1999). It can be used as an index of receptor stimulation, such as 5-HT_{1A} receptors (Alper and Nelson 1998, 2000; Hughes et al. 2005).

PROCEDURE

Sprague Dawley rats were killed by decapitation, the brains placed in ice-cold 0.9% NaCl for 1–3 min, the hippocampi dissected free-hand and placed in a vial on ice. The tissue was weighed and frozen at -70°C. Upon defrosting the tissue was homogenized using a Tekmar tissue homogenizer in cold Tris buffer (50 mM Tris base, pH 7.4). The homogenate was centrifuged (39,800 *g*, 4°C for 10 min), the supernatant decanted and the remaining pellet resuspended in the same Tris buffer. After homogenization the suspension was incubated at 37°C for 10 min in a shaking water bath. The suspension was then centrifuged, the supernatant decanted and the pellet again washed with cold Tris buffer. After one final centrifugation, the remaining pellet was homogenized in the same Tris buffer at a final concentration of approximately 100 mg tissue/ml. This suspension was frozen in aliquots at -70°C for later use. On the day of the assay, the frozen tissue suspension was defrosted, resuspended in approximately 35 ml Tris buffer and centrifuged as above. This final membrane pellet was suspended in assay buffer (4 mM $MgCl_2$, 160 mM NaCl, 0.267 mM EGTA, 67 mM Tris base, pH 7.4) to produce a protein concentration approximating 200 µg/ml.

GTPγS Binding Assay

To each assay tube was added 200 µl deionized water or drug, 200 µl [^{35}S]GTPγS (0.1 nM) in ligand buffer (assay buffer containing 1200 µM GDP to produce a final concentration of 300 µM), 200 µl assay buffer and 200 µl tissue homogenate (approximately 30–50 µg protein). The assay tubes were incubated for 30 min in a shaking water bath. All assays were conducted at 37°C. The reaction was terminated by rapid vacuum filtration through Whatman GF/B filters pre-

wet with 20 mM $Na_4P_2O_7 \cdot 10H_2O$ and pre-cooled with three washes of 2 ml cold 50 mM Tris buffer. After filtering the reaction mixture, the filters were washed 4 times with 1 ml cold 50 mM Tris buffer, placed into 7-ml scintillation vials and 5 ml Ready Protein scintillation cocktail added. The samples were shaken, allowed to sit for a minimum of 2 h, shaken again and counted (2 min/sample) in a Beckman scintillation counter. Non-specific binding was determined by the amount of [^{35}S]-GTPγS bound in the presence of 10 µM unlabeled GTPγS and was subtracted from all samples. Basal GTPγS binding is defined as the specific binding when 200 µl water containing no ligand was added to the assay tube. This is also referred to as agonist-independent binding.

E.2.1.3.3 Serotonin (5-HT_{1B}) Receptors in Brain: Binding of [^{3}H]5-Hydroxytryptamine ([^{3}H]5-HT)

PURPOSE AND RATIONALE

The purpose of this assay is to determine the affinity of test compounds for the serotonin (5-HT_{1B}) receptor in brain.

The existence of two populations of 5-HT_1 receptors in rat brain was shown by differential sensitivity to spiroperidol (Pedigo et al. 1981). The spiroperidol-sensitive receptors were designated as the 5-HT_{1A} subtype and the insensitive receptors were referred to as the 5-HT_{1B} subtype (Middlemiss and Fozard 1983). The 5-HT_{1B} subtype has been identified in the brain of rats and mice (Peroutka 1986) and can be selectively labeled by 5-HT in rat striatum when spiroperidol is included to mask the 5-HT_{1A} and 5-HT_2 receptors. In contrast to the situation in rats and mice,

[^{3}H]5-HT binding in the basal ganglia of other mammals displays a pharmacological profile characteristic of 5-HT_{1D} sites. The distribution of 5-HT_{1B} sites in rat brain is similar to that of 5-HT_{1D} sites in human brain (Segu et al. 1991; Boulenguez et al. 1992; Palacios et al. 1992). Several 5-HT_{1B} antagonists have been described (Price et al. 1997; Selkirk et al. 1998).

By comparing the results in the 5-HT_{1B} assay with those in the 5-HT_{1A}, 5-HT_2 and the 5-HT_3 receptor binding assays the relative affinity of a test compound for the major subclasses of 5-HT receptors in the rat brain can be determined.

PROCEDURE

Reagents

1. Tris buffers, pH 7.7
   a) 57.2 g Tris HCl
      16.2 g Tris base
      q.s. to 1 liter with distilled water (0.5 M Tris buffer, pH 7.7)
   b) Make a 1:10 dilution in deionized H_2O (0.05 M Tris buffer, pH 7.7)
   c) 0.05 M Tris buffer, pH 7.7 containing 10 mM pargyline, 4 mM $CaCl_2$ and 0.1% ascorbic acid.
      0.49 mg pargyline HCl
      110.99 mg $CaCl_2$
      250 mg ascorbic acid
      q.s. to 250 ml with 0.5 M Tris buffer, pH 7.7.
2. 5-Hydroxy[G-^{3}H]tryptamine creatinine sulfate (17–20 Ci/mmol) (Amersham). For IC_{50} determinations: a 40 nM stock solution is made up and 50 ml added to each tube (final concentration = 2.0 nM).
3. Serotonin creatinine sulfate. A 0.5 mM stock solution is made up in 0.01 N HCl and 20 ml added to 3 tubes for determination of nonspecific binding (final concentration = 10 µM).
4. Spiroperidol is dissolved in dilute glacial acetic acid. A 20 µM stock solution is prepared and 50 µl added to each tube to prevent binding to 5-HT_{1A} and 5-HT_2 receptors (final concentration in the assay = 1 µM).
5. Test compounds:
   For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 2×10^{-5} to 2×10^{-8} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used based on the potency of the drug.

Tissue Preparation

Male Wistar rats are sacrificed by decapitation. Striata are removed, weighed and homogenized in 20 volumes of 0.05 M Tris buffer, pH 7.7. The homogenate is centrifuged at 48,000 *g* for 10 min and the supernatant is discarded. The pellet is resuspended in an equal volume of 0.05 M Tris buffer, incubated at 37°C for 10 min and recentrifuged at 48,000 *g* for 10 min. The final membrane pellet is resuspended in 0.05 M Tris buffer containing 4 mM $CaCl_2$, 0.1% ascorbic acid and 10 mM pargyline.

Assay

800 µl	tissue
80 µl	0.05 M Tris + $CaCl_2$ + pargyline + ascorbic acid
20 µl	vehicle/ 5-HT/ drug
50 µl	[^{3}H]5-HT
50 µl	spiroperidol

Tubes are incubated for 15 min at 25°C. The assay is stopped by vacuum filtration through Whatman GF/B filters which are then washed 2 times with 5 ml of ice-cold 0.05 M Tris buffer. The filters are then placed into scintillation vials with 10 ml of Liquiscint scintillation cocktail and counted.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of 10 µM 5-HT. IC_{50} values are calculated from the percent specific binding at each drug concentration. The K_i value may then be calculated by the Cheng–Prusoff equation:

$$K_i = IC_{50}/1 + L/K_D$$

The K_D value for [^{3}H] 5-HT binding was found to be 16.5 nM by Scatchard analysis of a receptor saturation experiment.

MODIFICATIONS OF THE METHOD

[^{3}H]CP-96,501 = 3-(1,2,5,6-Tetrahydro-4-pyridyl-5-n-propoxyindole was recommended as a selective 5-HT_{1B} receptor radioligand (Koe et al. 1992; Lebel and Koe 1992).

Domenech et al. (1997) characterized human serotonin 1D and 1B receptors using [^{3}H]-GR-125743, a novel radiolabelled serotonin 5-$HT_{1D/1B}$ receptor antagonist.

[^{3}H]mesulergine has been used as radioligand for 5-HT_{1C} receptor binding (Jenck et al. 1993, 1994).

[^{3}H]-5-carboxytryptamine was recommended as label for 5-HT_{1D} binding sites (Mahle et al. 1991; Novak et al. 1993).

Massot et al. (1998) described molecular, cellular and physiological characteristics of 5-HT-moduline, a tetrapeptide (Leu-Ser-Ala-Leu), acting as endogenous modulator of the 5-HT_{1B} receptor subtype.

E.2.1.3.4
5-HT_3 Receptor in Rat Entorhinal Cortex Membranes: Binding of [^{3}H]GR 65630

PURPOSE AND RATIONALE

The purpose of this assay is to determine the affinity of test compounds for the 5-HT_3 binding site in the brain. This assay may be useful for predicting the potential of compounds to exhibit anti-emetic, anxiolytic or atypical antipsychotic profiles.

The 5-HT_3 binding site has also been characterized on operational, transductional and structural characteristics. Originally it was believed that 5-HT_3 binding sites existed only in the periphery (Costall et al. 1988). However, with the introduction of potent and selective 5-HT_3 antagonists such as GR65630, zacopride, ICS 205 930 and MDL 72222, and agonists, data from binding studies have indicated that 5-HT_3 binding sites are also located in selected areas of the brain (Kilpatrick et al. 1987, 1989; Barnes et al. 1988, 1990, 1992; Watling et al. 1988; Miller et al. 1992).

The highest levels of 5-HT_3 binding sites have been detected in limbic and dopamine containing brain areas (entorhinal cortex, amygdala, nucleus accumbens and tuberculum olfactorium) (Costall et al. 1988). Besides possessing selective binding in dopamine rich areas, 5-HT_3 antagonists have been reported to block behavioral effects associated with certain drugs of abuse (nicotine and morphine) and to be active in behavioral tests predictive of anxiolytic activity. Based on these selective regional binding results and behavioral studies, it has been speculated that 5-HT_3 antagonists may have a therapeutic benefit in disease states believed to be associated with excessive dopaminergic activity; i. e., schizophrenia, anxiety and drug abuse.

Several authors described synthesis, pharmacology and therapeutic potential of H_3 receptor agonists and antagonists (Leurs et al. 1995, 1998; Stark et al. 1996).

PROCEDURE

Reagents

1. 0.05 M Krebs-HEPES buffer, pH 7.4
   11.92 g HEPES
   10.52 g NaCl
   0.373 g KCl
   0.277 g $CaCl_2$
   0.244 g $MgCl_2 \cdot 6H_2O$
   q.s. to 1 liter with distilled H_2O bring pH up to 7.4 (at 4°C) with 5N NaOH
2. [^{3}H]GR65630 (87.0 Ci/mmol) is obtained from New England Nuclear. For IC_{50} determinations: [^{3}H]GR65630 is made up to a concentration of 1.0 nM in Krebs-HEPES buffer such that when 100 µl is added to each tube a final concentration of 0.4 nM is attained in the 250 µl assay.
3. Ondansetron HCl (GR 38032F) is made up to a concentration of 500 µM in Krebs-HEPES buffer. 50 µl is added to each of 3 tubes for the determination of nonspecific binding (yielding a final concentration of 100 µM in the 250 µl assay.
4. Test compounds. For most assays, a 50 µM stock solution is made up in a suitable solvent and serially diluted with Krebs-HEPES buffer such that when 50 µl of drug is combined with the total 250 µl assay, a final concentration from 10^{-5} to 10^{-8} M is attained. Characteristically seven concentrations are studied for each assay; however, higher or lower concentrations may be used, depending on the potency of the drug.

Tissue Preparation

Male Wistar rats (150–200 g) are decapitated, the entorhinal cortex removed, weighed and homogenized in 10 volumes of ice-cold 0.05 M Krebs-HEPES buffer, pH 7.4. The homogenate is centrifuged at 48,000 *g* for 15 min at 4°C. The resulting pellet is rehomogenized in fresh Krebs-HEPES buffer and recentrifuged at 48,000 *g* for 15 min at 4°C. The final pellet is resuspended in the original volume of ice-cold Krebs-HEPES buffer. This yields a final tissue concentration of 1.2–1.6 mg/ml with the addition of 100 ml to the assay. Specific binding is approximately 55–65% of total bound ligand.

Assay

100 µl	Tissue suspension
100 µl	[^{3}H]GR65630
50 µl	Vehicle (for total binding) or 500 mM ondansetron HCl (for nonspecific binding) or appropriate drug concentration

Sample tubes are kept on ice for additions, then vortexed and incubated with continuous shaking for 30 min at 37°C. At the end of the incubation period, the incubate is diluted with 5 ml of ice-cold Krebs-HEPES buffer and immediately vacuum filtered through Whatman GF/B filters, followed by two 5-ml washes with ice-cold Krebs-HEPES buffer. The filters are dried and counted in 10 ml of liquid scintillation cocktail.

EVALUATION

Specific GR65630 binding is defined as the difference between the total binding and that bound in the presence of 100 µM Ondansetron HCl. IC_{50} calculations are performed using computer-derived log-probit analysis.

MODIFICATIONS OF THE METHOD

Dunn et al. (1991) found that preclinical data with 5-HT_3 antagonists predict anxiolytic rather than antipsychotic activity.

Davies et al. (1999) found that the 5-HT_{3B} subunit is a major determinant of serotonin receptor function.

Reiser and Hamprecht (1989) reported that substance P and serotonin (via 5-HT_3 receptors) act synergistically to activate the cation permeability as measured by [^{14}C]guanidinium uptake in neuroblastoma × glioma hybrid cells.

Bönisch et al. (1993) studied the 5-HT_3 receptor-mediated cation influx into N1E-115 mouse neuroblastoma cells by the use of the organic cation [^{14}C]-guanidinium.

Emerit et al. (1993) assessed the [^{14}C]guanidium accumulation in cells of the hybridoma (mouse neuroblastoma × rat glioma) clone NG 108–15 exposed to serotonin 5-HT$_3$ receptor ligands and substance P.

Bonhaus et al. (1993) characterized the binding of [^{3}H]endo-N-(8-methyl-8-azabicyclo[3.2.1.]oct-3-yl)-2,3-dihydro-3-ethyl-2-oxo-1H-benzimidazolone-1-carboxamide hydrochloride ([^{3}H]BIMU-1), a benzimidazolone with high affinity to 5-HT$_3$ and 5-HT$_4$ receptors in NG 108 cells and guinea pig hippocampus.

Kooyman et al. (1994) studied the specific binding of [^{3}H]GR65630 to 5-HT$_3$ recognition sites in cultured N1E-115 mouse neuroblastoma cells.

Several other selective 5-HT$_3$ receptor radioligands were recommended:

[^{3}H]Quipazine (Perry 1990); [^{3}H]GR67330 (Kilpatrick et al. 1990); tritium-labeled 1-methyl-N-[8-methyl-8-azabicyclo[3.2.1]oct-3-yl)-1H-indazole-3-carboxamide (Robertson et al. 1990); [^{125}I]-(S)-iodozacopride (Gehlert et al. 1993); [^{3}H]-BRL46470 (Steward et al. 1995); [^{3}H]YM060 (Azukawa et al. 1995); (^{125}I)iodophenpropit (Jansen et al. 1994), (^{125}I)iodoproxyfan (Ligenau et al 1994), (S)-Des-4-amino-3-[^{125}I]iodozacopride (Mason et al. 1996; Hewlett et al. 1998,1999).

Tairi et al. (1998) and Hovius et al. (1999) studied ligand binding to the serotonin 5-HT$_3$ receptor with a novel fluorescence ligand and developed a total internal reflection fluorescence assay which is suitable for high-through-put screening.

Thompson et al. (2005) reported locating an antagonist in the 5-HT$_3$ receptor binding site using modeling and radioligand binding.

E.2.1.4 Histamine H_3 Receptor Binding in Brain

PURPOSE AND RATIONALE

Histamine receptors have been classified on the basis of pharmacological analysis (Hill et al. 1997). Histamine exerts its action via at least four receptor subtypes. The H_1 receptor couples mainly to $G_{q/11}$, thereby stimulating phospholipase C, whereas the H_2 receptor interacts with G_s to activate adenylyl cyclase. The histamine H_3 and H_4 receptors couple to G_i proteins to inhibit adenylyl cyclase, and to stimulate MAPK. The histamine H_3 receptor is regarded as a therapeutic target for cognitive and sleep disorders (Leurs et al. 1991, 1998, 2005; Passani et al. 2004).

Histamine modulates its own synthesis and release from depolarized brain slices or synaptosomes by interacting with H_3 autoreceptors with a pharmacology distinct from that of H_1 and H_2 receptors (Arrang et al. 1985, 1987, 1990; Hill 1990, 1992; Hill et al. 1997; Leurs et al. 1991, 1998). The R-isomer of α-methylhistamine (α-MeHA) was identified as a highly selective H_3-receptor agonist active at nanomolar concentrations. Furthermore, this compound in ^{3}H-labeled form is a suitable probe for the H_3-receptor.

PROCEDURE

The cerebral cortex from guinea pigs is dissected and homogenized in 50 volumes ice-cold 50 mM KH_2PO_4/Na_2HPO_4 buffer, pH 7.5, in a Potter homogenizer. The homogenate is centrifuged for 15 min at 750 g. The pellet is discarded and the supernatant centrifuged at 42,000 *g* for 15 min. The supernatant is discarded and the pellet washed superficially with and then resuspended in fresh buffer. The protein concentration of the membrane suspension as determined according to Lowry et al. (1951) is about 0.3–0.4 mg/ml.

Aliquots of the membrane preparation are incubated for 60 min at 25°C with ^{3}H(R) α-MeHA and unlabeled substances in a final volume of 1 ml. The assay is stopped by dilution with 2 × 3 ml ice-cold medium, followed by rapid filtration under vacuum over Millipore AAWP filters which are then rinsed twice with 5 ml of ice-cold medium. Radioactivity retained on the filters is measured by liquid scintillation spectroscopy.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of 10 µM unlabeled α-MeHA. IC_{50} values are calculated from the percent specific binding at each drug concentration. The K_i value may then be calculated by the Cheng–Prusoff equation:

$$K_i = IC_{50}/1 + L/K_D$$

MODIFICATIONS OF THE METHOD

Jansen et al. (1992) described [^{125}I]iodophenpropit as a radiolabeled histamine H_3 receptor antagonist.

E.2.2 Anticonvulsant Activity

E.2.2.1 Pentylenetetrazole (Metrazol) Induced Convulsions

PURPOSE AND RATIONALE

This assay has been used primarily to evaluate antiepileptic drugs. However, it has been shown that most anxiolytic agents are also able to prevent or antagonize Metrazol-induced convulsions.

PROCEDURE

Mice of either sex with a body weight between 18 and 22 g are used. The test compound or the reference drug is injected sc. or i.p. or given orally to groups of 10 mice. Another group of 10 mice serves as control. Fifteen min after sc.-injection, 30 min after i.p.-injection, or 60 min after oral administration 60 mg/kg MTZ (Metrazol) are injected subcutaneously. Each animal is placed into an individual plastic cage for observation lasting 1 h. Seizures and tonic-clonic convulsions are recorded. At least 80% of the animals in the control group have to show convulsions.

EVALUATION

The number of protected animals in the treated groups is calculated as percentage of affected animals in the control group. ED_{50}-values can be calculated. Furthermore, the time interval between MTZ-injection and occurrence of seizures can be measured. The delay of onset is calculated in comparison with the control group.

CRITICAL ASSESSMENT OF THE METHOD

The method is widely accepted as a screening procedure and has been modified by many investigators. Chlordiazepoxide (20 mg/kg i.p.), diphenylhydantoin

(10 mg/kg i.p.) and phenobarbitone sodium (20 mg/kg i.p.) were found to be effective. Predominantly, the muscle relaxant and anticonvulsant effects of benzodiazepines are measured by this test. Stimulant, anti-depressant, neuroleptic and some anti-epileptic drugs do not show MTZ-antagonism at tolerable doses (Lippa et al. 1979). Nevertheless, the antagonism of MTZ-induced seizures appears to be a suitable procedure for detecting compounds with potential anxiolytic activity. Among a battery of tests, the MTZ-antagonism has been proposed to study centrally acting skeletal muscle relaxants (Bastian et al. 1959; Domino 1964).

MODIFICATIONS OF THE METHOD

Different routes of administration (i.p., i.v., s.c.) have been used by various investigators. Moreover, the dose of MTZ which causes seizures in 80 to 90% of the animals varies with the strain being used.

Bastian et al. (1959) published a modification, whereby mice are infused with a MTZ-solution through a small-diameter polyethylene tubing into the tail vein. In the same animal 3 end-points are registered: 1. Onset of persistent clonic convulsions, 2. beginning of the tonic flexor phase, and 3. time to death. The three endpoints are affected differently by various drugs providing the basis for the determination of drug specificity.

Löscher et al. (1991) tested 8 clinically established antiepileptic drugs in three pentylentetrazole seizure models: (1) the threshold for different types of pentylentetrazole seizures, i. e., initial myoclonus twitch, generalized clonus with loss of righting reflexes and tonic backward extension of forelimbs (forelimb tonus) in mice; (2) the traditional pentylentetrazole seizure test with s.c. injection of the CD97 for generalized clonic seizures in mice; and (3) the s.c. pentylentetrazole seizure test in rats. Various factors may cause misleading predictions from pentylentetrazole seizure models.

E.2.2.2 Strychnine-Induced Convulsions

PURPOSE AND RATIONALE

The convulsing action of strychnine is due to interference with postsynaptic inhibition mediated by glycine. Glycine is an important inhibitory transmitter to motoneurons and interneurons in the spinal cord, and strychnine acts as a selective, competitive antagonist to block the inhibitory effects of glycine at all glycine receptors. Strychnine-sensitive postsynaptic inhibition in higher centers of the CNS is also mediated by glycine. Compounds which reverse the action of strychnine have been shown to have anxiolytic properties.

PROCEDURE

Groups of 10 mice of either sex with a weight between 18 and 22 g are used. They are treated orally with the test compound or the standard (e. g. diazepam 5 mg/kg). One hour later the mice are injected with 2 mg/kg strychnine nitrate i.p. The time until occurrence of tonic extensor convulsions and death is noted during a 1 h period. With this dose of strychnine convulsions are observed in 80% of the controls.

EVALUATION

ED_{50}-values are calculated using various doses taking the percentage of the controls as 100%. For time-response curves the interval between treatment and strychnine injection varies from 30 to 120 min.

CRITICAL ASSESSMENT OF THE METHOD

The method has been proven to be useful in a battery of tests to characterize CNS-active drugs. (Costa et al. 1975).

MODIFICATIONS OF THE METHOD

McAllister (1992) induced spinal seizures in mice by rotating them along the body axis clockwise and anticlockwise alternatively three times following pretreatment with a subconvulsive dose of strychnine.

Lambert et al. (1994) tested the antagonism of a glycine derivative against seizures induced by 3-mercaptopropionic acid (3-MPA).

McAllister KH (1992) N-Methyl-D-aspartate receptor antagonists and channel blockers have different effects upon a spinal seizure model in mice. Eur J Pharmacol 211:105–108

E.2.2.3 Picrotoxin-Induced Convulsions

PURPOSE AND RATIONALE

Picrotoxin induced convulsions are used to further evaluate CNS-active compounds. Picrotoxin is regarded as a $GABA_A$-antagonist modifying the function of the chloride ion channel of the $GABA_A$ receptor complex.

PROCEDURE

Groups of 10 mice of either sex with a weight between 18 and 22 g are treated either orally or i.p. with the test compound or the standard (e. g. 10 mg/kg diazepam i.p.). Thirty min after i.p. treatment or 60 min after oral administration the animals are injected with 3.5 mg/kg s.c. picrotoxin and are observed for the following symptoms during the next 30 min: clonic seizures, tonic seizures, death. Times of onset of seizures and time to death are recorded.

EVALUATION

For time-response curves the animals receive the drug 30, 60 or 120 min prior to picrotoxin. Protection is expressed as percent inhibition relative to vehicle control. The time period with the greatest percent inhibition is said to be the peak time of drug activity. ED_{50}-values are calculated taking the percentage of seizures in the control group as 100%.

CRITICAL ASSESSMENT OF THE METHOD

The method has been proven to be of value amongst a battery of tests for CNS-activity.

MODIFICATIONS OF THE METHOD

Buckett (1981) describes an intravenous bicuculline test in mice (see Sect. E.3.2.6). The compound bicuculline antagonizes the action of GABA by competition on postsynaptic receptors. In the whole animal bicuculline reproducibly induces myoclonic seizures. An intravenous dose of 0.55 mg/kg was found to induce myoclonic seizures in 90–100% of mice with less than 10% mortality. GABAergic compounds such as benzodiazepines at relatively low doses antagonize the bicuculline-induced myoclonic seizures.

E.2.2.4 Isoniazid-Induced Convulsions

PURPOSE AND RATIONALE

Isoniazid can precipitate convulsions in patients with seizure disorders. The compound is regarded as a GABA-synthesis inhibitor (Costa et al. 1975). Clonic-tonic seizures are elicited in mice which are antagonized by anxiolytic drugs.

PROCEDURE

Ten mice of either sex with a weight of 18 to 22 g are treated with the test compound or the standard (e. g. diazepam 10 mg/kg i.p.) by oral or intraperitoneal administration. Controls receive the vehicle only. 30 min after i.p. or 60 min after p.o. treatment the animals are injected with a subcutaneous dose of 300 mg/kg isoniazid (isonicotinic acid hydrazide). During the next 120 min the occurrence of clonic seizures, tonic seizures and death is recorded.

EVALUATION

The percentage of seizures or death occurring in the control group is taken as 100%. The suppression of these effects in the treated groups is calculated as percentage of controls. ED_{50}-values are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The method has been proven to be of value amongst a battery of tests for CNS-activity.

REFERENCES AND FURTHER READING

E.2.2.5 Yohimbine-Induced Convulsions

PURPOSE AND RATIONALE

Antagonism against yohimbine-induced seizures in mice is considered to be a model predictive of potential anxiolytic and GABA-mimetic agents (Dunn and Fielding 1987).

PROCEDURE

Male Swiss-Webster mice (20–30 g) are individually placed in clear plastic cylinders and test compounds are administered i.p. 30 min prior to 45 mg/kg s.c. of yohimbine HCl. The animals are observed for the onset and number of clonic seizures for 60 min.

EVALUATION

ED_{50} values with 95% confidence limits are calculated for the antagonism of yohimbine-induced clonic seizures by means of the Lichtfield-Wilcoxon procedure.

CRITICAL ASSESSMENT OF THE METHOD

The antagonism against yohimbine-induced seizures can be regarded as an useful test amongst a battery of tests for anxiolytic activity.

E.2.3 Anti-Aggressive Activity

E.2.3.1 Foot-Shock-Induced Aggression

PURPOSE AND RATIONALE

Since the discovery of the taming effects of benzodiazepines in vicious monkeys (Heise and Boff 1961; Randall et al. 1961) tests for agents with anti-aggressivity activity have been developed for various animal species. These tests include foot-shock induced aggression in mice and rats, fighting behavior of isolated mice and aggressiveness of rats which become extremely vicious after lesions in the septal area of the brain (Brady and Nauta 1953).

Foot-shock induced aggression is used for further characterization of centrally active drugs. Irwin et al. (1971) have attempted to compare drug classes with this method.

PROCEDURE

Male mice (NMRI, Ivanovas) with a weight between 20 and 30 g are used. Two mice are placed in a box with a grid floor consisting of steel rods with a distance of 6 mm. A constant current of 0.6 or 0.8 mA is supplied to the grid floor by a LVE constant current shocker with an associated scrambler. A 60-Hz current is delivered for 5 s followed by 5 s. intermission for 3 min. Each pair of mice is dosed and tested without previous exposure. The total number of fights are recorded for each pair during the 3-min period. The fighting behavior consists of vocalization, leaping, running, rearing and facing each other with some attempt to attack by hitting, biting or boxing. The test compound or the standard are applied either 30 min before the test i.p. or 60 min before the test orally. For a time response, the drug is given 30, 60 and 120 min prior to testing. Six pairs of drug-treated and two pairs of vehicle-treated animals are utilized for each time period. A dose range is tested at the peak of drug activity. A minimum of 3 doses (10 pairs of mice/dose) is administered for a range of doses. Control animals receive the vehicle.

EVALUATION

The percent inhibition of aggression is calculated from the vehicle control. ED_{50}-values are calculated.

CRITICAL ASSESSMENT OF THE METHOD

Not only anxiolytics but also other classes of drugs where found to be active in this test such as sedatives like meprobamate and phenobarbital, neuroleptics such as perphenazine, analgesics such as methadone, and ethyl alcohol.

MODIFICATIONS OF THE METHOD

A survey of aggressive behavior in the **rat** has been given by Blanchard and Blanchard (1977).

Induction of aggressive behavior by electrical stimulation in the hypothalamus of male rats was described by Kruk et al. (1979).

Mos and Olivier (1991) reviewed the concepts in animal models for pathological aggressive behavior in human.

Play fighting, a normal behavior in several species especially in young male rats (Pellis and McKenna 1995; Pellis et al. 1997; Pellis and Pellis 1998; Pellis 2002), has been used for evaluation of drugs by Siviy et al. (1995) and Hotchkiss et al. (2003). Schneider and Koch (2005) studied the effects of chronic pubertal treatment with cannabinoids on play behavior (pins, attacks, and defense) in rats.

E.2.3.2 Isolation-Induced Aggression

PURPOSE AND RATIONALE

Male mice, submitted to prolonged isolation, develop aggressive behavior against animals of the same sex. Compounds can be tested for their ability to suppress this isolation-induced aggression.

PROCEDURE

Male mice of NMRI-strain with an initial weight of 12 g are kept isolated in small Makrolon-cages for a period of 6 weeks. Prior to the administration of the test drug, the aggressive behavior of the animals is tested. A male mouse being accustomed to live together with other animals is placed into the cage of an isolated mouse for 5 min. Immediately, the isolated mouse will start to attack the "intruder". The aggressive behavior of the isolated mouse is characterized by hitting the tail on the bottom of the cage, screaming and biting. The reaction time until the first attack is less than 10 s for most of the isolated mice and relatively constant for one individual. After these initial tests, the isolated mice receive the test compound, the standard drug or the vehicle either orally or subcutaneously. The aggressive behavior is evaluated 60, 120 and 240 min after oral and 30, 60 and 120 min after sc. treatment. After treatment with certain centrally acting compounds the aggressive behavior of the isolated mice is changed. The reaction time until the first attack can be prolonged or shortened. The fighting reaction can be attenuated. Then, additional mechanical stimuli can be used to elicit the fighting behavior. With highly effective drugs the aggressive behavior is completely suppressed.

EVALUATION

The number of animals with complete suppression of the fighting behavior is calculated. In animals with

diminished aggressiveness the reaction time is registered. A gradual scale of inhibition of aggressiveness is established.

CRITICAL ASSESSMENT OF THE METHOD

The fighting behavior of isolated mice is not only altered by sedative and anxiolytic compounds but also by neuroleptics and antidepressants. For example, active doses are:

Lorazepam	2.5 mg/kg p.o.
Clonazepam	2.5 mg/kg sc.
Haloperidol	1.0 mg/kg p.o.
Chlorpromazine	10.0 mg/kg s.c.
Imipramine	25.0 mg/kg s.c.

In this way, anti-aggressive activity of several classes can be detected.

MODIFICATIONS OF THE METHOD

Krsiak (1974, 1979) described the effects of various drugs on behavior of aggressive **mice**.

Olivier and van Dalen (1982) discussed the social behavior in rats and mice as an ethologically based model for differentiating psychoactive drugs.

McMillen et al. (1987) tested the effects of drugs on aggressive behavior and brain monoaminergic neurotransmission.

Krsiak (1975) showed that about 45% of single-housed male mice showed timidity instead of aggression on interactions with group-housed male mice. Several drugs, such as benzodiazepines, chlorpromazine and barbitone inhibited the isolation induced timidity without reducing other motor activities in the timid mice.

Andrade et al. (1988) tested the effect of insulin-induced hypoglycemia on the aggressive behavior of isolated mice against intruders made anosmic by application of 25 µl of 4% zinc sulfate solution to the nasal tract 3 and 1 days before the encounters.

White et al. (1991) tested the effects of serotoninergic agents and other psychotropic compounds on isolation-induced aggression in mice at doses below those which produced debilitation in the rotarod performance. Guidotti et al. (2001) used the socially isolated mouse as a model to study the putative role of allopregnenolone and 5α-dihydroxyprogesterone in psychiatric disorders.

Francès (1988), Francès et al. (1990), Francès and Monier (1991) described an other phenomenon of isolation in rodents which can be used for evaluation of psychotropic drugs: the **isolation-induced behavioral deficit**. Male Swiss NMRI mice were either housed in groups of 6 in home cages or isolated at the age of 4–5 weeks for 7 days. Mice were tested in pairs (one isolated and one grouped mouse) under a transparent beaker. The number of escapes was counted for the first 2 min of observation. An attempt to escape was defined as one of the following: (1) the two forepaws were placed against the wall of the beaker, (2) the mouse was sniffing, its nose at the spout of the beaker, (3) the mouse was scratching at the glass floor. Behavioral observations were taped by an observer, blind to the treatment.

E.2.3.3 Resident-Intruder Aggression Test

PURPOSE AND RATIONALE

Sijbesma et al. (1991), Mos et al. (1992), Muehlenkamp et al. (1995) studied the effects of drugs in a test for offensive aggression, the isolation-induced resident intruder aggression model (Flannelly and Lore 1975; Brain et al. 1979), in the rat.

PROCEDURE

Sprague-Dawley rats weighing 250 to 450 g are housed in a light-dark (12L:12D)-, temperature (ca. 22°C)- and humidity (ca. 55%)-controlled room.

Resident male rats (about 450 g) are tested in their home cages for aggression against a smaller (250 g) male intruder. They are treated by intraperitoneal injection of test drug or saline 15 min before the test. The resident female is removed from the cage 30 min prior to the start of the test period. After placing the intruder rat in the territorial cage, the behavior of the resident male is observed. The time until the first attack (in seconds), number of attacks, and duration of each attack (in seconds) are recorded for the next 15 min by a blind observer. Furthermore, a total of 49 different behavioral elements are scored and grouped into 7 behavioral categories: offensive, exploration, social interest, inactivity, avoidance, body care, defense.

EVALUATION

Paired and unpaired *t*-tests are used for comparisons of means of absolute values.

E.2.3.4 Water Competition Test

PURPOSE AND RATIONALE

The competitive water consumption test in rats (Baenninger 1970; Syme 1974) can be used to study the influence of drugs on defensive aggression and dominance (Muehlenkamp et al. 1995).

PROCEDURE

Male Sprague-Dawley rats weighing 250 to 400 g are kept in a light-dark (12L:12D)-, temperature (ca. 22°C)- and humidity (ca. 55%)-controlled room.

Animals of equal weight are paired and housed in one cage. After 6 days, the animals are deprived of water for 23 h. Then, one water bottle is introduced with a shielded spout so that only one animal of a pair can drink at a time. Time (in seconds) and frequency of spout possession and water consumption are recorded in numbers with a special computer program for 5 min. Animals are then allowed another 55 min for water consumption. This test is repeated on 3 subsequent days. Saline or test substances are injected intraperitoneally 15 min before tests 3 and 4. The animal with

the longest duration of water consumption and frequency of spout possession is considered to be the more aggressive and/or dominant animal.

EVALUATION

Paired and unpaired *t*-tests are used for comparisons of means of absolute values, as well as means of differences of the absolute value of the two rats.

E.2.3.5 Maternal Aggression in Rats

PURPOSE AND RATIONALE

The model of 'maternal aggression' in rats was described by Olivier et al. (1985), Olivier and Mos (1986, 1992), Mos et al. (1987, 1989). Introduction of an intruder (male or female) in the cage of a parturient female rat, induces high levels of aggression against such intruders. Maternal aggression is characterized by short latency attacks of high intensity, mostly directed toward the head or neck of the intruder and is particularly pronounced during the first part of the lactating period. The behavior can be suppressed by several drugs, e. g., 5-HT_1 agonists (Mos et al. 1990; Olivier and Mos 1992).

PROCEDURE

Female rats weighing 250–350 g are placed with a breeding male in their home cages. On the bottom of each cage an iron gauze is placed which enables the collection of ejaculation plugs. After an ejaculation plug is detected the male is left for an other week with the female after which she is placed in the observation cage provided with nesting material where she stays for the rest of the experiment. These cages are situated in an observation room under a reversed day-night rhythm. The day of birth is marked as day 0. Every parturient female is tested each day against a naive male intruder which has about 25 g less body weight than the female. Tests are performed during the first part of the dark period under red light conditions. One male intruder is placed in the female's home cage for 5 min. The ongoing behavior is videotaped and analyzed later. Each intruder is used only once and sacrificed immediately afterwards with an i.p. overdose of pentobarbital, followed by shaving and describing the wounds on wound charts (Mos et al. 1984).

The aggressive behavior of the female is scored for:

- bite attack on the head (fierce biting on head and snout often causing severe wounds),
- bite attack on the body (mostly directed to the back),
- lateral threat (the animal kicks with a hindleg at the opponent),
- upright posture (accompanied by boxing),
- nipping (short and low intensity bite on the head of the opponent),
- pulling (the opponent is held by the teeth and drawn through the cage),
- lunge (very rapid movement toward the opponent, mostly followed by bite attacks),
- on top (the female holds down the opponent which lies on its back).

Besides the frequency and the duration of the elements, also the latency of the first attack and the number of attacks are recorded.

Drug experiments are performed on postpartum days 3, 5, 7, and 9 using a Latin-square design of dosage. Preceding days (day 1 and 2), intervening (4, 6 and 8) and following (10, 11, 12, and 13) days are used to establish an aggression base line and as washout days. Drugs are administered orally 60 min before testing.

EVALUATION

Analysis of variance is employed to detect overall significance, followed by Wilcoxon matched pairs comparison between dosages. Kruskal-Wallis analysis is used to test the differences in the bite target areas after drug treatment.

MODIFICATIONS OF THE METHOD

Postpartum aggression in rats did not influence threshold currents for electrical brain stimulation-induced aggression in rats (Mos et al. 1987).

Maternal aggression can be observed not only in rats but also in **mice** and **hamsters** (Mos et al. 1990).

Palanza et al. (1996) examined the effects of chlordiazepoxide on the differential response pattern in aggressive-naive and aggressive-experienced lactating female mice confronting intruders of either sex in a 10-min test.

Olivier et al. (1990) highlighted ethopharmacology as a creative approach to identification and characterization of novel psychotropics.

Olivier et al. (1995) gave a review on serotonin receptors and animal models of aggressive behavior.

E.2.3.6 Rage Reaction in Cats

PURPOSE AND RATIONALE

An emotional aggressive behavior (rage reaction) can be elicited in unrestrained cats by high frequency electrical stimulation of the hypothalamus. Benzodiazepines have been reported (Malick 1970; Mursaki et al. 1976) to elevate the stimulus threshold for eliciting this rage reaction.

PROCEDURE

Emotional aggressive behavior is evoked by stimulation of the perifornical area of the lateral hypothalamus through chronically implanted stainless steel bipolar concentric electrodes by using threshold impulses of 1.0–2.6 mA, delivered at 50 Hz, to evoke a control attack response. Stimulation is discontinued immediately after the slowly rising current has reached threshold strength, and is performed once before drug administration as well as every 30 min thereafter. Drugs are injected by intraperitoneal route.

EVALUATION

Post-drug values are expressed as percentage of the pre-drug control value. Student's paired *t*-test is used for each time interval.

CRITICAL ASSESSMENT OF THE TEST

The method has been used for evaluation of new drugs. Most studies were devoted to the role of neurotransmitters regulating feline aggression (Siegel and Schubert 1995; Siegel et al. 1998) and the neural bases of aggression and rage in the cat (Siegel et al. 1997, 1999).

E.2.4
Effects on Behavior

E.2.4.1
Anti-Anxiety Test (Light-Dark Model)

PURPOSE AND RATIONALE

Crawley and Goodwin (1980) Crawley (1981) described a simple behavior model in mice to detect compounds with anxiolytic effects. Mice and rats tend to explore a novel environment, but to retreat from the aversive properties of a brightly-lit open field. In a two-chambered system, where the animals can freely move between a brightly-lit open field and a dark corner, they show more crossings between the two chambers and more locomotor activity after treatment with anxiolytics. The numbers of crossings between the light and dark sites are recorded.

PROCEDURE

The testing apparatus consists of a light and a dark chamber divided by a photocell-equipped zone. A polypropylene animal cage, 44 × 21 × 21 cm, is darkened with black spray over one-third of its surface. A partition containing a 13 cm long × 5 cm high opening separates the dark one third from the bright two thirds of the cage. The cage rests on an Animex activity monitor which counts total locomotor activity. An electronic system using four sets of photocells across the partition automatically counts movements through the partition and clocks the time spent in the light and dark compartments. Naive male mice or rats are placed into the cage. The animals are treated 30 min before the experiment with the test drugs or the vehicle intraperitoneally and are then observed for 10 min. Groups of 6–8 animals are used for each dose.

EVALUATION

Dose-response curves are obtained and the number of crossings through the partition between the light and the dark chamber are compared with total activity counts during the 10 min.

CRITICAL ASSESSMENT OF THE METHOD

It has been shown that a variety of anxiolytics, including diazepam, pentobarbital and meprobamate produce a dose-dependent increase in crossings, whereas non-anxiolytic agents do not have this facilitatory effect. Furthermore, the relative potency of anxiolytics in increasing exploratory behavior in the two-compartment chamber agrees well with the potency found in clinical trials.

The test has the advantage of being relatively simple with no painful stimuli to the animals. The specificity of the method remains open.

MODIFICATIONS OF THE METHOD

Using a similar method, called black and white test box, Costall et al. (1987, 1988, 1989) studied the effects of anxiolytic agents and reported an anxiolytic effect of dopamine receptor antagonists, such as sulpiride and buspirone.

Sanchez (1995) presented a fully automated version of the black and white two-compartment box for mice.

Barnes et al. (1992) used this model to study the interaction of optical isomers modifying rodent aversive behavior.

Kilfoil et al. (1989) used a similar apparatus to test compounds for anxiogenic and anxiolytic activity.

Animal models of anxiety and their relation to serotonin-interacting drugs have been reviewed by Broekkamp et al. (1989) and by Griebel (1995).

Laboratory rats prefer to dwell on a solid floor rather than an grid one, particularly when resting. Manser et al. (1996) described an operant test in rats to determine the strength of preference for flooring. The apparatus consisted of a grid-floored cage and a solid-floored cage, joined via a central box containing a barrier whose weight was adjustable. The rats had to lift the barrier in order to explore the whole apparatus or were confined on the grid floor and then had to lift the barrier in order to reach the solid floor.

Hascoët and Bourin (1998) tested anxiolytic and psychostimulant drugs in a fully automated and computer-integrated two-compartment light/dark box.

E.2.4.2 Anticipatory Anxiety in Mice

PURPOSE AND RATIONALE

When group-housed mice are removed one by one from their home cage, the last mice removed have always higher rectal temperatures than those removed first (Borsini et al. 1989; Lecci et al. 1990). This phenomenon is interpreted as being caused by anticipatory fear for an aversive event (handling causes stress-induced hyperthermia). Consequently, this test is thought to be a model of anticipatory anxiety. The anticipatory increase in temperature was prevented by prior treatment with diazepam and buspirone, whereas several other drugs did not affect this phenomenon (Lecci et al. 1990). The usefulness of this model for obsessive-compulsive disorder in man is discussed.

PROCEDURE

Groups of 18 male albino Swiss mice weighing 25–30 g are housed at constant room temperature and relative humidity for at least 7 days in Makrolon cages to adapt to the environment. Test drugs or standard (diazepam) or solvent are administered orally in various doses to groups of 18 mice prior to the test. Thirty min later, the first 3 mice are removed from the cage and the rectal temperature registered by inserting a silicone lubricated thermistor probe (2 mm diameter) for 2.5 cm into the rectum. The average temperature of these 3 mice is taken as basal value. Mice number 4 through 15 are simply removed and again returned to the cage, and thereafter body temperature is determined in the remaining three animals. The difference of the mean value of these mice and the basal values is calculated as increase. Vehicle treated test groups display increases of 1.1 to 1.3°C.

EVALUATION

The mean increase values of treated groups ± SEM are compared by ANOVA statistics with the controls.

MODIFICATIONS OF THE METHOD

Van der Heyden et al. (1997) adapted the group-housed stress-induced hyperthermia paradigm to single housed animals in order to drastically reduce the number of animals used. Repeated, but not single, disturbance of animals resulted in a strong hyperthermia (Δt) within 10 min. The final test paradigm chosen involved repeated temperature measurements at 10 min intervals, thus providing both information on basal temperature and Δt in each animal within a short time frame.

E.2.4.3 Social Interaction in Rats

PURPOSE AND RATIONALE

In an unfamiliar and brightly lit environment, the normal social interaction of rats (e. g. sniffing, nipping, grooming) is suppressed. Anxiolytics counteract this suppression.

PROCEDURE

Male Sprague-Dawley rats (225–275 g body weight) are housed in groups of 5 animals The apparatus used for the detection of changes in social behavior and exploratory behavior consists of a Perspex open-topped box (51 × 51 cm and 20 cm high) with 17 × 17 cm marked areas on the floor. One hour prior to the test, two naive rats from separate housing cages are treated with the test compound orally. They are placed into the box (with 60 W bright illumination 17 cm above) and their behavior is observed over a 10-min period by remote video recording. Two types of behavior can be noted:

- social interaction between the animals is determined by timing the sniffing of partner, crawling under or climbing over the partner, genital investigation of partner, and following partner,
- exploratory motion is measured as the number of crossings of the lines marked on the floor of the test box.

Six pairs are used for each dose.

EVALUATION

The values of treated partners are compared with the data from 6 pairs of untreated animals using single factor analysis of variance followed by Dunnett's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

In spite of the fact that there may be some analogy between "social anxiety" in humans and the behavior of rats in the social interaction test, there appear some potential complications with this test, such as an increase of social interaction after anxiolytics independent from the environment, dependence on external variables such as time of the day, and the complicated nature of social interaction.

MODIFICATIONS OF THE TEST

Sams-Dodd (1995) described the automation of the social interaction test in rats by a commercially available video-tracking system.

Gheusi et al. (1994) studied the effects of tetrahydroaminoacridine (THA) on social recognition in rats indicating a dissociation of cognitive versus non-cognitive processes.

Doses of 1.0 to 4.0 mg/kg i.p. phencyclidine (PCP) reduce the social interaction time in rats in a dose-dependent fashion. Reversal of the PCP-induced social withdrawal has been used as an animal model for neuroleptic resistant schizophrenia (Carlsson and Carlsson 1990; Corbett et al. 1995).

Olfactory investigation of ovarectomized females by adult male mice decreases during repeated confrontations with the same female intruder, whereas aggressive behavior gradually increases (Winslow and Camacho 1995). Administration of scopolamine blocked decrements in olfactory investigation in repeated confrontations and significantly reduced aggression. Acetylcholinesterase inhibitors enhanced the rate of decrement of olfactory investigation, but had differential effects on aggression.

Wongwitdecha and Marsden (1996) investigated the effects of isolation rearing on anxiety using the social interaction paradigm and compared the effects of diazepam on social interactive behaviors in isolation and socially reared rats.

Sams-Dodd (1997) studied the effect of novel anti-psychotic drugs on phencyclidine-induced stereotyped behaviour and social isolation in the rat social interaction test.

The rat social interaction model has been used by various authors to characterize the potential anxiolytic effects of serotonin receptor antagonists, such as 5-HT_{1C} receptors antagonists (Kennett et al. 1989; Kennett 1992), 5-HT_2 receptor antagonists (Kennett et al. 1994, 1995, 1996a, b, 1997; Costall and Naylor 1995), 5-HT_3 receptor antagonists (Costall et al. 1990; Costall and Naylor 1992; Blackburn et al. 1993), 5-HT_4 receptor antagonists Kennett et al. (1997), cholestystokinin receptor antagonists (Hughes et al. 1990; Costall et al. 1991; Singh et al. 1991) and of nitric oxide synthase inhibitors (Volke et al. 1997).

File and Johnston (1989) reported a lack of effects of 5-HT_3 receptor antagonists in the social interaction test in the rat.

Woodall et al. (1996) described a **competition procedure** in rats. On the first week of experimentation groups of 3 rats (triads) are familiarized with the test box and sweetened milk from a drinking spout located

on the end wall. The drinking spout is surrounded by a Perspex tube (4.5 cm diameter) which ensures that only one animal is able to drink at a time. All animals are deprived of water overnight and on the following day placed into the testing box and given access to the sweetened milk for 15 min. On the second week of testing, the rats are not longer water deprived and are given access to the testing box and sweetened milk for 5 min. During the testing period, the rats are observed every 5 s, and a note is made which animal is drinking. This procedure is carried out twice a week for a period of 5 weeks. Drugs are administered to either the dominant or subordinate rat in each triad 15 min prior to testing. Following the drug study, all triads are tested for 2 trials to ensure that their rank orders return to baseline levels. The access of the subordinate member to sweetened milk is increased after administration of an anxiolytic drug.

E.2.4.4 Elevated Plus Maze Test

PURPOSE AND RATIONALE

Out of many possibilities to modify maze tests (e. g. water maze (Danks et al. 1991), Y-maze, radial maze (Di Cicco 1991)) the **elevated plus maze** (Montgomery 1958; Pellow et al. 1985; Corbett et al. 1991) has found acceptance in many laboratories (Liebisch et al. 1998; Landgraf et al. 1999; Schwarzberg et al. 1999; Keck et al. 2001; Brakebusch et al. 2002). The test has been proposed for selective identification of anxiolytic and anxiogenic drugs. Anxiolytic compounds, by decreasing anxiety, increase the open arm exploration time; anxiogenic compounds have the opposite effect.

For effects on learning and memory see Sect. F.3.3.3.

PROCEDURE

The plus-maze consists of two open arms, 43 × 15 cm (L × W), and two enclosed arms, 43 × 1523 cm (L × W × H), open to the top, arranged so that the two open arms are opposite to each other. The maze is elevated to a height of 70 cm (TSE Systems, Bad Homburg, Germany). The rats (200–250 g body weight) are housed in pairs for 10 days prior to testing in the apparatus. During this time the rats are handled by the investigator on alternate days to reduce stress. Groups consist of 6 rats for each dose. Thirty min after i.p. administration of the test drug or the standard, the rat is placed in the center of the maze, facing one of the enclosed arms. During a 5 min test period the following measures are taken: the number of entries into and time spent in the open and enclosed arms; the total number of arm entries. The procedure is conducted preferably in a sound attenuated room, with observations made from an adjacent room via a remote control TV camera.

EVALUATION

Motor activity and open arm exploratory time are registered. The values of treated groups are expressed as percentage of controls. Benzodiazepines and valproate decrease motor activity and increase open arm exploratory time.

CRITICAL ASSESSMENT OF THE METHOD

The method is rather time consuming, but can be regarded as a reliable measure of anxiolytic activity. Computerized automatic elevated plus maze systems may help to overcome these difficulties (TSE Systems, Bad Homburg, Germany).

MODIFICATIONS OF THE METHOD

Latency to enter a mirrored chamber by mice has been described as a behavioral assay for anxiolytic agents (Toubas et al. 1990).

Handley and McBlane (1993) provided an assessment of the elevated X-maze for studying anxiety and anxiety-modulating drugs.

Lapin (1995) studied the effect of handling, sham injection, and intraperitoneal injection of saline on the behavior of mice in an elevated plus-maze. These procedures produce behavior considered to be typical for anxiety inducing drugs. Saline-treated groups taken as controls possess the behavioral profile of stressed and anxious animals.

Pokk et al. (1996) described a method of small platform-induced stress whereby mice were individually placed for 24 h on a small platform (3 cm high, 3.5 cm in diameter) which was fixed at the center of a plastic chamber (20 cm diameter, 40 cm high) and was surrounded by water (1 cm deep) at 22°C.

Shepherd et al. (1994) described the **elevated "zero-maze"** as a modification of the elevated plus-maze model of anxiety in rats which incorporates both traditional and novel ethological measures in the analysis of drug effects. The design comprises an elevated annular platform with two opposite enclosed quadrants

and two open, removing any ambiguity in interpretation of time spent in the central square of the traditional design and allowing uninterrupted exploration. A similar equipment, built for mice (TSE Systems, Bad Homburg, Germany), was used by Cryan et al. (2004) and Korsgaard et al. (2005).

Jardim et al. (1999) evaluated the elevated T-maze as an animal model of anxiety in the mouse and found important differences between mice and rats.

Based on their plus-maze behavior, that is the time spent in the open arms, Ho et al. (2002) divided male Wistar rats into two subgroups with either "low" or "high" anxiety.

Silva and Frussa-Filho (2000) recommended the plus-maze discriminative avoidance task as a model to study memory–anxiety interactions. Mice are conditioned to choose between two enclosed arms (in one of which light and noise are presented as aversive stimuli) while avoiding the two open arms of the apparatus. The test has the advantage of measuring, at the same time and in the same animals, learning/memory (by the percentage of time spent in aversive closed arm) and anxiety (by the percentage of time spent in the open arms).

Montag-Sallaz and Montag (2003) tested cognitive and motor coordination deficits in Tenascin-R-deficient mice on an elevated plus maze. For 5 min, the behavior was recorded on videotape and the numbers of entries into the central part, the closed or the open arms were counted and the time spent in these departments was determined using the VideoMot 2 system (TSE Systems, Bad Homburg, Germany).

The same system was used by Karl et al. (2003) to study behavioral effects of neuropeptide Y in F344 rat substrains with reduced dipeptidyl-peptidase IV activity.

Korte and De Boer (2003) recommended fear-potentiated behavior in the elevated plus-maze in rats as a robust animal model of state anxiety.

E.2.4.5 Water Maze Test

PURPOSE AND RATIONALE

Spatial learning of rats can be tested in a water maze as described by Morris (1984) and McNaughton and Morris (1987).

For effects on learning and memory see Sect. F.3.3.5.

PROCEDURE

The water maze consists of a circular tank with 100 cm diameter and a wall 20 cm above the water level. A circular platform (9 cm diameter, covered with white linen material for grip) is hidden 2 cm below the water level. The water is made opaque using titanium dioxide suspension and is kept at about 23°C during the experiment. Training takes place on three consecutive days, with the rats receiving 4 consecutive trials per day with an inter-trial interval of 6–10 min. Each trial is started from one of four assigned polar positions with a different sequence each day. The latency to find the platform is measured as the time of placement of the rat in the water to the time it finds the platform. If the animal fails to find the platform in any trial within 3 min it is placed on it for 10 s.

EVALUATION

On day four a probe test is performed. The platform is removed and the time spent in the target quadrant (the quadrant in the center of which the platform has been located) and the number of annulus crossings (across the actual location where the platform has been located) in the first 60 s of exposure are measured. The time to the first annulus crossing is also taken as a measure of performance on the 13th (i. e. probe) trial.

Buspirone (Rowan et al. 1990) as well as benzodiazepines (McNaughton and Morris 1987) increase the latency to find the platform in the training period and impair the number and the time of annulus crossings.

CRITICAL ASSESSMENT OF THE METHOD

The water maze test measures learning and memory rather than the anxiolytic activity. If the test is used for memory, rats which have learned quickly and consistently to find the platform are kept in their cages for 2 weeks and then re-tested. Rats which solve the escape immediately, are considered to have retained memory (see also Sect. F.3.3.5).

MODIFICATIONS OF THE METHOD

Bane et al. (1996) used the Morris water maze to study the adverse effects of the non-competitive NMDA receptor antagonist dextromorphan on the spatial learning of rats.

Van der Staay (2000) studied the effects of the size of the Morris water tank on spatial discrimination learning in the CFW1 mouse. Mice can best be tested in a small pool, because the time and distance swam to find and escape onto the platform are decreased and the probability of success is increased.

Schmitt and Hiemke (2002) reported that a γ-aminobutyric acid transport inhibitor impairs spatial learning in the Morris water maze.

Winter et al. (2004) determined long-term functional outcome after mild focal cerebral ischemia by tracking swimming performance in a Morris water

maze with the computer-based VideoMot2 system (TSE Systems, Bad Homburg, Germany).

E.2.4.6 Staircase Test

PURPOSE AND RATIONALE

The staircase test for evaluating anxiolytic activity was originally described for rats by Thiebot et al. (1973). When introduced into a novel environment, rodents experience a conflict between anxiety and exploratory behavior manifested by increased vigilance and behavioral activity. In the staircase paradigm, step-climbing is purported to reflect exploratory or locomotor activity, while rearing behavior is an index of anxiety state. The number of rearings and steps climbed are recorded in a 5 min period. The dissociation of these parameters is considered to be characteristic for anxiolytic drugs. The test was modified for rapid screening of anxiolytic activity in mice (Simiand et al. 1984).

PROCEDURE

For experiments with mice the staircase is composed of five identical steps 2.5 cm high, 10 cm wide and 7.5 cm deep. The internal height of the walls is constant along the whole length of the staircase. Naive male mice (Charles River strain) with a weight between 18 and 24 g are used. Each animal is used only once. The drug or the standard is administered orally 1 h or 30 min subcutaneously before the test. The animal is placed on the floor of the box with its back to the staircase. The number of steps climbed and the number of rears are counted over a 3-min period. A step is considered to be climbed only if the mouse has placed all four paws on the step. In order to simplify the observation, the number of steps descended is not taken into account. After each test, the box has to be cleaned in order to eliminate any olfactory cues which might modify the behavior of the next animal.

EVALUATION

Twelve mice are used for the untreated control group, each drug group, and for the group receiving the standard. The average number of steps and rearings of the control group is taken as 100%. The values of treated animals are expressed as percentage of the controls.

CRITICAL ASSESSMENT OF THE METHOD

The staircase test has been proven as a simple and reliable method for screening of anxiolytics in several laboratories. Many applications and modifications have been described in the literature (Houri 1985; Steru et al. 1987; Keane et al. 1988; Emmannouil and Quock 1990; Simiand et al. 1993).

E.2.4.7 Cork Gnawing Test in the Rat

PURPOSE AND RATIONALE

Cork gnawing behavior in the rat has been proposed as a screening method for buspirone-like anxiolytics by Pollard and Howard (1991).

PROCEDURE

Adult male Evans rats serve as subjects. They are housed 4 per cage on a regular light/dark cycle with free access to food and water except for the period between injection and the end of a test session. For the test session one animal is placed in a stainless steel cage with wire mesh bottom. A session consists of placing the subject in the test cage with a cork stopper weighing between 2–3 g for 30 min. Initially, the amount gnawed is relatively high and variable within and between subjects. After 30 training sessions, the amount is low and stabilized. The test compounds are injected 30 min before the test and food is withdrawn.

EVALUATION

Each cork is weighed to the nearest 0.01 g before and after the session. The average cork loss during the previous control days is taken as baseline and the amount after drug treatment is expressed as percentage of baseline. Buspirone-related compounds as well as benzodiazepines and meprobamate show a dose dependent increase of cork gnawing, but amphetamine, chlorpromazine, imipramine and morphine do not.

CRITICAL ASSESSMENT OF THE METHOD

The test is worthwhile to be mentioned, since buspirone – whose anxiolytic action was discovered during clinical trials to assess possible antipsychotic action and not by use of animal tests for anxiolysis – is active in this test but not in most other classical tests for anxiolytic activity.

E.2.4.8 Distress Vocalization in Rat Pups

PURPOSE AND RATIONALE

Measurement of ultrasonic vocalization induced by tail-holding in rat pups was proposed as a simple screening method for anxiolytic drugs by Gardner (1985).

PROCEDURE

Wistar rat pups are bred on site and left undisturbed with their mother, except for cage-bedding replacement, until the day of testing. The pups are tested at 9–12 days of age. On the day of testing the pups are separated from their mother and taken in their home cage to the quiet experimental room. In the morning all pups are subjected to handling stress and the magnitude of their ultrasound emission is observed. The stress consists of holding the pup by the base of the tail, between forefinger and thumb of the experimenter, and thus suspending it 5 cm above the bench for 30 s. A prior control recording (30 s) is taken when the pup is held gently in the experimenter's hand, whereby the pups emit only a few ultrasounds. Responses when held by the tail are more than 10 times higher. This entire hand-holding-tail-holding procedure is immediately repeated. Ultrasounds are recorded with suitable detectors with 42 kHz as the center of a 10 kHz recording range. The output of the detectors is fed into pen recorders. The total number of ultrasonic cries in the two sessions of hand holding and the two sessions of tail holding are calculated and used as the control activity of each pup. Any pup producing a total of less than 50 ultrasounds when held by the tail is excluded from the drug study. The pups are kept in the home cage in the test laboratory until the afternoon. Three to four hours after the first test the pups are randomly allocated to several equally seized groups, weighed, marked, and dosed intraperitoneally either with the vehicle or drug and placed back in the home cage. Thirty min after dosing, each pup is subjected to the same handling stress as that used in the morning session, and the total number of sounds produced is calculated in the same way.

EVALUATION

The afternoon response to tail holding is expressed as a factor of the morning response. The mean factor for the saline-treated animals is taken to be 100% in calculations of percentage changes in ultrasound emission by drugs.

CRITICAL ASSESSMENT OF THE METHOD

Anxiolytic benzodiazepines dose-dependent inhibit vocalization. Amitriptyline and haloperidol have no effect. Chlorpromazine, muscimol and prazosin reduce sound at doses which also induce overt sedation.

Therefore, the method can be regarded as relatively specific for anxiolytic activity.

MODIFICATIONS OF THE METHOD

Kehne et al. (2000) used the ULTRAVOX system (Noldus Information Technology, Wageningen, the Netherlands) to detect and quantify separation-induced ultrasonic vocalization in rat pups.

Using this equipment, Siemiatkowski et al. (2001) reported opposite effects of olanzapine and haloperidol in the rat ultrasonic vocalization test.

Molewijk et al. (1996), Griebel et al. (2002), and Steinberg et al. (2002) used maternal separation-induced distress vocalization in **guinea pig** pups to test anxiolytic and antidepressant drugs.

Rupniak et al. (2000) investigated the stress-induced vocalizations by central NK_1 receptors using pharmacological antagonists in guinea pigs, a species with human-like NK_1 receptors, and transgenic NK1R–/– mice.

E.2.4.9 Schedule Induced Polydipsia in Rats

PURPOSE AND RATIONALE

Food deprived rats exposed to a procedure in which food is delivered intermittently will drink large amounts of water if given the opportunity to do so. This behavioral phenomenon is termed schedule-induced polydipsia and is an example of a more general class of behaviors termed adjunctive behaviors (Falk 1971; Pellon and Blackman 1992). Adjunctive behaviors have been cited as potential animal models of human obsessive-compulsive disorders (Pitman 1989).

PROCEDURE

Male Wistar rats weighing 180–250 g are individually housed at a 12 h/12 h light/dark cycle for a 1 week acclimation period with free access to food and water. Then they are placed on a restricted diet which maintains 80% of their free feeding body weight. To induce polydipsia, rats are placed in test chambers housed in sound attenuated boxes where a pellet dispenser automatically dispenses two 45 mg pellets on a fixed time 60-s (FT-60s) feeding schedule over a 150 min test session. Water is available at all times in the test chambers. After 4 weeks exposure to the FT-60s feeding schedule, approximately 80% of the rats meet the predetermined criterion for water consumption (greater than 60 ml water per session) and are considered to have polydipsic behavior.

Rats receive the test compounds in various doses daily or the vehicle intraperitoneally 60 min prior to testing. They are tested once a week to assess schedule induced polydipsia. Water bottles are weighed before and after the 150-min test sessions.

EVALUATION

The experimental data comparing the effects of chronic administration of compounds on schedule-induced polydipsia are analyzed with the Mann Whitney *U*-test.

MODIFICATIONS OF THE METHOD

Yadin et al. (1991) proposed spontaneous alternation behavior in rats as an animal model for obsessive-compulsive disorder. Food-deprived rats were run on a T-maze in which both a white and a black goal box were equally baited with a small amount of chocolate milk. Each rat was given 7 trials every other day during which it was placed in the start box and allowed to make a choice. The mean number of choices until an alternation occurred was recorded. After a baseline of spontaneous alternation was achieved the rats were treated with the non-selective serotonin agonist 5-methoxy-N,N-dimethyltryptamine (5-MeODMT) (1.25 mg/kg i.p.) or the selective 5-HT_{1A} agonist 8-hydroxy-2-(di-n-propylamino)-tetralin hydrobromide (8-OH-DPAT) (2 mg/kg i.p.) which both disrupted the spontaneous alternation. A course of chronic treatment (2 × 5 mg/kg for 21 days) with the selective 5-HT uptake blocking agent fluoxetine had a protective effect on the 5-MeODMT-induced disruption of spontaneous alternation behavior. The authors speculated that serotonergic manipulations of spontaneous alternation may be a simple animal model for the perseverative symptoms or indecisiveness seen in patients with obsessive-compulsive disorder.

Bös et al. (1997) and Martin et al. (1998) tested agonists of $5HT_{2C}$ receptors in the schedule-induced polydipsia task in rats and proposed them as improved therapeutics for obsessive compulsive disorder.

E.2.4.10 Four Plate Test in Mice

PURPOSE AND RATIONALE

The four plate test in mice has been described by Aron et al. (1971), Boissier et al. (1968) as a method for the rapid screening of minor tranquilizers.

PROCEDURE

The test box has the shape of a rectangle (25 × 18 × 16 cm). The floor is covered with 4 identical rectangular metal plates (8 × 11 cm) separated from one another by a gap of 4 mm. The plates are connected to a source of continuous current which applies to 2 adjacent plates a mild electrical shock of 0.35 mA for 0.5 s. This evokes a clear flight reaction of the animals.

Adult male Swiss albino mice, weighing 17 to 23 g, are randomly divided into different groups. Thirty min before the test the animals are injected intraperitoneally with the test drug or the vehicle.

At the beginning of the test, the mouse is gently dropped onto a plate and is allowed to explore the enclosure for 15 s. After this, every time the animal crosses from one plate to another, the experimenter electrifies the whole floor for 0.5 s, which evokes a clear flight-reaction of the mouse which often crosses 2 or 3 plates. If it continues running, no new shock is delivered during the following 3 min.

EVALUATION

The number of times the apparatus is electrified is counted each minute for 10 min. The delivery of shocks decreases dramatically the motor activity. The number of shocks received during the first min is taken as parameter. This number is increased by minor tranquilizers, such as benzodiazepines, but not by neuroleptics and psychoanaleptics.

CRITICAL ASSESSMENT OF THE METHOD

The test is of value to differentiate minor tranquilizers, such as benzodiazepine anxiolytics, from neuroleptics. However, some stimulants (e. g. amphetamine) produce an increase in punished plate crossings and some anxiolytics do not.

E.2.4.11 Foot-shock-Induced Freezing Behavior in Rats

PURPOSE AND RATIONALE

Footshock-induced freezing behavior in rats has been proposed as a model for anxiolytics by Conti et al. (1990).

PROCEDURE

Male Sprague-Dawley rats with a weight between 200 and 350 g are used. The animals receive a single i.p. injection of the test compound or the vehicle 30 min prior to being placed in a standard conditioning chamber (e. g., Coulborn Instruments) for a 6.5 min session. Two and 2.5 min after the start of the session, a scrambled footshock (0.5 mA, 0.5 s) is delivered through the grid floor of the chamber. Using an assembly of push buttons interfaced with a computer, an observer monitors the amount of time each animal spends engaged in the following mutually exclusive behaviors:

- Freezing: immobility with rigid body posture
- Sedated posture: sitting or sleeping
- Small exploratory movements: movements involving the torso or front paws only, vertical movements of the head, or sniffing.
- Locomotion: activity involving hind paws, grooming or rearing.

Frequency of rearing is also counted. All behaviors are monitored for the entire 6.5 min session.

EVALUATION

Duration of foot-shock induced freezing after the second shock is taken as the critical parameter. Time spent in freezing posture after administration of test compounds is compared with the controls. Anxiolytics like diazepam and buspirone show dose-dependent effects, but not haloperidol.

CRITICAL ASSESSMENT OF THE METHOD

The method seems to discriminate anxiolytics including buspirone from other centrally acting drugs.

MODIFICATIONS OF THE METHOD

Footshock-induced ultrasonic vocalization has been suggested as another model of anxiety (Tonoue et al. 1986; Kaltwasser 1990; Miczek et al. 1991; De Vry et al. 1993; Nielsen and Sánchez 1995; Schreiber et al. 1998). Test cages ($22 \times 22 \times 22$ cm) made of grey Perspex are equipped with a metal grid floor (distance between the bars = 1 cm). Electric footshocks are delivered from a 12 bit programmable shock source and ultrasounds are picked up by a microphone (range 18–26 Hz) placed in the center of the cage lid. The total vocalization time is measured. The rats are placed individually in the test cages and immediately receive a series of 0.5 mA inescapable footshocks each of 1 s duration with a shock interval of 5 s. The vocalization is measured for a 10 min period starting 1 min after the last shock. Drugs or saline are given subcutaneously 30 min before the test.

E.2.4.12 Experimental Anxiety in Mice

PURPOSE AND RATIONALE

Ogawa et al. (1966, 1990, 1993) designed a communication box to induce experimental anxiety in mice by employing intraspecies emotional communication. The inside of the communication box was divided into foot-shock and non-foot-shock compartments by transparent plastic boards. The animals, which were individually placed into each compartment, were unable to make physical contact with one another, but were able to receive other cues such as visual, auditory and olfactory sensations. During the foot shock period, the animals placed in the non-foot-shock compartments were exposed to the emotional cues from foot-shocked animals, such as shrieks, smell of feces or urine, and jumping response.

PROCEDURE

The floor of the communication box is equipped with grids for electric shock. The inside is divided into small compartments (10 × 10 cm), consisting of foot-shock compartments with a grid floor and non-foot-shock compartments with a grid floor covered by transparent plastic boards. The foot-shock compartments are arranged such as to surround the non-foot shock compartments.

The experimental groups consist of the following 3 groups: sender group, responder group, and food-yoked group to responder. Sender animals receive a foot shock of 10-s duration at intervals of 50 s for 3 h. The electric current for the shock is increased stepwise from 1.6 mA to 2.0 mA at a rate of 0.2 mA per 1 h. Responders are exposed daily to the emotional responses of sender animals, 3 h per day for 3 days. Sender animals are changed daily to naive mice to prevent a reduced emotional response to foot shock based on adaptation or learned helplessness due to repeated exposure. Both sender and responder animals are placed individually in each compartment of the communication box 15 min before beginning of the shock period. On day-1, responder animals are returned to their home cages after the 3-h foot shock period. On day-2, after completing the foot-shock period, they are transferred to metal cages and are housed in the cages with 4 animals per cage under food-deprivation condition. Food-yoked control animals are maintained to the metal cage during the foot-shock period under the aggregated housing condition (5 animals each) and then they are returned to the home cages after the foot shock period. From beginning of the day-2 experiment to completion of the day-3 experiment, they are maintained in the metal cages under aggregating housing. On day-3, just after completing the foot-shock period, the responders are sacrificed by chloroform, and their stomachs are removed. The stomachs are visually inspected for lesions.

Drugs are administered orally at different doses either with a single dose on day-3 or daily 30 min before the shock period.

EVALUATION

Data are reported as the incidence of mice with gastric lesions characterized by slight erosions or bleeding. Active anxiolytics reduce the incidence of gastric ulcers found in food-deprived animals. The incidence in food-yoked animals is much lower. The data are analyzed by Fisher's exact probability test.

E.2.4.13 mCPP-Induced Anxiety in Rats

PURPOSE AND RATIONALE

The metabolite of the antidepressant drug trazodone 1-(3-chlorphenyl)piperazine (= mCPP), classified as 5-HT_{1C} agonist (Rocha et al. 1993; Gibson et al. 1996) or 5-$HT_{1B/2C}$ agonist (Dryden et al. 1996), has been shown to be anxiogenic both in man and in rats (Curzon et al. 1991). The compound induces hypophagia (Samanin et al. 1979; Dryden et al. 1996; Yamada et al. 1996) and hypolocomotion (Kennett et al. 1996, 1997a), inhibits social interaction in rats, diminishes exploratory activity of rats in the open field test (Czyrak et al. 1994; Meert et al. 1997) and in the light-dark box test (Bilkei-Gorzo et al. 1998), induces hyperthermia (Aulakh et al. 1995; Kennett et al. 1997b)

and reduces ultrasound-induced defensive behavior in the rat (Beckett et al. (1996). Antagonism against these symptoms has been proposed as a screening model for anxiolytic drugs (Bilkei-Gorzo et al. 1996, 1998; Wallis and Lal 1998).

PROCEDURE

Male Sprague Dawley rats (220–250 g) are housed in groups of 6 under a 12 h light/dark cycle with free access to food and water.

mCPP-Induced Locomotion

Rats are placed in a room adjacent top the experimental room on the day of the procedure. They are dosed either orally 1 h, or i.p. 30 min before the locomotion test with test compound or vehicle, and injected 20 min before the test with 7 mg/kg mCPP i.p. or saline in groups of four. Rats are returned to their home cages after dosing. At 0 h they are each placed in automated locomotor activity cages made of black Perspex with a clear Perspex lid and sawdust covered floor under red light for 10 min. During this time, locomotion is recorded by means of alternately breaking two photocell beams traversing opposite ends of the box 3.9 cm above floor level.

mCPP-Induced Hypophagia

Rats are individually housed on day 1 and on day 3 they are deprived of food. Twenty-three hours later, the are orally treated with the test drug or vehicle and returned to their home cages. Forty min later, they are given 5 mg/kg mCPP or saline i.p. and again returned to their home cages. After a further 20 min, weighted amounts of their normal food pellets are placed in their food hoppers and the amount remaining after 1 h is measured.

EVALUATION

The effect of the test compound on mCPP-induced hypolocomotion is determined by one-way ANOVA and Newman-Keuls test. The dose producing 50% disinhibition of mCPP is also estimated. Feeding test data are subjected to one-way ANOVA and Dunnett's test.

MODIFICATIONS OF THE METHOD

Griebel et al. (1991) described neophobic and anxious behavior in mice induced by m-CPP.

Czyrak et al. (1994) measured the antagonism of anti-psychotics against the mCPP-induced hypothermia in mice.

E.2.4.14 Acoustic Startle Response in Rats

PURPOSE AND RATIONALE

The acoustic startle reflex is a relatively simple behavior that occurs naturally in mammals and is affected by a variety of treatments. It consists of a series of rapid movements beginning at the head and moving caudally involving contraction and extension of major muscle groups in response to auditory stimuli with a rapid onset, or rise time. Responses are graded in amplitude in relation to stimulus intensity, and may show habituation and sensitization. Startle response can be used to determine sites and mechanisms of drug action (Davis 1982).

PROCEDURE

Male Wistar rats weighing about 200 g are used. Acoustic startle reflexes are measured in a specially build apparatus, e. g., Coulborn Instruments Acoustic Response Test System or TSE Systems, Bad Homburg, Germany. The animals are individually placed in $8 \times 8 \times 16$ cm open air cages that restrict locomotion but do not immobilize the animal, and are placed on one of four platforms within a sound-attenuating acoustic chamber. A ventilating fan provides an ambient noise level. Acoustic stimuli consist of white noise bursts lasting 20 ms at 98 dB and 124 dB SPL. Simultaneously with the rapid onset of each stimulus, the animal's physical movement within the cage on the platform is measured for 200 ms as an electrical voltage change via a strain gauge which is converted to grams of weight change following analog to digital conversion. Data are recorded automatically by an interfaced microcomputer.

Pre-tests are performed with all animals to obtain control values. The animals are treated 2 h prior the experiment with test drugs or vehicle given orally or subcutaneously.

EVALUATION

The results are given as percentage of the change, related to the values obtained in the pre-test and assessed by a one-way ANOVA, followed by Dunnett's test when appropriate.

MODIFICATIONS OF THE METHOD

The test has been modified in various ways, e. g., inhibition by a prepulse (Keith et al. 1991; Rigdon and Viik 1991; Taylor et al. 1995) or fear-induced potentiation (Davis 1986, 1992).

Schulz et al. (1996) performed acoustic startle experiments in rats with a potent and selective nonpeptide antagonist of the corticotropin releasing factor receptors.

Walker and Davis (1997) found that the amplitude of acoustic startle response in rats was increased by high illumination levels.

Devices to register the intensity of fear-potentiated startle response in rats were described by Hijzen et al. (1995).Yilmazer-Hanke et al. (2002) studied fear-potentiated startle and exploration-related anxiety in inbred Roman high- and low-avoidance rats.

E.2.4.15 Unconditioned Conflict Procedure (Vogel Test)

PURPOSE AND RATIONALE

Vogel et al. (1971) described a simple and reliable conflict procedure for testing anti-anxiety agents. Thirsty, naive rats were administered shocks while licking water.

PROCEDURE

The apparatus is a clear Plexiglas box (38 × 38 cm) with a black Plexiglas compartment (10 × 10.5 cm) attached to one wall and an opening from the large box to the small compartment. The entire apparatus has a stainless-steel grid floor. A water bottle with a metal drinking tube is fitted to the outside of the small compartment, so that the tube extended into the box at a height 3 cm above the grid. Rats lick in bursts with a relatively constant rate of 7 licks per sec. A drinkometer circuit is connected between the drinking tube and the grid floor of the apparatus, so that the rat completes the circuit whenever it licks the tube. Shock is administered to the feet of the animal by switching the connections to the drinking tube and grids from the drinkometer to a shocker which applies an unscrambled shock between the drinking tube and the grid floor.

Naive adult male rats are used. Thirty min after intraperitoneal injection, the rat is placed in the apparatus and allowed to find the drinking tube and to complete 20 licks before shock (available at the tube for 2 s) is administered. The rat controls shock duration by withdrawing from the tube. A 3-min timer is automatically started after the termination of the first shock. During the 3-min period, shocks are delivered following each twentieth lick. The number of shocks delivered during the 3-min session is recorded for each animal.

EVALUATION

The number of shocks received after treatment is compared with untreated animals. Benzodiazepines increase dose-dependent the number of shocks. Barbiturates in low doses and meprobamate, but not d-amphetamine or scopolamine, are active in this test.

CRITICAL ASSESSMENT OF THE METHOD

The method is far more simple and less time consuming than the methods using conflict behavior after intensive training. The specificity may be less than that of the Geller paradigm.

MODIFICATIONS OF THE METHOD

The method and the apparatus have been modified by Patel and Malick (1982), Patel et al. (1983), Sanger et al. (1985), Langen et al. (2005), and Mathiasen and Mirza (2005).

Miklya and Knoll (1988) showed an increase of sensitivity of the method using rats deprived of food but supplied with tap water ad libitum for 96 h, than fed with dry pellets and punished for drinking during feeding. The punished drinking test has not only be used for identifying and studying anxiolytic agents, but also as a method for measuring anxiogenic activity (Uyeno et al. 1990).

La Marca and Dunn (1994) studied α_2-antagonists after intravenous administration in the Vogel lick-shock conflict paradigm.

E.2.4.16 Novelty-Suppressed Feeding

PURPOSE AND RATIONALE

Placing a hungry rat into an unfamiliar environment with access to food results in a suppression of feeding behavior relative to the condition when the test environment is familiar. This effect has been termed hyponeophagia (Shephard and Broadhurst 1982) and occurs because of the novelty of the test environment. The avoidance of novel foods is termed food neophobia. Both hyponeophagia and food neophobia have been assumed to measure emotionality or anxiety by eliciting a conflict situation arising from a fear of the novel setting and foods, and the drive to eat (Porschel 1971). A number of investigators have adopted these paradigms to explore the behavioral effects of anxiolytics (Soubrie et al. (1975;Cooper and Crummy 1978; Borsini et al. 1993).

PROCEDURE

The testing apparatus consists of individual Plexiglas open fields, $76 \times 76 \times 46$ cm. Thirty Purina lab chow pellets are placed in a pile directly in the center of the open field.

Animals are handled for 3 weeks prior the behavioral testing. Forty-eight hours prior to testing, all food is removed from the home cage, although water is still available ad lib. One h prior to testing, animals receive an intraperitoneal injection of test drugs or vehicle. At the time of testing, the animals are placed into individual open fields containing the food, and the latency to begin eating is measured. If the animal has not eaten within 720 s, the test is terminated and the animal is assigned a latency score of 720 s.

EVALUATION

The data are analyzed by a one-way analysis of variance followed by Fisher Last Significant Difference post hoc tests. An anxiolytic effect is defined as a significant decrease in mean latency to begin eating compared with vehicle controls.

CRITICAL ASSESSMENT OF THE METHOD

The test has the advantage of simplicity for screening procedures.

E.2.4.17 Shock Probe Conflict Procedure

PURPOSE AND RATIONALE

The shock probe conflict procedure, an assay responsive to benzodiazepines, barbiturates and related compounds, was described by Meert and Colpaert (1986). Rats being placed in a novel test environment containing a probe, explore the environment and also the probe. The exploration of the probe, quantified as the number of times that the animal makes physical contact with it, is reduced when the probe is electrified. Rats treated with anxiolytics continue to touch the electrified probe.

PROCEDURE

Apparatus: The test environment consists of a Plexiglas chamber, measuring 40 × 40 × 40 cm, and having a metal grid floor. A Teflon probe (∅: 1 cm) with two uninsulated wires (∅: 0.5 mm) each independently wrapped 25 times around it, is inserted from the front panel protruding for a length of 6.5 cm into the test box, 3 cm above the floor of the chamber. The wires are connected to a shocker. Whenever the animal touches both wires simultaneously with some part of its body, a DC current flows through the animal. At the same time, a counter is triggered. Normally, a shock intensity of 0.9 mA is used.

Sixty min after treatment with saline or test substance, the animal is placed in a back corner of the testbox facing away from the probe. The test session starts from the moment makes the first contact and receives the first shock. The number of responses the animal makes during the subsequent 5-min episode is counted.

EVALUATION

Dose-response curves can be established for various drugs at different shock intensities. The Mann-Whitney *U*-test is used to evaluate differences between experimental conditions. To control whether a drug treatment increases responding above the saline control level, an one-tail *t*-test is used; a two-tail test in other cases.

CRITICAL ASSESSMENT OF THE METHOD

The procedure requires neither behavioral training nor expensive equipment and overcomes some of the limitations that are typical for other conflict procedures. However, the procedure still uses electric shock as inhibitory stimulus.

E.2.4.18 Ultrasound Induced Defensive Behavior in Rats

PURPOSE AND RATIONALE

Rats exposed to aversive stimuli display specific defence behavior as a part of their natural survival strategy. One component of this behavior is the production of ultrasonic calls in the 20–27 kHz range, which are thought to serve a communication role. Artificially generated ultrasound produces intensity-related locomotion, characteristic of defensive behavior (Beckett et al. 1996).

PROCEDURE

The apparatus (Beckett and Marsden 1995) consists of a circular open field arena, 75 cm in diameter, 46 cm high walls, with a video camera suspended above. Locomotor behaviors are recorded and analyzed using a computer automated tracking system capable of following rapid movements (VideoTrack, CPL Systems, Cambridge, UK). This allows the ultrasound-induced change in locomotor behavior to be quantified in maximum speed, average speed and distance traveled by the animals. Data are expressed as 15 sequential 20-s bins over the duration of the experiment.

Ultrasound (continuous tone, square wave, 20 kHz) is produced using a multifunction signal generator at sound pressure intensities of 65, 72 and 75 dB, as measured from the arena, 20 cm horizontally from the speaker. Sound is delivered to the testing arena via a high frequency piezo electric speaker mounted at a height of 40 cm on the wall of the testing arena. The signal frequency and intensity delivered to the speaker are monitored using a digital oscilloscope. White noise is generated using a standard generator and the sound intensity measured as above.

Animals are placed in the test arena 20 min after intraperitoneal injection of drug or vehicle and locomotor activity is measured. After 2 min they are exposed to a 1-min, 20 kHz, square wave ultrasound tone (65, 72 or 75 dB sound pressure intensity, randomized) followed by a further 2 min without sound. This procedure is repeated for each intensity with a 1-min interprocedure interval. Locomotor activity values are then calculated for the maximum speed, average speed and total distance traveled throughout the 5-min test period and expressed as a series of 15–20-s time epochs.

EVALUATION

Maximum speed is analyzed using a two-way ANOVA. Significant interactions between treatment

and time are followed by one-way ANOVAs for individual time points with post-hoc Duncan's new multiple range test.

MODIFICATIONS OF THE METHOD

Moleweijk et al. (1995) evaluated ultrasound vocalizations of adult male rats in association with aversive stimulation as a screening method for anxiolytic drugs.

E.2.4.19 Anxiety/Defense Test Battery in Rats

PURPOSE AND RATIONALE

Blanchard et al. (1989, 1990, 1992) described a set of procedures designed to assess the defensive reactions of rats to a natural predator, the cat. These tests involve a brief confrontation of laboratory rats with an unconditioned threat stimulus (cat) which, to preclude physical contact, is presented behind a wire mesh barrier. The primary measures, taken both during and after cat presentation, include movement arrest and risk assessment (proxemics/activity test) and the inhibition of non-defensive behaviors (eat/drink or freezing test).

PROCEDURE

The test apparatus for both the proxemics/activity and eat/drink procedures consists of two parallel subject chambers (53 × 20 × 25 cm). The inside walls of each chamber are constructed of opaque black Plexiglas, while outer walls and lids are clear Plexiglas to allow video recording from lateral and overhead views. The end wall of each chamber, constructed of wire mesh, adjoins a separate cat compartment. Subject movements are monitored by five photocells mounted at equal distances over the length of each chamber, and a food hopper and drinkometer are positioned 2.5 cm to each side of the central photocell. Access to the food hopper/drinkometer can be prevented by insertion of Plexiglas gates.

Each rat (Long-Evans strain, female or male, about 100 days old) receives the same injection (drug or saline) in each of the two successive paradigms. The initial study assesses the effects of cat exposure on proxemics/activity, followed 7 days later by analysis of eat/drink behavior during and after cat exposure. Both procedures are carried out under dim red light.

Proxemic/activity testing. Rats are individually placed in each compartment of the test apparatus. Following a 5-min pre-cat period, the cat is introduced to the cat compartment for 5 min. Following removal of the cat, behavior is recorded for a further 15 min post-cat period, for which measures are summed in three, 5-min blocks. The test session is video recorded for analysis of lying, crouching, rearing, locomotion and grooming. Proxemic location is measured by a digitizing system which divides the length of the subject compartment into thirds, indicating animal's location near the cat compartment, in the midsection of the box, or far from the cat compartment. Assessment of transits indicate movement from one section to another.

Eat/drink testing. Rats are individually given 2 g of finely crushed chocolate cereal on the 2 days after the proxemic/activity test, to familiarize them with this highly preferred food. In order to induce a mild water deprivation, water bottles are removed, 24 h prior to eat/drink testing. On the test day, animals are individually placed in the subject compartments for a 5-min pre-cat period, during which the food hopper and water dispenser are concealed with Plexiglas gates. At the beginning of the 5-min cat period, these gates are removed allowing free access to the crushed chocolate cereal and water. After removal of the cat, the rats are monitored for a further 15-min post-cat period. Measures of eating frequency and duration, and drinking frequency are taken for the cat and post-cat periods.

EVALUATION

The data are analyzed by analysis of variance (ANOVA). Subsequent comparisons between treatment groups and control are carried out using Newman-Keuls procedures.

MODIFICATIONS OF THE TEST

Farook et al. (2001, 2004a, 2004b) and Wang et al. (2003) described a **cat-freezing test apparatus**. The apparatus consisted of a completely enclosed, black, cat compartment (55 × 38 × 30 cm) with a wire mesh floor opening 42 × 19 cm, and an open-top rat compartment (38 × 24 × 19 cm) made of clear Plexiglas to allow observation. The cat compartment could be placed stably on the top of the rat compartment. Male PVG hooded rats weighing 210–260 g were used. Locomotor activity was monitored using an Opto-Varimex Mini (Columbus Instruments), which measured the in-

terruptions of optical beams that were placed 2.5 cm apart. The predator cat was a 4.3-kg male, which was selected for a total absence of aggressive behavior toward the rodents. During a 20-min test period, the duration of freezing, defined as the absence of all movements except movements related to breathing, was monitored. Freezing was expressed as the percentage of time the rat spent frozen during this 20-min session.

Blanchard et al. (1986a, b, 1989) developed a battery of tests designed to elicit a wide range of active and passive defensive activities in **wild rats**.

Griebel et al. (1997, 1998a, 1998b, 2001, 2002) designed a mouse defense test battery in which **Swiss mice** were confronted with a natural threat (a rat) and behaviors associated with this threat were recorded.

E.2.4.20 Repetitive Transcranial Magnetic Stimulation

PURPOSE AND RATIONALE

Transcranial magnetic stimulation was introduced by Barker et al. (1985). The regional electrical activity in the brain is influenced by a pulsed magnetic field. Repetitive transcranial magnetic stimulation can cause functional changes in the cortex. Effects have been demonstrated in humans as well as in animals (Weissman et al. 1992; Fleischmann et al. 1995; Zyss et al. 1997; Ji et al. 1998; Ben-Shachar et al. 1999; Hausmann et al. 2000; Luft et al. 2001). Most studies indicated an antidepressant or anxiolytic effect (Keck et al. 2000, 2001; Tsutsumi et al. 2002; Kanno et al. 2003); however, this effect is dependent on frequency of stimulation (Sachdev et al. 2002) and duration of treatment (Hedges et al. 2003, 2005; Isogawa et al. 2003). Isogawa et al. (2005) found that 10-day repetitive transcranial magnetic stimulation induced anxiety in normal rats, as evidenced by expression of anxiety behaviors in the elevated plus-maze.

PROCEDURE

Male Wistar rats were used. All animals received repetitive transcranial magnetic stimulation for 10 days. On day 10, groups of 5 rats were treated with saline i.p., or anxiolytics or antidepressants.

Magnetic stimulation was delivered via a high-frequency magnetic stimulator with a round coil (4 cm in diameter) positioned over the rat's head. The stimulator delivered a biphasic cosine current with a pulse width of 200 μs in duration. The switching elements transfer up to 250 J per pulse to the coil, depending on the intensity setting. The peak magnetic flux at the

center of the coil is approximately 2.2 T at maximal output. The stimulus amplitude was set at an intensity of 1.5 motor thresholds for motor-evoked potentials recorded from the gastrocnemius muscles.

To deliver the stimulation, awake animals were gently held by hand to minimize any discomfort. The coil was held tangentially in direct physical contact with the rat's head. To keep the same brain region stimulated, the center of the coil was set at the center of the vertex of the skull. All animals received one set of training stimuli daily between 13:00 and 18:00 hours for 10 days. To control for the auditory stimulation that accompanies high-frequency magnetic stimulation, sham stimulations were performed with the coil held far enough away (15 cm) from the induced magnetic field.

On the first day of testing, all rats were evaluated on the elevated plus-maze. This consisted of two opposite open arms (50×10 cm) without side walls and two opposite enclosed arms ($50 \times 8 \times 40$ cm), and was elevated 50 cm above the floor. At the beginning of the test, rats were placed in the middle of the maze facing one of the open arms, immediately left alone in the test room, and were observed for 300 s using a video camera. The following parameters were measured: (1) the time spent in the open arms, (2) total number of entries into the open arms, (3) total number of entries into the closed arms, (4) number of stretched-attend postures, and (5) number of head dips over the edge of the platform.

As a measure of exploratory activity, animals were placed in a standard apparatus. General motor activity was determined by the number of infrared photobeam breaks in a 2-h period. Rats were tested again after treatment with drugs on day 10.

EVALUATION

The results are presented as the means ± SEM of individual values from each group. Overall statistical significance was determined using one-way ANOVA with a post-hoc Dunnett test. For general motor activity, results were analyzed using two-way ANOVA.

E.2.4.21 Marmoset Human Threat Test

PURPOSE AND RATIONALE

The behavior of the common marmoset (*Callithrix jacchus*) as described by Stevenson and Poole (1976) can

be used for evaluation of potential anxiolytic drugs (Costall et al. 1988).

PROCEDURE

Male or female laboratory bred common marmosets weighing 350–400 g are housed in single sex pairs. Holding rooms are maintained at 25°C at a humidity of 55% on a 12 h light/dark cycle. Tests are conducted between 13:30 and 15:30 in the normal holding room. The holding cages are 75 cm high, 50 cm wide and 60 cm deep.

A behavioral change characterized by retreat from, and posturing toward a human threat is initiated by a human observer standing in close proximity in front of the holding cage. Changed behavior is recorded over a 2 min period by the observer. The behavioral measures selected are:

i. the % of time spent on the cage front in direct confrontation with the human threat,
ii. the number of body postures, primarily shown as raising the tail to expose the genital region with varying degrees of piloerection, anal scent marking and slit stare with flattened ear tufts.

The animals are used at 7 day intervals and are subject to a random cross-over of treatments.

Drugs are administered 45 min before exposure to the human threat situation.

EVALUATION

Statistical analysis is performed with one-way analysis of variance followed by Dunnett's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

The human threat test in marmosets has the advantage of using primates instead of rodents. However, it is subject to individual scoring of the observer.

MODIFICATIONS OF THE TEST

Cilia and Piper (1997) developed a method of measuring conspecific confrontation-induced behavioral changes in common marmosets together with automated monitoring of locomotor activity as a possible model of anxiety.

Barros et al. (2000) measured fear and anxiety in the marmoset (*Callithrix penicillata*) with a novel predator confrontation model. The wild cat (*Felis tigrina*) was chosen as taxidermized predator to induce anxiety-related behaviors.

Borsini et al. (1993) used female **cynomolgus monkeys** to test aggressiveness against the observer.

E.2.4.22 Psychosocial Stress in Tree Shrews

PURPOSE AND RATIONALE

Male tree shrews (*Tupaia belangeri*) provide an animal model to study the neurobehavioral and endocrine consequences of chronic psychosocial stress (Fischer et al. 1985; Fuchs et al. 1993, 1996; Fuchs and Flügge 2002; Fuchs 2005). When living in visual and olfactory contact with a male conspecific by which it has been defeated, the subordinate tree shrew shows dramatic behavioral, physiological, and neuroendocrine changes. The pattern of these changes resembles a depression-like symptomatology.

PROCEDURE

Animals are subjected to a 10-day period of psychosocial conflict to elicit stress-induced behavioral and endocrine alterations before the onset of drug treatment. For a treatment period of 30 days, animals are given either saline or an oral dose of test compound.

EVALUATION

At the end of the test period, the following parameters are recorded: behavioral changes (marking, groom-

ing, locomotor activity) and endocrine changes (urinary cortisol and norepinephrine excretion).

MODIFICATIONS OF THE METHOD

Lucassen et al. (2004) found that treatment with an antidepressant reduces apoptosis in the hippocampal dentate gyrus and temporal cortex induced by a 7-day stress period in tree shrews.

Czéh et al. (2005) examined the effects of a NK_1 receptor antagonist in the chronic psychological stress model of adult male tree shrews.

Shively et al. (2005) described social stress-associated depression in adult female **cynomolgus monkeys**.

E.2.4.23 Aversive Brain Stimulation

PURPOSE AND RATIONALE

Electrical stimulation of brain aversive areas, in particular the midbrain central gray, induces defensive reaction and/or flight behavior in several species and, therefore, may be viewed as an animal model of anxiety or of panic attack. Most studies used intracerebral microinjections of neurotransmitters, their agonists and antagonists to elucidate the mechanisms of aversive or antiaversive effects (Schütz et al. 1985; Graeff et al. 1986, 1990, 1991 1993, 1997; Audi et al. 1988, 1991; Brandão et al. 1991, 1993; Broekkamp et al. 1991; Nogueira and Graeff 1991, 1995; Motta and Brandão 1993; Aguiar and Brandão 1994, 1996; Melo and Brandão 1995; Motta et al. 1995; De Araujo et al. 1998). Other groups evaluated the effect of drugs, e. g., serotonin receptor antagonists, on periaqueductal gray stimulation induced aversion after peripheral application (Bovier et al. 1982; Clarke and File 1982; Jenck et al. 1989, 1995, 1996, 1998, 1999; Beckett and Marsden 1997). Dorsal periaqueductal gray-induced aversion is considered as a model of panic anxiety.

PROCEDURE

Surgery. A stainless steel bipolar twisted electrode, insulated to the tip which is cut square to the shaft, is implanted to the dorsal part of the periaqueductal gray matter of male Wistar rats weighing 370–450 g under pentobarbital anesthesia. According to the atlas of Paxinos and Watson (1982), the coordinates for the electrode tip are 5.8 mm posterior to the bregma, 0.2 mm lateral to the midline and 5.0 mm ventral to the surface of the skull. The electrode is held in place with dental cement and five screws threaded into the skull.

Behavioral Procedure. Animals are placed in a rectangular cage ($20 \times 36 \times 20$ cm high) with a grid floor and a 2 cm high barrier dividing the cage in half. They are allowed to explore freely for 10–15 min before the stimulation begins.

Brain stimulation consists of constant current square wave, 0.1 ms duration, monophasic pulses conducted from the neurostimulator (Grass S88 + stimulus isolation unit SIU8) to the electrode by way of flexible wire leads. Pulse duration, pulse frequency and stimulation intensity are monitored by an oscilloscope. Animals are screened for stimulation-induced aversion using a fixed stimulation frequency of 50 Hz; current is raised slowly until aversive behavioral signs are observed. Aversive effects are first characterized by visible autonomic reactions (increase in respiratory rates, piloerection, eventually mydriasis) in animals which are behaviorally frozen. Increasing the intensity induces, following a freezing period, active behavioral signs, ranging from ear dressing and head weaving to sudden running and attempts to escape out of the cage.

With this fixed stimulation intensity, aversive behavior is shaped into an operant escape response: rats are trained to stop the stimulation by escaping from one compartment to the opposite compartment of the cage. Brain stimulation is switched off when the rat crosses the middle line separating the two compartments or after a maximal cut-off time of 20 s. A trial is

applied every min. Three to 10 daily sessions of 30 trials are required to obtain stable responses.

Self-Interruption Threshold Determination

Once an animal displays steady performances during 3 consecutive days on this task with fixed intensity and fixed stimulation frequency, it undergoes the next step of training aimed at determining its stimulation frequency threshold for escape reaction. This consists of testing the animals in a threshold procedure in which the frequency is varied while stimulation intensity is held constant. This procedure keeps the size of the stimulation field around the electrode tip constant.

A stimulation intensity is chosen and defined as the threshold intensity eliciting escape when the stimulation frequency is 50 Hz. With this intensity held fixed, a method of limits is employed to determine the frequency threshold for escape: the stimulation frequency is either decreased or increased depending on the response displayed by the animal on the previous trial. Starting from 50 Hz, stimulation frequency is decreased by 5 Hz steps following a trial in which the rat responds to the stimulation, and is increased by 5 Hz steps, in case the animal fails to respond to the stimulation. When a response is made, the time elapsing between the onset of the stimulation and the moment the animal crosses the midline barrier is also recorded as escape latency; no response is associated with the maximum cut-off time of 20 s.

Frequency threshold is calculated as the average frequency eliciting an escape reaction during a 20-min pre-injection session; an average escape latency is calculated the same way. Drugs are then injected intraperitoneally at various doses and 35 min following administration, frequency threshold is determined again over a 25–30 min post-injection session. Drug effects can be estimated by comparing thresholds and latencies for each animal before and after injection. Doses are injected at least 4 days in a counterbalanced order. Animals serve as their own controls and can undergo several treatments.

EVALUATION

Data are analyzed by means of analysis of variance, followed by paired *t*-tests. Dose-response curves are established for active drugs.

MODIFICATIONS OF THE METHOD

The group of Graeff and Brandão (1986) used an electrode-cannula, called chemitrode, for electrical stimulation and microinjection of drugs or neurotransmitters at the same place of the periaqueductal gray. This chemitrode was made of stainless steel cannula (outside diameter 0.6 mm, length 12.5 mm) glued to a brain electrode made of stainless steel (diameter 250 mm) enamel insulated except at the cross-section of the tip, reaching 1 mm below the lower end of the cannula (Nogueira and Graeff 1995).

Schenberg et al. (2001) appraised the isomorphism of dorsal periaqueductal gray-evoked defensive behaviors and panic attacks both in rats and humans.

E.2.5
Conditioned Behavioral Responses

E.2.5.1
Sidman Avoidance Paradigm

PURPOSE AND RATIONALE

Sidman (1953) described an apparatus for the evaluation of two temporal parameters (shock-shock interval and response-shock interval) of the maintenance of avoidance behavior by the white rat. The procedure has been widely used to evaluate CNS depressant compounds, neuroleptics, anxiolytics and sedatives.

PROCEDURE

The test cage is equipped with a single lever and a light. This cage is enclosed in a sound-attenuating chamber with a fan and with a speaker emitting a white-noise auditory background. The test cage has a grid floor of steel bars which are attached to a scrambled shock source. The data are recorded in an adjacent room. Male Sprague-Dawley rats with a starting weight of 250 to 300 g are housed in individual cages. They are trained to avoid an unsignalled shock by repetitive lever-pressing responses. A shock (1.5 mA for 0.5 s) is delivered to the grid floor every 15 s if no responses occur (shock-shock interval of 15 s = SS-15 s). A lever press (response) will delay the oncoming shock for 30 s (response-shock interval of 30 s = RS-30 s). The responses do not accumulate for delays of shock; a shock will be delivered 30 s after the last response is made even if 10 responses are made 31 s prior. Every 30 min, the total number of shocks received and the total number of responses made are accumulated and constitute the basic data. The animals are trained until they maintain a stable response rate and receive no more than 100 shocks/five hour test session. After reaching these criteria of performance, experimental compounds are administered and their effects on the performance of this learned avoidance behavior are evaluated. The experimental compounds or the standard are usually administered by i.p. injection immediately prior to testing in volumes of 1 ml/kg of body weight. Depressant drugs lower the rate of lever presses and increase the number of shocks received. Stimulant drugs increase the rate of lever pressing.

EVALUATION

The effect of a drug on the performance of an animal is compared to the data generated in the previous non-drug sessions. Each animal thereby serves as its own control. The basic measures of performance during a specific time interval, responses and shocks are used for evaluation. Responses are reported both as total and as percent of control responses. Shocks are reported as totals and as shock-avoided (SHA) as percent of control. This latter measure is computed by subtracting the number of shocks received from the total number of possible shocks if no responses had been made. In the initial screening of experimental compounds, the results are reported in terms of the total effect during a five-hour test. However, an ED_{50} is usually estimated during a representative time of peak activity.

CRITICAL ASSESSMENT OF THE METHOD

Anxiolytics show activity in this test, however, it has been proven to be more reliable for neuroleptic activity. Apparently, the present conditioned active avoidance paradigms do not constitute a reliable method for screening anxiolytic agents, in spite of their homologies with human anxiety.

MODIFICATIONS OF THE METHOD

Heise and Boff (1962) and Galizio et al. (1990) extended the method by using two levers, an "avoidance lever" and an "escape lever" for calculating ratios between shock rate, escape failure rate and avoidance rate.

Balfour (1990) described the effect of drugs on rat behavior in an unsignalled Sidman avoidance schedule.

Wadenberg et al. (1998) described and evaluated a newly designed apparatus for the assessment of conditioned avoidance response performance in rats.

Patel and Migler (1982) reported a sensitive and selective conflict test in **squirrel monkeys**.

Szewczak et al. (1995) tested antipsychotic agents using continuous avoidance behavior in adult male squirrel monkeys.

E.2.5.2 Geller Conflict Paradigm

PURPOSE AND RATIONALE

Experimentally induced conflict by punishing food-rewarded behavior has been used to differentiate between various psychoactive drugs by Geller and Seifter (1960). The basic principle has been used and modified by many authors to reveal possible anti-anxiety effects of experimental compounds.

PROCEDURE

Male albino rats with a starting body weight of 300–400 g are housed individually. They are food deprived until the body weight is gradually reduced by approximately 20% of original and it is maintained at this level by restricted food diet. Conditioning is carried out in commercially available Skinner boxes (e. g. Campden Instruments, London, UK) equipped with a house light, a single lever, cue lights, a liquid dripper, and a grid-floor connected to a shocker. Sweetened condensed milk delivered by the liquid dipper serves as the positive reinforcer. The data are recorded on cumulative recorders.

The animals are trained to lever press for the milk reward in two distinct response-reward sections. In the anxiety or "conflict" segment (signalled by onset of both tone and cue lights), a dipper of milk is delivered in response to each lever press (continuos reinforcement schedule = CRF) However, lever presses during this period are also accompanied by a 40-ms pulse of aversive foot-shock through the grid floor. This creates a conflict between milk reward and the a painful foot shock. This conflict period is 3 min in duration.

During the other segment of this paradigm, the lever presses produce a drop of milk only at variable intervals of time from 60 to 210 s with an average reward of once per 2 min (variable interval = VI-2 min). No shocks are administered during this variable interval phase of testing which is 15 min in duration.

The test procedure consists of four 15 min non-shock variable interval segments where reinforcement is available on a restricted basis. Each variable interval period is followed by a three minute CRF-conflict period phase when reinforcement is constantly available but always accompanied by an aversive footshock. The shock level is adjusted for each subject to reduce the CRF responding to a total of less than 10 lever presses during the entire test. The rats are tested 2 to 4 days a week. Drugs are administered once per week and the performance is compared to the previous day's control trial. The VI responses are used to evaluate any general

debilitating drug effects while the CRF responses are used to evaluate any anti-anxiety effects as indicated by the increased responding during the CRF conflict period.

The test compounds are administered intraperitoneally 30 min or orally 60 min before the test period.

EVALUATION

The total number of lever presses during the conflict periods (CRF) and the non-conflict periods (VI) are counted. Values of treatment sessions are expressed as percentage of values of the preceding non-treatment day. An increase of lever presses in the conflict period is regarded as indication of an anti-anxiety effect, and a decrease of lever presses in the non-conflict period as an indication for a sedative effect. In this procedure linear dose-response curves are rarely found. Therefore, minimal effective doses (MED) are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The method is suitable to distinguish anxiolytics from other centrally active drugs, such as sedatives and neuroleptics. The relative potency of various anxiolytic agents in a number of species compares favorably with their relative potency in humans. The negative aspects are the time consuming procedure, the high expenses for the apparatus and the difficulty to obtain ED_{50}-values.

The relevance of this test and other models has been challenged by Bignami (1988).

MODIFICATIONS OF THE METHOD

The method has been modified by many authors.

Davidson and Cook (1969), Cook and Davidson (1973) introduced a schedule of 10 lever presses for the delivery of one food pellet together with an electric foot-shock. In the variable interval reinforcement period, responses were reinforced by food delivery at varying intervals of time; the mean interval was 30 s. Also under these conditions differentiation of various psychotropic drugs could be achieved.

Iorio et al. (1986) and Chipkin et al. (1988) used a procedure during which a tone (5 s) preceded and then overlapped for 10 s with scrambled footshocks. After the start of the tone, the rat has the option to avoid (in the no shock period) or escape (in the shock period) the shock by jumping onto a platform located 17 cm above the grid floor.

Thiébot et al. (1991) developed the method further by introducing "safety signal withdrawal", a behavioral paradigm in rats sensitive to both anxiolytic and anxiogenic drugs.

Commissaris and Fontana (1991) published a potential animal model for the study of antipanic treatments. Rats were trained to drink their daily water ration during 10-minute sessions. These sessions were characterized by alterations of silence (unpunished periods) and the presence of a tone (punished periods). Tube contact during the tone periods resulted in a 0.25–0.5 mA shock delivered to the mouth of the animal for the duration of the tube contact. After 4 weeks of training, subjects received either chronic post-test treatment with an antidepressant or vehicle, twice daily, seven days per week. Acute pre-test administration of traditional anxiolytics (benzodiazepines, barbiturates) increased dramatically the number of punished contacts made in a dose-dependent manner. Typical antidepressants were not active after pre-test administration, however, active after chronic post-test treatment.

Beaufour et al. (1999) investigated the effects of chronic antidepressants in the conditioned suppression of operant behavior in rats. In daily 18-min sessions, three periods of non-punished lever pressing for food alternated with two 4-min periods signaled by a light-on conditioned stimulus during which 50% of the responses were randomly punished by electric foot shocks. Antidepressants were administered once daily for 7–8 weeks to trained, food-restricted rats.

The conflict test has also be adapted to the **mouse** (Prado de Carvalho et al. 1986).

The conflict behavior and anticonflict effect of anxiolytics has been demonstrated in a variety of species, including **pigeons** (Morse 1964; Wuttke and Kelleher 1970; McMillan 1973; Gleeson et al. 1989; Barrett et al. 1989; Barrett 1991; Schipper et al. 1991; Pollard et al. 1992; Barrett et al. 1994; Mos et al. 1997).

Patel and Migler (1982) described a sensitive and selective conflict model in male squirrel **monkeys** in which anti-anxiety agents exhibit pronounced anticonflict activity.

Ervin et al. (1987), Ervin and Cooper (1988), van Heest et al. 1991; Simiand et al. (1993) used **conditioned taste aversion** as a conflict model. Moderate taste aversions were induced by pairing the initial consumption of 0.25% sodium saccharin with either 25 mg/kg 5-hydroxytryptophan or 30 mg/kg i.p. LiCl. Antagonism was found with benzodiazepines and non-benzodiazepine-anxiolytic drugs.

E.2.5.3 Progressive Ratio Procedure

PURPOSE AND RATIONALE

The progressive ratio schedule was introduced as a model for studying the psychomotor stimulant activity of drugs in the rat by Poncelet et al. (1983). Male Wistar rats were trained to press a lever with food reinforcement according to a continuously reinforced schedule (CRF). Afterwards, rats were subjected to three experimental sessions (30 min each) during which responding was rewarded according to a progressive ratio schedule (following an initial 2-min CRF period, the number of presses necessary for the pellet delivery was doubled every second minute). Responding during the first half of each session, i. e., pressing for food, was maintained at a significant level, whereas it was almost suppressed during the second part of the session. Animals treated with stimulants showed an increased rate of responding.

Several authors used the progressive ratio test (Richardson and Roberts 1991; McGregor et al. 1993; Bourland and Frenche 1995; Ferguson and Paule 1996; Pulvirenti et al. 1997, 1998; Duvauchelle et al. 1998; Grottick et al. 2000; Mobini et al. 2000; Wilcox et al. 2000; Woolverton et al. 2002; Schneider und Koch 2002,2003; Kozinowski et al. 2003; Solinas et al. 2004).

PROCEDURE

Drews et al. (2005) studied the effects of a cannabinoid agonist on operant behavior and locomotor activity in rats. The progressive ratio test was conducted in an operant chamber ($24 \times 28 \times 28$ cm) (Operant Behavior System, TSE Systems, Bad Homburg, Germany). First, male Wistar rats were habituated for 1 day to the test chamber, the palatable casein pellets and the noise of the magazine response. After shaping, rats were trained over 3 days at lever pressing in sessions of 30 min on a continuous reinforcement schedule until they reached a stable baseline. After lever pressing was completed, one progressive ratio test session (for 30 min) was conducted on the next day. The progressive ratio schedule (i. e., lever presses for one pellet) was changed every second minute according to the following exponential progression: 1, 2, 4, 6, 9, 12, 15,. . . , derived from the formula $5 \cdot e^{02\,n} - 5$, where n is the position in the sequence of ratios (Mobini et al. 2000). The so-called break point, the conventional index of performance on a progressive ratio schedule of reinforcement (Reilly 1999), was defined as the first progressive ratio sequence where lever pressing decreased $\leq 50\%$ relative to the previous phase without increasing $\geq 100\%$ in the following phase.

EVALUATION

Student's *t*-test was used to evaluate operant responding in the progressive ratio test.

MODIFICATIONS OF THE METHOD

Barr and Phillips (1999) found that withdrawal following exposure to d-amphetamine decreases responding for a sucrose solution as measured by a progressive ratio schedule of reinforcement. The authors concluded that the progressive ratio procedure may be a useful technique for evaluating changes in motivation to natural reinforcing stimuli following withdrawal from psychostimulant drugs.

For safety studies, the response requirement increases for every infusion or after a fixed period of time until the animal ceases to lever-press for a pre-determined interval, defined as the breaking point. The presumption of progressive ratio studies is that the higher the breaking point the greater the reinforcing effectiveness, although the same potential complications regarding pharmacokinetics that were noted above for a simple (FR) schedule of self administration also apply to progressive ratio schedules.

Weed et al. (1997) studied the relationship between reinforcing effects and *in vitro* effects of D1 agonists in **rhesus monkeys**.

E.2.5.4 Conditioned Defensive Burying in Rats

PURPOSE AND RATIONALE

Besides the well known defensive reactions of animals in typical laboratory settings, like freezing, fleeing, and attacking, rats tested in the presence of bedding material develop a peculiar behavior when shocked through a stationary prod by burying the shock source. This behavior has been proposed as a new paradigm for the study of anxiolytic agents (Pinel and Treit 1978, 1983; Treit et al. 1981).

PROCEDURE

Male adult rats weighing 250–400 g are used. The testing is performed in $44 \times 30 \times 44$ cm Plexiglas test chambers, the floor of which is covered with 5 cm of a commercial bedding material. In the center of each of the four walls, 2 cm above the level of the bedding material, is a small hole though which a $6.5 \times 0.5 \times 0.5$ cm wire-wrapped wooden dowel (i. e., the shock prod) can be inserted. Electric current is administered through the two uninsulated wires wrapped around the prod. The behavior of each rat is monitored for 15 min from a separate room via closed circuit television.

Before each of the experiments, the rats are placed in the Plexiglas test chamber in groups of 5 or 6 for 30-min periods on each of 4 consecutive days. In the experiments, groups of 10 animals are used for each dose and control. The rat is injected intraperitoneally with the test drug or saline before being placed into the test chamber in which the shock prod is inserted. The animal is placed into the center of the chamber so that is faces away from the prod. When the rat first touches the prod with its forepaw, it receives a brief electric shock (1 mA) which typically elicits a flinch away from the prod and withdrawal towards the back of the chamber. Afterwards, the rat moves directly towards the prod, pushing and spraying a pile of bedding material ahead with rapid shoveling movements of its snout and alternating pushing movements of its forepaws. The prod is buried in a pile of bedding material. The duration of burying is recorded.

EVALUATION

The mean duration of burying in treated animals is compared with controls. Anxiolytics as well as neuroleptics shorten the burying behavior dose-dependent at low shock intensity (1 mA). A second measure is the height of the bedding material. At high shock intensity (10 mA) only neuroleptics but not benzodiazepines are active.

CRITICAL ASSESSMENT OF THE METHOD

The method of conditioned defensive behavior can be regarded as a simple and reliable method to detect anxiolytic activity of benzodiazepines and neuroleptics. However, using higher shock intensity – where only

chlorpromazine was found to be active – a separation between benzodiazepines and neuroleptics has been demonstrated.

The drug-class specificity of the test has been challenged by Craft et al. (1988).

MODIFICATIONS OF THE METHOD

Diamant et al. (1991) used telemetry to register autonomic and behavioral responses in the shock-prod burying test in rats.

Wiersma et al. (1996) reported that microinfusion of corticotropin-releasing hormone in the central amygdala of freely moving rats enhanced the active behavior responses in the conditioned defensive burying paradigm.

Fernandez-Guasti and Lopez-Rubalcava (1998) used the rat burying behavior test to study the effect of various potential anxiolytics.

Broekkamp et al. (1986), Njung'e and Handley (1991a, b; Gacsályi et al. 1997) described burying of marbles by *mice* as harmless objects without punishment by electrical shocks as a model for detection of anxiolytics. Thirty min after treatment with drugs, male Swiss mice, weighing 20–24 g, were individually placed in a 23 × 17 × 14 cm cage with 25 glass marbles, 1.5 cm in diameter. The glass marbles were placed in close contact in the middle of the cage on a 5 cm layer of sawdust. The mice were left in the cage with the marbles for 30 min after which the test was terminated by removing the mice and counting the number of marbles that were more than two thirds covered with sawdust.

DeBoer and Koolhaas (2003) reviewed the ethology, neurobiology and psychopharmacology of defensive burying in rodents.

E.2.5.5 Taste Aversion Paradigm

PURPOSE AND RATIONALE

When ingestion of a taste stimulus is paired with internal malaise the animal remembers the taste and rejects its ingestion thereafter. This phenomenon is called a conditioned taste aversion or taste aversion learning. In the classical experiment in rats, the conditioned stimulus is a 0.01 M drinking solution of saccharin paired with an intraperitoneal injection of 0.15 M LiCl solution as unconditioned stimulus. The underlying neural mechanisms (Yamamoto 1993; Agüero et al. 1993, 1996; Swank et al. 1995) as well as facilitating and inhibiting factors (Lipinski et al. 1995; Sobel et al. 1995) were investigated. Moreover, drugs by themselves can be studied. Rats are presented a fluid with palatable taste and immediately after consumption of this liquid injected with a drug, whose effect the animals have not experienced before. Subsequently, on a later occasion and under non-drug conditions, avoid-

ance of the taste associated with the drug is measured (De Beun et al. 1996).

PROCEDURE

Male Wistar rats weighing 220–250 g are housed in groups of four per cage under a normal 12L:12D regime at 22–23°C with free access to food and water. Twenty-four hours before the first conditioned taste aversion session, the animals are water deprived and fluid access is from then on restricted to daily experimental sessions of 15 min which takes place individually in a test cage. After each session, the animals are returned to their home cages. Food is freely available in the home cages throughout the procedure, but not available during the sessions. For a given subject, all six session required to complete a conditioned taste aversion experiment take place in the same test cage. Animals designated to the same experimental group are run in parallel. During the first four sessions (day 1 through day 4), both bottles contain plain tap water. During this phase of the procedure, the animal learns to drink a reasonable amount of fluid in a short period of time. For the 5th session (day 5, conditioning session), both bottles are filled with a 0.1% saccharin solution and immediately after completion of this session the animals are injected with either the vehicle or different doses of the test drug. Per animal, only one dose (or the vehicle) of a particular drug is tested. On days 6 and 7, no sessions are conducted (washout period) and the animals have free access to tap water in the home cages from the end of day 5 until the morning of day 7, when the animals are again deprived of water, 24 h prior to the final 6th session (day 8, test session). During this last session, one bottle contains the saccharin solution and the other bottle is filled with tap water. To control for location bias, the saccharin is presented in the left bottle for half of the animals in each group and in the right bottle for the other half. By measuring the amount of fluid consumed from both bottles separately, drug-induced conditioned taste aversion can be determined by comparison of the relative saccharin intake in the drug treated groups and their vehicle-treated controls.

EVALUATION

Data of test drugs are submitted separately to one-way analysis of variance, with the between-subjects factor DOSE. The dependent variable is the ratio of (saccharin solution/saccharin solution+tap water) intake. Fluid intake scores are calculated in grams. Post hoc analyses are used with Tukey HSD multiple comparisons. Results are considered significant when $p < 0.05$.

MODIFICATIONS OF THE METHOD

Besides LiCl, several other drugs were used to induce taste aversion, such as ethanol (Gauvin and Holloway 1992; June et al. 1992; Thiele et al. 1996; Bienkwoski et al. 1997), morphine (Miller et al. 1990; Bardo and Valone 1994), cocaine (Van Haaren and Highes 1990; Glowa et al. 1994), naloxone (Mucha 1997), apomorphine (McAllister and Pratt (1998), caffeine (Brockwell et al. 1991), d-amphetamine (Davies and Wellman 1990; Lin et al. 1994), nicotine (Shoaib and Stolermman 1996), quinine (Parker 1994), cisplatin (Mele et al. (1992), benzodiazepine and nonbenzodiazepine anxiolytics (Neisewander et al. 1990), 5-hydroxytryptamine (Rudd et al. 1998), dopamine D_3 agonists (Bevins et al. 1996), cyclosporine A (Exton et al. 1998), cholecystokinin (Ervin et al. 1995; Mosher et al. 1996) and Δ9-tetrahydrocannabinol (Parker and Gillies 1995).

Turenne et al. (1996) found individual differences in reactivity to the aversive properties of drugs. Rats were assigned to high conditioned taste avoidance and low conditioned taste avoidance groups on the basis of their intake of saccharin solution previously paired with morphine, amphetamine, lithium, or fenfluramine.

Willner et al. (1992) investigated the influence of drugs on taste-potentiated odor aversion learning in rats.

Rabin and Hunt (1992) studied taste aversion learning in **ferrets**.

E.2.5.6 Cued and Contextual Fear Conditioning

PURPOSE AND RATIONALE

Fear-conditioning is a form of Pavlovian conditioning where an animal is trained to associate a neural stimulus (e. g., a 10-s presentation of light) with an aversive, unconditioned stimulus (US), such as an electric foot shock. After such pairings, the light alone predicts the occurrence of the shock and acts as a conditioned stimulus (CS), eliciting a state of fear. Tones, lights, odors and tactile stimuli have been used as CS in fear-conditioning experiments (Anagnostaras et al. 1999; Fendt and Fanselow 1999). A startle response is elicited by a sudden acoustic, visual or tactile stimulus and is composed of a fast, sequential muscle contraction, with the most prominent reaction around the face, neck, and shoulders.

The **fear-potentiated startle paradigm** was initially described by Brown et al. (1951). Rats are given several pairings of light CS and foot shock. After this procedure, the mean amplitude of the acoustic startle response to a loud noise is usually 50%–100% higher in the presence of the light CS than to the noise alone. The difference between these two trial types represents

the fear potentiation of the startle response and acts as a measure of fear.

In the **cued and contextual fear conditioning paradigm,** animals learn to associate a novel environment (context) and a previously neutral stimulus (conditioned stimulus, a tone) with an aversive foot shock stimulus. Testing then occurs in the absence of the aversive stimulus. Conditioned animals, when exposed to the conditioned stimuli, tend to refrain from all but respiratory movement. Freezing responses can be triggered by exposure to either the context in which the shock was received (context test) or the conditioned stimulus.

Sullivan et al. (2003) determined the effects of doxapram for cue and contextual fear conditioning in rats.

PROCEDURE

Fear Conditioning Apparatus

Pavlovian fear conditioning was performed using a clear polycarbonate conditioning chamber encased by a sound-attenuating outer box and fitted with metal bars as a floor that can deliver current (context 1). For fear conditioning to cue, the context was changed between the conditioning and the testing day to enhance the specificity of the fear response to the tone cue on testing. For the testing day, striped walls were placed on the outer surface of the clear chamber walls, the floor was fitted with a black panel covering the bars, the ambient light was lower, and the floor had a peppermint odor from cleaning with a scented detergent (context 2). A microcamera on the ceiling of the chamber allowed observation during the experiments and a videotape record for scoring of behavior.

Cued fear conditioning behavioral procedure

On conditioning day 0, adult male Sprague Dawley rats were habituated to the conditioning chamber for 15 min. On conditioning day 1 the rats received an intraperitoneal injection of drug and were returned to the home cages. After 10 min each rat was placed in the conditioning chamber (context 1) and was trained with two trials of tone-shock pairings. The tone (10 kHz, 72 dB) lasted 20 s and co-terminated with a 0.5-s, 7-mA shock. The intertrial interval was variable (mean 120 s) and was generated by a computer program. Videotape of the conditioning allowed later scoring of the level of freezing during each tone. On test days 1, 2, and 3, rats were tested with the different contextual stimuli in the chamber (context 2). On each day they received ten presentations of the 20-s tone (no shocks) while being videotaped for later scoring of the time spent freezing during each tone. Rats were matched by weight for control and various doses of test drug.

Contextual fear-conditioning behavioral procedure

On conditioning day 0, the rats were habituated to the conditioning chamber (context 1) for 20 min. On conditioning day 1, the rats received an intraperitoneal injection of drug and were returned to their home cages. After 7 min, each rat was placed in the same chamber (context 1), and at 8 min after injection the computer program was initiated that trained with two shocks separated by a variable intertrial interval (mean 120 s). The shocks were 1.5 mA and lasted 0.5 s, and the total time in the chamber was 8 min for all subjects. On day 2, rats were tested in the same chamber (context 1) for 5 min while being videotaped for later scoring. The 30-s periods before and after shock 1, the 30-s period after shock 2, and the first 30 s of each minute during the 5 min of testing were scored for freezing. Rats were matched by weight for vehicle and drug-treated groups.

EVALUATION

Data were analyzed with a series of one-way analyses of variance with repeated measures or with Student's *t*-tests.

MODIFICATIONS OF THE METHOD

Several modifications of this procedure have been used for various purposes (Phillips and LeDoux 1992; Lu and Wehner 1997; Maren 1998; Laurent-Demir and Jaffard 2000; DeLorey et al. 2001; Gupta et al. 2001; Malkani and Rosen 2001; McKay et al. 2002; Riedel et al. 2002; Cambon et al. 2003; Fischer et al. 2003; Maciejak et al. 2003; Walker and Carrive 2003; Sienkiewicz-Jarosz et al. 2003; Célérier et al. 2004; Kudo et al. 2004; Mesches et al. 2004; Roberts et al. 2004; Takahashi 2004; Wehner et al. 2004).

Zhang et al. (2004) used a telemetric system for recording cardiovascular data and automated measurement of conditioned freezing behavior.

Contarino et al. (2002) described automated assessment of conditioning parameters for context and cued fear in mice.

Several authors (Radulovic et al. 1998; Stiedl et al. 1999, 2000; Kishimoto et al. 2000; Eckart et al. 2001; Maciejak et al. 2003; Tezval et al. 2004; Võikar et al. 2004; Radyushkin et al. 2005; Tovote et al. 2005) used a commercially available fear-conditioning system (TSE Systems, Bad Homburg, Germany) consist-

ing of the following components: up to four boxes with animal location sensors, shock grid and test arena; box housing with software-controlled loud speaker, software-controlled light and ventilator; control unit with integrated shocker/scrambler; fear-conditioning software; PC-interface.

Crestani et al. (2002) and Gould et al. (2004) distinguished between delay fear conditioning and trace fear conditioning. For delay fear conditioning, after 3 min exposure to the chamber mice received three successive tone-shock pairings with the shock delivered during the last 500 ms of the tone. Freezing was recorded 48 h later in a modified context (new olfactory, tactile, and visual cues) for 3 min and subsequently in the presence of the tone for 8 min. For trace fear conditioning, the procedure was similar to that for delay conditioning, except that an empty trace interval of 1 s was interposed between the tone and the foot shock in three learning trials.

E.2.6
Effects on the Endocrine System

E.2.6.1
Plasma Catecholamine Levels During and After Stress

PURPOSE AND RATIONALE

A wide variety of stressors causes significant biochemical, physiological, and behavioral changes. These changes include marked increases in plasma catecholamines, heart rate and blood pressure. Treatment with anxiolytic drugs can attenuate the stress induced increases of norepinephrine and epinephrine in plasma (Vogel et al. 1984; Livesey et al. 1985; Taylor et al. 1989; de Boer et al. 1990; Krieman et al. 1992).

PROCEDURE

Male Sprague-Dawley rats, 300–350 g, are individually housed and given food and water ad libitum. After 1 week of acclimatization, an aortic catheter is surgically implanted in each animal, running on top of the psoas muscle and brought out through an incision at the back of the neck. The catheters are flushed daily with heparinized saline. After a recovery period of 48 h baseline (time –15) blood samples are drawn and blood pressure recordings are taken using a Grass model 7 polygraph. The animals are then given an i.p injection of the test compound or the vehicle. 15 min after the injection (time 0), blood samples, and heart rate and blood pressure measurements are taken. Animals in control and treatment groups are then stressed by immobilization for 1 h and blood samples, heart rate and blood pressure recordings are taken at time 15, 30 and 60 min during stress. Immobilization is performed by taping the legs of the animals to the laboratory bench. After the stress period of 1 h, the animals are released, returned to the home cage for recovery and 1 h post-stress samples and recordings are taken. Non-stressed, compound or vehicle treated animals remain in the home cage for the entire test period and are sampled in the same manner as the stressed animals. Approximately 0.3 ml blood is withdrawn for each sample and an equal amount of 0.9% saline is reinfused to prevent changes in blood volume.

EVALUATION

Determinations of norepinephrine and epinephrine in plasma are made using an radio-enzymatic assay. Heart rate and systolic and diastolic blood pressure are determined directly from the polygraph tracings. The data are analyzed using a three-way analysis of variance (ANOVA) with repeated measures, two-way ANOVA, Students *t*-test, Student-Newman-Keuls and the trapezoidal rule for the area under the curve.

CRITICAL ASSESSMENT OF THE METHOD

Reduction of catecholamine levels but no changes of the cardiovascular parameters could be found after treatment with anxiolytics. The test can be used as a method for evaluation of the influence of psychoactive drugs on the endocrine system (Krieman et al. 1992).

E.2.6.2 Plasma Corticosterone Levels Influenced by Psychotropic Drugs

PURPOSE AND RATIONALE

Corticosterone levels in the blood of rats are elevated not only after stress but also after application of selective 5-HT receptor agonists (Koenig et al. 1987). This has been used to differentiate typical and atypical neuroleptics (Nash et al. 1988).

PROCEDURE

Male Sprague Dawley rats weighing 200–250 g are housed 6 per cage under temperature and light/dark controlled conditions with free access to food and water. On the day prior to an experiment, the animals are transferred to the experimental room. On the day of the experiment, various doses of test drugs or saline are injected intraperitoneally. After 60 min 2.5 mg/kg 6-chloro-2-(1-piperazinyl)pyrazine (MK-212) are injected intraperitoneally followed by decapitation after further 60 min. Trunk blood is collected and allowed to clot. Serum is obtained following centrifugation and stored at –20°C for the radioimmunoassay of corticosterone.

EVALUATION

Data are analyzed with a two-way analysis of variance. Differences between treatment groups are evaluated using the Student-Newman-Keuls test.

MODIFICATIONS OF THE METHOD

Korte et al. (1991) studied the effect of a 5-HT_{1A} agonist on behavior and plasma corticosterone levels in male Wistar rats before and after psychological stress of defeat.

Broqua et al. (1992) measured corticosterone and glucose levels in blood together with parameters of 5-HT metabolism in brain in stressed animals treated with the anti-depressant tianeptine.

Rittenhouse et al. (1992) measured plasma concentrations of renin, corticosterone, ACTH, and prolactin in rats after treatment with a 5-HT_{1A} agonist in three stress paradigms: immobilization, forced swim and conditioned fear.

Groenink et al. (1995) studied the corticosterone secretion in rats after application of 5-HT_{1A} receptor agonists and antagonists.

Aulakh et al. (1988, 1993) reported higher baseline levels of plasma corticosterone in fawn-hooded rats relative to Wistar and Sprague-Dawley strain rats. Long-term treatment (21 days) with antidepressant drugs significantly decreased plasma corticosterone in fawn-hooded rats. The authors recommended this strain as a genetic model of depression.

E.2.7
Benzodiazepine Dependence

E.2.7.1
General Considerations

Benzodiazepine dependence is a hypothetical construct for the adaptive changes that occur as a result of chronic drug exposure. Two measures are usually considered to reflect dependence: the development to a drug's effects, and the abstinence signs of drug withdrawal.

REFERENCES AND FURTHER READING

File SE, Hitcott PK (1991) Benzodiazepine dependence. In: Briley M, File SE (eds) New Concepts in Anxiety. McMillan Press Ltd., London, pp 237–255

E.2.7.2
Benzodiazepine Tolerance and Dependence in Rats

PURPOSE AND RATIONALE

Induction of benzodiazepine tolerance and physical dependence has been reported for several animal species, such as rats, mice, dogs and monkeys. Ryan and Boisse (1983) and Boisse et al. (1986) developed a reproducible model exemplified for chlordiazepoxide in rats.

PROCEDURE

Male Sprague Dawley rats weighing 350–575 g are used. Chordiazepoxide hydrochloride is administered as solution 75 mg/ml by gavage after an initial loading dose of 450 mg/kg given at 7:00 A.M. and 5:00 P.M. Impairment of motor function is evaluated by a neurological screen including five different ladder and open field tests.

Neurological Test	Maximum Depression Points
Ladder, head down	2
Ladder, head up	4
Ladder, grasp reflex	1
Motor activity	3
Walking	5
Maximum	15

The animals are rated by three independent observers. Once dependence is revealed, lower doses are used which are then increased in appropriate steps to induce an average depression rating of about five. Treatment is continued for 5 weeks during which time the dose has to be increased. The degree of increase (about 5-fold for in the case of chlordiazepoxide) reflects the **tolerance** of the test compound.

To test **dependence**, rats are challenged with the benzodiazepine receptor antagonist Ro 15–1788 (flumazenil; ethyl-8-fluoro-5,6-dihydro-5-methyl-6-oxo-4H-imidazo(1,5a)(1,4)benzodiazepine-3-carboxylate) at a dose of 25 mg/kg i.p. Withdrawal reactions are recorded just before, and 5, 15, 30 and 60 min after administration of the antagonist. Motor, autonomic and behavioral signs are monitored by operational defined criteria, such as position of the claws, salivation and diarrhea. The total withdrawal expression for each observation and each animal is estimated by summing the grades of all signs as recorded by three independent observers.

EVALUATION

For each animal and observation time, the scores are estimated by the average of all co-observers. From these estimates group means are computed and compared by *t*-test between control and test and by paired *t*-test for self-control comparisons before and after antagonist administration

MODIFICATIONS OF THE METHOD

Further studies in *rat* with benzodiazepines were preformed by Vellucci and File (1979), Treit (1985) and Nath et al. (1997).

File (1985) found very different rates at which tolerance develops to the sedative, anticonvulsive and anxiolytic actions of benzodiazepines.

Bonnafous et al. (1995) studied the increase of gastric emptying induced by benzodiazepine withdrawal in rats. Gastric emptying was measured with a test meal containing ^{51}Cr sodium chromate administered in rats, either previously receiving 15 mg/kg diazepam or DMSO i.p. for 7 days.

Benzodiazepine-like dependence potential of a putative 5-HT_{1A} agonist anxiolytic was assessed in rats by Goudie et al. (1994).

Studies in *mice* on tolerance and physical dependence with benzodiazepines were performed by Patel et al. (1988), Gallaher et al. (1986), Stephens and Schneider (1985), Nutt and Costello (1988) and Piot et al. (1990).

These phenomena were studied in *dogs* by McNicolas et al. (1988) and Löscher et al. (1989).

Studies in monkeys were performed by Lukas and Griffiths (1982), Yanagita (1983), Lamb and Griffiths 1984) and France and Gerak (1997).

E.2.8 Genetically Modified Animals in Psychopharmacology

E.2.8.1 General Considerations

The use of genetically altered animals in biological research has also affected psychopharmacology. Genetically engineered strains of mice, modified by transgenesis or gene targeting ("knockout") have been generated and are used as research tools for deciphering the genetic basis of behavior. These animals are designed to evaluate the efficacy of new pharmacological and gene therapy treatments in human hereditary diseases (Crnic 1996; Mayford et al. 1997; Costentin 1998; Picciotto and Wickmanm 1998; Anagnostopoulos et al. 2001).

E.2.8.2 Special Reports on Genetically Altered Animals Useful for Evaluation of Drugs Against Anxiety

Wilson et al. (1996) reported that the **transgenic (mREN2) rat**, basically a model of genetically engineered hypertension, showed an anxiogenic profile in several tests, e. g., open field or elevated X-maze.

Saudou et al. (1994) found enhanced aggressive behavior in **mice lacking the 5-HT_{1B}receptor**. When confronted with an intruder, mutant mice attacked the intruder faster and more violently than did wild-type mice.

Trillat et al. (1998) studied the antidepressant effect of selective serotonin reuptake inhibitors (SSRIs) in homozygote mice deficient in the serotonin **5-HT_{1B}receptor**. The findings suggested that 5-HT_{1B} autoreceptors limit the effect of SSRIs particularly in the hippocampus while postsynaptic 5-HT_{1B} receptors are required for the antidepressant activity of SSRIs.

Parks et al. (1998) described increased anxiety in **mice lacking the serotonin 1A receptor**. Mice with an inactivated gene encoding the 5-HT_{1A} receptor have an increased tendency to avoid a novel and fearful environment and to escape a stressful situation.

Likewise, Heisler et al. (1998) found elevated anxiety and antidepressant-like responses in serotonin **5-HT_{1A} mutant mice**.

Ramboz et al. (1999) described **serotonin receptor 1A knockout mice** as an animal model of anxiety-related disorder. The authors demonstrated that mice without 5-HT_{1A} receptors display decreased exploratory activity and increased fear of aversive environments (open or elevated spaces). 5-HT_{1A} knockout mice also exhibited a decreased immobility in the forced swim test, an effect commonly associated with antidepressant treatment. These results showed that 5-HT_{1A} receptors are involved in the modulation of exploratory and fear-related behaviors and suggested that reductions in 5-HT_{1A} receptor density due to genetic defects or environmental stressors might result in heightened anxiety.

Gross et al. (2000) used genetically altered mice to determine the influence of different neurotransmitter receptors on fear and anxiety. **Mice with a genetic deletion of the 5-HT_{1A} receptor** were more fearful in a number of behavioral conflict tests, confirming the importance of this receptor in modulating anxiety.

Knapp et al. (2000) bred rats selectively for high or low hypothermic responses to the specific 5-HT_{1A} receptor agonist 8-hydroxy-2-di-n-propylamino tetralin (8-OH-DPAT). These rats differed in responses related to anxiety and depression.

Holmes (2001) reviewed targeted gene mutation approaches to the study of anxiety-like behavior in mice.

Schramm et al. (2001) found that the α_{2A}-adrenergic receptor plays a protective role in mice behavioral models of depression and anxiety. The genetic **knockout of the α_{2A}-adrenergic receptor** makes mice less active in a modified Porsolt's swim test and insensitive to the antidepressant effect of imipramine in this paradigm. Furthermore, α_{2A}-adrenergic receptor knockout mice appear more anxious than wild-type C57 Bl/6 mice in rearing and light/dark models of anxiety.

Quinlan et al. (2000) reported that **mice lacking the long splice variant of the gamma 2 subunit of the $GABA_A$ receptor** are more sensitive to benzodiazepines. Lack of the gamma 2L subunits may shift the $GABA_A$ receptor from an inverse-agonist-preferring toward an agonist-preferring configuration.

Yamada et al. (2000) described neurobehavioral alterations in mice with a targeted **deletion of the tumor necrosis factor-alpha gene** and the implications for emotional behavior.

Miyakawa et al. (2001) studied the behavior of **mice lacking the M_1 muscarinic acetylcholine receptor**. The animals exhibited a pronounced increase in locomotor activity in various tests, including open field, elevated plus maze, and light/dark transition tests. However, hippocampus-dependent learning was intact.

Picciotto et al. (2001) studied physiological and behavioral phenotypes of **neuronal nicotine acetylcholine receptor subunit knockout mice** and discussed possible implications for drug development.

Rupniak et al. (2001) used assays for antidepressant and anxiolytic drugs, such as resident-intruder or the forced swim test, to compare the phenotype of **NK1R–/– mice** with pharmacological blockade of the substance P (NK1) receptor.

Montag-Sallaz and Montag (2003) found severe cognitive and motor coordination deficits in **Tenascin-R-deficient mice**. The animals were tested for grip strength, open field behavior, elevated plus maze, light-dark avoidance, hole board examination, in the Morris water maze and in two-way active avoidance learning using several systems from TSE Systems, Bad Homburg, Germany).

Bilkei-Gorzo et al. (2004) studied behavioral and drug effects in **pre-proenkephalin-deficient mice** in the elevated zero-maze maze (using the VideoMot 2 system), the light-dark test using the animal activity monitor Actimot, and in the startle response test (all systems provided by TSE Systems, Bad Homburg, Germany)

E.3 Anti-Epileptic Activity

E.3.0.1 General Considerations

Epilepsy is a disease of high prevalence, being well known since thousands of years as "morbus sacer". In spite of intensive investigations, the pathophysiology of epilepsy is still poorly understood. Studies with various animals models have provided ample evidence for heterogeneity in the mechanisms of epileptogenesis. New evidence derives from investigations of kindling, which involves the delivery of brief, initially subliminal, electrical or chemical stimuli to various areas of the brain. After 10 to 15 days of once-daily stimulation, the duration and intensity of after-discharges reach a stable maximum and a characteristic seizure is produced. Subsequent stimulation then regularly elicits seizures.

Surveys of methods being used to test compounds with anticonvulsant properties have been provided by Toman and Everett (1964), Woodbury (1972), Hout et al. (1973), Swinyard (1973), Koella (1985), Meldrum (1986), Rump and Kowalczyk 1987; Löscher and Schmidt (1988), Fisher (1989), Rogawski and Porter (1990), Porter and Rogawski (1992).

Epilepsy becomes drug resistant in 20%–30% of patients. Out of the animal models, the amygdala-kindled rat seems to be a suitable approach (Löscher 1997, 1998, 2002a, 2002b). Furthermore, the rat cortical dysplasia model is recommended (Smyth et al. 2002).

Several biochemical hypotheses have been advanced, involving the inhibitory GABAergic system and the system of the excitatory amino acids glutamate and aspartate. Excitatory receptors have been divided into subtypes according to the actions of specific agonists or antagonists. Agents which reduce $GABA_A$ synaptic function provoke convulsions. A convulsive state is induced by the direct blockade of $GABA_A$ receptors (e. g. to the action of bicuculline) or a reduction in the GABA-mediated opening of the chloride ion channel (e. g., by picrotoxin). One major factor in epileptogenesis seems to be a decreased function of $GABA_A$ synapses.

More recently, research has focused on the therapeutic potential of blocking excitatory amino acids – in particular glutamate. Of the three receptors of glutamate, the NMDA (N-methyl-D-aspartate)-receptor is considered the one of most interest in epilepsy and competitive NMDA receptor antagonists are proposed as potential anti-epileptic drugs. Excessive excitatory amino acid neurotransmission is thought to be associated with the neuropathologies of epilepsy, stroke and other neurodegenerative disorders. Antagonism of NMDA receptor function appears to be the mechanism of action of some novel anticonvulsant and neuroprotective agents. Excitatory amino acid receptors have been classified into at least three subtypes by electrophysiological criteria: NMDA, quisqualic acid (QA) and kainic acid (KA) (Cotman and Iversen 1987; Watkins and Olverman 1987).

Fabene and Sbarbati (2004) underlined the value of *in vivo* MRI in different models of experimental epilepsy.

E.3.1.4 ^{3}H-GABA Uptake in Rat Cerebral Cortex Synaptosomes

PURPOSE AND RATIONALE

Roberts (1974) and others have proposed that the inhibitory action of the amino acid γ-aminobutyric acid (GABA) is the fine tuning control for pacemaker neurons. Disruption of this interplay due to inadequacies of the GABA system result in various disorders, in particular convulsive seizures (Roberts 1974; Korgsgaard-Larsen 1985). The nonspecific action of GABA-mimetics makes inhibition of the uptake mechanism, which terminates the neurotransmitters action, the ideal choice for increasing GABA's concentration at specific sites (Roberts 1974; Tapia 1975; Meldrum et al. 1982; Brehm et al. 1979). Demonstration of the high affinity mechanism that best reflects the *in vivo* condition utilizes GABA depleted cerebral cortex synaptosomes (Ryan and Roskoski 1977; Iversen and Bloom 1972; Roskoski 1978).

Although the physiological role of GABA transport systems is still unclear, uptake inhibitors such as THPO [4,5,6,7-tetrahydroisoxazolo-(4,5-C)pyrid-3-ol], nipecotic acid, cis-4-hydroxynipecotic acid, and guvacine exhibit anticonvulsant effects (Meldrum et al. 1982; Brehm et al. 1979). Furthermore, a number of neuroleptics have been shown to inhibit GABA uptake (Fjalland 1978). In particular, fluspirilene was found to be equivalent to the most potent uptake inhibitors known.

The assay is used as a biochemical screen for potential anticonvulsants or GABA (γ-aminobutyric acid) mimetic compounds that act by inhibiting GABA uptake.

PROCEDURE

Reagents

1. 0.5 M Tris buffer, pH 7.4
2. Ringer's solution+10 mM Tris buffer, pH 7.4 containing
   - glucose 10.0 mM,
   - NaCl 150.0 mM,
   - KCl 1.0 mM,
   - $MgSO_4$ 1.2 mM,
   - Na_2HPO_4 1.2 mM.
3. Depolarizing Ringer's solution, pH 7.4 reagent 2 containing
   - KCl 56 mM,
   - $CaCl_2$ 1 mM.
4. 0.32 M sucrose
5. ^{3}H-GABA is diluted to 2.5×10^{-4} M with distilled water. Forty µl of this solution in 1 ml of reaction mixture will yield a final concentration of 10^{-5} M.
1. Test compounds
   A 10 mM stock solution is made up in distilled water, ethanol, or DMSO and serially diluted, such that the final concentration in the assay ranges from 10^{-3} to 10^{-8} M. Total and nonspecific controls should use solvent of test compound.

Tissue Preparation

Male Wistar rats are decapitated and the brains rapidly removed. Cerebral cortex is weighed and homogenized in 9 volumes of ice-cold 0.32 M sucrose using a Potter-Elvejhem homogenizer. The homogenate is centrifuged at 1000 *g* for 10 min. The supernatant (S_1) is decanted and recentrifuged at 1000 *g* for 10 min. The pellet (P_2) is resuspended in 9 volumes of 0.32 M sucrose and centrifuged at 24,000 *g* for 10 min. The washed pellet is resuspended in15 volumes of depolarizing Ringer's solution, incubated at 25°C for 10 min and centrifuged at 3000 *g* for 10 min. The resulting pellet is resuspended in 15 volumes of Ringer's solution and is ready for use.

Assay

60 µl	Ringer's solution,
100 µl	vehicle or appropriate drug concentration,
800 µl	tissue suspension.

Microcentrifuge tubes are set up in triplicate. Nonspecific controls are incubated at 0°C and totals at 25°C for 10 min. Forty µl of ^{3}H-GABA are added and the tubes are reincubated for 10 min. All tubes are centrifuged at 13,000 *g* for 1 min. The supernatant is aspirated and 1 ml of solubilizer (Triton X-100 + 50% EtOH, 1:4, v/v) is added and mixed to dissolve pellets. Tubes are incubated at 90°C for 3 min, then centrifuged at 13,000 *g* for 15 min. 40 µl of supernatant is counted in 10 ml Liquiscint scintillation cocktail.

EVALUATION

Active uptake is the difference between cpm at 25°C and 0°C. The percent inhibition at each drug concentration is the mean of three determinations. IC_{50} values are derived from log-probit analysis.

E.3.1.5 GABA Uptake and Release in Rat Hippocampal Slices

PURPOSE AND RATIONALE

The GABA transporter, the subsynaptic $GABA_A$-receptor, and the $GABA_B$-autoreceptor are therapeutically the most relevant targets for drug actions influencing GABAergic synaptic transmission. Uptake inhibitors are potential anticonvulsants.

PROCEDURE

For measurement of GABA uptake, rat hippocampal slices are cut with a McIlwain tissue slicer (100 µm-thick prisms) and dispersed in ice-cold Krebs-Ringer solution with HEPES buffer (pH 7.4). Following two washes, slices (15 mg) are incubated at 37°C for 15 min in the presence or absence of test compound. [^{3}H]-GABA is added and samples are incubated for an additional 5 min before filtration through Whatman GF/F filters. Samples are then washed twice with 5 ml ice-chilled 0.9% saline. Distilled water is added and samples are allowed to sit at least 60 min before measured for radioactivity by liquid scintillation spectroscopy. Blanks are treated in an identical manner but are left on ice throughout the incubation.

For measurement of GABA release, rat hippocampal slices are prepared and dispersed in ice-cold HEPES-buffered (pH 7.2) Krebs Ringer solution and incubated with 0.05 µM [^{3}H]-GABA for 15 min at 37°C. Following two washes, the slices are incubated for an additional 15 min and finally resuspended in medium. Tissue (10 mg) is incubated at 37°C for a 15 min release period in the presence or absence of test compound. At the end of the release period, the medium is separated from tissue by centrifugation at 500 *g* for approximately 1 min and poured into 0.5 ml of perchloric acid (0.4 N). The tissue is homogenized in 0.13 N perchloric acid. Radioactivity in the samples is measured by using liquid scintillation spectroscopy.

EVALUATION

For GABA-uptake, IC_{50}-values (µM) are determined.

In GABA-release experiments, results are expressed as the amount of radioactivity released as a percent of the total radioactivity.

MODIFICATIONS OF THE METHOD

Roskoski (1978) studied the net uptake of GABA by high affinity synaptosomal transport systems.

Nilsson et al. (1990, 1992) tested GABA uptake in astroglial primary cultures.

The **isolated nerve-bouton preparation** was used to study GABA release (Jang et al. 2001; Kishimoto et al. 2001; Akaike et al. 2002; Akaike and Moorhouse 2003). The technique was developed by Drewe et al. (1988), Vorobjev (1991), Haage et al. (1998), Rhee et al. (1999), and Koyama et al. (1999).

The method is based on the local application of mechanical vibration directly to the chosen site of a brain slice and does not require the enzymatic pretreatment of the tissue. The mechanical vibration is applied via a glass rod (0.5 mm in diameter) mounted on a piezoelectric bimorph crystal at the site of the chosen brain tissue. The dissociated cells are allowed to settle at the bottom of a Petri dish for 20 min. The cell bodies are usually 10–15 µm at their longest axis, rounded or elongated in shape. Some cells had remaining neurites up to 100 µm long. The majority of cells had neurites less than 15 µm long.

In other studies (Koyama et al. 1999; Kishimoto et al. 2001), a custom-built vibrating stylus was placed in the appropriate region for mechanical dissociation. The glass capillary (1.5 mm o.d.) was pulled to a fine tip and fire-polished. The tip was placed within the appropriate region by a manipulator. The vibrating stylus was driven by an electronic relay and the tip was horizontally moved (excursions of 2–3 mm at 0.5–2 Hz) for 2 min.

Neurons with adherent functional synaptic terminals were investigated by tight-seal whole-cell recordings from the postsynaptic cells.

E.3.1.6 Glutamate Receptors: [^{3}H]CPP Binding

PURPOSE AND RATIONALE

The ionotropic glutamate receptors are ligand-gated ion channels that mediate the vast majority of excitatory neurotransmission in the brain. The family comprises three pharmacologically defined classes that were originally named after reasonably selective ligands: *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA), and kainate (Cotman and Iversen 1987; Watkins and Olverman 1987; Collingridge and Lester 1989; Monaghan et al. 1989; Carlsson and Carlsson 1990; Young and Fagg 1990; Nakanishi 1992; Cunningham et al. 1994; Herrling 1994; Iversen and Kemp 1994; Mayer et al. 1994; Meldrum and Chapman 1994; Monaghan and Buller 1994; Watkins 1994; Bettler and Mulle 1995; Fletcher and Lodge 1995; Becker et al. 1998; Danysz and Parsons 1998; Meldrum 1998; Chittajallu et al. 1999; Dingledine et al. 1999; Hatt 1999; Gallo and Ghiani 2000; Lees 2000; Meldrum 2000). It turned out that NMDA, AMPA and kainate receptor subunits are encoded by at least six gene families as defined by sequence homology: a single family of AMPA receptors, two for kainate, and three for NMDA (Dingledine et al. 1999; Mayer and Armstrong 2004).

The NMDA subtype is a hetero-oligomer consisting of an NR1 subunit combined with one or more NR2 subunits and a third subunit, NR3 (Loftis and Janowsky 2003). The receptor has two amino acid recognition sites, one for glutamate and one for glycine, both of which must be occupied to promote channel opening. A variety of drugs have been identified which block the channel selectively (Bräuner-Osborne et al. 2000; Kemp and McKernan 2002).

The AMPA subtype is a hetero-oligomer formed from combinations of iGluR1–4. Selective agonists and competitive antagonists acting at the glutamate recognition site have been useful for defining the physiological and pathophysiological roles played by the receptor. AMPA receptor modulators have been discussed as cognitive enhancers (Lynch 2004).

The kainate subtype consists of hetero-oligomers, comprising five subunits (Hollmann and Heinemann 1994; Huettner 2003).

Excessive excitatory amino acid neurotransmission has been associated with the neuropathologies of epilepsy, stroke and other neurodegenerative disorders (Cotman and Iversen 1987; Watkins and Olverman 1987; Parsons et al. 1998). Antagonism of NMDA receptor function appears to be the mechanism of action of some anticonvulsant and neuroprotective agents (Loscher 1998; Tauboll and Gjerstad 1998). The binding site for [^{3}H]2-amino-4-phosphonobutyric acid (AP4) may represent a fourth site which is less well characterized (Thomsen 1997). NMDA receptors are believed to be coupled to a cation channel

which converts to an open state with NMDA receptor activation (Kemp et al. 1987; Mukhin et al. 1997). The opening and closing of this cation channel are also modulated by glycine, Mg^{2+} and Zn^{2+}. Dissociative anesthetics, such as phencyclidine (PCP) and ketamine, and novel anticonvulsants, such as MK-801, block the ion channel and are noncompetitive NMDA receptor antagonists. Competitive NMDA receptor antagonists, such as CPP and the phosphono analogs of L-glutamate, AP7 and AP5 (2-amino-5-phosphonopentanoic acid), are inhibitors at the excitatory amino acid binding site (Olverman et al. 1986; Davies et al. 1986; Harris et al. 1986; Murphy et al. 1987; Lehmann et al. 1987).

The following assay is used to assess the affinity of compounds for the excitatory amino acid binding site of the NMDA receptor complex. [^{3}H]CPP 3-[(±)-2-carboxypiperazin-4-yl]-1-phosphonic acid is a structurally rigid analog of the selective NMDA receptor antagonist 2-AP7 (2-amino-7-phosphonoheptanoic acid).

PROCEDURE

Reagents

1. Buffer A: 0.5 M Tris HCl, pH 7.6
   60.0 g Tris HCl
   13.9 g Tris Base
   q.s. to 1 liter with distilled water
2. Buffer B: 50 mM Tris HCl, pH 7.6
   Dilute buffer A 1:10 with distilled water
3. L-Glutamic acid, 5×10^{-3} M
   Dissolve 7.36 mg of l-glutamic acid (Sigma G1251) with 10.0 ml distilled water. Aliquots of 20 µl to the assay tube will give a final concentration of 10^4M.
4. [^{3}H]CPP is obtained from New England Nuclear, specific activity 25–30 Ci/mmol. For IC_{50} determinations, a 200 nM stock solution is made with distilled water. Aliquots of 50 µl are added to each tube to yield a final concentration of 10 mM.
5. Test compounds. A stock solution of mM is made with a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. Higher or lower concentrations may be used, depending on the potency of the drug.
6. Triton-X 100, 10% (v/v) (National Diagnostics, EC-606) A stock solution of Triton-X100, 10%, can be prepared and stored in the refrigerator. Dilute 1.0 ml of Triton-X100 to 10.0 ml with distilled water. On the day of the assay, the tissue homogenate (1:15 dilution) is preincubated with an aliquot of Triton-X 100, 10%, to give a final concentration of 0.05% (v/v).

Tissue Preparation

Cortices of male Wistar rats are dissected over ice and homogenized in ice-cold 0.32 M sucrose, 15 volumes of original wet weight of tissue, for 30 s with a Tissumizer setting at 70. The homogenate is centrifuged at 1000 *g* for 10 min. (SS34, 3000 rpm, 4°C). The supernatant is centrifuged at 20,000 *g* (SS34, 12,000 rpm, 4°C) for 20 min. Resuspend the pellet in 15 volumes of ice-cold distilled water (Tissumizer setting 60, 15 s) and spin at 7600 *g* (SS34, 8000 rpm, 4°C) for 20 min. Save the supernatant, swirl off the upper buffy layer of the pellet and add to the supernatant. Centrifuge the supernatant at 48,000 *g* (SS34, 20,000 rpm, 4°C) for 20 min. Resuspend the pellet with 15 volumes of cold distilled water and centrifuge. Discard the supernatant and store the pellet at –70°C.

On the day of the assay, resuspend the pellet in 15 volumes ice-cold 50 mM Tris buffer, pH 7.6. Preincubate the homogenate with Triton-X in a final concentration 0.05% (v/v) for 15 min at 37°C with agitation. Centrifuge the homogenate at 48,000 *g* (SS34, 20,000 rpm, 4°C for 20 min. Wash the pellet an additional 3 times by resuspension with cold buffer and centrifugation. The final pellet is resuspended in a volume 20 times the original wet weight.

Assay

1. Prepare assay tubes in triplicate.

380 µl	distilled water
50 µl	buffer A, 0.5 M Tris HCI, pH 7.6
20 µl	L-glutamic acid, 10^{-4} M, or destilled water, or appropriate concentration of inhibitor
50 µl	[^{3}H]CPP
500 µl	tissue homogenate

2. Following the addition of the tissue, the tubes are incubated for 20 min at 25°C with agitation. Place the tubes in an ice bath at the end of the incubation. Terminate the binding by centrifugation (HS4, 7000 rpm, 4°C) for 15 min. Return the tubes to ice. Aspirate the discard the supernatant. Carefully rinse the pellet three times with 1 ml ice-cold buffer, avoiding disruption of the pellet. Transfer the pellet to scintillation vials by vortexing the pellet with 2 ml scintillation fluid, rinse the tubes twice with 2 ml and add an additional 4 ml scintillation fluid.

EVALUATION

Specific binding is determined from the difference of binding in the absence of presence of 10^{-4} M L-

glutamic acid and is typically 60–70% of total binding. IC_{50} values for the competing drug are calculated by log-probit analysis of the data.

MODIFICATIONS OF THE ASSAY

Glutamate (Non Selective)

The assay measures the binding of glutamate, which binds non selectively to ionotropic glutamate receptors including the NMDA, AMPA, and kainate subtypes (Foster and Fagg 1987). In addition, glutamate binds to a family of metabotropic glutamate receptors.

Whole brains (except cerebellum) are obtained from male Wistar rats. A membrane fraction is prepared by standard techniques. Ten mg of membrane preparation is incubated with 1.6 nM [^{3}H]L-glutamate for 10 min at 37°C. Non-specific binding is estimated in the presence of 50 µM L-glutamate. Membranes are filtered and washed 3 times to separate bound from free ligand and filters are counted to determine [^{3}H]L-glutamate bound.

Convulsions induced in mice by intravenous injections of 2.0 mmol/kg L-glutamic acid can be inhibited by glutamate antagonists (Piotrovsky et al. 1991).

Glutamate AMPA

The assay measures the binding of [^{3}H]AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid), a selective agonist which binds to the AMPA receptor subtype of glutamate-gated ion channels (Honore et al. 1982; Olsen et al. 1987; Fletcher and Lodge 1995).

Membranes are prepared from male rat brain cortices by standard techniques. Fifteen mg of membrane preparation is incubated with 5 nM [^{3}H]AMPA for 90 min at 4°C. Non-specific binding is estimated in the presence of 1 mM L-glutamate. Membranes are filtered and washed 3 times and the filters are counted to determine [^{3}H]AMP bound.

Mutel et al. (1998) recommended [^{3}H]Ro 48–8587 as specific for the AMPA receptor.

Fleck et al. (1996) described AMPA receptor heterogeneity in rat hippocampal neurons. AMPA receptor antagonists were described by Kohara et al. (1998), Wahl et al. (1998), Kodama et al. (1999), Nielsen et al. (1999) and reviewed by Chimirri et al. (1999).

Glutamate Kainate

The assay measures the binding of [^{3}H]kainate, a selective agonist that binds to the kainate subtype of the ionotropic glutamate receptors in rat brain (London and Coyle 1979; Clarke et al. 1997).

Whole brains (except cerebellum) are obtained from male Wistar rats. Fifteen mg of a membrane fraction prepared by standard techniques is incubated with 5.0 nM [^{3}H]kainate for 1 h at 4°C. Non-specific binding is estimated in the presence of 1 mM L-glutamate. Membranes are filtered and washed 3 times to separate free from bound ligand and filters are counted to determine [^{3}H]kainate bound.

Toms et al. (1997), Zhou et al. (1997) recommended [^{3}H]-(2S,4R)-4-methylglutamate as kainate-receptor selective ligand.

Irreversible inhibition of high affinity [^{3}H]kainate binding by a photoactivatable analogue was reported by Willis et al. (1997).

Worms et al. (1981) described the behavioral effects of systemically administered kainic acid.

Hu et al. (1998) described neuronal stress and seizure-induced injury in C57/BL mice after systemic kainate administration.

Glutamate NMDA-Agonist Site

The assay measures the binding of CGS 19755, a selective antagonist, to the agonist site of the NMDA receptor (Lehmann et al. 1988; Murphy et al. 1988; Jones et al. 1989)

E.3.1.7 NMDA Receptor Complex: [^{3}H]TCP Binding

PURPOSE AND RATIONALE

The purpose of this assay is to determine the binding affinity of potential noncompetitive NMDA antagonists at the phencyclidine (PCP) binding site which is believed to be within or near the NMDA-regulated ion channel. TCP, 1-[1-(2-thienyl)cyclohexyl]-piperidine, is a thienyl derivative of PCP.

Excessive activity of excitatory amino acid neurotransmitters has been associated with the neuropathologies of epilepsy, stroke and other neurodegenerative disorders (Cotman and Iversen 1987; Watkins and Olverman 1987). Antagonism of NMDA receptor function appears to be the mechanism of action of some novel anticonvulsant and neuroprotective agents. Excitatory amino acid receptors have been classified into at least three subtypes by electrophysiological criteria: NMDA, quisqualic acid (QA) and kainic acid (KA) (Cotman and Iversen 1987; Watkins and Olverman 1987). The binding site for [^{3}H]2-

amino-4-phosphonobutyric acid (AP4) may represent a fourth site which is less well characterized. NMDA receptors are believed to be coupled to a cation channel which converts to an open state following activation (Kemp et al. 1987). The opening and closing of this cation channel are also modulated by glycine, Mg^{2+}, Zn^{2+} and polyamines (Loo et al. 1986; Snell et al. 1987; Reynolds et al. 1988; Thomson 1989; Snell et al. 1988; Sacaan and Johnson 1989; Thedinga et al. 1989; Williams et al. 1989). Dissociative anesthetics, such as phencyclidine (PCP) and ketamine, and the neuroprotective agent MK-801 block the ion channel and are noncompetitive NMDA receptor antagonists. Competitive NMDA receptor antagonists, such as 3-[(±)-2-carboxypiperazin-4-yl]-1-phosphonic acid (CPP), and the phosphono analogs of L-glutamate, 2-amino-7-phosphonoheptanoic acid (2-AP7) and 2-amino-5-phosphonopentanoic acid (2-AP5), are inhibitors at the excitatory amino acid recognition site.

Molecular cloning and functional expression of rat and mouse NMDA receptors (Moriyoshi et al. 1991; Meguro et al. 1992), a family of AMPA-selective glutamate receptors (Keinänen et al. 1990) and the metabotropic glutamate receptors mGluR1–mGluR6 (Schoepp et al. 1990; Masu et al. 1991; Abe et al. 1992; Bashir et al. 1993; Nakajima et al. 1993; Tanabe et al. 1993) have been reported.

PROCEDURE I

Reagents

1. Buffer A: 0.1 M HEPES, pH 7.5
   Weigh 23.83 g HEPES
   Add approximately 900 ml distilled water.
   Adjust pH to 7.5 with 10 N NaOH.
   q.s. to 1 liter with distilled water.
2. Buffer B: 10 mM HEPES, pH 7.5
   Dilute buffer A 1:10 with distilled water and adjust pH to 7.5.
3. L-Glutamic acid, 5×10^{-3} M
   Dissolve 7.36 mg with 10.0 ml distilled water.
   Aliquots of 20 µl to the assay tube will give a final concentration of 10^{-4} M.
4. Glycine, 5×10^{-4} M
   Dissolve 3.75 mg with 10.0 ml distilled water.
   Dilute 1:10 with distilled water.
   Aliquots of 20 µl to the assay tube will give a final concentration of 10^{-5} M.
5. Phencyclidine HCl (PCP) is used for nonspecific binding.
   Dissolve 0.7 mg in 0.5 ml distilled water.
   Aliquots of 20 µl to the assay tube will give a final concentration of 10^{-4} M.
6. [^{3}H]TCP is obtained from New England Nuclear, specific activity 42–60 Ci/mmole. For IC_{50} determinations, a 50 nM stock solution is made with distilled water. Aliquots of 50 µl are added to each tube to yield a final concentration of 2.5 nM.
7. Test compounds. A stock solution of 5 mM is made up with a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. Higher or lower concentrations may be used, depending on the potency of the drug.

Tissue Preparation

Cerebral cortex of male Wistar rats, 7–10 weeks of age, is dissected over ice and homogenized in ice-cold 0.32 M sucrose, 30 volumes of original tissue weight, for 60 s with a Tissumizer setting at 70. The homogenate is centrifuged at 1000 *g* for 10 min. (SS34, 3000 rpm, 4°C). The supernatant is centrifuged at 20,000 *g* for 20 min. (SS34, 12,000 rpm, 4°C). The pellet is resuspended with cold distilled water, to 50 volumes of original tissue weight, using the Tissumizer, 60 s at setting of 70. The homogenate is incubated at 37°C for 30 min, transferred to centrifuge tubes, and centrifuged at 36,000 *g* for 20 min. (SS34, 16,500 rpm, 4°C). The pellet is again resuspended in 50 volumes distilled water, incubated and centrifuged. All resuspensions with the Tissumizer are for 60 s at a setting of 70. The resulting pellet is resuspended in 30 volumes of ice-cold 10 mM HEPES buffer, pH 7.5, centrifuged, and washed once again (resuspension and centrifugation) with buffer. Following resuspension in 30 volumes of buffer, the homogenate is frozen in the centrifuge tube and stored at –70°C until the day of the assay.

On the day of the assay, the homogenate is thawed and centrifuged at 36,000 *g* for 20 min. (SS34, 16,500 rpm, 4°C). The pellet is washed three times by resuspension with ice-cold 10 mM HEPES buffer, pH 7.5, centrifuged and finally resuspended in 30 volumes of buffer. Aliquots of 500 µl are used for each assay tube, final volume 1000 µl, and correspond to approximately 0.2 mg protein.

Assay

1. Prepare assay tubes in triplicate. For each test compound, inhibition of [^{3}H]TCP binding is measured both in the absence (basal) and presence (stimulated) of 100 µM L-glutamic acid and 10 mM glycine.

Basal	Stimulated	
380 µl	340 µl	Distilled water
50 µl	50 µl	Buffer A, 0.1 M HEPES, pH 7.5
20 µl	20 µl	PCP (reagent A5) or distilled water, or appropriate concentration of inhibitor
0 µl	20 µl	L-glutamic acid (reagent A3)
0 µl	20 µl	Glycine (reagent A4)
50 µ	50 µl	[^{3}H]TCP (reagent A6)
500 µl	500 µ	Tissue homogenate

2. Following the addition of the tissue, the tubes are incubated for 120 min at 25°C with agitation. The assay is terminated by separating the bound from nonbound radioligand by rapid filtration with reduced pressure over Whatman GF/B filters, pre-soaked in 0.05% polyethylene-imine, using the Brandell cell harvesters. The filters are rinsed once with buffer before filtering the tubes, and rinsed two times after filtration. The filters are counted with 10 ml Liquiscint.

EVALUATION

Specific binding is determined from the difference of binding in the absence or presence of 10^{-4} M PCP. Specific binding is typically 50% of total binding in basal conditions, and 90% of total binding when stimulated by L-glutamic acid and glycine. L-Glutamic acid and glycine typically increase specific binding to 300% and 200% of basal binding, respectively. The combination of L-glutamic acid and glycine typically produce a greater than additive effect, increasing specific binding to 700% of basal binding. IC_{50} values for the competing drug are calculated by log-probit analysis of the data.

Protocol Modification for Crude Membrane Homogenates

This modified procedure for the preparation of membrane homogenates does not use extensive lysing and washing of the tissue to remove endogenous L-glutamate, glycine and other endogenous compounds which enhance [^{3}H]TCP binding. This procedure may be used for rapid screening of compounds for inhibition of [^{3}H]TCP binding site without specifically defining an interaction at the ion channel or modulatory sites of the NMDA receptor complex.

PROCEDURE II

Reagents

1. Buffers A and B are prepared as described above.
2. Phencyclidine HCl is used for nonspecific binding and is prepared as described above.
3. [^{3}H]TCP is prepared as described above.
4. Test compounds are prepared as described above.

Tissue Preparation

Cortical tissue is dissected, homogenized in 30 volumes of 0.32 M sucrose and a crude P_2 pellet is prepared as described above. The pellet is resuspended in 30 volumes of 10 mM HEPES, pH 7.5, centrifuged at 36,000 *g* (SS34, 16,500 rpm, 4°C) for 20 min, and again resuspended in 100 volumes of buffer. This homogenate is used directly in the assay in aliquots of 500 µl.

Assay

1. Prepare assay tubes in triplicate.

Volume	Solution
380 µl	Distilled water
50 µl	Buffer A, 0.1 M HEPES, pH 7.5
20 µl	PCP (reagent IA5) or distilled water, appropriate concentration of inhibitor
50 µl	[^{3}H]TCP (reagent IA6)
500 µl	Tissue homogenate

2. Following the addition of the tissue, the tubes are incubated for 120 min at 25°C with agitation. The assay is terminated by rapid filtration as described above. The filters are rinsed and counted for bound radioactivity as above.

EVALUATION

Specific binding is determined from the difference of binding in the presence or absence of 10^{-4} M PCP. Specific binding is typically 90% of total binding. IC_{50} values for the competing drug are calculated by log-probit analysis.

MODIFICATIONS OF THE METHOD

Instead of [^{3}H]TCP, radiolabeled [^{3}H]MK-801 has been used as ligand (Wong et al. 1988; Javitt and Zukin 1989; Williams et al. 1989).

Sills et al. (1991) described [^{3}H]CGP 39653 as a N-methyl-D-aspartate antagonist radioligand with low nanomolar affinity in rat brain.

Nowak et al. (1995) reported that swim stress increases the potency of glycine to displace 5,7-[^{3}H[dichlorokynurenic acid from the strychnine-insensitive glycine recognition site of the *N*-methyl-D-aspartate receptor complex.

NMDA receptor cloning studies have shown that NMDA receptors contain at least one of seven different NMDAR1 subunits (NR1A–NR1G) (Sugihara

et al. 1992) and at least one of four NMDAR2 subunits (NR2A–NR2D) (Kutsuwada et al. 1992; Ishii et al. 1993). While the NR1 subunits are generated by alternative splicing of a single gene, the NR2 subunits are products of four highly homologous genes. Thus, there are thousands of potential subunit combinations yielding complexes of four or five subunits.

Grimwood et al. (1996) reported generation and expression of stable cell lines expressing recombinant human NMDA receptor subtypes, two cell lines expressing NR1a/NR2A receptors and one cell line expressing NR1a/NR2B receptors.

NR2B selective NMDA antagonists were described by Fischer et al. (1997), Kew et al. (1998), Reyes et al. (1998), Chenard and Menniti (1999).

For discovery of novel NMDA receptor antagonists, Bednar et al. (2004) developed a high-throughput functional assay based on fluorescence detection of intracellular calcium concentrations. Mouse fibroblasts L(tk-) cells expressing human NR1a/NR2B NMDA receptors were plated in 96-well plates and loaded with fluorescence calcium indicator fluo-3 AM. NR2B antagonists were added after stimulation of NMDA receptors with 10 µM glutamate and 10 µM glycine. Changes in fluorescence after addition of the antagonists were fitted with a single exponential equation providing k_{obs}.

E.3.1.8 Metabotropic Glutamate Receptors

PURPOSE AND RATIONALE

In addition to ionotropic (AMPA, kainate and NMDA) receptors, glutamate interacts with a second family of receptors, metabotropic or mGlu receptors (Tanabe et al. 1992, 1993; Schoepp and Conn 1993; Hollmann and Heinemann 1994; Nakanishi and Masu 1994; Okamoto et al. 1994; Watkins and Collingridge 1994; Knöpfel et al. 1995, 1996; Pin and Duvoisin 1995; Conn and Pin 1997; Alexander et al. 2001; Skerry and Generver 2001; DeBlasi et al. 2001; Pin and Acher 2002; Conn 2003). Three groups of native receptors are distinguishable on the basis of similarities of agonist pharmacology, primary sequence, and G protein-effector coupling: Group I ($mglu_1$ and $mglu_5$ and splice variants) are coupled via $G_{q/11}$ to phosphoinositide hydrolysis. Group II ($mglu_2$ and $mglu_3$) are negatively coupled via G_i/G_o to adenylyl cyclase and inhibit the formation of cAMP following exposure of cells to forskolin or activation of an intrinsic G_s-coupled receptor (e. g. adenosine A_2 receptor). The group III receptors ($mglu_4$, $mglu_6$, $mglu_7$, and $mglu_8$) also inhibit forskolin-stimulated adenylyl cyclase.

Various agonists and antagonists for metabotropic glutamate receptors were described (Ishida et al. 1990, 1994; Porter et al. 1992; Jane et al. 1994; Watkins and Collingridge 1994; Knöpfel et al. 1995; Annoura et al. 1996; Bedingfield et al. 1996; Thomsen et al. 1996; Acher et al. 1997; Doherty et al. 1997; Brauner-Osborne et al. 1998; Kingston et al. 1998; Monn et al. 1999; Jane and Doherty 2000). Schoepp et al.

(1999) reviewed pharmacological agents acting at subtypes of metabotropic glutamate receptors. Gssparini et al. (2002) described allosteric modulators of group I metabotropic glutamate receptors as novel subtype-selective ligands and their therapeutic perspectives.

Several radioligands for metabotropic glutamate receptors were described:

- for subtype mGluR4a receptor by Eriksen and Thomsen (1995),
- for group II mGlu receptors by Cartmell et al. (1998), by Ornstein et al. (1998), and by Schaffhauser et al. (1998).

Riedel and Reymann (1996) discussed the role of metabotropic glutamate receptors in hippocampal long-term potentiation and long-term depression and their importance for learning and memory. Furthermore, possible roles in the treatment of neurodegenerative disorders (Nicoletti et al. 1996; Bruno et al. 1998), and of Parkinson's disease (Konieczny et al. 1998) were discussed. Anticonvulsive properties (Attwell et al. 1998; Thompson and Dalby 1998; Gasparini et al. 1999) as well as anxiolytic properties (Helton et al. 1998) of metabotropic glutamate receptor ligands were reported. Christoffersen et al. (1999) found a positive effect on short-term memory and a negative effect on long-term memory of the class I metabotropic glutamate receptor antagonist, AIDA, in rats.

PROCEDURE

Cultured cells are prepared from cerebral cortex of 17-day embryos of Wistar rats. Prior to the experiments, the culture is maintained for 8–12 days with minimum essential medium (MEM) containing 5% fetal calf serum and 5% horse serum.

For **cyclic AMP assays**, the cultured cells are preincubated with HEPES-buffered Krebs-Ringer solution containing 5.5 mM glucose (HKR) for 1–1.5 h, then exposed to various agonists for 15 min in the absence or presence of 10 μM forskolin. The content of cyclic AMP is measured using a radioimmuno-assay kit after homogenization with 0.1 M HCl.

For **phosphoinositide turnover assays**, the cultured cells are prelabeled with myo-1,2-[^{3}H]inositol in MEM for 8–10 h. The cells are washed twice with HKR containing 10 mM LiCl, and then exposed to various agonists in HKR containing 10 mM LiCl for 30 min. The reaction is terminated with 2% trichloroacetic acid, and the homogenized samples are analyzed for inositol constituents by anion exchange chromatography (Berridge et al. 1982). The extracts are applied to columns containing 1 ml of Dowex 1 in the formate form. The phosphate esters are then eluted by the step-wise addition of solutions containing increasing concentrations of formate. Glycerophosphoinositol and inositol 1:2-cyclic phosphate are eluted with 5 mM-sodium tetraborate plus 150 mM sodium formate. The penultimate solution contains 0.1 M-formic acid plus 0.3 M-ammonium formate, followed by 0.1 M-formic acid plus 0.75 M-ammonium formate, each of which removes more polar inositol phosphates.The 1 ml fractions eluted from the columns are counted for radioactivity after addition of 10 ml of Biofluor.

The percentage of radioactivity of inositol phosphates to the total applied to the column is calculated.

EVALUATION

Dose-response curves for inhibition of forskolin-stimulated cAMP formation and for percentage of phosphoinositide hydrolysis are established for each test compound.

MODIFICATIONS OF THE METHOD

Thomsen et al. (1993, 1994) used baby hamster kidney (BHK) cells stably expressing $mGluR_{1\alpha}$, $mGluR_2$ or $mGluR_4$ for measurements of phosphoinositol hydrolysis or cAMP formation.

Varney and Suto (2000) recommended functional high throughput screening assay for the discovery of subtype-selective metabotropic glutamate receptor ligands.

E.3.1.9 Excitatory Amino Acid Transporters

PURPOSE AND RATIONALE

Glutamate is not only the predominant excitatory neurotransmitter in the brain but also a potent neurotoxin. Following release of glutamate from presynaptic vesicles into the synapse and activation of a variety of ionotropic and metabotropic glutamate receptors, glutamate is removed from the synapse. This is achieved through active uptake of glutamate by transporters located pre- but also post-synaptically, or glutamate can diffuse out of the synapse and be taken up by transporters located on the cell surface of glial cells. The excitatory amino acid transporters form a gene family out of which at least 5 subtypes were identified (Robinson et al. 1993; Seal and Amara 1999). A role for glutamate transporters has been postulated for acute conditions such as stroke, CNS ischemia, and seizure, as well as in chronic neurodegenerative diseases, such as Alzheimer's disease and amyotrophic lateral sclerosis. Glutamate transport is coupled to sodium, potassium and pH gradients across the cell membrane creating an electrogenic process. This allows transport to be measured using electrophysiological techniques (Vandenberg et al. 1997).

PROCEDURE

Complementary DNAs encoding the human glutamate transporters, EAAT1 and EAAT2, are subcloned into pOTV for expression in X. laevis oocytes (Arriza et al. 1994; Vandenberg et al. 1995). The plasmids are linearized with BAMHI and cRNA is transcribed from each of the cDNA constructs with T7 RNA polymerase and capped with 5′,7-methyl guanosine using the mMESSAGE mMACHINE (Ambion, Austin TX). cRNA (50 ng) encoding either EAAT1 or EAAT2 is injected into defolliculated Stage V X. laevis oocytes. Two to 7 days later, transport is measured by two-electrode voltage-clamp recording using a Geneclamp 500 amplifier (Axon Instruments, Foster City, CA) and a MacLab 2e recorder (ADI Instruments, Sydney, Australia) and controlled using a pCLAMP 6.01 interfaced to a Digidata 1200 (Axon Instruments). Oocytes are voltage-clamped at –60 mV and continuously superfused with ND96 buffer (96 mM NaCl, 2 mM KCl, 1.8 mM $CaCl_2$, 1 mM $MgCl_2$ and 5 mM HEPES, pH 7.5). For transport measurement, this buffer is changed to one containing the indicated concentration of substrate and/or blocker. The voltage dependence of block of glutamate transport is measured by clamping the membrane potential at –30 mV and then applying a series of 100 ms voltage pulses from –100 mV to 0 mV and measuring the steady state current at each membrane potential. This protocol is applied both before and during the application of the compound in question and then the base-line current at each membrane potential is subtracted from the current in the presence of the compounds to get a measure for the transport specific current at the various membrane potentials.

EVALUATION

Current (I) as a function of substrate concentration ([S]) is fitted by least squares to

$$I = I_{max}[S]/(K_m + [S])$$

where I_{max} is the maximal current and K_m is the Michaelis transport constant. The I_{max} values for the various substrates are expressed relative to the current generated by a maximal dose of L-glutamate in the same cell. I_{max} and K_m values are expressed as mean ± standard error and are determined by fitting data from individual oocytes. The potent competitive

blockers are characterized by Schild analysis (Arunlakshana and Schild 1959) and the K_b estimated from the regression plot. The less potent blockers are assumed to be competitive and K_i values calculated from IC_{50} values using the equation

$$K_i = IC_{50}/(1 + [\text{glutamate}]/K_m)$$

where K_i is the inhibition constant, IC_{50} is the concentration giving half maximum inhibition, K_m is the transport constant and [glutamate] is 30 µM. The fraction of the membrane electric field sensed by transport blockers when bound to the transporters is estimated using the Woodhull equation (Woodhull 1973),

$$K_i = K_i^0 \exp(-\zeta \delta FE/RT)$$

where K_i is the inhibition constant, $K_i{}^0$ is the inhibition constant at 0 mV, ζ is the charge on the blocker, δ is the fraction of the membrane field, F is Faraday's constant, E is the membrane potential, $R$is the gas constant and T is temperature in K.

E.3.1.10 [^{35}S]TBPS Binding in Rat Cortical Homogenates and Sections

PURPOSE AND RATIONALE

To screen potential anticonvulsant agents which interact at the convulsant binding site of the benzodiazepine/GABA/chloride ionophore complex by measuring the inhibition of binding of [^{35}S]TBPS to rat cortical membranes.

TBPS, t-butylbicyclophosphorothionate, is a potent convulsant which blocks GABA-ergic neurotransmission by interacting with the convulsant (or picrotoxin) site of the GABA/benzodiazepine/chloride ionophore receptor complex (Casida et al. 1985; Gee et al. 1986; Olsen et al. 1986; Squires et al. 1983; Supavilai and Karabath 1984). Picrotoxin, pentylenetetrazol and the so-called "cage convulsants" are believed to change the state of the chloride channel to a closed conformation, and thereby block GABA-induced increases in chloride permeability. Anticonvulsants such as the barbiturates and the pyrazolopyridines, cartazolate, etazolate and tracazolate, appear to interact at depressant sites allosterically coupled to the convulsant sites, and facilitate the effects of GABA on chloride permeability, by converting the ionophore to the open conformation. Benzodiazepines interact at a separate recognition site to modulate the actions of GABA. Convulsant compounds and some anticonvulsants can inhibit [^{35}S]TBPS binding. These two classes can be differentiated by their effects on dissociation kinetics (Macksay and Ticku 1985; Trifiletti et al. 1984, 1985). [^{35}S]TBPS dissociates slowly, half-life approximately 70 min, in a monophasic manner in the presence of convulsant compounds; anticonvulsants produce a biphasic dissociation, with rapid and slow phase components. It has been postulated that the rapid and slow phases of [^{35}S]TBPS dissociation may correspond to the open and closed conformation of the chloride ionophore.

PROCEDURE

Reagents

1. Buffer A 0.05 M Tris with 2 M KCl, pH 7.4

   6.61 g Tris HCl

   0.97 g Tris Base

   149.1 g KCl

   q.s. to 1 liter with distilled water
2. Buffer B
   a 1:10 dilution of buffer A in distilled water (5 mM Tris, 200 mM KCl, pH 7.4)
3. [^{35}S]TBPS is obtained from New England Nuclear with a high initial specific activity, 90–110 Ci/mmol. For an inhibition assay with a 2 nM final concentration of TBPS, a specific activity of 20–25 Ci/mmol will provide sufficient counts due to a high counting efficiency (87%)

for ^{35}S. The specific activity of [^{35}S]TBPS can be reduced with the addition of 3–5 volumes (accurate measurement with a Hamilton syringe) of an equimolar ethanolic solution of non-radiolabeled TBPS (7.9×10^{-6} M). The new specific activity (Ci/mmol) is calculated by dividing the number of Curies by the number of mmoles TBPS. Since [^{35}S]TBPS has a relatively short half-life, 87.1 days, the specific activity is calculated for each assay, based on the exponential rate of decay:

A_0 = initial specific activity
A = specific activity at time t
t = days from date of initial calibration of specific activity
$t_{1/2}$ = half-life of [^{35}S] in days (87.1)

For IC_{50} determinations, a 40 nM stock solution is made with distilled water and 25 µl is added to each tube to yield a final concentration of 2 nM in the assay.

4. Unlabeled TBPS is available from New England Nuclear. A stock dilution of 7.923×10^{-6} M is prepared in ethanol.
5. Picrotoxin, is obtained from Aldrich Chemical Company. A solution of 5×10^{-4} M is prepared with distilled water, with sonication if necessary. Aliquots of 10 µl are added to assay tubes to give a final concentration of 10^{-5} M.
6. Test compounds. A stock solution of 1 mM is made up with a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. Higher or lower concentrations may be used, depending on the potency of the drug.

Tissue Preparation

Whole cerebral cortex of male Wistar rats is dissected over ice and homogenized with a Tekmar Tissumizer, 20 s at setting 40, in 20 volumes of 0.32 M sucrose, ice-cold. The homogenate is centrifuged at 1000 *g* for 10 min (SS34, 3000 rpm, 4°C). The supernatant is then centrifuged at 40,000 *g* for 30 min (SS34, 20,000 rpm, 4°C). The resulting pellet is resuspended in 20 volumes of ice-cold distilled water with two 6-s bursts of the Tissumizer, setting 40. The homogenate is centrifuged at 40,000 *g* for 30 min. The pellet is washed (resuspended and centrifuged) once with 20 volumes ice-cold buffer (Tris HCl 5 mM, KCl 200 mM, pH 7.4). The resulting pellet is resuspended with 20 volumes buffer and frozen at –70°C overnight. The following day, the tissue homogenate is thawed in a beaker of warm water, approximately 15 min, and then centrifuged at 40,000 *g* for 30 min (SS34, 20,000 rpm, 4°C). The pellet is washed twice with 20 volumes of ice-cold buffer, and then resuspended and frozen at –70°C for future use. On the day of the assay, the homogenate is thawed and centrifuged at 40,000 *g* for 30 min. The resulting pellet is washed once with 20 volumes ice-cold buffer and finally resuspended in 30 volumes buffer. Aliquots of 250 µl are used for each assay tube, final volume 500 µl, and correspond to 8.35 mg original wet weight tissue per tube, approximately 0.2 mg protein.

Assay

1. Prepare assay tubes in triplicate:

190 µl	distilled water
25 µl	Tris 0.05 M, KCl 2M, pH 7.4
10 µl	picrotoxin, 10^{-5} M final concentration or distilled water or inhibitor 25 µl [^{35}S]-TBPS, final concentration 2 nM
250 µl	tissue preparation, 1:30 homogenate

2. Following the addition of the tissue, the tubes are incubated at 25°C for 150 min with agitation. The assay is terminated by rapid filtration over Whatman GF/B filter circles, presoaked in buffer, with 5 × 4 ml rinses of ice-cold buffer. Vacuum filtration is performed with the 45-well filtration units to avoid contamination of the Brandell harvesters with [^{35}S]. The filters are counted with 10 ml Liquiscint.

EVALUATION

Specific binding is determined from the difference between binding in the absence or presence of 10 mM picrotoxin, and is typically 85–90% of total binding. The percent inhibition at each drug concentration is the mean of triplicate determinations. IC_{50} values for the competing drug are calculated by log-probit analysis of the data.

Modifications for Dissociation Experiments

1. Prepare assay tubes as follows:

185 µl	distilled water
25 µl	Tris 50 mM, KCl 2 M, pH 7.4
10 µl	test compound or vehicle

2. Add 250 ml tissue homogenate to tubes. Vortex. Pre-incubate 30 min at 25°C.
3. Add 25 ml [^{35}S]-TBPS. Vortex. Incubate 180 min at 25°C.
4. Add 5 ml picrotoxin (10^{-3} M) to give a final concentration of 10^{-5} M. Vortex.

5. At various times after the addition of picrotoxin (0–120 min) tubes are filtered and rinsed as described above.

Modification for [^{35}S]-TBPS Autoradiography

1. Sections of rat brain, 20 mm thickness, are collected onto gel-chrome alum subbed slides, freeze-dried for approximately 1 h and stored at –70°C until used.
2. After thawing and drying at room temperature, the sections are preincubated for 30 min in buffer B.
3. Preparation of slide mailers for incubation:
   a) for scintillation counting:
      2.47 ml distilled water
      0.325 ml buffer A
      3.25 ml buffer B
      0.13 ml picrotoxin, 10^{-5} M final concentration or distilled water or inhibitor
      0.325 ml [^{35}S]TBPS, final concentration 2 nM
      6.50 ml final volume
   b) for autoradiography:
      4.56 ml distilled water
      0.60 ml buffer A
      6.00 ml buffer B
      0.24 ml picrotoxin, 10^{-5} M final concentration or distilled water or inhibitor
      0.60 ml [^{35}S]TBPS, final concentration 2 nM
      12.0 ml final volume
4. Sections are incubated in slide mailers at room temperature with [^{35}S]TBPS in the absence or presence of appropriate inhibitors for 90 min.
5. Slides are transferred to vertical slide holders and rinsed in ice-cold solutions as follows: dip in buffer B, two 5 minute rinses in buffer A and a dip in distilled water.
6. Slides are dried under a stream of cool air and desiccated overnight at room temperature.
7. Slides are mounted onto boards with appropriate [^{35}S] brain mash standards.
8. In the dark room under safelight illumination (GBX filter), slides are opposed to Kodak X-OMAT AR film and stored in cassettes for 7–10 days.
9. Develop films as described in "X-OMAT AR Film Processing".

E.3.1.11 [^{3}H]glycine Binding in Rat Cerebral Cortex

PURPOSE AND RATIONALE

The amino acid glycine is a major inhibitory transmitter in the vertebrate system. Glycinergic synapses are particularly abundant in spinal cord and brain stem, but are also found in higher regions, including the hippocampus. The inhibitory actions of glycine are potently blocked by strychnine. Glycine modulates and may activate the excitatory amino acid receptors of the NMDA-subtype (Thomson 1989; Laube et al. 2002).

The strychnine-sensitive, postsynaptic glycine receptor is a ligand-gated chloride channel protein that belongs to the nicotinic acetylcholine receptor family. It is a pentameric transmembrane protein composed of α and β subunits (Lynch 2004).

Glycine has been shown *in vitro* to potentiate the effects of l-glutamate or NMDA on the stimulation of [^{3}H]TCP binding (Snell et al. 1987, 1988; Bonhaus 1989) and [^{3}H]norepinephrine release (Ransom et al. 1988), and *in vivo* to act as a positive modulator of the glutamate-activated cGMP response in the cerebellum (Danysz et al. 1989; Rao et al. 1990). The activation of NMDA receptors requiring the presence of glycine is necessary for the induction of long-term potentiation (LTP), a type of synaptic plasticity which may be fundamental to learning processes (Oliver et al. 1990). A [^{3}H]glycine binding site in the brain has been identified and characterized as a strychnine-insensitive site associated with the NMDA receptor complex (Kessler et al. 1989; Monahan et al. 1989; Cotman et al. 1987). Autoradiographic studies have shown a similar distribution of [^{3}H]glycine and [^{3}H]TCP (NMDA ion channel radioligand) binding sites (Jansen et al. 1989). Compounds which interact with the glycine site offer a novel mechanism of action for intervention with NMDA receptor function.

Schmieden and Betz (1995) reviewed the pharmacology of the inhibitory glycine receptor, the agonist and antagonist actions of amino acids and piperidine carboxylic compounds.

Hyperekplexia is a hereditary neurological disorder in humans characterized by an excessive startle response which can be caused by mutations in the α_1-subunit of the heteropentameric inhibitory glycine receptor (Rees et al. 2002). Becker et al. (2002) generated transgenic mice resembling this disease.

The following assay is used to assess the affinity of compounds for the glycine binding site associated with the *N*-methyl-D-aspartate (NMDA) receptor complex using [^{3}H] glycine as the radioligand.

PROCEDURE

Reagents

1. Buffer A: 0.5M Tris maleate, pH 7.4
   59.3 g Tris maleate
   q.s. to 0.5l
   Adjust pH to 7.4 with 0.5M Tris base.
2. Buffer B: 50 mM Tris maleate, pH 7.4
   Dilute buffer A 1:10 with distilled water; adjust pH with 50 mM Tris maleate (acid) or 50 mM Tris base.
3. Glycine, 5×10^{-2} M
   Dissolve 3.755 mg of glycine (Sigma G7126) with 1.0 ml distilled water. Aliquots of 20 µl to the assay tube will give a final concentration of 10^{-3} M
4. [^{3}H]Glycine is obtained from New England Nuclear, specific activity 45–50 Ci mmol. For IC_{50} determinations, a 200 nM stock solution is made with distilled water. Aliquots of 50µl are added to yield a final assay concentration of 10 nM.
5. Test compounds. A stock solution of 5 mM is prepared with a suitable solvent and serially diluted, such that the final concentrations in the assay ranges from 10^{-4} to 10^{-7} M. Higher or lower concentrations may be used, depending on the potency of the compound.
6. Triton-X 100, 10% (v/v) (National Diagnostics, EC-606). A stock solution of Triton-X 100, 10% can be prepared and stored in the refrigerator. Dilute 1.0 ml of Triton-X 100 to 10.0 ml with distilled water. On the day of the assay, the tissue homogenate (1:15 dilution) is preincubated with an aliquot of the 10% solution to give a final concentration of 0.04% (v/v).

Tissue Preparation

Cortices of male Wistar rats are dissected over ice and homogenized in ice-cold 0.32 M sucrose, 15 volumes

of original wet weight of tissue, for 30 s with a Tissumizer setting at 70. Three cortices are pooled for one preparation. The homogenate is centrifuged at 1000 *g* for 10 min (SS34, 3000 rpm, 4°C). The supernatant is centrifuged at 20,000 *g* (SS34, 12,000 rpm, 4°C) for 20 min. Resuspend the pellet in 15 volumes of ice-cold distilled water (Tissumizer setting 70, 15 s) and spin at 7600 *g* (SS34, 8000 rpm 4°C) for 20 min. The pellet is resuspended with 15 volumes of cold distilled water and centrifuged. Discard the supernatant and store the pellet at –70°C.

On the day of the assay, the pellet is resuspended in 15 volumes ice-cold 50 mM Tris maleate, pH 7.4. Preincubate the homogenate with Triton-X in a final concentration of 0.04% (v/v) for 30 min at 37°C with agitation. Centrifuge the suspension at 48,000 *g* (SS34, 20,000 rpm, 4°C) for 20 min. Wash the pellet an additional 3 times by resuspension with cold buffer and centrifugation. The final pellet is resuspended in a volume 25 times the original wet weight.

Assay

1. Prepare assay tubes in quadruplicate.

380 µl	distilled water
50 µl	buffer A, 0.5 M Tris maleate, pH 7.4
20 µl	glycine, 10^{-3} M final concentration, or distilled water or appropriate concentration of inhibitor
50 µl	[^{3}H] glycine, final concentration 10 nM
500 µl	tissue homogenate.
1000 µl	final volume

2. Following the addition of the tissue, the tubes are incubated for 20 min in an ice-bath at 0–4°C. The binding is terminated by centrifugation (HS4, 7000 rpm, 4°C) for 20 min. Aspirate and discard the supernatant. Carefully rinse the pellet twice with 1 ml ice-cold buffer, avoiding disruption of the pellet. Transfer the pellet to scintillation vials by vortexing the pellet with 2 ml scintillation fluid, rinse the tubes twice with 2 ml and add an additional 4 ml scintillation fluid.

EVALUATION

Specific binding is determined from the difference of binding in the absence or in the presence of 10^{-4} M glycine and is typically 60–70% of total binding. IC_{50} values for the competing compound are calculated by log-probit analysis of the data.

MODIFICATIONS OF THE METHOD

Baron et al. (1996), Hofner and Wanner (1997), Chazot et al. (1998) described [^{3}H]MDL 105,519 as a high affinity ligand for the NMDA associated glycine recognition site.

E.3.1.12 [^{3}H]strychnine-Sensitive Glycine Receptor

PURPOSE AND RATIONALE

The strychnine-sensitive glycine receptor is a member of the family of ligand-gated ion channel receptors. Within this family, the glycine receptor is most closely related to the GABA-receptor. Like the $GABA_A$-receptor, the glycine receptor has an inhibitory role, mediating an increase in chloride conductance. However, in contrast to the $GABA_A$-receptor, the glycine receptor is located mainly in the spinal cord and lower brainstem, where glycine appears to be the major inhibitory neurotransmitter. Purification and molecular cloning has shown that the glycine receptor is an oligomeric transmembrane protein complex composed of three α and two β subunits. The inhibitory actions of glycine are potently blocked by strychnine. In addition to strychnine, the steroid derivative RU5135 (Simmonds and Turner 1985), phenylbenzene-ω-phosphono-α-amino acid (Saitoh et al. 1996), and 5,7-dichloro-4-hydroxyquinoline-3-carboxylic acid (Schmieden et al. 1996) antagonize glycine responses in cultured neurons or cells expressing recombinant glycine receptors.

A glycine receptor agonist may be a potential antispastic agent.

PROCEDURE

Male Wistar rats weighing about 200 g are sacrificed. About 220 mg of frozen pons and medulla are homogenized in 2×10 ml ice-cold 50 mM potassium phosphate buffer, pH 7.1, by an Ultra-Turrax homogenizer. The homogenate is centrifuged for 10 min at 30,000 *g* at 0–4°C in a refrigerated centrifuge. The pellet is rehomogenized in another 2×10 ml portion of the same buffer and recentrifuged as before. This washing procedure is repeated a total of four times. The final pellet is resuspended in 200 vol/g original tissue in ice-cold 50 mM potassium phosphate buffer, pH 7.1, with or without 1000 mM NaCl, and used directly for binding assays.

Binding assays consist of 1 ml tissue homogenate, 50 µl test solution (water or 5% v/v ethanol/water is used for serial dilutions), 50 µl water, 5% ethanol/water or glycine solution (40 mM final concentration), and 25 µl [^{3}H]strychnine working solution, final concentration 2 nM. The samples are mixed well and incubated for 20 min in an ice bath. Free and bound radioactivity are separated by filtration through Whatman GF/C glass fiber filters followed by washing with 2×10 ml ice-cold 50 mM potassium phosphate buffer, pH 7.1. Tritium on the filters is monitored by convential scintillation counting in 3 ml Hydroluma. Nonspecific binding is binding in the presence of 40 mM glycine and is always subtracted from total binding to give specific binding.

EVALUATION

K_i values are calculated as

$$K_i = (IC_{50}/1 + [K_D]/[L])$$

whereby: IC_{50} are the concentrations that inhibit by 50% the specific binding of [^{3}H]strychnine determined

in two independent experiments using at least 3 concentrations of the agent in duplicate assays, [L] is the concentration of the radioligand, K_D is the affinity constant in the absence or the presence of 1000 mM NaCl.

NaCl shift used for differentiating glycine agonists from glycine antagonists is the ratio K_i 1000 mM NaCl versus K_i 0 mM NaCl.

E.3.1.13 Electrical Recordings from Hippocampal Slices in Vitro

PURPOSE AND RATIONALE

The transverse hippocampal slice has been described as a well-defined cortical structure maintained *in vitro* (Skrede and Westgard 1971). The hippocampus slice has the advantage that each slice may contain all hippocampal structures: The chain of neurons goes from the perforant path to granule cells of the dentate gyrus, through mossy fibres to CA-3 pyramidal cells and then through Schaffer collaterals to CA-1 cells with their axons leaving the hippocampus through the alveus. The pyramidal cells lie close together and can be easily seen and penetrated with fine microelectrodes.

PROCEDURE

Male guinea pigs weighing 300–400 g are anesthetized with ether, the brains removed and the hippocampi dissected. Transverse slices of the hippocampus (300–400 µm thick) are cut in parallel to the alvear fibres. After preparation, the slices are submerged in 28°C warm saline which is equilibrated with 95% O_2 and 5% CO_2. After a preincubation period of 2 h, slices are transferred in a Perspex chamber (1.5 × 4 cm) and attached to the bottom consisting of optically plain glass. The chamber is mounted on an inverted microscope allowing detailed inspection of the excised tissue. The slices are superfused by an approximately 3 mm thick layer of 32°C warm saline. Intracellular recordings are achieved by means of micropipettes with tip diameters of less than 0.5 µm which are filled with 3 mol/l potassium chloride. Under microscopic control the tips of the micropipettes are placed within the stratum pyramidale and moved by means of a step motor driven hydraulic microdrive. For intracellular injections of drugs, e. g., pentylenetetrazol, via the recording microelectrode, a passive bridge is used. Alternatively, drugs are added to the incubation bath.

EVALUATION

The resting membrane potential and paroxysmal depolarizations are recorded before and after application of drugs.

CRITICAL ASSESSMENT OF THE METHOD

The hippocampal slice has been one of the most useful models for the study of basic mechanisms underlying the epilepsies. The model has also been recommended for screening of putative anticonvulsant drugs.

MODIFICATIONS OF THE METHOD

Harrison and Simmonds (1985) performed quantitative studies on some antagonists of N-methyl-D-aspartate in slices of rat cerebral cortex consisting of cerebral cortex and corpus callosum.

Tissue culture models of epileptiform activity were described by Crain (1972).

Oh and Dichter (1994) studied the effect of a GABA uptake inhibitor on spontaneous postsynaptic currents in cultured rat hippocampal neurons by the whole cell patch clamp method.

Blanton et al. (1989) described whole cell recordings from neurons in slices of reptilian and mammalian cerebral cortex. Synaptic currents and membrane properties could be studied in voltage and current clamps in cells maintained within their endogenous synaptic currents.

Gähwiler (1988), Stoppini et al. (1991) described methods for organotypic cultures of nervous tissue. Hippocampal slices from 2–23-day old rats were maintained in culture at the interface between air and the culture medium. They were placed on a sterile, transparent and porous membrane and kept in Petri dishes in an incubator. This yielded thin slices which remained 1–4 layers thick and were characterized by a well preserved organotypic organization. Excitatory and inhibitory synaptic potentials could be analyzed using extra- or intracellular recording techniques. After a few days in culture, long-term potentiation of synaptic responses could reproducibly be induced.

Using this method, Liu et al. (1995) studied dopaminergic regulation of transcription factor expression in organotypic cultures of developing striatum of newborn rats.

Stuart et al. (1993) reported the implementation of infrared differential interference contrast video microscopy to an upright compound microscope and a procedure for making patch-pipette recordings from visually identified neuronal somata and dendrites in brain slices.

Bernard and Wheal (1995) described an *ex vivo* model of chronic epilepsy using slices of rat hippocampus previously lesioned by stereotactic injections of kainic acid. Extracellular population spikes were recorded from the stratum pyramidale of CA1 after stimulation by bipolar twisted wire electrodes placed in the stratum radiatum of CA1 area proximally to stratum pyramidale near the recording electrode.

Using hippocampal slices prepared from brain tissue of patients undergoing neurosurgery for epilepsy, Schlicker et al. (1996) showed that the serotoninergic neurons of the human hippocampus are endowed with presynaptic inhibitory autoreceptors.

E.3.1.14 Electrical Recordings from Isolated Nerve Cells

PURPOSE AND RATIONALE

The use of the cell-attached patch clamp configuration to record action potential currents has shown to have utility in the testing for drug actions on ion channels in excitable cell membranes (Kay and Wong 1986; McLarnon 1990, 1991).

PROCEDURE

Preparation of Cultured Cells

The cultured cells are obtained from the hippocampus or the hypothalamus of rat brain. The isolation of the hippocampal CA1 neurones is performed according the procedure of Banker and Cowan (1977). The dissociated hypothalamic neurons are prepared according to Jirikowski et al. (1981). The hippocampal and hypothalamic neurons that are selected for electrophysiological recording are bipolar in shape with the long axis dimension between 10–15 µm. The neurons are studied over a period of 5–10 days after isolation.

Electrophysiology

The cell-attached patch clamp configuration is used to record spontaneous action potentials in the cultured neurons. The bath solution contains 140 mM NaCl, 5 mM KCl, 0.5 mM $CaCl_2$, 1 mM $MgCl_2$, 5 mM HEPES, pH 7.3. The composition of the patch pipette solution is the same as the bath solution. The drugs used in the experiments are added to the bath solution.

The patch pipettes (Corning 7052 glass) are fabricated using a specific patch pipette puller (PP-83; Narishige, Tokyo) are fire-polished and filled immediately prior to use. The resistance of the pipettes is in the range 4–8 MΩ and the tip diameters are between 1 and 2 µm. An axopatch amplifier (Axon Instruments, Foster City, CA), with low-pass filter set at 5 kHz, is used to record the capacitative currents. After recording, at a sampling frequency of 5 kHz, the data are stored on hard disc or video tape for subsequent analysis. All data are obtained at room temperature (21–24°C).

EVALUATION

The capacitative component of current recorded by the patch pipettes is proportional to the rate of change of membrane potential and can be expressed as $I_C = C\mathrm{d}V/\mathrm{d}t$, where C is the specific membrane capacitance. Assuming a value of C of 1 µF/cm^2 and a tip diameter of the patch pipette of 2 µm, the membrane area isolated by the patch pipette is about 3×10^{-8} cm^2. Using a value of $\mathrm{d}V/\mathrm{d}t$ of 100 mV/ms gives an approximate expected magnitude of I_C near 3 pA. When a class III antiarrhythmic drug that blocks a delayed rectifier K^+ channel is added to the bath, the portion of I_C corresponding to the after-hyperpolarization component of the action potential is completely abolished. The Na^+ spike is not altered by the drug. The cell-attached recordings of I_C can also be used to determine effects on the Na^+ spike when tetrodotoxin is included in the bath solution. Thus, the spontaneous action potential can be used for evaluation of drug effects on both K^+ and Na^+ channels in excitable membrane.

MODIFICATIONS OF THE METHOD

Chen et al. (1990) measured current responses mediated by $GABA_A$ receptors in pyramidal cells acutely dissociated from the hippocampus of mature guinea pigs according to the procedure of Kay and Wong (1986) using whole-cell voltage-clamp recordings.

Caulfield and Brown (1992) studied inhibition of calcium current in NG108–15 neuroblastoma cells by cannabinoid receptor agonists using whole-cell voltage-clamp recordings.

Gola et al. (1992, 1993) performed voltage recordings on non-dissociated sympathetic neurones from rabbit coeliac ganglia using the whole-cell configuration of the patch clamp technique (Neher and Sakmann 1976; Sakmann and Neher 1983).

Stolc (1994) used the voltage-clamp technique in internally dialyzed single neurones isolated from young rat sensory ganglia to study the effects of pyridoindole stobadine on inward sodium and calcium currents and on slow non-inactivating components of potassium outward current.

McGivern et al. (1995) examined the actions of a neuroprotective agent on voltage dependent Na^+ currents in the neuroblastoma cell line, NIE-115, using the whole cell variant of the patch clamp technique.

Smith (1995) reviewed the use of patch- and voltage clamp procedures to study neurotransmitter transduction mechanisms.

Using whole-cell and perforated-patch recordings, Delmas et al. (1998) examined the part played by endogenous G-protein $\beta\gamma$ subunits in neurotransmitter-mediated inhibition of N-type Ca^{2+} channel current in dissociated rat superior cervical sympathetic neurones.

Gonzales et al. (1985) registered membrane potentials with intracellular electrodes in cultured olfactory chemoreceptor cells.

E.3.1.15 Isolated Neonatal Rat Spinal Cord

PURPOSE AND RATIONALE

The spinal cord of the neonatal rat is a useful *in vitro* preparation, originally proposed by Otsuka and Konishi (1974). In this preparation, ventral root potentials of ten seconds of duration can be recorded after supramaximal electrical stimulation of the lumbar dorsal root. Variously implicated in the generation of these slow ventral root potentials are tachykinins, such as substance P and neurokinin B (Yanagisawa et al. 1982; Akagi et al. 1985; Otsuka and Yanagisawa 1988; Guo et al. 1998) and agonists at the glutamate receptor sites (Evans et al. 1982; Ohino and Warnick 1988 1990; Shinozaki et al. 1989; Ishida et al. 1990, 1991, 1993; Woodley and Kendig 1991; Bleakman et al. 1992; King et al. 1992; Thompson et al. 1992; Zeman and Lodge 1992; Pook et al. 1993; Jane et al. 1994; Boxall et al. 1996). These long lasting reflexes are thought to reflect a nociceptive reflex for several reasons; the threshold of activation corresponds to that of C fibre primary afferents (Akagi et al. 1985); they can be depressed by opioids (Yanagisawa et al. 1985; Nussbaumer et al. 1989; Faber et al. 1997) and α_2-adrenoceptor agonists (Kendig et al. 1991) and a similar response can be evoked by peripheral noxious stimulation (Yanagisawa et al. 1995).

PROCEDURE

Preparation of Spinal Cord

Male Wistar rats aged 6–9 days are used. Under ether anesthesia the spinal column is quickly removed from the animal and placed in a Petri dish, filled with oxygenated physiological solution. A laminectomy is performed on the dorsal surface of the spinal column at room temperature. The spinal cord of the mid-thoracic to mid-sacral level is then carefully removed from the column and hemisected in the longitudinal plane under a dissecting microscope. After removal of the dura mater, the hemisected cord is completely submerged in the recording chamber (total volume: approximately 0.5 ml), which is perfused with physiological solution (124 mM NaCl, 5 mM KCl, 1.3 mM $MgSO_4$, 2.5 mM $CaCl_2$, 1.2 mM KH_2PO_4, 15 mM $NaHCO_3$, 11 mM glucose) at a flow rate of 1.5 to 2.5 ml/min. The perfusion medium is continuously bubbled with a gas mixture of 95% O_2 and 5% CO_2 and the temperature is kept at 25 ± 0.5°C. The cut ends of the corresponding dorsal and ventral roots in an $L_{3–5}$ segment are fixed to a pair of suction electrodes for stimulating and recording. The preparation is stabilized in the recording chamber for at least 90 min to allow recovery from the dissection and the sealing of the roots to suction electrodes.

Recording of Monosynaptic Reflexes

Test stimulations, composed of square wave pulses of 0.05–0.2 ms duration and 5–30 V, are applied to the dorsal root every 10 s. The discharges of the corresponding ventral root are recorded with a suction electrode, amplified and monitored on an oscilloscope and stored on an analog data recorder or computer discs for later analysis. The mean values for the waveform of the monosynaptic reflex (amplitude, area and latency) are obtained from 6–18 successive responses in each experiment before and during application of drugs.

Recording of Single Motoneuron Activity

Test pulses (0.01–0.1 ms duration and 5–15 V) are applied to the dorsal or ventral root every 2 s. The activity of single motoneurons is recorded extracellularly using glass microelectrodes (electrical resistance approximately 10–30 MΩ) filled with 3 M sodium chloride or 2 M sodium acetate. The microelectrode is inserted into the ventral part of the cord through the hemisected surface while monitoring the field potential. The motoneurons in the ventral horn are identified by the short and consistent latency of antidromic spikes (1.66 ± 0.46 ms, $n = 5$), following the stimulation of the ventral root. The motoneurons also produce transsynaptic spikes with orthodromic stimulation of the dorsal root, of which the latency is 10.26 ± 1.05 ms upon supramaximal stimulation. The spike generation of motoneurons is displayed on an oscilloscope and stored on magnetic tapes. The spontaneous firing of the motoneuron is also monitored on an oscilloscope and recorded through a window discriminator and spike counter. The mean number and latency of spikes and latency of the dorsal root-elicited spikes are obtained from 20–40 successive responses in each experiment. Comparisons are made before and 3–5 min after application of drugs.

EVALUATION

All data are expressed as the mean ± SEM. Statistical significance of the data is determined by repeated measures analysis of variance (ANOVA) and, when appropriate, Student's *t*-test. A P value of less than 0.05 is considered statistically significant.

MODIFICATIONS OF THE METHOD

Smith and Feldman (1987), Wong et al. (1996) described an *in vitro* neonatal rat brainstem/spinal cord preparation. The brainstem and cervical spinal cord were isolated from 0–4 days old ether anesthetized Sprague Dawley rats. The en bloc neuraxis was pinned down with ventral surface upward in a recording chamber and superfused continuously with artificial cerebrospinal fluid. Respiratory activity was recorded with suction electrodes from the C_4 ventral root.

E.3.1.16 Cell Culture of Neurons

PURPOSE AND RATIONALE

Cell culture of neurons, especially of hippocampal neurons, has become a widely used tool in pharmacological studies (Banker and Cowan 1977; Skaper et al. 1990, 1993, 2001; Araujo and Cotman 1993; Brewer 1997, 1999; Brewer et al. 1998; Li et al. 1998; Mitoma et al. 1998; Semkowa et al. 1998, 1999; Chaudieu and Privat 1999; May et al. 1999; Hampson et al. 2000; Novitskaya et al. 2000; Pickard et al. 2000; Vergun et al. 2001).

The basic information on methodology of cell culture of rat hippocampal neurones was given by Banker and Cowan (1977). One modification used by Skaper et al. (1990, 2001) studying the role of mast cells on potentiation by histamine of synaptically mediated excitotoxicity in cultured hippocampal neurones is described below.

PROCEDURE

Preparation of Hippocampus

Timed pregnancies are obtained in female Sprague Dawley rats by daily checking vaginal washings for sperm, the day on which sperm is found being regarded as day 0. At the appropriate stage of gestation the pregnant rats are anesthetized and the uterus removed to a sterile dish. The remainder of the cell preparations is performed in a sterile hood.

The brains are removed from the fetuses with a pair of fine scissors, and the cerebral hemispheres separated from the brain stem. When the hemisphere of an 18- to 19-day-old fetus in viewed in a dissecting microscope the hippocampus can be clearly seen on its medial surface. The hippocampal fissure, usually marked by a conspicuous group of blood vessels, indicates the approximate junction between the hippocampus and the adjoining subicular and entorhinal cortex. The developing fimbria is seen as a white translucent band along the free margin of the hippocampus. Before separating the hippocampus from the hemisphere, the meninges

and adherent chorioid plexus are carefully pulled off with fine forceps. At this stage the full depth of the hippocampal fissure can be seen. Then with iridectomy scissors the hippocampus is separated from the adjoining cortex by a cut parallel to the hippocampal fissure, and by transverse cuts at its rostral and caudal ends.

Cell Culture

Hippocampi isolated from embryonic rats (gestational age 17.5 days) are incubated with 0.08% trypsin, and dissociated in Neurobasal medium containing 10% heat-inactivated calf serum. Cells are pelleted by centrifugation (200 *g*, 5 min) and resuspended in Neurobasal medium containing B27 (Life Technologies, Inc.) supplements (with antioxidants), 25 µM glutamate, 1 mM sodium pyruvate, 2 mM L-glutamine, 50 U/ml penicillin, and 50 µg/ml streptomycin. The cell suspension is plated onto poly-D-lysine (10 µg/ml) coated 48-well culture plates at a density of 4.5×10^4 cells per cm^2. Cultures are maintained at 37°C in a humidified atmosphere of 5% CO_2-95% air. After 5 days, one-half of the medium is replaced with an equal volume of maintenance medium (plating medium but containing B27 supplements without antioxidants, and lacking glutamate). Additional medium exchanges (0.5 volume) are performed every 3–4 days thereafter. Cells are used between 14 and 16 days in culture. During this period, neurones develop extensive neuritic networks, and form functional synapses.

Mast cells are collected from the peritoneal lavage of male Sprague Dawley rats and isolated over a bovine serum albumin gradient to >90% purity, as judged by toluidine blue and safranin staining.

Neurotoxicity Assays

Cultures are washed once with Locke's solution (pH 7.0–7.4) with or without 1 mM $MgCl_2$. Drug treatments are carried out for 15–30 min (25°C) in a final volume of 0.5 ml. In the case of mast-cell-neurone co-cultures, transwell inserts (3-µm pore size, 9 mm diameter) are seeded with 5×10^4 mast cells in RPMI-1640 medium and placed in 24-well plates overnight. Inserts with mast cells are then placed into wells with hippocampal cells. Mast cells activation is achieved using an antigenic stimulus (0.3 µg/ml anti-DNP IgE/0.1 µg/ml DNP albumin). The mast cell containing inserts are removed at the end of the Mg^{2+}-free incubation. After this time all cell monolayers are washed with complete Locke's solution and returned to their original culture medium for 24 h. Cytotoxicity is evident during 24 h after the insult. Viable neurons have phase-bright somata of round-to-oval shape, with smooth, intact neurites. Neurones are considered nonviable when they exhibit neurite fragmentation and somatic swelling and vacuolation. Cell survival is quantified 24 h after the insult by a colorimetric reaction with 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT).

EVALUATION

Data are analyzed by one-way ANOVA with Student-Newman-Keuls *post hoc* test for differences between groups.

MODIFICATIONS OF THE METHOD

Brewer (1997) reported the isolation and culture of adult rat hippocampal neurons. Using different proteases and special separation techniques, about 90000 viable neurons could be isolated from each hypothalamus at any age rat from birth to 24–36 months. Neurons were cultured for more than 3 weeks.

Flavin and Ho (1999) found that propentofylline protects hippocampal neurons in culture from death triggered by macrophage or microglia secretory products.

To study neurite outgrowth in cultured hippocampal cells from Wistar rat embryos, 5000 cells/well were seeded in 8-well LabTec tissue culture slides with a grown surface of permanox plastic and grown in Neurobasal medium supplemented with B27 (Life Technologies, Inc.), 20 mM HEPES, 0.4% bovine serum albumin, penicillin (100 IU/ml), and streptomycin (100 µg/ml). (Novitskaya et al. 2000). For image analysis, cells were fixed in 4% paraformaldehyde and stained for 20 min with Coomassie Blue R250. Cover slides were observed in an inverted microscope using phase contrast optics. To measure neurite outgrowth from hippocampal neurons, an unbiased counting frame containing a grid with a number of test lines was superimposed on the images of cells. The number of intersections of cellular processes with the test lines was counted and related to the number of cell bodies, thereby allowing quantification of neurite length per cell.

Cell culture experiments were also performed with **neuronal cells from other areas of the brain** besides the hippocampus.

Brain tissue samples of rat embryos containing either septum plus preoptic area or retrochiasmatic hypothalamus were dissociated and cultured for 14 and 21 days by Jirikowski et al. (1981). By means of immunofluorescence, LHRH, α-MSH, vasopressin and neurophysin-containing hormones could be identified.

Sinor et al. (2000) studied NMDA and glutamate evoked excitotoxicity at distinct cellular locations in rat cortical neurones *in vitro*.

Canals et al. (2001) examined neurotrophic and neurotoxic effects of nitric oxide on neuronal enriched fetal midbrain cultures from embryonic Sprague Dawley rats.

López et al. (2001) investigated the release of amino acid neurotransmitters in cultured cortical neurons obtained from gestation day 19 rats by nicotine stimulation.

Ehret et al. (2001) studied the modulation of electrically evoked acetylcholine release in cultured septal neurones from embryonic Wistar rats.

Tang et al. (2001) found a lack of replicative senescence in cultured rat oligodendrocyte precursor cells.

Yamagishi et al. (2001) used cultured rat cerebellar granule neurons as a model system for studying neuronal apoptosis.

Noh and Koh (2000) prepared mixed **mouse** cortical cultures containing both neurons and astrocytes, and pure astrocyte cultures, from fetal (15 d of gestation) and neonatal (1–3 postnatal days) mice.

Saluja et al. (2001) found that PPAR δ agonists stimulate oligodendrocyte differentiation in glial cell culture of mouse cerebra.

Ushida et al. (2000) succeeded to directly isolate clonogenic **human** central nervous system stem cells from fresh human brain tissue, using antibodies to cell surface markers and fluorescence-activated cell sorting.

For further studies with brain cell cultures see Sect. F.2.0.10.

E.3.2
In Vivo Methods

E.3.2.1
Electroshock in Mice

PURPOSE AND RATIONALE

The electroshock assay in mice is used primarily as an indication for compounds which are effective in grand mal epilepsy. Tonic hindlimb extensions are evoked by electric stimuli which are suppressed by anti-epileptics but also by other centrally active drugs.

PROCEDURE

Groups of 6–10 male NMRI mice (18–30 g) are used. The test is started 30 min after i.p. injection or 60 min after oral treatment with the test compound or the vehicle. An apparatus with corneal or ear electrodes (Woodbury and Davenport 1952) is used to deliver the stimuli. The intensity of stimulus is dependent on the apparatus, e. g., 12 mA, 50 Hz for 0.2 s have been used. Under these conditions all vehicle treated mice show the characteristic extensor tonus.

EVALUATION

The animals are observed closely for 2 min. Disappearance of the hindleg extensor tonic convulsion is used as positive criterion. Percent of inhibition of seizures relative to controls is calculated. Using various doses, ED_{50}-values and 95% confidence interval are calculated by probit analysis.

ED_{50}-values after oral administration are:

- Diazepam 3.0 mg/kg
- Diphenylhydantoin 20.0 mg/kg

CRITICAL ASSESSMENT OF THE METHOD

The electroshock test in mice has been proven to be a useful tool to detect compounds with anticonvulsant activity.

MODIFICATIONS OF THE METHOD

Cashin and Jackson (1962) described a simple apparatus for assessing anticonvulsant drugs by the electroshock seizure test in mice.

Kitano et al. (1996) developed the increasing-current electroshock seizure test, a new method for assessment of anti- and pro-convulsant activities of drugs in mice. A single train of pulses (square wave, 5 ms, 20 Hz) of linearly increasing intensity from 5 to 30 mA was applied via ear electrodes. The current at which tonic hindlimb extension occurred was recorded as the seizure threshold. The method allows the determination of seizure threshold current for individual animals.

These tests, already described for evaluation of the anti-convulsive activity of anxiolytics, can be used and show activity for anti-epileptics.

Many other agents induce seizures in animals and have been used to test the anticonvulsant activity of drugs (Stone 1972), e. g., glutarimides (Hahn and Oberdorf 1960), pilocarpine (Tursky et al. 1987), methionine sulfoximine (Toussi et al. 1987), *N*-methyl-D-aspartic acid (Leander et al. (1988), γ-hydroxybutyrate (Snead 1988).

Shouse et al. (1989) described mechanisms of seizure suppression during rapid-eye-movement (REM) sleep in cats. Spike-wave paroxysms in the EEG accompanied by bilateral myoclonus of the head and the neck were induced by i.m. injection of 300000 to 400,000 IU/kg sodium penicillin G.

E.3.2.6
Bicuculline Test in Rats

PURPOSE AND RATIONALE

Seizures can be induced by the $GAGA_A$-antagonist bicuculline and are antagonized by known anti-epileptics.

PROCEDURE

Female Sprague-Dawley rats are injected i.v. with 1 mg/kg bicuculline. At this dose, a tonic convulsion appears in all treated rats within 30 s after injection. Test compounds are administered orally 1 or 2 h before bicuculline injection. Dose-response curves can be obtained.

EVALUATION

Percentage of protected animals is evaluated. ED_{50}-values and 95% confidence limits are calculated by probit analysis.

CRITICAL ASSESSMENT OF THE METHOD

Like the electroshock test, the bicuculline test is considered to be relatively specific for anti-epileptic activity.

MODIFICATIONS OF THE METHOD

Czuczwar et al. (1985) studied the antagonism of N-methyl-D,L-aspartic acid-induced convulsions by antiepileptic drugs and other agents.

E.3.2.7 4-Aminopyridine-Induced Seizures in Mice

PURPOSE AND RATIONALE

The K^+ channel antagonist 4-aminopyridine is a powerful convulsant in animals and in man. The drug readily penetrates the blood-brain barrier and is believed to induce seizure activity by enhancing spontaneous and evoked neurotransmitter release. Although both excitatory and inhibitory synaptic transmission is facilitated by 4-aminopyridine, the epileptiform activity induced by the drug is predominantly mediated by non-NMDA type excitatory amino acid receptors. In mice, parenterally administered 4-aminopyridine induces clonic-tonic convulsions and lethality.

PROCEDURE

Male NIH Swiss mice weighing 25–30 g are allowed to acclimatize with free access to food and water for a 24-h period before testing. Test drugs are administered in various doses intraperitoneally 15 min prior to s.c. injection of 4-aminopyridine at a dose of 13.3 mg/kg which was found to be the LD_{97} in this strain of mice. Controls treated with 4-aminopyridine only exhibit characteristic behavioral signs, such as hyperreactivity, trembling, intermitted forelimb/hindlimb clonus followed by hindlimb extension, tonic seizures, opisthotonus and death. The mean latency to death at the LD_{97} is about 10 min. Groups of 8 mice are used for each dose.

EVALUATION

The percentage of protected animals at each dose is used to calculate ED_{50} values. Phenytoin-like anticonvulsants such as carbamazepine and broad spectrum anticonvulsants such as phenobarbital and valproate are effective whereas GABA-enhancers such as diazepam, several NMDA antagonists, and CA^{2+} channel antagonists such as nimodipine are not.

CRITICAL ASSESSMENT OF THE METHOD

The profile of drugs effective in this seizure model is distinct from other chemoconvulsant models and more similar to those that prevent tonic hindlimb extension in the maximal electroshock seizure test. The test is useful to differentiate the mode of action of anticonvulsant drugs.

MODIFICATIONS OF THE METHOD

Morales-Villagran et al. (1996) described protection against seizures induced by intracerebral or intra-cerebroventricular administration of 4-aminopyridine by NMDA receptor antagonists.

E.3.2.8 3-Nitropropionic Acid-Induced Seizures in Mice

PURPOSE AND RATIONALE

3-Nitropropionic acid is a naturally occurring toxin demonstrated to impair energy metabolism via irreversible inhibition of a mitochondrial complex II component, succinate dehydrogenase (Alston et al. 1977; Ludolph et al. 1991). 3-Nitropropionic acid evokes seizures in mice after i.p. injection of 100–200 mg/kg (Urbańska et al. 1998, 1999). Urbańska et al. (1998) and Zuchora et al. (2005) evaluated anticonvulsants for their protective effect against 3-nitropropionic-acid-induced seizures.

PROCEDURE

Male albino Swiss mice weighing 20–25 g were injected i.p. with 210 mg/kg 3-nitropropionic acid, which is equal to the ED_{97} dose (i. e., the dose required to evoke seizures in 97% of the animals). Groups of eight mice received in addition various doses of the anticonvulsant drugs. Percentage of animals with seizures and latency until occurrence of seizures were determined. Mortality rate was determined 2 h after injection of 3-nitropropionic acid.

EVALUATION

ED_{50} and LD_{50} values together with their confidence limits were estimated by computerized fitting of the data by linear regression analysis according to Litchfield and Wilcoxon. Statistical comparisons of latency data were performed by means of one-way analysis of variance (ANOVA) followed by adjustment of *P* value by the Bonferroni method.

E.3.2.9 Epilepsy Induced by Focal Lesions

PURPOSE AND RATIONALE

Intrahippocampal injections of noxious agents or certain cerebral lesions can induce seizures in animals. Cavalheiro et al. (1982) studied the long-term effects of intrahippocampal kainic acid injections in rats.

PROCEDURE

Adult male Wistar rats are anesthetized with a chloral hydrate/Nembutal mixture and placed in a stereotactic apparatus. For injections, a 0.3 mm cannula is inserted through a burr hole in the calvarium. The coordinates for hippocampal injections are based on a stereotactic atlas, e. g., Albe-Fessard et al. (1971). Kainic acid is dissolved in artificial serum and infused in various doses (0.1 to 3.0 µg) in a volume of 0.2 µl over a period of 3 min. For recording, bipolar twisted electrodes (100 µm) are positioned stereotaxically and fixed on the skull with dental acrylic cement. Depth recording sites include the dorsal hippocampus and amygdala ipsilateral to the injected side. Surface electrodes are guided from jeweler's screws over the occipital cortex. An additional screw in the frontal sinus serves as indifferent electrode for grounding. Signals are recorded by an EEG polygraph.

EVALUATION

EEG recordings and observations of convulsive seizures are performed during the acute phase and during the chronic phase (up to 2 months) with and without drug treatment.

MODIFICATIONS OF THE METHOD

Several agents have been used as convulsants after topical administration, e. g., application of alumina cream (Kopeloff et al. 1942, 1955; Ward 1972; Feria-Velasco et al. 1980), implantation of cobalt powder (Dow et al. 1962; Fischer et al. 1967), injection of a colloidal gel of tungstic acid (Blum and Liban 1960; Black et al. 1967), topical application of penicillin (Matsumoto and Marsan 1964), subpial injection of saturated $FeCl_3$ solution (Reid et al. 1979; Lange et al. 1980), intracerebral injections of zinc sulfate (Pei et al. 1983), intracerebral injection of antibodies to brain gangliosides (Karpiak et al. 1976, 1981), microinjections of cholinergic agonists (Ferguson and Jasper 1971; Turski et al. 1983), topical application of atropine (Daniels and Spehlman 1973), injection of tetanus toxin into the hippocampus (Mellanby et al. 1984; Hawkins and Mellanby 1987), injection of strychnine in the visual or somato-sensory cortex (Atsev and Yosiphov 1969), electrophoretic application of bicuculline from a fluid filled microelectrode (Campell and Holmes 1984).

Bernhard et al. (1955, 1956) evaluated the anticonvulsive effect of local anaesthetics in cats and monkeys. The head was fixed in light Nembutal anaesthesia, the parietal areas exposed and covered with paraffin oil. Stimulating electrodes were placed at the surface of the parietal region. The cortex was stimulated with repetitive square wave shocks (duration 1–3 ms) with a frequency of 25 per s for 5 s. In order to avoid muscular movements, d-tubocurarine was given. Cortical afterdischarge was registered before and after injection of local anaesthetics.

Cortical epileptic lesions were produced by local freezing (Stalmaster and Hanna 1972; Hanna and Stalmaster 1973; Loiseau et al. 1987).

Repetitive electrical stimulation of discrete regions of the central nervous system has been used as a convenient method for reproduction of the ictal phenomena of epilepsy (Marsan 1972; Racine 1972).

Remler and Marcussen (1986), Remler et al. (1986) studied the pharmacological response of systemically derived focal epileptic lesions. A defined area of left hemisphere of rats was radiated by α-particles from a cyclotron destroying the blood brain barrier. After a period of 150 days following irradiation, bicu-

culline was injected intraperitoneally resulting in focal lesions with EEG spikes and convulsions. Anticonvulsant drugs decreased these effects.

Walton and Treiman (1989) and Walton et al. (1994) described a model of cobalt-lesioned rats in which status epilepticus was induced by injection of homocysteine thiolactone.

Anderer et al. (1993) pointed out that restriction to a limited set of EEG-target variables may lead to misinterpretation of pharmaco-EEG results.

Krupp and Löscher (1998) developed a cortical ramp-stimulation model allowing repeated determinations of seizure threshold at short time intervals in individual rats without inducing postictal threshold increases.

E.3.2.10 Kindled Rat Seizure Model

PURPOSE AND RATIONALE

Kindling, first described by Goddard et al. (1969), results from repetitive subconvulsive electrical stimulation of certain areas of the brain. Initially, local after-discharge is associated with mild behavioral signs; however, with continued stimulation electrical activity presumably spreads, and generalized convulsions occur. Although the pathogenesis of kindled seizures is not fully understood, it serves as a useful tool for investigating the efficacy of experimental anticonvulsant agents.

PROCEDURE

Adult female Sprague-Dawley rats (270–400 g) are used. The rats are implanted with an electrode in the right amygdala according to the coordinates of Pellegrino et al. (1979): frontal, 7.0; lateral, –4.7; horizontal, 2.5. At least 1 week has to elapse before electrical stimulation of the brain is started. After discharge threshold is determined for each rat. Duration and amplitude, behavioral seizure duration and seizure stage are recorded with increased stimuli afterdischarges. Seizure severity is classified into 5 stages (Racine 1972). Rats are considered to be kindled on the first stimulation causing a stage 5 seizure which is followed by at least 2 consecutive stage 5 seizures.

The animals are tested on the day before and after treatment with the test compound (i.p. or orally). Amygdala stimulation is applied at various time intervals.

EVALUATION

The occurrence and the degree of seizures are compared between control results and the those after administration of the test compound.

CRITICAL ASSESSMENT OF THE METHOD

The kindled seizure model offers an approach to study anticonvulsive drugs on the basis of a pathophysiological model. This method may give more relevant results than the simpler methods using maximal electroshock or chemically induced convulsions.

MODIFICATIONS OF THE METHOD

Generalized convulsive seizures have been induced by daily amygdaloid stimulation in **baboons** (Wada and Osawa 1976), and in **rhesus monkeys** (Wada et al. 1978).

The kindling effect can be produced by intermittent administration of small doses of pentylenetetrazol (Mason and Cooper 1972).

Dürmüller et al. (1994) tested a competitive (NBQX) and a non-competitive (GYKI 52446) AMPA antagonist, and a competitive NMDA antagonist (D-CPPene) against the development of kindling and against fully kindled seizures in amygdala-kindled rats.

Croucher et al. (1996) described a chemical kindling procedure in rats by daily focal microinjection of NMDA into the right basolateral amygdala and the inhibition of seizures by a NMDA receptor antagonist.

Suzuki et al. (1996) studied the anticonvulsant action of metabotropic glutamate receptor agonists in kindled amygdala of rats.

Löscher et al. (1993), Ebert et al. (1997), and Ebert and Löscher (1999) studied the effect of phenytoin on the spread of seizures in the amygdala kindling model in rats. Sprague Dawley rats implanted with a stimulation and recording electrode in the basolateral amygdala showed an increase in current intensity necessary for eliciting after-discharges of about 200% after administration of phenytoin, while seizure severity at threshold was increased compared to controls. Phenytoin-resistant kindled rats are considered as a model of drug-resistant epilepsy.

Löscher (1998) discussed the pharmacology of glutamate receptor antagonists in the kindling model of epilepsy.

The kindling procedure can also be used to evaluate antidepressant drugs (Babington 1975).

E.3.2.11
Posthypoxic Myoclonus in Rats

PURPOSE AND RATIONALE

The syndrome of posthypoxic myoclonus in man was described by Lance and Adams (1963). Lance (1968), Fahn (1986). Troung et al. (1994), Jaw et al. (1994, 1995, 1996) reported on a model in rats resembling this human disorder.

PROCEDURE

Male Sprague Dawley rats fasted 12–24 h prior surgery are anesthetized with 100 mg/kg ketamine i.p., supplemented by 0.4 mg/kg atropine. The animal is placed on a circulating water pad and kept at a constant body temperature by a heating lamp. The rat is intubated and ventilated with 30% O_2 in N_2O. A femoral artery and vein are cannulated for monitoring blood pressure and delivery of drugs, respectively. Electrocardiogram and blood pressure are recorded with a polygraph. The rat is then paralyzed with 2 mg/kg succinylcholine i.v. and ventilator settings are adjusted to a rate of 60 strokes/min and a volume of 7.5 ml/kg, which yields blood gases of >150 mm Hg pO_2, 35–40 mm Hg pCO_2, and a pH of 7.35–7.40. N_2O is replaced with N_2 and an equilibrium period of 5 min is allowed.

Cardiac arrest is accomplished with a transthoracic intracardiac injection of KCl and cessation of the respiration. Resuscitation is begun 10 min after the arrest by turning on the ventilator (100% O_2), manual thoracic compressions, and i.v. injections of 20 µg/kg epinephrine hydrochloride and sodium bicarbonate (4 mEq/kg). The rat is then weaned from the ventilator over 2–4 h and extubated.

Auditory-induced myoclonus: Rats are presented with a series of 45 clicks from a metronome (1 Hz, 95 dB, 40 ms), and the response to each click is scored as follows: 0 = no response, 1 = ear twitch, 2 = ear and head jerk, 3 = ear, head, and shoulder jerk, 4 = whole body jerk, 6 = whole body jerk of such severity that it causes a jump. The total myoclonus score of each rat is determined by summing up the scores yielded over 45 clicks.

Since rats ranging from 3 to 14 days post cardiac arrest show similar susceptibility to audiogenic stimulation, animals within this period are used for pharmacological tests. Myoclonus scores are assessed 30 min before and 60 min after intraperitoneal drug application.

EVALUATION

Changes in myoclonus scores are analyzed by paired two-tailed Student's *t*-test.

CRITICAL ASSESSMENT OF THE TEST

Some anticonvulsant drugs, such as clonazepam and valproic acid were reported to be active in this test; however, phenytoin is not. Posthypoxic myoclonus may present a special pathological condition.

E.3.2.12 Rat Kainate Model of Epilepsy

PURPOSE AND RATIONALE

Temporal lobe epilepsy is characterized by complex partial seizures that involve and apparently originate in the mesial temporal structures of the limbic system. These complex partial seizures can evolve into secondarily generalized, tonic-clonic seizures. Patients become resistant to the treatment with the usual antiepileptic drugs. The kainate-treated rat is one of several models used to study temporal lobe epilepsy. Examination of the hippocampus and dentate gyrus from kainate-treated rats has revealed a similar pattern of neurodegeneration in the hippocampus and the presence of mossy fiber sprouting in the inner molecular level of the dentate gyrus. Several authors used this model to find drugs for treatment-resistant epilepsy (Bolanos et al. 1998; Hellier et al. 1998; Longo and Mello 1998; Maj et al. 1998; Bouilleret et al. 1999; Pitkänen et al. 1999; Cilio et al. 2001; Madsen et al. 2001; Ebert et al. 2002; Tamagami et al. 2004). Maj et al. (1998) tested the activity of several drugs against kainate-induced status epilepticus and hippocampal lesions in the rat.

PROCEDURE

Male Wistar rates weighing 225–250 g are anesthetized with sodium pentobarbital (50 mg/kg i.p.). The are implanted extradurally with electrodes over the frontal and parietal cortex and with a reference electrode on the cerebellum. Caution is taken not to break the inner table of the diploe. All the electrodes are connected to plugs and held to the skull with dental acrylic cement. At least 7 days after surgery, rats are treated with either saline or test drugs intraperitoneally. Then, 15 min later, the rats receive a single i.p. dose of kainic acid (10 mg/kg). EEG recordings and behavioral observations are performed up to 240 min after kainic acid administration. Status epilepticus is defined as a sustained ictal EEG pattern lasting 20 min or longer without any interruption longer than 1 min.

Seven days later, the rats are sacrificed, the brains removed and immersed for 48 h in 10% formalin. Coronal sections (4 μm) are stained with hematoxylin-eosin. Hippocampal injury is assessed by counting the number of histologically normal CA4 pyramidal neurons.

EVALUATION

The percentage of animals protected from status epilepticus is analyzed using Fisher's exact test. For calculation of the latency to status epilepticus (min) and duration of status epilepticus (min), all animals are included regardless of whether they showed status epilepticus or not. The data are evaluated by analysis of variance (ANOVA) followed by Dunnett's test. Neuronal counts are analyzed using the Mann-Whitney non-parametric test.

MODIFICATIONS OF THE METHOD

Cilio et al. (2001) used immature rats to test the anticonvulsant action and long-term effects of gabapentin.

Hellier et al. (1998) used repeated low-dose systemic treatment in order to reduce the mortality associated with single injections with kainate.

Since intracerebroventricular administration of kainic acid decreases hippocampal neuronal number

and increases dopamine receptor binding in the nucleus accumbens, kainic lesions have been discussed as an animal model of schizophrenia (Bardgett et al. 1995; Csernansky et al. 1998).

Humphrey et al. (2001) described methods for inducing neuronal loss in preweanling rats using an intracerebroventricular infusion of kainic acid.

Hu et al. (1998) investigated neuronal stress and injury in C57/BL **mice** after systemic kainic acid administration.

Bouilleret et al. (1999) tested recurrent seizures and hippocampal sclerosis following intrahippocampal kainate injection in adult **mice**.

E.3.2.13 Pilocarpine Model of Epilepsy

PURPOSE AND RATIONALE

Several post-status models are described in which epilepsy develops after a chemically induced status epilepticus, such as the kainate, the pilocarpine and the pilocarpine-lithium model (Löscher 2002). Several modifications of the pilocarpine and the lithium-pilocarpine model are reported in the literature (Cavalheiro et al. 1991; Leite and Cavalheiro 1995; André et al. 2001; Biagini et al. 2001; Klitgaard et al. 2002; Leite et al. 2002; Wallace et al. 2003; Arida et al. 2004; Leroy et al. 2004; Lyon et al. 2004; Rigoulot et al. 2004; Setkowicz et al. 2004). When rats are pretreated with lithium chloride, status epilepticus can be produced with a substantially lower dose of pilocarpine, and rats display the same clinical and EEG features of status epilepticus as with pilocarpine alone (Honchar et al. 1983). André et al. (2001) and Rigoulot et al. (2004) tested antiepileptic drugs in the lithium-pilocarpine model of epilepsy.

PROCEDURE

Male Wistar rats weighing 225–250 g were anesthetized for electrode implantation by an i.p. injection of 2.5 mg/kg diazepam and 1 mg/kg ketamine chlorhydrate. Two single-contact recording electrodes were placed on the skull, one on each side of the parietal cortex, and one bipolar deep recording electrode was placed in the right hippocampus (Vergnes et al. 1982).

One week after surgery, rats received 3 mEq/kg lithium chloride i.p. On the following day, 1 mg/kg methylscopolamine bromide was administered s.c. to limit the peripheral effects of the convulsant. Status epilepticus was induced by injecting pilocarpine (25mg/kg s.c.) 30 min after methylscopolamine. Various doses of test drug (i.p.) or 2.5 mg/kg diazepam (i.m.) were injected at 1 h after the onset of status epilepticus. The onset of status epilepticus corresponds to the moment at which rats experience successive seizures without recovery. Continuous spiking of the

EEG occurs 30–60 min after pilocarpine administration. The bilateral EEG cortical activity and the unilateral EEG hippocampal activity were recorded during the whole duration of status epilepticus and concurrent behavioral changes were noted.

Quantification of neuronal damage was performed 14 days after status epilepticus. Brains of rats sacrificed in pentobarbital anesthesia were removed and coronal sections containing the hippocampus from the anterior to the posterior level were prepared. Quantification of cell density was performed with a microscopic grid. The numbers of cells obtained in 12 counted fields were averaged.

EVALUATION

Statistical analysis of neuronal damage and epilepsy between the different groups was performed by means of analysis of variance followed by a posthoc Dunnett's test for multiple comparisons.

MODIFICATIONS OF THE METHOD

Hort et al. (1999) studied the relation between spontaneous recurrent seizures and the derangement of cognitive function in pilocarpine-induced status epilepticus,

Tang et al. (2004) recorded EEG in freely moving mice after pilocarpine-induced status epilepticus. A transmitter (TSE Systems, Bad Homburg, Germany) was fixed on the electrode socket by plug connection with wires attached to the skull by two screws 3 days before pilocarpine induction. The EEG signals were telemetrically received via an HF receiver which passed the signals to the computer.

E.3.2.14 Self-Sustained Status Epilepticus

PURPOSE AND RATIONALE

Status epilepticus causes neuronal damage that is associated with cognitive impairment. Self-sustained status epilepticus (SSSE) can be induced in rats by electrical stimulation of the perforant pathway (Halonen et al. 1996, 1999, 2001; Pitkänen et al. 1996; De Vasconcelos et al. 1999; Mazarati et al. 1999, 2004). This model is used to find antiepileptic drugs for patients with therapy-resistant epilepsy. Pitkänen et al. (1996), Halonen

et al. (1996, 1999, 2001), and Mazarati et al. (2004) studied the effect of drugs on status epilepticus in rats.

PROCEDURE

Under ketamine (60 mg/kg) and xylazine (15 mg/kg) anesthesia, male Wistar rats weighing 260–280 g were implanted with a bipolar stimulation electrode into the angular bundle of the perforant path (0.5 mm anterior and 4.5 mm left to lambda) and a bipolar recording electrode into the ipsilateral dentate gyrus (3 mm posterior and 2.5 mm left to bregma). The depth of the electrode was 3.5–4 mm from the brain surface and was optimized by finding the maximal population spike evoked from the dentate gyrus by stimuli applied to the perforant path.

For induction of self-sustained status epilepticus perforant path stimulation was delivered using a Grass stimulator model 8800, for 30 min with the following parameters: 10-s, 20-Hz trains for 1 ms, 30-V pulses delivered every minute, together with continuous 2 Hz stimulation using the same parameters.

Test drugs were injected i.v. into the tail vein either 20 min before perforant path stimulation, or 10 or 40 min after the end of perforant path stimulation. Control animals were treated with saline.

Electrographic activity was acquired and analyzed off-line using Harmonie software (Stellate Systems, Montreal), configured for automatic detection and saving spikes and seizures. Analysis of EEG was performed by a "blinded" unbiased investigator. All seizure EEGs were reviewed manually.

EVALUATION

The following indices were used to quantify seizure activity: duration of self-sustained status epilepticus (= time between the end of perforant path stimulation and the end of the last electrographic seizure); cumulative seizure time (the sum of the duration of all individual seizures); number of seizure episodes; average duration of individual seizures (cumulative seizure time divided by number of seizures); number of spikes per hour. Statistical analysis was carried out with one-way ANOVA followed by Newman-Keuls post hoc test, or, if the normality test failed, ANOVA on ranks followed by Mann-Whitney post hoc test.

MODIFICATIONS OF THE METHOD

Brown et al. (1953) and Barton et al. (2001) characterized the 6 Hz psychomotor seizure model of partial epilepsy in rats.

Nissinen et al. (2000) described a model of chronic temporal lobe epilepsy induced by electrical stimulation of the lateral nucleus of the amygdala in rats.

Walton et al. (1996) induced status epilepticus in rats with actively epileptogenic cortical cobalt lesions by administration of homocysteine thiolactone.

Laurén et al. (2003) described selective changes in gamma-aminobutyric acid type A receptor subunits in the hippocampus in spontaneously seizing rats with chronic temporal lobe epilepsy.

Brandt et al. (2003) studied epileptogenesis and neuropathology after different types of status epilepticus induced by prolonged electrical stimulation of the basolateral amygdala in rats.

E.3.2.15 Rat Model of Cortical Dysplasia

PURPOSE AND RATIONALE

Epilepsy becomes drug resistant in 20%–30% of patients. Cortical dysplasia is implicated as a major contributing factor of many types of epileptic disorders that are resistant to pharmacological intervention (Becker 1991; Aicardi 1994). Several animal models of cortical dysplasia with specific clinical pathologies have been described (Amano et al. 1996; Jacobs 1996; Jacobs et al. 1999; Lee et al. 1997; Hirotsune et al. 1998; Chevassus au Louis et al. 1999; Zhu and Roper 2000; Wenzel et al. 2001; Benardete and Kriegstein 2002; Morimoto et al. 2004; Jacobs and Prince 2005).

Baraban and Schartzkroin (1995, 1996), Baraban et al. (2000), and Smyth et al. (2002) exposed rats *in utero* to methylazoxymethanol (MAM).

PROCEDURE

Dysplastic and control rats were generated by injecting pregnant Sprague Dawley rats on day 15 of gestation with 25 mg/kg i.p. MAM or vehicle (10% DMSO in 0.3 ml 0.9% saline).

For *in vitro* studies, recordings were performed using acute hippocampal slices from adult vehicle or MAM-treated rats. Hippocampi were not dissected out, and all slices included entorhinal cortex and other overlying cortical structures. After cutting, slices remained submerged in a holding chamber containing oxygenated recording medium (nACF) consisting of (in mM): 124 NaCl, 3 KCl, 1.25 NaH_2PO_4, 2 $MgSO_4$, 26 $NaHCO_3$, 2 $CaCl_2$ and 10 dextrose. A slice was then transferred to a gas-interface recording chamber and perfused with oxygenated nACF at a flow rate of 2.5 ml/min at 33.5°C. Borosilicate glass electrodes were pulled, filled with 2 M NaCl (2–8 MΩ) and placed in the CA1 region of stratum pyramidale and/or within neuronal heterotopias under visual microscopic control. A mono-polar stimulating electrode was placed in stratum radiatum. Voltage was recorded with a Neurodata IR-283 amplifier and monitored on a PC running pClamp software. Spontaneous field activity and evoked population spikes were stored on hard disk for later blinded analysis. Interictal epileptiform burst activity was initiated with perfusion of nACF containing 4-aminopyridine (100 µM), a potassium channel blocker known to cause seizures in humans and spontaneous epileptiform activity in hippocampal slice preparations. The 4-aminopyridine *in vitro* seizure model is based on blockade of A-type potassium channels leading to the appearance of giant excitatory postsynaptic potentials generated by the prolonged firing of pyramidal neurons in CA3 burst-generating regions of hippocampus. Burst frequency was determined by counting the number of interictal epileptiform events per second during a 3-min epoch before and after 60 min of antiepileptic drug co-perfusion, and was expressed as Hz. Burst amplitude (1.5–6 mV) was determined by measuring the average peak-to-peak interval for ten consecutive representative bursts during the same epoch. Evoked synaptic responses were analyzed by averaging the number of population spikes obtained on ten consecutive sweeps recorded after stratum radiatum stimulation (0.3- to 3-mA pulses 100 µs pulse-width). A downward voltage deflection ≥ 0.5 mV superimposed on the population excitatory post-synaptic potential (EPSP) was defined as a "population spike"; the number of population spikes was compared for each slice during perfusion with normal ACSF (baseline), ACSF plus 4-aminopyridine and ACSF plus 4-aminopyridine and antiepileptic drug. For each slice experiment, the population spike was monitored every 15 min.

For *in vivo* studies, control and MAM-exposed rats were administered 15 mg/kg kainic acid, a concentration that reliably produces acute seizure activity. Behavioral activity was scored on a 6-stage scale (Germano and Sperber 1997). Animals were treated with 400 mg/kg i.p. valproate 30 min before kainate injection. Latencies to the first sign of hyperexcitability and to the first tonic-clonic seizure were recorded.

EVALUATION

Date were plotted graphically as "survival" curves, and differences in mean latencies were ranked and analyzed using a non-parametric Kruskal-Wallis one-way ANOVA.

CRITICAL ASSESSMENT OF THE TEST

Since the MAM-exposed rats exhibit a dramatically reduced sensitivity to commonly prescribed antiepileptic drugs, this model is considered to be relevant for drug-resistant epilepsy.

MODIFICATIONS OF THE METHOD

Leré et al. (2002) described a model of "epileptic tolerance" for investigating neuroprotection, epileptic susceptibility and gene expression-related plastic changes. Expression of status epilepticus was triggered

by infusion of the excitotoxic agent kainate in the right hippocampus of adult rats. An appropriate dose of kainate was used to cause brain damage to the homolateral, but not contralateral, hippocampus. At various times following the preconditioning insult, kainite was then re-administered into the lateral ventricle and neuroprotection was observed in the contralateral side between 1 and 15 days later.

E.3.2.16 Genetic Animal Models of Epilepsy

PURPOSE AND RATIONALE

Several animal species exhibit epilepsy with spontaneous recurrent seizures such as dogs, rats, and mice (Löscher 1984). Serikawa and Yamada (1986) described spontaneous epileptic rats which are double mutants and exhibit both tonic and absence-like seizures.

PROCEDURE

Spontaneous epileptic rats are obtained by mating the tremor heterozygous rat (*tm/+*) with the zitter homozygous rat (*zi/zi*) found in a Sprague-Dawley colony. The behavior of the spontaneous epileptic rats is recorded weekly for 2 h on videotapes. The frequency of tonic convulsions and wild jumping occurring in the absence of external stimuli are recorded. Under anesthesia silver ball-tipped and monopolar stainless-steel electrodes are chronically implanted in the left frontal cortex and hippocampus. An indifferent electrode is placed on the frontal cranium. The frequency of absence-like seizures and tonic convulsions, as well as the duration of each seizure, are measured on the EEG. A mild tactile stimulus is given on the back of the animal every 2.5 min to induce consistent tonic convulsions. Compounds are given i.p. or orally.

EVALUATION

The number of seizures and the duration of each seizure are obtained and the total duration of the seizures (number × duration) is calculated every 5 min before and after injection of the drug. Percent changes between values before and after drug administration are calculated.

CRITICAL ASSESSMENT OF THE TEST

Studies in spontaneous epileptic rats and other genetic models are of value for an in depth investigation of a potential anti-epileptic drug.

MODIFICATIONS OF THE METHOD

The **tremor rat (*tm/tm*)** was described as a model of petit mal epilepsy (Serikawa and Yamada 1986;

Serikawa et al. 1987). Seki et al. (2002) attempted to determine whether gene transfer of aspartoacyclase inhibited absence-like seizures in tremor rats using recombinant adenovirus. Noda et al. (1998) and Iida et al. 1998) described the **NER rat strain** (Noda epileptic rat) as a genetic model in epilepsy research, which was developed by inbreeding rats with spontaneous tonic-clonic seizures in a stock of Crj:Wistar.

The **genetic epileptic WAG/RiJ rat** has been recommended as a useful model for general absence epilepsy in humans (Van Luijtelaar and Coenen 1986; Coenen et al. 1992; Budziszewska et al. 1999; Van Luijtelaar et al. 2003; Sarkisova et al. 2003; Bouwman and van Rijn 2004). Danober et al. (1995, 1998), Deransart et al. (2000), Lakaye et al. (2002), and Nehling and Boehrer (2003) studied the **GAERS rat**, the genetic absence epilepsy rat from Strasbourg, which shows generalized non-convulsive absence seizures characterized by the occurrence of synchronous and bilateral spike and wave discharges.

Amano et al. (1996) developed an **epileptic rat mutant with spontaneous limbic-like seizures** by successive mating and selection from an inherited cataract rat.

Racine et al. (1999) reported selective breeding of **kindling-prone** and kindling-resistant **rats**. The selection of these strains was based on their rates of amygdala kindling. From a parent population of Long Evans hooded and Wistar rats, the males and females that showed the fastest and slowest amygdala kindling rates were selected and bred.

Sarkisian et al. (1999) described seizures in the **Flathead (FH) rat** as a genetic model in early postnatal development.

Tsubota et al. (2003) identified the **Wakayama epileptic rat (WER)** in a colony of Wistar rats, a mutant exhibiting both tonic-clonic seizures and absence-like seizures

Several other genetic animal models have been described (Löscher and Frey 1984; Löscher and Meldrum 1984) showing epilepsy with spontaneous recurrent seizures, such as:

dogs (Cunningham 1971; Edmonds et al. 1979),

rats with petit mal epilepsy (Vergnes et al. 1982), rats with two mutations, zitter and tremor (Serikawa and Yamada 1986; Xie et al. 1990), rats with absence-like states and spontaneous tonic convulsions (Sasa et al. 1988),

tottering mice (Green and Sidman 1962; Noebels 1979; Noebels and Sidman 1979; Fletcher et al. 1966; Tehrani et al. 1997),

leaner mutant mice with severe ataxia and atrophic cerebellum (Herrup and Wilczynnski 1982; Heckroth and Abbott 1994),

the quaking mouse (Sidman et al. 1966; Chermat et al. 1981) having deficiencies in myelinization in the nervous system (Hogan 1977; Li et al. 1993; Bartoszewicz et al. 1995) and alterations in the dopaminergic (Nikulina et al. 1995) and α_2-adrenergic (Mitrovic et al. 1992) brain system,

the stargazer mutant mouse which shows generalized non-convulsive spike wave seizures with behavioral arrest that resembles the clinical phenotype of general absence epilepsy (Noebels et al. 1990; Di Pasquale et al. 1997) with a disrupted Cacng2 gene (Letts et al. 2005),

the lethargic (lh/lh) mouse as a model of absence seizures (Hosford et al. 1999).

There are models of **epilepsy with reflex seizures**, such as:

baboons with photomyoclonic seizures (Killam et al. 1966, 1967; Stark et al. 1970; Naquet and Meldrum 1972; Killam and Killam 1984; Smith et al. 1991; Chapman et al. 1995),

photosensitive fowls (Crawford 1969, 1970),

the Fayoumi strain of chickens (Fepi) (Batini et al. 2004),

audiogenic seizure susceptible mice (Collins 1972; Seyfried 1979; Chapman et al. 1984; Stenger et al. 1991),

mechanically stimulated mice (Imaizumi et al. 1959; Oguro et al. 1991),

the EL mouse which is a strain highly susceptible to convulsive seizures after repeated sensory stimulation (Seyfried et al. 1986; King and LaMotte 1989; Green and Seyfried 1991; Wang et al. 1997; Suzuki 2004),

audiogenic seizure susceptible rats (Wistar Audiogenic Rats WAR) (Consroe et al. 1979; Reigel et al. 1986; Smith et al. 1991; Patel et al. 1990; Scarlatelli-Lima et al. 2003; Galvis-Alonzo et al. 2004; Magalhães et al. 2004).

The genetically epilepsy-prone rat GEPR responding to acoustic stimulation has been described by Ko et al. (1982), Dailey and Jobe (1985), Dailey et al. (1989), Faingold et al. (1988), Faingold et al. (1992, 1994), Jobe et al. (1992, 1995) and Laird (1989). The inferior colliculus is strongly implicated as a critical initiation

site within the neuronal network for audiogenic seizures. Two strains were characterized: **GEPR-3** exhibiting moderate or clonic convulsions, and **GEPR-9** exhibiting more severe tonic extensor convulsions (Dailey et al. 1996; Kurtz et al. 2001; Moraes et al. 2005).

Gerbils with reflex seizures were described by Thiessen et al. (1968); Loskota et al. (1974); Majkowski and Kaplan (1983); Lee and Lomax (1984), Bartoszyk and Hamer (1987), and Lee et al. (1987).

Löscher et al. (1989) discussed **the sz mutant hamster** as a genetic model of epilepsy or of paroxysmal dystonia.

Quesney (1984) reported **generalized photosensitive epilepsy in cats** after long-term intramuscular administration of low-dose penicillin.

Famula et al. (1997) and Oberbauer et al. (2003) described the epidemiology of epilepsy in **tervurens** (**Belgian shepherd dogs**); Srenk et al. (1994) in **Golden Retrievers.**

Seizure susceptibility was described in ***Drosophila*** (Kuebler and Tanouye 2000; Kuebler et al. 2001; Zhang et al. 2002).

E.3.2.17 Transgenic Animals as Models of Epilepsy

PURPOSE AND RATIONALE

The availability of transgenic animals has stimulated research on pathogenesis of epilepsy. Several surveys on this topic are available (Allen and Walsh 1999; Meldrum et al. 1999; Noebels 1999; Prasad et al. 1999; Toth and Tecott 1999; Schauwecker 2002; Weinshenker and Szot 2002; Upton and Stratton 2003; Giorgi et al. 2004; Yang and Frankel 2004). Several studies contribute to the understanding of pathology of epilepsy (Butler et al. 1995; Zeng et al. 1997; Campbell et al. 2000; Liang et al. 2000; Musumeci et al. 2000; Viswanath et al. 2000; Kearney et al. 2001; Knuesel et al. 2002; Potschka et al. 2002; Shimizu et al. 2002; Ludwig et al. 2003; Ferri et al. 2004; Diano et al. 2005; Peters et al. 2005).

Lüthi et al. (1997) found that mutant mice overexpressing protease nexin-1 (PN-1) in brain under the control of the Thy-1 promoter (Thy 1/PN-1) or lacking PN-1 (PN-1 –/–) develop epileptic activity *in vivo*. An endogenous serine protease inhibitor modulated epileptic activity and hippocampal long-term potentiation.

Kunieda et al. (2002) recommended mice with systemic overexpression of the alpha 1B-adrenergic receptor as an animal model of epilepsy.

Some of the studies gave hints for further development of antiepileptic drugs, such as the neuropeptide galanin (Kokaia et al. 2001; Mazarati et al. 2004) or the neuropeptide-Y (Shannon and Yang 2004). Several studies were devoted on the role of brain-derived neurotrophic factor (BDNF) (Lahteinen et al. 2002, 2003, 2004).

E.4 Hypnotic Activity

E.4.0.1 General Considerations

The term "hypnotic" has to be defined. In man, the purpose of taking hypnotics is to obtain a "normal" night's sleep from which the patient can be aroused without any subsequent hangover. In animal experiments, the term "hypnotic" has been applied to a much deeper stage of central depression of drug induced unconsciousness associated with loss of muscle tone and of righting reflexes. Therefore, most of the pharmacological models are questionable in regard to their predictivity to find an ideal hypnotic for human therapy. Many of the pharmacological tests are based on the potentiation of sleeping time induced by barbiturates or other sedative agents.

Since the biochemical events during sleep are rather unknown no *in vitro* method exists for testing compounds with potential hypnotic activity.

E.4.1 In Vivo Methods

E.4.1.1 Potentiation of Hexobarbital Sleeping Time

PURPOSE AND RATIONALE

The test is used to elucidate CNS-active properties of drugs. Not only hypnotics, sedatives, and tranquilizers but also antidepressants at high doses are known to prolong hexobarbital induced sleep after a single dose of hexobarbital. The loss of righting reflex is measured as criterion for the duration of hexobarbital-induced sleeping time. Mice are used in this test, since metabolic elimination of hexobarbital is rapid in this species.

PROCEDURE

Groups of 10 male NMRI-mice with an average weight of 18–22 g are used. They are dosed orally, i.p. or s.c. with the test compound or the reference standard (e. g., 3 mg/kg diazepam p.o.) or the vehicle. Thirty min after i.p. or s.c. injection or 60 min after oral dosing 60 mg/kg hexobarbital is injected intravenously. The animals are placed on their backs on a warmed (37°C) pad and the duration of loss of the righting reflex (starting at the time of hexobarbital injection) is measured until they regain their righting reflexes. Injection of 60 mg/kg hexobarbital usually causes anesthesia for about 15 min. If there is any doubt as to the reappearance of the righting reflex, the subject is placed gently on its back again and, if it rights itself within one minute, this time is considered as the endpoint.

EVALUATION

Mean values of duration of anesthesia (min) are recorded in control and experimental groups. The percent change in duration of anesthesia is calculated in the experimental groups as compared to those of the controls. ED_{50} values can be calculated. ED_{50} is defined as the dose of drug leading to a 100% prolongation in duration of anesthesia in 50% of the animals.

CRITICAL ASSESSMENT OF THE METHOD

The anxiolytic agents of the benzodiazepine type show an uniform pattern with oral ED_{50} values of less than 1 mg/kg. This is in agreement with the fact that barbiturates also show anxiolytic activity in anti-anxiety

tests with animals as well as in patients. Neuroleptics, such as chlorpromazine and haloperidol, also prolong hexobarbital sleeping time in low doses. The test is considered to be unspecific since compounds which inhibit liver metabolism of hexobarbital also prolong time of anesthesia. Balazs and Grice (1963) discussed the relationship between liver necrosis, induced by CCl_4 or nitrosamines, and pentobarbital sleeping time in rats.

OTHER USES OF THE TEST

Hexobarbital sleeping time is not only prolonged by the simultaneous administration of many compounds but also shortened under special conditions. Several CNS-active compounds (analeptics and stimulants like amphetamine and related compounds and methylxanthines) reduce hexobarbital sleeping time. Standard compounds for this kind of procedure are pentylenetetrazol, methamphetamine and aminophylline.

After repeated administrations, induction of metabolic enzymes in the liver is caused by many compounds and leads to an increased destruction of hexobarbital. Due to the accelerated metabolism of hexobarbital, sleeping time is reduced (Remmer 1972).

MODIFICATIONS OF THE TEST

Instead of hexobarbital, another barbiturate, thiopental can be used which has been proven in clinical use to be a short acting anesthetic. Test compounds or the standard are given 60 min before i.v. injection of 25 mg/kg thiopental to mice with a weight between 18 and 22 g. The animals are placed on their backs and the reappearance of the righting reflex is observed. The ED_{50} which results in a 100% prolongation in duration of anesthesia is between 2.5 and 4.0 mg/kg diazepam p.o.

Simon et al. (1982) tested the interaction of various psychotropic agents with sleep induced by barbital or pentobarbital in mice. Pentobarbital (50 mg/kg) or barbital (180 mg/kg) were injected i.p. and the latency and duration of sleep (loss of righting reflex) were recorded. The test compound was usually administered i.p. 30 min before the injection of the barbiturate. The test was recommended for detecting sedative or anti-sleep activity. Since pentobarbital is metabolized by the liver whereas barbital is not, a comparative study using the two compounds can be useful for determining whether an eventual potentiation or antagonism can be ascribed to enzymatic inhibition or induction.

Fujimori (1965) recommended the use of barbital-Na instead of hexobarbital for the sleeping time test since barbital is not biotransformed by the liver microsomal system.

E.4.1.2 Experimental Insomnia in Rats

PURPOSE AND RATIONALE

James and Piper (1978) described a method for evaluating potential hypnotic compounds in rats. Usually, the compounds are tested in normal animals where they do not significantly decrease wakefulness. Footshock induced "insomnia" in rats is proposed as suitable model for insomnia in patients.

PROCEDURE

Male Wistar rats (200–275 g) are prepared for chronic electroencephalographic and electromyographic recordings. Four silver/silver chloride epidural electrodes and two disc nuchal electrodes are implanted. A minimum of 10 days is allowed for recovery from surgery. The animals are placed into sound-attenuated recording chambers with grid floors. The frontal-occipital electroencephalogram and the electromyogram are recorded via nonrestraining recording leads on a polygraph and a tape recorder.

On the control day, the animals are dosed with the vehicle and a control nonstress recording is obtained for 8 h. On the next day, the animals are again injected with the vehicle and then exposed to electric footshocks for 8 h. The footshock is delivered through the grid floor of the recording chamber using the EMG

leads as indifferent electrodes, in the form of a 0.5 mA pulse of 15 ms width for 30 s at 1 Hz. During the footshock the EEG and EMG recording circuits are automatically interrupted. The delivery of electric footshock is triggered automatically by two adjustable timers. In this way, each shock period of 30 s is followed by an interval of 30 min. On the next day the rats are dosed with the test compound or the standard and recordings are obtained during a shock session of 8 h.

EVALUATION

The sleep-wake cycle is definitely altered by the stress procedure. The amounts of arousal and of slow wave sleep I are increased, whereas slow wave sleep II and paradoxical sleep are decreased. Phenobarbital and benzodiazepines antagonize these changes at least partially.

CRITICAL ASSESSMENT OF THE METHOD

For screening procedures, the method is too expensive and time-consuming. However, the EEG-parameters in a situation of insomnia similar to men can indicate the usefulness of a new compound.

MODIFICATIONS OF THE METHOD

Gardner and James (1987) described a modified shortened protocol in which a 2.5-h nonstressed control period is followed by drug or vehicle administration and a further 5.5-h recording of the electrocorticogram in the presence of intermittent footshock.

Laval et al. (1991) studied the effect of anxiolytic and hypnotic drugs on sleep circadian rhythms in the rat.

E.4.1.3 EEG Registration in Conscious Cats

PURPOSE AND RATIONALE

The effect of hypnotics on sleep pattern of EEG tracings can be studied in conscious, freely moving cats with chronically implanted electrodes (Heinemann et al. 1970, 1973; Wallach et al. 1976; Hirotsu et al. 1988).

PROCEDURE

Female cats weighing 2.5–3.5 kg are anesthetized and prepared with bipolar subcortical electrodes in the reticular formation (A3, L3, H –1), dorsal hippocampus (A5, L –5, H8), and either amygdala (A12, L –9, H –5), or caudate nucleus (A11, L9.5, H –2). Cortical screw electrodes are placed over the anterior suprasylvian, lateral, medial suprasylvian and ectosylvian gyri. Two Teflon coated steel wires are placed in the cervical neck muscles. All wires are connected to a subminiature socket and implanted in dental acrylic. Cats of this chronic colony are then intermittently utilized for drug experiments at interdrug intervals of at least two weeks.

On experimental days, the cats are taken into an experimental chamber $70 \times 80 \times 80$ cm high. The box is lighted and ventilated with room air at 21°C. The cat is immediately connected to a cable which exits through the top center of the cage into a mercury swivel. This prevents the cable from becoming twisted and restricting the cat's movement. Recordings of the cortical EEG, cervical neck muscle tone and reticular formation multiple unit activity are obtained. Continuous recordings for up to 96 h are amplified and stored in a recorder. The recordings of cortical EEG, cervical neck muscle tone and reticular formation multiple unit activity are analyzed for REM sleep, slow wave sleep, and wakefulness. Undefined periods which can not be identified either as slow wave sleep or as wakefulness are included in the awake total. Since a first night effect was observed (Wallach et al. 1996) drugs are given at the third or fourth day.

EVALUATION

The data are analyzed by analysis of variance with subjects, days, and drug as factors.

MODIFICATIONS OF THE METHOD

Schallek and Kuehn (1965) measured the effects of benzodiazepines on spontaneous EEG and arousal responses in cats with implanted electrodes.

In addition to EEG and electromyogram, Holm et al. (1991) registered the electro-oculogram in conscious cats.

EEG studies in immobilized cats were performed by Ongini et al. (1982) for evaluation of a benzodiazepine hypnotic. Adult mongrel cats of both sexes were anesthetized with halothane. A tracheal cannula

was inserted and artificial respiration was maintained throughout the experiment. The spinal cord was transected at C_2 level (Encephalè isolè preparation). The femoral vein was cannulated for i.v. injection of drugs. Cortical electrodes were inserted into the skull in the frontal, parietal and occipital areas. All incisions were infiltrated with mepivacaine 1% to produce local anesthesia. The body temperature was maintained at 36.5–38.0°C by an electrical heat pad. After recovery from surgery and anesthesia, a continuous EEG recording of 2 h was taken prior to drug administration. Test drugs were injected intravenously at various doses. Electrocortical activity was recorded using a 8-channel electroencephalograph. In addition, two electrodes were connected with an EEG-analyzer for the on-line evaluation of the EEG power spectrum. This was computed by the Fast Fourier Transform at a frequency range of 0–32 Hz. Power spectral plots averaging 30 s of electrocortical activity were derived during the experiment.

Shibata et al. (1994) administered various local anesthetics intravenously with constant rates of equipotent doses to cats with implanted electrodes until EEG seizures appeared. During slow rates of infusion, a tetraphasic sequence of changes was found.

Wetzel (1985) evaluated EEG recordings in freely moving **rats** by visual analysis for wakefulness, slow wave sleep or paradoxical sleep.

Krijzer et al. (1991) presented a subclassification of antidepressants based on the quantitative analysis of the electrocorticogram in the rat.

Sarkadi and Inczeffy (1996) described an integrated quantitative electroencephalographic system for pharmacological and toxicological research in the rat. Peak latencies and amplitudes of visual-evoked potentials, occurrence, duration, and linear excursions of photically evoked afterdischarges, activity, mobility, complexity according to Hjorth (1970), and absolute spectral powers of delta, theta, alpha, and beta frequency bands of background activity of visual cortex and frontal-visual leads were measured in freely moving rats.

Rinaldi-Carmona et al. (1992) performed temporal EEG analysis of the sleep-waking cycle in rats with implanted electrodes after administration of a 5-hydroxytryptamine$_2$ receptor antagonist.

Lozito et al. (1994) compared loss of righting with EEG changes in rats with implanted electrodes after single and multiple infusions of fentanyl analogues.

Jones and Greufe (1994) described a quantitative electroencephalographic method in **dogs**.

E.4.1.4 Automated Rat Sleep Analysis System

PURPOSE AND RATIONALE

Ruigt et al. (1988a, b, 1993) described an automated rat sleep classification system in rats which allows classification of psychotropic drugs such as potential antidepressants, antipsychotics and stimulants (Ruigt and von Proosdij 1990; de Boer and Ruigt 1995).

The system records and analyzes bioelectrical signals from several animals over extended periods of time. The analysis is based on 3 signals, the parieto-occipital EEG, nuchal EMG and a movement indicator signal.

PROCEDURE

Epidural screw electrodes are implanted over the parieto-occipital cortex of male rats weighing 250–300 g for the recording of EEG against a frontal electrode. Stainless-steel wire electrodes are inserted in the dorsal neck musculature for recording the electromyogram (EMG). After recovery from surgery animals are separately housed in a light- (12:12 h light-dark cycle) and temperature- (21°C) controlled room. Twenty-nine hour EEG and EMG recordings are made in sound-attenuated Faraday cages from 32 rats simultaneously. Movements of the rats are detected as capacitative artefacts generated in an open-ended wire of the non-restraining flat cable connecting the rats to a swivel commutator and to amplification and A/D conversion units, which are hooked up through a data controller to a dedicated PDP-11/83 minicomputer system for on-line spectral EEG analysis and data compression.

Off-line sleep staging on a micro VAX is done per 2-s epoch based on 5 spectral EEG band values (1.0–3.0, 3.0–6.0, 6.0–9.0, 9.5–20.0, 20.0–45.0 Hz), the integrated EMG level and the movement level. A first sleep stage assignment per epoch is done by application of a discriminant function to these epoch values. The discriminant function is derived from a discriminant analysis of visually classified representative recording segments from different sleep stages recorded during a separate calibration experiment for each rat. A moving average EEG smoothing procedure and a set of syntactic classification rules are then used to give a final sleep stage assignment to each specific EEG epoch.

Six sleep-wake stages are distinguished including 2 waking stages: (1) active waking characterized by movement, theta activity and high EMG, and (2) quiet waking without movement. Four sleep stages are discriminated: (3) quiet sleep, characterized by EEG spindles; (4) deep slow-wave sleep with prominent delta activity; (5) pre-REM sleep with spindles against a background of theta activity and low EMG, and (6) REM sleep with theta activity and low EMG.

Each experiment consists of 32 rats divided over maximally 4 groups, including various drug treatment groups (generally several doses of the same drug) and always one placebo group. Drug administration is done at the beginning of the light cycle of the rats. After each experiment 2–3 weeks are allowed for wash-out. Drug effects on sleep-waking behavior are assessed on several parameters extracted from the hypnogram, among which percentage time spent in each of the sleep stages per 30-min period and per rat. This gives for each compound a profile of changes over sleep stages and over time.

EVALUATION

Sleep stage-dependent and sleep-independent parts of the EEG power spectrum are defined by a procedure originally developed by Fairchild et al. (1969, 1971, 1975). First, a normal canonical discriminant analysis is done on 4 EEG frequency bands (1–3, 3–6, 6–9, 9.5–20 Hz) from representative segments of only 3 visually classified sleep stages (quiet waking, deep sleep and REM sleep), the sleep stage being the dependent variable. This results in 2 sleep stage-dependent canonical variables covering 100% of the variance in the data set and two residual canonical variables which are independent of sleep stage assignment. These 2 residual variables are subsequently used in

a second canonical discriminant analysis in which the presence or absence of the drug is used as the dependent variable, resulting in a single canonical variable (the drug score) associated with the drug effect on the sleep stage-independent variance of the EEG spectral parameters.

CRITICAL ASSESSMENT OF THE METHOD

According to the author's own judgment, antidepressants, antipsychotics and stimulants can be discriminated from each other and from placebo successfully from each other and from placebo by this method, whereas nootropics classified as placebo. Unfortunately, anxiolytics, hypnotics and anticonvulsants are classified poorly.

E.5 Neuroleptic Activity

E.5.0.1 General Considerations

Neuroleptics have been defined as therapeutics effective against schizophrenia. One has to bear in mind that the effect of certain drugs has not been predicted by pharmacological tests but has been found in clinical trials by serendipity. The clinical discoveries were followed by pharmacological studies in many laboratories (Courvoisier 1956).

Various studies have demonstrated the blockade of postsynaptic catecholamine receptors, especially D_2-receptors to be the main mode of action of most neuroleptics. Several *in vitro* methods measure the receptor blockade by neuroleptics.

Pharmacological models in the development of antipsychotic drugs were reviewed by Costall et al. (1991).

E.5.1 In Vitro Methods

E.5.1.1 D_1 Receptor Assay: [^{3}H]-SCH 23390 Binding to Rat Striatal Homogenates

PURPOSE AND RATIONALE

Dopamine receptors are the primary targets in the development of drugs for the treatment of schizophrenia, Parkinson's disease and Huntington's chorea (Seeman and Van Tol 1994).

Reviews on dopamine receptors and their subtypes were given by Baldessarini and Tarazi (1996, Missale et al. 1998), and by the NC-IUPHAR subcommittee on dopamine receptors (Schwartz et al. 1998).

Multiple dopamine receptors are known. Two groups are most studied, designated as D_1 and D_2. In the group of D_1-like dopamine receptors the subtypes D_{1A} and D_5/D_{1B} have been described. To D_2-like dopamine receptors belong the D_{2S}, the D_{2L}, the D_3, and the D_4 receptor (Sokoloff et al. 1990; Civelli et al. 1991; Grandy et al. 1991; Van Tol et al. 1991; Lévesque et al. 1992; Baldessarini et al. 1993; Ginrich and Caron 1993; Todd and O'Malley 1993; Waddington and Deveney 1996).

D_1 receptors are positively linked to adenylate cyclase and the D_2 receptor has been shown to be negatively linked to adenylate cyclase. For typical neuroleptic agents, like butyrophenones, a good correlation was found between D_2 receptor binding and clinically effective doses. Atypical neuroleptics, like cloza-

pine, were found to be potent inhibitors of D_1 and D_4 receptor binding, renewing interest in these receptor types. The compound SCH 23390 was found to be selective for the D_1 receptor.

PROCEDURE

Reagents

[N-Methyl-^{3}H] Sch 23390 (Amersham Lab., specific activity 67–73 Ci/mmol). For IC_{50} determinations, ^{3}H-Sch 23390 is made up to a concentration of 10 nM and 50 µl is added to each tube. This yields a final concentration of 0.5 nM in the assay.

d-Butaclamol (Ayerst Laboratories). A 1 mM stock solution is made and diluted 1:20.

20 µl are added to 3 tubes for the determination of nonspecific binding.

For the test compounds a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assays ranges from 10^{-5} to 10^{-8} M.

Tissue Preparation

Male Wistar rats are decapitated, brains rapidly removed, striata dissected and weighed. The striata are homogenized in 100 volumes of 0.05 M Tris buffer, pH 7.7, using a Tekmar homogenizer. The homogenate is centrifuged at 40,000 *g* for 20 min and the final pellet is resuspended in the original volume of 0.05 Tris buffer, pH 7.7, containing physiological ions (NaCl 120 mM, KCl 5 mM, $MgCl_2$ 1 mM and $CaCl_2$ 2 mM).

Assay

50 µl	0.5 M Tris buffer, pH 7.7, containing physiological ions
380 µl	H_2O
20 µl	vehicle or butaclamol or appropriate concentration of test compound
50 µl	^{3}H-SCH 23390
500 µl	tissue suspension.

The tubes are incubated at 37°C for 30 min. The assay is stopped by rapid filtration through Whatman GF/B filters using a Brandell cell harvester. The filter strips are then washed 3 times with ice-cold 0.05 M Tris buffer, pH 7.7, and counted in 10 ml Liquiscint scintillation cocktail.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of 1 µM d-butaclamol. IC_{50} calculations are performed using log-probit analysis. The percent inhibition at each drug concentration is the average of duplicate determinations.

MODIFICATIONS OF THE METHOD

Wamsley et al. (1992) recommended the radioactive form of a dopamine antagonist, [^{3}H]SCH39166 as ligand for obtaining selective labeling of D_1 receptors.

Sugamori et al. (1998) characterized the compound NNC 01–0012 as a selective and potent D_{1C} receptor antagonist.

E.5.1.2 D_2 Receptor Assay: [^{3}H]-Spiroperidol Binding

PURPOSE AND RATIONALE

The neuroleptic compound haloperidol has been used as binding ligand to study the activity of other neuroleptics. The use of haloperidol has been superseded by spiroperidol. Dopamine receptor binding assays employing dopaminergic antagonists in mammalian striatal tissue, a dopamine-enriched area of the brain, have been shown to be predictive of *in vivo* dopamine receptor antagonism and antipsychotic activity. Significant correlations exist between neuroleptic binding affinities and their molar potencies in antagonism of apomorphine- or amphetamine-induced stereotypy,

apomorphine-induced emesis in dogs, and antipsychotic activity in man. Spiroperidol is considered to be an antagonist specific for D_2 receptors.

PROCEDURE

Tissue Preparation

Male Wistar rats are decapitated, their corpora striata removed, weighed and homogenized in 50 volumes of ice-cold 0.05 M Tris buffer, pH 7.7. The homogenate is centrifuged at 40,000 *g* for 15 min. The pellet is rehomogenized in fresh buffer and recentrifuged at 40,000 *g*. The final pellet is then resuspended in Tris buffer containing physiological salts (120 mM NaCl, 5 mM KCl, 2 mM $CaCl_2$ and 1 mM $MgCl_2$) resulting in a concentration of 10 mg/ml.

Assay

The membrane preparations are incubated with ^{3}H-spiroperidol (0.25 nM) and various concentrations of test drug at 37°C for 20 min in a K/Na phosphate buffer (50 mM, pH 7.2), followed by cooling in an ice bath for 45 min. To determine non-specific binding, samples containing 10 mM (+)-butaclamol are incubated under identical conditions without the test compound.

Bound ligand is separated by rapid filtration through Whatman GF/B glass fiber filters. The filters are washed three times with ice-cold buffer, dried, and shaken thoroughly with 3.5 ml scintillation fluid. Radioactivity is determined in a liquid scintillation counter. Specific binding is defined as the difference between total binding and the binding in the presence of 2.0 mM (+)-butaclamol.

EVALUATION

The following parameters are determined:

- total binding of ^{3}H-spiroperidol
- non-specific binding: binding of samples containing 2 mM butaclamol
- specific binding = total binding – non-specific binding
- % inhibition: 100–specific binding as percentage of the control value.

IC_{50} values are determined using at least 3–4 different concentrations of the test compound in triplicate. Results are presented as mean ± standard deviation.

Dissociation constants (K_d) are determined, using ^{3}H-spiroperidol concentrations ranging between 0.1 and 1.0 nM. K_i values (inhibitory constants) are calculated using the following equation:

$$K_i = \frac{IC_{50}}{1 + c/K_d}$$

c = ^{3}H-spiroperidol concentrations used to determine IC_{50}.

Standard values: K_i of haloperidol = 6.0 ± 1.2 nM.

MODIFICATIONS OF THE METHOD

Two isoforms of the D_2 receptor were found by alternative splicing: the long (D_{2L}) and the short (D_{2S}) isoform (Dal Toso et al. 1988; Giros et al. 1989; Monsma et al. 1989; Itokawa et al. 1996).

Niznik et al. (1985) recommended [^{3}H]-YM-09151–2, a benzamide neuroleptic, as selective ligand for dopamine D_2 receptors.

Hall et al. (1985) used [^{3}H]-eticlopride, a substituted benzamide, selective for dopamine-D_2 receptors, for *in vitro* binding studies.

Radioactive ligands for the D_2 and the D_3 receptor were described by Seeman and Schaus (1991), Chumpradit et al. (1994), Booze and Wallace (1995), Gackenheimer et al. (1995), Seeman and van Tol (1995), Van Vliet et al. (1996).

Vessotskie et al. (1997) characterized binding of [^{125}I]S(–)5-OH-PIPAT to dopamine $D_{2\text{-like}}$ receptors.

Neve et al. (1992) used a special apparatus, the 'cytosensor microphysiometer' which measures the rate of proton excretion from cultured cells (McConnell et al. 1991, 1992; Owicki and Parce 1992). In C_6 glioma cells and L fibroblasts expressing recombinant dopamine D_2 receptors, the dopamine D_2 receptor agonist, quinpirole, accelerated the rate of acidification of the medium dose-dependent up to 100 nM quinpirole. The response was inhibited by the D_2 antagonist spiperone. The D_2 receptor stimulated acidification was due to transport of protons by a Na^+/H^+ antiporter which was verified by the inhibition with amiloride or methylisobutyl-amiloride.

The isolated rabbit ear artery was recommended as a useful model to characterize dopamine D_2 agonists and antagonists (Hieble et al. 1985).

Human Recombinant Dopamine D_{2A} and D_{2B} Receptors

Hayes et al. (1992) described functionally distinct human recombinant subtypes of the dopamine D_2 receptor, D_{2A} and D_{2B}.

D_{2A} Receptor Binding

In a radioligand binding assay the binding of [^{3}H]-spiperone to membranes prepared from COS cells

transiently expressing a recombinant human dopamine D_{2A} receptor is measured.

Twenty mg of membrane is incubated with [^{3}H]-spiperone at a concentration of 2.0 nM for 2 h at 25°C. Non-specific binding is estimated in the presence of 10 mM haloperidol. Membranes are filtered and washed 3 times with binding buffer, and filters are counted to determine [^{3}H]-spiperone bound.

D_{2B} Receptor Binding

In a radioligand binding assay the binding of [^{3}H]-spiperone to membranes prepared from COS cells transiently expressing a recombinant human dopamine D_{2B} receptor is measured.

Fifteen mg of membrane is incubated with [^{3}H]-spiperone at a concentration of 0.7 nM for 2 h at 37°C. Non-specific binding is estimated in the presence of 10 mM haloperidol. Membranes are filtered and washed 3 times with binding buffer, and filters are counted to determine [^{3}H]-spiperone bound.

E.5.1.3 Dopamine D_2 Receptor Autoradiography (^{3}H-Spiperone Binding)

PURPOSE AND RATIONALE

Autoradiography of ^{3}H-spiperone binding sites using selective labeling conditions permits the visualization of the anatomical locations of D_2-dopamine receptors (Palacios et al. 1981). Quantitative measurements of the binding to receptors can be obtained with computer-assisted video analysis of the autoradiograms with a greater anatomical resolution and sensitivity than in membrane homogenates (Altar et al. 1984, 1985). Using autoradiographic techniques, it has been demonstrated that striatal D_2 receptors are present on intrinsic neurons (Trugman et al. 1986; Joyce and Marshall 1987) and that the distribution of D_2 receptors within the striatum is not homogeneous (Joyce et al. 1985). Anatomically discrete interactions of drugs with D_2 receptors can be examined *in vitro* with inhibition experiments and *ex vivo* following acute or chronic drug treatment of the whole animal.

Since ^{3}H-spiperone labels serotonin-2 (5-HT_2) sites in many brain regions, a masking concentration of a 5-HT_2 receptor blocker, e. g., ketanserin, is included to selectively define binding to D_2 receptors. This is necessary if the test compound inhibits 5-HT_2 binding, or if the brain region of interest has a low D_2 receptor density.

The assay is used to determine potential antipsychotic activity of compounds via direct interaction with the D_2 dopamine recognition site in discrete regions of the rat brain.

PROCEDURE

Reagents

1a. 0.5 M Tris+1.54 M NaCl, pH 7.4

1b. 0.05 M Tris+0.154 M NaCl, pH 7.4

2. ^{3}H-spiperone (specific activity 70–90 Ci/mmol) is obtained from Amersham (TRK.818).
   For IC_{50} determinations: ^{3}H-spiperone is prepared at a concentration of 8 nM and 0.55 ml is added to each slide mailer (yields a final concentration of 0.4 nM in the 11.0 ml assay volume).
   For saturation experiments: ^{3}H-spiperone is prepared at a concentration of 20 nM. The final concentrations should range from 0.2–1.0 nM. Typically, six concentrations are used by adding 0.55 ml or less to each mailer (for smaller volumes, add water to bring total addition of 0.55 ml).
3. Sulpiride is obtained from Sigma. A stock solution of 5×10^{-4} M is made by dissolving the sulpiride in 1.0 ml of 0.01 N acetic acid and bringing the final volume to 10 ml with distilled water. 0.22 ml of the stock solution is added to the nonspecific binding slide mailers (final concentration 10 µM). All other mailers receive 0.22 ml of vehicle (1 ml of 0.01 N acetic acid in a final volume of 10 ml with distilled water).
4. Ketanserin (free base or tartrate salt) is obtained from Janssen. A stock solution of 10^{-3} M is made by dissolving the ketanserin in 0.5 ml 1 N acetic acid and bringing the final volume to 10 ml with distilled water. The tartrate salt is water-soluble. This is further diluted to 5×10^{-6} M (50 µl q.s. to 10 ml). 0.22 ml is added to all mailers.
5. Test compounds (for IC_{50} determinations). For most assays, a 5×10^{-3} M stock solution is made up in a suitable solvent and serially diluted, such that the final concentrations in the assay range from 10^{-5} to 10^{-8} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used depending on the potency of the drug.

Tissue Preparation

Rat brain sections are collected from plates 9 (rostral nucleus accumbens) through plate 17 (caudal striatum) of "The Rat Brain Atlas in Stereotaxic Coordinates" by Paxinos and Watson.

1. For *in vitro* inhibition experiments, 3–5 sets of 10 slides are collected with 3–4 sections per slide.
2. For saturation experiments, 3–5 sets of 12 slides are collected with 3–4 sections per slide.
3. For *ex vivo* inhibition experiments, a set of 8 slides is used, 4 for total binding and 4 for nonspecific binding.
4. For experiments in which the tissue sections will be swabbed and counted with scintillation fluid, 2 sections per slide are collected.

Assay

1. Preparation of slide mailers (11.0 ml volume/slide mailer):
   Note: If slides with sections are to be wiped for scintillation counting, a final volume of 6.5 ml is

sufficient to cover 2 sections. A proportional adjustment of the volumes to be pipetted is made.

a) *In vitro* inhibition experiments
Separate mailers are prepared for total binding, nonspecific binding and 7–8 concentrations of test compound. Ketanserin is included in all mailers to mask binding of [^{3}H]-spiperone to 5-HT_2 sites so that inhibition of binding is D_2-selective.

5.50 ml	buffer 1b
0.55 ml	buffer 1a
0.55 ml	[^{3}H]-spiperone, 0.4 nM final concentration
3.96 ml	distilled water
0.22 ml	ketanserin, 5×10^{-6} M, final concentration 100 nM or vehicle
0.22 ml	test compound, final concentration 10^{-8}–10^{-5} M or sulpiride 5×10^{-4}, final conc. 10 µM or vehicle

b) *Ex vivo* inhibition experiments
Separate mailers are prepared for total and nonspecific binding, as described above, including ketanserin to mask 5-HT_2 receptor binding.

c) Saturation experiments
Separate mailers are prepared for total and nonspecific binding at each radioligand concentration. Ketanserin is not included in the mailers, in saturation experiments, since specific binding is defined as sulpiride-displaceable.

5.50 ml	buffer 1b
0.55 ml	buffer 1a
0.55 ml	[^{3}H]-spiperone, final concentration 0.2–1.0 nM
4.18 ml	distilled water
0.22 ml	5×10^{-4} M sulpiride, final concentration 10 µM or vehicle

2. Slides are air-dried for 10–15 min at room temperature, preincubated in 0.05 M Tris+0.154 M NaCl, pH 7.4 for 5 min and further incubated for 60 min with [^{3}H]-spiperone. Slides are then rinsed with ice-cold solutions as follows: dipped in buffer 1b, rinsed in buffer 1b for 2 × 5 min, and dipped in distilled water.
Slides used for wipes: both sections are wiped with one Whatman GF/B filter and radioactivity is counted after addition of 10 ml of scintillation fluid.
Slides used for autoradiography: slides are dried under a stream of air at room temperature and are stored in a desiccator under vacuum at room temperature (usually over night). Slides are then mounted onto boards, along with ^{3}H-standards (Amersham RPA 506).
In the dark room under safelight illumination (Kodak GBX-2 filter), slides are exposed to Amersham Hyperfilm or LKB Ultrofilm for 14–17 days.

E.5.1.4 Binding to the D_3 Receptor

PURPOSE AND RATIONALE

Sokoloff et al. (1990) reported molecular cloning and characterization of a dopamine receptor (D_3) as a potential target for neuroleptics. The D_3 receptor is localized in limbic areas of the brain which are associated with cognitive, emotional and endocrine functions. Together with the D_{2S}, the D_{2L} and the D_4 receptor, the D_3 receptor belongs to the group of D_2-like dopamine receptors (Ginrich and Caron 1993). 7-[^{3}H]hydroxy-*N*,*N*-di-n-propyl-2-aminotetralin (Lévesque et al. 1992), R(+)-7-OH-DPAT (Baldessarini et al. 1993; and [^{125}I]trans-7-OH-PIPAT-A (Kung et al. 1993) have been recommended as ligands for receptor binding studies.

Chio et al. (1993) compared the heterologously in Chinese hamster ovary cells expressed D_3 dopamine receptors with D_2 receptors.

Damsma et al. (1993) described R-(+)-7-OH-DPAT (R-(+)-7-hydroxy-2-(N,N-di-n-propylamino)tetralin) as a putative dopamine D_3 receptor ligand.

Functional correlates of dopamine D_3 receptor activation in the rat *in vivo* and their modulation by the selective agonist, (+)-S 14297, have been described by Millan et al. (1995).

Isoforms of the D_3 receptor have been described (Pagliusi et al. 1993).

Akunne et al. (1995) described binding of the selective dopamine D_3 receptor agonist ligand [^{3}H]PD 128907=4aR,10bR-(+)-trans-3,4,4a,10b-tetrahydro-4-n-propyl-2H,5H-[1]benzopyrano[4,3-b]1,4-oxazin-9-ol.

PROCEDURE

Human dopamine D_3 receptor is expressed in Chinese hamster ovary cells. Cells are grown in Dulbecco's modified Eagle's medium containing 10% fetal bovine serum. Cells are harvested by trypsin treatment (0.25%) for 4–5 min and centrifugation at 2000 *g* for 5 min. They are homogenized with a Polytron in 10 mM Tris-HCl (pH 7.5) containing 1 mM EDTA and are centrifuged at 35,000 *g* for 15 min. The pellet is then resuspended by sonication in a buffer containing 50 mM NaHepes, 1 mM EDTA, 50 µM 8-hydroxyquinoline, 0.005% ascorbic acid, and 0.1% bovine serum albumin (pH 7.5) (incubation buffer). Membrane suspensions (15–25 µg protein) are added to polypropylene test tubes containing [^{3}H]7-OH-DPAT (7-[^{3}H]hydroxy-*N*,*N*-di-n-propyl-2-aminotetralin) for the D_3 receptor assay. Competing drugs are dissolved in incubation buffer, the final volume being 1 ml. Tubes are incubated in triplicate for 1 h at room temperature. The incubations are stopped by rapid filtration under reduced pressure through Whatman GF/C glass filters coated with 0.1% bovine serum albumin, followed by 3 rinses with 3–4 ml ice-cold buffer. Non-specific binding is measured in the presence of 1 µM dopamine.

EVALUATION

Saturation curves are analyzed by computer non-linear regression using a one-site cooperative model to obtain equilibrium dissociation constants (K_D) and maximal density of receptors (B_{max}). Inhibition constants (K_i) are estimated according to the equation

$$K_i = IC_{50}/1 + L/K_D$$

E.5.1.5 Binding to D_4 Receptors

PURPOSE AND RATIONALE

Van Tol et al. (1991) reported cloning of the gene of a human dopamine D_4 receptor with high affinity for the antipsychotic clozapine. Together with the D_{2S}, the D_{2L} and the D_3 receptor, the D_4 receptor belongs to

the group of D_2-like dopamine receptors (Ginrich and Caron 1993). Recognition and characterization of this dopamine binding site may be useful in the design of new types of antipsychotic drugs.

Dopamine D_4 receptors have been localized in GABAergic neurons of the primate brain (Mrzljak et al. 1996).

PROCEDURE

A plasmid construct of a 3.9-kb gene-cDNA hybrid subcloned into the expression vector pCD-PS is introduced into COS-7 cells by calcium phosphate mediated transfection. Cells are cultivated and homogenized (Teflon pestle) in 50 mM Tris-HCl (pH 7.4 at 4°C) buffer containing 5 mM EDTA, 1.5 mM $CaCl_2$, 5 mM KCl, and 120 mM NaCl. Homogenates are centrifuged for 15 min at 39,000 *g*, and the resulting pellets resuspended in buffer at a concentration of 150–250 µg/ml. For saturation experiments, 0.25 ml of tissue homogenate are incubated in duplicate with increasing concentrations of [^{3}H]spiperone (70.3 Ci mmol^{-1}; 10–3000 pM final concentration) for 120 min at 22°C in a total volume of 1 ml. For competition binding experiments, assays are initiated by the addition of 0.25 ml membrane and incubated in duplicate with various concentrations of competing ligands (10^{-14}–10^{-3} M) and [^{3}H]spiperone (150–300 pM) either in the absence or the presence of 200 µM Gpp(NH)p for 120 min at 22°C. Assays are terminated by rapid filtration through a Titertek cell harvester and filters then monitored for tritium. For all experiments, specific binding is defined as that inhibited by 10 µM (–)sulpiride.

EVALUATION

Both saturation and competition binding data are analyzed by the non-linear least-square curve-fitting program LIGAND run on a suitable PC.

MODIFICATIONS OF THE METHOD

Human Recombinant Dopamine $D_{4,2}$, $D_{4,4}$, $D_{4,7}$ and D_5 Receptors

Van Tol et al. (1992) described multiple dopamine D_4 receptor variants in the human population.

Sunahara et al. (1991) reported the cloning of the gene for a human D_5 receptor.

Human Recombinant Dopamine $D_{4,2}$ Receptor Binding

In a radioligand binding assay the binding of [^{3}H]-spiperone to membranes prepared from COS cells transiently expressing a recombinant human dopamine $D_{4,2}$ receptor is measured.

Fifteen µg of membrane is incubated with [^{3}H]-spiperone at a concentration of 0.7 nM for 2 h at 25°C. Non-specific binding is estimated in the presence of 10 µM haloperidol. Membranes are filtered and washed 3 times with binding buffer, and filters are counted to determine [^{3}H]-spiperone bound.

Human Recombinant Dopamine $D_{4,4}$ Receptor Binding

In a radioligand binding assay the binding of [^{3}H]-spiperone to membranes prepared from COS cells transiently expressing a recombinant human dopamine $D_{4,4}$ receptor is measured.

Twenty-five µg of membrane are incubated with [^{3}H]-spiperone at a concentration of 1.0 nM for 2 h at 25°C. Nonspecific binding is estimated in the presence of 10 µM haloperidol. Membranes are filtered and washed 3 times with binding buffer, and filters are counted to determine [^{3}H]-spiperone bound.

Human Recombinant Dopamine $D_{4,7}$ Receptor Binding

In a radioligand binding assay the binding of [^{3}H]-spiperone to membranes prepared from COS cells transiently expressing a recombinant human dopamine $D_{4,7}$ receptor is measured.

Fifteen µg of membrane is incubated with[^{3}H]-spiperone at a concentration of 0.7 nM for 2 h at 25°C. Non-specific binding is estimated in the presence of 10 µM haloperidol. Membranes are filtered and washed 3 times with binding buffer, and filters are counted to determine [^{3}H]-spiperone bound.

Human Recombinant Dopamine D_5 Receptor

In a radioligand binding assay the binding of [^{3}H]SCH 23390 to membranes prepared from COS cells expressing a recombinant human dopamine D_5 receptor is measured.

First, 40 µg of membrane is incubated with [^{3}H]SCH 23390 at a concentration of 2 nM for 2 h at 25°C. Non-specific binding is estimated in the presence of 10 µM *cis*-flupentixol. Membranes are filtered and washed 3 times with binding buffer, and filters are counted to determine [^{3}H]SCH 23390 bound.

Several selective dopamine D_4 antagonists were described: Hikada et al. (1996), Merchant et al. (1996), Rowley et al. (1996), Bristow et al. (1997).

Some radioligands were proposed as being selective for dopamine D_4 receptors: [^{3}H]clozapine (Ricci et al. 1997a, b), [^{3}H]NGD 94–1 (Thurkauf 1997; Primus et al. 1997), RBI-257 (Kula et al. 1997).

E.5.1.6 Determination of Dopamine Autoreceptor Activity

PURPOSE AND RATIONALE

The method describes the procedure to determine if a compound possesses autoreceptor blocking activity without the interference from postsynaptic effects. Striatal DOPA (3,4-dihydroxyphenylalanine), DOPAC (3,4-dihydroxyphenylacetic acid) and DA (dopamine) are quantitated following *in vivo* treatment with drug, apomorphine, gamma butyrolactone and NSD-1015. Antipsychotic compounds that block striatal dopaminergic presynaptic autoreceptors are believed to possess a greater liability for producing EPS.

PROCEDURE

Reagents

1. 0.1 M HCl
2. 1 N NaOH
3. 0.1 M perchloric acid (PCA) containing 4.3 mM EDTA
4. 2 mM solutions of DOPAC, DA and DOPA in 0.1 M HCl, 0.5 ml aliquots are stored at –60°C until use.
5. Preparation of 2° standard mixture
   10 µM solution of DOPAC, DA and DOPA diluted from reagent 4 with 0.1 M PCA/EDTA);
   The 2° standard solution is used for the preparation of standard curves.
6. Mobile phase/MeOH-buffer (4 : 96, v/v) buffer: 0.012 mM sodium acetate, 0.036 M citric acid and 152 µM sodium octane sulfonate, mobile phase: methanol/buffer (80 ml + 1920 ml) is filtered through a 0.2 µm nylon 66 filter.
7. Preparation of dosing solutions
   a) Apomorphine (2 mg/kg) is prepared in saline containing 1% Tween 80 + 0.1% ascorbic acid to prevent oxidation.
   b) GBL (750 mg/kg) is prepared as a solution in saline containing 1% Tween 80.
   c) NSD-1015 (100 mg/kg) is prepared as a solution in saline containing 1% Tween 80.

HPLC-Instrumentation

Consists of a

- pump, model SP8810 (Spectra Physics),
- injector, WISP 710B (Waters Associates),
- detector, 5100A electrochemical with a 5011 analytical cell and 5020 guard cell (ESA),

- integrator, D-2000 (Hitachi), used as a back-up for the data collection/integrator, CS 9000 (IBM) system
- analytical column: C18-ODS Hypersil, 3 µm, 100 × 4.6 mm (Shandon)

Tissue Preparation

Following treatment with test drug, rats are sacrificed by decapitation at the pre-determined time. The brain is rapidly removed, the striatum is dissected on ice and frozen on dry ice. The tissue is analyzed by HPLC the same day.

Tissue is homogenized in 500 µl 0.1 M PCA/EDTA. The homogenate is centrifuged for 6 min using a microcentrifuge (model 5413, Eppendorf). The supernatant is transferred to 0.2 µm microfilterfuge™ tubes and centrifuged for 6–8 min as before. The filtrate is transferred to WISP vials. Standards are included every 12–15 samples.

Five µl of the striatum homogenate is injected into the HPLC column.

HPLC flow rate is 1.5 ml/min, run time is 20 min. Helium flow is constant in mobile phase.

For protein analysis, 1.0 ml 1 N NaOH is added to the tissue pellet. The next day, the protein analysis is performed as described by Bradford (1976) using the BioRad assay kit.

EVALUATION

Peak area is used for quantitation. The mg of protein and pmoles of DOPAC, DA and DOPA are calculated from linear regression analyses using the corresponding standard curve. Final data are reported as pmoles/mg protein.

E.5.1.7 Dopamine-Sensitive Adenylate Cyclase in Rat Striatum

PURPOSE AND RATIONALE

Agonist stimulation of dopamine D_1 receptors leads to increased cAMP formation mediated by a guanine nucleotide-binding regulatory protein. This effect is blocked by selective antagonists like SCH 23390.

Agonist stimulation of the dopamine D_2 receptor leads to a decreased cAMP formation mediated by a guanine nucleotide binding protein. Apomorphine is a potent agonist with full intrinsic activity at D_2 receptors. Phenothiazines block both D_1 and D_2 receptors, whereas butyrophenones and related drugs are very potent antagonists at D_2 receptors.

Studies on cAMP formation may be useful for differentiation of antipsychotic drugs.

PROCEDURE

Tissue Preparation

Male Wistar rats are sacrificed by decapitation, the brains removed, and the striata dissected out and weighed. Striatal tissue from 2 rats is homogenized in 25 volumes of ice-cold 0.08 M Tris-maleate buffer, pH 7.4, containing 2 mM EGTA. Protein content of an aliquot is determined. A 50 µl aliquot is used in the cyclase enzyme assay.

Enzyme Assay

The following volumes are placed in conical centrifuge tubes kept in an ice-water bath:

200 µl	incubation buffer (equal amounts of 0.8 mM Tris-maleate, pH 7.4; 60 mM $MgSO_4$; 100 mM theophylline and 4 mM EGTA)
50 µl	1 mM dopamine HCl or water
25 µl	test drug or water
125 µl	distilled water
50 µl	tissue homogenate

After incubation for 20 min at 0°C, the enzyme reaction is started by addition of 50 µl of 15 mM ATP solution. The tube rack is placed in a shaking water bath preset at 30°C for 2.5 min. The reaction is terminated by placing the tube rack in a boiling water bath for 4 min. Then, the tubes are centrifuged at 1000 *g* for 10 min.

A 25 µl aliquot of the supernatant in each tube is removed and the cAMP determined using a commercial RIA kit (Amersham).

EVALUATION

Results are expressed as pmoles cAMP/mg protein of dopamine stimulated vs. non dopamine stimulated level. Percentage inhibition of this dopamine stimulated level by test drugs is calculated and IC_{50} values determined by log-probit analysis.

E.5.1.8 α_1-Adrenergic Receptor Binding in Brain

PURPOSE AND RATIONALE

The use of neuroleptic and antidepressant drugs is sometimes limited by their side effects, such as orthostatic hypotension and sedation. These side effects are attributed to blockade of central and peripheral adrenergic α-receptors. For neuroleptics the ratio between their dopamine antagonistic and their α-receptor antagonistic potencies should be taken into account rather than their absolute α-blocking effect. WB-4101 is a specific and potent antagonist of the α_1-adrenoreceptor, characterized *in vitro* in rat brain, heart, vascular smooth muscle and gastrointestinal smooth muscle.

The *in vitro* [^{3}H]-WB 4101 receptor binding assay quantitates the α-adrenergic blocking properties of psychoactive agents and is used to assess a compound's potential to cause orthostatic hypotension and sedation as well as primary blood pressure lowering effects through α_1-receptor blockade.

PROCEDURE

Reagents

[Phenoxy-3-^{3}H(N)]-WB 4101 = (2,6-dimethoxyphenoxyethyl)-aminomethyl-1,4-benzodioxane, New England Nuclear, (specific activity 20–35 Ci/mmol).

For IC_{50} determinations [^{3}H]-WB 4101 is made up to a concentration of 2 nM in Tris buffer and 500 µl is added to each tube (yields a final concentration of 0.5 nM in the 2 ml assay)

L-norepinephrine bitartrate (Sigma Chemical Company). A 800 µM solution is prepared in Tris buffer and 250 µl is added to each of 3 tubes to determine nonspecific binding. This yields a final concentration of 100 µM in the 2 ml assay.

Test compounds: A 80 µM stock solution is made up in a suitable solvent and serially diluted with Tris buffer, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. Usually, seven concentrations are studied for each assay.

Tissue Preparation

Male Wistar rats (100–150 g) are sacrificed by decapitation. The whole brain minus cerebellum is homogenized in 75 volumes of ice-cold 0.05 M Tris buffer, pH 7.7. The homogenate is centrifuged at 40,000 *g* at 4°C for 15 min. The supernatant is discarded and the pellet is rehomogenized in fresh Tris buffer and recentrifuged at 40,000 *g* at 4°C for 15 min. The final pellet is resuspended in the original volume of ice-cold 0.05 M Tris buffer. The final tissue concentration in the assay is 10 mg/ml. Specific binding is approximately 80% of total bound ligand.

Assay

1200 µl	tissue suspension
500 µl	^{3}H-WB 4101
250 µl	vehicle (for total binding) or
800 µM	L-norepinephrine bitartrate (for nonspecific binding) or appropriate drug concentration

Sample tubes are kept in ice for additions, then vortexed and incubated for 15 min at 25°C. The binding is terminated by rapid vacuum filtration through Whatman GF/B filters, followed by three 5 ml washes with ice-cold 0.05 M Tris buffer. The filters are counted in 10 ml of Liquiscint scintillation cocktail.

EVALUATION

Specific WB 4101 binding is defined as the difference between the total binding and that bound in the presence of 100 µM norepinephrine. IC_{50} calculations are performed using computer-derived log-probit analysis.

E.5.1.9 [^{3}H]Spiroperidol Binding to 5-HT$_2$ Receptors in Rat Cerebral Cortex

PURPOSE AND RATIONALE

The purpose of this assay is to determine the anti-serotonin activity of neuroleptics, antidepressants and antihypertensive compounds, by measuring the displacement of [^{3}H]spiroperidol from serotonergic antagonist binding sites in cerebral cortical membranes. The regulation of 5-HT$_2$ receptor density by chronic antidepressant treatment is discussed in a separate protocol (see Sect. E.6.1.6).

The receptor binding of serotoninergic sites in the CNS has been investigated using [^{3}H]serotonin (5-HT) (Bennett and Snyder 1976), [^{3}H]LSD (Peroutka and Snyder 1979) and [^{3}H]spiroperidol (Peroutka and Snyder 1979; List and Seeman 1981; Leysen et al. 1978) as the radioligand. Receptor sites have been defined kinetically and classified as 5-HT$_1$ sites (labeled by [^{3}H]5-HT, displaced by agonists) and 5-HT$_2$ sites (labeled by [^{3}H]-spiroperidol and displaced by antagonists). [^{3}H]LSD labels both 5-HT$_1$ and 5-HT$_2$ binding sites (Peroutka and Snyder 1979). Of the brain regions tested, the frontal cerebral cortex contained the greatest density of 5-HT$_2$ binding sites. Lesioning studies indicate that 5-HT$_2$ binding sites are post synaptic and not linked to adenylate cyclase (Peroutka et al. 1979).

The inhibition of 5-HT$_2$ binding correlates with the inhibition of quipazine-induced head twitch, which may reflect decreased behavioral excitation. The physiological and pharmacological role of these receptors is not clear. Although numerous neuroleptics and antidepressants of varying chemical structures are potent inhibitors of 5-HT$_2$ binding, there is no clear-cut relationship to the efficacy of these drugs. Methysergide and cyproheptadine are both potent inhibitors of 5-HT$_2$ binding without having neuroleptic or antidepressant effects. However, potent interaction with 5-HT$_2$ receptors may indicate a reduced potential for catalepsy, since methysergide blocks catalepsy induced by haloperidol (Rastogi et al. 1981). The interaction of serotonergic neurons with cholinergic neurons in the striatum (Samanin et al. 1978) may also be decreased by potent 5-HT$_2$ antagonists. In addition, the ratio of activity at D$_2$ and 5-HT$_2$ receptors may be useful in the screening of atypical antipsychotic agents (Meltzer et al. 1989). Furthermore, it has been shown that ketanserin, a selective 5-HT$_2$ antagonist, is an effective hypotensive agent which blocks peripheral vascular 5-HT receptors.

5-HT$_2$ receptors have been subdivided into 5-HT$_{2A}$, 5-HT$_{2B}$ and 5-HT$_{2C}$ receptors. The new 5-HT receptor classification has been published by the VII. International Union of Pharmacology Classification of Receptors for 5-Hydroxytryptamine (Serotonin) (Hoyer et al. 1994). Further comments were given by Humphrey et al. (1993), Martin and Humphrey (1994), Saxena (1994), Tricklebank (1996).

Several compounds with HT$_{2A}$ antagonistic activity are described, such as tradozone (Clements-Jewery

et al. 1980; Hingtgen et al. 1984; Stryjer et al. 2003), MDL 100,907 (Kehne et al. 1996; Moser et al. 1996), and sarpogrelate (Hayashi et al. 2003).

McCullough et al. (2006) described the 5-HT_{2B} antagonist and 5-HT_4 agonist activities of tegaserod in the anesthetized rat.

PROCEDURE

Reagents

1. 0.5 M Tris buffer, pH 7.7
   a) 57.2 g Tris HCl
      16.2 g Tris base
      q.s. to 1 liter (0.5 M Tris buffer, pH 7.7)
   b) Make a 1:10 dilution in distilled H_2O (0.05 M Tris buffer, pH 7.7)
2. Tris buffer containing physiological ions
   a) Stock buffer

      NaCl 7.014 g
      KCl 0.372 g
      $CaCl_2$ 0.222 g
      $MgCl_2$ 0.204 g

      q.s. to 100 ml in 0.5 M Tris buffer
   b) Dilute 1:10 in distilled H_2O
      This yields 0.05 M Tris HCl, pH 7.7; containing NaCl (120 mM), KCl (5 mM), $CaCl_2$ (2 mM) and $MgCl_2$ (1 mM)
3. [Benzene-^{3}H] spiroperidol (20–35 Ci/mmol) is obtained from New England Nuclear. For IC_{50} determinations: ^{3}H-spiroperidol is made up to a concentration of 30 nM in 0.01 N HCl and 50 µl added to each tube (yields a final concentration of 1.5 nM in the 1 ml assay).
4. Methysergide maleate is obtained from Sandoz. Methysergide maleate stock solution is made up to 0.25 mM for determination of nonspecific binding. The final concentration in the assay is 5 µM, when 20 µl of the stock solution is added to the reaction tube.
5. Test compounds. For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. Seven concentrations are used for each assay and higher or lower concentrations may be used, depending on the potency of the drug.

Tissue Preparation

Male Wistar rats are decapitated and the cerebral cortical tissue is dissected, weighed and homogenized in 50 volumes of 0.05 M Tris buffer, pH 7.7 (buffer 1b) with the Brinkman Polytron, then centrifuged at 40,000 *g* for 15 min. The supernatant is discarded and the pellet resuspended and recentrifuged as described above. This pellet is resuspended in 50 volumes of buffer 2b and stored in an ice bath. The final tissue concentration is 10 mg/ml. Specific binding is 7% of the total added ligand and 50% of total bound ligand.

Assay

50 µl	0.5 M Tris-physiological salts (buffer 2a)
380 µl	H_2O
20 µl	vehicle (for total binding) or 0.25 mM methysergide (for nonspecific binding) or appropriate drug concentration
50 µl	[^{3}H]spiroperidol
500 µl	tissue suspension

The samples are incubated for 10 min at 37°C, then immediately filtered under reduced pressure using Whatman GF/B filters. The filters are washed with three 5 ml volumes of ice-cold 0.05 M Tris buffer, pH 7.7 mM methysergide.

EVALUATION

IC_{50} calculations are performed using log-probit analysis. The percent inhibition at each drug concentration is the mean of triplicate determinations.

MODIFICATION OF THE METHOD

The receptor binding properties of the 5-HT_2 antagonist ritanserin were reported by Leysen et al. (1985).

Preclinical characterization of a putative antipsychotic as a potent 5-HT_{2A} antagonist was reported by Kehne et al. (1996).

Using [^{125}I]LSD and [^{3}H]5-HT binding assays Siegel et al. (1996) characterized a structural class of 5-HT_2 receptor ligands.

[^{3}H]Ketanserin has been described as a selective ^{3}H-ligand for 5-HT_2 receptor binding sites. (Leysen et al. 1981).

[^{3}H]RP 62203, a potent and selective 5-HT_2 antagonist was recommended for *in vivo* labeling of 5-HT_2 receptors (Fajolles et al. 1992).

Other selective 5-HT_2 receptor radioligands were recommended:

[^{125}I]-EIL (radioiodinated D-(+)-N1-ethyl-2-iodolysergic acid diethylamide) (Lever et al. 1991); [^{3}H]-MDL100,907 (Lopez-Gimenez et al. 1998).

E.5.1.10 Serotonin 5-HT_2 Receptor Autoradiography (^{3}H-Spiperone Binding)

PURPOSE AND RATIONALE

Autoradiography of ^{3}H-spiperone binding sites with selective labeling conditions permits the visualization of the anatomical locations of 5-HT_2 receptors (Palacios et al. 1981; Pazos et al. 1985; Altar et al. (1985). Quantitative measurements of the binding to receptors can be obtained with computer-assisted video analysis of the autoradiograms with a greater anatomical resolution and sensitivity than in membrane homogenates (Pazos et al. 1985; Altar et al. (1984). Using autoradiographic techniques, it has been demonstrated that there is a heterogeneous distribution of 5-HT_2 receptors, with much higher levels in telencephalic areas such as the neocortex and the claustrum than in meso- or metencephalic areas. Within the cortex, 5-HT_2 receptors are abundant in layers IV and V (Pazos et al. 1985). The high concentration of 5-HT_2 receptors in the frontoparietal motor area and the claustrum which connects to the motor cortex and other motor areas suggests a physiological role for 5-HT_2 receptors in some motor syndromes (Cadet et al. 1987; Costall et al. 1975; Kostowski et al. 1972). The high affinity of the atypical antipsychotic clozapine for 5-HT_2 receptors (Fink et al. 1984; Altar et al1986) and the down-regulation of 5-HT_2 receptors following chronic administration of clozapine (Reynolds et al. 1983; Lee and Tang 1984; Wilmot and Szczepanik 1989) suggests that 5-HT_2 receptor interaction may be a significant factor in the lack of extrapyramidal side effects and tardive dyskinesias with its clinical use.

Since ^{3}H-spiperone labels α_1-noradrenergic sites in the cerebral cortex, a masking concentration of the α_1-blocker prazosin is included to selectively define binding to 5-HT_2 receptors (Morgan et al. 1984). This is necessary if the test compound also inhibits α_1-receptors which may be present in the brain region of interest.

The assay is used to determine the direct interaction of potential antipsychotic compounds with the serotonin-5-HT_2 recognition site in discrete regions of the rat brain either *in vitro* or after *ex vivo* treatment of the whole animal.

PROCEDURE

Reagents

1a. 0.5 M Tris+1.54 M NaCl, pH 7.4

1b. 0.05 M Tris+0.154 M NaCl, pH 7.4

2. ^{3}H-spiperone (specific activity 70–90 Ci/mmol) is obtained from Amersham.
   - For IC_{50} determinations: ^{3}H-spiperone is made up to a concentration of 20 nM and 0.55 ml is added to each slide mailer (yields a final concentration of 1.0 nM in the 11.0 ml assay volume).
   - For saturation experiments: ^{3}H-spiperone is made up to a concentration of 20 nM. The final concentration should range from 0.5–2.5 nM. Typically, six concentrations are used by adding 0.55 ml or less to each mailer (for smaller volumes, add water to bring total addition of 0.55 ml).

3. Methysergide is used to determine nonspecific binding in brain sections of the frontal cortex.
   Methysergide maleate is obtained from Sandoz. A stock solution of 2.5×10^{-4} M is made by dissolving in distilled water. A volume of 0.22 ml of the stock solution is added to the nonspecific binding slide mailers (final concentration 5 µM). All other mailers receive 0.22 ml of vehicle (1 ml of 0.01 N acetic acid in a final volume of 10 ml with distilled water).

4. Ketanserin is used to determine nonspecific binding in those slide mailers containing sections with the nucleus accumbens and striatum.
   Ketanserin (free base or tartrate salt) is obtained from Janssen. A stock solution of 10^{-3} M is made by dissolving the ketanserin (free base) in 0.05 N acetic acid or the tartrate salt in distilled water. This is further diluted to 5×10^{-6} M (50 µM q.s 10 ml with distilled water). A volume of 0.22 ml is added to the slide mailers to give a final concentration of 100 nM.

5. Prazosin is used to mask α_1-receptors in cortical brain section.
   Prazosin HCl is obtained from Pfizer. A stock solution of 10^{-4} M is made by dissolving prazosin in 0.01 N acetic acid and bringing the final volume to 10 ml with distilled water. This is further diluted to 5×10^{-6} M (100 µM q.s 10 ml). A volume of 0.22 ml is added to those slide mailers to

be used for cortical brain sections to give a final concentration of 100 nM.

6. Sulpiride is used to mask D_2 receptor binding in brain sections from the nucleus accumbens and striatum.
   Sulpiride is obtained from Sigma. A stock solution of 10^{-4} M is made by dissolving sulpiride in 1.0 ml of 0.01 N acetic acid and bringing the final volume to 10 ml with distilled water. A volume of 0.22 ml is added to the appropriate slide mailers to give a final concentration of 10 µM.
7. Test compounds (for *in vitro* IC_{50} determinations). For most assays, a 5×10^{-3} M stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used depending on the potency of the drug.

Tissue Preparation

Frontal cortical brain sections are collected from plates 5 through 8 and nucleus accumbens/striatal sections are collected from plates 9 (rostral n. accumbens) through plate 17 (caudal striatum) of "The Rat Brain Atlas in Stereotaxic Coordinates" by Paxinos and Watson.

1. For *in vitro* inhibition experiments, 3–5 sets of 10 slides are collected with 4–5 sections per slide.
2. For saturation experiments, 3–5 sets of 12 slides are collected with 4–5 sections per slide.
3. For *ex vivo* inhibition experiments, a set of 8 slides is used, 4 for total binding and 4 for nonspecific binding.
4. For experiments in which the tissue sections will be swabbed and counted with scintillation fluid, two sections per slide are collected.

Assay

1. Preparation of slide mailers (11.0 ml volume/slide mailer):
   Note: If slides with sections are to be wiped for scintillation counting, a final volume of 6.5 ml is sufficient to cover 2 sections. A proportional adjustment of the volumes to be pipetted is made.
   a) *In vitro* inhibition experiments
      Separate mailers are prepared for total binding, nonspecific binding and 7–8 concentrations of test compound.
      1. For frontal cortical brain sections, prazosin is included in all mailers to mask the binding of [^{3}H]-spiperone to α_1-receptors and nonspecific binding is defined with 5 µM methysergide.
         5.50 ml buffer 1b
         0.55 ml buffer 1a
         0.55 ml [^{3}H]-spiperone, 1.0 nM final concentration
         3.96 ml distilled water
         0.22 ml prazosin 5×10^{-6} M, final concentration 100 nM or vehicle
         0.22 ml test compound, final concentration 10^{-8}–10^{-5} M or methysergide 2.5×10^{-4} M, final concentration 5 µM or vehicle
      2. For brain sections with the nucleus accumbens and striatum in which there is negligible binding of [^{3}H]-spiperone to α_1-receptors, prazosin is not included. Since levels of 5-HT_2 receptors in these brain areas are low, 10 µM sulpiride is included in all mailers to mask the binding of [^{3}H]-spiperone to D_2 receptors.
         Ketanserin, final concentration of 100 nM, is used to determine nonspecific binding since methysergide has a weak affinity for D_2 receptors (IC_{50} approximately 1–5 µM).
         5.50 ml buffer 1b
         0.55 ml buffer 1a
         0.55 ml [^{3}H]-spiperone, 1.0 nM final concentration
         3.96 ml distilled water
         0.22 ml sulpiride 5×10^{-4} M, final concentration 10 µM or vehicle
         0.22 ml test compound, final concentration 10^{-8}–10^{-5} M or ketanserin 5×10^{-5} M final concentration 100 nM or vehicle
   b) *Ex vivo* inhibition experiments
      Separate mailers are prepared for total and nonspecific binding, as described above, including sulpiride to mask D_2 receptor binding with brain sections through the nucleus accumbens and striatum and prazosin to mask α_1-receptors in cortical brain sections.
   c) Saturation experiments
      Separate mailers are prepared for total and nonspecific binding at each radioligand concentration. Prazosin is not included in the mailers in saturation experiments, since specific binding is defined by methysergide which has negligible affinity for α_1-receptors.

      5.50 ml buffer 1b

0.55 ml buffer 1a

0.55 ml [^{3}H]-spiperone, final concentrations 0.5–2.5 nM

4.18 ml distilled water

0.22 ml 2.5×10^{-4} M methysergide, final concentration 5 µM or vehicle

2. Slides are air-dried for 10–15 min at room temperature, preincubated in 0.05 M Tris+0.154 M NaCl, pH 7.4 for 5 min and further incubated for 60 min with [^{3}H]-spiperone. Slides are then rinsed with ice-cold solutions as follows: dipped in buffer 1b, 2 × 5 min rinsed in buffer 1b, dipped in distilled water.

   Slides used for wipes: both sections are wiped with one Whatman GF/B filter and radioactivity is counted after addition of 10 ml of scintillation fluid.

   Slides used for autoradiography: slides are dried under a stream of air at room temperature and are stored in a desiccator under vacuum at room temperature (usually overnight). Slides are then mounted onto boards, along with ^{3}H-standards (Amersham RPA 506).

   In the dark room under safelight illumination (Kodak GBX-2 filter), slides are exposed to Amersham Hyperfilm or LKB Ultrofilm for 14–17 days.

E.5.1.11 Binding to the Sigma Receptor

PURPOSE AND RATIONALE

Sigma receptors, as a class of binding sites in the brain, were originally described as a subtype of the opiate receptors. Efforts to develop less addicting opiate analgesics led to the study of several benzomorphan derivatives which produce analgesia without causing the classical morphine-induced euphoria. Unfortunately, these compounds, like N-allylnormetazocine (SKF 10,047) produced a variety of psychotic symptoms. This psychotomimetic effect is thought to be mediated by sigma receptors. This binding site is sensitive to many neuroleptics, most notably the typical antipsychotic haloperidol, leading to the hypothesis that drug interactions with the sigma site may be a new approach for the discovery of novel antipsychotics which are not dopamine receptor antagonists. D_2 receptor antagonism is thought to be linked with the occurrence of extrapyramidal symptoms in the form of hyperkinesia and Parkinson symptoms or tardive dyskinesia limiting the therapeutic use of traditional antipsychotic medication. It is hoped that ligands to the sigma receptor do not produce these adverse reactions. The sigma site is believed to be distinct from the binding site for the psychotomimetic drug phencyclidine.

PROCEDURE

Reagents

(+)-SKF 10,047 is prepared as a stock solution of 5×10^{-3} M with distilled water. 130 µl added to the 6.5 ml assay yields a final concentration of 10^{-4} M.

^{3}H-(+)-SKF 10,047 (specific activity 40 Ci/mmol) is obtained from New England Nuclear. A 200 nM stock solution is made up with distilled water for IC_{50} determinations. 325 µl added to each tube yields a final concentration of 10 nM in the 6.5 ml assay.

Test Compounds

A 5 mM stock solution is prepared in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M.

Tissue Preparation

The assay utilizes slide-mounted cross-sections of brain tissue from male Hartley guinea pigs. Whole brain sections of 10 µm thickness are obtained from the hippocampus, thaw-mounted onto gel-chrome alum subbed slides, freeze-dried and stored at –70°C until use. On the day of the assay, the sections are thawed briefly at room temperature until the slides are dry and then used in the assay at a final volume of 6.5 ml.

Assay

Incubation solutions are prepared in plastic slide mailer containers as follows:

3.250 ml 0.05 M Tris buffer, pH 7.7

2.470 ml distilled water

0.325 ml 0.5 M Tris buffer, pH 7.7

0.130 ml (+)-SKF 10,047 or vehicle

0.325 ml [^{3}H](+)-SKF 10,047

Dried slides with tissue sections are added to the slide mailers and incubated at room temperature for 90 min. Non-bound radioligand is removed by rinsing the slides sequentially in two 5-min rinses in ice-cold 0.05 M Tris buffer and a dip in ice-cold distilled water. The sections are either swabbed with Whatman GF/B filters for scintillation counting of tissue-bound radioligand or exposed to tritium-sensitive film for autoradiography of the binding sites.

EVALUATION

Specific binding is determined from the difference of binding in the absence or presence of 10^{-4} M (+)-SKF 10,047 and is typically 60–70% of total binding. IC_{50} values for the competing drug are calculated by log-probit analysis of the data.

MODIFICATIONS OF THE METHOD

[^{3}H]-(+)-pentazocine has been recommended as a highly potent and selective radioligand for µ receptors (de Costa et al. 1989; DeHaven-Hudkins et al. 1992).

Classification of sigma binding sites into σ_1 and σ_2 receptors has been proposed (Walker et al. 1990; Quirion et al. 1992; Abou-Gharbia et al. 1993).

Hashimoto and London (1993) characterized [^{3}H]ifenprodil binding to σ_2 receptors in rat brain.

Ganapathy et al. (1999) provided evidence for the expression of the type 1 sigma receptor in the Jurkat human T lymphocyte cell line.

E.5.1.12 Simultaneous Determination of Norepinephrine, Dopamine, DOPAC, HVA, HIAA, and 5-HT from Rat Brain Areas

PURPOSE AND RATIONALE

To measure the effects of potential antipsychotic drugs on catecholamines and indols, a quantitative method for the determination of norepinephrine (NE), dopamine (DA), 3,4-dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA), 5-hydroxyindolacetic acid (5HIAA) and 5-hydroxytryptamine (5-HT) from rat brain regions is used. These catecholamines and indols are measured in rat brain prefrontal cortex, nucleus accumbens and striatum.

PROCEDURE

Reagents

1. 0.1 M HCl
2. 1 N NaOH
3. 2 mM solutions of NE, DOPAC, DA, HVA, 5HIAA and 5-HT in 0.1 M HCl;
   0.5 ml aliquots are stored at –60°C until use.
4. Preparation of 2° Standard Mixture
   - 10 µM solution of NE, DOPAC, DA, HVA, 5HIAA and 5-HT (diluted from reagent 3) in mobile phase (reagent 5)
   - the 2° Standard solution is used for the preparation of standard curves.
5. Mobile phase/MeOH: buffer (7.5:92.5, v/v)
   - buffer: 0.07 M sodium acetate, 0.04 M citric acid, 130 µM EDTA and 230 µM sodium octane sulfonate
   - mobile phase: methanol/buffer (150 ml + 1850 ml) is filtered through a 0.2 µm nylon 66 filter

HPLC-Instrumentation

- pump, model SP8810 (Spectra Physics),
- injector, WISP 710B (Waters Associates),
- detector, 5100A electrochemical with a 5011 analytical cell and 5020 guard cell (ESA),
- integrator, D-2000 (Hitachi), used as a back-up for the data collection/integrator, CS 9000 (IBM) system,
- analytical column: C18-ODS Hypersil, 3 µm, 100 × 4.6 mm (Shandon)

Animal Treatment

Six rats per group (150–250 g) are dosed with 4–5 different concentrations of the putative antipsychotic drug; usual concentrations range from 0.03 to 30 mg/kg. At a predetermined time, usually 60 min, the rats are sacrificed.

Tissue Preparation

Following treatment with test drug, rats are sacrificed by decapitation. The brain is rapidly removed and placed on ice. The striatum, nucleus accumbens and/or prefrontal cortex are dissected and placed in 1.5 ml microcentrifuge tubes. The tubes are capped and immediately placed in dry ice. The frozen brain sections are stored at –60°C until HPLC analysis.

Tissue is homogenized in mobile phase (striatum: in 600 µl, nucleus accumbens and prefrontal cortex: in 300 µl). The homogenates are centrifuged for 6 min using a microcentrifuge (model 5413, Eppendorf). The supernatants are transferred to 0.2 µm microfilterfuge™ tubes and centrifuged for 6–8 min as before. The filtrate is transferred to WISP vials. Standards are included every 12–15 samples.

The following volumes are injected to the HPLC column:

- striatum: 5 µl; nucleus accumbens: 20 µl; prefrontal cortex: 50 µl.

- HPLC flow rate is 1.0 ml/min, run time is 25 min. Helium flow is constant in mobile phase.

For protein analysis, 1 N NaOH is added to the tissue pellets as follows:

- striatum: 1.0 ml;
- nucleus accumbens and prefrontal cortex: 0.5 ml.

The next day, the protein analysis is run in duplicate with 5 µl of striatum. 20 µl of nucleus accumbens and prefrontal cortex as described by Bradford (1976) using the BioRad assay kit.

EVALUATION

Peak area is used for quantitation. The mg of protein and pmoles of NE, DOPAC, DA, HVA, 5HIAA and 5-HT are calculated from linear regression analysis using the corresponding standard curve. Final data are reported as pmoles/mg protein.

E.5.1.13 Measurement of Neurotransmitters by Intracranial Microdialysis

PURPOSE AND RATIONALE

Methods to measure neurotransmitters and their metabolites in specific areas of the brain by microdialysis were introduced by Ungerstedt and his group (Ungerstedt et al. 1982; Zetterström et al. 1982, 1983; Zetterström and Ungerstedt 1983; Ungerstedt 1984; Stähle et al. 1991; Lindefors et al. 1989; Amberg and Lindefors (1989) and by Imperato and di Chiara 1984, 1985). In brain dialysis, a fine capillary fibre is implanted in a selected brain area. Low molecular weight compounds diffuse down their concentration gradients from the brain extracellular fluid into a physiological salt solution that flows through the capillary fibre at a constant rate. The fluid is collected and analyzed.

PROCEDURE

Several designs of dialysis probes have been used (Santiago and Westerink 1990; Kendrick 1991):

1. Horizontal Probe

A straight tube (Vita Fiber, 3 × 50 Amicon) with an outer diameter of 0.34 mm and a molecular weight cut-off of 50000 is used. The outer surface of the tube is porous and can easily be sealed by epoxy which is applied by passing the tube through a droplet of epoxy and then through a narrow hole corresponding to the outer diameter of the tube. The wall of the tube is sealed in this way except for the area where the dialysis is intended to take place. The length of this region can be varied from 2 to 8 mm depending upon which structure of the brain will be perfused. During the coating and all other handling of the tube it is supported by a thin tungsten or steel wire inserted into its lumen. One end of the tube is glued into a steel cannula (6 mm long, outer diameter 0.64 mm).

Male Sprague Dawley rats weighing 250–300 g are anesthetized with halothane and held in a stereotactic instrument. The animals are maintained under halothane anesthesia during the entire experiment.

Holes are drilled bilaterally (5.7 mm below and 1.5 mm in front of bregma) in the temporal bones after the temporal muscles have been retracted from the bones and folded away.

During the implantation, the cannula is held by the micromanipulator of the stereotactic instrument and the dialysis tube is passed horizontally through the brain through the holes drilled on both sides of the skull. A polyethylene tubing carrying the perfusion

fluid is connected to the steel cannula. The perfusate is collected at the other end.

2. Loop Probe

The probe is made of a flexible cellulosic tubing (Dow 50, outer diameter 0.25 mm). Both ends of the tube are inserted into 0.64 mm diameter steel tubes, one of which is bent in an angle. A very thin microsuture (0.1 mm in diameter) is inserted into the tube and positioned half between the steel tubes. Before implantation, the tube is moistened and bent in such a way that the two steel tubes are held closely together in the micromanipulator of the stereotactic instrument. A tungsten wire is inserted into the straight steel tube and passed down the lumen of the dialysis tube in order to stretch it and make it rigid enough to be implanted into the brain. The tube is implanted vertically and the steel cannulae are attached to the skull by dental cement. The tungsten wire is removed before starting the experiment. The cellulosic tube is flexible enough to withstand the bending at the lower end. The microsuture keeps the bend open.

Loop-shaped or U-shaped microdialysis probes have been used by several authors, e. g., Ichikawa and Meltzer (1990), Jordan et al. (1994), Westerink and Tuinte (1986), Auerbach et al. (1995).

3. Vertical Probe

The probe is sealed at one end by epoxy. The other end is glued into a 0.64-mm diameter steel tube. A thin inner cannula made of a steel tube or a glass capillary carries the fluid to the bottom of the dialysis tube where it leaves the inner capillary and flows upwards and leaves the probe by a lateral tube. This vertical probe can also be coated with epoxy. It is especially suited for reaching ventral parts of the brain and performing dialysis in small nuclei of the brain.

A similar device has been described for continuous plasma sampling in freely moving rats by Chen and Steger (1993).

Most of the commercially available microdialysis probes are based on this principle.

4. Commercially Available Microdialysis Probes

The microdialysis probes CMA/10, manufactured by Carnegie Medicine, Stockholm, Sweden, consist of a tubular membrane (polycarbonate; length: 3 mm; outside diameter: 0.50 mm; and inside diameter: 0.44 mm) glued to a cannula (outside diameter: 0.60 mm), and sealed with a glue at the tip (Stähle et al. 1991). The perfusion medium is carried to the dialyzing part of the probe by a thin cannula inside the probe. The medium leaves the inner cannula through two holes, flows back between the membrane and the inner cannula, and is collected at the outlet of the probe. The perfusion medium is delivered by means of a high precision micro-syringe pump.

This probe was used by several authors, e. g., Wood et al. (1988), Benveniste et al. (1989), Rollema et al. (1989), Scheller and Kolb (1991), Wang et al. (1993), Kreiss and Lucki (1995), Fink-Jensen et al. (1996).

CMA/11 probes were used by Boschi et al. (1995), Romero et al. (1996), Gobert et al. (1997).

Dialysis fibres with a semipermeable membrane AN 69-HF, Hospal-Dasco, Bologna, Italy, were used by de Boer et al. (1994), Rayevsky et al. (1995), Arborelius et al. (1996), Gainetdinov et al. (1996), Tanda et al. (1996).

EVALUATION

Samples of the dialysate are collected for different time intervals and analyzed for neurotransmitters. For the **evaluation of neuroleptics**, most authors measured dopamine, 3,4-dihydroxyphenyl acetic acid (DOPAC) and homovanillinic acid (HVA) by HPLC using appropriate detectors. See and Lynch (1996) analyzed dialysis samples for glutamate and GABA concentrations.

For the **evaluation of antidepressants** the concentrations of 5-hydroxytryptamine (5-HT), 5-hydroxy indole acetic acid (5-HIAA), dopamine (DA), dihydroxyphenylacetic acid (DOPAC), or noradrenaline (NA) were measured in the effluent by HPLC. Wood et al. (1988), Egan et al. (1996) used 3-methoxytyramine accumulation as an index of dopamine release.

CRITICAL ASSESSMENT OF THE METHOD

The results obtained from brain dialysis depend on at least three variables: type of probe, post-implantation interval, and whether anesthetized or freely moving animals are used (Di Chiara 1990).

Several authors analyzed the diffusion processes underlying the microdialysis technique and described the limitations of the experiments (Jacobson et al. 1985; Amberg and Lindefors 1989; Beneviste et al. 1989; Scheller and Kolb 1991; Le Quellec et al. 1995).

As a matter of fact, brain microdialysis has been used for the evaluation of many drugs in various indications, such as:

- for **neuroleptics** by Ichikawa and Meltzer 1990; Meil and See 1994; Hernandez and Hoebel 1994; See et al. 1995; Schmidt and Fadayel 1995; Semba et al. 1995; Rayevsky et al. 1995; Fink-Jensen et al.

1996; See and Lynch 1996; Gainetdinov et al. 1996; Egan et al. 1996; Klitenick et al. 1996,
- for **antidepressants** by de Boer et al. 1994; Jordan et al. 1994; Arborelius et al. 1995; Ascher et al. 1995; Auerbach et al. 1995; de Boer 1995, 1996; Casanovas and Artigas 1996; Gobert et al. 1995; Ichikawa and Meltzer 1995; Kreiss and Lucki 1996; Petty et al. 1996; Potter 1996; Romero et al. 1995; Sharp et al. 1996; Tanda et al. 1996a, b,
- for studies in **Parkinson** models by Rollema et al. 1989; Parsons et al. 1991.

MODIFICATIONS OF THE METHOD

Ferrara et al. (1990) continuously monitored ethanol levels in the brain by microdialysis.

Hernandez and Hoebel (1994) performed simultaneous cortical, accumbens, and striatal microdialysis in freely moving rats.

Hegarty and Vogel (1995) assayed dopamine, DOPAC and HVA in the brain of rats after acute and chronic diazepam treatment and immobilization stress.

Casanovas and Artigas (1996) implanted microdialysis probes simultaneously in six different brain areas of rats (frontal cortex, dorsal striatum, ventral hippocampus, dorsal hippocampus, dorsal raphe nucleus, median raphe nucleus).

Beneviste et al. (1984) determined extracellular concentrations of glutamate and aspartate in rat hippocampus during transient cerebral ischemia monitored by intracerebral microdialysis.

Boschi et al. (1995) showed that microdialysis of small brain areas in mice is feasible using the smallest commercially available probes.

E.5.1.14 Use of Push-Pull Cannulae to Determine the Release of Endogenous Neurotransmitters

PURPOSE AND RATIONALE

Originally reported by Gaddum (1961), the push-pull cannula has become recognized and utilized as a powerful tool in conjunction with sufficiently sensitive assays to measure low levels of neuroregulator release in distinct brain areas *in vivo*. (Philippu 1984).

This method has been used for various purposes, e. g.,

- to perfuse the ventricles of the brain with drugs, or to determine the release of labelled or endogenous compounds in the CSF (Bhattacharya and Feldberg 1958; Korf et al. 1976),
- to perfuse distinct brain areas with drugs and to study their effects on functions of the central nervous system (Myers et al. 1976; Bhargava et al. 1978; Ruwe and Myers 1978),
- to inject labelled monoamines or amino acids and to investigate the resting or induced release of radioactive compounds and their metabolites (Sulser et al. 1969; Strada and Sulser 1971; Kondo and Iwatsubo 1978),
- to perfuse distinct brain areas with labelled transmitter precursors and to determine the patterns of release of the newly synthesized transmitters (Philippu et al. 1974; Chéramy et al. 1977; Nieoullon et al. 1977; Gauchy et al. 1980),
- to perfuse distinct brain areas of anesthetized and conscious animals and to determine the release of endogenous neurotransmitters in the perfusate (Dluzen and Ramirez 1991).

PROCEDURE

The superfusion of the hypothalamus of the conscious, freely moving rabbit has been described by Philippu et al. (1981), Philippu (1984). Rabbits of both sexes are anesthetized with 40 mg/kg sodium pentobarbital i.p. Guide cannulae are mounted on a metal plate which is fixed on the skull with screws and dental cement. Some days after the operation, the guide cannulae are replaced with push-pull cannulae which are 4 mm longer than the guide cannulae, thus reaching the areas which are intended for superfusion. The push-pull cannulae are connected by tubing to two peristaltic pumps: one to push and another one to pull the fluid. The second pump is essential, because the superfusate is not directly collected from the side branch of the push-pull cannula, but from tubing which is connected to the side branch. The superfusate is automatically collected every 10 s in fraction collectors.

EVALUATION

The concentrations of neurotransmitters, e. g., epinephrine, norepinephrine, or dopamine are determined with appropriate analytical methods (Wolfensberger 1984) before and after stimulation.

MODIFICATIONS OF THE METHOD

Experiments in cats were described by Dietl et al. (1981), in rats by Tuomisto et al. (1983).

The cortical cup technique for collection of neurotransmitters has been described by Moroni and Pepeu (1984).

E.5.1.15 Fos Protein Expression in Brain

PURPOSE AND RATIONALE

The proto-oncogene c-fos encodes a 55,000 mol wt, 380 amino-acid phosphoprotein (FOS), which after translation in the cytoplasm, re-enters the nucleus and binds to DNA (Morgan and Curran 1989). C-fos induction can occur as a consequence of synaptic activation. An increase in fos immunoreactivity is associated with an increased metabolic demand on a neuron, i. e., a marker for neurons that are metabolically activated. Intermediate early genes such as c-fos have been tentatively classified or linked to third messengers, whose function is to produce a long-term effect on the recipient neuron.

Acute administration of antipsychotics induces c-fos expression in several areas of the rat forebrain as was shown with immunocytochemical methods (Dragunow et al. 1990; Nguyen et al. 1992; Robertson and Fibiger 1992; MacGibbon et al. 1994). Fos protein is believed to act as an initiator of long-term cellular changes (neural plasticity) in response to a variety of extracellular stimuli, including drugs (Graybiel et al. 1990; Rogue and Vicendon 1992). Typical (e. g. haloperidol) and atypical (e. g. clozapine) neuroleptic drugs have different antipsychotic effects and side-effects. A differential FOS-protein induction in rat forebrain regions after haloperidol and clozapine treatment was found (Deutch et al. 1992; Fibiger 1994; Fink-Jensen and Kristensen 1994; Merchant et al. 1994; Sebens et al. 1995). The induction pattern of Fos-like immunoreactivity in the forebrain could serve as predictor of atypical antipsychotic drug activity (Robertson et al. 1994).

PROCEDURE

Groups of 4–6 male Wistar rats weighing 350–450 g are injected subcutaneously with saline (control) or with various doses of the standard drugs or compounds with putative antipsychotic activity. After two hours, the animals are deeply anesthetized by intraperitoneal injection of 100 mg/kg pentobarbital and perfused with 200 ml saline followed by 200 ml of 4% paraformaldehyde in phosphate buffer solution (PBS). Each brain is removed immediately after perfusion and placed in fresh fixative for at least 12 h.

After the postfixative period, 30-µm sections are cut from each brain using a vibratome. Several antisera to detect Fos can be used, such as a sheep polyclonal anti-body directed against residues 2 to 16 of the N-terminal region of the Fos molecule, or a polyclonal antiserum raised in rabbits against Fos peptide (4–17 amino acids of human Fos).

Sections are washed 3 times with 0.02 mM PBS and then incubated in PBS containing 0.3% hydrogen peroxide for 10 min to block endogenous peroxidase activity. Sections are then washed 3 times in PBS and incubated in PBS containing 0.3% Triton X-100, 0.02% azide and Fos primary antisera (diluted 1:200) for 48 h. The sections are then washed 3 times with PBS and incubated with a biotinylated rabbit antisheep secondary antibody (diluted 1:200) for 1 h. The sections are washed three times with PBS and incubated for 1 h with PBS containing 0.3% Triton X-100 and 0.5% avidin-biotinylated horseradish peroxidase com-

plex. After 3 washes in PBS the sections are rinsed in 0.1 M acetate buffer, pH 6.0. Fos immunoreactivity is revealed by placing the sections in a solution containing 0.05% 3,3′-diaminobenzidine, 0.2% ammonium nickel sulfate and 0.01% H_2O_2. The reaction is terminated with a washing in acetate buffer. The sections are mounted on chrome-alum-coated slides, dehydrated and prepared for microscopic observation.

Drug induced changes in Fos-like immunoreactivity are quantified by counting the number of immunoreactive nuclei in the medial prefrontal cortex, nucleus accumbens, medial and dorsolateral striatum and the lateral septal nucleus. The number of Fos-positive nuclei are counted with a 550 × 550 µm grid placed over each of these regions with a 100 × magnification.

Typical and atypical antipsychotics can be classified on the basis of difference between Fos-like immunoreactivity in the nucleus accumbens and lateral striatum. For this purpose, the data are corrected for the effects which are produced by the injection procedure itself. The injection corrected value for the dorsolateral striatum is subtracted from the corresponding accumbal value for each drug dose.

This manipulation yields a value termed the atypical index, i. e. number of Fos-positive neurons in the nucleus accumbens minus the number in the lateral striatum = atypical index. A negative index indicates the probability of side-effects, like extrapyramidal syndrome, exerted by the typical neuroleptics, a positive value to be devoid of it.

EVALUATION

A one-way analysis of variance is performed on the cell count data for each dose and the corresponding vehicle control. If the analysis of variance is significant, multiple comparisons are performed by using the Newman-Keuls test.

MODIFICATIONS OF THE METHOD

Graybiel et al. (1990) reported a drug-specific activation of c-fos gene in striosome-matrix compartments and limbic subdivisions of the striatum by amphetamine and cocaine.

Deutch et al. (1991) found that stress selectively increases Fos protein in dopamine neurons innervating the prefrontal cortex.

Gogusev et al. (1993) described modulation of C-fos and other proto-oncogene expression by phorbol diester in a human histiocytosis DEL cell.

Deutch et al. (1995) studied the induction of Fos protein in the thalamic paraventricular nucleus as locus of antipsychotic drug action.

E.5.1.16 Neurotensin

E.5.1.16.1 General Considerations on Neurotensin and Neurotensin Receptors

Neurotensin is a 13-amino-acid peptide originally isolated from calf hypothalamus (Carraway and Leeman 1973). It is secreted by peripheral and neuronal tissues and produces numerous pharmacological effects in animals suggesting **analgesic** (Coguerel et al. 1988; Clineschmidt and McGuffin 1977; Smith et al. 1997), **wound healing** (Brun et al. 2005), **cardiovascular** (Carraway and Leeman 1973; Schaeffer et al. 1998; Seagard et al. 2000), **endocrine** (Rostene and Alexander 1997), **hypothermic** (Bissette et al. 1976; Benmoussa et al. 1996; Tyler-McMahon et al. 2000), and **antipsychotic** (Nemeroff 1986; Sarhan et al. 1997; Feifel et al. 1999; Kinkead et al. 1999; Cusack et al. 2000) actions. Neurotensin is even considered to be an endogenous neuroleptic (Ervin and Nemeroff 1988; Gully et al. 1995). Radke et al. (1998) studied synthesis and efflux of neurotensin in different brain areas after acute and chronic administration of typical and atypical antipsychotic drugs.

Neurotensin affects **gastrointestinal functions**, such as stimulating the growth of various gastrointestinal tissues (Feurle et al. 1987), modulating pre- and post-prandial intestinal motility (Pellissier et al. 1996), inhibiting gastric acid secretion (Zhang et al. 1989a), stimulating responses in rat stomach strips (Quirion et al. 1980), inducing contractile responses in intestinal smooth muscle (Unno et al. 1999), and maintaining gastric mucosal blood flow during cold water restraint (Zhang et al. 1989b; Xing et al. 1998).

Neurotensin acts as a **growth factor** on a variety of normal and cancer cells (Wang et al. 2000).

Like other neuropeptides, neurotensin is synthesized as part of a larger precursor which also contains neuromedin N, a six amino acid neurotensin-like peptide belonging to the gastrin-releasing peptide/bombesin family (see J.3.1.8).

Several peptidic and non-peptidic neurotensin agonists and antagonists have been synthesized and analyzed in pharmacological tests as potential drugs mainly in psychopharmacology (Gully et al. 1995, 1996, 1997; Azzi et al. 1996; Castagliuolo et al. 1996; Chapman and See 1996; Mule et al. 1996; Hong et al. 1997; Johnson et al. 1997; Sarhan et al. 1997; Betancur et al. 1998; Gudasheva et al. 1998; Schaeffer at al 1998; Kitabgi 2002). Furthermore, inhibitors of neurotensin-degrading enzymes were described (Bourdel et al. 1996). Binder et al. (2001) reviewed neurotensin and dopamine interactions.

E.5.1.16.2 Neurotensin Receptor Binding

PURPOSE AND RATIONALE

Neurotensin interacts with two cloned receptors that were originally differentiated on the basis of their affinity to the antihistaminic drug levocabastine (Schotte et al. 1986). The high sensitive, levocabastine-insensitive rat neurotensin receptor (*NTR1*) was cloned first (Tanaka et al. 1990) and shown to mediate a number of peripheral and central neurotensin responses, including the neuroleptic-like effects of the peptide (Labbé-Jullié et al. 1994). The human NTR1 has been cloned from the colonic adenocarcinoma cell line HT29 (Vita et al. 1993) and shown to consist of a 416 amino acid protein that shares 84% homology with rat NTR1. A second human NTR1 receptor differing only in one amino acid has been cloned from substantia nigra by Watson et al. (1993).

The lower-affinity, levocabastine-sensitive neurotensin receptor (*NTR2*) was cloned by Chalon et al. (1996), Mazella et al. (1996) and characterized by Yamada et al. (1998). Studies by Dubuc et al. (1999) indicate that NTR2 mediates neurotensin-induced analgesia.

A third neurotensin receptor (*NTR3*) was cloned from a human brain cDNA library (Mazella et al. 1998; Vincent et al. 1999; Mazella 2001; Mazella and Vincent 2006). It is identical with sortilin, a receptor-like protein, cloned from human brain (Petersen et al. 1997, 1999). The NT3/gp95/sortilin protein is a transmembrane neuropeptide receptor which does not belong to the superfamily of G-protein-coupled receptors.

Gully et al. (1997) described a binding assay for the neurotensin1 receptor.

PROCEDURE

Cell Culture

CHO cells transfected with cDNA of the human neurotensin receptor cloned from HT 29 cells (h-NTR1-CHO cells) are cultured at 37°C in modified Eagles medium without nucleosides, containing 10% fetal calf serum, 4 mM glutamine and 300 µg/ml geneticin (G418), in a humidified incubator under 5% CO_2 in O_2. The colonic adenocarcinoma HT 29 cell line (American Type Culture Collection, Rockville, MD) is cultured under similar conditions in Dulbecco's modified Eagle's medium/F-12 medium supplemented with 10% fetal calf serum, 4 mM glutamine, 200 IU/ml penicillin and 200 mg/ml streptomycin. One week after seeding, confluent monolayer cultures are washed three times with 3 ml PBS and harvested by enzymatic dissociation with trypsin. After dilution with PBS, cells are resuspended in the same culture medium at a density of 5×10^4 cells/ml and are plated into 35-mm-diameter, fibronectin-coated Petri culture dishes.

Membrane Homogenate Preparation and Binding Assay

Whole brains of male Sprague-Dawley rats albino guinea pigs or cell pellets are homogenized in 10 volumes of ice-cold 50 mM Tris-HCl buffer (pH 7.4) for 30 s, using a Polytron homogenizer (setting 5). After 20 min centrifugation at 30,000 *g*, the pellet is washed, centrifuged again under the same conditions, resuspended in a storage buffer containing 50 mM Tris-HCl (pH 7.4), 1 mM EDTA, 0.1% BSA, 40 mg/liter bacitracin, 1 mM 1,10-orthophenanthroline and 5 mM dithiothreitol and stored as aliquots in liquid nitrogen until used.

Aliquots of membranes (10, 50, 300 and 500 µg of protein for h-NTR1-CHO cells, HT 29 cells, rat and guinea pig brain, respectively) are incubated for 20 min at 20°C in the incubation buffer (0.5 ml final volume) containing appropriate concentrations of [^{125}I-Tyr^3]neurotensin (25–100 pM) and unlabeled drugs. After incubation, the assay medium is diluted with 4 ml of ice-cold 50 mM Tris-HCl buffer (pH 7.4) supplemented with 0.1% BSA and 1 mM EDTA, and the mixture is rapidly filtered under reduced vacuum through Whatman GF/B glass fibre filters that have been pretreated with 0.1% polyethyleneimine. The filters are washed under the same conditions three times and radioactivity is measured. Nonspecific binding is determined in the presence of 1 µM unlabeled neurotensin. All experiments are performed in triplicate, and data are expressed as the mean ± SEM of at least three separate determinations.

EVALUATION

The IC_{50} is the value of ligand that inhibits 50% of the specific binding and is determined using an iterative nonlinear regression program (Munson and Rodbard 1980).

MODIFICATIONS OF THE METHOD

Cusack et al. (1995) studied species selectivity of neurotensin analogs at the rat and two human NTR1 receptors.

Lugrin et al. (1991) produced a series of pseudopeptide analogs of neurotensin by systematically replacing peptide bonds in neurotensin with CH_2NH bonds. The compounds were screened *in vitro* for agonist or antagonist activity and for metabolic stability.

Le et al. (1997) cloned the human neurotensin receptor gene and determined the structure.

Labbé-Jullié et al. (1998) attempted to identify residues in the rat NTR1 that are involved in binding of a nonpeptide neurotensin antagonist.

Souazé et al. (1997), Najimi et al. (1998) studied the effects of a neurotensin agonist and showed in human colonic adenocarcinoma HT 29 cells after short incubation an increase, after prolonged exposure a decrease of mRNA levels and in the human neuroblastoma cell line CHP 212 a high affinity neurotensin receptor gene activation.

Ovigne et al. (1998) described a monoclonal antibody specific for the human NTR1.

Nouel et al. (1999) found that both NT2 and NT3 neurotensin receptor subtypes were expressed by cortical glial cells in culture.

Cusack et al. (2000) developed a neurotensin analog, NT34, that can distinguish between rat and human

neurotensin receptors, and exhibits more than a 100-fold difference in binding affinities.

Neuromedin N, a peptide belonging to the gastrin-releasing peptide/bombesin family (see J.3.1.7) shows a high affinity to brain neurotensin receptors and is rapidly inactivated by brain synaptic peptidases (Checler et al. 1990).

E.5.1.17
Genetically Altered Monoamine Transporters

Monoamine transporters, such as the dopamine transporter, 5-hydroxytryptamine transporter and noradrenaline transporter, in the plasma membrane pro-

vide effective control over the intensity of monoamine-mediated signaling by recapturing neurotransmitters released by presynaptic neurons (Gainetdinov et al. 2002). These transporters act also as molecular gateways for neurotoxins (Uhl and Kiayama 1993; Miller et al. 1999; Vincent et al. 1999).

Takahashi et al. (1997) found that heterozygote animals of VMAT2 knockout mice display reduced amphetamine-conditioned reward, enhanced amphetamine locomotion, and enhanced MPTP toxicity.

E.5.1.17.1 Dopamine Transporter Knockout Mice

Many drugs exert their psychotropic action via dopamine transporters (Amara and Kuhar 1993; Giros and Caron 1993).

Dopamine transporter knockout mice, which are generated by disruption of the gene encoding the dopamine transporter by homologous recombination (Giros et al. 1996; Sora et al. 1998), have a distinct biochemical and behavioral phenotype. At the neurochemical level, the homoeostasis of dopamine-containing neurons is altered markedly, including disrupted clearance of dopamine, an elevated extracellular concentration of dopamine and dramatically decreased intraneuronal storage of dopamine (Jones et al. 1998; Gainetdinov et al. 1998; Benoit-Marand et al. 2000).

In response to the elevated dopamine-mediated tone, both presynaptic and postsynaptic dopamine receptors are downregulated (Giros et al. 1996), but although autoreceptor functions are lost (Jones et al. 1999), some postsynaptic responses appear to be enhanced (Gainetdinov et al. 1999a; Fauchey et al. 2000).

Dopamine transporter knockout mice are hyperactive (Gainetdinov et al. 1999b; Spielewoy et al. 2000) and have a much reduced body size (Bossé et al. 1997). These animals have cognitive deficits (Gainetdinov et al. 1999a, 1999b), disrupted sensorimotor gating (Ralph et al. 2001) and sleep dysregulation (Wisor et al. 2001). Dopamine transporter knockout mice appear to provide a model of some aspects of manic behavior (Ralph-Williams et al. 2003).

Abnormalities in skeletal structure (Bliziotes et al. 2000) and altered regulation of gastrointestinal tract motility (Walker et al. 2000) are also observed.

E.5.1.17.2
Serotonin Transporter Knockout Mice

The serotonin transporter has a key role in regulating the intensity of 5-HT-mediated transmission and is the primary target for several antidepressants and psychostimulants (Amara and Kuhar 1993; Bengel et al. 1996).

Disruption of 5-HT uptake in serotonin transporter knockout mice increases the extracellular concentration of 5-HT sixfold and reduces intracellular concentration by 60%–80% (Fabre et al. 2000).

Holmes et al. (2003) found that mice lacking the serotonin transporter exhibit $5HT_{1A}$ receptor-mediated abnormalities in tests for anxiety-like behavior.

Lira et al. (2003) reported altered depression-related behaviors and functional changes in the dorsal raphe nucleus of serotonin-transporter-deficient mice.

Marked desensitization of both presynaptic and postsynaptic 5-HT_{1A} receptors is observed in electrophysiological studies (Gobbi et al. 2001).

There is a significant decrease in 5-HT_{1A} receptor binding sites, mRNA and protein in some, but not all, 5-HT-containing brain areas. Altered hypothermic and neuroendocrine responses to 8-hydroxy-2-(di-n-propylamino)-tetraline (8-OH-DPAT) are also reported (Li et al. 1999).

Thermal hyperalgesia in mice after chronic constrictive sciatic nerve injury was absent in serotonin-transporter-deficient mice (Vogel et al. 2003).

Decreases in 5-HT_{1A} and 5-HT_{1B} receptor coupling are observed, accompanied by disruption of the neurochemical responses to the 5-HT_{1A} receptor agonist ipsapirone and the 5-HT_{1A}/5-HT_{1D} receptor agonist GR127935 (Fabre et al. 2000).

The hyperlocomotor effect of MDMA, but not that of high doses of d-amphetamine, is disrupted in serotonin receptor knockout mice (Bengel et al. 1996).

In double knockout mice that lack the dopamine transporter and have no or one copy of the gene that encodes the serotonin transporter, no place preference for cocaine was observed (Sora et al. 2001).

E.5.1.17.3
Noradrenaline Transporter Knockout Mice

The noradrenaline transporter has a role similar to that of the dopamine transporter and the serotonin transporter with respect to noradrenaline-mediated transmission (Blakely et al. 1994).

Noradrenaline-transporter knockout mice have been generated using homologous recombination (Xu et al. 2000).

Wang et al. (1999) reviewed genetic approaches to studying norepinephrine function using knockout of the mouse norepinephrine transporter gene.

The prolonged synaptic lifetime of noradrenaline in noradrenaline transporter knockout mice results in elevation of the extracellular concentration of noradrenaline and depletion of the intraneuronal stores. In addition, in noradrenaline transporter knockout mice, the α_1-adrenoceptor decreased in the hippocampus (Xu et al. 2000), although α_{2A}-adrenoceptor density did not change in the spinal cord (Bohn et al. 2000).

Noradrenaline-transporter knockout mice have a lower body weight and reduced locomotor responses to novelty. In the tail-suspension test used for screening antidepressant drugs, noradrenaline transporter knockout mice behaved like antidepressant-treated, wild-type animals and no additional effects of the antidepressants desimipramine, paroxetine and bupropion were observed in mutant mice in this test (Xu et al. 2000).

In the tail-flick assay, morphine induced greater analgesia in noradrenaline transporter knockout mice compared with wild-type mice (Bohn et al. 2000).

In synaptosomes from the frontal cortex of noradrenaline transporter knockout mice, cocaine and nisoxetine had no inhibitory effect on the uptake of dopamine, whereas in the nucleus accumbens the effectiveness of cocaine was somewhat reduced. Uptake of dopamine in brain regions that have low levels of dopamine transporter may depend primarily on the noradrenaline transporter (Morón et al. 2002).

Locomotor responses to cocaine and amphetamine are elevated in noradrenaline knockout mice and chronic administration of cocaine did not induce further sensitization. The enhanced responses to psychostimulants in noradrenaline transporter knockout mice correlate with the suppression of presynaptic dopamine function and supersensitivity to postsynaptic D2 and D3 receptors (Xu et al. 2000).

Haller et al. (2002) studied behavioral responses to social stress in noradrenaline transporter knockout mice.

E.5.2 In Vivo Tests

E.5.2.1 Golden Hamster Test

PURPOSE AND RATIONALE

"Innate behavior" of many species including man has been described by Lorenz (1943, 1966). The "Golden-hamster-test" (Ther, Vogel and Werner 1959) uses the innate behavior of this species (*Mesocricetus auratus*) for differentiation between neuroleptic and sedative – hypnotic activity. The aggressive behavior of male golden hamsters is suppressed by neuroleptics in doses which do not impair motor function.

PROCEDURE

Ten to 20 male golden hamsters with an average weight of 60 g are crowded together in Makrolon$^{(R)}$ cages for at least 2 weeks. During this time the animals develop a characteristic fighting behavior. For the test single animals are placed into glass jars of 2 liters. In this situation the hamsters assume a squatting and resting position during the day. If the animals are touched with a stick or a forceps they wake up from their daytime sleep and arouse immediately from the resting position. If one tries to hold the hamster with a blunted forceps, a characteristic behavior is elicited: The hamster throws himself onto his back, tries to bite and to push the forceps away with his legs, and utters angry shrieks. Touching the animals is repeated up to 6 times followed by punching with the forceps. Only animals responding to the stimulus with all three defense reactions (turning, vocalizing, biting) are included into the test.

The test compounds are applied either subcutaneously, intraperitoneally, or orally. Six animals are used for each dose.

EVALUATION

The stimuli are applied every 20 min for 3 h. The number of stimuli until response is recorded. Furthermore, the suppression of the defense reactions (turning, biting and vocalizing) is evaluated. An animal is regarded to be completely "tamed", if all defense reactions are suppressed even after punching with the forceps at least once during the test period.

After each stimulation the "tamed" animal is placed on an inclined board with 20 degree inclination. Normal hamsters and hamsters tamed by neuroleptics are able to support themselves or to climb on the board. Impaired motor function causes sliding down. This experiment is repeated three times after each testing of the defense reactions. An animal's coordination is considered to be disturbed if it falls three times during two tests of the experiments.

For each dose the number of tamed hamsters and the number of animals with impaired motor function is recorded. Using different doses, ED_{50} values can be calculated for the taming effect and for impairment of motor function.

The ED_{50} values of taming were 1.5 mg/kg for chlor-promazine s.c. and 0.2 mg/kg for reserpine s.c. Much higher doses (10 times of chlorpromazine and 5 times of reserpine) did not elicit motor disturbances. On the contrary, while ED_{50} values of 10 mg/kg phenobarbital s.c. and 180 mg/kg meprobamate p.o. for the taming effect were found, these doses already caused severe motor disturbances. The taming dose of diazepam was 10 mg/kg p.o. which already showed some muscle relaxing activity. The term "neuroleptic width" indicates the ratio between the ED_{50} for taming and the ED_{50} for motor disturbances. Only for neuroleptic drugs are ratios found between 1:5 and 1:30.

CRITICAL ASSESSMENT OF THE METHOD

The method has the advantage that neuroleptics can easily be differentiated from sedative and hypnotic drugs. Anxiolytics with pronounced muscle relaxing activity also show no significant differences between taming and impaired motor function. Moreover, the method has the advantage that no training of the animals and no expensive apparatus is needed.

E.5.2.2 Influence on Behavior of the Cotton Rat

PURPOSE AND RATIONALE

The "cotton-rat test" is another attempt to use the innate behavior as described for several animal species by Lorenz (1943, 1966) for the differentiation of psychotropic drugs (Vogel and Ther 1960). The cotton rat (*Sigmodon hispidus*) is a very shy animal which conceals himself at any time. This innate flight reflex is suppressed by centrally active drugs. Simultaneous evaluation of motor function allows the differentiation between neuroleptic and sedative drugs.

PROCEDURE

Cotton rats are bred in cages equipped with a clay cylinder of 20 cm length and 10 cm diameter. This cylinder is used by the animals for hiding, sleeping and breeding. Moreover, the animals which bite easily can be transported from one cage to another just by closing the cylinder on both ends. For the test young animals with a body weight of 40 g are used. Young animals are as shy as old ones but less vicious. Nevertheless, leather gloves have to be used for handling of cotton rats. Normal cages ($25 \times 30 \times 20$ cm) with a wire lid are used. A tunnel of sheet metal (half of a cylinder) 20 cm long and 7 cm high is placed into the cage. The cotton rats hide immediately in this tunnel. If the tunnel is lifted and placed on another site of the cage, the cotton rats immediately hide again.

Three rats are placed in one cage and tested for their behavior. Selective shaving of the fur enables the observer to recognize each animal. If the rats behave as described, they are then treated with the test compound subcutaneously or orally. At least 6 animals divided in two cages are used for each dose of test compound or standard. Fifteen min after application of the drug the test period of three h is started. The tunnel is lifted and placed to another site. If the animals do not show the immediate flight reflex an airstream of short duration is blown through the wire lid. If the animal still does not respond with the flight reflex it is considered to be positively influenced. Afterwards, the animal is placed on an inclined board with 35 degree of inclination and tested for disturbance of motor coordination. A normal animal is able to climb upwards. If coordination is disturbed the rat slides down.

EVALUATION

The test procedure is repeated every 15 min over a period of 3 h. The animals which show at least one suppression of the flight reflex during the test period are counted as well as those who slide down on the inclined board. Using different doses ED_{50} values are calculated for both parameters. The ratio between these two ED_{50} values is regarded as "neuroleptic width" which is 1:20 for chlorpromazine and 1:30 for reserpine whereas ratios of 1:2 for phenobarbital and 1:1.5 for meprobamate indicate the absence of neuroleptic activity.

CRITICAL ASSESSMENT OF THE METHOD

The method allows the differentiation of drugs with neuroleptic activity against other centrally active drugs. No training of the animals and no expensive equipment are necessary.

E.5.2.3 Artificial Hibernation in Rats

PURPOSE AND RATIONALE

Giaja (1938, 1940, 1953, 1954) studied the effects of reduced oxygen tension and cold environment on rats. The animals were placed in hermetically closed glass vessels which were submerged in ice-water. Due to the respiratory activity, the oxygen tension diminishes and the carbon dioxide content increases. Under the influence of cooling and of hypoxic hypercapnia, the rectal temperature falls to 15°C and the animal is completely anesthetized and immobilized. The rat can survive in this poikilothermic state for more than twenty hours. Complete recovery occurs after warming up. This kind of artificial hibernation was augmented by chlorpromazine (Courvoisier et al. 1953; Giaja and Markovic-Giaja 1954). Vogel (1959), Ther et al. (1959, 1963) used these observations for evaluation of neuroleptics and opioid analgesics.

PROCEDURE

Male Wistar rats weighing 100–150 g are deprived of food with free access to tap water overnight. The test compounds are injected subcutaneously 15 min prior to the start of the experiment. First, the rats are placed in ice-cold water to which surfactant is added in order to remove the air from the fur for 2 min. Then, the animals are placed into hermetically closed glass vessels of 750 ml volume which are placed into a refrigerator at 2°C temperature. During the following hour, the vessels are opened every 10 min for exactly 10 s allowing some exchange of air and reducing the carbon dioxide accumulation. At each time, animals are removed from the glass vessel and observed for signs of artificial hibernation which are not shown by control animals under these conditions. Treated animals, lying on the side, are placed on the back and further examined. An animal is considered positive, when it remains on the back, even if the extremities are stretched out. In this state, cardiac and respiration frequency are reduced and the rectal temperature has fallen to 12–15°C. The rigor of the musculature allows only slow movements of the extremities. The animals recover completely within a few hours if they are brought to their home cages at room temperature. Artificial hibernation is induced dose-dependent by neuroleptics of the phenothiazine type and by some opioid analgesics like meperidine and methadone. In contrast, morphine shows only slight activity.

EVALUATION

Various doses are applied to groups of 10 animals. Percentage of positive animals is calculated for each group and ED_{50} values with confidence limits are estimated according to Litchfield and Wilcoxon.

E.5.2.4 Catalepsy in Rodents

PURPOSE AND RATIONALE

Catalepsy in rats is defined as a failure to correct an externally imposed, unusual posture over a prolonged period of time. Neuroleptics which have an inhibitory action on the nigrostriatal dopamine system induce catalepsy (Costall and Naylor 1974; Chermat and Simon 1975; Sanberg 1980) while neuroleptics with little or no nigrostriatal blockade produce relatively little or no cataleptic behavior (Honma and Fukushima 1976). Furthermore, cataleptic symptoms in rodents have been compared to the Parkinson-like extrapyramidal side effects seen clinically with administration of antipsychotic drugs (Duvoisin 1976).

PROCEDURE

Groups of 6 male Sprague-Dawley or Wistar rats with a body weight between 120 and 250 g are used. They are dosed intraperitoneally with the test drug or the standard. Then, they are placed individually into translucent plastic boxes with a wooden dowel mounted horizontally 10 cm from the floor and 4 cm from one end of the box. The floor of the box is covered with approximately 2 cm of bedding material. White noise is presented during the test. The animals are allowed to adapt to the box for 2 min. Then, each animal is grasped gently around the shoulders and under the forepaws and placed carefully on the dowel. The amount of time spent with at least one forepaw on the bar is determined. When the animal removes its paws, the time is recorded and the rat is repositioned on the bar. Three trials are conducted for each animal at 30, 60, 120 and 360 min.

EVALUATION

An animal is considered to be cataleptic if it remains on the bar for 60 s. Percentage of cataleptic animals is calculated. For dose-response curves, the test is repeated with various doses and more animals. ED_{50} values can be calculated. A dose of 1 mg/kg i.p. of haloperidol was found to be effective.

CRITICAL ASSESSMENT OF THE METHOD

The phenomenon of catalepsy can be used for measuring the efficacy and the potential side effects of neuroleptics.

MODIFICATIONS OF THE METHOD

Catalepsy induced by neuroleptic drugs can also be measured by the **PAW test**, which measures increase in forelimb and hindlimb retraction time in rats (Ellenbroek et al. 1987, 2001; Ellenbroek and Cools 1988, 2000; Prinssen et al. 1994, 1995).

The test is performed 30 min after intraperitoneal injection of test drug. Male Wistar rats weighing 220–300 g are placed on a Perspex platform (30 × 30 cm with a height of 20 cm) containing two holes for the forelimbs (40 mm) and two for the hindlimbs (50 mm), and a slit for the tail. The distance between the right and left forelimb holes is 15 mm, and the distance between forelimb and hindlimb holes is 55 mm. The rat is held behind the forelimbs, and the hindlimbs are gently placed in the holes. The forelimb retraction time and the hindlimb retraction time are defined as the time the animal needs to withdraw one forelimb and one hindlimb, respectively. The average forelimb retraction time and hindlimb retraction time (the mean of three measurements) is calculated for each rat.

Extrapyramidal syndromes after treatment with typical and atypical neuroleptics were measured in nonhuman primates (Cebus monkeys) by Casey (1989, 1991, 1993), Gerlach and Casey (1990).

E.5.2.5 Pole Climb Avoidance in Rats

PURPOSE AND RATIONALE

The pole-climb avoidance paradigm is an avoidance-escape procedure used to separate neuroleptics from sedatives and anxiolytics. Whereas sedative compounds suppress both avoidance and escape responding at approximately the same doses, neuroleptic drugs reduce avoidance responding at lower doses than those affecting escape responding (Cook and Catania 1964).

PROCEDURE

Male rats of the Long-Evans strain with a starting body weight of 250 g are used. The training and testing of the rats is conducted in a $25 \times 25 \times 40$ cm chamber that is enclosed in a dimly lit, sound-attenuating box. Scrambled shock is delivered to the grid floor of the chamber. A 2.8-kHz speaker and a 28-V light are situated on top of the chamber. A smooth stainless-steel pole, 2.5 cm in diameter, is suspended by a counterbalance weight through a hole in the upper center of the chamber. A microswitch is activated when the pole is pulled down 3 mm by a weight greater than 200 g. A response is recorded when a rat jumps on the pole and activates the microswitch. The rat can not hold the pole down while standing on the grid floor because of the counterbalance tension and can not remain on the pole any length of time because of its smooth surface. The activation of the light and the speaker together are used as the conditioning stimulus. The conditioning stimulus is presented alone for 4 s and then is coincident with the unconditioned stimulus, a scrambled shock delivered to the grid floor, for 26 s. The shock current is maintained at 1.5 mA. A pole climb response during the conditioned stimulus period terminates the conditioned stimulus and the subsequent conditioned and unconditioned stimuli. This is considered an avoidance response. A response during the time when both the conditioned and unconditioned stimuli are present terminates both stimuli and is considered an escape response. Test sessions consist of 25 trials or 60 min, whichever comes first. There is a minimum intertrial interval of 90 s. Any time remaining in the 30 s allotted to make the pole climb is added to the 90 s intertrial interval. Responses during this time have no scheduled consequences; however, rats having greater than 10 intertrial interval responses should not be used in the experiment. Before testing experimental compounds, rats are required to make at least 80% avoidance responses without any escape failures.

EVALUATION

Data are expressed in terms of the number of avoidance and escape failures relative to the respective vehicle control data. ED_{50} values can be calculated using different doses.

E.5.2.6 Foot-Shock Induced Aggression

PURPOSE AND RATIONALE

The test as described by Tedeschi et al. (1959) using mice which fight after foot-shock induced stimulation

is useful to detect neuroleptics but also shows positive effects with anxiolytics and other centrally effective drugs. The method has been used by several authors to test drugs with neuroleptic activity. The test is described in Sect. E.2.3.1.

E.5.2.7 Brain Self Stimulation

PURPOSE AND RATIONALE

In several species, electrical stimulation of selected brain loci produces effects which are positively reinforcing and pleasurable (Olds and Milner 1954; Olds 1961, 1972). Most of the data available have been obtained from experiments using rats with electrodes chronically implanted in the median forebrain bundle at the level of hypothalamus. Minute electrical pulses sustain a variety of operant behaviors such as lever pressing. Neuroleptics have been shown to be potent blockers of self stimulation (Broekkamp and Van Rossum 1975; Koob et al. 1978; Gallistel and Freyd 1987). Conversely, compounds that facilitate catecholaminergic transmission such as d-amphetamine and methylphenidate, will increase responding for such stimulation.

PROCEDURE

Male Wistar rats (350–400 g) are anesthetized with 50 mg/kg pentobarbital i.p. and their heads placed on a level plane in a Kopf stereotactic instrument. A midline incision is made in the scalp and the skin held out of the way by muscle retractors. A small hole is drilled in the scull with a dental burr at the point indicated by the stereotactic instrument for the structure it is desired to stimulate. Using bregma as a reference point, the electrode (Plastic Products MS303/1) is aimed at the medium forebrain bundle according to the atlas of Paxinos and Watson (1986), using the coordinates of AP = –0.8 mm, Lat = +2.8 mm, and DV = –7.2 mm below dura. The assembly is then permanently affixed to the scull using stainless steel screws and bone cement.

After a minimum of 10 days for recovery, the animals are trained to bar press for electrical stimulation on a continuous reinforcement schedule in a standard operant box outfitted with a single lever. The reward stimulus is a train of biphasic square-wave pulses generated by a Haer stimulator (Pulsar 4i). The parameters are set at a pulse duration of 0.5 ms with 2.5 ms between each pulse pair. The train of pulses may vary between 16 and 30/s, and the intensity of the pulses that are delivered range from 0.1 to 0.5 mA using the lowest setting that will sustain maximal responding. After consistent baseline responding is obtained for 5 consecutive 30 min sessions, the animals are ready for testing with standard agents. Compounds are administered 60 min prior to testing. All data are collected on both cumulative recorders and counters.

EVALUATION

The number of drug responses are compared to the number of responses made during each animal's 30 min control session on the preceding day, which is considered to be equal to 100%. Testing various doses, ED_{50} values with 95% confidence limits can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

Since there is sufficient evidence that self-stimulation behavior is maintained by catecholamines the method gives indirectly insight into the catecholaminergic facilitating or blocking properties of a compound. Active neuroleptic drugs inhibit the self-stimulation behavior in very small doses. The relative potency observed in this test of clinically efficacious drugs parallels their potency in the treatment of schizophrenia.

MODIFICATIONS OF THE METHOD

Reinforcing brain stimulation by electrodes placed in the medial forebrain bundle of rats is decreased after lesion of the internal capsule in the region of the diencephalic-telencephalic border. This decrement in rewarding processing can be reversed by antidepressant drugs (Cornfeldt et al. 1982).

Depoortere et al. (1996) used electrical self stimulation of the ventral tegmental area to study the behavioral effects of a putative dopamine D_3 agonist in the rat.

Anderson et al. (1995) examined the interaction of aversive and rewarding stimuli in self stimulating rats in terms of duration and direction. The rats were implanted with two moveable electrodes, one in a region supporting self-stimulation (the ventral tegmental area) and another in a region supporting escape (the nucleus reticularis gigantocellularis).

Kokkinidis et al. (1986) used amphetamine withdrawal for a behavioral evaluation. Mice implanted with stimulating electrodes in the lateral hypothalamus demonstrated stable and reliable rates of self-stimulation responding. After exposure to a chronic sched-

ule of amphetamine treatment response rates were severely depressed.

Post-amphetamine depression of self-stimulation from the substantia nigra can be reversed by cyclic antidepressants (Kokkinidis et al. 1980).

Moreau et al. (1992) reported that antidepressant treatment prevents chronic unpredictable mild stress-induced anhedonia as assessed by ventral tegmentum self-stimulation in rats.

E.5.2.8 Prepulse Inhibition of Startle Response

PURPOSE AND RATIONALE

Prepulse inhibition is a model of sensorimotor gating which can be assessed in both animals and humans using the startle reflex response. When a fixed startle eliciting stimulus (i. e., the pulse) is preceded by 30–500 ms by a weak, non-startle-eliciting stimulus (i. e., the prepulse), the magnitude of the startle response is significantly reduced to the pulse alone. Schizophrenic patients have decreased prepulse inhibition relative to normal control subjects, and this is thought to reflect an impairment in their ability to filter irrelevant sensory stimuli (Braff and Geyer 1990; Geyer 1998). Similar reductions in prepulse inhibition are produced in rats by administration of psychotomimetic drugs such as the dopamine agonists amphetamine and apomorphine or the non-competitive NMDA antagonists phencyclidine and dizocilpine (MK801) (Mansbach and Geyer 1989; Swerlow et al. 1998; Geyer et al. 2001; Rowley et al. 2001; Weiss and Feldon 2001; Pouzet et al. 2002). Most antipsychotics tested are able to antagonize prepulse inhibition disruption produced by dopamine antagonists, whereas prepulse inhibition disruption by NMDA antagonists may be selectively sensitive to antipsychotics with atypical features (Bakshi and Geyer 1995; Bubenikova

et al. 2005; Fox et al. 2005). Haloperidol failed to block the effects of phencyclidine and dizocilpine prepulse inhibition of startle (Keith et al. 1991).

Feifel et al. (Feifel and Reza 1999; Feifel et al. 1999a, 1999b) tested the effects of a neurotensin agonist on prepulse inhibition of startle in rats.

PROCEDURE

Male Sprague Dawley rats were treated with various doses of test compound or saline s.c. Immediately afterwards, rats receive a second s.c. injection consisting of 2 mg/kg d-amphetamine, or 0.5 mg/kg apomorphine, or 0.1 mg/kg dizocilpine or saline. Then, 10 min later, animals were placed in special startle chambers (SR-LAB, San Diego Instruments, San Diego, Calif., USA). Startle chambers consist of a Plexiglas cylinder 8.2 cm in diameter resting on a 12.5 × 25.5 cm Plexiglas frame within a ventilated enclosure housed in a sound-attenuated room exposed to 70-dB background noise. After a 5-min acclimation period, acoustic stimuli were presented via a speaker mounted 24 cm above the animal. Acoustic stimuli consisted of a 120-dB pulse by itself (pulse alone) or a 120-dB pulse preceded by 100 ms by prepulses 3, 5, and 10 dB above background noise. There was an average of 15 s between stimuli. A piezoelectric accelerometer mounted below the Plexiglas frame detected and transduced the motion within the cylinder. Startle amplitude was defined as the degree of motion detected by this accelerometer. Each rat was tested on four separate occasions separated by 7 non-test days. On each test day, the dose of test compound was kept constant, but the specific psychotomimetic agent was alternated across test days in a counterbalanced fashion.

EVALUATION

Prepulse inhibition was calculated as the percentage of the pulse-alone startle amplitude using the following formula: [1 – (startle amplitude after prepulse–pulse pair/startle amplitude after pulse only)] × 100. Analysis of data was then carried out using a three-factor repeated-measures analysis of variance (ANOVA). Significant factor results from the ANOVA were followed up with separate one-way ANOVAs for each psychotomimetic agent and then, when indicated, with individual group mean comparisons using post hoc *t* tests for multiple comparisons using the Bonferroni method.

MODIFICATIONS OF THE METHOD

Sipes and Geyer (1995) studied the disruption of prepulse inhibition of the startle response in the rat by DOI [(2,5-dimethoxy-4-iodophenyl)-2-aminopropane hydrochloride], which is mediated by 5-HT_{2A} receptors. The authors suggested that studies of the serotonergic substrates of prepulse inhibition may provide a model of the possible serotonergic role in the sensorimotor gating abnormalities in patients with schizophrenia and with obsessive compulsive disorder.

Ellenbroeck et al. (1998) described the effects of an early stressful life event on sensorimotor gating in adult rats.

Andersen and Pouzet (2001) compared the effects of acute versus chronic treatment with typical or atypical antipsychotics on d-amphetamine-induced sensorimotor gating deficits in rats.

Heidbreder et al. (2000) used the prepulse inhibition of acoustic startle for behavioral, neurochemical and endocrinological characterization of the early social isolation syndrome.

Krebs-Thomson et al. (2001) reported that postweanling handling attenuates isolation-rearing disruption of prepulse inhibition in rats.

Weiss et al. (2001) studied the dissociation between the effects of pre-weaning and/or post-weaning social isolation on prepulse inhibition and latent inhibition in adult Sprague Dawley rats.

E.5.2.9 N40 Sensory Gating

PURPOSE AND RATIONALE

The N40 auditory-evoked potential has been used to develop an animal model for the study of sensory gating mechanisms (Boutros et al. 1997a; Boutros and Kwan 1998). The method has been applied to evaluation of psychotropic compounds (Adler et al. 1986; Boutros et al. 1994, 1997b). Bickford-Wimer et al. (1990) localized one possible source of the N40 waveform to the CA3 region of the hippocampus.

Fox et al. (2005) used the N40 sensory gating model in mice for evaluation of a potential antipsychotic drug.

PROCEDURE

Male DBA/2 mice were stereotaxically implanted with tripolar stainless steel wire head stages for EEG recordings in the CA3 region of the hippocampus. The mice were first anesthetized with a solution of 2.8% ketamine, 0.28% xylazine, and 0.05% acepromazine. Three access holes for the electrodes were made at AP –1.8 mm from the bregma, and in a plane perpendicular to the suture, ML 0.6 (cortical electrode), 1.6 (reference electrode), and 2.6 mm electrode directed at the hippocampus). The depth of the hippocampal electrode tip was DV 1.65–1.70 mm below the surface of the cortex. The depths of the cortical and reference electrodes were DV 0.5 mm from the surface of the skull, resulting in contact, but not penetration of the cortical tissue. The tripolar electrode was lowered into position with a stereotaxic electrode holder and affixed using cyanoacrylic gel and dental acrylic and two anchor screws. Mice were allowed to recover for 3 days before commencement of the experiments. Awake mice were recorded in acoustically isolated chambers. Flexible tethers and electrical swivels were used to convey EEG signals to differential AC EEG amplifiers and allowed the mice free movement within the chambers. The EEG was amplified 1000 × with

a 50- to 60-Hz notch filter engaged, and high- and low-pass filters were set at 1 and 100 Hz, respectively. Hippocampal auditory-evoked potentials were generated by presentation of 60 sets of 3 kHz paired tone bursts from a speaker within the recording chamber at a distance of 15–20 cm to the mouse. The first tone of the pair is referred to as the conditioning stimulus, and the second is referred to as the test stimulus. The duration of both the condition and test stimuli was 5 ms, with 0.5 s between the stimuli and 20 s between pairs. Data acquisition software recorded EEG signals 100 ms before and for 899 ms after the initial conditioning stimulus. The software averaged the 60 paired responses into one composite-evoked response. Various doses of test drug were administered i.p. 20–30 min before mice were placed into the recording chambers and initiation of auditory-evoked potential recording. Recording of paired auditory potentials continued for two 20-min sessions, each comprised of 60 paired stimuli. Each mouse was administered every treatment dose and a control vehicle treatment in a balanced order on separate days with at least 48 h between treatments. This within-subject design allowed each mouse to serve as its own control. The hippocampal response to auditory stimuli was identified as the highest positive peak deflection in the ongoing EEG at a latency of 10–20 ms after the stimulus (P20), followed by the lowest negative peak deflection in the ongoing EEG at 20–45 ms after the stimulus (N40). The difference in amplitude between P20 and N40 was defined as the N40 amplitude in microvolts.

EVALUATION

N40 amplitudes were determined for both the averaged conditioning and test-evoked potentials, and a ratio was derived between the two responses by dividing the test amplitude by the conditioning amplitude (T/C ratio).

MODIFICATIONS OF THE METHOD

Flack et al. (1996) studied sensory gating in a computer model of the CA3 neural network of the hippocampus.

Stevens et al. (1998) investigated changes in auditory information processing after kainic acid lesions in adult rats used as a model of schizophrenia.

E.5.2.10 Latent Inhibition

PURPOSE AND RATIONALE

Latent inhibition has been recommended as an animal model of schizophrenia (Feldon and Weiner 1992; Swerdlow et al. 1996; Vaitl and Lipp 1997; Moser et al. 2000; Bender et al. 2001). Latent inhibition refers to the retarded acquisition of a conditioned response that occurs if the subject being tested is first pre-exposed to the to-be-conditioned stimulus without the paired unconditioned stimulus. Because the "irrelevance" of the to-be-conditioned stimulus is established during non-contingent pre-exposure, the slowed acquisition of the conditioned stimulus–unconditioned stimulus association is thought to reflect the process of overcoming this learned irrelevance. Latent inhibition has been reported to be diminished in acutely hospitalized schizophrenia patients. Several authors used the latent inhibition model in rats to test psychotropic compounds (Solomon et al. 1981; Feldon and Weiner 1991; Moran and Moser 1992; De la Casa et al. 1993; Lacroix et al. 2000; Alves et al. 2002). Trimble et al. (2002) tested the effects of selective D_1 antagonists on latent inhibition in the rat.

PROCEDURE

Animals

Male Sprague Dawley rats weighing 300–400g were housed two to a cage under a 12-h reversed cycle lighting with food and water ad libitum. All experimental manipulations were carried out in the dark phase of the dark/light cycle.

Apparatus

Modified metal Skinner boxes (24.5 × 24.5 × 21 cm measured from a raised grid floor) were located in darkened, sound-insulated, ventilated outer boxes. A removable water bottle was located on one side of each Skinner box through a hole of 1.0 cm diameter, positioned 2 cm above the grid floor. When water was not required, the water bottle was removed. Licks at the spout of each water bottle were recorded using a lickometer (model 453, Campden Instruments, London, UK). The pre-exposed stimulus was a flashing light (10 s duration with three light flashes per second) situated in the middle of the roof of each Skinner box. The grid floor consisted of steel bars (0.5 cm in diameter) spaced 1 cm apart. Shock generators with scramblers were calibrated to produce 0.5-mA shocks via the grid floor.

Procedure

Rats were randomly assigned to experimental groups and were allocated to a particular Skinner box. They had experience of only that box for the duration of the experiment. After adaptation to the housing conditions for 1 week, rats were placed immediately on a 23-h water deprivation schedule that continued until the end of the experiments. Food remained freely available.

Baseline days (days 15–19)

After 7 days on the water deprivation period, 5 days of pre-training commenced. Each rat was placed in a Skinner box for 15 min. The water bottle was present and each rat could drink freely. After the baseline session was over, each rat was returned to its home cage and allowed access to water for 45 min.

Pre-exposure (day 20)

With the water bottle removed, each rat was placed in a Skinner box. Rats received ten stimulus (flashing house-light) presentations of 10 s duration (three light flashes per second) with a fixed stimulus interval of 50 s. Afterwards the rats were returned to their home cages and allowed access to water for 1 h.

Conditioning (day 21)

With the water bottle removed, each rat was placed in a Skinner box. Then, 5 min later, each rat received the first of two light foot-shock pairings. House-light parameters were identical to those of the pre-exposure period. The house-light was immediately followed by the footshock (0.5 mA, 1 s). The second light-shock pairing was given 5 min later. After the conditioning period had terminated, animals were returned to their home cages and allowed access to water for 1 h.

Re-baseline day (day 22)

With the water bottle present, each rat was placed in a Skinner box and allowed to drink as in the baseline sessions.

Test day (day 23)

With the water bottle present, each rat was placed in a Skinner box and allowed to drink. When each rat completed 75 licks, the flashing house-light was presented and continued until 5 min had elapsed from stimulus onset. Time bins of 30 s duration commenced from the time of stimulus presentation and the number of licks made by each rat within every time bin was recorded. This measure allowed the pattern of drinking over the course of stimulus presentation to be shown. The amount of suppression of licking for each rat was assessed using a suppression ratio calculated from the time (in seconds) to complete licks 51–75 (pre-stimulus) divided by the time (in seconds) to complete licks 51–100 (pre-stimulus + stimulus on). A suppression ratio of 0.01 indicates total suppression of licking (no latent inhibition), while a ratio of 0.5 indicates no change in licking rate from the pre-stimulus period to the stimulus-on period (latent inhibition).

DRUG Treatment

Test drugs or vehicle were administered by subcutaneous injection in various doses 30 min prior to pre-exposure and conditioning.

EVALUATION

Times to complete licks and the suppression ratios were analyzed independently using a 2 × 6 ANOVA with main factors of pre-exposure and drugs.

MODIFICATIONS OF THE METHOD

Lehmann et al. (1998) studied the long-term effects of repeated maternal separation on three different latent inhibition paradigms.

Pouzet et al. (2004) reported that latent inhibition is spared by NMDA-induced ventral hippocampal lesions, but is attenuated following local activation of the ventral hippocampus by intracerebral NMDA infusion.

Bethus et al. (2005) examined the effects of prenatal stress and gender in latent inhibition.

E.5.3 Tests Based on the Mechanism of Action

E.5.3.1 Amphetamine Group Toxicity

PURPOSE AND RATIONALE

It is well known that aggregation of mice in small cages greatly enhances the toxicity of amphetamine. The death rate can be reduced by pretreatment with neuroleptics. This phenomenon is generally accepted as an indicator of neuroleptic activity. The increased toxicity results from increased behavioral activation due to aggregation inducing an increase of circulating catecholamines. The mechanism can be understood by the fact that amphetamine is an indirectly acting sympathomimetic amine that exerts its effects primarily by releasing norepinephrine from storage sites in the sympathetic nerves. After administration of high doses of amphetamine, mice exhibit an elevated motor activity which is highly increased by aggregation. This increased behavioral activation is followed by death within 24 h in 80–100% of control animals. Neuroleptics reduce this death rate. In contrast, non-neuroleptic sympatholytics and psychosedative agents like the barbiturates do not produce a dose-related protection. Moreover, anxiolytic agents like benzodiazepines are also found to be ineffective in the prevention of amphetamine group toxicity.

PROCEDURE

Ten male mice of the NMRI-strain are used for each group. They are dosed with the test compound or the standard either orally or intraperitoneally and all placed in glass jars of 18 cm diameter. Untreated animals serve as controls. The test has to be performed at room temperature of 24°C. Thirty min after i.p. or 1 h after oral administration the mice receive 20 mg/kg d-amphetamine subcutaneously. The mortality is assessed 1, 4 and 24 h after dosing.

EVALUATION

The mortality of amphetamine only treated animals is at least 80%. If less than 80% die due to low ambient temperature the test has to be repeated. The estimation of ED_{50} values for protection and their confidence limits are calculated by probit analysis of the data using the number of dosed vs. the number of surviving animals. Doses of 10 mg/kg chlorpromazine p.o. and 1 mg/kg haloperidol have been found to be effective.

CRITICAL ASSESSMENT OF THE METHOD

The amphetamine group toxicity test has been used by many investigators and has been found to be a reliable method for detecting neuroleptic activity.

E.5.3.2 Inhibition of Amphetamine Stereotypy in Rats

PURPOSE AND RATIONALE

Amphetamine is an indirect acting sympathomimetic agent which releases catecholamines from its neuronal storage pools. In rats the drug induces a characteristic stereotypic behavior. This behavior can be prevented by neuroleptic agents.

PROCEDURE

Groups of 6 Wistar rats with a body weight between 120 and 200 g are used. They are injected simultaneously with d-amphetamine (10 mg/kg s.c.) and the test compound intraperitoneally and than placed individually in stainless-steel cages (40 × 20 × 18 cm). The control groups receive d-amphetamine and vehicle. Stereotypic behavior is characterized by continuous sniffing, licking or chewing and compulsive gnawing. The animals are observed 60 min after drug administration. An animal is considered to be protected, if the stereotypic behavior is reduced or abolished.

EVALUATION

The percent effectiveness of a drug is determined by the number of animals protected in each group. A dose response is obtained by using 10 animals per group at various doses. ED_{50} values can be calculated. The standard neuroleptic drugs have the following ED_{50} values: chlorpromazine 1.75 mg/kg i.p and haloperidol 0.2 mg/kg i.p.

CRITICAL ASSESSMENT OF THE METHOD

Inhibition of amphetamine-induced stereotypies in rats can be regarded as a simple method to detect neuroleptic activity. However, this may reflect the effects in the corpus striatum which are thought to be responsible for the Parkinsonism-like side effects of neuroleptics.

MODIFICATIONS OF THE METHOD

Ljungberg and Ungerstedt (1985) described a rapid and simple behavioral screening method for simultaneous assessment of limbic and striatal blocking effects of neuroleptic drugs. A low dose of 2 mg/kg d-amphetamine i.p. induces both increased locomotion, thought to reflect an increased dopamine transmission in the nucleus accumbens, and weak stereotypies, thought to reflect an increased dopamine transmission in the neostriatum. The behavior is measured in a combined open field apparatus with holes on the bottom to measure nose-pocking and registration of time spent in the corners. Neuroleptics with less propensity to induce unwanted extrapyramidal side effects can be differentiated from classical drugs with more extrapyramidal adverse reactions.

Segal and Kuczenski (1997) described an escalating dose "binge" model of amphetamine psychosis. Rats were exposed to escalating doses of amphetamine (1.0–8.0 mg/kg) before multiple daily injections of relatively high doses of the drug (8 mg/kg every 2 h × 4 injections).

Atkins et al. (2001) described stereotypic behaviors in mice selectively bred for high and low methamphetamine-induced stereotypic chewing.

Machiyama (1992) recommended chronic methylamphetamine intoxication in **Japanese monkeys** (*Macaca fuscata*) as a model of schizophrenia in animals.

Ellenbroek (1991) described the ethological analysis of **Java monkeys** (*Macaca fascicularis*) in a social setting as an animal model for schizophrenia.

Sams-Dodd and Newman (1997) described the effects of the administration regime on the psychotomimetic properties of d-amphetamine in the Squirrel monkey (*Saimiri sciureus*).

E.5.3.3 Inhibition of Apomorphine Climbing in Mice

PURPOSE AND RATIONALE

Administration of apomorphine to mice results in a peculiar climbing behavior characterized initially by rearing and then full-climbing activity, predominantly mediated by the mesolimbic dopamine system (Costall et al. 1978). The ability of a drug to antagonize apomorphine-induced climbing behavior in the mouse has been correlated with neuroleptic potential (Protais et al. 1976; Costall et al. 1978).

PROCEDURE

Groups of 10 male mice (20–22 g) are treated i.p. or orally with the test substance or the vehicle and placed individually in wire-mesh stick cages. Thirty min afterwards, they are injected s.c. with 3 mg/kg apomorphine. Ten, 20 and 30 min after apomorphine administration, they are observed for climbing behavior and scored as follows:

0 = four paws on the floor,
1 = fore feet holding the vertical bars,
2 = four feet holding the bars.

EVALUATION

The average values of the drug-treated animals are compared with those of the controls, the decrease is expressed as percent. The ED_{50}-values and confidence limits are calculated by probit analysis. Three dose levels are used for each compound and the standard with a minimum of 10 animals per dose level.

CRITICAL ASSESSMENT OF THE TEST

Similar to the enhancement of compulsive gnawing of mice after apomorphine by antidepressant drugs, the suppression of climbing behavior of mice after apomorphine can be used for testing neuroleptic drugs. The test has been modified by various authors.

In contrast to other strains of mice, apomorphine climbing is not induced in DBA2 mice unless subchronic manipulations of brain dopamine transmission are performed (Duterte-Boucher and Costentin 1989).

E.5.3.4 Inhibition of Apomorphine Stereotypy in Rats

PURPOSE AND RATIONALE

Apomorphine induces a stereotyped behavior in rats, characterized by licking, sniffing and gnawing in a repetitive, compulsive manner, which is an indication of striatal dopaminergic stimulation (Anden et al. 1967; Ernst 1967; Costall and Naylor 1973). Compounds which prevent apomorphine-induced stereotypy antagonize dopamine receptors in the nigrostriatal system (Ljungberg and Ungerstedt 1978; Tarsy

and Baldessarini 1974). Furthermore, antagonism of this behavior is predictive of propensity for the development of extrapyramidal side effects and tardive dyskinesias (Klawans and Rubivits 1972; Tarsy and Baldessarini 1974; Christensen et al. 1976; Clow et al. 1980).

PROCEDURE

For screening, groups of 6 male Wistar rats with a body weight between 120 and 200 g are used. The test drug or the standard are administered i.p. 60 min prior apomorphine dosage. Apomorphine HCl is injected s.c. at a dose of 1.5 mg/kg. The animals are placed in individual plastic cages. A 10 s observation period is used to measure the presence of stereotypic activity such as sniffing, licking and chewing 10 min after apomorphine administration. An animal is considered protected if this behavior is reduced or abolished.

EVALUATION

The percent effectiveness of a drug is determined by the number of animals protected in each group. With a group size of 10 animals dose response curves are obtained and ED_{50} values calculated. ED_{50} values were found to be 0.2 mg/kg s.c. for haloperidol and 5.0 mg/kg for chlorpromazine, whereas clozapine was ineffective even at high doses.

MODIFICATIONS OF THE METHODS

Puech et al. (1978) studied the effects of several neuroleptic drugs on hyperactivity induced by a low dose of apomorphine in mice.

Apomorphine induces stereotypic behavior in a variety of species including pigeons. The symptoms in pigeons are manifested as pecking against the wall of the cage or on the floor. Aksas et al. (1984) described a method registering the pecking after apomorphine by a microphone, amplification through a pulse preamplifier and registration with a polygraph. The effect of apomorphine was dose-dependent decreased by yohimbine and neuroleptics.

Stereotyped behavior in guinea pigs induced by apomorphine or amphetamine consisting in continuous gnawing and sniffing of the cage floor was described by Klawans and Rubovits (1972) and used as an experimental model of tardive dyskinesia.

E.5.3.5 Yawning/Penile Erection Syndrome in Rats

PURPOSE AND RATIONALE

Yawning is a phylogenetically old, stereotyped event that occurs alone or associated with stretching and/or penile erection in humans and in animals from reptiles to birds and mammals under different conditions (Argiolas and Melis 1998). The yawning-penile erection syndrome can be induced in rats by apomorphine and other dopamine autoreceptor stimulants (Ståhle

and Ungerstedt 1983; Gower et al. 1984) and can be antagonized by haloperidol and other dopamine antagonists. Antagonism against this syndrome can be regarded as indication of antipsychotic activity (Furukawa 1996).

Besides the **dopaminergic** system in this behavior (Mogilnicka and Klimek 1977; Baraldi et al. 1979; Benassi-Benelli et al. 1979; Nickolson and Berendsen 1980; Gower et al. 1984, 1986; Dourish et al. 1985; Doherty and Wisler 1994; Kurashima et al. 1995; Bristow et al. 1996; Fujikawa et al. 1996a; Asencio et al. 1999) also the **serotoninergic** (Baraldi et al. 1977; Berendsen and Broekkamp 1987; Berendsen et al. 1990; Protais et al. 1995; Millan et al. 1997), the **cholinergic** (Yamada and Furukawa 1980; Fujikawa et al. 1996b), the **GABAergic** (Zarrindast et al. 1995), the **NO system** (Melis et al. 1995, 1996, 1997a, b), and **steroid** as well as **peptide hormones** (Bertolini and Baldari 1975; Bertolini et al. 1978; Holmgren et al. 1980; Berendsen and Nickolson 1981; Berendsen and Gower 1986; Gully et al. 1995) are involved (Argiolas and Melis 1998).

PROCEDURE

Naive male Wistar rats, weighing 220–280 g, are housed under controlled 12 h light-dark cycle with free access to standard food pellets and tap water. Rats are pretreated with subcutaneous injection of the antagonist 30 min prior to injections of the agonist, such as apomorphine (0.02 to 0.25 mg/kg s.c.) or physostigmine (0.02 to 0.3 mg/kg s.c. or i.p.). After administration of the agonist, rats are placed in individual transparent Perspex cages. A mirror is placed behind the row of observation cages to facilitate observation of the animals for penile erections and yawns. Yawning is a fixed innate motor pattern characterized by a slow, wide opening of the mouth. A penile erection is considered to occur when the following behaviours are present: repeated pelvic thrusts immediately followed by an upright position, an emerging, engorged penis which the rats proceeds to lick while eating the ejaculate. The number of penile erections and yawns is counted for 30 min following the last injection.

EVALUATION

The results are expressed as the mean number of yawns and of penile erections per group ± SEM The statistical significance is determined by comparing the results of each group with the results of the relevant control group using a non-parametric rank sum test.

CRITICAL ASSESSMENT OF THE METHOD

Ferrari et al. (1993) published some evidence that yawning and penile erection in rats underlie different neurochemical mechanisms. Nevertheless, the procedure can be regarded as an useful behavioral tool to study putative antipsychotic activity of new compounds.

MODIFICATIONS OF THE METHOD

Two sublines of Sprague Dawley rats were bred for high- and low yawning frequency in males (Eguibar and Moyaho 1997).

Apomorphine produced more yawning in Sprague Dawley rats than in F344 rats (Tang and Himes 1995)

Sato-Suzuki et al. (1998) evoked yawning by electrical or chemical stimulation in the paraventricular nucleus of anesthetized rats.

The yawning – penile erection syndrome in rats can be elicited by injections of 50 ng NMDA or AMPA (Melis et al. 1994, 1997b) into the paraventricular nucleus of the hypothalamus or intracerebroventricular injection of 50 ng oxytocin (Melis et al. 1997a) or ACTH (Genedani et al. 1994; Poggioli et al. 1998) or α-MSH (Vergoni et al. 1998).

Champion et al. (1997), Bivalacqua et al. (1998) studied the effect of intracavernosal injections of adrenomedullin and other peptide hormones on penile erections in **cats**.

Dopaminergic influences on male sexual behavior of **rhesus monkeys** were studied by Pomerantz (1990, 1992).

E.5.3.6 Inhibition of Mouse Jumping

PURPOSE AND RATIONALE

Lal et al. (1975) described a jumping response in mice after administration of L-dopa in amphetamine pretreated animals where the number of jumps can be objectively counted. The mouse jumping is due to dopaminergic overstimulation similar to that seen in rats when stereotypy is induced by higher doses of amphetamine. The phenomenon can be blocked by neuroleptics.

PROCEDURE

Male CD-1 mice weighing 22–25 g are injected with 4 mg/kg d-amphetamine sulfate, followed 15 min later by an i.p. injection of 400 mg/kg L-dopa. The mice spontaneously begin to jump at a high rate. A median of 175 jumps can be observed in these mice during 60 min. Since mice do not show any jumping after saline administration, the responses after drug administration are specific and can be measured automatically through a pressure-sensitive switch closure or properly positioned photoelectric beam disruptions. Test compounds are administered 60 min prior to L-dopa injection.

EVALUATION

Jumps of mice treated with test drugs or standard are counted and expressed as percentage of jumps in amphetamine/L-dopa treated animals. Using various doses, ED_{50} values with 95% confidence limits are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The method has been found to be sensitive and rather specific for neuroleptic drugs.

E.5.3.7 Antagonism Against MK-801 Induced Behavior

PURPOSE AND RATIONALE

Dizocilpine (MK-801), a non-competitive NMDA antagonist, induces a characteristic behavior in rat and mice, which is regarded as a model of psychosis (Andiné et al. 1999). In mice MK-801 induces a characteristic stereotypy marked by locomotion and falling behavior through both dopamine dependent and dopamine independent mechanisms (Carlson and Carlson 1989; Verma and Kulkarni 1992). Antipsychotic agents dose-dependent antagonize this MK-801 induced behavior.

PROCEDURE

Male CD-1 mice (20–30 g) are individually placed in activity boxes lined with wire mesh flooring and allowed to acclimate for 60 min. The animals are then dosed with compounds 30 min prior to subcutaneous administration of MK-801 at 0.2 mg/kg. The mice are observed for locomotion and the presence of falling behavior 15 min following MK-801 administration.

EVALUATION

ED_{50} values and 95% confidence limits are calculated by the Litchfield and Wilcoxon method.

MODIFICATIONS OF THE METHOD

Deutsch and Hitri (1993), Rosse et al. (1995), Deutsch et al. (2002, 2003), and Mastropaolo et al. (2004) described methods to measure the MK-801-induced explosive behavior in mice, called “popping”.

Farber et al. (1996) showed that neuroleptic drugs can prevent neuronal vacuolization and necrosis induced by MK-801 (Fix et al. 1993).

E.5.3.8 Phencyclidine Model of Psychosis

PURPOSE AND RATIONALE

Phencyclidine- (PCP-) induced symptoms in rats are considered as a model of psychosis (Ogawa et al. 1994; Halberstadt 1995; Steinpreis 1996; Abi-Saab et al. 1998; Sams-Dodd 1998a; Jentsch and Roth 1999; Phillips et al. 2000; Farber 2003; Morris et al. 2005).

PCP-induced symptoms can be antagonized by neuroleptic drugs (Witkin et al. 1997; Sams-Dodd 1998b; Javitt et al. 2004).

Cartmell et al. (1999) found that metabotropic glutamate receptor agonists selectively attenuate phencyclidine versus d-amphetamine motor behaviors in rats.

PROCEDURE

Behavior of male Sprague Dawley rats weighing 250–300 g was monitored while in transparent, plastic shoebox cages of the dimensions 45 × 25 × 20 cm, with 1 cm depth of wood clips as bedding, and a metal grill on the top of the cage. Motor monitors consisted of a rectangular rack of 12 photobeams arranged in a 8 × 4 formation. Shoe boxes were placed inside these racks, enabling the activity of the rat to be monitored in a home-cage environment. The lower rack was positioned at a height of 5 cm, which allowed the detection of PCP-induced head movements in addition to movements of the body of the rat. Rearing activity was detected by a second rack placed 10 cm above the first. Rats were placed in the cage for an acclimation period of 30 min, then removed, administered the test compounds s.c. or sterile water and then returned to the same cages. After 30 min, the rats were given an s.c. injection of PCP or amphetamine or sterile water and once again returned to the cages. Motor activity was monitored for the following 60 min resulting in the measurement of three different parameters: ambulations (pattern of beam breaks indicating that the animal had relocated its entire body), fine movements (non-ambulatory beam breaks), and time at rest. An indication of rearing activity was detected in the upper rack of photobeams.

EVALUATION

Data were analyzed by a one-way ANOVA, and then post-hoc comparisons for each dose group versus control or PCP alone or PCP and test compound were made using Newman-Keuls Multiple Comparison test.

MODIFICATIONS OF THE METHOD

Furuya et al. (1998) investigated the effects of a strychnine-insensitive glycine site antagonist on the hyperactivity and the disruption of prepulse inhibition induced by phencyclidine (PCP) in rats.

Redmond et al. (1999) tested the effects of acute and chronic antidepressant administration on PCP-induced locomotor hyperactivity.

Boulay et al. (2004) tested a putative atypical antipsychotic for improvement of social interaction deficits induced by PCP in rats.

E.5.3.9 Inhibition of Apomorphine-Induced Emesis in the Dog

PURPOSE AND RATIONALE

The blockade of centrally acting dopaminergic mechanisms is considered to play a major role in suppression of psychotic reactions in schizophrenia. Apomorphine, regarded as a direct dopaminergic agonist, produces a pronounced emetic effect in dogs and the blockade of apomorphine emesis is used as an indication of dopaminergic blockade. However, although both antiemetic activity and antipsychotic activity are thought to be due to dopaminergic blockade, the sites of action are in different brain areas and there is a lack of complete correlation of these activities.

PROCEDURE

Adult beagle dogs of either sex are used in treatment groups of three to nine dogs/dose. The dogs are given the test compounds in a gelatin capsule; they are then dosed with 0.15 mg/kg apomorphine s.c. at various intervals after administration of the test compound. The dogs are first observed for overt behavioral effects, e. g., pupillary response to light, changes in salivation, sedation, tremors, etc; then, after the administration of apomorphine, the dogs are observed for stereotypic sniffing, gnawing and the emetic response. Emesis is defined as wretching movements followed by an opening of the mouth and either attempted or successful ejection of stomach content.

EVALUATION

If the experimental compound is anti-emetic in the primary screen, the dose is progressively lowered to obtain a minimal effective dose or an ED_{50} value. The ED_{50} values for haloperidol and chlorpromazine were found to be 0.06 mg/kg p.o. and 2.0 mg/kg p.o., respectively. Clozapine was not effective at doses between 2 and 10 mg/kg. p.o.

CRITICAL ASSESSMENT OF THE METHOD

The method has been extensively used by several laboratories. However, since non-classical neuroleptics like clozapine did not show pronounced activity the test has been abandoned. Moreover, tests in higher animals like dogs are limited due to regional regulations.

E.5.3.10 Purposeless Chewing in Rats

PURPOSE AND RATIONALE

Purposeless chewing can be induced in rats by directly acting cholinergic drugs or cholinesterase inhibitors (Rupniak et al. 1983), which can be blocked by anti-muscarinic agents. The chewing behavior has been proposed to be mediated through central M_2 receptors rather than via central M_1 sites (Stewart et al. 1989). Chewing can also be induced by chronic administration of neuroleptics in rats (Clow et al. 1979; Iversen et al. 1980). Purposeless chewing is mediated by dopaminergic and nicotinic mechanisms.

PROCEDURE

Male albino rats are housed 10 per cage at room temperature and kept on a 12 h light-dark cycle. For the experiments, rats are placed individually in a large glass cylinder (height 30 cm, diameter 20 cm) at 21 ± 1°C and allowed to habituate for 15 min before injection of drugs. The antagonists, e. g. sulpiride or mecamylamine as standards, are given at different doses 30 min before treatment either with 0.01 mg/kg nicotine or 1 mg/kg pilocarpine i.p. Number of chewings are counted by direct observation immediately after drug administration. The results are presented as number of chews in a 30 min period.

EVALUATION

Analysis of variance (ANOVA), followed by Newman-Keuls tests, are used to evaluate the significance of the results obtained. $P < 0.05$ is considered as significant.

MODIFICATIONS OF THE METHOD

Tremulous jaw movements induced by tacrine (Cousins et al. 1999) can be antagonized by antipsychotic drugs (Betz et al. 2005; Ishiwarii et al. 2005).

E.5.3.11 Models of Tardive Dyskinesia

PURPOSE AND RATIONALE

Tardive dyskinesia is a severe side-effect of traditional neuroleptics affecting a considerable number of patients probably based on a genetic disposition, being characterized by involuntary movements of the oral region. Various authors used rats as animal model for tardive dyskinesia, either after treatment with reserpine (Waddington et al. 1990; Neisewander 1994; Bergamo et al. 1997; Quieroz and Frussa-Filho 1999; Andreassen 2000; Casey 2000; Van Kampen et al. 2000; Calvente et al. 2002; Abílio et al. 2003; Peixoto et al. 2003) or haloperidol (Takeuchi et al. 1998; Harvey and Nel 2003; Naidu et al. 2003; Burger et al. 2005). Several authors compared the effects of different neuroleptics (See and Ellison 1990; Tamminga et al. 1994) or studied potential antagonistic effects (Takeuchi et al. 1998; Quieroz and Frussa-Filho 1999; Abílio et al. 2003; Naidu et al. 2003; Peixoto et al. 2003).

Burger et al. (2005) found that ebselen attenuates haloperidol-induced orofacial dyskinesia and oxidative stress in rat brain.

PROCEDURE

Male Wistar rats weighing 270–320 g were injected sc. once a week with 12 mg/kg haloperidol decanoate for 4 weeks. Another group was pretreated with 30 mg/kg ebselen and received in addition to haloperidol every other day an ip. injection of 30 mg/kg ebselen.

The animals were observed for the quantification of orofacial dyskinesia just before haloperidol administration and on the 7th, 14th, 21st and 28th day after the first administration of haloperidol.

Rats were placed individually in cages (20 × 20 × 19 cm) containing mirrors under the floor and behind the back wall of the cage to allow behavioral quantification when the animal was faced away from the observer. To quantify the occurrence of oral dyskinesia, the incidence of tongue protrusions, vacuous chewing movements frequency, and the duration of facial twitching were recorded for 15 min. Observers were blind to drug treatment.

EVALUATION

Data were analyzed by a three-way ANOVA, followed, when appropriate, by univariate analysis and Duncan's Post Hoc test.

MODIFICATIONS OF THE METHOD

Several authors used monkeys (*Cebus apella* or *Macaca speciosa*) to evaluate the effect of neuroleptics to induce tardive dyskinesia-like symptoms (Gunne and Barany 1979; Domino 1985; Werge et al. 2003).

E.5.3.12 Single Unit Recording of A9 and A10 Midbrain Dopaminergic Neurons

PURPOSE AND RATIONALE

Interactions with central nervous system dopamine pathways are crucial for the expression of antipsychotic effects seen with clinically effective neuroleptics. These interactions also have a role in the expression of several of the neurological side effects seen with these agents. Extracellular single unit recording techniques of rat A9 (substantia nigra) and A10 (ventral tegmental area) dopamine neurons show that after acute treatment with neuroleptics the number of spontaneously firing cells is increased in both areas. After repeated treatment (21 days) a decrease was found with all neuroleptics in the A10 neurons, whereas in the A9 cell only compounds with clinically evident extrapyramidal side effects induced a decrease. Clozapine which is believed not to produce extrapyramidal side effects resulted in the depolarization inactivation of A10 neurons but not A9 cells. The method provides a prediction of a compound's anti-psychotic potential as well as potential neurological side effects (Chiodo and Bunney 1983).

PROCEDURE

Male Wistar rats weighing 280–360 g are anesthetized with chloralhydrate intraperitoneally. The animal is mounted in a stereotaxic apparatus (Kopf, model 900). The cranium is exposed, cleaned of connective tissue and dried. The skull overlying both the substantia nigra (A9: anterior (A) 3000–3400 µm, lateral (L) 1800–2400 µm from lambda), and the ventral tegmental area (A10: A 3000–3400 µm, L 400–1000 µm from lambda) (Paxinos and Watson 1986) is removed. Using the dura as point of reference, a micropipette driven by a hydraulic microdrive is lowered through the opening of the skull at vertical 6000–8500 µm. Spontaneously firing dopamine neurons within both the substantia ni-

gra and the ventral tegmental area are counted by lowering the electrode into twelve separate tracks (each track separated from the other by 200 µm) in each region. The sequence of these tracks is kept constant, forming a block of tissue which can be reproducibly located from animal to animal.

Extracellular neuronal signals are sampled using a single barrel micropipette approximately one µm at its tip, and filled with 2 M NaCl saturated with 1% pontamine sky blue dye (*in vitro* impedance between 5 and 10 MΩ). Electrical potentials are passed through a high-impedance preamplifier and the signal is sent to a window discriminator which converts potentials above background noise levels to discrete pulses of fixed amplitude and duration. Only cell whose electrophysiological characteristics match those previously established for midbrain dopamine neurons are counted. In an anesthetized rat, a neuron is considered to be dopaminergic if it displays a triphasic positive-negative-positive spike profile of 0.4 to 1.5 mV amplitude and 2.5 ms duration, firing in an irregular pattern of 3 to 9 Hz with occasional bursts characterized by progressively decreasing spike amplitude and increasing spike duration.

At the end of each experiment, the location of the last recorded track tip is marked by passing 25 microampere cathodal current through the recording micropipet barrel for 15 min in order to deposit a spot of dye. The rat is sacrificed, the brain is then removed, dissected and frozen on a bed of dry ice. Frozen serial sections (20 µm in width) are cut, mounted and stained with cresyl violet and examined using a light microscope.

Animals pretreated with vehicle prior to neuronal sampling serve as controls. For animals that are used in an acute single-unit dopamine neuron sampling assay, test compounds are administered intraperitoneally one hour prior to the beginning of dopamine neuron sampling. For animals used in a chronic single-unit dopamine sampling assay, the compounds are administered once a day for 21 days, and dopamine neuron sampling is begun 2 h after the last dose on the 21st day.

EVALUATION

Drug treatment groups are compared to vehicle groups with a one-way ANOVA with a post hoc Neuman-Keuls analysis for significance.

MODIFICATIONS OF THE METHOD

Nybäck et al. (1975) tested the influence of tricyclic antidepressants on the spontaneous activity of norepinephrine-containing cells of the locus caeruleus in anesthetized rats.

Scuvée-Moreau and Dreese (1979) studied the effect of various antidepressant drugs on the firing rate of locus caeruleus and dorsal raphe neurons of the anesthetized rat with extracellular microelectrodes.

Using the method of single-unit recording of spontaneous firing of locus caeruleus neurons in rats, Cedarbaum and Aghajanian (1977) studied the inhibition by micro-iontophoretic application of catecholaminergic agonists.

Marwaha and Aghajanian (1982) examined in single unit studies the actions of adrenoceptor antagonists at *alpha*-1 adrenoceptors of the dorsal raphe nucleus and the dorsal lateral geniculate nucleus and *alpha*-2 adrenoceptors of the nucleus locus caeruleus.

Mooney et al. (1990) studied the organization and actions of the noradrenergic input to the superior colliculus of the hamster using micro-iontophoretic techniques together with extracellular single unit recording.

Bernardini et al. (1991) studied *in vitro* with brain slices of mice the amphetamine-induced and spontaneous release of dopamine from A9 and A10 cell dendrites.

Santucci et al. (1997) investigated the effects of synthetic neurotensin receptor antagonists on spontaneously active A9 and A10 neurones in rats.

E.5.3.13 In Vivo Voltammetry

PURPOSE AND RATIONALE

Various groups (Lane et al. 1979, 1987, 1988; Blaha and Lane 1983, 1984, 1987; Crespi et al. 1984; Marsden et al. 1984; Maidment and Marsden 1987a, b; Armstrong-James and Millar 1979, 1984; Kawagoe et al. 1993) described *in vivo* voltammetry as an electrochemical technique that uses carbon fiber microelectrodes stereotactically implanted in brain areas to monitor monoamine metabolism and release. De Simoni et al. (1990) reported on a miniaturized optoelectronic system for telemetry of *in vivo* voltammetric signals in freely moving animals.

PROCEDURE

Carbon fibre working electrodes are made from pyrolytic carbon fibres supported in a pulled glass capillary (Armstrong-James and Millard 1979; Sharp et al. 1984) and electrically pretreated for simultaneous recording of ascorbic acid DOPAC and 5-HIAA (Crespi et al. 1984).

Male Sprague Dawley rats weighing 270–340 g are anesthetized with a 2–3% halothane O_2/NO_2 mixture (1:1) and held in a stereotactic frame. Reference and auxiliary electrodes are positioned on the surface of the dura through 1 mm holes drilled in the cranium and held in place with dental cement. Holes, approx. 2 mm in diameter, are drilled in the cranium above the left or right nucleus accumbens and contralateral anterior striatum, and the underlying dura is broken with a hypodermic needle. A working electrode is lowered in one of the above regions and cemented in place. A second electrode is then implanted in the remaining structure. The coordinates, measured from the bregma, are as follows: nucleus accumbens–rostro-caudal +3.4 mm; medio-lateral ± 1.4 mm; dorso-ventral –7 mm; striatum–rostro-caudal +2.8 mm; medio-lateral ± 2.6 mm; dorso-ventral –5.5 mm.

Drugs are injected subcutaneously. Voltammograms are recorded using a Princeton Applied Research 174A polarographic analyzer alternatively from each region every 5 min and after a 1 h stabilization period.

EVALUATION

Voltammetric data are expressed as percentage changes from pre-injection control values using the mean of the last 6 peak heights before administration of drug as the 100% value. However, statistical analysis of the data is carried out on the absolute peak heights using a paired Student's *t*-test to compare 6 pre-injection control peak heights with those after administration of drug at selected time points.

MODIFICATIONS OF THE METHOD

Swiergiel et al. (1997) constructed voltammetric probes from stainless steel and fused silica tubing sheathing carbon fibers and compared them with commercially available glass-sealed IVEV-5 electrodes. This type of electrodes can be easily manufactured and does not require any special equipment.

Parada et al. (1994, 1995) described a triple-channel swivel suitable for intracranial fluid delivery and microdialysis experiments which can be equipped with three electrical channels for *in vivo* voltammetry and measurement of intracranial temperature with a thermocouple.

Frazer and Daws (1998) used electrodes coated with a perfluorinated ion exchange resin (Nafion) to assess serotonin transporter function *in vivo* by **chrono-amperometry** whereby voltage is applied to the electrode in a pulsed manner and the current obtained measured as a function of time.

E.5.4
Genetic Models of Psychosis

E.5.4.1
The Heterozygous Reeler Mouse

PURPOSE AND RATIONALE

Reelin is an extracellular matrix protein secreted by GABAergic interneurons that, acting through pyramidal neuron integrin receptors, provides a signal for dendritic spine plasticity. The gene responsible for a mouse mutant strain is called reeler (D'Arcangelo and Curran 1998; Lombroso and Goldowitz 1998; Fatemi 2001; Pappas et al. 2003). Heterozygous reeler mice that exhibit a 50% downregulation of reelin expression replicate the dendritic spine and GABAergig defects described in human schizophrenia (Larson et al. 2003). The heterozygote reeler mouse was recommended as a model for the development of a new generation of antipsychotics (Tueting et al. 1999; Rowley et al. 2001; Costa et al. 2002). This view has been challenged by Podhorna and Didriksen (2004).

Tomasiewicz et al. (1993) and Wood et al. (1998) proposed **NCAM-180 knockout mice** with a deletion of the neural cell adhesion molecule variant (N-CAM-180) displaying increased lateral ventricle size and a reduced prepulse inhibition of startle response as model for schizophrenia.

Dirks et al. (2003) reported reversal of startle gating deficits in **transgenic mice overexpressing corticotropin-releasing factor** by antipsychotic drugs.

Van den Buuse (2003) showed deficient prepulse inhibition of acoustic startle in **Hooded-Wistar** rats compared with Sprague Dawley rats suggesting that the Hooded-Wister line could be a useful genetic animal model to study the interaction of glutaminergic and dopaminergic mechanisms in anxiety and schizophrenia.

E.5.4.2
The Hooded-Wistar Rat

PURPOSE AND RATIONALE

Van den Buuse (2003), Lodge et al. (2003), and Martin et al. (2004) suggested that the Hooded-Wistar line (fawn-hooded rats) could be a useful genetic animal model to study the interaction of glutamatergic and dopaminergic mechanisms in anxiety and schizophrenia.

Broderick (2002) compared hippocampal serotonin and norepinephrine release during open-field behavior in Sprague Dawley animals with the Fawn-Hooded animals model of depression.

E.6 Antidepressant Activity

E.6.0.1 General Considerations

The first antidepressant drugs were detected by serendipity in clinical trials. Iproniazid was developed for the treatment of tuberculosis. The observation of mood-elevating effects was followed by the detection of the inhibition of the enzyme monoamine oxidase. During clinical investigation of phenothiazine analogs as neuroleptics, imipramine was found to be relatively ineffective in agitated psychotic patients but showed remarkable benefit in depressed patients. Later on, inhibition of uptake of biogenic amines was found to be the main mechanism of action resulting in downregulation of β-receptors (Vetulani et al. 1976). Influence on α_2-adrenoreceptors (Johnson et al. 1980) was discussed as well. Several lines of preclinical and clinical evidence indicate that an enhancement of 5-HT-mediated neurotransmission might underlie the therapeutic effect of most antidepressant treatments (Blier and de Montigny 1994).

Animal models of depression have been reviewed by Porsolt et al. (1991), Panksepp et al. (1991), Willner and Muscat (1991), and Cryan et al. (2002).

E.6.1 In Vitro Methods

E.6.1.1 Inhibition of [^{3}H]-Norepinephrine Uptake in Rat Brain Synaptosomes

PURPOSE AND RATIONALE

As shown by Hertting and Axelrod (1961) the neuronal re-uptake mechanism for norepinephrine is the most important physiological process for removing and inactivating norepinephrine in the synaptic cleft. This uptake is inhibited by cocaine, certain phenylethylamines and antidepressants. This mechanism is considered as one of the most important modes of action of anti-depressants leading to receptor down-regulation. In the brain, the hypothalamus shows the highest level and greatest uptake of noradrenaline. Therefore, this region is used for testing potential antidepressant drugs.

PROCEDURE

Tissue Preparation

Male Wistar rats are decapitated and the brains rapidly removed. The hypothalamic region is prepared, weighed, and homogenized in 9 volumes of ice-cold 0.32 M sucrose solution using a Potter-Elvejhem homogenizer. The homogenate is centrifuged at 1000 *g* at 0–4°C for 10 min. The supernatant is decanted and used for the uptake experiments.

Assay

200 µl of tissue suspension are incubated with 800 µl 62.5 nM ^{3}H-norepinephrine in Krebs-Henseleit bicarbonate buffer and 20 µl of the appropriate drug concentration (or the vehicle) at 37°C under a 95% O_2/5% CO_2 atmosphere for 5 min. For each assay, 3 tubes are incubated with 20 µl of vehicle at 0°C in an ice bath. After incubation all tubes are immediately centrifuged at 4000 *g* for 10 min. The supernatant fluid is aspirated and the pellets dissolved adding 1 ml of solubilizer (Triton X-100 + 50% ethanol, 1:4). The tubes are vigorously shaken, decanted into scintillation vials, and counted in 10 ml of liquid scintillation cock-

tail. Active uptake is the difference between cpm at 37°C and 0°C.

EVALUATION

The percent inhibition at each drug concentration is the mean of 3 determinations. IC_{50} values are derived from log-probit analysis. IC_{50} values for the standard drugs desipramine and nortriptyline are around 20 nM.

MODIFICATIONS OF THE METHOD

Pacholczyk et al. (1991) described the expression cloning of a cocaine- and antidepressant-sensitive human noradrenaline transporter.

Tejani-Butt (1992) recommended [3H]nisoxetine as radioligand for quantitation of norepinephrine uptake sites.

E.6.1.2 Inhibition of [^{3}H]-Dopamine Uptake in Rat Striatal Synaptosomes

PURPOSE AND RATIONALE

High affinity, saturable, temperature and sodium-dependent transport of ^{3}H-dopamine has been observed in various tissue preparations from different brain regions. The area striata has a high content of dopamine and is suitable for uptake experiments. The ^{3}H-dopamine uptake is inhibited by cocaine, certain phenylethylamines and antidepressants like nomifensine and bupropion, but not by tricyclic antidepressants. The test can be used to characterize the mode of action of antidepressant drugs.

PROCEDURE

Tissue Preparation

Male Wistar rats are decapitated and the brains rapidly removed. Corpora striata are prepared, weighed and homogenized in 9 volumes of ice cold 0.32 M sucrose solution using a Potter-Elvejhem homogenizer. The homogenate is centrifuged at 1000 *g* at 0–4°C for 10 min. The supernatant is decanted and used for the experiments.

Assay

100 µl of tissue suspension are mixed with 900 µl 55.5 nM ^{3}H-dopamine solution in Krebs-Henseleit bicarbonate buffer and 20 µl of drug solution in appropriate concentration (or the vehicle as control). The tubes are incubated at 37°C under a 95% O_2/5% CO_2 atmosphere for 5 min. For each assay, 3 tubes are incubated with 20 µl of vehicle at 0°C in an ice bath. After incubation all tubes are immediately centrifuged at 4000 *g* for 10 min. The supernatant fluid is aspirated and the pellets dissolved by adding 1 ml of solubilizer (Triton X-100 + 50% ethanol, 1:4). The tubes are vigorously shaken, decanted into scintillation vials, and counted in 10 ml liquid scintillation counting cocktail. Active uptake is the difference between cpm at 37°C and 0°C.

EVALUATION

The percent inhibition at each drug concentration is the mean of 3 determinations. IC_{50} values are derived from log-probit analyses. IC_{50} values for nomifensine are 460 nM, but >20,000 nM for tricyclic antidepressants.

MODIFICATIONS OF THE METHOD

Elsworth et al. (1993) differentiated between cocaine-sensitive and -insensitive dopamine uptake in various brain areas.

Cloning and pharmacological characterization of rat, bovine, and human dopamine transporters have been described (Giros et al. 1991; Kilty et al. 1991; Shimada et al. 1991; Usdin et al. 1991; Giros et al. 1992).

Binding characteristics of the dopamine transporter were studied (Reith et al. 1992; Rothman et al. 1992).

[^{3}H]-3β-(*p*-fluorophenyl)tropan-2β-carboxylic acid methyl ester ([^{3}H]WIN 35,428) is used as ligand

for the dopamine transporter (Carroll et al. 1992; Cline et al. 1992).

[^{3}H]GBR12935 (1-[2-(diphenylmethoxy)ethyl]-4-(3-phenylpropyl)piperazine) was used as labelled ligand by Richfield (1991), Nakachi et al. (1995).

Cocaine receptors are specifically labeled with [^{3}H]WIN 35,428 indicating the role of the dopamine transport system in mediating the behavioral effects and the abuse of cocaine (Madras et al. (1989).

Laruelle et al. (1993) reported **single photon emission computed tomography** (SPECT)} imaging of dopamine and serotonin transporters in nonhuman primates.

E.6.1.3 Inhibition of [^{3}H]-Serotonin Uptake

PURPOSE AND RATIONALE

Selective inhibitors of serotonin uptake (SSRIs) became the most powerful and widely used antidepressants (Pacher et al. 2001; Fray et al. 2006). These include citalopram (D'Amato et al. 1987; Brøsen and Narajo 2001), fluoxetine, sertraline, paroxetine (Pacher et al. 2001), and escitalopram (Sánchez et al. 2003; Murdoch and Keam 2005).

These antidepressants block the reuptake of 5-HT. ^{3}H-5-HT transport in brain has been found to be saturable, sodium- and temperature-dependent, to be inhibited by several agents, such as ouabain, tryptamine analogs, and tricyclic antidepressants. Apparently, the 5-HT uptake can be differentiated from catecholamine uptake. Therefore, the test can be used to detect com-

pounds that inhibit serotonin uptake into rat brain synaptosomes and may be potential antidepressants.

PROCEDURE

Tissue Preparation

Male Wistar rats are decapitated and the brains rapidly removed. Either the whole brain minus cerebellum or the hypothalamus is weighed and homogenized in 9 volumes of ice-cold 0.32 M sucrose solution using a Potter-Elvejhem homogenizer. The homogenate is centrifuged at 1000 *g* at 0–4°C for 10 min. The supernatant is decanted and used for further uptake experiments.

Assay

Two hundred µl of tissue suspension are mixed with 800 µl 62.5 nM ^{3}H-5-HT solution in Krebs-Henseleit bicarbonate buffer and 20 µl of drug solution in the appropriate concentration (or the vehicle as control). The tubes are incubated at 37°C under 95% O_2/5% CO_2 atmosphere for 5 min. For each assay, 3 tubes are incubated with 20 µl of the vehicle at 0°C in an ice bath. After incubation all tubes are immediately centrifuged at 4000 *g* for 10 min. The supernatant is aspirated and the pellets are dissolved by adding 1 ml of solubilizer (Triton X100+50% ethanol, 1+4). The tubes are vigorously shaken, decanted into scintillation vials, and counted in 10 ml of liquid scintillation counting cocktail. Active uptake is the difference between cpm at 37°C and 0°C.

EVALUATION

The percent inhibition of each drug concentration is the mean of 3 determinations. IC_{50} values are calculated from log-probit analyses. Standard drugs, such as chlorimipramine show IC_{50} values in the order of 10 nM for ^{3}H-5-HT uptake in rat synaptosomes from hypothalamus.

MODIFICATIONS OF THE METHOD

Similar methods were used by D'Amato et al. (1987), Weinshank et al. (1992), Cheng et al. (1993), Hatanaka et al. (1996), and Tordera et al. (2002).

Sánchez et al. (2003) and Chen et al. (2005) studied [^{3}H]-5-HT uptake inhibition in a COS-1 cell line stably transfected with h5-HTT.

Hallstrom et al. (1976) studied the platelet uptake of 5-hydroxytryptamine and dopamine in patients with depression.

Cloning of functional serotonin transporters has been described by Blakely et al. (1991) and by Hoffman et al. (1991).The role of serotonin in the mode of action of antidepressant drugs has been discussed by Hyttel and Larsen (1985), Åsberg and Mårtensson (1993), Hyttel (1994), Blier and de Montigny (1997), Keane and Soubrié (1997).

E.6.1.4 Binding to Monoamine Transporters

PURPOSE AND RATIONALE

There is substantial clinical and experimental evidence that lesions in the serotonergic and noradrenergic systems are responsible for depression and that antidepressant treatment can reverse these alterations (Leonard 2000). Monoamine transporters are principle targets of widely used therapeutic drugs including antidepressants, psychostimulants and the addictive drug cocaine (Madras et al. 1996; Fleckenstein et al. 1999). The termination of neurotransmission is achieved by rapid uptake of the released neurotransmitter by high-affinity neurotransmitter transporters. Most of these transporters are encoded by a family of genes (Na^+/Cl^- transporters) having a similar membrane topography of 12 transmembrane helices. An evolutionary tree revealed five distinct subfamilies: GABA-transporters, monoamine transporters, amino acid transporters, "orphan" transporters and bacterial transporters (Nelson 1998).

Tatsumi et al. (1997) described the pharmacological profile of antidepressants at human monoamine transporters.

PROCEDURE

Expression of Human Transporters

The human serotonin transporter cDNA is directionally ligated into the expression vector pRc/CMV and transfected into HEK293 (human embryonic kidney) cells by the Ca^{2+} method. The human dopamine transporter cDNA is directionally ligated into the expression vector pcDNA3 and transfected into HEK293 cells, also by the Ca^{2+} method.

Cell Culture

The cell lines are grown, passaged, and harvested in 150 mm Petri dishes with 17.5 ml of Dulbecco's modified Eagle's medium containing 0.1 mM nonessential amino acid solution, 5% fetal clonebovine serum product and 1 U/µl penicillin and streptomycin solution. They are incubated in 10% CO_2, 90% air at 37°C and 100% humidity. The selecting antibiotic geneticin sulfate (250 µg/ml) is used continuously for culture of cells expressing the norepinephrine transporter.

Membrane Preparations

For the preparation of the homogenates, the medium is removed by aspiration. The cells are washed with 4 l modified Puck's D1 solution (solution 1) (Pfenning and Richelson 1990) and then incubated for 5 min at 37°C in 10 ml solution 1 and 100 mM EGTA. Afterwards cells are removed from the surface by scraping with a rubber spatula, placed in a centrifuge tube, and collected by centrifugation at 110 *g* for 5 min at 4°C. The supernatants are decanted. The pellets are resuspended in the respective binding assay buffer by use of a Polytron (Brinkman Instruments, Westbury, NY) for 10 s at setting 6. The mixture is then centrifuged at 35,600 *g* for 10 min at 4°C. The pellets are suspended in the same volume of the respective buffer and the centrifugation is repeated. The supernatants are decanted and the final pellets are suspended in the respective buffer and stored at –80°C until assayed. The final protein concentration is determined by the Lowry assay using bovine serum albumin as standard.

Radioligand Binding Assays

[^{3}H] imipramine Binding to Human Serotonin Transporter. Radioligand binding assays are performed by a modification of the method of O'Riordan et al. (1990) with a binding buffer containing 50 mM Tris, 120 mM NaCl, and 5 mM KCl (pH 7.4). Compounds to be tested are dissolved in 5 mM HCl and run in duplicate over at least 11 different concentrations against 1 nM [^{3}H]imipramine (specific activity 46.5 Ci/mmol) with 15 µg/tube membrane protein for 30 min at 22°C. Nonspecific binding is determined in the presence of 1 µM imipramine. With the use of a 48-well Brandel cell harvester, the assay is terminated by rapid filtration through a GF/B filter presoaked with 0.2% polyethylenimine. The filter strips are rinsed five times with ice-cold 0.9% NaCl. Finally, each filter is placed in a scintillation vial containing 6.5 ml of Redi-Safe (Beckman Instruments, Fullerton, CA) and counted in a liquid scintillation counter.

[^{3}H] Nisoxetine Binding to Human Norepinephrine Transporter. Radioligand binding assays are performed by a modification of the method of Jayanthi et al. (1993) in binding buffer containing 50 mM Tris, 300 mM NaCl and 5 mM KCl (pH 7.4). [^{3}H]nisoxetine (specific activity 85.0 Ci/mmol, from Amersham, Arlington Hts., IL) at 0.5 nM is incubated with competing drugs and 25 µg/tube membrane protein for 60 min at 22°C. Nonspecific binding is determined in the presence of 1 µM nisoxetine. The remainder of the assay is exactly as described above.

[^{3}H] WIN35428 Binding to Human Dopamine Transporter. Radioligand binding assays are performed using a modification of the method of Pristupa et al. (1994) in a binding buffer containing 50 mM Tris and 120 mM NaCl (pH 7.4). [^{3}H]WIN35428 (Dupont New England Nuclear, Boston MA, specific activity 83.5 Ci/mmol) at 1 nM is incubated with competing drugs and 30 µg/tube membrane protein for 120 min at 4°C. Nonspecific binding is determined in the presence of 10 µM WIN35428. The remainder of the assay is exactly as described above.

EVALUATION

The data are analyzed using the LIGAND program (Munson and Rodbard 1980) for calculation of K_D values and Hill coefficients.

MODIFICATIONS OF THE METHOD

Using the same methods, Tatsumi et al. (1999) described the pharmacological profile of several neuroleptics at human monoamine transporters.

Gu et al. (1994) constructed stable cell lines expressing transporters for dopamine, norepinephrine and serotonin using parental LLC-PK_1 cells which do not express any of these neurotransmitter transporters.

Meltzer et al. (1997) described inhibitors of monoamine transporters using dopamine- and serotonin-transporter assays. Membranes were prepared from coronal slices from caudate-putamen of brain from adult cynomolgus monkeys.

Owens et al. (1997) measured the affinity of several antidepressants and their metabolites for the rat and human serotonin and norepinephrine transporters.

Inazu et al. (1999) characterized dopamine transport in cultured rat astrocytes.

Siebert et al. (2000) used rat neuronal cultures and transfected COS-7 cells to characterize the interaction of haloperidol metabolites with neurotransmitter transporters.

Sato et al. (2000) studied the selective inhibition of monoamine neurotransmitter transporters by synthetic local anesthetics using cloned transporter cDNAs with transient functional expression in COS cells and stable expression in HeLa cells.

E.6.1.5 Antagonism of p-Chloramphetamine Toxicity by Inhibitors of Serotonin Uptake

PURPOSE AND RATIONALE

p-Chloramphetamine causes selective toxicity to serotonin neurons. At 10 mg/kg i.p. p-chloramphetamine (p-CA) causes long-term decreases in 5-HT, 5HIAA, [^{3}H]-5-HT-uptake and tryptophan hydroxylase. After acute administration of p-CA, serotonin uptake into synaptosomes isolated from whole brain is reduced for several hours and returns to control values between 1 and 2 days, after which there is a marked long-lasting decrease due to toxic destruction of 5-HT neurones. The initial behavioral effects of p-CA are due to release of dopamine and serotonin. The serotonergic toxicity of p-CA requires active transport into 5-HT neurones where a cytotoxic intermediate compound is formed. Therefore, compounds which block 5-HT uptake will prevent this toxicity. Antagonism of the long-term p-CA induced reduction of synaptosomal ^{3}H-5-HT *in vitro* uptake is a highly useful index of a compound's ability to inhibit 5-HT re-uptake *in vivo*.

PROCEDURE

Reagents

Two mg/ml dextrose and 0.30 mg/ml iproniazid phosphate are added to Krebs-Henseleit bicarbonate buffer. The mixture is aerated for 1 h with carbogen.

Serotonin creatinine sulfate (Sigma Chemical Co) as a 0.1 mM stock solution in 0.01 N HCl is used to dilute the specific activity of the radiolabeled 5-HT.

A solution of 62.5 nM ^{3}H-5-HT (5-[1,2-^{3}H(N)]-hydroxytryptamine creatinine sulfate, specific activity 20–30 Ci/mmol, New England Nuclear) is prepared in Krebs-Henseleit bicarbonate buffer.

(d,l)-p-Chloramphetamine (Regis Chemical Co) is dissolved in 0.9% NaCl at a concentration of 10 mg/ml.

Drug Treatment

Groups of 8 male Wistar rats, weighing 150–200 g are injected intraperitoneally with saline or molar equivalent doses of the test drug. For initial studies, the dose given is 37,5 µmol/kg (equivalent to 10 mg/kg desipramine base). After 30 min, 4 rats from each group are injected with saline or with p-CA 10 mg/kg i.p. Three days after treatment, the rats are sacrificed. For multiple dosing, the rats are pretreated with the test drug twice up to 4 times in 2 h intervals.

Tissue Preparation

The rats are decapitated and the brains rapidly removed. Whole brain minus cerebellum is weighed and homogenized in 9 volumes of ice-cold 0.32 M sucrose using a Potter-Elvejhem homogenizer. The homogenate is centrifuged at 1000 *g* at 0–4°C for 10 min. The crude synaptosomal supernatant is decanted and used for uptake experiments.

Assay

800 µl Krebs-Henseleit bicarbonate buffer+[^{3}H]-5-HT

200 µl Tissue suspension

Tubes are incubated at 37°C under a 95% O_2/5% CO_2 atmosphere for 5 min. For each assay, 3 tubes are incubated at 0°C in an ice bath. After incubation all tubes are immediately centrifuged at 4000 *g* at 0–4°C for 10 min. The supernatant fluid is aspirated and the pellets dissolved by adding 1 ml of solubilizer (Triton X-100 and 50% ethanol, 1:4, v/v). The tubes are vigorously vortexed, decanted into scintillation vials, and counted in 10 ml of aqueous (Liquiscint) scintillation counting cocktail. Active uptake is the difference between cpm at 37°C and 0°C.

EVALUATION

The percent protection is calculated according to the following formula:

$$\%\ \text{protection} = \frac{\text{cpm}[(\text{sal/sal}) - (\text{sal/pCA})]}{\text{cpm}[(\text{sal/sal}) - (\text{sal/pCA})]} - \frac{\text{cpm}[(\text{sal/sal}) - (\text{drug/pCA})]}{\text{cpm}[(\text{sal/sal}) - (\text{sal/pCA})]}$$

E.6.1.6 Receptor Subsensitivity After Treatment with Antidepressants: Simultaneous Determination of the Effect of Chronic Anti-Depressant Treatment on β-Adrenergic and 5-HT_2 Receptor Densities in Rat Cerebral Cortex

PURPOSE AND RATIONALE

The catecholamine and indolamine systems are thought to be involved in affective disorders such as depression. The effect of antidepressants on biogenic amine re-uptake *in vitro* is immediate; whereas the onset of clinical activity is delayed and parallels more closely the time course of receptor changes measured in animal studies. Therefore, the experiment is designed to determine the *in vivo* effects of chronic (10 days) treatment with known and potential antidepressants on the β-receptor, as a measurement of noradrenergic interaction, and on the 5-HT_2 receptor as a measurement of serotoninergic interaction in the rat brain. Both receptor densities are measured in cortical tissue from the same animal and compared after treatment with test compounds at doses similar to those of standard drugs.

PROCEDURE

Drug Treatment

Groups of 4 male Wistar rats, receiving food and water at libitum are maintained on a 12-h diurnal light cycle and given i.p. injections twice daily for 10 days with saline or molar equivalent doses of the experimental drugs (equivalent to 10 mg/kg imipramine). Twenty-four hours after the last dose, the rats are decapitated and the cerebral cortices split along the mid-sagittal sinuses. One half is used for the (^{3}H)-DAH assay and the other half is used for the (^{3}H)-spiroperidol assay. This protocol allows the determination of effects of antidepressants on β-receptors and 5-HT_2-receptors in cerebral cortical tissue from the same animal.

Reagents

- (–)-[propyl-1,2,3-^{3}H]Dihydroalprenololol hydrochloride (45–52 Ci/mmol) is obtained from New England Nuclear.
- (±)-propranolol HCl is obtained from Ayerst.
- [Benzene-^{3}H]spiroperidol (20–35 Ci/mmol) is obtained from New England Nuclear.

Tissue Preparation

^{3}H-Dihydroalprenolol (^{3}H-DHA) Binding. The cerebral cortices are dissected free, weighed and homogenized in 50 vol of ice-cold 0.05 M Tris buffer, pH 8.0. This homogenate is centrifuged at 40,000 *g* and the supernatant decanted. The pellet is resuspended and again centrifuged at 40,000 *g*. The final pellet is resuspended in 0.05 M Tris buffer, pH 8.0. This tissue suspension is then stored on ice until use. The final tissue concentration is 10 mg/ml.

^{3}H-Spiroperidol Binding. The cerebral cortices are dissected, weighed and homogenized in 50 vol of 0.05 M Tris buffer, pH 7.7, and then centrifuged at 40000*g* for 15 min. The supernatant is discarded, the pellet resuspended and again centrifuged at 40,000 *g*. The final pellet is resuspended in 50 vol of 0.05 M Tris buffer, pH 7.7 and stored in an ice bath. The final concentration in the assay is 10 mg/ml.

Assay

^{3}H-DAH Binding

380 µl	H_2O
50 µl	0.5 M Tris buffer pH 8.0
20 µl	vehicle (for total binding) or 50 µM propranolol (for nonspecific binding)
50 µl	^{3}H-DAH stock solution
500 µl	tissue suspension

The tissue homogenates are incubated for 15 min at 25°C with varying concentrations of ^{3}H-DHA (0.25–4.0 nM). With each ligand concentration triplicate samples are incubated with 1 µM propranolol under identical conditions to determine nonspecific binding. The total added ligand is determined by counting 50 µl of each (^{3}H)-DHA concentration. The assay is stopped by vacuum filtration through Whatman GF/B filters which are washed 3 times with 5 ml of ice cold 0.05 M Tris buffer, pH 8.0. The filters are counted in 10 ml liquid scintillation cocktail.

^{3}H-Spiroperidol Binding

50 µl	0.5 M Tris-physiological salts
380 µl	H_2O
20 µl	H_2O (for total binding) or 0.25 mM methysergide (for nonspecific binding)
50 µl	^{3}H-spiroperidol stock solution
500 µl	tissue suspension

The tissue homogenates are incubated for 10 min at 37°C with varying concentrations of ^{3}H-spiroperidol (0.1–3.0 nM). With each ligand concentration, triplicate samples are incubated in the presence of 5 µM methysergide under identical conditions to determine nonspecific binding. The total added ligand is determined by counting 50 µl of each (^{3}H)-spiroperidol concentration. The assay is stopped by vacuum filtration through Whatman GF/B filters which are washed 3 times with 5 ml of ice cold 0.05 M Tris buffer, pH 7.7. The filters are transferred to scintillation vials and counted in 10 ml of liquid scintillation cocktail.

EVALUATION

Specific binding is defined as the difference in CPM in the presence or absence of excess "cold" ligand. The free ligand concentration is the difference between the total added and the specifically bound fraction at each concentration. The equilibrium binding constants (K_d and B_{max}) are determined by Scatchard analyses using least square regression analysis of the binding data. The Scatchard plot shows "bound/free" versus "bound". The K_d value is the reciprocal of the slope and B_{max} is the x-intercept. Significant differences of drug treatment are determined by either Dunnett's or Tukey's test after one way analysis of variance.

MODOFICATIONS OF THE METHOD

Buckett et al. (1988) found a rapid down-regulation of β-adrenoceptors in brains of rats after 3 days of oral treatment with sibutramine.

E.6.1.7 Measurement of β-Adrenoreceptor Stimulated Adenylate Cyclase

PURPOSE AND RATIONALE

Noradrenaline stimulates the β-adrenoreceptor linked adenylate cyclase in rat brain. Reduction of this stimulation after treatment with antidepressants is an indicator for receptor down-regulation.

PROCEDURE

Groups of male Sprague-Dawley rats are treated intraperitoneally twice daily for 14 days with saline, 10 mg/kg desimipramine or the test compound. The rats are decapitated and frontal cortices are removed, and placed into ice-cold Krebs physiological buffer (120 mM NaCl, 5 mM KCl, 2.5 mM $CaCl_2$, 2 mM KH_2PO_4, 2 mM $MgSO_4$, 25 mM $NaHCO_3$, 100 µM $Na_2S_2O_5$, 25 µM EDTA, and 10 mM glucose), pH 7.4. Cortices are cut 350 × 350 µ at right angles, added to 20 ml Krebs physiological buffer in 50 ml conical flasks, and separated by vortex mixing. The slices are incubated at 37°C for 1 h in a shaking water bath with the buffer replaced by freshly oxygenated medium every 15 min. After this step, 20 µl [^{3}H]adenine is added to each flask. The flasks are capped, and the slices are incubated for an additional 30 min at 37°C. This medium is then discarded and the slices are washed with 20 ml fresh buffer. Most of the medium is removed and 30 µl aliquots of the packed slices are pipetted into tubes containing 300 µM 3-isobutyl-1-methylxanthine in 270 µl Krebs physiological buffer. After incubation at 37°C for 15 min, 30 µl of noradrenaline (final concentration 100 µM) or 30 µl buffer are added to each tube and incubated for an additional 10 min. The reaction is stopped by addition of 0.5 ml 1 M HCl. The tubes are placed in ice for 10 min before addition of 0.5 ml NaOH and then centrifuged at 3000 *g* for 10 min at 4°C. The supernatants are transferred to tubes containing [^{14}C]-cyclic AMP (approximately 10,000 cpm) to monitor the recovery of [^{3}H]-cyclic AMP. The radio-labelled cyclic nucleotides are sep-

arated by two-stage column chromatography on alumina neutral WN-3 and Dowex AG 50W-X4 anion exchange resin.

EVALUATION

The activity of adenylate cyclase is calculated as the conversion of [^{3}H]-adenine to [^{3}H]-cyclic AMP. After treatment with antidepressants, this conversion rate is not altered without stimulation by noradrenaline, but significantly reduced in slices treated with the maximally stimulating concentration of 100 µM noradrenaline.

CRITICAL ASSESSMENT OF THE METHOD

Determination of β-adrenoreceptor stimulated adenylate cyclase is another parameter for measurement of down-regulation of adrenoreceptors by chronic treatment with antidepressants.

E.6.1.8 [^{3}H]Yohimbine Binding to α_2-Adrenoceptors in Rat Cerebral Cortex

PURPOSE AND RATIONALE

This binding assay is used to investigate the interaction of compounds at central α_2 receptors and may indicate possible modes of action for antidepressant, anti-hypertensive and other classes of compounds.

[^{3}H]Yohimbine is a selective antagonist for α_2-receptors (Starke et al. 1975). The use of an antagonist radioligand avoids the complexity of saturation curves that can be observed with radio-labeled agonist ligands. Furthermore, a [^{3}H]antagonist label for the α_2 receptor permits a better evaluation of α_2/α_1 selectivity than a [^{3}H]agonist label, since α_1 affinities are measured with a [^{3}H]antagonist ([^{3}H]WB 4101).

Chronic treatment with desipramine has been shown to decrease the binding of [^{3}H]DHA to rat brain cortical β-receptors. Some investigators have reported that co-administration of yohimbine causes β-receptor down-regulation to occur after fewer antidepressant treatments (Johnson et al. 1980; Scott and Crews 1983). Therefore, it may be of interest to investigate compounds with yohimbine-like properties as antidepressant candidates themselves or in conjunction with antidepressant candidates.

PROCEDURE

Reagents

1. 20-fold concentrated buffer:

   2.36 M NaCl 137.92 g/liter

   100 mM KCl 7.45 g/liter

   200 mM glucose 36.03 g/liter in 0.5 M Tris, pH 7.4

2. 2-fold concentrated buffer:
   - fold dilution of reagent 1 in deionized water
3. Standard buffer:
   - 20-fold dilution of reagent 1 in deionized water
4. [Methyl-^{3}H] yohimbine (72–86 Ci/mmol) is obtained from New England Nuclear
   - For IC_{50} determinations: [^{3}H] Yohimbine is diluted to 40 nM in deionized H_2O
   - Fifty µl of this solution is a 2-ml reaction volume gives a final concentration of 1 nM
5. L-NE bitartrate is made up to 10 mM in 0.01 N HCl. 20 µl of this solution gives a final concentration of 100 µM in 2 ml of reaction mixture.

6. Test compounds. For most assays, a 10 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-4} to 10^{-7} M. Six or seven concentrations are used routinely.

Tissue Preparation

Male Wistar rats are decapitated and their brains rapidly removed. The cortices are weighed and homogenized in 9 volumes of ice-cold 0.32 M sucrose using a Potter-Elvehjem glass homogenizer fitted with a Teflon pestle (0.009–0.010 cm clearance). The homogenate is centrifuged at 1000 *g* for 10 min (approximately 3000 rpm using the Sorvall RC-5 centrifuge with heads SS-34 or SM-24). The supernatant is then recentrifuged at 17,000 *g* for 20 min (approximately 12,500 rpm using the Sorvall RC-5 centrifuge, and heads SS-34 or SM-24). The pellet (P_2) is resuspended in the original volume of 0.32 M sucrose and stored on ice.

Binding Assay

430 µl	H_2O
1000 µl	2-fold concentration buffer (reagent 2)
20 µl	drug or 10 mM L-NE bitartrate or vehicle
50 µl	^{3}H-yohimbine (reagent 4)
500 µl	tissue

Tubes are vortexed and incubated at 25°C for 10 min. Bound [^{3}H]yohimbine is captured via filtration under reduced pressure. The filters are washed three times with 5 ml aliquots of buffer (reagent 3). The filters are then counted in 10 ml of Liquiscint scintillation fluid.

EVALUATION

Specific binding of [^{3}H]yohimbine is the difference between total bound (in the presence of vehicle) and non-specifically bound (in the presence of 100 µM L-NE bitartrate). Percent inhibition of specific [^{3}H]yohimbine binding is calculated for each concentration of test drug and IC_{50} values determined by computer-derived log-probit analysis.

E.6.1.9 Test for Anticholinergic Properties by [^{3}H]-QNB Binding to Muscarinic Cholinergic Receptors in Rat Brain

PURPOSE AND RATIONALE

Several tricyclic antidepressants exert considerable anti-cholinergic effects which limit the therapeutic use in some patients. Amitryptiline has the greatest incidence of these side effects and is the most potent in binding to muscarinic receptors. Desipramine, which exhibits less incidence of atropine like side effects shows a lower affinity for muscarinic receptors. Since there is no evidence that the anticholinergic effects contribute to the therapeutic efficacy, antidepressant drugs with low anti-cholinergic effects are desired.

Quinuclidinyl benzilate (QNB) is a specific muscarinic cholinergic antagonist in both peripheral and central tissues. The binding characteristics of ^{3}H-QNB were first described by Yamamura and Snyder (1974), who showed that this ligand was displaced by muscarinic antagonists, but not by nicotinic or non-cholinergic drugs. The levorotatory isomer being more potent than the racemate is used as the radioactive ligand.

PROCEDURE

Reagents

L-[Benzilic-4,4′-^{3}H]-quinuclidinyl benzilate (30–40 Ci/mmol) is obtained from New England Nuclear. For IC_{50} determinations [^{3}H]-QNB is made up to a concentration of 40 nM and 50 µl is added to each tube (yielding a final concentration of 1 nM in the assay).

Atropine sulfate is obtained from Sigma Chemical Co.

Test compounds: For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, so that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M.

Tissue Preparation

Male Wistar rats are killed by decapitation and their brains rapidly removed. After removal of the cerebellum, each brain is homogenized in 10 volumes of ice-cold 0.32 M sucrose in a Potter-Elvejhem glass homogenizer. The homogenate is then centrifuged at

1000 *g* for 10 min and the pellet discarded. The resultant supernatant is further dispersed and used for [^{3}H]-QNB binding studies. Specific binding is 20% of the total added ligand and approximately 95% of the total bound ligand.

Assay

100 µl	0.5 M Na/K phosphate buffer, pH 7.4 (134 g $Na_2HPO_4 \cdot 7H_2O$+68 g KH_2PO_4)
780 µl	H_2O
50 µl	^{3}H-QNB stock solution
20 µl	vehicle (for total binding) or 2 mM atropine (for nonspecific binding)
1000 µl	0.05 M Na/K phosphate buffer (1:10 diluted) pH 7.4
50 µl	tissue suspension

Tissue homogenates are incubated for 60 min at 25°C with 1 nM ^{3}H-QNB and varying drug concentrations. With each binding assay, triplicate samples containing 2 µM atropine sulfate are incubated under identical conditions to determine nonspecific [^{3}H]-QNB binding. After incubation, the samples are cooled and then rapidly filtered through glass filters (Whatman GF/B) under reduced pressure. The filters are washed 3 times with 5 ml of ice-cold phosphate buffer and then placed in scintillation vials. After the addition of 10 ml of counting cocktail, radioactivity is assayed by liquid scintillation spectrophotometry.

EVALUATION

Specific [^{3}H]-QNB binding is determined by the difference between total [^{3}H]-QNB and bound radioactivity in the presence of 2 µM atropine sulfate. Data are converted to percent specific bound [^{3}H]-QNB displaced by test drugs and IC_{50} values obtained from computer derived log-probit analysis. The inhibition at each drug concentration is the mean of triplicate determinations.

E.6.1.10 Monoamine Oxidase Inhibition: Inhibition of Type A and Type B Monoamine Oxidase Activities in Rat Brain Synaptosomes

PURPOSE AND RATIONALE

The mood-elevating effects of the antituberculosis drug iproniazid have been observed clinically. The mode of action was elucidated to be the inhibition of the enzyme monoamine oxidase. This was followed by wide use of monoamine oxidase inhibitors for the treatment of depression. However, side effects due to interaction with dietary amines have been observed. The biological role of monoamine oxidase is to regulate the levels of endogenous amines (norepinephrine, dopamine and serotonin) and exogenously administered amines. Based on different substrate and inhibitor specificities two forms of monoamine oxidase (A and B) were described. Dopamine and tyramine are substrates for both types, serotonin and epinephrine are substrates for type A, and β-phenylethylamine and benzylamine are substrates for type B. Iproniazid and tranylcypromine are nonselective inhibitors, clorgyline is a selective inhibitor of type A, deprenyl and pargyline are selective inhibitors of type B. It has been suggested that treatment with selective blockers of type B results in less detrimental food interactions.

PROCEDURE

Tissue Preparation

Male Wistar rats weighing 150–250 g are sacrificed and the brains rapidly removed. Whole brain minus cerebellum is homogenized in 9 volumes of ice-cold, phosphate-buffered 0.25 M sucrose, using a Potter-Elvejhem homogenizer. The homogenate is centrifuged at 1000 *g* for 10 min and the supernatant decanted and recentrifuged at 18,000 *g* for 20 min. The resulting pellet (P_2) is resuspended in fresh 0.25 M sucrose and recentrifuged at 18,000 *g* for 20 min. The washed pellet is resuspended in the original volume

of 0.25 M sucrose and serves as the tissue source for mitochondrial monoamine oxidase.

Assay

50 µl 0.5 M PO_4 buffer, pH 7.4

450 µl H_2O

100 µl H_2O or appropriate drug concentration

200 µl tissue suspension

The tubes are preincubated for 15 min at 37°C and the assay is started by adding 100 µl of substrate (^{14}C-5-HT or ^{14}C β-phenylethylamine) at 10 s intervals. The tubes are incubated for 30 min at 37°C and the reaction is stopped by the addition of 0.3 ml of 2 N HCl. Tissue blank values are determined by adding the acid before the substrate. Seven ml of diethylether are added, the tubes are capped and shaken vigorously for 10 min to extract the deaminated metabolites into the organic phase, which is separated from the aqueous phase by centrifugation at 1000 *g* for 5 min. A 4 ml aliquot of the ether layer is counted in 10 ml of liquid scintillation counting cocktail.

EVALUATION

The percent inhibition at each drug concentration is the mean of triplicate determinations. IC_{50} values are determined by log-probit analyses.

For example, deprenyl shows IC_{50}-values of 3.9×10^{-6} against MAO A and 3.0×10^{-8} against MAO B.

MODIFICATION OF THE METHOD

Colzi et al. (1992) measured dopamine and 3,4-dihydroxyphenylacetic acid (DOPAC) outflow after a reversible MAO-A inhibitor with a brain microdialysis technique in rats.

Frankhauser et al. (1994) tested the interaction of MAO inhibitors and dietary tyramine by measurement of peak systolic blood pressure in conscious rats. The increase of blood pressure after oral application of tyramine was potentiated by pretreatment with MAO inhibitors. Reversible MAO inhibitors could be differentiated from non-selective, irreversible MAO inhibitors.

E.6.2 In Vivo Tests

E.6.2.1 Catalepsy Antagonism

PURPOSE AND RATIONALE

Observations about **cataleptic behavior in chicken** have first been described more than 300 years ago (Schwenter 1636; Kircher 1646), and again reported about 100 years ago (Czermak 1873; Heubel 1877; Verworn 1898). This phenomenon was used by Vogel and Ther (1963) as a simple method to detect antidepressants besides other central stimulants.

PROCEDURE

Adult white Leghorn chicken are used. The animal is grasped with both hands whereby the left hand pushes the chicken slightly down and the right hand supports the animal from the ventral side. Immediately, the chicken is turned on its back and hold with the

right hand for 1 min. Usually, cataleptic numbness occurs immediately. The cataleptic state can be sustained by slight pushing the head of the animal on the table. After 1 min the right hand is carefully withdrawn. The chicken remains in the cataleptic state for several min up to 1 h. The cataleptic rigor is interrupted by noise or fast movements of the observer. Clapping of the hands above the head arouses the chicken which jumps up and runs away. The chicken is always aroused by pulling on the wings. The animals are pretested in order to be sure about the cataleptic behavior of an individual chicken. As already found by previous investigators, the experiment can be repeated several times. Control studies showed that in untreated animals the phenomenon could be elicited 6 times every 30 min during a period 5 days. After the control experiments, the animals are injected i.p. with the test compound or the vehicle. The test is performed 4 times every 30 min during 2 h.

EVALUATION

The test is considered to be positive if the cataleptic rigor does not occur after treatment or is interrupted spontaneously within 1 min at least twice during the 2 h test period. The suppression of the cataleptic phenomenon is the criterion for a positive response. Furthermore, the arousal after hand-clapping or pulling on the wings is recorded in order to register central sedative effects. In order to obtain dose-response curves 12 animals per group are treated with various doses. ED_{50} values are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The specificity of the method has been tested. Antidepressant agents like imipramine and ethyltryptamine-acetate or other monoamino-oxydase-inhibitors and d-desoxyephedrine show a dose dependent effect. Moreover, the effects were dependent on time. ED_{50} values decreased on consecutive days after imipramine and monoamino-oxydase inhibitors but not after d-desoxyephedrine. Therefore, the test can be considered as specific for central stimulants allowing the possibility to distinguish between antidepressants and central stimulants of the amphetamine type.

MODIFICATIONS OF THE METHOD

Simiand et al. (2003) and Gabriel et al. (2005) described **tonic immobility in gerbils** as a model for detecting antidepressant-like effects. When grasped by the skin of the nape and lifted into the air, the young of many altricial mammals exhibit an immobility response in which they tuck their limbs against their bodies and remain inert. Such a response can be induced also in adults of some species, such as Mongolian gerbils (De la Cruz and Junquera 1993). To test antidepressant-like effects in the tonic immobility paradigm in gerbils, animals (six to nine per group) were held on a flat surface and were firmly pinched for 15 s at the scruff of the neck using the thumb and the index finger. They were then placed on parallel bars (4 mm in diameter, 28 cm long, spaced 5 cm apart and having a 3-cm difference in height). The front paws were gently placed on the upper bar and the hind paws on the lower bar. The duration of tonic immobility was measured in five successive trials with a 30-s intertribal interval. Each trial ended when an animal started to move or after 90 s of immobility. Experiments were started 30 min after i.p. administration of test drug.

E.6.2.2 Despair Swim Test

PURPOSE AND RATIONALE

Behavioral despair was proposed as a model to test for antidepressant activity by Porsolt et al. (1977, 1978). It was suggested that mice or rats forced to swim in a re-

stricted space from which they cannot escape are induced to a characteristic behavior of immobility. This behavior reflects a state of despair which can be reduced by several agents which are therapeutically effective in human depression.

PROCEDURE

Male Sprague-Dawley rats weighing 160–180 g are used. They are brought to the laboratory at least one day before the experiment and are housed separately in Makrolon cages with free access to food and water. Naive rats are individually forced to swim inside a vertical Plexiglas cylinder (height: 40 cm; diameter: 18 cm, containing 15 cm of water maintained at 25°C). Rats placed in the cylinders for the first time are initially highly active, vigorously swimming in circles, trying to climb the wall or diving to the bottom. After 2–3 min activity begins to subside and to be interspersed with phases of immobility or floating of increasing length. After 5–6 min immobility reaches a plateau where the rats remain immobile for approximately 80% of the time. After 15 min in the water the rats are removed and allowed to dry in a heated enclosure (32°C) before being returned to their home cages. They are again placed in the cylinder 24 h later and the total duration of immobility is measured during a 5 min test. Floating behavior during this 5 min period has been found to be reproducible in different groups of rats. An animal is judged to be immobile whenever it remains floating passively in the water in a slightly hunched but upright position, its nose just above the surface. Test drugs or standard are administered one hour prior to testing. Since experiments with the standard drug (imipramine) showed that injections 1, 5 and 24 h prior the test gave the most stable results in reducing floating these times are chosen for the experiment.

EVALUATION

Duration of immobility is measured in controls and animals treated with various doses of a test drug or standard. Antidepressant drugs, but also stimulants like amphetamine and caffeine, reduce duration of immobility. Dose-responses can be evaluated.

CRITICAL ASSESSMENT OF THE METHOD

The method, also called "forced swim test," has been used and modified by many authors, e. g. Kauppila et al. (1991, van der Heyden et al. 1991).

Advantages of the method are the relative simplicity and the fact that no interaction with other drugs is necessary. Like in other behavioral tests, e. g. the catalepsy test in chicken, not only antidepressants and monoamino-oxydase inhibitors but also central stimulants give positive results.

In a critical review of the forced swimming test, Borsini and Meli (1988) discussed the various modifications and proposed rats to be more suitable than mice for detecting antidepressant activity.

The model is purely behavioral without presuppositions concerning the mechanism of action of potential antidepressants. It is sensitive to a large number of atypical antidepressants otherwise inactive in the more classical tests. The rat version seems to be more selective (fewer false positives) and the mouse version more sensitive (fewer false negatives) (Porsolt et al. 1991).

Natoh et al. (1992) reviewed the theoretical background of the forced swimming test and the various factors which can possibly affect the results.

MODIFICATIONS OF THE METHOD

Wallach and Hedley (1979) reported positive results with antihistamines and Giardina and Ebert (1989) with an ACE-inhibitor. Differentiation is achieved by the simultaneous evaluation of motor activity.

Cervo and Samanin (1987) suggested potential antidepressant activities of a selective serotonin$_{1A}$ agonist based on anti-immobility activity in the forced swimming test in rats without effect on open-field activity.

Nishimura (1988, 1989, 1993) published a modification of the forced swim test using straw suspension in the water tank. The apparatus used was a vertical glass cylinder (height: 40 cm, diameter: 18 cm) equipped with 4 pieces of straw (length 24 cm, diameter: 0.4 cm) that were suspended from above. The cores of the straws were filled with cotton rope. The straws were painted black from the surface of the water to a height of 10 cm. The apparatus was filled with water to a height of 15 cm and maintained at 25°C. Thirty min after treatment with drugs or saline, the rats were placed in the apparatus without straw suspension and the total duration of immobility measured for a period of 5 min. Immediately thereafter, 4 pieces of straw were suspended and the total duration of immobility in the following 5-min observation period again measured.

In an effort to enhance the sensitivity of the traditional forced swim test in the rat so that it can be responsive to specific serotonin reuptake inhibitors, Lucki (1997) proposed several simple procedural modifications. These developments include increasing the water depth to 30 cm from the traditional 15–18 cm, and using a time sampling technique to rate the predominant behavior over a 5-s interval. Spe-

cific components of active behavior can be distinguished: (1) climbing behavior (also known as trashing), which is defined as upward-directed movements of the forepaws along the side of the swim chamber; (2) swimming behavior, the movement (usually horizontal) throughout the swim chamber that also includes crossing into another quadrant; and (3) immobility, which is defined as when no additional activity is observed other than that required to keep the rat's head above the water. As a result of the increase in water depth, there is considerably less immobility than in the traditional test because the animals cannot have contact with the cylinder bottom. The major advantage of this modified test is that it reveals that catecholaminergic agents decrease immobility with a corresponding increase in climbing behavior, whereas 5-HT-related compounds, such as specific serotonin reuptake inhibitors, also decrease immobility but increase swimming behavior.

López-Rubalcava and Lucki (2000) described strain differences in the behavioral effects of antidepressant drugs in the rat forced swim test when the noradrenergic antidepressant, desipramine, and the serotonergic antidepressants fluoxetine and 8-OH-DPAT were tested in Wistar–Kyoto rats and Sprague Dawley rats.

Sun and Alkon (2003, 2004) described the **open space swimming test** to index antidepressant activity. Rats were place individually in a round pool, with a diameter of 152 cm and a height of 60 cm and was filled with 40 cm water at 21°C. Rats were free to swim (or not to swim) for 15 min and then returned to their home cage. The same procedure was followed 24 h later for 3 days. The swimming/drifting path was recorded with a video tracking system. The measurement is considered to be more objective than the forced swimming test. The procedure induces depressive behavior and impairs learning and memory in the rats.

Galea et al. (2001) found that estradiol alleviates depressive-like symptoms in an animal model of post-partum depression. The effect of hormone withdrawal following hormone-simulated pregnancy on depressive-like behavior in the forced swim test was investigated in female Long-Evans rats.

Using the forced swim test or elevated plus-maze, Stoffel and Craft (2004) studied ovarian hormone withdrawal-induced "depression" in female rats.

Gregus et al. (2005) used the forced swim test to study the effect of repeated corticosterone injections and restraint stress on anxiety and depression-like behavior in male rats.

Buckett et al. (1982) described an automated apparatus for behavioral testing of typical and atypical antidepressants in **mice**. A multichannel system can test 10 mice simultaneously. Each mouse is placed in the beam of a Doppler radar head and horn assembly. The moving mouse causes reflections of a frequency differing from the transmitted signal. Within the Doppler head these reflected waves are mixed with a proportion of transmitted waves to produce a difference signal proportional to the activity of the mouse within the beam. The output of each Doppler head is fed to an amplifier whose gain has been calibrated to compensate for differences in sensitivity between individual heads. The method is claimed to eliminate human error and bias and to allow the testing of large numbers of compounds.

Alpermann et al. (1992) used a slightly modified behavioral despair test in mice. Sixty min after administration of the test compounds, the animals are placed in glass cylinders containing water up to a height of 10 cm (water temperature 22–24°C). From the second minute onward, immobility of each mouse is rated every 30 s. After 10 observations mean values and standard deviations in each treatment group are calculated. Compared with the immobility score of the control group percent reduction can be calculated.

Nomura et al. (1982) published a modification of the despair swim test in mice involving a small water wheel set in a water tank. Mice placed on this apparatus turned the wheel vigorously but, when they abandoned attempts to escape from the water, the wheel stopped turning. The number of rotations of the water wheel were counted.

Hata et al. (1995) studied the behavioral characteristics of SART (specific alterations of rhythm in temperature)-stressed mice in forced swimming tests and evaluated the effects of anxiolytics and antidepressants.

Weiss et al. (1998) reported selective breeding of rats for high and low motor activity in the swim test. Sprague Dawley rats were selectively bred for low motor activity (low struggling time/high floating time), while others were bred for high motor activity (high struggling time/low floating time).

Lucki et al. (2001) investigated the sensitivity to desipramine, a selective norepinephrine reuptake inhibitor, and fluoxetine, a selective serotonin reuptake inhibitor, in seven inbred and four outbred mouse strains. Considerable differences in the results of the forced swim test were found.

Sachdev et al. (2002) used the forced swim model of depression in rats to investigate the antidepressant effect of different frequencies of transcranial magnetic stimulation.

Krahe et al. (2002) tested the effects of rotational side preferences in immobile behavior of normal mice in the forced swimming test.

Buckley et al. (2004) used both the mouse forced swim test and the rat forced swim test to characterize a nicotinic agonist.

E.6.2.3 Tail Suspension Test in Mice

PURPOSE AND RATIONALE

The "tail suspension test" has been described by Steru et al. (1985) as a facile means of evaluating potential antidepressants. The immobility displayed by rodents when subjected to an unavoidable and inescapable stress has been hypothesized to reflect behavioral despair which in turn may reflect depressive disorders in humans. Clinically effective antidepressants reduce the immobility that mice display after active and unsuccessful attempts to escape when suspended by the tail.

PROCEDURE

Male Balb/cJ mice weighing 20–25 g are used preferentially. They are housed in plastic cages for at least 10 days prior to testing in a 12 h light cycle with food and water freely available. Animals are transported from the housing room to the testing area in their own cages and allowed to adapt to the new environment for 1 h before testing. Groups of 10 animals are treated with the test compounds or the vehicle by intraperitoneal injection 30 min prior to testing. For the test the mice are suspended on the edge of a shelf 58 cm above a table top by adhesive tape placed approximately 1 cm from the tip of the tail. The duration of immobility is recorded for a period of 5 min. Mice are considered immobile when they hang passively and completely motionless for at least 1 min.

EVALUATION

The percentage of animals showing the passive behavior is counted and compared with vehicle treated controls. Using various doses, ED_{50} values can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

The tail suspension test has been found to be an easy method to test potential antidepressant compounds. However, it has been reported that several mouse strains are essentially resistant to tail-suspension induced immobility.

MODIFICATIONS OF THE METHOD

Chermat et al. (1986) adapted the tail suspension test to the rat.

Porsolt et al. (1987), Stéru et al. (1987) recommended the use of the automated tail suspension test for the primary screening of psychotropic agents. A specially developed computerized device automatically measures the duration of immobility of 6 mice at one time and at the same time provides a measure of the energy expended by each animal, the power of the movements.
